Primary Lung Tumors Other Than Bronchogenic Carcinoma: Benign and Malignant

Reshma Biniwale • Steven M. Keller

Bronchogenic carcinoma represents the overwhelming majority of pulmonary neoplasms; however, a great variety of tumors originate in the lung. Benign neoplasms of the lung (Table 107-1) comprise less than 1 percent of all resected lung tumors, and non-bronchogenic primary pulmonary malignancies (Table 107-2) account for 3 to 5 percent of all lung tumors. Numerous classifications of these rare tumors have been devised, although none are widely accepted. Due to the disparate histogenesis of these varied tumors, it is best to discuss them individually.

BENIGN TUMORS

Mucous Gland Adenoma

Mucus gland adenoma, also known as bronchial cystadenoma, originates in the bronchial submucous glands and presents as an exophytic endobronchial mass. The tumor occurs in the segmental or lobar bronchi and symptoms are due to obstruction or hemorrhage. Histologically, mucous-filled acini are lined by well differentiated mucous-secreting cells, without any evidence of invasion. Radiologically, they appear as coin lesions on chest radiograph, or as an "air-meniscus" sign on computed tomography (CT) scan. Treatment is endoscopic local excision. However, lobectomy may be required if the distal lung is destroyed.

Squamous Papilloma

Juvenile-onset recurrent respiratory papillomatosis (RRP) is associated with a bronchial papilloma in 5 percent of patients. Tracheobronchial extension of RRP is causally related to a previous tracheotomy in 92 percent of cases. Radiologically, it appears as a pulmonary nodule with central cavitary necrosis or as pneumatoceles. Histologically, papillomata consist of stratified squamous epithelium with a fibrovascular core. Parakeratosis and koilocytosis are typical. Infection with

Table 107-1

Benign Tumors of the Lung

Solitary Tumors	Other Solitary Tumors	Multiple Tumors
Epithelial tumors	Alveolar adenoma	Benign metastasizing leiomyoma
Clara cell adenoma	Pulmonary paraganglioma—chemodectoma	Lymphangioleiomyomatosis
Mucous gland adenoma	Glomus tumor	Cystic fibrohistiocytic tumors
Oncocytoma	Nodular amyloid	
Squamous papilloma	Pleomorphic adenoma—mixed tumor	
Soft tissue tumors	Pulmonary meningioma	
Cavernous hemangioma	Sclerosing hemangioma—pneumocytoma	
Chondroma	Sugar tumor—benign clear cell tumor	
Fibroma fibrous polyp	Teratoma	
Fibromyxoma		
Inflammatory pseudotumor—fibrous histiocytoma, fibroxanthoma, plasma cell granuloma		
Granular cell myoblastoma		
Hamartoma		
Leiomyoma		
Lipoma		
Neurilemoma—schwannoma		
Neurofibroma		
Pulmonary hyalinizing granuloma		

HPV 11 rather than HPV6 is associated with a more severe course of RRP. Sporadic malignant transformation is seen after radiotherapy. Local endoscopic excision is the treatment of choice. Solitary bronchial papillomas are rare and affect adults in their fifth to seventh decade. They may cause obstructive bronchiectasis, which may necessitate resection of distally destroyed lung.

Cavernous Hemangioma

Cavernous hemangiomas are extremely rare primary neoplasms of the lung, found in all age groups and may be single or multiple. They may be asymptomatic, or present with symptoms of hemoptysis, respiratory distress, or congestive heart failure. Histologically, they consist of flattened endothelial cells lining dilated vascular spaces. These cells stain positive for anti-von Willebrand factor antibody and CD34, identifying them as endothelial in origin. The treatment of choice for solitary lesions is surgical excision.

Chondroma

Chondromas of the lung may be solitary or multiple, unilateral, or bilateral, and are usually asymptomatic slow-growing tumors. The association of multiple peripheral pulmonary chondromas with gastric stromal sarcoma and extraadrenal paraganglionomas has been described as the "Carney triad." The majority of tumors present at a young age (7–48 years), and 85 percent occur in females. Microscopically, they consist of benign cartilaginous tissue, although Carney also described foci of mature bone, and stellate mesenchymal cells in a myxoid stroma. Lung-sparing resections are curative in 44 percent, the rest develope new chondromas. Recently, MRI-guided laser thermotherapy has been described for ablation of multiple chondromas.

Intrapulmonary Fibroma/Fibrous Tumor

Intrapulmonary fibrous tumors are usually found in a subpleural location. They are diagnosed following resection of an asymptomatic lung mass found on routine radiography. The lung is the most common location of these tumors, but they may also be found in the retroperitoneum, mediastinum, and parietal surfaces of abdominal viscera. Histologically, interlacing bundles of spindle cells without nuclear atypia are seen in a collagenous stroma. Tumor cells are immunoreactive for vimentin but not keratin, desmin, or actin, suggesting fibroblastic differentiation from a submesothelial origin. Treatment is parenchyma-sparing resection.

Inflammatory Pseudotumor (Plasma Cell Granuloma)

Inflammatory pseudotumor of the lung (also known as fibrous histiocytoma, fibroxanthoma, and plasma cell granuloma) is the most common benign lung tumor in children,

Table 107-2

Rare Primary Malignant Neoplasms of the Lung

Blastoma
Carcinoid tumors
Carcinosarcoma
Epithelioid hemangioendothelioma (IVBAT)
Malignant lymphoreticular disorders Hodgkin's disease Non-Hodgkin's lymphoma Plasmacytoma
Malignant melanoma
Malignant germ cell tumors Malignant teratoma Choriocarcinoma
Salivary gland-type tumors Adenoid cystic carcinoma Mucoepidermoid carcinoma Acinic cell tumor
Sarcoma Chondrosarcoma Osteosarcoma Soft tissue sarcoma
Miscellaneous Ependymoma, malignant Ewing's sarcoma Lymphoepithelioma
Pseudomesotheliomatous carcinoma

although it is also commonly found in adults. Patients are usually symptomatic, presenting with cough, fatigue, or weight loss. Previously thought to be an unchecked inflammatory response to viral/foreign antigens, inflammatory pseudotumor has been confirmed to be of neoplastic origin with evidence of rearrangement of the anaplastic lymphoma kinase gene on chromosome 2p23, resulting in the expression of ALK-1 protein. Inflammatory pseudotumor is locally aggressive, and can be multifocal, relapse, and even metastasize. Radiologically, inflammatory pseudotumor presents as a large pulmonary mass or nodules closely related to the airways without evidence of mediastinal adenopathy. Histologically, plasma cells and spindle cells are seen with varying degrees of mitosis, necrosis, and vascular invasion. Inflammatory pseudotumor stains for vimentin, actin, and epithelial membrane antigen. Transbronchial/transthoracic biopsy often reveals mixed inflammatory cells with predominantly plasma cells in a background of fibroblastic proliferation, granulation tissue, and histiocytes with nuclear atypia. Thus, both fine-needle aspiration and frozen section are nonspecific and complete resection is necessary for establishing a diagnosis. Incomplete resection can result in recurrence, which can be treated with re-resection. Symptoms, incomplete resection, as well as large size are predictors of mortality. Steroids, chemotherapy, and radiation therapy are controversial in the treatment of inflammatory pseudotumors.

Granular Cell Myoblastoma

Granular cell tumors are uncommon benign neoplasms that are thought to arise from Schwann cells. Usually discovered incidentally on a chest radiograph, they are endobronchial in location and multicentric. Peribronchial extension is seen in half the tumors. However, distant metastases have not been reported. They occur equally in men and women, with a median age of 42 years. Microscopically, sheets of granular cells with abundant lysosomes that stain positive with periodic acid-Schiff stain are present. Tumor cells also stain positive for S-100 and myelin basic proteins. Large tumor size, necrosis, increased mitosis, and p53, as well as Ki-67 immunoreactivity are consistent with malignant change. Treatment consists of local excision, either endoscopically (laser) or by sleeve resection. Larger resections are reserved for postobstructive bronchiectasis or abscess. Up to 13 percent of granular cell tumors coexist with other neoplasms such as esophageal, renal, and lung carcinoma.

Hamartoma

Hamartomas (mesenchymomas) are the most common benign tumors of the lung. They are derived from peribronchial mesenchyme, are slow-growing, present in adulthood, and have a 3/1 male predominance. Most are detected incidentally as peripheral round nodules on a chest radiograph, only 20 percent are endobronchial. The classic popcorn calcification is seen only in 30 percent of hamartomas. Cavitations are due to the fat content. Histologically, they consist of cartilage, fat, bone, connective tissue, and smooth muscle cells surrounding clefts lined by bronchial epithelium. Fine-needle aspiration has a high false-positive rate and low accuracy in diagnosing hamartomas. Malignant transformation is rare. Therefore, small peripheral hamartomas may be safely observed. Excision is indicated for obstructive symptoms or if the diagnosis is in doubt (Fig. 107-1). Parenchyma sparing resection should be performed. Recurrences are rare, although hamartomas may be associated with increased risk of developing other primary lung cancers.

Leiomyoma

Primary solitary leiomyoma accounts for 2 percent of all benign lung tumors and may present as pulmonary obstruction, or as an asymptomatic peripheral radiographic nodule.

Figure 107-1 Pulmonary hamartoma seen at thoracoscopy. The tumor is easily visualized in a subpleural location. Incising the overlying pleural allows the lesion to be "popped" out.

Patients are typically in their fourth decade. The tumor is slightly more common in women. Surgical resection is the treatment of choice, although laser resection of endobronchial tumors offers prolonged palliation. Benign metastasizing leiomyoma consists of multiple pulmonary nodules of well-differentiated smooth muscle, resulting from hematogenous spread from a benign uterine leiomyoma. These tumors are ER and PR positive and respond to hormonal therapy.

MALIGNANT TUMORS

Pulmonary Blastoma

Pulmonary blastomas are divided into three subgroups: Biphasic pulmonary blastoma (BPB), well-differentiated fetal adenocarcinoma (WDFA), and pleuropulmonary blastoma (PPB). WDFA contains neoplastic epithelial glandular elements in an endometrial pattern without mesenchymal malignancy. PPB is a dysontogenic neoplasm having mesenchymal malignant elements (liposarcoma, rhabdomyosarcoma, or chondrosarcoma) without epithelial malignancy. BPB contains both epithelial and mesenchymal malignant elements, which mimic fetal lung. PPB is further subclassified as type I (purely cystic), type II (cystic and solid), and type III (purely solid). PPB occurs in infants and young children, WDFA and BPB occur in young adults, with a mean age of 35 years. All three are fast-growing symptomatic tumors that present in the periphery of the lung with a predilection for lower lobes. Radiologically they appear as large solitary smooth masses (Fig. 107-2). Fine-needle aspiration is usually non-diagnostic due to extensive necrosis and lack of cellular material. Neoadjuvant chemotherapy has been used to downstage the tumors before surgical resection. Adjuvant cisplatinum based chemotherapy is combined with local radiation for control after resection. Poor prognostic factors are large tumor size, mediastinal or pleural involvement, and nodal metastasis. CNS is the commonest site of distant metastasis followed by bone. Mutations of p53 gene are seen more frequently with BPB and PPB than with WDFA, suggesting a worse prognosis. Types II and III PPB have an overall survival of 42 percent at 5 years, despite multimodality treatment.

Carcinoid

Carcinoid tumors are malignant neuroendocrine tumors arising from Kulchitsky (APUD system) cells and are classified by the World Health Organization into typical (TC) and atypical carcinoids (AC) on the basis presence of necrosis and greater than 2 mitosis per 2 square mm. Mean age at presentation is 55 years, but AC are seen in significantly older patients with a history of smoking. Seventy-five percent of carcinoids are central, endobronchial, and present commonly with postobstructive pneumonia, hemoptysis, or wheezing. Uncommonly, carcinoids may present with paraneoplastic syndromes such as Cushing's syndrome due to ectopic ACTH

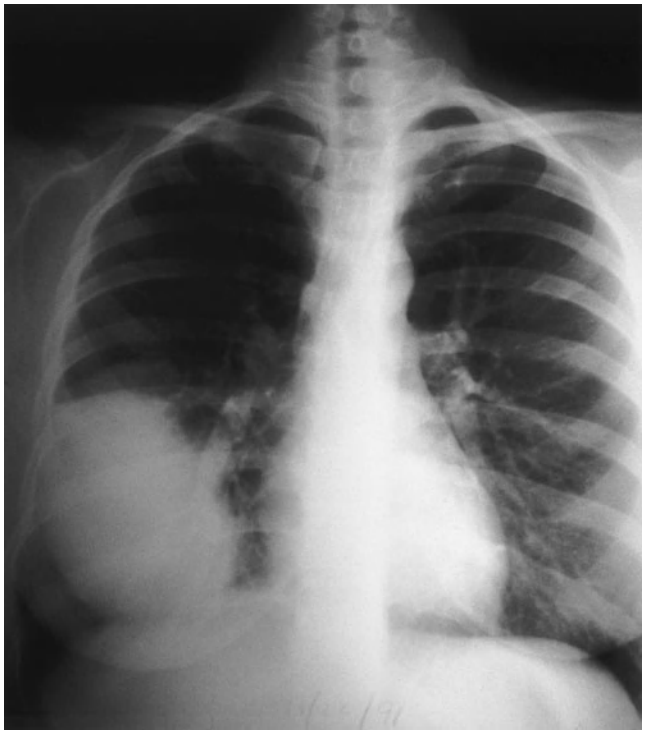

Figure 107-2 Chest radiograph demonstrating a pulmonary blastoma. The lesion presented as a large mass in the right lower lobe of a 25-year-old nonsmoking woman.

production, or even acromegaly from ectopic GH and insulin-like growth factor-1 production.

Bronchoscopy frequently demonstrates a polypoid pinkish/yellow mass with intact overlying epithelium. Brushings and washings are usually nondiagnostic. Endobronchial biopsy is diagnostic in 51 percent of patients, but may precipitate a carcinoid crisis. Carcinoids are characterized by an organoid growth pattern with uniform cells containing finely granular eosinophilic cytoplasm and nuclei with a fine chromatin pattern. Radiologically, carcinoids present as solitary nodules (30 percent), infiltrates (60 percent), and as calcified nodules (30 percent) (Fig. 107-3). CT scan reveals a well-defined central tumor deforming an airway with punctate calcification and homogenous contrast enhancement with or without hilar lymphadenopathy. Carcinoids demonstrate high signal intensity on T2-weighted MRI. FDG-PET scans, however, have a high false-negative rate, as carcinoids are hypometabolic. Somatostatin receptor scintigraphy can be used in detecting occult primary tumors, staging, and localization of metastatic disease. Chromosome analysis shows evidence of 11q and 3p deletion in AC, with loss of 18q in metastatic carcinoid. Overexpression of p53 and loss of heterozygosity of 11q13 is seen in AC, which correlates with tumor aggressiveness. Five percent of patients with MEN I syndrome have associated sporadic carcinoids. Inactivation of the MEN I gene is seen in 67 percent of TC, and 25 percent of AC.

Treatment of choice for TC is surgical resection. Lobectomy and lymph node dissection is preferred because 20 percent of TC and 60 percent of AC are associated with nodal metastases. Bronchoplastic sleeve-resection for central lesions of early stage TC is preferable to pneumonectomy. Cis-platinum and etoposide-based chemotherapy is indicated for unresectable disease as well as metastases. However, the response rate is only 22 percent with a median survival of 20 months. Bio-therapy with interferon alpha and octreotide is used for the treatment of carcinoid syndrome with symptomatic relief in 70 percent of patients. Liver embolization can be used to debulk liver metastases in symptomatic patients. Targeted radiotherapy with radiolabeled octreotide or MIBG remains investigational.

Recurrence-free survival is commonly seen in TC. Tumor histology and nodal status are the main predictors of mortality. Completeness of resection, symptoms, and age are also significant prognostic factors. Five-year survival following complete resection of TC and AC is 87 to 100 percent and 44 to 77 percent, respectively. Survival decreases to 25 to 69 percent in the presence of nodal metastases. There is no correlation between tumor size and presence of nodal involvement. Sixty-three percent of patients with nodal mediastinal nodal metastases develop distant metastases, most commonly in the liver. Carcinoid syndrome occurs rarely (2 percent) and results from release of 5HT. Urinary 5HIAA is used to monitor disease activity in patients with carcinoid syndrome.

Carcinosarcoma

Carcinosarcoma is a biphasic tumor consisting of carcinomatous and sarcomatous elements containing differentiated cartilage, bone, or skeletal muscle. This tumor is seven times more common in males than females. The median age of presentation is 65 years. The upper lobes are affected in 60 percent of cases. Carcinosarcomas are divided into two groups: central endobronchial and peripheral solid parenchymal (Fig. 107-4). Symptoms of airway obstruction or postobstructive pneumonia are common. However, one-third of all patients are asymptomatic. These tumors eventually invade the mediastinum and chest wall, causing pain. Carcinosarcomas are firm, rubbery, or fleshy masses with areas of necrosis and cavitation. The carcinomatous elements are squamous cell carcinoma (46 percent), adenocarcinoma (31 percent), and adenosquamous carcinoma (19 percent). The sarcomatous elements are rhabdomyosarcoma (51 percent), chondrosarcoma, and osteosarcoma. The carcinomatous elements are often displaced to the periphery, suggesting rapid growth of the central sarcomatous elements, which form the bulk of the tumor. Immunohistochemical staining for keratin is positive for both the epithelial and mesenchymal components, suggesting that carcinosarcomas are of a monoclonal epithelial origin that has undergone sarcomatoid metaplasia. Metastases are found in lymph nodes, bone, kidney, liver, and lung and commonly contain only one of the components of the primary tumor. Complete surgical resection is usually possible and the 5-year survival rates ranges from 21 to 49 percent. Endobronchial location and tumor stage do not correlate with survival. However, tumor size greater than 6 cm is associated with poor survival.

Epithelioid Hemangioendothelioma

Originally named intravascular bronchoalveolar tumor (IVBAT), this neoplasm has since been demonstrated to be of endothelial origin on the basis of immunohistochemical staining for factor VIII–related antigen and CD34. Epithelioid hemangioendothelioma is best considered a low-grade sarcoma and is usually multicentric in origin. It is a disease of young women, with 80 percent of cases seen in women under the age of 40 years. Patients are usually asymptomatic, although they may present with respiratory symptoms. Multiple perivascular nodules less than 1cm in diameter or diffuse thickening of interlobular septae are present on CT scan. Microscopically, epithelioid hemangioendothelioma consists of eosinophilic cells forming trabeculae or nests with characteristic central acellular sclerotic areas and lymphovascular and bronchiolar invasion. Pleural, intravascular, and endobronchial spread is associated with a poor prognosis, as are liver and lymph node metastases. Complete resection is the treatment for localized tumors. Diffuse tumors have been treated with chemotherapy, interleukin-2 and interferon-α2b with mixed results. Radiation is ineffective and is used only for palliation of bone pain. Partial spontaneous regression also has been reported occasionally.

Lymphomas

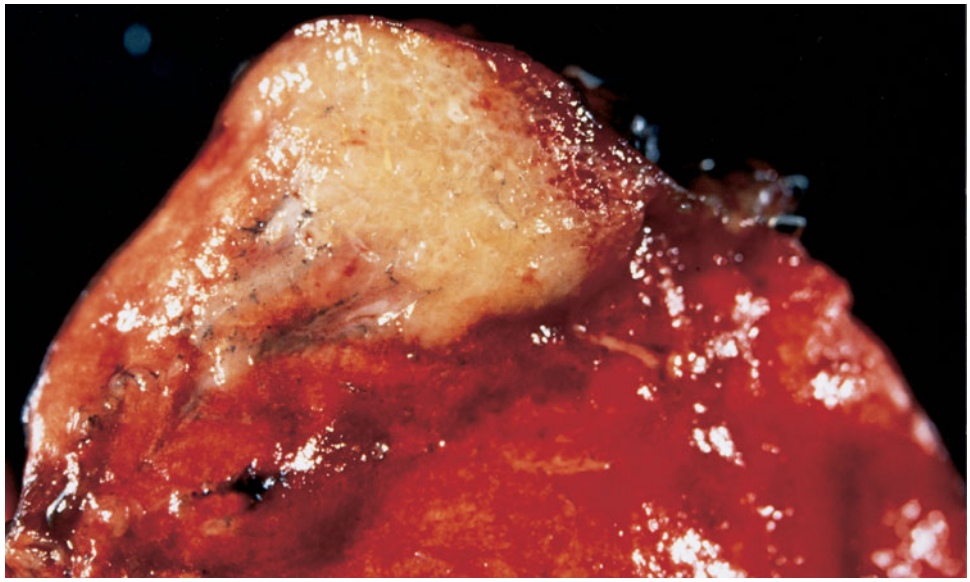
Primary pulmonary lymphomas (PPL) are rare neoplasms accounting for less than 1 percent of all lung cancers. Criteria used for diagnosis of primary pulmonary lymphoma include involvement of the lung with or without mediastinal involvement, and absence of extrathoracic lymphoma at the time of diagnosis or for 3 months thereafter.

Primary pulmonary B cell non-Hodgkin's lymphoma (NHL) is also known as MALT (mucosa-associated lymphoid tissue) or BALT (bronchus-associated lymphoid tissue) and accounts for up to 80 percent of PPL. This is a low-grade small B lymphocyte lymphoma that is associated with a 5-year survival greater than 80 percent. The tumor is thought to arise due to chronic inflammation secondary to smoking, infection or autoimmune disease (Sjögren's). Age of onset is 50 to 60 years, with equal distribution between the sexes. Half of the patients are asymptomatic on presentation. Pulmonary manifestations include cough, dyspnea, and hemoptysis. Extrapulmonary symptoms such as fever and weight loss occur in less than 25 percent of patients. Radiologically, a localized alveolar opacity with blurred margins is seen associated with air bronchograms. CT demonstrates bilateral multifocal disease in 70 percent of cases. CT-guided biopsy is diagnostic in 25 percent. Bronchoalveolar lavage is diagnostic if it shows lymphocytic alveolitis with greater than 10 percent of the total cells being B lymphocytes. Microscopically MALT PPL is defined as a lesion containing: small lymphoid cells, lymphoepithelial lesions showing migration of lymphoid cells from the marginal zone to bronchiolar epithelium, reactive follicular hyperplasia, and rare blastic cells (Fig. 107-5). Immunohistochemistry demonstrates B-cell phenotype (CD19, CD20) and monoclonality. Bone marrow biopsy may show involvement in 25 percent of cases. Evaluation of other mucosal sites with endoscopy, ENT examination, and CT scan of salivary and lacrimal glands should be performed. Serum immunoelectrophoresis will reveal a monoclonal gammopathy (IgM) in 20 to 60 percent of patients. Elevated β2 microglobulin is associated with a poor prognosis. Solitary tumors should be removed. Long-term surveillance is necessary due to late local or systemic relapse after resection. Chemotherapy is recommended for residual, bilateral, progressive, or recurrent disease. Various regimens, including CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) have been used with success.

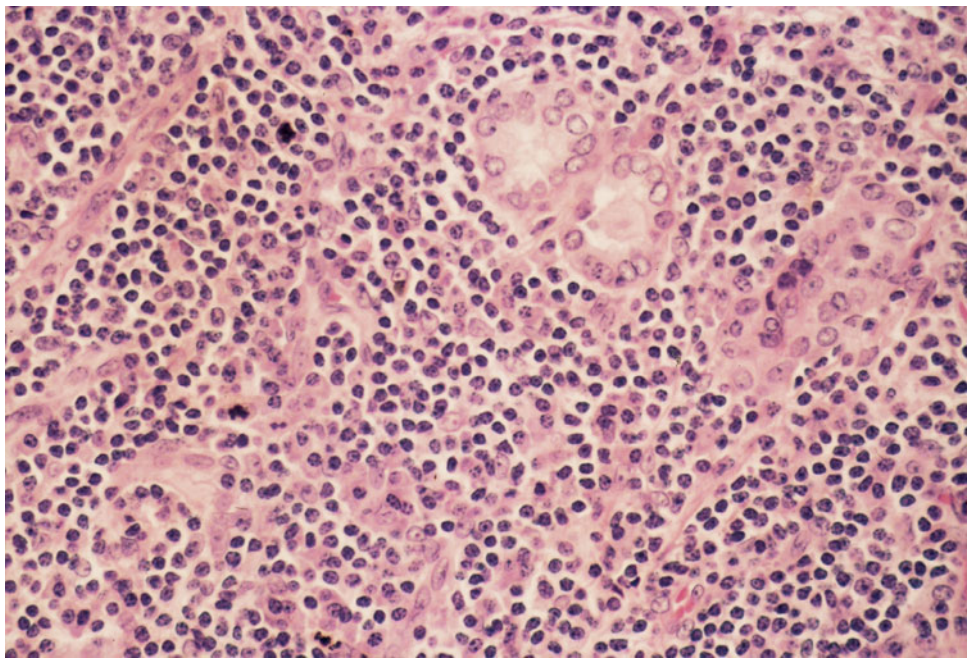
High-grade PPL NHL-B, also known as large B-cell lymphoma, accounts for up to 15 percent of PPL. Immunosuppression, HIV infection, and Sjögren's syndrome are underlying disorders often associated with large B-cell lymphomas. These lymphomas are usually found in the elderly and commonly present with either pulmonary or systemic symptoms. A solitary lung mass often associated with a pleural effusion is present. Bronchoscopy may reveal infiltrative stenosis. Transbronchial biopsy is often diagnostic. Microscopically, large blast-like lymphoid cells with frequent mitosis, necrosis and bronchovascular invasion are seen. Survival is poorer than in small B-cell lymphomas, especially in those with underlying disorders. Resection is followed by combination chemotherapy. Progression of disease and recurrence occurs earlier and more commonly than in small B-cell lymphoma.

Lymphomatoid granulomatosis (LG) also known as an angiocentric immunoproliferative lesion (AIL) is rare. The age of onset is around 50 years. Almost all patients present with either pulmonary or systemic symptoms. Radiologically, multiple bilateral ill-defined nodular opacities, mainly affecting the lower lobes, are seen. These opacities can cavitate and disappear secondary to infarction of the granulomatosis lesions. Extrapulmonary involvement is seen mainly in the CNS, skin, ENT, or renal systems. Neurological deficits can be central, cranial nerve affection, or peripheral neuropathies. Skin lesions are erythema or nodules with or without ulceration. Arthralgia and ocular and gastrointestinal manifestations have also been reported. Microscopically, an angiocentric lymphocytic infiltrate is seen mixed with occasional large blastic cells, which compresses the lumen of arterioles and erodes into bronchioles. Immunohistochemistry demonstrates the B-cell origin of the lymphocytes, which also express EBV LMP protein. Initial assessment should include brain MRI, CT scan of the abdomen for renal or lymphoid involvement, and a bone marrow biopsy. Localized LG should be removed. Combination chemotherapy is reserved for diffuse disease. Radiotherapy is useful in CNS involvement. Despite aggressive therapy the prognosis remains poor and median survival is about 4 years. Poor prognostic factors include early age of onset, CNS involvement, hepatosplenomegaly, leucopenia, fever, anergy, and predominant blast cells with necrosis on biopsy.

NK/T cell primary pulmonary lymphoma is an extremely rare diagnosis with only 13 cases reported in the



A



B

world. Patients are elderly; females are twice as commonly affected as males. Radiographically, bilateral diffuse nodularities are seen. Diagnosis requires an open lung biopsy and immunohistochemistry, which reveals T-cell markers. Microscopically, homogenous cells with architectural effacement and dysplasia are seen. Monoclonality of the T cells is demonstrated by TCR gene rearrangement. Prognosis is very poor despite surgical resection and CHOP based chemotherapy.

Primary pulmonary Hodgkin's lymphoma is also very rare with 61 reported cases. There is a bimodal age distribution with peaks in the third and sixth decades. Most patients are female. Symptoms may be pulmonary or systemic. Radiologically, multinodular and massive parenchymal involvement is seen with occasional cavitation. Bronchoscopy and BAL are inconclusive, and often open biopsy is required to confirm the diagnosis. The most frequent histologic subtype is the nodular sclerosing variety. Combination chemotherapy, radiation, and surgery are the common modalities of treatment. A poor prognosis is predicted in patients with multilobar or bilateral disease.

Plasmacytoma

Plasmacytomas are tumors arising from monoclonal plasma cells. The diagnostic criteria for extramedullary plasmacytoma are biopsy-proven plasma cell proliferation, absence of bone marrow infiltration and absence of osteolytic lesions, renal failure, and hypercalcemia. The average age of presentation is 54 years, with equal distribution between males and females. Plasmacytomas commonly present as a hilar mass, but lobar consolidation or bilateral diffuse infiltrates with air bronchograms may also be seen. Serum electrophoresis reveals an M-protein spike, which usually consists of IgG κ chains, and correlates with the tumor burden. Treatment is surgical resection, but chemotherapy with melphalan and prednisolone has been used with good results. The 5-year survival rate is 40 percent. These tumors need to be distinguished from marginal zone B-cell lymphomas of MALT origin. Forty percent of patients develop multiple myeloma; therefore, surveillance with serum and urine electrophoresis, bone marrow biopsy, skeletal bone survey and clinical monitoring is necessary.

Malignant Melanoma

Primary pulmonary melanoma is an extremely rare lung tumor for which several theories have been suggested: aberrant migration of melanocytes from the primitive foregut, melanogenic metaplasia of bronchial epithelium, or melanocytic differentiation of neuroendocrine precursor Kulchitsky cells. Jensen and Egedorf first suggested the clinical criteria for the diagnosis of primary pulmonary melanoma: no previously removed skin or ocular melanomas, solitary tumor, morphology compatible with a primary tumor, no melanoma in other organs at surgery, and no evidence of primary tumor elsewhere on autopsy. Histopathological criteria include junctional change with nesting of malignant cells beneath bronchial epithelium, and invasion of bronchial epithelium in an area without ulceration. Aggressive resection is the treatment of choice and offers the best chance for cure. Chemotherapy and immunotherapy is used for widespread disease.

Malignant Germ Cell Tumors

Malignant teratoma and choriocarcinoma are the two types of malignant germ cell tumors that arise in the lung. Teratomas show elements from all three germ layers. Half of the primary pulmonary teratomas are malignant. Patients present with cough, hemoptysis, or chest pain. The most specific symptom, trichoptysis, is rarely present. Radiologically, the mass may show calcification with peripheral radiolucency. Resection is the treatment of choice. Adjuvant chemotherapy is usually a combination of cis-platinum, bleomycin, and etoposide.

Choriocarcinomas are usually seen in women or elderly men who present with symptoms of feminization. The commonest symptom is cough with hemoptysis. Various theories have been postulated to explain the origin of choriocarcinomas of the lung. Neoplastic transformation of misplaced primordial germ cells, spontaneous regression of an occult genital primary leaving behind pulmonary metastatic lesions, neoplastic transformation of placental emboli at the time of delivery or abortion, and neoplastic transformation of somatic neoplastic cells, have all been postulated. These tumors manifest as the choriocarcinoma syndrome: bleeding from the primary lung lesion and elevation of β-HCG. Differentiation from a large cell carcinoma producing ectopic human chorionic gonadotropin can be done by immunohistochemistry, which shows staining for thyroid transcription factor (TTF)-1 (a marker of pulmonary origin) and not for β-HCG. Histologically, cytotrophoblastic cell nests are seen covered by syncytiotrophoblasts, with evidence of widespread necrosis and hemorrhage, and a lack of fibrovascular stroma. Surgical resection is recommended, followed by adjuvant chemotherapy. Choriocarcinomas are unresponsive to radiation, unlike their gestational counterparts. Distant metastases can occur in the contralateral lung, brain, and kidney.

Salivary Gland-Type Tumors

Adenoid cystic carcinoma (ACC) is the most common salivary-gland tumor found in the lung. It is believed to arise from ductal/myoepithelial cells of bronchial submucosal glands. Centrally located ACC arises in the trachea or mainstem bronchi and presents as an exophytic endobronchial mass causing obstructive symptoms. Overlying mucosa is often grossly normal. Peripheral ACC is uncommon. Males and females are equally affected. Histologically there are three subtypes: cribriform, tubular, and solid. ACC are slow-growing neoplasms that exhibit centripetal spread in the airways as well as perineural growth. Therefore, extensive resections are required. These tumors are extremely radiosensitive and local recurrences or residual disease may be treated with radiation. Following complete resection, 5- and 10-year survivals of 91 and 76 percent, respectively, have been reported.

Mucoepidermoid carcinomas usually arise in mainstem bronchi or the proximal portion of the lobar bronchi. The right bronchial tree is more commonly affected in children. Patients present with symptoms of obstruction due to a polypoid endobronchial mass. Bronchoscopic biopsy is diagnostic. Three histological grades have been defined (low, intermediate, and high) based on the presence of cystic spaces, cell type (mucous cells, intermediate cells, and epidermoid cells), cellular pleomorphism, and mitosis. Complete resection with mediastinal lymph node dissection is the treatment of choice. High-grade tumors are more common in adults and may invade adjacent structures, lymph nodes, vascular, and perineural spaces. Incomplete resection is more likely in high-grade tumors, and postoperative chemoradiation may be necessary. High-grade tumors are uniformly fatal in 11 to 28 months.

Acinic cell tumors (Fechner tumors) are usually found in the salivary glands, and hence a diligent search for an extrathoracic primary is essential. Symptoms vary and are determined by whether the tumor is central endobronchial or peripheral in location. Microscopy demonstrates a pattern

resembling a neuroendocrine tumor and may need to be differentiated from the more common carcinoid tumor. Acinic cell tumors are slow-growing and recurrence or metastases after complete excision has not been reported.

Sarcomas

Primary pulmonary sarcomas are rare tumors, accounting for less than 0.5 percent of all lung tumors. Mean age at presentation is 53 years, with a slight predominance in males. A history of smoking or previous radiation exposure may be present. Usual symptoms are chest pain and cough. Sarcomas appear as large (mean diameter 5 cm), solitary peripheral or hilar nodular opacities usually located in the upper lobes. Bronchoscopy may show either extrinsic compression or a polypoid endobronchial mass. The variety of soft tissue pulmonary sarcomas reflects the range of mesenchymal tissue found in the lung (Table 107-3). The most common primary pulmonary sarcoma is leiomyosarcoma (30 percent), followed by malignant fibrous histiocytoma and synovial sarcoma. Histological subtypes can be differentiated on the basis of immunohistochemical markers such as vimentin, desmin, actin, and epithelial membrane antigen. Treatment is wide resection with mediastinal lymph node dissection. Residual disease is treated with radiotherapy or reresection. Recurrences can be resected with good results. Ifosfamide-based chemotherapy has also been used in the neoadjuvant and adjuvant setting for positive margins or positive lymph nodes. Median survival is 48 months and 5-year survival is 38 to 69 percent. Size and grade do not correlate with increased mortality. Incomplete resection is associated with poor survival.

Kaposi's sarcoma
Liposarcoma

Chondrosarcomas of the lung can occur either within central bronchi or peripherally in the lung parenchyma. Tumors consist of islands of chondroid and osteoid with foci of mineralization within sheets of small hyperchromatic mesenchymal cells. Chondrosarcomas are slow growing and rarely metastasize. Complete resection is usually curative.

Osteosarcomas of the lung present with cough or hemoptysis and appear as large cavitating masses. These are rapidly growing tumors with a poor prognosis. Recurrence is seen in 50 percent of patients after resection. The majority of patients succumb within months from metastases to the lung, liver, lymph nodes and bone. The role of adjuvant therapy for the treatment of this tumor is still unproved.

Extrapulmonary Syndromes Associated with Lung Tumors

Bruce E. Johnson • John P. Chute

Lung cancers are the most common tumors associated with paraneoplastic syndromes. The paraneoplastic syndromes can be classified into endocrine, hematologic, and neurologic syndromes. Endocrine and hematologic syndromes associated with lung tumors are listed in Table 108-1.

The endocrine syndromes are characterized by the ectopic production of biologically active peptide hormones by tumor cells that bind to receptors in adjacent or distant organs, giving rise to a clinical syndrome. The ectopic adrenocorticotropic hormone (ACTH) syndrome, the hyponatremia of malignancy, and hypercalcemia of malignancy are examples of this model. In order to establish the diagnosis of an endocrine paraneoplastic syndrome, the following criteria should be met: (1) a decrease in the level of the hormone after treatment of the tumor; (2) demonstration of hormone synthesis and secretion by tumor cells in vitro; (3) high concentrations of the hormone in the tumor; and (4) an arteriovenous gradient in hormone levels across the tumor bed.

Lung cancers also produce extrapulmonary syndromes by other mechanisms. Hematologic syndromes develop in

This chapter has been slightly modified from the version that appeared in the third edition of *Fishman's Pulmonary Diseases and Disorders.*

Table 108-1

Endocrine and Hematologic Syndromes Associated with Lung Tumors

Syndrome	Tumor	Proteins/Cytokines
Hypercalcemia of malignancy	Non–small-cell	Parathyroid hormone–related peptide Parathormone
Hyponatremia of malignancy	Small-cell Non–small-cell	Arginine vasopressin Atrial natriuretic peptide
Ectopic ACTH syndrome	Small-cell Carcinoid tumors	Adrenocorticotropic hormone Corticotropin-releasing hormone
Acromegaly	Carcinoid tumors Small-cell	Growth hormone–releasing hormone Growth hormone
Granulocytosis	Non–small-cell	G-CSF GM-CSF IL-6
Thrombocytosis	Non–small-cell Small-cell	IL-6
Thromboembolism	Non–small-cell Small-cell	Unknown

patients with lung cancer through the production of cytokines by tumor cells that activate progenitor cells in the bone marrow. Neurologic syndromes, such as encephalomyelitis and subacute sensory neuropathy, are caused by the induction of antibodies directed against proteins expressed by the lung cancer cells and antigens present on cells in the nervous system.

Although lung cancers produce and express various hormones, many (e.g., the gastrin-releasing peptide) do not cause a clinically evident syndrome. Other peptide hormones, such as ACTH precursors, are translated into prohormones, which are not processed into mature peptides. As a result, levels of the immunoreactive proteins in plasma are increased without a clinical syndrome.

This chapter focuses on the extrapulmonary syndromes that are encountered in clinical practice. An understanding of the extrapulmonary syndromes is important for several reasons: (1) the syndrome is often the presenting feature of the underlying cancer; (2) the course of the endocrine and hematologic syndromes usually parallels the course of the lung cancer, although the neurologic syndromes frequently do not; and (3) appropriate treatment of the extrapulmonary syndrome often reduces the patient's morbidity and may allow definitive treatment of the cancer. In general, definitive treatment of the underlying tumor by surgical resection, radiotherapy, or chemotherapy is the most effective form of therapy for the paraneoplastic syndrome.

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia is the most common paraneoplastic syndrome. Approximately 1 percent of patients with lung cancer have hypercalcemia when first seen, but 10 to 20 percent of patients develop hypercalcemia during the course of their disease. Lung cancer is the most common solid tumor associated with hypercalcemia, accounting for 30 to 40 percent of all paraneoplastic cases. Hypercalcemia is commonly seen in patients with squamous cell carcinoma of the lung, uncommonly in patients with adenocarcinoma, and very rarely in patients with small-cell lung cancer.

Hypercalcemia in patients with lung cancer is usually not caused by local osteolytic effects of bony metastases. Most cases of hypercalcemia in patients with lung cancer are caused by the ectopic production of parathyroid hormone–related peptide (PTHrP) by tumor cells (humoral hypercalcemia of malignancy).

Biology

Ectopic production of PTHrP accounts for 80 to 90 percent of humoral hypercalcemia of malignancy in patients with lung cancer. The PTHrP gene expresses three messenger RNAs (mRNAs); these encode for three distinct peptides, which differ at the COOH-terminal region (Fig. 108-1). Eight of the first 13 amino acids in PTHrP are homologous with PTH, so

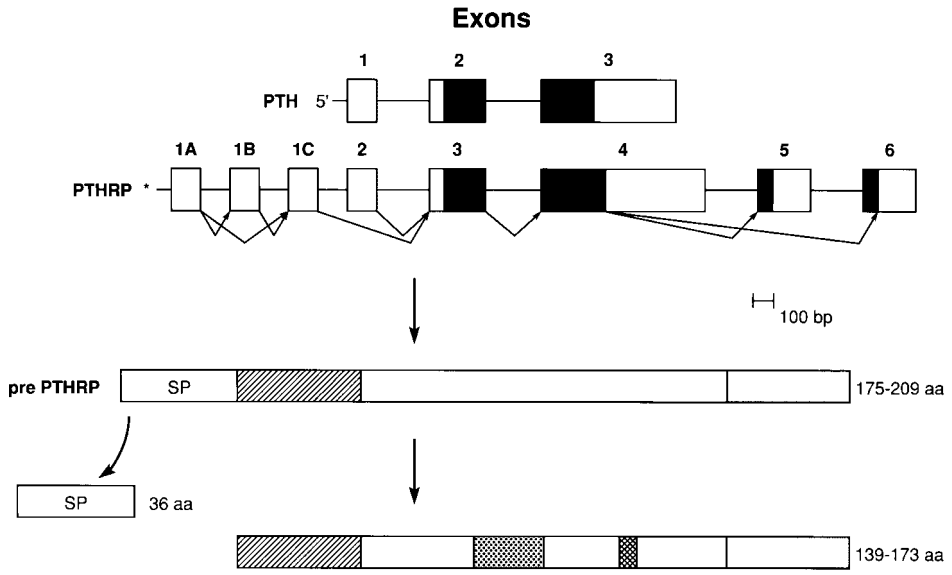

Figure 108-1 Parathyroid hormone and parathyroid hormone–related peptide. The human PTH gene has three exons, which constitute the protein-coding segments. The protein coding segments are represented by the black boxes. The PTHrP gene is more complex, with eight exons. Through alternative splicing, three different isoforms of mRNA can be produced. These isoform mRNAs encode the pre-PTHrP proteins, which vary in size from 175 to 209 amino acids (aa). Thirty-six amino acids are removed from the amino terminal end as the signal peptide. Three different PTHrP molecules are produced, with 139 to 173 amino acids. The rectangular region at the carboxy terminal represents the different lengths of PTHrP. The N-terminal region (aa 1–34) mimics the classic PTH-like function (hatched box). The midregion (aa 67–86) of the peptide stimulates placental calcium transport (shaded box). The C-terminal region (aa 107–111) inhibits osteoclastic bone resorption (double hatched box).

similar functional activity is shared between the two peptides. PTHrP messenger RNA and peptides have been demonstrated in cancer cells from patients with lung cancer and hypercalcemia. PTHrP has been shown to bind to PTH receptors in the bone and kidney, causing increased osteoclastic bone resorption, decreased bone formation, and decreased calciuria, leading to hypercalcemia. Levels of 1,25-dihydroxyvitamin D_3 are suppressed in patients with PTHrP-induced hypercalcemia but are raised in patients with primary hyperparathyroidism. This difference occurs because renal α-hydroxylase activity is low in PTHrP-induced hypercalcemia, unlike primary hyperparathyroidism. PTH production by lung cancer cells has also been described, but it is a very rare cause of humoral hypercalcemia.

Other factors that cause bone resorption have been identified in the plasma of patients with lung cancer, including transforming growth factor-α and a vitamin D metabolite. These are very rare, however, and their causative role in hypercalcemia has not been shown conclusively.

Diagnosis

The early symptoms of hypercalcemia include thirst, malaise, fatigue, anorexia, polyuria, constipation, nausea, and vomiting. As the hypercalcemia becomes increasingly severe, confusion, lethargy, coma, and death can occur. The demonstration of an increased concentration (greater than 10.5 mg/dl) of calcium in the serum of a patient with non–small-cell lung cancer should suggest this paraneoplastic syndrome.

When hypercalcemia is identified in a patient with lung cancer, other potential causes of elevated serum calcium should be excluded. Thiazide diuretics, vitamin D or lithium administration, hyperthyroidism, and sarcoidosis are potential causes. A PTH radioimmunoassay should be performed because up to 10 percent of hypercalcemia in patients with cancer is caused by primary hyperparathyroidism. Bone scintiscan should be obtained to exclude bone metastases, and a PTHrP level should be determined. An elevated PTHrP level in the absence of bone metastases establishes the diagnosis of humoral hypercalcemia of malignancy caused by ectopic PTHrP.

Treatment

As with other paraneoplastic syndromes, treatment of the underlying cancer is the most effective method of treating the humoral hypercalcemia associated with lung cancer. Patients in whom lung cancer cannot be eradicated can be treated with intravenous saline plus furosemide diuresis. Subcutaneous calcitonin has a rapid onset of action and is most useful in severe cases. Mithramycin and long-acting biphosphonates, such as pamidronate, are effective for long-term control of hypercalcemia. Corticosteroids exert their effect through inhibition of dihydroxyvitamin D_3 synthesis and therefore have less effect in patients with elevated PTHrP.

This syndrome usually develops in patients with advanced progressive cancer. Therefore, reversal of hypercalcemia should be undertaken only when there is some hope

for control of the underlying cancer. It may be inappropriate to treat hypercalcemia in patients with far-advanced lung cancer, having them regain consciousness only to die of their underlying disease.

HYPONATREMIA OF MALIGNANCY

Hyponatremia is a frequent complication in patients with cancer. More than 90 percent of cases occur in patients with small-cell lung cancer. Ten to 15 percent of patients with small-cell lung cancer and 1 percent of patients with non–small-cell lung cancer present with hyponatremia. Most of these cases are caused by the ectopic production of arginine vasopressin (AVP). This subset of hyponatremia is recognized as the *syndrome of inappropriate antidiuretic hormone* (SIADH). Ectopic production of atrial natriuretic peptide (ANP) may also play a role in the hyponatremia of malignancy, but the exact contribution of this hormone remains to be defined.

Biology

AVP is a 9–amino acid peptide normally produced by the neurohypophysis. The peptide binds to receptors in the kidney to reduce the excretion of free water. When plasma osmolality exceeds 280 mOsmol/kg, the release of arginine vasopressin from the pituitary increases, causing the kidney to retain more free water and maintain fluid and osmolar balance. In patients with small-cell lung cancer, ectopic production of AVP causes hyponatremia by inhibiting free-water excretion in the distal tubule of the kidney. Arginine vasopressin mRNA is expressed in small-cell lung cancer cells, and the peptide is translated and secreted (Fig. 108-2). Levels of AVP in plasma are increased.

A subgroup of patients with small-cell lung cancer and hyponatremia have been identified in whom the cancer and the cancer cell lines do not produce ectopic arginine vasopressin. The tumors from these patients express ANP mRNA, secrete the peptide, and have high levels of ANP in their plasma. ANP is the leading candidate to be the natriuretic factor that Bartter and Schwartz proposed in their original description of SIADH. Further investigation into the precise role of ANP in patients with small-cell lung cancer and hyponatremia of malignancy is ongoing.

Diagnosis

In patients with lung cancer, hyponatremia is most frequently diagnosed as a laboratory abnormality in the absence of significant symptoms. The symptoms associated with acute hyponatremia do not typically occur because the syndrome develops over a prolonged period in concert with the growth of the lung cancer. The symptoms of mild hyponatremia (more than 120 mEq/ml) include headache, difficulty concentrating, nausea, weakness, and fatigue. Patients who develop a more acute hyponatremia may manifest confusion, lethargy, seizures, coma, and death.

In patients with lung cancer, nonmalignant causes of hyponatremia—including diuretic use, renal disease, cardiac dysfunction, hypoadrenalism, thyroid disease, and dilutional hyponatremia—should be considered in the initial evaluation. Medications that can induce SIADH include the chemotherapeutic agents cisplatin, vincristine, cyclophosphamide, and melphalan, along with narcotics, which are

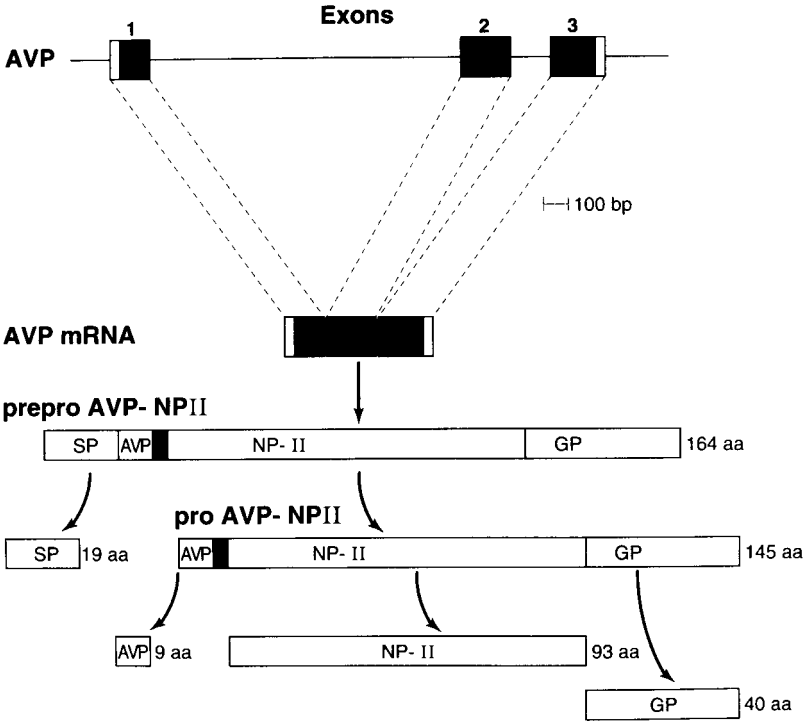

Figure 108-2 Arginine vasopressin. The three exons of the human AVP gene rise to a 700-base arginine vasopressin mRNA. The mRNA is translated into a 164-amino acid (aa) preprohormone with a 19–amino acid amino terminal signal peptide (SP). The signal peptide is cleaved, giving rise to a 145–amino acid prohormone. This prohormone is processed into the AVP nonapeptide (AVP), a 93–amino acid neurophysin (NP), and a 40–amino acid glycoprotein (GP). The black portions of the boxes represent the protein-coding portion of the gene and mRNA.

commonly used in patients with lung cancer. The subgroup of hyponatremic patients with the diagnosis of SIADH should satisfy the following criteria: (1) plasma hypoosmolality (under 280 mOsmol/kg); (2) osmolality of urine greater than serum (usually over 500 mOsmol/kg); (3) persistent urinary excretion of sodium in the absence of diuretics (more than 20 meq/l); (4) absent signs of volume depletion; and (5) normal renal, adrenal, and thyroid function.

Treatment

The initial therapy for hyponatremia caused by lung cancer is treatment of the underlying malignancy. This requires chemotherapy and/or radiotherapy for patients with small-cell lung cancer and surgery for non–small-cell lung cancers. In many patients, despite an initial tumor response to chemotherapy, the syndrome of hyponatremia persists or recurs after the cancer regrows. In these patients, the short-term treatment for mild hyponatremia is fluid restriction of 500 ml per day. Many patients with cancer cannot tolerate this level of fluid restriction for extended periods, so other treatments are usually required. Demeclocycline is the medication of choice for chronic management of SIADH in patients with small-cell lung cancer. When given in doses of 600 to 1200 mg orally per day, demeclocycline blocks the action of AVP on the renal tubule, inducing a diabetes insipidus that will correct the hyponatremia in most patients. Lithium and phenytoin also can be used to inhibit the effects of AVP on the renal tubule, but administration of these agents is limited by their neurologic side effects.

In patients who present with severe, symptomatic hyponatremia, the intravenous administration of 3 percent hypertonic saline, along with the intravenous administration of furosemide, is recommended. The intravenous administration of furosemide rapidly causes an increase in the net free-water clearance. This method has been used successfully in patients with small-cell lung cancer. It can increase the concentration of sodium in serum from 120 to 133 mEq/l in 6 to 8 h. Overly rapid correction of the level of sodium in serum (more than 2 mEq/h) in patients with hyponatremia has been associated with a central pontine myelinolysis. Therefore, frequent measurements of serum sodium during treatment with hypertonic saline are required to avoid this complication.

ECTOPIC ACTH SYNDROME

Cushing's syndrome was first recognized in a patient with lung cancer caused by the ectopic production of ACTH. Twenty to 30 percent of Cushing's syndrome is caused by biologically active ACTH, which is produced by nonpituitary neoplasms. Lung cancers are the most common neoplasms that cause ectopic ACTH production and Cushing's syndrome, accounting for 50 percent of all cases. Small-cell carcinoma accounts for 80 to 90 percent of cases associated with lung cancers, but carcinoid tumors (10 percent) and bronchial adenocarcinomas (5 percent) have also been reported to produce biologically active ACTH. Although one-half of all cases of ectopic ACTH production are caused by small-cell carcinoma, fewer than 3 percent of patients with small-cell lung cancer have Cushing's syndrome at the time of diagnosis.

Biology

Most cases of ectopic ACTH syndrome associated with lung cancers are caused by ectopic production of ACTH by the tumor. The precursor gene, pro-opiomelanocortin (POMC), is expressed in the cancer cells, and a 241–amino acid prohormone is translated and then cleaved into ACTH (39 amino acids), melanocyte-stimulating hormone, and opiatelike hormones (Fig. 108-3). The ACTH binds to receptors in the adrenal gland, causing them to produce excessive glucocorticoid and mineralocorticoid hormones.

A small number of patients with small-cell lung cancer or bronchial carcinoids have been reported to produce corticotropin-releasing hormone (CRH), thereby causing Cushing's syndrome. CRH is a 41–amino acid normally produced in the paraventricular nuclei of the hypothalamus, which stimulates the release of ACTH from the pituitary. In patients with small-cell carcinoma or bronchial carcinoid, CRH is produced by the cancer cells, thereby stimulating ACTH production by the pituitary gland and causing Cushing's syndrome.

Diagnosis

Ectopic ACTH production occurs with equal frequency in males and females—unlike Cushing's syndrome, which has an 8:1 female preponderance. Patients who have slow-growing tumors (carcinoids) often present with the clinical features of Cushing's syndrome: truncal obesity, moon facies, striae, polyuria, and polydipsia. In contrast, patients with small-cell lung cancer often present with other signs of mineralocorticoid and glucocorticoid excess due to the rapidity of tumor growth: edema, weakness, hypertension, and hypokalemic alkalosis.

The diagnosis of ectopic ACTH syndrome is established by the demonstration of increased 24-h excretion of urinary free cortisol (more than 400 nmol a day), increased plasma cortisol level (more than 600 nmol/l), and increased plasma ACTH level (over 22 pmol/l), which do not decrease in response to the administration of high-dose dexamethasone. Bronchial carcinoids are an exception because, in some tumors, ACTH and cortisol levels have been suppressed by dexamethasone. In patients in whom the dexamethasone suppression test does not establish the diagnosis of ectopic ACTH production, a CRH stimulation test or bilateral inferior petrosal vein sampling will provide the definitive diagnosis. After CRH infusion, pituitary tumors release increased amounts of ACTH, whereas pituitary-independent lung tumors should not. Similarly, in pituitary-dependent Cushing's syndrome, petrosal vein sampling will reveal a gradient between the level

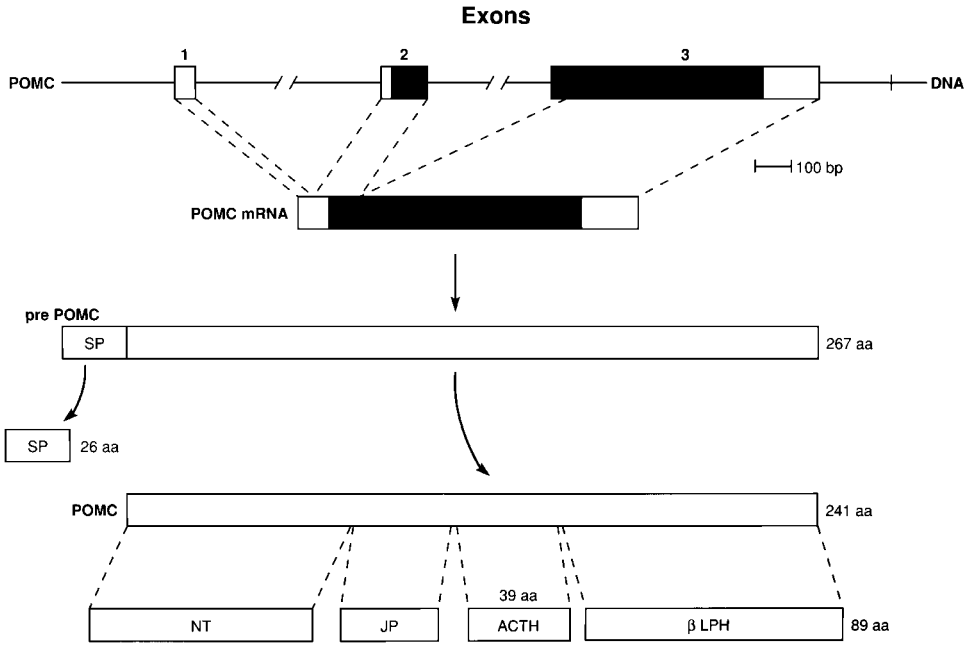

Figure 108-3 Pro-opiomelanocortin. The three exons of the POMC gene give rise to a 1072-base POMC mRNA. The mRNA is translated into a 267-amino acid pre-POMC with a 26–amino acid amino terminal signal peptide (SP). The signal peptide is cleaved, creating the 241–amino acid POMC. The POMC peptide is cleaved into many products, including the N-terminal peptide (NT), the joining peptide (JP), a 39–amino acid mature ACTH, and β-lipotropin (BLPH). The molecules can also undergo further processing. The black portions of the exons represent the protein-coding portion of the gene and mRNA.

of ACTH in the petrosal vein and the peripheral concentration. In contrast, patients in whom ACTH is ectopically produced demonstrate no gradient between the petrosal vein and the peripheral blood.

Treatment

Management of a patient with lung cancer and ectopic ACTH syndrome requires therapy directed at both the underlying tumor and the hypercortisolism. The treatment for a patient with ectopic ACTH production is to remove the source of the ACTH. This requires combination chemotherapy, with or without irradiation, for patients with small-cell lung cancer and surgical resection and/or radiation for patients with carcinoid tumors. Chemotherapy for patients with small-cell lung cancer and ectopic ACTH syndrome has been only minimally successful. Patients often have a poor response to chemotherapy and are susceptible to early infection and death. Early control of a patient's glucocorticoid excess is beneficial and may reduce the morbidity of treatment.

When removal of the ectopic source of ACTH is not possible, medical therapy directed at decreasing adrenal secretion may be successful. Ketoconazole is an imidazole derivative that inhibits steroidogenesis at both adrenal and gonadal sites. A recent review of medical therapy for ectopic ACTH syndrome suggests that ketoconazole may be the most effective and least toxic agent available. Metapyrone and aminoglutethimide also have shown limited success by inhibiting adrenal steroid synthesis. Octreotide, a somatostatin analogue, can suppress ectopic ACTH production and has been reported to be useful in some of these patients.

In some patients, the clinical signs and symptoms of ectopic ACTH production develop before the development of a clinically obvious lung cancer. In these cases, symptomatic management of hypercortisolism is undertaken and periodic imaging studies are performed because these patients may have a slow-growing carcinoid tumor that will be amenable to surgical resection.

ACROMEGALY

Carcinoid tumors of the lung and intestine are responsible for 70 percent of cases of ectopic acromegaly. Ectopic production of growth hormone–releasing hormone (GHRH) by tumor cells can be demonstrated in most patients, whereas a minority of tumors produce growth hormone.

Biology

The ectopic production of GHRH or GH by lung cancers has been demonstrated to cause acromegaly. In most cases, the GHRH gene is expressed by the cancer cells, and a 40– or 44–amino acid peptide is produced. This peptide is secreted into the circulation and binds to receptors in the pituitary gland, causing the production of excessive amounts of GH. GH then

mediates its effects through GH receptors in soft tissue and by stimulating the production of insulinlike growth factor–1 (IGF-1).

Immunoreactive GHRH can be identified in many bronchial carcinoids and small-cell lung cancers, but acromegaly occurs in a minority of these patients. Ectopic GHRH production may not cause clinically evident acromegaly because: (1) the tumor produces inadequate amounts of GHRH to cause the clinical syndrome; (2) the hormone is synthesized but not secreted; or (3) the rapid progress of the malignancy prevents the full development of clinical features of acromegaly.

Diagnosis

The earliest features of GH excess are hypertrophy of the extremities and face (forcing increased glove, shoe, and ring size), thickened leathery skin, prominent skin folds, increased skin pigmentation, and hair growth. Bony changes, hypertension, and diabetes mellitus are later, less common findings.

The presentation of a patient with a lung mass and signs of acromegaly should raise suspicion of the paraneoplastic syndrome of acromegaly. This is particularly true if the lung tumor is a carcinoid. The diagnosis is established by the presence of increased levels of GHRH and IGF-1 in the patient's plasma, the absence of a pituitary tumor, and the demonstration of GHRH or GH in tumor tissue by immunohistochemistry or mRNA expression studies. Because coincidental pituitary tumors and solid tumors have been described, patients who have lung cancer in association with low GHRH levels and high GH and IGF-1 levels should undergo magnetic resonance imaging (MRI) to exclude a pituitary tumor.

Treatment

The treatment of choice for ectopic acromegaly is removal of the GHRH- or GH-secreting tumor. This can often be achieved in patients with lung carcinoid tumors. Radiation therapy has also been effective. Patients with ectopic acromegaly whose tumors cannot be removed or irradiated should undergo medical therapy using the somatostatin analogue octreotide or bromocriptine. Bromocriptine acts by inhibiting GH release by the pituitary; octreotide lowers both GH and IGF-1 levels in plasma and also appears to inhibit GHRH release by tumors. Clinical abatement of acromegalic features has been reported in patients treated with octreotide.

HEMATOLOGIC SYNDROMES

Most hematologic syndromes associated with lung tumors are not as well characterized as the endocrine syndromes, because the ectopic hormone responsible for the syndrome has not been identified in most tumor tissues. In many of the hematologic syndromes, such as granulocytosis and thrombocytosis, clinical sequelae are often absent. As with the endocrine paraneoplastic syndromes, the most appropriate therapy for the hematologic syndromes is the treatment of the underlying neoplasm.

Granulocytosis

Non–small-cell lung cancer is the most common cancer associated with granulocytosis. Twenty percent of patients with non–small-cell lung cancer have granulocytosis, with absolute white blood counts ranging from 10,100 to 25,000 (normal range is 4000 to 10,000).

Although granulocyte colony–stimulating activity can be demonstrated in serum and/or urine in 80 percent of patients, the specific peptide hormone causing the syndrome has not been identified. Tumor production of granulocyte colony–stimulating factor (G-CSF), granulocyte-monocyte colony–stimulating factor (GM-CSF), and interleukin-6 (IL-6) has been shown in a minority of patients.

Virtually all patients with lung cancer who present with tumor-associated granulocytosis are asymptomatic. The diagnosis is suggested by the presence of an increased white blood count in which neutrophils predominate without immature forms, in the absence of nonneoplastic causes. An increased leukocyte alkaline phosphatase score and a normal bone marrow are consistent with this diagnosis.

Thrombocytosis

Thrombocytosis is common in patients with lung cancer, afflicting 40 percent of patients with both non–small-cell and small-cell tumors.

The pathogenesis of thrombocytosis in patients with lung cancer has not been definitively elucidated. IL-6, which is a cytokine for megakaryocytes, has been demonstrated in cell lines from patients with lung cancer and thrombocytosis, and increased levels of IL-6 have been demonstrated in the plasma of such patients. The recent identification of the thrombopoietin gene should lead to a better understanding of the role of this protein in paraneoplastic thrombocytosis.

Patients with thrombocytosis are nearly always asymptomatic and do not have an increased incidence of thromboembolism. The diagnosis of cancer-associated thrombocytosis is suggested by an increased platelet count (above $500{,}000/mm^2$) in a patient with newly diagnosed lung cancer. A primary myeloproliferative disorder can be excluded only by a bone marrow biopsy.

Thromboembolism

Twenty percent of patients with lung cancer develop venous thromboembolism during the course of their disease. Twenty percent of patients who present with recurrent idiopathic venous thrombosis are found to have an underlying diagnosis of cancer. The spectrum of causes of thrombosis in patients with lung cancer is broad, including disseminated intravascular

coagulation (DIC), Trousseau's syndrome (recurrent migratory venous thrombophlebitis), nonbacterial thrombotic endocarditis, and obstruction of great vessels. Surgical procedures and chemotherapy have also been demonstrated to increase cancer patients' risk of thrombotic complications.

The treatment for venous thrombosis in patients with lung cancer depends on the underlying hematologic diagnosis. If the patient has an isolated venous thrombosis in the absence of DIC or Trousseau's syndrome, oral warfarin therapy is appropriate with the aim of an international normalized ratio two to three times normal. If there are recurrent thromboses, long-term subcutaneous heparin is more efficacious than warfarin.

NEUROLOGIC SYNDROMES

Neurologic dysfunction as a paraneoplastic manifestation of lung cancer was first described more than 30 years ago. Encephalomyelitis, cerebellar degeneration, retinopathy, opsoclonus/myoclonus, and the Lambert-Eaton syndrome have all been associated with lung tumors, most commonly small-cell lung cancer. Most of these neurologic paraneoplastic syndromes appear to be caused by an autoimmune response directed at antigens that are shared by the cancer cells and normal neural tissue. Unlike that of the endocrine and hematologic syndromes associated with lung cancer, the clinical courses of the neurologic syndromes are typically independent of the course of the underlying disease. The autoantibodies associated with each neurologic syndrome are listed in Table 108-2.

Encephalomyelitis/Subacute Sensory Neuropathy

The paraneoplastic syndrome of encephalomyelitis/subacute sensory neuropathy was initially discovered in a patient with small-cell lung cancer. Currently, more than 70 percent of cases of paraneoplastic encephalomyelitis are diagnosed in patients with small-cell lung cancer. A specific antibody, anti-Hu, which reacts with the HuD antigen expressed by lung cancer cells and neuronal tissues, has been associated with the development of this syndrome.

Biology

The anti-Hu antibody is an IgG antibody found in the sera of patients with sensory neuropathy and encephalomyelitis. This antibody reacts with 35- to 40-kD neuronal nuclear antigens in the cerebral cortex, brain stem, cerebellum, spinal cord, and dorsal root ganglia, and it reacts with surface proteins on some small-cell lung cancer cells. The HuD gene has been mapped to the chromosome 1p region and appears to be a marker of neuroendocrine differentiation in these cells.

Diagnosis

The clinical features of this syndrome are diverse. One-half of patients undergo progressive sensory loss in the hands and feet. Others present with a limbic encephalopathy characterized by memory loss, behavioral changes, and seizures. Focal myelopathy with weakness, brain stem signs (nystagmus, dysarthria), and autonomic nervous system dysfunction also occur in patients with this syndrome. These clinical signs and symptoms can antedate the diagnosis of lung cancer, so a full evaluation for occult cancer in patients who present with encephalomyelitis or subacute sensory neuropathy is warranted. CT scans are typically normal in these patients, but MRI studies may show increased T2 signal in affected areas of the brain. Pathologic examination of brain biopsies show inflammatory infiltrates and neuronal destruction in the brain stem, hippocampus, spinal cord, and dorsal root ganglia. The demonstration of anti-Hu antibodies in a patient with encephalomyelitis and a diagnosis of small-cell lung cancer establishes the diagnosis.

Treatment

Treatment of the encephalomyelitis/subacute sensory neuropathy syndrome associated with lung cancer is treatment of the primary tumor. Immunosuppressive therapy with

Table 108-2

Neurologic Syndromes Associated with Lung Cancer

Syndrome	Tumor	Antibody	Antigen
Encephalomyelitis/subacute sensory neuropathy	Small-cell	Anti-Hu	Hu-D antigen: 35- to 40-kD neuronal nuclear protein
Cancer-associated retinopathy	Small-cell	Antirecoverin	23-kD protein specific to photoreceptor cells (recoverin)
Lambert-Eaton syndrome	Small-cell	Anti-P/Q channel	P/Q-type calcium channel

corticosteroids and plasmapheresis directed at removal of the offending immunoglobulin from the patient's serum have been shown to be effective in only 10 to 20 percent of patients. Patients who are severely affected by the anti-Hu syndrome can die from neurologic sequelae (e.g., cardiovascular collapse) rather than from the underlying lung cancer.

Paraneoplastic Cerebellar Degeneration

A syndrome of cerebellar degeneration has also been noted in patients with small-cell lung cancer. This is believed to be a variant of the paraneoplastic cerebellar degeneration (PCD) observed in patients with gynecologic and breast tumors. In patients with gynecologic tumors and PCD, a specific anti-Purkinje cell antibody called anti-Yo has been identified that binds to 34- to 38-kD and 62- to 64-kD proteins in the cytoplasm of Purkinje cells. Patients with small-cell lung cancer and cerebellar degeneration have anti-Hu antibodies in their sera and do not have the anti-Yo antibody. These patients are considered to have the anti-Hu syndrome and frequently go on to develop encephalitis or sensory neuropathy.

Opsoclonus and Myoclonus

Opsoclonus is a disorder consisting of involuntary rapid conjugate eye movements in vertical and horizontal directions. It is often associated with myoclonus in patients with solid tumors. This syndrome of opsoclonus/myoclonus has been associated with both small-cell and non–small-cell lung cancer in numerous case reports, but less is known about this syndrome than about the syndrome of paraneoplastic encephalomyelitis/subacute sensory neuropathy.

A specific antibody called anti-Ri has been identified that binds to 55-kD nuclear proteins expressed in the dentate nucleus. Although this antibody is considered to be the cause of the opsoclonus/myoclonus syndrome in patients with gynecologic tumors, the antibody has not been demonstrated in patients with lung cancer.

The anti-Hu antibody has been identified in some patients with small-cell lung cancer and opsoclonus/myoclonus. As in patients with the anti-Hu antibody and cerebellar degeneration, patients who have opsoclonus and the anti-Hu antibody may have a variant of the encephalomyelitis/subacute sensory neuropathy syndrome. Patients who present with lung cancer and opsoclonus should be evaluated for the anti-Hu antibody.

CANCER-ASSOCIATED RETINOPATHY

Cancer-associated retinopathy is a rare paraneoplastic syndrome that occurs predominantly in patients with small-cell lung cancer. Many autoantibodies have been identified in patients with this disorder; they bind to a photoreceptor-specific protein called recoverin.

Biology

Retinal ganglion cells and their processes are characteristically lost in this disorder because of the autoantibodies that bind to recoverin, a 23-kD photoreceptor-specific protein found in rods and cones as well as in small-cell lung cancer cells. The autoantibodies that cause the cancer-associated retinopathy specifically bind to the recoverin protein and do not recognize other retinal proteins.

Diagnosis

The clinical triad of photosensitivity, ring-scotomata visual field loss, and attenuation of retinal arteriole caliber is considered highly suggestive of cancer-associated retinopathy. The typical patient presents with symptoms of rapid visual loss, night blindness, and color loss. On physical examination, most patients show visual field deficits, disk pallor, and cells in the vitreous body, along with arteriolar narrowing.

Demonstration of the antirecoverin antibody in a patient with signs of retinopathy establishes the diagnosis. As with paraneoplastic cerebellar degeneration, cancer-associated retinopathy is often the first sign of an occult carcinoma. Therefore, an evaluation for lung cancer should be performed in all patients who present with this syndrome.

Treatment

In contrast to those with the other paraneoplastic neurologic syndromes, more than half of patients with cancer-associated retinopathy have been reported to respond with visual improvement after systemic steroid therapy. Treatment of the primary tumor without immunosuppressive therapy has not been shown to cause visual improvement in patients with cancer-associated retinopathy. Most of these patients develop progressive visual loss and blindness within 18 months.

LAMBERT-EATON SYNDROME

The Lambert-Eaton syndrome afflicts fewer than 2 percent of lung cancer patients but has been reported in up to 5 percent of patients with small-cell lung cancer. Sixty percent of all patients who present with the Lambert-Eaton syndrome have small-cell lung cancer.

Biology

In patients with Lambert-Eaton syndrome and small-cell lung cancer, an IgG autoantibody has been identified that binds to calcium channels in motor and autonomic nerve terminals, thereby inhibiting acetylcholine release. This antibody also binds to the 58-kD synaptic vesicle protein synaptotagmin, which is present in small-cell lung cancer cells. Recent evidence suggests that the P/Q calcium channel is the specific target of these antibodies. The antibody binding of the

P/Q calcium channel weakens the neuromuscular signal, and neurologic dysfunction follows. It has also been postulated that these autoantibodies induce the production of acetylcholinesterase, which would also diminish the neuromuscular signal.

Diagnosis

Clinical features include weakness of the pelvic girdle and thigh, fatigue, dry mouth, dysarthria, dysphagia, blurred vision, and muscle pain. Unlike the situation with myasthenia gravis, muscle strength improves with exercise and does not improve significantly with the administration of anticholinesterases (e.g., edrophonium). Electromyography performed in these patients demonstrates increased muscle action potential with repeated nerve stimulation. In patients with the Lambert-Eaton syndrome, IgG autoantibodies should be demonstrable in serum.

Treatment

Treatment of the underlying small-cell lung cancer with chemotherapy can effectively treat the associated Lambert-Eaton syndrome. For patients whose neuromuscular status does not improve with chemotherapy, immune modulation with azathioprine (2.5 mg/kg per day), plasma exchange, or intravenous γ-globulin (400 mg/kg per day for 5 days) has been shown to induce remissions. 3,4-Diaminopyridine in doses of 10 to 100 mg a day has also been used successfully to bring about short-term control of this syndrome.

CONCLUSION

The paraneoplastic syndromes have long fascinated and perplexed oncologists, and only in recent years have the molecular bases for these syndromes been appreciated. Not only has this new knowledge led to more effective palliation of symptoms, but it may also offer new clues to the pathogenesis of malignancy. The presence of signs and symptoms that suggest a paraneoplastic syndrome should prompt a search for malignancy.

Pulmonary Metastases

Richard S. Lazzaro • Joseph LoCicero, III

Pulmonary metastasis represents the dissemination of cancer cells with establishment of local residence in the pulmonary parenchyma. Recent advances in technology have allowed basic science to further elucidate not only the cellular and metastatic signature, but also the metastatic cascade. Krishnan describes a six-step model of the metastatic cascade involving intravasation, resistance to anoikis, evasion of the immune system, extravasation, dormancy, and proliferation. Matrix metalloproteases, up-regulated by cancer cells, have the ability to degrade the extracellular matrix, allowing the cells access to the vasculature. Krishnan states, "Loss of cell-cell or cell-matrix interaction triggers the activation of the caspase proteases, the hallmark of cell death." Metastatic cancer cells that do not undergo apoptosis survive through the development of homotypic as well as heterotypic interactions, thereby resisting anoikis (apoptotic cell death when a cell loses interaction with the extracellular matrix). These cells can avoid immunosurveillance through down-regulation of antigens as well as production of immunosuppressive cytokines. Extravasation requires interaction of metalloproteases and degradation of extracellular matrix along with the addition of basement membrane to cell adhesion molecules (CAM). Metastases may remain dormant for many years, becoming clinically relevant only when turned on by angiogenesis controls, immune mediated growth suppression, or other mechanisms. The process of neovascularization leads to proliferation. Potential therapeutic strategies include anti-VEGF monoclonal antibody, tyrosine kinase inhibitors, and the anti-EGFR antibody cetuximab.

However, the presence of metastatic disease connotes a negative prognosis for the patient. SEER (Surveillance Epidemiology and End Results) Cancer statistics review (1975–2003; Table 109-1) shows 5-year survival rates for patients with colon and rectal carcinoma sink to 9.1 percent versus 90.5 percent for patients with distant versus localized disease. Five-year survival rates for breast cancer are reduced from 97.5 to 24.2 percent when the patient develops distant disease. Five-year survival from esophagus cancer is reduced from 29.4 to 2.5 percent when the patient goes from localized to distant disease. The SEER report shows similar trends for lung, pancreas, melanoma, and stomach cancer. Despite improvements in multimodality therapy for oncologic disease, survival from metastatic disease remains poor. However, multiple retrospective observational studies demonstrate a survival benefit for carefully selected patients who present with pulmonary metastasis and who can tolerate complete resection of all metastatic disease.

In 1882, Weinlechner performed the first lung resection for pulmonary metastasis. The principles established by Alexander and Haight in 1947 regarding a controllable

Table 109-1

Five Year Survival Data by Primary Cancer Site

Primary Histology	Distant Disease	Local Disease
Lung	2%	59%
Breast	21%	100%
Colon and rectum	8%	96%
Pancreas	1.7%	17%
Melanoma	15.1%	97.6%
Stomach	2.8%	60%

primary site of malignant disease, and the absence of extrapulmonary metastasis in conjunction with a medically fit patient remain cornerstones of surgical management decisions regarding patients with pulmonary metastasis. Furthermore, the international registry of lung metastases in 1997 developed a model of prognostic grouping, based on resectability, disease-free interval, and number of metastases. Resectable patients with isolated solitary pulmonary metastasis and prolonged disease-free interval of more than 36 months had a median survival of 61 months compared with resectable patients with a disease-free interval of less than 16 months and multiple metastases (greater than 1). In 2007, Petersen and colleagues reviewed their experience with 1720 patients with pulmonary metastatic melanoma and corroborated the above, noting that the number of pulmonary nodules, disease-free interval, and presence of extrathoracic metastasis are significant prognostic factors.

Metastasectomy has always and continues to be controversial. The current salient issues include: patient selection, operability and resectability, tissue histology, disease-free interval, number of metastasis, presence of extrathoracic disease, the role of mediastinal lymph node evaluation, open versus thoracoscopic approach, unilateral versus bilateral assessment, and the role of removal of radiographic disease versus palpable disease.

PATIENT SELECTION, OPERABILITY, AND RESECTABILITY

Patients presenting with pulmonary metastatic disease often are evaluated by the thoracic surgical oncology team in a similar manner to a primary lung cancer patient. After establishing that the metastatic burden is confined to the lungs and that the primary site is controlled or controllable, cardiac risk assessment and pulmonary functional assessment should be performed. Patients who can tolerate resection of all pulmonary metastases are recommended to undergo pulmonary metastasectomy. Patients with metastatic colorectal cancer to liver and lung are an exception to the requirement of no extrathoracic metastatic disease. Such patients can benefit from hepatic and pulmonary metastasectomy with anticipated 30 to 44 percent 5-year survival.

TISSUE HISTOLOGY, DISEASE-FREE INTERVAL, AND NUMBER OF METASTASES

Sarcoma

Following the principles previously outlined, pulmonary metastasectomy for osteosarcoma and soft tissue sarcoma can lead to 43.6 percent (range 22.6–43.6 percent) 5-year survival. Repeat metastasectomy also has prolonged 5-year survival. Pfannschmidt et al. reported on pulmonary metastasectomy in 50 patients with soft tissue sarcoma who underwent systematic hilar and mediastinal lymph node dissection. Lymph node metastases were identified in 24 percent ($n = 12$). Survival was decreased in the patients with lymph node involvement, but was not statistically significant. Currently, routine mediastinal and hilar lymph node evaluation for patients with metastatic soft tissue sarcoma to the lungs cannot be recommended and needs further trials.

For sarcomas, a disease-free interval of more than 1 year and primary tumor necrosis greater than 98 percent following neoadjuvant chemotherapy have been shown to correlate with improved survival following pulmonary metastasectomy.

Colorectal Carcinoma

Five-year survival rates between 35 and 45 percent can be achieved with pulmonary metastasectomy for colorectal pulmonary metastasis. Elevated CEA levels greater than 10 as well as regional hilar and mediastinal lymph node involvement are negative prognostic indicators. Saito et al. stated in 2002:

> Five-year survival was 53.6% for patients without hilar or mediastinal lymph node metastasis, versus 6.2% at 4 years for patients with metastases ($p < 0.001$). Five-year survival of patients with a prethoracotomy carcinoembryonic antigen level less than 10 ng/mL was 42.7%, versus 15.1% at 4 years for patients with a carcinoembryonic antigen level 10 ng/mL or greater ($p < 0.0001$).

Therefore, it seems prudent that routine mediastinal as well as hilar nodal sampling should be considered for patients undergoing pulmonary metastasectomy for colorectal metastasis. Prolonged disease-free interval has not consistently correlated with improved outcome. Multiple pulmonary metastases (greater than 3 lesions) have been shown to negatively affect survival.

Metastatic Melanoma

Petersen and colleagues reviewed the Duke experience with 1720 patients who experienced metastatic pulmonary melanoma. Overall 5-year survival was 6 percent. Nodular histology of the primary tumor, two or more metastases, disease-free interval less than 5 years, and the presence of extrathoracic metastasis were associated with poorer prognosis. Similar to the international registry of lung metastases, prognostic grouping was performed. Five-year survival decreased from 26 percent to 11 percent to 4 percent to 2 percent as associated risk factors increased from 0 to 1 to 2 to 3 or more. They performed unilateral thoracotomy in 255 patients undergoing resection, thoracoscopy in 40 patients, and bilateral thoracotomy in 23 patients. Wedge resection was the most frequent type of resection.

Non-Seminomatous Germ Cell Tumors

Non-seminomatous germ cell tumors disseminate along the course of the thoracic duct, leading to mediastinal metastases as well as pulmonary metastases. Cisplatin-based chemotherapy is the primary treatment, with surgical salvage for residual disease. The majority of patients with residual disease have either conversion to mature teratoma (59 percent) or necrotic tumor (15 percent). Pulmonary metastasectomy is associated with prolonged survival in patients with metastatic non-seminomatous germ cell tumors, from 59 to 82 percent 5-year survival. The presence of an increase in elevated tumor markers (AFP and B-HCG), viable tumor cells, incomplete resection, four or more metastases, and pulmonary as opposed to mediastinal metastases negatively affect survival. The disease-free interval has not been shown to affect survival.

Breast Carcinoma

Complete resection of pulmonary metastatic breast cancer can be accomplished in 77 to 84 percent of patients. Although 5-year survival following pulmonary metastasectomy secondary to breast carcinoma approaches 38 to 50 percent, effective medical oncologic management is preferred over surgery for initial treatment. Disease-free intervals greater than 36 months are associated with improved survival following metastasectomy. If the size of the largest metastasis is greater than 20 mm, there is negative impact on survival.

Although multiple metastatic lesions have not been shown conclusively to affect survival negatively, treatment of the solitary pulmonary nodule in a patient with a history of breast carcinoma remains a challenge. This is particularly true because the ability to distinguish a solitary metastasis from primary lung carcinoma may not be possible. Thus, solitary pulmonary nodules should be treated as primary lung carcinoma until proved otherwise. When treated as a primary lung cancer, the planned resection is different and includes mediastinal lymphadenectomy or nodal sampling.

Other Cancers Metastatic to the Lungs

Prolonged 5-year survival following pulmonary metastasectomy may be realized for renal cell carcinoma, uterine cancer, hepatocellular carcinoma, and head and neck cancers.

EXTENT OF AND APPROACH TO RESECTION

The goal of pulmonary metastasectomy is to accomplish a complete (R0) resection while using optimal pulmonary conservation techniques (i.e., wedge resection). Dowling, et al. at University of Pittsburgh reported the first use of video-assisted thoracic surgery (VATS) for pulmonary metastasectomy in 1992. Subsequent to that report, many centers routinely perform VATS pulmonary metastasectomy. Ketchedjian et al. argue that VATS metastasectomy should be limited to two or fewer metastases located in the outer one-third of the lung and be resectable by VATS. Opponents of VATS or a minimally invasive approach to pulmonary metastasectomy argue that it is necessary to perform bimanual palpation of the lung to assess for additional metastases not identified on preoperative radiographic evaluation. Complete resection (R0) rendering the patient pathologically free of metastatic disease can be accomplished by this approach. McCormack et al. from Memorial Sloan-Kettering Cancer Center (MSKCC) performed VATS metastasectomy of all radiographically identified nodules (inclusion criteria were no more than two unilateral nodules) followed by immediate conversion to thoracotomy and bimanual palpation. They found that additional malignant nodules were present in 10/18 (56 percent) of their patients. Helical CT was used in 2 of 18 patients. They concluded that VATS was an inadequate surgical option for resecting all disease (R0 resection). Despite the fact that pulmonary metastases are hematogenous in origin, mandatory exploration of the radiologically negative hemithorax is not the standard approach for these investigators and was not performed in this experimental cohort. Of the International Registry of Lung Metastases database of 5206 patients who had metastasectomies, 4572 (88 percent) patients underwent R0 resections: 2.4 percent had residual microscopic disease (R1), and an additional 9.7 percent had residual macroscopic disease (R2). Of the 88 percent of patients who underwent an R0 resection, only 2 percent had minimally invasive approach or thoracoscopy and 58 percent had a monolateral thoracotomy. Based on pathological assessment, single metastases were identified in 46 percent of patients. Radiologic accuracy for unilateral thoracotomy was 75 percent; underestimation of tumor burden occurred in 16 percent. If one were to extrapolate the data from MSKCC regarding the finding that bimanual palpation reveals additional metastases in 56 percent of the patients, one would expect a lower percentage of solitary metastasectomy to have been performed in the international registry group. This is not the case. Repeat metastasectomy in the international registry was associated with 44 percent 5-year survival

("remarkably good"). As we learn more about the metastatic cascade, it seems plausible that metastatic dormancy, avoidance of immunosurveillance through antigen down-regulation, and production of immunosuppressive cytokines may be partially responsible for the good results achieved with VATS metastasectomy as well as unilateral thoracotomy for pulmonary metastasectomy.

With evolving technology, such as 64 slice CT scanners, the ability to detect smaller lesions will continue to improve. The improvement in PET scans to detect probable mitotic activity continues to gain better resolution at lower levels. Use of intraoperative ultrasound as well as wire-guided localizations, in conjunction with minimally invasive techniques, will allow surgeons to identify and remove metastatic nodules not previously identified radiographically, but appreciated on bimanual palpation. Radiologic complete resection is merging with complete resection of all palpable disease. Thus, consideration for a new paradigm may be warranted. Now is the time to establish the category of radiographic complete resection (R-R0). Such an approach would require postoperative surveillance CT scans and possibly PET scans at 3-month intervals following resection.

ROLE OF MEDIASTINAL NODAL EVALUATION AND EFFECT ON OUTCOME

Routine mediastinal and hilar nodal sampling is not performed uniformly. Although the International Registry of Lung Metastases found a 4.6 percent incidence of lymph node metastases, only 5 percent of patients underwent mediastinal lymph node evaluation. Autopsy studies of patients with non-pulmonary carcinoma demonstrate a 33 percent incidence of mediastinal lymph node metastases. Since there is a trend toward decreased survival when mediastinal or hilar lymph node metastases are present, Pfannschmidt and colleagues have attempted to elucidate further the incidence as well as impact of mediastinal lymph node metastases. They reported on pulmonary metastasectomy in 50 patients with soft tissue sarcoma who underwent systematic hilar and mediastinal lymph node dissection. Lymph node metastases were identified in 24 percent ($n = 12$). Survival tended to be decreased in the patients with lymph node involvement, but was not statistically significant from those without nodal metastasis. Routine mediastinal and hilar lymph node evaluation for patients with metastatic soft tissue sarcoma to the lungs currently cannot be recommended and needs further study.

Also, Pfannschmidt et al. evaluated mediastinal lymph nodes in 167 patients undergoing metastasectomy for colorectal carcinoma spread to the lungs. Lymph node metastasis was identified in 19.1 percent of patients. Five-year survival decreased from 38.7 to 0 percent when nodes were involved ($p < 0.03$). At the current time, mediastinal lymph node evaluation should be considered for all patients undergoing pulmonary metastasectomy secondary to colorectal carcinoma prior to pulmonary metastasectomy. Mediastinal node involvement should be considered a contraindication to metastasectomy.

Pfannschmidt et al. later evaluated 191 patients with pulmonary metastases secondary to renal cell carcinoma and found a 29.8 percent incidence of lymph node metastases. Despite a significant decrease in 3-year survival from 55.4 to 31.4 percent for patients with mediastinal or pulmonary lymph node metastases ($p = 0.0038$), prolonged survival is seen in patients with pulmonary and thoracic nodal metastatic renal cell carcinoma. Therefore, the presence of mediastinal adenopathy in these patients is not a contraindication to metastasectomy.

For other histology, further investigation is warranted to evaluate the role of mediastinal lymph node evaluation, mediastinal lymph node dissection, mediastinal lymph node impact on survival, and the decision to proceed with pulmonary metastasectomy.

ISOLATED LUNG PERFUSION

Isolated lung perfusion is a technique designed to allow the delivery of a variety of agents to the pulmonary parenchyma with minimal systemic exposure. Currently, tumor necrosis factor-α, doxorubicin, melphalan, cisplatin, and other agents have been studied. The pharmacokinetics of these agents as well as systemic agent leakage have been studied. Despite extensive study, isolated lung perfusion remains an investigational modality that may help in the multimodality approach to cancer. It may play a role in tumor reduction, conversion of unresectable patients to resectable, and ultimately survival.

CONCLUSIONS

Pulmonary metastasectomy can be performed in selected patients with acceptable long-term survival, when other treatment options are not available. Patients must meet the tenets of controllable primary disease, no extrathoracic disease (colorectal and germ cell tumors may be exceptions), and have sufficient cardiac and pulmonary reserve to tolerate complete resection. Mediastinal lymph node evaluation prior to pulmonary metastasectomy should be performed on all patients with a primary colorectal cancer. Positive mediastinal nodal metastases, secondary to colorectal carcinoma, are a contraindication to pulmonary metastasectomy. The finding of positive mediastinal lymph node involvement for sarcoma, as well as for renal cell carcinoma, does not support routine mediastinal nodal evaluation for these patients. Routine mediastinal nodal evaluation prior to pulmonary metastasectomy for other primary tumors

needs further investigation and should be considered for mediastinoscopy or transtracheal, transbronchial fine-needle aspirate.

Since repeat pulmonary metastasectomy has been shown to have good survival, patients who undergo pulmonary metastasectomy must undergo routine surveillance CT and/or PET-CT scanning to identify recurrent disease at 3-month intervals. Minimally invasive approaches to pulmonary metastasectomy produce similar survival to open approaches and enable the surgeon to perform a complete radiologic resection (R-R0). A minimally invasive approach to pulmonary metastasectomy in conjunction with serial radiographic follow-up and repeat metastasectomy is essential for achieving a complete pathological response.

CHAPTER

Lymphoproliferative and Hematologic Diseases Involving the Lung and Pleura

Douglas B. Flieder

Lymphoproliferative disorders of the lung and pleura comprise a varied but rare group of localized and diffuse processes that span the morphologic gamut from reactive to neoplastic and include several peculiar lesions that do not fit conventional definitions of either hyperplasia or neoplasia. Although most diagnoses are based on light microscopy, immunohistochemical and molecular investigations are practically *de rigueur*. Nomenclature and classification schemes have undergone drastic changes over the past quarter century and current definitions appear reasonable. Malignant lesions are best classified according to the current World Health Organization (WHO) scheme. This chapter presents the clinicopathologic features of primary and secondary pulmonary and pleural hematolymphoid lesions.

ANATOMY AND HISTOLOGY OF THE PULMONARY LYMPHOID SYSTEM

Pulmonary lymphatics are divided into two interconnecting channels that drain to peribronchial, hilar, and/or mediastinal lymph nodes and eventually into the thoracic duct, right lymphatic duct, and subclavian veins. One system drains through

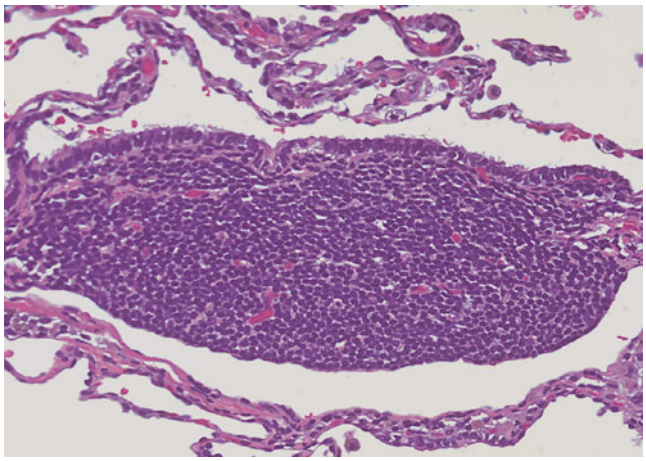

Figure 110-1 Bronchus-associated lymphoid tissue. The submucosal collection of lymphoid cells is intimately associated with overlying bronchiolar epithelium. Hematoxylin and eosin, 40× original magnification.

the visceral pleura around the lung into mediastinal lymph nodes and the other drains from central lung parenchyma to peribronchial and hilar lymph nodes. The lymphatics communicate at lobar, lobular, and pleural boundaries and thus serve each other as potential collaterals. Although not usually obvious in histologic sections of normal lung, lymphatics are prominent in disease states ranging from pulmonary edema to lymphangitic carcinoma. In the latter, lymphatic channels distended with malignant cells are apparent within the visceral pleura, interlobular septa, and adventitia of arteries, veins, and bronchioles. Of note, alveolar septa do not contain lymphatic channels. All lymphatics contain valves and flat endothelial cells line the discontinuous basal lamina. Larger lymphatics contain smooth muscle and collagen.

Small submucosal aggregates of lymphoid cells are often prominent at bronchial bifurcations and near distal respiratory bronchioles (pulmonary microtonsils) and represent bronchus-associated lymphoid tissue (BALT) (Fig. 110-1). Whether humans are born with this specialized secondary lymphoid system, or whether the aggregates of B lymphocytes, T lymphocytes, HLA-DR+ interdigitating cells, follicular dendritic cells, and lymphoid follicles with an overlying flattened and attenuated specialized epithelium develop in response to antigenic stimulation is controversial. Viruses, connective tissue disorders, tobacco use, and obstructive pneumonia are just a few pathologic processes known to induce BALT (Table 110-1). Unlike typical lymph nodes that rely on afferent lymphatics for antigen retrieval, BALT is integrated into lung tissue and antigen is sampled directly from the bronchial and bronchiolar lumens through specialized "lymphoepithelia." Immunoglobulins, most notably IgA, are synthesized and secreted by lymphocytes directly into airway lumens. Amazingly, this system appears capable of mounting a competent adaptive immune response. In addition, BALT B-lymphocytes circulate and "home" to other mucosal sites such as the conjunctiva, salivary glands, stomach, and intestines to create a common mucosal immune system, the mucosa-associated lymphoid system (MALT). Thus, responses induced in one location can be replicated at other sites. Malignant lymphomas arising in one MALT location can secondarily involve other MALT sites. Bronchus-associated lymphoid tissue appears to be the origin of many of the primary pulmonary lymphoid lesions.

Intrapulmonary lymph nodes (IPLs) may be part of the pulmonary immune system and may also be induced by antigenic stimuli rather normal embryologic development. Autopsy studies suggest a prevalence of 18 percent, and although many are related to bronchi of the first few orders, peripheral subpleural locations are not uncommon. In this age of high-resolution computed tomography (HRCT) and lung cancer screening programs, up to 80 percent of reported cases occur in men with histories of tobacco use and almost 35 percent of cases are multiple. These up to 2.0 cm round to angulated sharply circumscribed subpleural opacities are found along interlobular septa or within major and minor fissures and histologically resemble classic lymph nodes with

Table 110-1

Diseases Associated with Hyperplasia of Bronchus-Associated Lymphoid Tissue

Autoimmune diseases
Allergy such as asthma
Autoimmune hemolytic anemia
Celiac sprue
Hashimoto's thyroiditis
Myasthenia gravis
Pernicious anemia/ agammaglobulinemia
Primary biliary cirrhosis
Rheumatoid arthritis
Systemic lupus erythematosus
Sjögren's syndrome
Transverse myelitis
Immunodeficiency syndromes
Common variable immunodeficiency
Unexplained childhood immunodeficiency
Virus-associated
Epstein-Barr virus
Hepatitis viruses
Human immunodeficiency virus
Drug-induced forms
Allogeneic bone marrow transplantation
Dilantin
Infections
Chylamydia
Mycoplasma
Tuberculosis
Familial

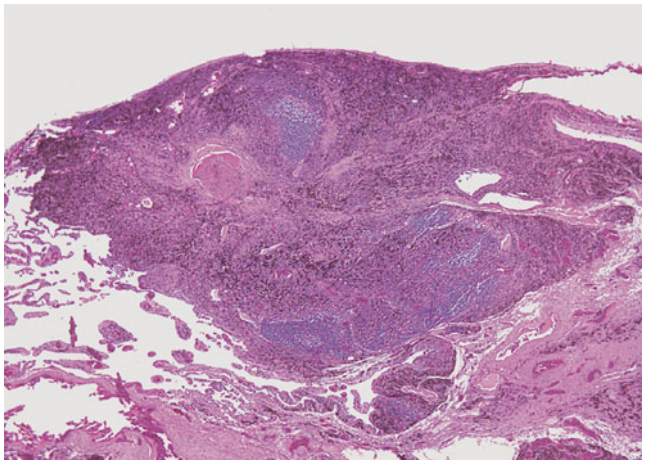

Figure 110-2 Intrapulmonary lymph node. Subpleural lymph nodes often accumulate carbon pigment and become fibrotic. The radiologic differential diagnosis includes carcinoma while a fine needle aspirate sample may mimic malignant lymphoma. Hematoxylin and eosin, 4× original magnification.

well-developed cortical and medullary areas. Sinus histiocytes frequently contain abundant anthracosilicotic pigment and silicotic nodules with calcifications may form (Fig. 110-2). In patients with chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), IPLs may be involved and, rarely, primary lung carcinoma or carcinoma from a nonpulmonary site can metastasize to IPLs. Most importantly, IPLs can be clinically, radiographically and cytologically mistaken for malignancy. Although fine-needle aspirates can exclude the possibility of carcinoma, an erroneous diagnosis of lymphoma might be considered.

GENERAL CONSIDERATIONS

Although internists, pulmonologists, and radiologists often diagnose pulmonary diseases on the basis of clinical and radiographic findings and rely on tissue samples merely for confirmation, lymphoid lesions of the lung are often unsuspected diagnoses rendered by pathologists. Yet clinical and radiologic studies are essential in the interpretation of all lesions. Often, light microscopic considerations can be excluded purely on the basis of radiographic findings. For example, whereas pulmonary lymphomas can be localized or diffuse, lymphoid interstitial pneumonia (LIP) is always bilateral and diffuse.

Pulmonary lymphoid lesions almost always require wedge biopsies or excisions for diagnosis. Although fine-needle aspirate biopsies and transbronchial biopsies supplemented with ancillary studies may suffice for a diagnosis of malignant lymphoma, architectural and cytologic variability necessitates generous sampling. Such is especially the case, as cellular monotony is not the sole criterion for malignancy. Whereas sheets of uniform cells may be diagnostic of lymphoma, many malignant processes such as Hodgkin's lymphoma (HL) and T-cell lymphoma are polymorphous and admixed with inflammatory cells. Secondary changes and biopsy-related artifacts may also confound the interpretation of a small sample.

Larger samples also allow for low-magnification pattern recognition. A "lymphatic distribution" may be seen in non-lymphoid processes such as sarcoidosis, yet is most striking in lymphoproliferative lesions reflecting the homing of lymphoid cells to endogenous pulmonary lymphatic routes. Although malignant lymphoid processes usually obliterate underlying lung architecture, diffuse alveolar septal expansion with lymphoid cells without a beaded lymphangitic pattern tends to represent an inflammatory rather than neoplastic process.

In addition to histologic examination, immunophenotyping is routinely performed and has become indispensable in diagnosing and classifying lymphoid lesions of the lung. Immunohistochemical studies can be reliably performed on formalin-fixed, paraffin-embedded tissue, whereas flow cytometry is useful for demonstrating immunoglobulin light-chain restriction. Aberrant antigen expression by either method also allows for subclassification. Polymerase chain reaction (PCR) may be required in up to 20 percent of cases to prove clonality. Either rearrangement of the immunoglobulin heavy-chain gene joining region (J_H) or the T-cell receptor γ-chain gene (TCR-γ) can be investigated. Lastly, chromosomal abnormalities indicative of specific lymphomas such as t(14;18) translocation and bcl-2 gene rearrangement in follicular lymphoma or t(11;14) translocation and cyclin D1 (bcl-1) gene rearrangement in mantle cell lymphoma may be helpful.

Given the complex evaluation required of these lesions, it is incumbent upon the clinician to deliver the fresh tissue sample to the pathologist along with his or her concern for lymphoma. Although formalin-fixed or B5 fixed, paraffin-embedded samples may suffice for diagnosis and immunohistochemical evaluation, cell suspensions and fresh-frozen tissue are required for flow cytometry, cytogenetics, and many molecular studies.

Lastly, although clonality indicates malignancy, clonality in pulmonary lymphoid lesions may not predict clinical outcome. Many pulmonary lymphomas have long indolent courses with 10-year survival rates of more than 80 percent yet lymphoid interstitial pneumonia, a polyclonal process, is progressive with one-third of affected patients dying of end-stage pulmonary fibrosis.

REACTIVE LYMPHOID PROCESSES

Although the terminology used to describe inflammatory processes of the lung has remained relatively static over the past 20 years, immunohistochemistry and molecular genetic analysis have redefined diagnostic criteria. Processes arising from BALT include nodular lymphoid hyperplasia (NLH), follicular bronchitis/bronchiolitis (FB/FBB), diffuse lymphoid hyperplasia (DLH), and LIP. Pulmonary hyalinizing granuloma is included in this section for historical reasons

only. Although the lesions are best considered either localized or diffuse, clinicopathologic entities including Castleman's disease can manifest with either distribution.

Localized Reactive Lymphoid Processes

Nodular Lymphoid Hyperplasia

Known to previous generations of pulmonologists and hematopathologists as "pseudolymphoma," this reactive process was recognized as a form of BALT hyperplasia in the mid 1980s. Although once quite common, ancillary studies have convincingly demonstrated that most cases were actually low-grade lymphomas. Thus NLH is now considered a legitimate but exceedingly rare polymorphous nodular lymphoid lesion of the lung. Neutrophilic microabscesses and foreign body giant cells found in several reported lesions indicate that the lesion may be the result of an inflammatory stimulus. Interestingly, immunohistochemical studies have documented B-cell lymphomas of BALT within preexisting reactive masses of BALT, such that one could, in the most general sense, consider NLH a precursor lesion.

Most affected individuals are middle-aged with a nearly equal gender incidence. Patients are usually asymptomatic, although a small percentage may have autoimmune diseases such as systemic lupus erythematosus or Sjögren's syndrome, or polyclonal hypergammaglobulinemia. Lesions most often appear as solitary subpleural radiographic nodules with air bronchograms, but several nodules or localized infiltrates can be seen, the latter finding serving as a reminder that the distinction between nodular and diffuse processes is arbitrary. Up to one-third of cases feature regional lymphadenopathy.

Excised tan-white rubbery to firm nodules measure from 0.6 to 6.0 cm. Histologically, the well-demarcated lesions may feature slight extension along alveolar septa and central scarring. Normal lung parenchyma is overrun by large reactive germinal centers with well-preserved mantel zones, and lymphoepithelial lesions are not seen (Fig. 110-3). Interfollicular areas are filled with plasma cells and mature lymphocytes. The follicles are clearly reactive with a variety of cell types, mitoses, and tingible body macrophages. Regional lymph nodes often feature reactive follicular hyperplasia.

Immunohistochemical studies demonstrate a mixture of B- and T-cells. The B-cells express both κ and λ light chains, i.e., lack light chain restriction. Aberrant B-cell staining for CD5, CD23, or CD43 is not seen, and the germinal centers do not stain with BCL-2. Immunoglobulin heavy chain gene rearrangement or evidence of t(14,18) breakpoints is not observed. These ancillary findings are of the utmost importance since light microscopy alone may not differentiate NLH from an extranodal marginal zone B-cell lymphoma of MALT. The latter usually features infiltrative growth, but may have reactive follicles and polytypic plasma cells with only a focal monotypic cell population.

Surgical excision is usually curative, although a small percentage of patients develop local recurrences at the original surgical site. Neither systemic spread nor death has been reported.

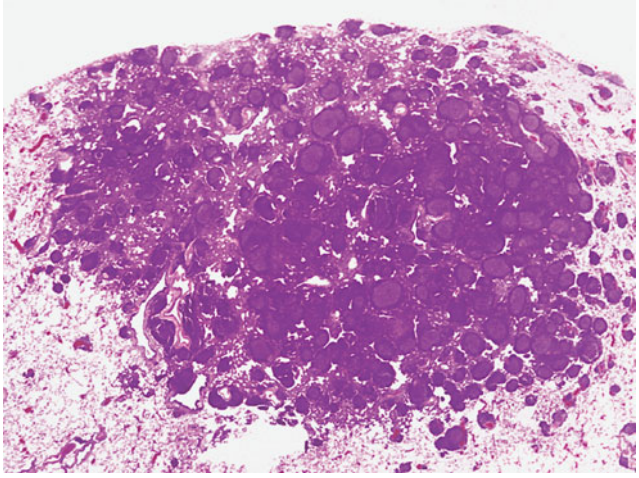

Figure 110-3 Nodular lymphoid hyperplasia. The lesion is composed of benign reactive germinal centers. Although radiographically nodular, germinal centers spill out into surrounding lung. Immunohistochemistry is required to exclude a diagnosis of malignant lymphoma. Hematoxylin and eosin, 1× original magnification.

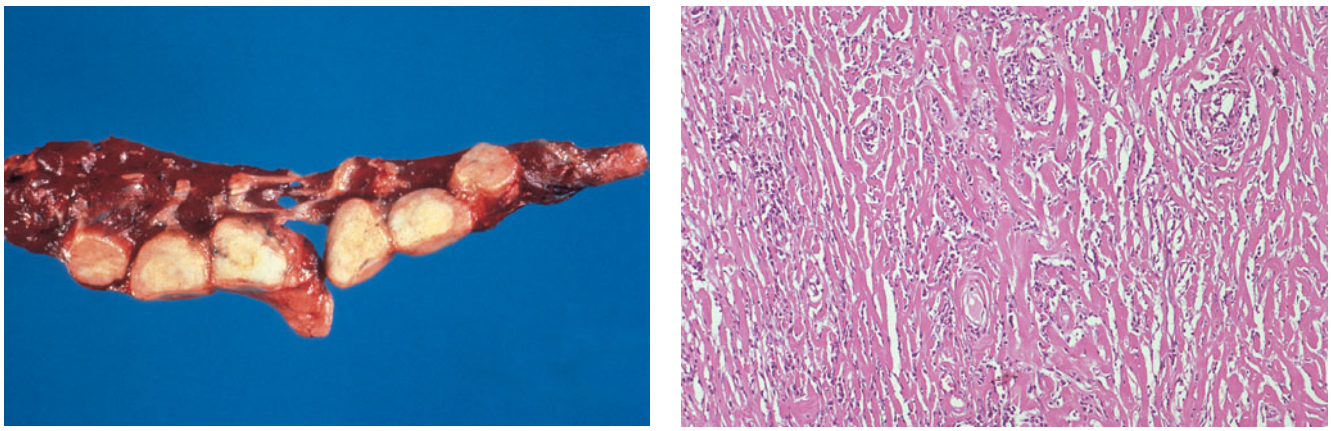
Pulmonary Hyalinizing Granuloma

Pulmonary hyalinizing granuloma (PHG) is not a lymphoid lesion per se, but an ever-present lymphoid component allows for its discussion in a hematolymphoid chapter. This peculiar fibrosing process shares clinicopathologic and morphologic features with sclerosing mediastinitis, inflammatory pseudotumor of the orbit, Riedel thyroiditis, and idiopathic retroperitoneal fibrosis. In fact, approximately one-fourth of cases feature concomitant mediastinal or retroperitoneal disease. The etiology is unknown; however, probably represents either an autoimmune phenomenon or exaggerated host response to mycobacteria or fungi.

Age at presentation ranges from 24 to 77 years and women are affected twice as often as men. Most patients present with mild symptoms including cough, shortness of breath, fever, and fatigue but up to 25 percent of reported individuals are asymptomatic. Laboratory studies include positive antinuclear antibodies, rheumatoid factor, antineutrophil cytoplasmic antibodies, and Coombs'-positive hemolytic anemia. Skin testing usually demonstrates exposure to *Mycobacterium tuberculosis* or *Histoplasma capsulatum,* but cultures and stains for microbes are negative. Radiographs reveal less than 4.0 cm bilateral and multilobar ill-defined homogeneous nodules that resemble metastases. Unilateral and solitary cases measuring up to 15 cm have been reported. Although not common, focal central irregular calcification may suggest metastatic bone-forming neoplasms. Central cavitation is rare.

Lesions are sharply circumscribed white-tan rubbery masses composed of irregular concentric whorls of hyalinized collagen encasing vessels and airways (Fig. 110-4*A*). The center of the lesion is paucicellular, whereas peripheral thick collagen bands are separated by mature T-lymphocytes, plasma cells, fibroblasts, and occasional giant cells (Fig. 110-4*B*).



A *B*

Figure 110-4 Pulmonary hyalinizing granulomas. *A*. Multiple well-circumscribed tan firm nodules can compromise respiratory function. *B.* Pink hyalinized collagen bands encircle vessels. Scant benign lymphoid infiltrates percolate between the collagen. Hematoxylin and eosin, 10× original magnification.

Blood vessels may feature transmural inflammation without necrosis. Microscopic calcifications can be seen, but granulomas are not present despite the designation PHG. The tumoral interface with lung parenchyma features reactive germinal centers, whereas adjacent lung may feature organizing pneumonia and hyperplasia of BALT. The morphologic differential diagnosis includes rheumatoid nodule, amyloidosis, Wegener's granulomatosis, malignant lymphoma, inflammatory myofibroblastic tumor, and infections. Clinicians should not be comfortable with a diagnosis of PHG rendered on anything less than a completely removed lesion.

Pulmonary hyalinizing granuloma tends to enlarge slowly and does not recur after surgical resection. However, growth of unresected or unresectable nodules can lead to respiratory compromise.

Amyloidosis and Light-Chain Deposition Disease

Immunoglobulin light chains can accumulate in many tissues in different forms, depending on the underlying condition and particular organ cytoskeleton. Clinically recognizable disease in the lung can manifest as tracheobronchial disease, solitary or multiple nodules, or in a diffuse interstitial parenchymal pattern. Most cases of diffuse light chain deposition in the lung are part of multiorgan involvement, associated with plasma cell dyscrasia, have dismal clinical outcomes and are not discussed further in this section.

Solitary and multiple amyloidoma are seen most often in older individuals, with a mean age of 67 years. Central and solitary lesions are often incidental findings but airway or visceral pleural distortion may produce cough, hemoptysis, or pleuritic chest pain. A radiographic diagnosis can be suggested when calcification or ossification is noted (20–50 percent of the time); otherwise, the clinical impression is that of a neoplasm.

Serum or urine monoclonal proteins are found in 10 percent of patients, and this lung pathology may be associated with lymphoproliferative diseases such as benign monoclonal gammopathy of undetermined significance, Sjögren's syndrome, Crohn's disease, NLH, lymphoid interstitial pneumonia, extranodal marginal zone B-cell lymphoma of MALT, or multiple myeloma. Solitary amyloidoma without underlying blood dyscrasias probably represent a hyperimmune response to unknown antigens.

Waxy hard gritty and yellow-tan nodules measure up to 15 cm and are composed of amorphous eosinophilic hyaline material that obliterates lung parenchyma but spares many arterioles (Fig. 110-5). Lymphocytes, plasma cells, and multinucleated giant cells percolate through the amyloid, but the infiltrate is most dense at the periphery of the nodules. Calcification and ossification with secondary marrow space formation is common. Congo red staining examined by polarizing microscopy reveals lesional apple-green birefringence. Immunohistochemical studies usually demonstrate λ

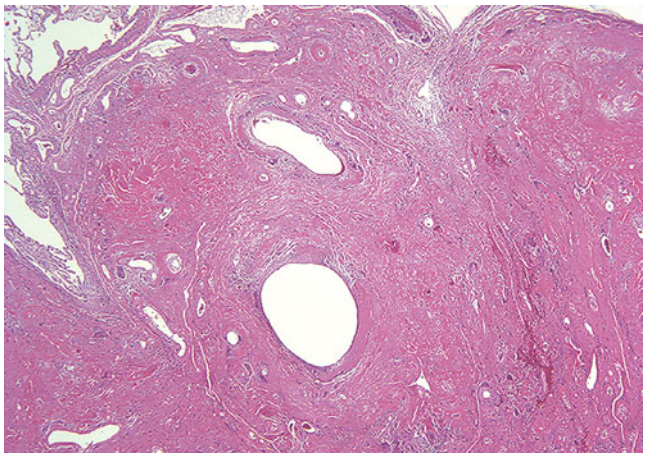


Figure 110-5 Nodular amyloidosis. Amorphous pink material replaces airspaces and overruns airways. In the absence of Congo red apple-green birefringence one should consider the possibility of nodular light chain deposition. Hematoxylin and eosin, 4× original magnification.

light-chain composition and negative immunoreactivity for amyloid A and transthyretin. Plasma cells are most often polytypic; however, small foci of monoclonal plasma cells within foci of polytypic plasma cells have been identified. Ultrastructurally, amyloid is composed of disorderly nonbranching hollow-core 8- to 10-nm fibrils. These extracellular deposits of chemically diverse proteins form a three-dimensional twisted β-pleated sheet.

Surgical excision is curative, but patients should be screened for underlying monoclonal B-cell proliferations including multiple myeloma and overt B-cell malignancies.

In stark contrast to nodular amyloidosis, nodular deposition of light chain deposition disease (LCDD) is associated with an underlying blood dyscrasia or renal failure in more than 50 percent of affected individuals. Most patients have free κ monoclonal light chains (IgG, IgA, and IgM in decreasing order) in their urine or serum. The clinical and light microscopic appearance of LCDD is similar to amyloid, and one might mistake a case lacking the characteristic Congo red staining as simply a poorly stained example of amyloid. These light chain deposits are composed of amorphous granular or globular electron dense material. One should consider this entity when dealing with a non-amyloidotic deposit given its strong association with lymphoid malignancies.

Diffuse Reactive Lymphoid Processes

Although NLH most likely represents a local response to an extrinsic stimulus and is clinically relevant owing to its radiographic appearance as a coin lesion and morphologic similarity with extranodal marginal zone B-cell lymphoma of MALT, the diffuse lymphoid hyperplasias FB/FBB and LIP represent a continuum of BALT hyperplasia often seen in patients with systemic diseases (Table 110-1). The extent of lung involvement is due in large part to host immune factors. Although thoracoscopic or open lung biopsies are required to establish these "diagnoses" and exclude other processes, including interstitial lung diseases and malignant lymphoma, morphology does not suggest etiology.

Follicular Bronchitis/Bronchiolitis and Diffuse Lymphoid Hyperplasia

Diffuse lymphoid hyperplasia *restricted* to the walls of airways and peribronchial tissue is often seen in individuals with bronchiectasis, chronic infections, and chronic obstructive pulmonary diseases, including asthma. The pattern may manifest as pulmonary disease in those with connective tissue diseases, congenital or acquired immunodeficiencies, and bone marrow transplantation, or as a hypersensitivity reaction. When the process spreads along lymphatic routes of the pulmonary lobule some prefer the designation DLH instead of FB/FBB.

Those with connective tissue disease are usually in their forties and most often suffer from rheumatoid arthritis (RA) or Sjögren's syndrome. Patients with immunodeficiency syndromes such as acquired immunodeficiency syndrome (AIDS), common variable immunodeficiency, IgA deficiency, and Evan's syndrome present in childhood, whereas a poorly defined subgroup with hypersensitivity syndromes is usually in their sixth decade of life. Those with DLH may also suffer with chronic low-grade infections such as *Mycoplasma, Chlamydia,* or Epstein-Barr virus (EBV).

Individuals present with dyspnea, cough, and fever; some may have recurrent pneumonia or weight loss. Pulmonary function tests reveal a restrictive pattern in most cases, but obstructive or normal patterns have been reported. Those with RA often have a very high rheumatoid factor on the order of 1:640 to 1:2560. Peripheral eosinophilia may be noted in those with hypersensitivity syndromes. Arterial blood gases show arterial hypoxia with a widened $AaPO_2$ gradient and hypocapnia. Chest radiographs feature bilateral diffuse reticular and nodular opacities, whereas high-resolution CT show up to 12-mm centrilobular and peribronchial nodules with or without areas of ground-glass opacity.

Gross pathology demonstrates numerous minute (1- to 2-mm) nodules adjacent to airways. Microscopically, nodular aggregates of B-cell rich lymphocytes and plasma cells with reactive germinal centers expand bronchial and/or bronchiolar submucosa and budge into and permeate overlying epithelium (Fig. 110-6). Rare T cells wander beyond the follicles into adjacent alveolar septa. Smaller airway lumens are distorted and narrowed predisposing to mucostasis and subsequent infections. Lymphoid follicles along interlobular septa and beneath the pleura represent a more diffuse form of lymphoid hyperplasia and warrant the descriptive diagnosis DLH.

Treatment with corticosteroids has variable results since this lung pathology is essentially a manifestation of an underlying disease. Those with peripheral eosinophilia are reportedly steroid responsive.

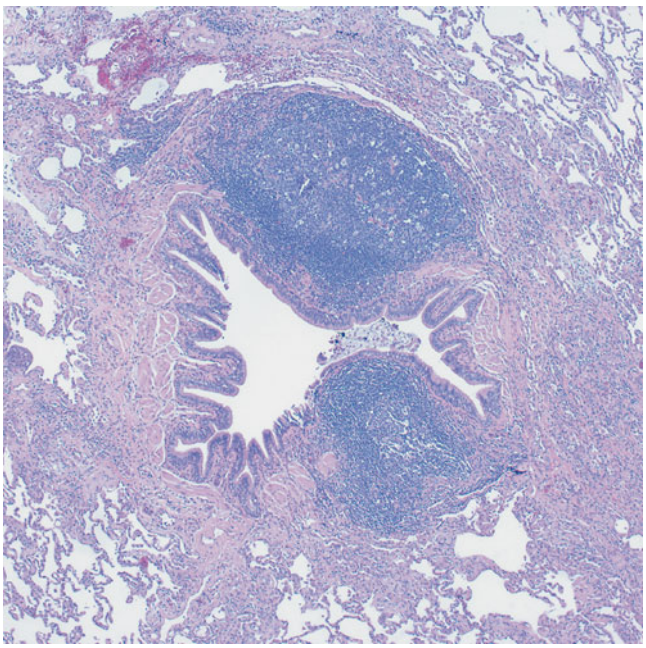

Figure 110-6 Follicular bronchitis/bronchiolitis. Reactive germinal centers expand airway submucosa and compress the lumen. Mucus accumulation often leads to infection and bronchiolectasis. Alveolar parenchyma is spared. Hematoxylin and eosin, 4× original magnification.

Figure 110-7 Lymphocytic interstitial pneumonia. *A.* Diffuse alveolar septal expansion with lymphocytes is usually a manifestation of underlying disease. Hematoxylin and eosin, 50× original magnification. *B.* Benign lymphocytes and plasma cells interfere with gas exchange. The morphologic differential diagnosis includes *Pneumocystis* infection. Hematoxylin and eosin, 60× original magnification.

Lymphocytic Interstitial Pneumonia

Although LIP is included in the American Thoracic Society/European Respiratory Society (ATS/ERS) classification of idiopathic interstitial pneumonias, this multi-factorial but rarely idiopathic process represents the most florid BALT hyperplasia and may be difficult to differentiate from DLH and low-grade malignant lymphoma. Almost all patients with LIP have immunologic disorders, dysproteinemias, or viral infections, including EBV and, especially in children, human immunodeficiency virus (HIV). The age and sex distribution reflect these different populations. This clinicopathologic process is exceedingly rare in the HIV-negative population, in which patients are usually middle-aged Caucasian women, but represents a pulmonary manifestation of chronic graft-vs.-host disease in bone marrow transplant patients. A strong association with Sjögren's syndrome is also noted.

The clinical presentation is that of interstitial lung disease with cough and/or dyspnea in addition to symptoms and signs related to underlying diseases. More than 60 percent of patients have dysproteinemias which can precede the onset of LIP or occur any time during the clinical course. Most are hypergammaglobulinemia, yet 10 percent of cases have a hypogammaglobulinemia. A monoclonal spike on serum immunoelectrophoresis suggests a diagnosis of lymphoma rather than LIP. Pulmonary function tests reveal reduced lung volumes and lowered diffusing capacity for carbon dioxide (D_{LCO}), and hypoxia is common. Bronchoalveolar lavage (BAL) analysis shows an increased percentage of lymphocytes.

Chest radiographs feature bilateral reticular and nodular opacities, ground-glass opacities, and parenchymal consolidation with lower lung zone predilections. Computed tomography demonstrates diffuse ground-glass opacities, ill-defined centrilobular nodules, bronchovascular and interlobular thickening, and scattered less than 3.0 cm thin-walled cysts. Lymphadenopathy is more commonly seen than fibrosis and honeycomb lung.

The lungs are typically firm and tan-gray and end-stage cases feature honeycomb change with subpleural cysts. Although the radiographs and gross appearance suggest parenchymal consolidation, histologically LIP shows a diffuse prominently *interstitial* infiltrate of small lymphocytes, plasma cells, larger mononuclear cells, and histiocytes (Fig. 110-7*A*). Although these infiltrates are centered on airways, vessels, and interlobular septa, and include peribronchiolar lymphoid follicles, infiltration into alveolar septa is always present and distinguishes LIP from FB/FBB and DLH (Fig. 110-7*B*). Small non-necrotizing granulomas, reactive germinal centers, and infiltration into overlying respiratory epithelium are often seen, whereas lymphocytes frequently spill into alveolar spaces. In long-standing lesions, hyaline, collagen, or even amyloid widens the interstitium leading to honeycomb fibrosis.

The lymphoid follicles largely consist of cytologically bland B cells, whereas the interstitial lymphocytes are mostly T cells. This pattern suggests that the lung can function like a giant lymph node. Immunoglobulin heavy chain restriction or gene rearrangement is lacking. In addition to malignant lymphoma, nonspecific interstitial pneumonia-pattern interstitial lung disease (NSIP) and infections including *Pneumocystis* should be excluded.

Given the rarity of the process, controlled treatment trials have not been undertaken. Corticosteroids are the primary therapy in addition to other immunosuppressive agents, such as cyclophosphamide and chlorambucil with variable results. One-third of patients have resolution, one third stabilize and the remaining third progress. Non-responders usually die of therapy-related infections, but occasional individuals die of end-stage pulmonary fibrosis. Lymphomatous change is very unusual; older reports of such most likely represented malignant lymphomas from the start.

In patients with HIV infections or AIDS, LIP is part of a spectrum of pulmonary lymphoid proliferations with virtually identical morphologies, but differing clinical

B

Figure 110-8 Solitary Castleman's disease. *A.* Involved peribronchial lymph nodes are often mistaken for pulmonary parenchymal disease. Airway and vessel distortion may cause symptoms. *B.* Solitary lymph nodes and rare lung lesions feature hyaline-vascular morphology. Small germinal centers are penetrated by hyalinized venules. The follicle mantle zone rings the burnt-out center in an onionskin pattern. Hematoxylin and eosin, 20× original magnification.

presentations. Individuals with so-called *diffuse infiltrative lymphocytosis syndrome* (DILS) featuring sicca syndrome with increased numbers of circulating CD8+ T-cells in the blood, generalized lymphadenopathy and enlarged parotid glands, are at high risk of developing LIP.

Lymphocytic interstitial pneumonia is most common is HIV-positive children and is a CDC category B indicator condition in children younger than age 13. In fact, up to 17 percent of HIV-positive children have LIP. Most present in their second or third year with lung infiltrates, failure to thrive, and increasing respiratory distress. The chest radiograph shows a diffuse micronodular or linear interstitial pattern with hilar and mediastinal widening. Therapy is uncertain, response to steroids is unpredictable, and mean survival is 33 months.

In HIV-positive adults, LIP is quite rare, and tissue sampling is required for diagnosis. Most patients present with generalized lymphadenopathy and polyclonal hypergammaglobulinemia. Bronchoalveolar lavage samples feature lymphocytes with CD8+ cells comprising up to 90 percent of the lymphoid cells. Histologically, the lymphoid infiltrates are predominantly T cells with few plasma cells. Germinal center formation is not a frequent finding. HIV-positive adults with LIP rarely die of the process, but rather of other AIDS-related diseases.

Castleman's Disease

Castleman's disease (CD), the eponymous term for angiofollicular lymph node hyperplasia, encompasses two clinically and pathologically distinct entities. Solitary lesions usually feature hyaline-vascular (HV-CD) morphology, whereas multicentric disease always has a plasma cell pattern (PC-CD).

Solitary CD is an uncommon form of lymphoid hyperplasia that usually presents as an incidental mediastinal mass in asymptomatic young to middle-aged individuals of either gender. Pleural, chest wall, and extrathoracic involvement have been reported, but pulmonary parenchymal disease is a true rarity and most reported cases likely represent nodal rather than true pulmonary disease (Fig. 110-8*A*). Solitary HV-CD lesions are usually asymptomatic or rarely cause pressure-related symptoms.

Ninety percent of solitary CDs feature hyaline-vascular morphology, whereas the remainder are the plasma cell variant. Hyaline-vascular Castleman's disease lymph nodes are enlarged and feature prominent lymphoid follicles with small atrophic germinal centers penetrated by hyalinized venules with plump endothelial cells originating in the interfollicular zone (Fig. 110-8B). Expanded mantle zones have concentric rings of lymphocytes imparting an onionskin appearance. The solitary plasma cell variant only involves lymph nodes and has not been reported in the lung. Lymph nodes are hyperplastic with enlarged germinal centers and sheets of interfollicular plasma cells. Surgical extirpation is both diagnostic and therapeutic since clinical suspicion of malignancy requires excision and excision results in the disappearance of any symptoms.

Multicentric Castleman's disease (MCCD) is best considered a virus-driven polyclonal lymphoproliferative process that shares virtually no features with solitary CD. In general, MCCD presents in the fourth and fifth decades of life but earlier in HIV-positive individuals. Signs and symptoms include fever, sweating, malaise, anemia, lymphadenopathy, hepatosplenomegaly, ascites, and pleural and pericardial effusions; all attributed to Kaposi's sarcoma herpesvirus/human herpesvirus 8 (KSHV/HHV8) induction of interleukin-6. Laboratory abnormalities include an elevated erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and bone marrow plasmacytosis that may lead to pancytopenia. A chronic demyelinating polyneuropathy may present as part of POEMS syndrome (Crow-Fukase disease). Patients

may also develop non-Hodgkin's lymphoma. HIV-positive patients with MCCD have a greater likelihood of pulmonary involvement.

Histomorphology correlates with high-resolution CT scan findings of peribronchovascular interstitial thickening and centrilobular nodules (Fig. 110-9*A*). Polyclonal peribronchiolar lymphoplasmacytic infiltrates with focal extension into interlobular and alveolar septa may rarely be associated with honeycomb change (Fig. 110-9B). Polymerase chain reaction and in situ hybridization with a KSHV probe is almost always positive in lung samples including bronchoalveolar lavage fluid. Although MCCD shares many features with LIP, the plasma cell-rich nature of the infiltrate and presence of KSHV discriminate between the two.

Treatment is primarily nonsurgical but survival beyond 5 years is rare. Although splenectomy may provide brief relief from hematologic symptoms, chemotherapeutic regimens with or without immunotherapy, including anti-IL-6 and anti-CD20 monoclonal antibodies, appear to induce the longest remissions. Highly active anti-retroviral therapy is also utilized in the HIV-positive population.

MALIGNANT LYMPHOID LESIONS

Within the hematopathology field, past decades will probably be best remembered for the myriad of classification schemes and ever-changing nomenclature. Thankfully, the current WHO classification represents a consensus list of lymphoid neoplasms that appear to be distinct clinical entities. Although complex, this scheme is reproducible among trained pathologists. Diagnoses are based on clinical, morphologic, immunophenotypic, and genetic features and not simply on morphologic, immunophenotypic, or even clinical subtleties. B-cell neoplasms, T- and NK-cell neoplasms, and Hodgkin's lymphoma are subgrouped according to lineage and stage of differentiation. Within this general context one can understand the practicality of a seemingly cumbersome diagnosis, such as pulmonary extranodal marginal zone B-cell lymphoma of MALT type, given the belief that these lymphomas arise from acquired BALT.

Primary Pulmonary Non-Hodgkin's Lymphoma

Although more than half of patients with nodal lymphoma have lung involvement, primary pulmonary lymphomas comprise less than 0.5 percent of primary lung neoplasms. Furthermore, the most common primary lung lymphoma, marginal zone non-Hodgkin's lymphoma of MALT origin, represents less than 10 percent of extranodal lymphomas. Non-Hodgkin's lymphomas are considered lung primaries when the lung is the major site of disease at the time of diagnosis. Thus, up to 20 percent of these lung lymphomas involve hilar and/or mediastinal lymph nodes. Pulmonary lymphomas have a range of morphologies and clinical aggressiveness such that separating the tumors into low- and high-grade categories is a dangerous oversimplification. Although most lung non-Hodgkin's lymphomas differ from nodal lymphomas and are thought to have their origin in BALT, traditional nodal non-Hodgkin's lymphomas, such as follicle center lymphoma, mantle cell lymphoma, diffuse large B-cell lymphoma, peripheral T-cell lymphoma, and $CD30^+$ anaplastic large cell lymphoma, also present as pulmonary primaries (Table 110-2).

Extranodal Marginal Zone B-Cell Lymphoma of MALT Type

Recent recognition that most primary pulmonary lymphomas arise from BALT revolutionized our thinking about extranodal lymphoid lesions. This hypothesis suggests that some degree of lymphoid hyperplasia is a necessary precondition for the development of these lymphomas and explains

Table 110-2

Lymphoid neoplasms commonly involving the lungs

- B-cell neoplasms
  - Mature B-cell neoplasms
    - Chronic lymphocytic leukemia/small lymphocytic lymphoma
    - Lymphoplasmacytic lymphoma
    - Plasma cell myeloma
    - Extraosseous plasmacytoma
    - Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT-lymphoma)
    - Nodal marginal zone B-cell lymphoma
    - Follicular lymphoma
    - Mantle cell lymphoma
    - Diffuse large B-cell lymphoma
    - Intravascular large B-cell lymphoma
    - Burkitt lymphoma/leukemia
  - B-cell proliferations of uncertain malignant potential
    - Lymphomatoid granulomatosis
    - Post-transplant lymphoproliferative disorder
- T-cell and NK-cell neoplasms
  - Mature T-cell and NK-cell neoplasms
    - Mycosis fungoides
    - Sézary syndrome
    - Peripheral T-cell lymphoma, unspecified
    - Angioimmunoblastic T-cell lymphoma
    - Anaplastic large cell lymphoma
- Hodgkin lymphoma
  - Classical Hodgkin lymphoma
    - Nodular sclerosis classical Hodgkin lymphoma
    - Lymphocyte-rich classical Hodgkin lymphoma
    - Mixed cellularity classical Hodgkin lymphoma

the association with inflammatory and autoimmune processes as well as the common finding of reactive germinal centers in lymphomas of BALT. These relatively indolent lymphomas must be discerned from both reactive processes, including NLH and LIP as well as more aggressive lymphomas.

Patients tend to be in their fifth through seventh decades of life with a slight male preponderance. Those younger, including children, almost always have preexisting immunosuppression such as HIV infection. Most individuals are asymptomatic and are noted to have an abnormality on a routine chest radiograph; however, dyspnea, cough, hemoptysis, and shortness of breath reflect extensive disease causing airway constriction, poor compliance, and atelectasis. "B" symptoms are rare. Mean lymphocyte counts are typically normal and peripheral blood does not show a leukemic phase, whereas a monoclonal gammopathy, usually IgM, is noted in up to 30 percent of patients.

Chest radiographs and HRCT scans show either peripheral or perihilar solitary or multiple masses or alveolar opacities with air bronchograms. Cavitation, calcification, and pleural effusions are very rare, whereas hilar adenopathy is present in less than 25 percent of cases. The interval between the finding of a radiologic abnormality and definitive pathologic diagnosis has a mean of over 5 years, demonstrating the tendency of this tumor to remain localized for a long period. Thus, it is not surprising that up to 80 percent of individuals present with stage I disease.

Grossly, nodular areas vary from 2.0 to 20 cm and are tan and fleshy. Underlying lung architecture may be preserved (Fig. 110-10*A*). At low magnification these lymphomas appear as diffuse infiltrates surrounding reactive follicles with peripheral tracking along bronchovascular bundles and interlobular septa (Fig. 110-10*B* and *C*). Invasion of bronchial cartilage and visceral pleura are common. At high magnification, the small lymphoid cells may have round nuclei with little cytoplasm (centrocyte-like) or irregular nuclear contours and abundant clear cytoplasm (monocytoid differentiation) (Fig. 110-10*D*). Plasmacytic differentiation is also common. Scattered larger cells (immunoblasts) can also be seen. Malignant cells often infiltrate reactive germinal centers (follicular colonization) as well as bronchial, bronchiolar, and alveolar epithelium (lymphoepithelial lesions). This latter finding is seen in up to 90 percent of cases, but is not a useful diagnostic criterion. Secondary features include fibrosis, sclerosis, and amyloid and sarcoidal granulomas. Involved mediastinal lymph nodes feature typical morphology of nodal marginal zone B-cell non-Hodgkin's lymphoma.

When light microscopic features favor a diagnosis of this lymphoma, all available ancillary studies should be utilized to make a definitive diagnosis. The neoplastic cells are monoclonal B cells, which may be identified with CD20 or CD79a stains. Light chain restriction is present in all cases with equal κ and λ percentages; however, amplification of the immunoglobulin heavy chain gene from paraffin sections with the PCR detects monoclonality in only 60 percent of tumors. Fifty to 60 percent of marginal zone B-cell lymphoma of MALT type demonstrate t(11;18), whereas t(1;14) or trisomy 3 may also occur.

The differential diagnosis includes NLH, LIP as well as pulmonary involvement with a variety of different malignant lymphomas, such as lymphoplasmacytoid lymphoma/immunocytoma. These distinctions are of paramount importance and the surgical pathologist or hematopathologist has the necessary tools to make a correct diagnosis.

Pulmonary marginal zone B-cell lymphomas of MALT are indolent tumors with 85 to 95 percent 5- and 10-year survival rates. In several studies, median survival was not reached at 10 years. Thus, patients with resectable disease are treated with resection, but those with diffuse lung involvement may be followed and treated with chemotherapy with or without anti-CD20 antibodies. Patients with systemic symptoms at

A

B

Figure 110-10 Extranodal marginal zone B-cell lymphoma of MALT type. *A.* Tan fleshy tumor fills alveolar spaces but preserves lobular architecture. *B.* Malignant lymphoid cells overrun lung tissue. Germinal centers are usually prominent. Hematoxylin and eosin, 4× original magnification. *C.* Malignant lymphoma often tracks along lymphatic pathways beyond the dominant mass lesion. If such a region was sampled the differential diagnosis would include diffuse lymphoid hyperplasia. Involvement of visceral pleura suggests the malignant nature of the process. Hematoxylin and eosin, 4× original magnification. *D.* Most pulmonary marginal zone B-cell lymphomas of MALT type are composed of small monotonous round (centrocyte-like) B-lymphocytes. Hematoxylin and eosin, 40× original magnification.

presentation may have a worse prognosis. Lymphoma recurs in the lungs or in other MALT sites such as salivary gland, orbital, or gastrointestinal tract in almost half of patients, and up to 15 percent of patients experience transformation of their lymphomas into more aggressive and usually deadly forms including diffuse large B-cell non-Hodgkin's lymphoma (DLBCL).

Other Non-Hodgkin's Lymphomas

Non-Hodgkin's lymphomas other than extranodal marginal zone B-cell lymphomas originating in the lung are very rare and comprise less than one-fourth of primary lung lymphomas. These tumors represent a heterogeneous group consisting primarily of DLBCL with fewer cases of follicle center cell lymphoma, and rare examples of mantle cell lymphoma,

lymphoplasmacytic lymphoma/immunocytoma, Burkitt's lymphoma, anaplastic large cell lymphoma, and peripheral T-cell lymphomas. The latter almost always represent secondary involvement by systemic lymphoma rather than lung primaries. Rare AIDS-related primary pulmonary B- and T-cell lymphomas related to severe immunodeficiency containing EBV RNA have also been described. Of note, only primary pulmonary DLBCL appears to arise from BALT and is also weakly associated with both fibrosing interstitial lung diseases and collagen vascular diseases.

Although each lymphoma subtype has particular morphologic features, primary pulmonary DLBCL is best characterized. Patients are usually adults but younger individuals with immunodeficiency states may be affected. Unlike those with extranodal marginal zone B-cell lymphomas of MALT, most patients present with shortness of breath, fever, chest pain and hemoptysis and often develop extrapulmonary lesions and paraneoplastic syndromes shortly after diagnosis. Restrictive physiology is often observed while imaging studies reveal solitary or multifocal nodules or infiltrates measuring at least 3.0 cm. Cavitation and pleural effusions are frequently seen and regional lymph nodes are involved in up to 50 percent of cases.

Resected lesions are white-tan and fleshy with areas of necrosis. Histologically, largely necrotic nodules or striking lymphangitic growth with parenchymal destruction are accompanied by inflammatory infiltrates. Infarction is not uncommon. Sheets of malignant mitotically active B cells are two to four times the size of normal lymphocytes (Fig. 110-11). Vascular infiltration and pleural involvement are common features and airway destruction leads to postobstructive pneumonia. Residual BALT hyperplasia and low-grade marginal zone lymphoma may be seen at the periphery of the mass.

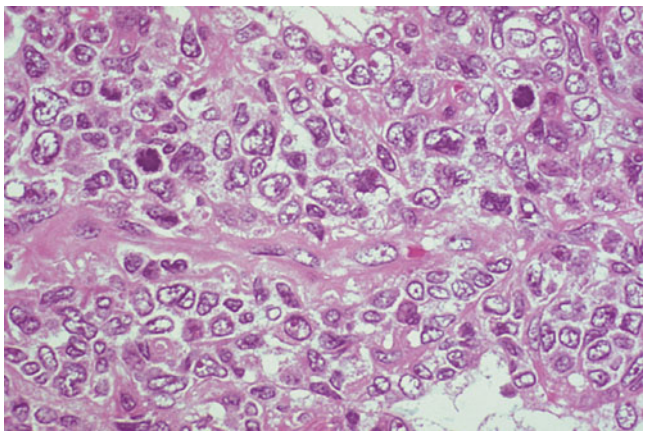

Figure 110-11 Diffuse large B-cell lymphoma. This lymphoma is composed of large cells with irregular nuclear features and significant mitotic activity. The B-cell phenotype is demonstrated by flow cytometry or immunohistochemistry. This lymphoma not only looks more aggressive than marginal zone B-cell lymphoma of MALT type, but also follows an aggressive clinical course. Hematoxylin and eosin, 40× original magnification.

Neoplastic cells express pan-B antigens CD20 and CD79a. Monotypic immunoglobulin light chain expression can be demonstrated with frozen tissue samples.

Although the cytologic atypia and necrosis in these lymphomas make it easy to distinguish them from benign lymphoid processes and extranodal marginal zone lymphomas, confusion with poorly differentiated carcinomas or Hodgkin's lymphoma can occur.

Localized DLBCL is potentially curable with surgery and Adriamycin-based chemotherapy, but 5-year survival rates do not surpass 60 percent and the median survival is only 3 years. Only half of HIV-positive patients achieve clinical remission and those remissions usually last only 6 months.

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis (LYG) is one of the most confusing lesions in all of human disease. The original investigators were not certain whether this lung-based process, which also involves the central nervous system, skin and other organs, was a malignant lymphoma or a variant of Wegener's granulomatosis. Since that time erroneous ideas concerning its etiology and histogenesis have muddled the entity even further. We now recognize LYG as an EBV-driven B-cell lymphoproliferative disorder arising in individuals with either obvious or clinically undetected defects in cell-mediated and perhaps also humoral immunity. In many ways, LYG is similar to posttransplant lymphoproliferative disorders (PTLD) with a spectrum of clinical behaviors.

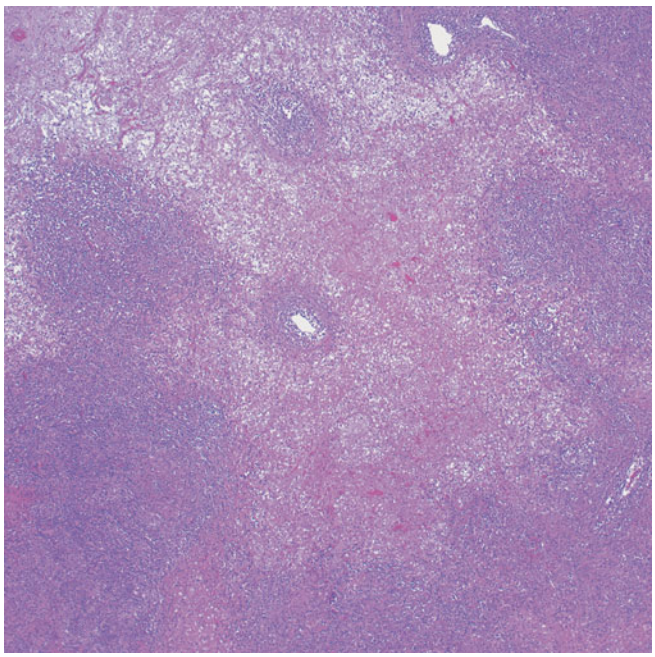
Although quite rare, LYG has characteristic clinical features. Patients usually present in the fifth or sixth decades of life but children and the elderly can be strickened. Men are affected two to three times as often as women. Dyspnea, cough, chest pain along with fever, and malaise and weight loss are the most common presenting complaints and up to 40 percent of patients also have skin nodules, ulcers, rashes, peripheral neuropathies, or other symptoms referable to central nervous system involvement. Gastrointestinal, musculoskeletal, or nodal involvement is uncommon, whereas a diagnosis following resection of an asymptomatic solitary lung nodule is very rare.

Laboratory findings can include either leukocytosis or leukopenia and elevated serum IgG or IgM. Cerebrospinal fluid may have abnormal protein and glucose levels. Serologies for autoimmune diseases are negative but evidence of EBV infection has been reported.

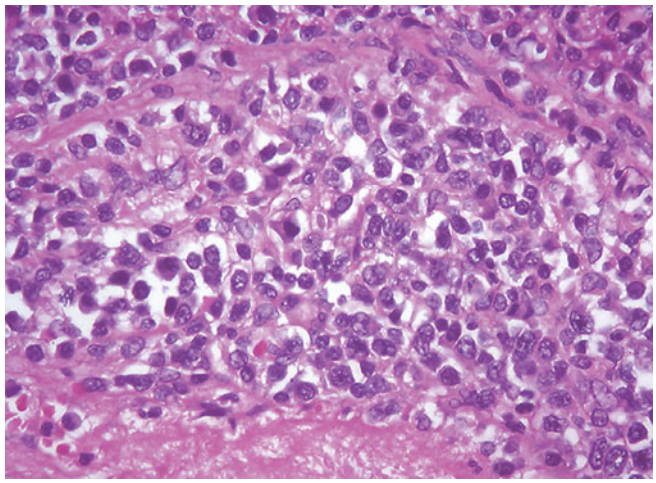
Radiographically, up to 70 percent of patients show bilateral middle and lower zone lung nodules as large as 10 cm. Coalescence and cavitation are often seen. Nonspecific reticulonodular infiltrates as well as solitary infiltrates or masses are less common findings. Pleural effusion is present in up to one-third of patients.

Macroscopically the lungs and other affected organs contain yellow-white well-demarcated masses with either solid or granular textures (Fig. 110-12*A*). Microscopically LYG is composed of nodular lymphoid infiltrates centered

A



B



C

Figure 110-12 Lymphomatoid granulomatosis. *A.* Most lesions are well circumscribed with central necrosis. However, this macroscopic appearance is not pathognomonic for LYG. *B.* Lung parenchyma often features irregular areas of necrosis with preserved vessels. Hematoxylin and eosin, 4× original magnification. *C.* The lymphoid infiltrate expands a vessel wall. Morphology does not suggest lymphoma yet cytologic atypia is noted. This grade II lesion was treated with combination chemotherapy but clinical remission was not achieved. Hematoxylin and eosin, 60× original magnification.

on lymphatic routes including bronchovascular bundles. As the lesions increase in size, blood vessels are encircled, infiltrated, and perhaps occluded but not obliterated by the process (Fig. 110-12*B*). The infiltrate and nodules are composed of a heterogeneous population of small, intermediate and large lymphocytes (Fig. 110-12*C*). The large cells are in the minority but can be very atypical or pleomorphic, stain as B cells ($CD20^+$ and $CD79a^+$) and are EBV-infected according to PCR and in situ hybridization studies. CD30 positivity is also noted in infected monoclonal cells. The smaller and more numerous cells stain as T cells ($CD3^+$, $CD4^+$, and/or $CD8^+$). Secondary features include interstitial and consolidative pneumonia. Despite its designation, granulomas are not seen.

Depending on the relative number of EBV-infected cells one observes more necrosis and a more aggressive clinical course. The grading system is based on the number of atypical large EBV-infected cells (Table 110-3). Grade 1 lesions probably include cases of so-called *benign lymphocytic angiitis* and *granulomatosis,* whereas grade 3 proliferations are alternatively considered a subtype of diffuse large cell lymphoma (DLCL). Given the complex histologic features of LYG and need to identify scattered large cells in an inflammatory mass, diagnosis and accurate grading almost always requires a surgical lung biopsy.

Although similar to T-cell–rich B-cell lymphomas such as angiocentric nasal NK/T-cell lymphoma and PTLDs, the former entity lacks EBV-infected monoclonal B cells and the latter lacks the angiocentricity of LYG. Other diagnostic considerations include Hodgkin's lymphoma and necrotizing inflammatory conditions.

The natural history is variable and clinical behavior ranges from indolent to aggressive. Spontaneous remissions and therapy-induced remissions occur but more than

Table 110-3

Histologic and *In Situ* Hybridization Grading of Lymphomatoid Granulomatosis

Grade 1
Angiocentric polymorphous infiltrate without atypia or necrosis
Rare Epstein-Barr virus infected cells (<5 per high-power (40×) field)
Grade 2
Angiocentric predominantly polymorphous infiltrate with occasional large or atypical lymphoid cells and parenchymal necrosis
Scattered EBV-infected cells (5–20 per high-power (40×) field)
Grade 3
Angiocentric and destructive monomorphous infiltrate with widespread necrosis
Sheets of EBV-infected cells (>20 per high-power (40×) field)

60 percent of patients die with a median survival of 14 months. Although most organ systems can be involved, lymphoid tissue including the spleen is only involved in the 25 percent of patients who develop grade 3 lesions. Hemophagocytic syndrome is related to systemic EBV infection rather than bone marrow involvement. Histologic grade correlates with outcome. Most patients have either grade 1 or 2 disease but only one-third of those with grade 1 lesions progress to grade 3/malignant lymphoma, whereas two-third of those with grade 2 lesions develop grade 3/malignant lymphoma. Asymptomatic patients or those with minimal disease and grade 1 or 2 histology may be observed; those with symptomatic grade 1 or 2 histology require treatment with corticosteroids or single or multiagent chemotherapy. Clinically aggressive grade 1 and 2 and all grade 3 lesions are treated as DLCL with combination chemotherapy. Therapies targeting EBV-bearing B-cells (interferon-$\alpha 2\beta$) or reactive T cells (i.e., cyclosporine) as well as stem cell transplantation, have been reported.

Intravascular Lymphomatosis

Intravascular lymphomatosis (IVL) is a rare non-Hodgkin's lymphoma characterized by lymphoma cells only in the lumina of small vessels, particularly capillaries. Although IVL most often manifests with neurologic or dermatologic manifestations, individuals in their fifth to seventh decades of life may complain of fever, dyspnea, cough, chest pain, or present with respiratory failure. Hypoxia and decreased diffusion capacity are seen and radiographs demonstrate reticulonodular infiltrates, whereas CT scans can show patchy ground glass opacities.

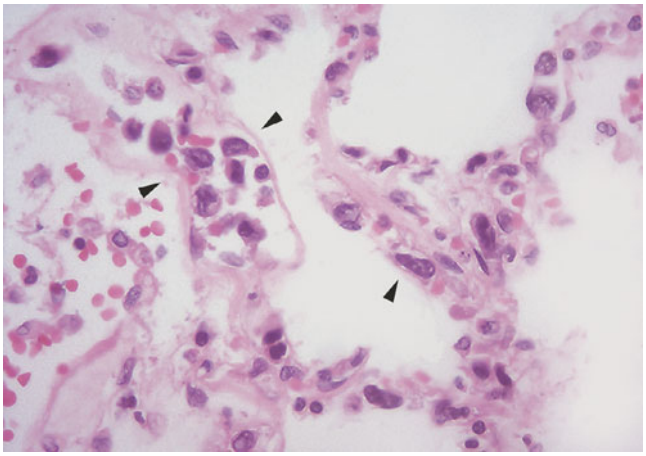


Figure 110-13 Intravascular large B-cell lymphoma. Malignant lymphoid cells remain confined to vascular channels (arrowheads). Hematoxylin and eosin, 60× original magnification.

Low magnification histology demonstrates a diffuse interstitial process resembling cellular interstitial pneumonia yet higher magnification reveals large cells with prominent nucleoli confined to arteries, veins, lymphatics, and especially capillaries (Fig. 110-13). Fibrin thrombi may be noted.

Although most reported cases of IVL are B-cell lymphoma ($CD19^+$, $CD20^+$, $CD79a^+$) and the WHO classifies the process as intravascular large B-cell lymphoma, a T-cell phenotype associated with EBV has been described. Although the intravascular nature of the lymphoma is not understood, absence of adhesion molecules CD54 (I-CAM-1) and CD29 ($\beta_1$integrin) may prevent neoplastic cell–endothelial cell interactions and extravascular spread.

Half of cases are diagnosed at autopsy yet a diagnosis is possible on thoracoscopic and even transbronchial biopsies. Immunohistochemical stains are necessary to discern IVL from metastatic carcinoma, malignant melanoma, and leukemia. Although prognosis is poor, complete remission and long-term survival can be achieved with prompt diagnosis and aggressive combination chemotherapy.

Hodgkin's Lymphoma

Primary pulmonary HL is very rare. This is in part due to the requirement that, unlike non-Hodgkin's lymphoma, regional lymph nodes be free of disease in order to qualify as a lung primary.

Primary pulmonary HL shows the usual bimodal age distribution of systemic HL but the age is slightly older with a mean of 42 years. Women outnumber men by 1.5 to 1. Symptoms include cough, dyspnea, hemoptysis, and chest pain and one-third of patients experience B symptoms. Radiographs demonstrate reticulonodular and linear infiltrates or multiple nodular lesions. Solitary lesions and consolidation are also seen. Upper lobe disease is most common, whereas atelectasis and cavitation are frequently observed.

Tumors have a multinodular white firm macroscopic appearance and histologically grow along lymphatic routes in the lung. As small nodules coalesce, central necrosis becomes apparent. Visceral pleura is often infiltrated while bronchial involvement can result in plaque-like nodules, polypoid endobronchial masses, or airway collapse. Within the WHO histological classification of HL, one cannot be certain if nodular lymphocyte predominant HL and the four subtypes of classical Hodgkin's lymphoma all involve the lung. Nodular sclerosis and mixed cellularity subtypes of HL are more commonly seen than lymphocyte rich, whereas lymphocyte depleted has not been reported in primary pulmonary HL. Diagnosis requires the identification of Reed-Sternberg cells or variants (usually $CD15^+$ or $CD30^+$) within the appropriate inflammatory background. Central necrosis, granulomatous inflammation, and vascular permeation by the polymorphous infiltrate are commonly seen.

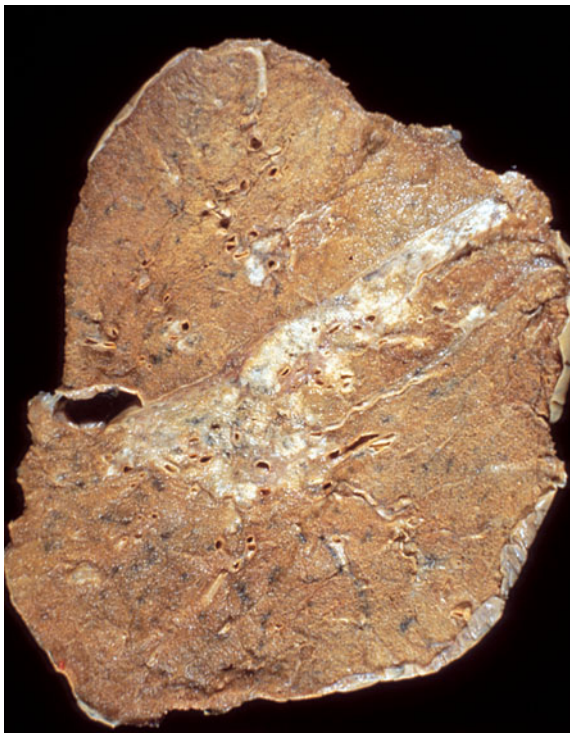
The morphologic differential diagnosis includes inflammatory and malignant processes. Infections, Wegener's granulomatosis, and sarcoidosis as well as poorly differentiated carcinomas, LYG, and a variety of non-Hodgkin's lymphomas must be considered. The non-neoplastic entities can be discerned histologically, whereas the neoplasms require at least immunohistochemical studies.

The prognosis for patients with primary pulmonary HL is variable. Although individuals with all types and stages of HL have a 5-year survival of almost 75 percent, small patient group studies suggest only a 50 percent 2-year disease-free period for this subgroup of clinical stage IE disease. Relapses occur in the lung and elsewhere and appear associated with multiple lobe involvement, pleural invasion, cavitation, and presence of B symptoms.

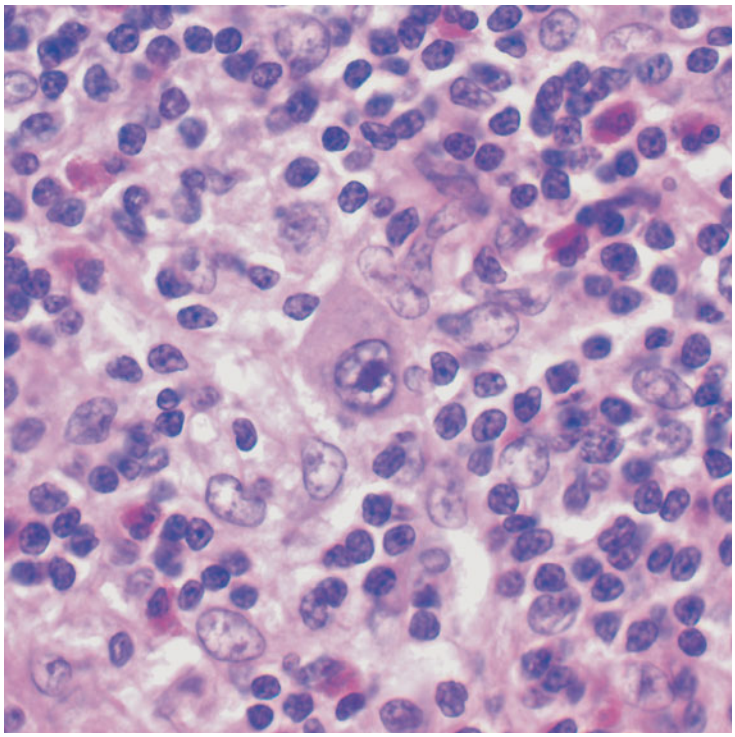
Secondary Lymphoma Involving the Lung

Secondary lung involvement with nodal and extranodal lymphomas is significantly more common than primary pulmonary lymphoma. Lung involvement with common nodal and disseminated lymphomas surpasses 50 percent during life and at autopsy. Clinical and radiologic features may suggest an infectious process, but tissue samples demonstrate a lymphangitic pattern of disease (Fig. 110-14A). Patchy infiltrates and endobronchial masses are, however, not uncommon.

Morphology does not usually allow for distinction between primary and secondary lung disease. For example, pulmonary involvement with nodal marginal zone lymphoma is indistinguishable from primary pulmonary extranodal B-cell lymphoma of MALT. Thus, clinical history and review of previous diagnostic material are necessary for proper diagnosis. Secondary lymphomas involving the lung can also transform to more aggressive histology with increased numbers of large



A



B

Figure 110-14 Lung involvement with Hodgkin's lymphoma. *A.* The striking lymphangitic distribution of this dense white tumor indicates secondary pulmonary involvement. *B.* A uninucleate Reed-Sternberg cell with typical prominent nucleolus (center) is surrounded by lymphocytes and eosinophils. Hematoxylin and eosin, 60× original magnification.

cells. This phenomenon is not infrequently seen in samples from patients with CLL/SLL.

Several particular systemic lymphoproliferative disorders that may present with significant lung pathology warrant additional discussion.

Mycosis fungoides may involve the lung after dissemination of cutaneous disease or as part of the Sézary syndrome and is the second most common extracutaneous site after lymph nodes. Clinical and radiographic features often mimic pneumonia or even acute respiratory distress syndrome with nodular and diffuse disease. Tissue samples demonstrate airspace and interstitial infiltrates along lymphatic routes in addition to occasional granulomas, extensive vascular infiltration, and necrosis. Cells range from small with irregular twisted nuclei to large with prominent nucleoli.

The lungs are also frequently involved with angioimmunoblastic T-cell lymphoma. Although originally described as a reactive process (angioimmunoblastic lymphadenopathy with dysproteinemia), this malignant disease in the lung can be mistaken for interstitial pneumonia. However, the lymphatic distribution of atypical "clear" cells with indented nuclei admixed with immunoblasts, plasma cells, and histiocytes should be distinguished from HL.

Pulmonary involvement with HL is recognized at presentation in more than 10 percent of patients with mediastinal or extrathoracic disease, 50 percent of patients have relapses in the lung and almost 60 percent are noted to have pulmonary involvement at autopsy. Unlike primary pulmonary HL, secondary involvement rarely manifests with large nodules, whereas infiltrates often surround blood vessels and may feature greater numbers of atypical cells and fewer inflammatory cells than in primary HL (Fig. 110-14*B*).

Plasmacytoma/Multiple Myeloma

Extraosseous plasmacytomas most often affect the upper respiratory tract. Primary plasmacytomas of the lung are exceedingly rare; patients are usually in their fifth and sixth decades of life and asymptomatic. Cough, dyspnea, and hemoptysis have been reported. Unlike multiple myeloma, individuals may lack a serum M-protein or Bence Jones light chains in the urine. Radiographs demonstrate a midlung or hilar solitary mass, but peripheral lesions amenable to transthoracic needle aspiration biopsy occur.

Tumors range from 2.5 to 8.0 cm and most often involve a major bronchus with occasional involvement of regional lymph nodes. Histologically, sheets of plasma cells including binucleate forms overrun lung parenchyma and bronchial cartilage (Fig. 110-15). Fibrous bands course through the tumor and amyloid or light chain may be associated with the neoplasm. κ and λ light chains as well as IgG, IgA, and IgD can be expressed immunohistochemically or produced as M-proteins by the tumor. The pathologist must discriminate between plasmacytoma and marginal zone lymphoma with plasmacytoid features as well as inflammatory myofibroblastic tumor.

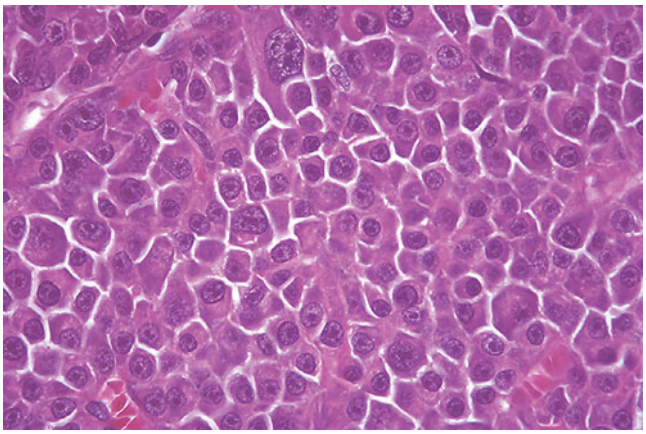


Figure 110-15 Plasmacytoma of lung. Sheets of plasma cells usually form a solitary nodule. Cytologic atypia is often seen. Since this lesion is less common than pulmonary involvement with multiple myeloma, clinical correlation is always required. Hematoxylin and eosin, 40× original magnification.

Although the natural history of this rare tumor is not well delineated, it appears that cases are either cured with either surgical excision or radiation therapy, or evolve into multiple myeloma. The presence or absence and amount of M protein may mirror tumor burden and clinical course while an increase or decrease in levels may be associated with recurrence or successful treatment. An overall 5-year survival of 40 percent has been reported.

Pulmonary involvement with multiple myeloma is more common than pulmonary plasmacytoma. Lung involvement may be nodular or have a diffuse lymphangitic pattern. Nodular or diffuse amyloid deposition may accompany the neoplastic cells. Intracytoplasmic crystalline casts similar to those seen in the kidney are occasionally observed.

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDER

PTLD is a lymphoid proliferation or lymphoma that develops as a consequence of immunosuppression in solid organ or bone marrow allograft recipients. Eighty percent of cases are associated with EBV infection in the setting of decreased T-cell immune surveillance; the etiology of EBV negative PTLD is unknown. Most cases are of host origin while approximately 10 percent of cases are of donor origin. Those of donor origin are more common in lung and heart-lung transplantation patients due to the presence of donor BALT in the lungs.

Allograft and extranodal MALT sites including Waldeyer's ring, lung and gastrointestinal tract, are usually involved and incidence varies based on type of allograft and immunosuppression regimen. One percent of renal transplant patients but almost 20 percent of lung transplant recipients are stricken. In solid organ transplants

treated with azathioprine PTLD develops after years but those treated with cyclosporine A often present within weeks of transplantation.

Approximately 10 percent of PTLDs manifest with pulmonary lesions. Individuals may be asymptomatic or present with constitutional symptoms. In lung transplant patients, organ failure may occur. Radiographs demonstrate nodular or diffuse reticulonodular infiltrates, solitary nodules, or multiple mass lesions with or without regional lymphadenopathy.

Morphologic categories of PTLD include early lesions, polymorphic PTLD, monomorphic PTLD, Hodgkin's lymphoma, and Hodgkin's lymphoma-like PTLD (Table 110-4). Most proliferations are B-cell processes, although T-cell lesions are seen. Early lesions usually involve lymph nodes and Waldeyer's ring rather than lung; lymphoid tissue is hyperplastic with either sheets of plasma cells or paracortical expansion with immunoblasts. The latter resembles infectious mononucleosis morphology. Polymorphic and polyclonal proliferations feature mixtures of small lymphocytes, plasma cells, and immunoblasts and may progress to monomorphic monoclonal proliferations with sheets of large transformed cells resembling aggressive lymphoma (Figs. 110-16*A* and *B*). In fact, the monomorphic monoclonal proliferations are subclassified according to lymphoma classification. Hodgkin's lymphoma and Hodgkin's lymphoma-like PTLD are very rare and purportedly similar to methotrexate-related HL. The morphologic findings may be difficult to differentiate from allograft rejection; immunophenotyping is essential, whereas molecular genetic testing for clonality and in situ hybridization studies for EBV may be necessary. For these reasons, tissue procurement rather than fine-needle aspiration biopsy is preferred for diagnosis.

Treatment starts with reductions in immunosuppression despite the risk of losing the allograft. Early lesions

B

Figure 110-16 Posttransplant lymphoproliferative disorder. *A.* This polymorphic lesion features small and large lymphocytes admixed with plasma cells. Hematoxylin and eosin, 60× original magnification. *B.* Monomorphic lesions are often comprised of large atypical cells with numerous mitoses. According to the WHO scheme this lesion is classified as a diffuse large B-cell lymphoma. Hematoxylin and eosin, 60× original magnification. *(Photomicrograph courtesy of Dr. A. Chadburn, Weill Medical College of Cornell University, New York, NY.)*

usually regress while only a proportion of polymorphic and monomorphic PTLD respond. Neither morphology nor molecular characterization of the PTLD can predict response to reduction in immunosuppression. Non-responders are then treated with cytotoxic chemotherapy and perhaps radiation therapy. Anti-CD20 antibody therapy plays a limited role. Although early diagnosis with prompt reduction of immunosuppression followed by cautious chemotherapy administration has improved the prognosis of patients with PTLD, mortality rates in solid organ transplants and bone marrow transplant recipients are 60 and 80 percent, respectively.

LEUKEMIC INFILTRATES INVOLVING THE LUNG

Significant lung involvement with leukemia affects less than 10 percent of individuals but secondary effects of leukemia or therapy including infections, alveolar proteinosis, leukemic cell lysis pneumopathy, hemorrhage, and chemotherapy toxicity afflict most leukemia patients. Leukemic lung infiltration is often found at autopsy or as an "incidental" finding in a tissue sample demonstrating an infectious process, and only causes symptoms in those patients with high (40 percent or greater) blast counts.

Cough, dyspnea, and hemoptysis may precede the leukemia diagnosis for months or develop suddenly. Bronchiolar involvement producing asthma-like symptoms has been reported. Radiographic findings run the gamut from localized to diffuse infiltrates.

All leukemia subtypes can involve the lung but acute myeloid leukemia, acute lymphoblastic leukemia, and CLL/SLL are most often seen. Infiltrates are predominantly restricted to the pulmonary lymphatic distribution and rarely form micronodules (Fig. 110-17). Bronchiolocentricity may be mistaken for bronchiolitis. Infiltrates can be subtle and chloroacetate esterase and myeloperoxidase stains may be useful in diagnosis and subtyping. Leukemic counts greater than 200,000/μm cause capillary leukostasis with resultant thrombosis. Pulmonary edema, infarct, and diffuse alveolar damage may result.

Patients with agnogenic myeloid metaplasia (myelofibrosis) occasionally have pulmonary manifestations. Diffuse and nodular foci of extramedullary hematopoiesis usually follow lymphatic routes and associated fibrous tissue can form large nodules. Interstitial fibrosis can result and may be mistaken for a primary chronic fibrosing interstitial pneumonia.

In addition to acute complications of leukemia, patients undergoing bone marrow transplantation for leukemia may experience a variety of pulmonary complications including pulmonary edema, diffuse alveolar damage/acute respiratory distress syndrome, bacterial, fungal, and viral infections and graft-vs.-host disease. Acute graft-v.-host (GVH) rarely involves the lung but lymphocytic bronchiolitis, LIP, constrictive bronchiolitis, and pulmonary fibrosis are all considered within the spectrum of chronic pulmonary GVH. However, these manifestations may represent cytotoxic chemotherapeutic effect.

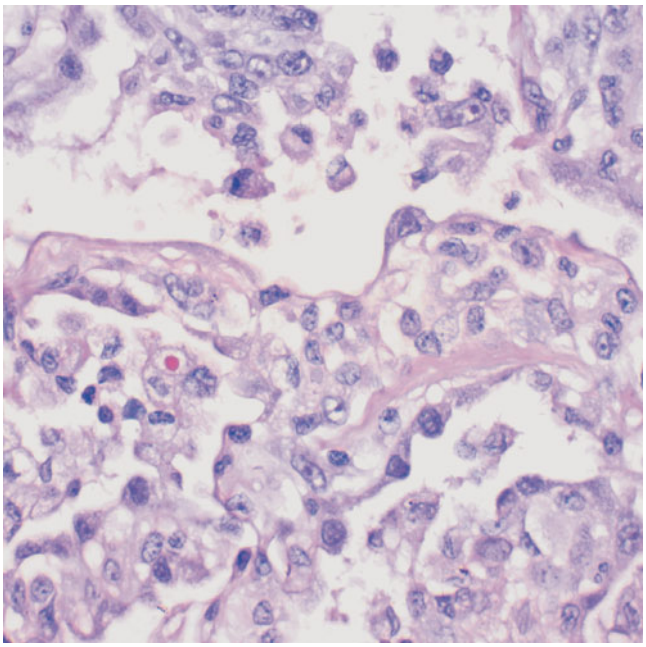

Figure 110-17 Leukemic infiltrate in the lung. Primitive mononuclear cells with clumped chromatin (blasts) expand alveolar septa and spill into air spaces. Although an infectious process was suspected clinically, acute myeloid leukemia represented the only lung pathology. Hematoxylin and eosin, 60× original magnification.

PLEURAL LYMPHOMAS

Disseminated lymphomas frequently affect the visceral pleura and pleural cavity. Non-Hodgkin's lymphomas often invade the visceral pleura while HL often causes pleural effusions due to mediastinal lymph node involvement and secondary lymphatic obstruction. Leukemia and multiple myeloma rarely manifest with pleural involvement. Diagnosis can be established with effusion cytology and parietal pleural biopsies are rarely required.

Primary pleural lymphomas are much less common and only two have been described; primary effusion lymphoma (PEL) and pyothorax-associated lymphoma (PAL). Both are associated with EBV but similarities end there.

Primary Effusion Lymphoma

Primary effusion lymphoma is a rare large B-cell lymphoma that presents as either a pleural, pericardial or peritoneal cavity effusion without a detectable tumor mass. All cases are associated with KSHV/HHV8 and most occur in young to middle-aged HIV-positive homosexual males. Rare cases have been reported in supposedly immunocompetent elderly individuals and HIV-negative cardiac transplant patients. Some

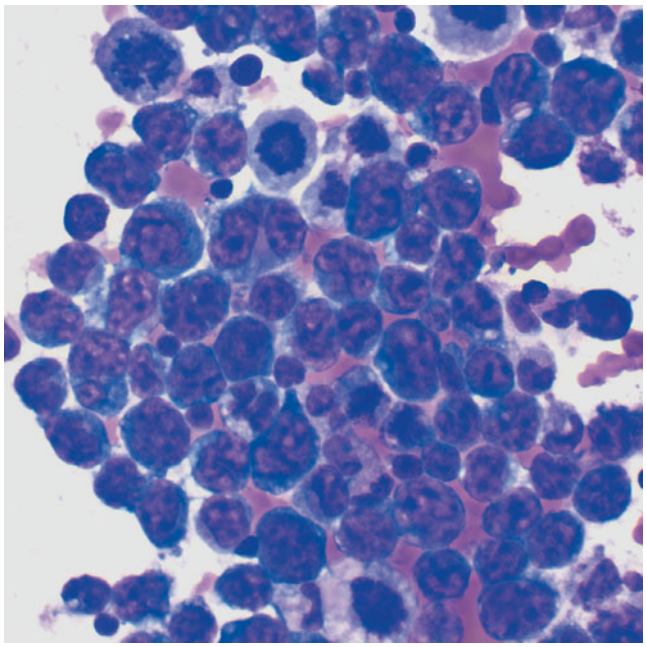

Figure 110-18 Primary effusion lymphoma. This pleural cytology demonstrates a large cluster of pleomorphic cells. This KSHV/HHV8 associated lymphoma is of B-cell origin despite the absence of immunohistochemical staining for B-cell markers. Modified Wright-Giemsa, 60× original magnification.

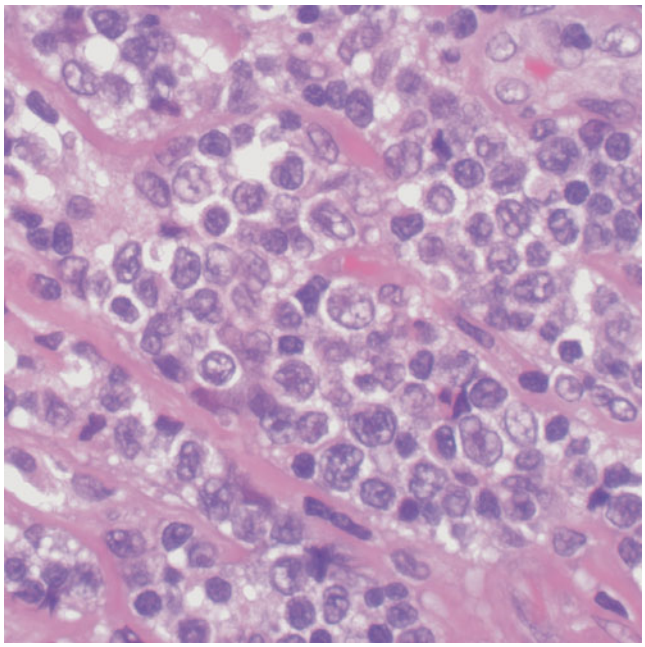

Figure 110-19 Pyothorax-associated lymphoma. Unlike primary effusion lymphoma, this aggressive large cell B-cell lymphoma is pathogenetically linked to EBV and forms a mass lesion. Hematoxylin and eosin, 60× original magnification.

patients have preexisting Kaposi sarcoma and rare cases are associated with MCCD. In addition, most cases are co-infected with EBV but a pathogenetic role for this virus has not been elucidated.

Effusion cytology specimens demonstrate large lymphoid cells with large round to irregular nuclei and frequent multinucleation as well as numerous mitotic figures (Fig. 110-18). Plasma cell features may be prominent and anaplastic cells can be seen. Biopsies feature tumor cells admixed with fibrin. Parietal or visceral pleura invasion is a very rare finding. B-cell lineage is confirmed by immunoglobulin gene rearrangement studies but neoplastic cells rarely express B-cell markers! Leukocyte common antigen (CD45), CD30, CD38, and CD138 (plasma cell-related markers) are expressed. These findings suggest a post-germinal center B cell origin. Two cases with T-cell lineage have been reported.

This lymphoma is extremely aggressive with survival measured in months. Combined antiviral therapy and chemotherapy are offered.

Pyothorax-Associated Lymphoma

Pyothorax-associated lymphoma develops in the pleural cavities of immunocompetent patients with chronic suppurative pleuritis. Most cases arise following long-standing artificial pneumothorax for treatment of tuberculosis or pleuritis secondary to pulmonary asbestosis. Approximately 2 percent of individuals with chronic pyothorax develop PAL. Epstein-Barr virus is strongly associated but the pathogenesis is not clearly understood. It is postulated that immunocompetent cells cannot enter the diseased pleural cavity resulting in local immunodepression facilitating proliferation of EBV-infected lymphocytes.

Patients are often in their sixth to eight decades of life and usually present with chest pain, back pain or shoulder pain and dyspnea. Radiographic studies demonstrate a visceral or parietal pleural mass invading chest wall, lung, pericardium, or diaphragm in the setting of pleural fibrosis and calcification. In contrast to PEL, pleural effusion is not seen.

Biopsy and resection specimens show masses composed of sheets of large atypical lymphoid cells with prominent nucleoli and basophilic cytoplasm (Fig. 110-19). Mitotic figures and apoptotic bodies as well as necrosis abound. Immunohistochemical studies discern this high-grade lymphoma from PEL. Typically lymphoma cells stain for B-cell antigens CD20 and CD79a, plasma cell markers CD38 and CD138 and on occasion a T-cell marker such as CD2, CD3, CD4, or CD7. Immunohistochemistry is positive for EBV, whereas KSHV/HHV8 is absent.

The prognosis for patients with PAL is dismal with most deaths occurring within one year. However, combination chemotherapy and radiotherapy may prolong survival with 5-year survival rates of 20 percent.

CONCLUSIONS

Pulmonary and pleural lymphomas and reactive processes are uncommon entities with rich historical contexts. Current immunohistochemical and molecular methods allow for

accurate reproducible classification. Since most lesions arise from BALT, using this construct to order most lung lymphoid proliferations is very appealing. The wide variety of diseases associated with underlying immunologic disorders is only surpassed by the complexities of the primary lymphoproliferative disorders themselves. Clinicopathologic correlation is required for interpretation of virtually all these lesions. Sound diagnoses combined with improved therapies will hopefully improve patient quality of life and survival.

PART

XVI

Infectious Diseases of the Lungs

This page intentionally left blank

111
CHAPTER

Pulmonary Clearance of Infectious Agents

Galen B. Toews

The primary function of the lungs is the exchange of gases at a rate required to support tissue metabolism. During gas exchange processes, the lung is exposed to a varied burden of foreign materials, including infectious agents. In addition, the lung is repeatedly exposed to microbes via aspiration of secretions from the upper respiratory tract, particularly during sleep. The lung must defend itself against this potentially hostile environment to perform gas exchange adequately. This group of nonrespiratory functions has been collectively termed *pulmonary host defenses* (Fig. 111-1).

MECHANICAL DEFENSES

Nasopharyngeal Airways

Nasal hairs remove most particulates bigger than 10 μm. Rapid airflow and quick changes in direction of the airstream in the nose favor inertial deposition of large particulates; these particulates are cleared primarily by swallowing, sneezing, or coughing. Mucociliary clearance participates in the removal of particulates from the nasopharynx. Ciliated mucosa is present on the nasal septum and turbinates; mucociliary action sweeps mucus toward the posterior pharynx, where secretions are either swallowed or cleared from the throat.

Conducting Airways

Mucociliary Escalator

Most particulates larger than 2 μm in diameter affect the conducting airways. Mucociliary clearance and coughing are the principal means of mechanical defense (Fig. 111-2). The mucosa of the conducting airways is lined with mucus secreted by goblet cells, bronchial glands, and Clara cells. The mucous blanket is composed of two distinct layers: a watery sublayer, in which most ciliary movement takes place, and

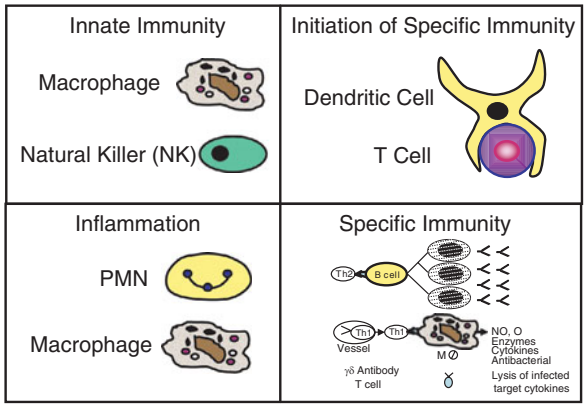

Figure 111-1 Pulmonary immune defenses. Three immune defense systems protect the airways and lower respiratory tract. Alveolar macrophages and pulmonary natural killer cells effectively remove certain microbes. Inflammatory responses, which lead to the recruitment of polymorphonuclear (PMN) leukocytes and monocytes, are crucial for the pulmonary clearance of most microbes. The initiation of specific immune responses requires dendritic cell–T lymphocyte interactions. Specific immune responses are required for effective pulmonary clearance of viruses, encapsulated bacteria, fungi and mycobacteria. The expression of immune responses requires the interaction of Th1 lymphocytes and macrophages and Th2 lymphocytes and B cells.

an upper viscous layer that is just penetrated by the ciliary tip.

Mucus is propelled up the respiratory tract by the pseudostratified ciliated epithelium that lines the conducting airways. Approximately 200 cilia are present on each ciliated cell. Ciliary length is approximately 5 to 6 μm, and ciliary frequency is 12 to 14 beats per seconds. Particulates can be cleared from the trachea with a half-time of 30 minutes and from distal airways with a half-time of hours.

Oxidants impair cilliary function and elastase damages cilia. Interferon (IFN)-γ, tumor necrosis factor (TNF)-α, and interleukin (IL)-1 increase cilia beating by a mechanism that is dependent on nitric oxide. Cigarette smoke adversely affects cells that produce mucus; mucus production is increased, and its biochemical and biophysical characteristics are altered.

Airway Secretion

Airway epithelial cells secrete nonimmune host defense molecules. Iron is an essential ingredient for survival of many microbes. Iron is sequestered in cells or firmly complexes to transport proteins. Microbes compete for this iron with their own transport proteins, known as siderophores. Lactoferrin, found predominantly in the airways, and transferrin, found predominantly in the alveolar spaces, effectively complex any free iron in mucosal secretions, suppressing bacterial growth by making iron difficult for bacteria to obtain.

Lysozyme is secreted in large quantities in human airways (10–20 mg per day). Lysozyme catalyzes the hydrolysis of bonds between constituents of the cell walls of most bacteria and *Cryptococcus neoformans* and *Coccidioides immitis*. Lysozyme inhibits chemotaxis and the production of toxic oxygen radicals by stimulated neutrophils. Airway secretions also contain both serum-derived antiproteases (α1-antitrypsin, α_2-chymotrypsin, and α_2-macroglobulin) and an airway epithelial cell-derived antiproteases (elafin). Elafin is produced by Clara cells in the airway.

INNATE IMMUNITY

Host defenses against invading microbial pathogens consist of two components: innate immunity and acquired immunity. Innate immune recognition occurs via germ-line encoded receptors that recognize conserved structures present on microorganisms (Fig. 111-2).

Innate Immune Recognition

Microbial recognition is problematic because microbes evidence molecular heterogeneity and have high mutation rates. The innate immune system recognizes a broad spectrum of pathogens using a repertoire of invariant receptors that recognize highly conserved microbial molecules including combinations of sugars, proteins, lipids, and distinct nucleic acid motifs. The receptors recognize molecular patterns and have, therefore, been termed pathogen recognition receptors (PRRs). Several hundred receptors accomplish the task of innate immune recognition. The ligands recognized by PRRs are pathogen-associated molecular patterns (PAMP). PAMPs share certain features. PAMPs are invariant structures shared by classes of pathogens, are produced only by microbes, and are essential for microbial pathogenicity or microbial survival. Cells that express PRRs include macrophages, dendritic cells (DCs), mast cells, neutrophils, eosinophils, natural killer (NK) cells, epithelial cells, and fibroblasts.

PRRs can be divided into three classes: secreted, endocytic and signaling receptors. C-reactive protein (CRP), mannan-binding lectin (MBL) and serum amyloid protein (SAP) are secreted pattern recognition molecules. CRP and SAP function as opsonins and bind to Clq to activate the classic complement pathway. MBL binds to mannose residues that are abundant on the surface of many microbes. Macrophage mannose receptor (MMR) interacts with gram-positive and gram-negative bacteria and fungal pathogens and mediates phagocytosis. Macrophage scavenger receptor (MSR) has broad specificity for a variety of ligands including double-stranded RNA, LPS, and lipoteichoic acid. Signaling PRRs induce expression of inflammatory cytokines and co-stimulatory molecules on antigen presenting cells following the recognition of PAMPs. Toll-like receptors (TLRs) are signaling PRRs. Thirteen TLRs have been described in mammals. TLRs differ from one another in ligand specificity, expression patterns, and the genes they induce.

TLR2 recognizes a wide range of microbial products. These include lipoproteins/lipopeptides, peptidoglycan, lipoteichoic acid, lipoarabinomannan, and zymosan. TLR2 forms heterophilic dimers with other TLRs such as TLR1 and TLR6, likely accounting for its ability to recognize numerous

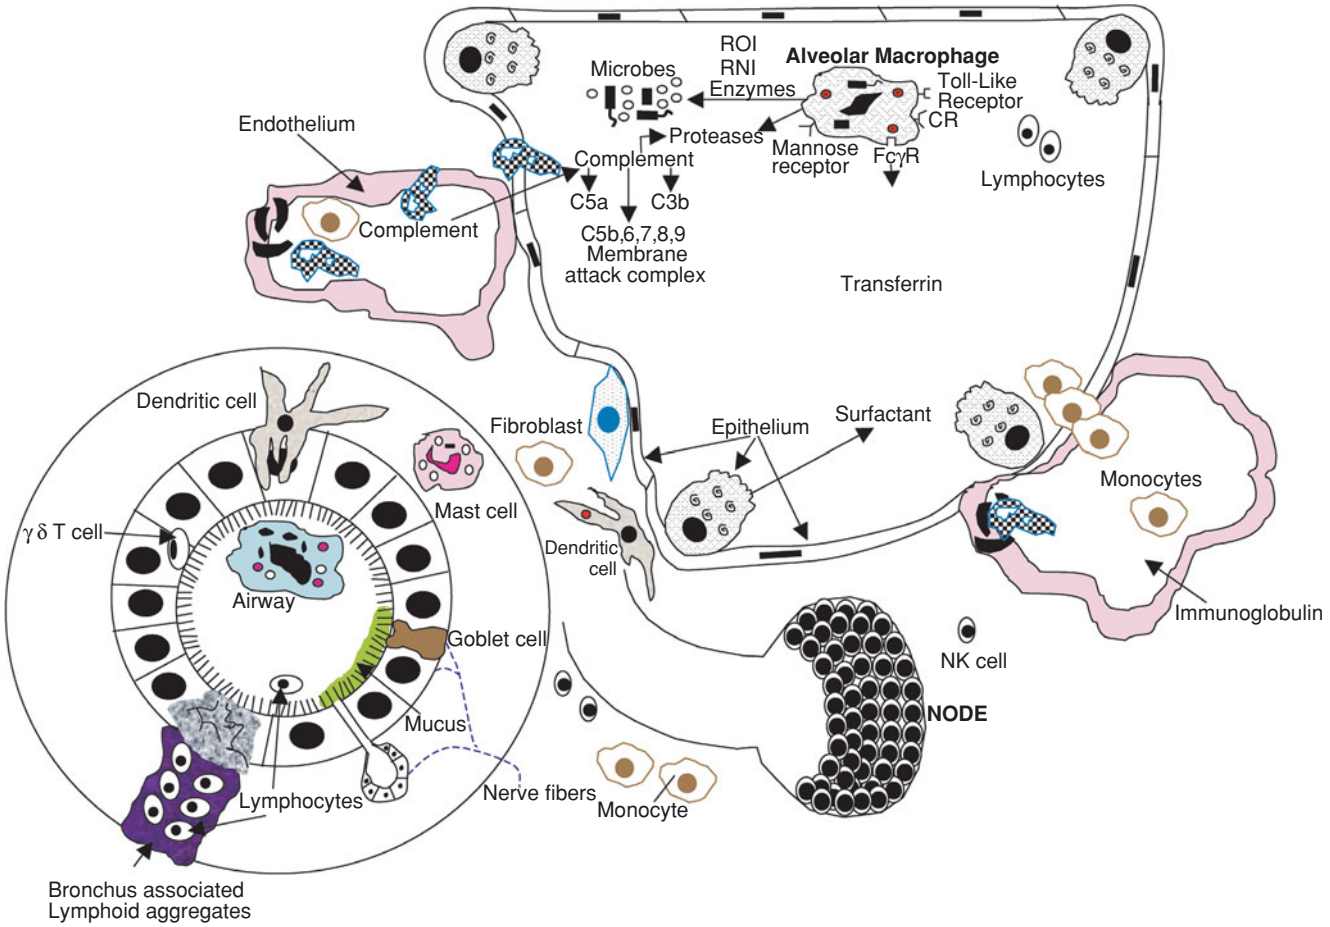

Figure 111-2 Resident defenses of conducting airways and alveoli. Conducting airways are lined by ciliated epithelium, which moves mucus generated by bronchial glands and goblet cells cephalad, where it is expectorated or swallowed. Airway macrophages ingest and kill small inocula of most aspirated and airborne bacteria. The alveolar spaces rely on innate immunity for the clearance of microbes that reach the alveolar surface. Alveolar macrophages are the first line of defense against microbes. Complement, surfactant, and iron-binding proteins are important humoral microbicidal factors.

ligands. TLR4 is an essential receptor for LPS recognition. TLR4 also recognizes endogenous ligands such as heat-shocked proteins and portions of fibronectin, hyaluronic acid, heparin sulfate, and fibrinogen. TLR5 recognizes flagellin, the principal structural component of bacterial flagella. TLR1, TLR2, TLR4, TLR5, and TLR6 are expressed on the surface of cells. TLR7, TLR8, and TLR9 are in the endosomal compartment and TLR3 is intracellular, although its exact location has not been defined. TLR3 recognizes double-stranded RNA (dsRNA) produced by most viruses during their replication. TLR7 and TLR8 are structurally highly conserved proteins and recognize the same ligand in some instances. TLR7 and TLR8 recognize single-stranded RNA (ssRNA) from viruses such as human immunodeficiency virus and influenza virus. TLR9 recognizes unmethylated CpG motifs in bacterial DNA. Mammalian DNA is methylated, whereas bacteria lack CpG methylation enzymes, allowing bacterial recognition.

Alveolar Macrophages

Alveolar macrophages are a heterogeneous population of phagocytes that constitute the first line of defense against microbes that reach the alveolar surface (see Fig. 111-2). Alveolar macrophages are derived from monocytes and proliferating macrophage precursors in the interstitium of the lung. Alveolar macrophages undergo differentiation within the lung. Alveolar macrophages have a life span of months to years. The signals and ligands that modulate monocyte traffic into the normal lung have not been defined.

The microbicidal function of alveolar macrophage is dependent on four critical attributes. Macrophages recognize signals, ingest particulates, secrete mediators, and migrate in response to stimuli (Table 111-1). Macrophages recognize signals in their microenvironment via PRRs and surface receptors capable of binding specific ligands, including complement proteins, immunoglobulins, cytokines, PAMPS, and toxins. Activation of TLRs induces transcriptional activation of inflammatory mediators (TNF-α, IL-1, IL-6, IFN-α, IFN-β), chemokines, costimulatory molecules of T-cell activation (CD80, CD86), and signals that regulate the differentiation of lymphocytes (IL-4, IL-5, IL-10, IL-12), transforming growth factor (TGF-β and IFN-γ). Receptor-ligand interactions allow macrophages to ingest microorganisms and respond to cytokines and proteins.

Table 111-1

Secretory Products of Macrophages

Cytokines, Growth Factors, and Hormones
- Growth factors
  - GM-CSF
  - M-CSF
  - G-CSF
- Proteins involved in host defense and inflammation
  - C1
  - C2
  - C3
  - C4
  - C5
  - Factor B
  - Factor D
  - Properdin
  - C3b inactivation
  - βIH
  - Lysozyme
  - Interferon-γ
  - Fibronectin
  - Lactoferrin
- Cytokines that promote acute inflammation and regulate lymphocytes
  - TNF
  - IL-1α/β
  - IL-6
  - IL-8
  - IL-12
  - GROα/β/γ
  - CTAPIII
  - β-Thromboglobulin
  - IP-10
  - MCP-1
  - MIP-1α
  - MIP-1β
- Cytokines that inhibit acute inflammation and lymphocyte responses
  - IL-10
  - TGF-β_1, -β_2, -β_3
  - IL-1 receptor antagonist

Reactive Oxygen Intermediates
- O_2^-
- H_2O_2
- $OH^{\cdot}$

Reactive Nitrogen Intermediates
- $NO^{\cdot}$
- NO_2
- NO_3

Enzymes Active in Microbicidal Activity and Inflammation
- Acid hydrolases
- Acid phosphatases
- Cathepsins
- Cytolytic proteinase
- Hyaluronidase
- Lysozyme
- Phospholipase A_2
- Plasminogen activator

Inhibitors of Enzymes
- α_1-Antiprotease
- α_2-Macroglobulin
- Inhibitors of plasminogen
- Inhibitors of plasminogen activator
- Lipomodulin

Lipids Active in Host Defense and Inflammation
- PGE_2
- $PGF_2\alpha$
- Prostacylin
- Thromboxane A_2
- Leukotrienes B, C, D, and E
- Mono-HETES
- Di-HETES
- PAF
- Lysophospholipids

Macrophages express two distinct receptors for the third component of complement. Complement receptor 1 (CR1) preferentially binds C3b and complement receptor 3 (CR3, Mo-1, MAC-1, CD11b/18) is a member of the β_2 integrin family. CR3 is essential for migration of leukocytes functioning in cell-cell and cell-substrate adhesion. Genetic deficiency in the CD18 complex causes recurrent life-threatening infections.

Three Fcγ receptors recognize the Fc domain of immunoglobulin G (IgG). All FcRs function as signal-transducing molecules. FcγRI, FcγRII, and FcγRIII trigger both phagocytosis and cytolytic responses. Patients who lack FcγRI have no increased susceptibility to infection.

The redundancy of the three FcγRs may confer a selective advantage. The mannose receptor binds mannose and mediates phagocytosis of yeasts, zymosan particles, and *Pneumocystis carinii* (see Fig. 111-2).

Phagocytosis follows recognition of the microbe. Particle engulfment requires engagement of specific receptors and the generation of transmembrane signals that induce movement of the phagocyte plasma membrane over a ligand-coated particle. Phagocytosis requires sequential,

circumferential interaction of phagocyte surface receptors with complementary ligands on the surface of the particle.

The ingested microbe is initially contained within a phagosome that subsequently fuses with lysosomes. TLR stimulation is linked to phagosomal maturation. Resident alveolar macrophages require activation for microbicidal killing. Activation stimuli include microbial products, inflammatory cytokines and plasma proteins. IFN-α and/or IFN-β provide priming signals to augment macrophage microbicidal activity. GM-CFS is a potent stimulator of macrophage activation. Interactions with microbes lead to production of IFN-γ by NK cells.

Both oxidative and nonoxidative processes are used to kill ingested microbes. Alveolar macrophages have less antimicrobial activity than monocytes. Loss of granular peroxidase and a decrease in the magnitude of the respiratory burst account for a portion of the decline. Resident alveolar macrophages contain minimal myeloperoxidase (MPO): the MPO-H_2O_2-halide system is lest robust in resident macrophages than in recruited macrophages.

Microbes are also killed by macrophage-dependent nonoxidative mechanisms, including proteases, lysozyme, and defensins. Defensins are a multiple-member family of broad-spectrum cytotoxic peptides that kill many gram-positive organisms (*S. aureus, S. epidermidis, Streptococcus*) and gram-negative species (*Escherichia coli, Pseudomonas aeruginosa, Klebsiella pneumoniae*). Defensins also kill fungi and inactivate certain viruses. Defensins are present in the alveolar macrophages of some species.

NK Cells

NK cells are present within the lung. Active NK cells are located primarily in the interstitium of the lung. Pulmonary NK cells play a proactive role in influenza infections and in fungal infections. Engagement of TLRs induces macrophages to produce IL-12 and TNF-α which induce IFN-γ production by NK cells. Early IFN-γ activates macrophages and enhances their microbicidal activity.

Complement

Normal alveolar lavage fluids contain a functional alternative complement pathway. C3b, has opsonic activity and promotes receptor-mediated phagocytosis of microbes by macrophages. C5a is a chemoattractant for PMNs.

Alveolar Epithelial Cells

Alveolar epithelial cells secrete proteins important in innate immune responses. SP-A and SP-D are members of the collectin family. SP-A facilitates alveolar macrophage and type 2 alveolar epithelial cell uptake of microbes. SP-A increases secretion of GM-CSF, promotes movement of alveolar macrophages and regulates macrophage oxidant production. SP-D mediates agglutination of gram-negative bacteria.

INFLAMMATORY RESPONSES

A dual phagocytic system involving resident alveolar macrophages and recruited polymorphonuclear leukocytes (PMN) is required for the clearance of bacteria from the lower respiratory tract. Recruitment of PMNs into the alveoli is initiated by the generation of chemotaxins within the alveolar space (Fig. 111-3). A super-gene family of chemotactic cytokines, chemokines, possesses high degrees of specificity for inflammatory cells; accordingly they play important roles in the selective recruitment of blood-borne leukocytes to sites of inflammation. CXC, CC, C, and CX_3C chemokine families have been characterized. CXC chemokine family members (IL-8, MIP-2, GRO, ENA-78, NAP2) are chemotaxins for PMN. The CC family (MCP-1-4, RANTES, MIP-1α and MIP-1β) are chemotaxins for macrophages, lymphocytes, basophils, eosinophils, and mast cells. Lymphotoxin is a C chemokine family member and fractalkine is a CX_3C chemokine.

Activation of TLRs on innate immune cells induces transcriptional activation of inflammatory genes. TLR activation induces TNF-α and IL-1, both of which induce gene expression and secretion of CXC chemokines from endothelial cells, fibroblasts and pulmonary epithelial cells. Macrophages also generate leukotriene B4, a potent chemotactic substance. Sentinel dendritic cells and macrophages also produce IL-23 within a few hours after exposure to LPS and microbial products. This triggers rapid (hours) production of IL-17 from tissue resident α/β, $\gamma\delta$, and NK T cells. IL-17 promotes production of IL-1, IL-6, TNFα, and CXC chemokines from fibroblasts, epithelial cells and endothelial cells. Mice lacking the receptor for IL-17 evidence blunted G-CSF and MIP-2 responses, decreased neutrophil recruitment, have larger bacterial burden and worsening mortality in a murine model of *Klebsiella pneumoniae* infection. The alveolar capillary membrane is a dynamic assembly of innate immune cells that generate chemokines required to recruit specific inflammatory cells during microbial insults.

Neutrophils ingest microbes by phagocytosis. Effective killing requires products of granule constituents and molecular oxygen. Hydrogen peroxide and reactive oxygen intermediates are involved in neutrophil mediated killing. The MPO-H_2O_2-halide system is a crucial participant in oxygen-dependent killing by neutrophils. Granule components are also crucial in PMN mediated microbial killing. Lactoferrin chelates iron and lysozyme hydrolyzes bacterial cell walls. Cathepsin G, elastase and cationic proteins found in azurophil granules kill bacteria. Human neutrophils contain defensins which kill gram-positive and gram-negative bacteria and fungi.

ADAPTIVE IMMUNE RESPONSES

Microbial infections that elude the innate defense mechanisms and inflammatory responses generate a threshold

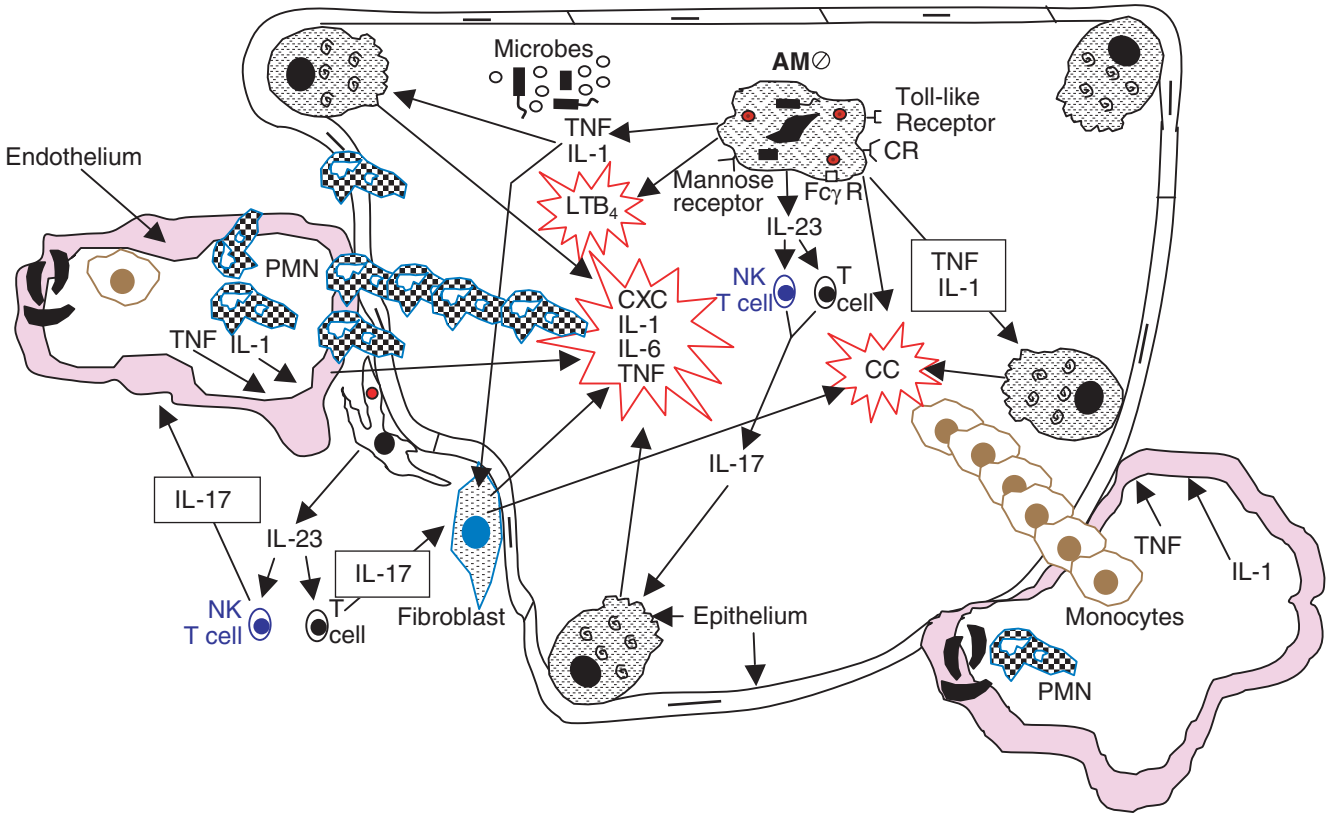

Figure 111-3 Initiation of inflammatory responses in the lower respiratory tract. Chemotaxins are generated sequentially following the entry of bacteria or bacterial products into the alveolus. LPS stimulates alveolar macrophages to produce TNFα, IL-1β, IL-8, and leukotriene B4. TNFα and IL-1β induce gene expression and production of chemokines by epithelial cells and fibroblasts present in the alveolar-capillary wall and induce the expression of adherence molecules on inflammatory cells and endothelial cells. Microbes induce dendritic cells and macrophages to produce IL-23. IL-23 induces resident lymphocytes and monocytes to produce IL-17. IL-17 induces production of IL-1, IL-6 and CXC chemokines by parenchymal cells.

dose of antigen, which is needed to trigger adaptive immune responses. Adaptive immune responses consist of two major effector systems, antibody- and cell-mediated immunity, which are generated by antigen specific B and T lymphocytes, respectively. B and T lymphocytes rearrange their Ig and T-cell receptor (TCR) genes to maintain approximately 10^{11} different clones of B and T lymphocytes that express distinct antigen receptors. B lymphocytes recognize native antigens including carbohydrates, proteins, and simple chemical groups. T-lymphocyte receptors recognize only peptides derived from protein antigens bound to cell-surface proteins from the major histocompatibility complex (MHC). Clones of lymphocytes are triggered by antigen-presenting cells (APCs) to proliferate and differentiate into effector cells. Antigen-specific lymphocytes remain expanded after elimination of an infection (memory lymphocytes). Memory lymphocytes provide a more rapid response to a second exposure to antigen.

Antigen-specific immune responses require at least 7 to 10 days for their development; this time is required for the proliferation and differentiation of antigen-specific T and B lymphocytes. During the development of specific immune responses, pathogens may continue to grow in the host or be held in check by innate and inflammatory mechanisms. The generation of specific immune responses to infectious antigens can be divided into three phases: the afferent phase, central control/processing phase, and efferent phase.

Afferent Immune Response

Antigen presenting cells (APCs) provide an essential link between innate and adaptive immunity (Fig. 111-4). DCs are the most potent APC for T cells. DCs are bone marrow-derived cells which take up residence in peripheral tissues at epithelial borders throughout the mammalian host where they become specialized for recognition of pathogens and microenvironmental tissue damage. DCs signal the presence of "danger" to cells of adaptive immunity.

Two broad subsets of DC have been identified: myeloid DC (mDC) and plasmacytoid DC (pDC). mDC express CD11c, CD11b, varying levels of MHC class II and costimulatory molecules (CD40, CD80, and CD86). Human pDC express blood DC antigen (BDCA)2, whereas murine pDC express CD11c, GR-1, and B220. mDC contribute to a variety of T-cell responses or tolerance and pDC have been implicated in antiviral immunity and in murine models of asthma.

DC exist in both immature and mature forms. Immature DC are concerned mainly with antigen capture.

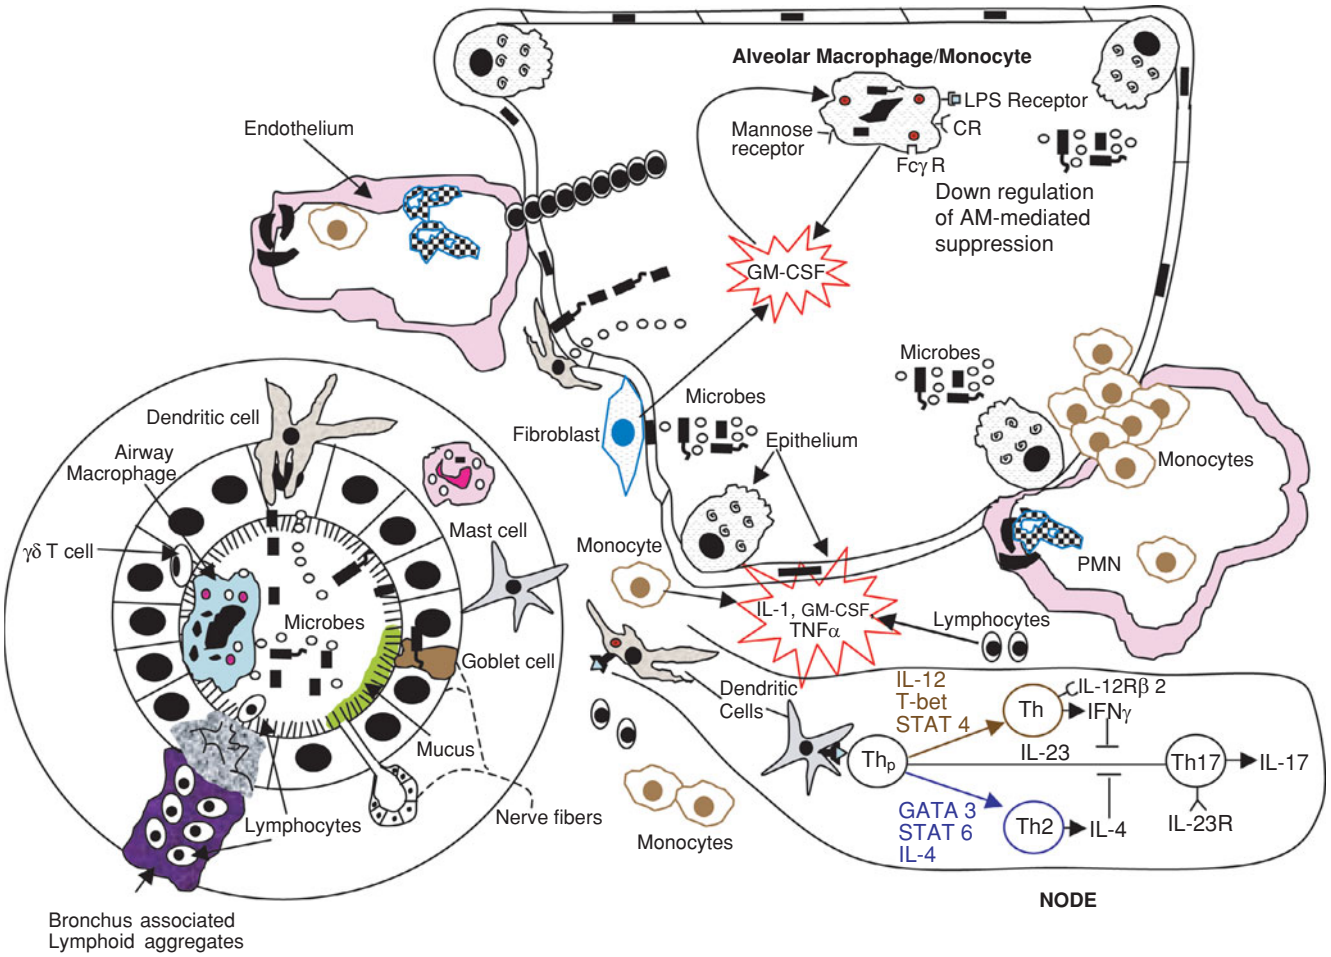

Figure 111-4 Initiation of specific immune responses in the lung. Dendritic cells located in the interstitium of the lung and in the airway epithelium function as sentinel antigen-presenting cells. Dendritic cells reside in close contact to airway epithelial cells, alveolar epithelial cells, and interstitial macrophages. Following exposure to microbial antigens, DC differentiation occurs as a result of exposure to cytokines produced by cells of the innate immune system (macrophages) and cytokine produced as a result of injury to epithelial cells. Differentiated DC migrates to local nodes and present antigen to naive T lymphocytes. The control of CD4 T-lymphocyte subset differentiation occurs via complex, cross-regulatory interactions mediated by lymphokines. The development of CD8 effector cells and plasma cells usually requires cognate interactions with DC4 regulatory T lymphocytes.

DC are mobilized from bone marrow precursors to peripheral blood in response to pulmonary inflammation. Monocytes contribute to the pool of newly recruited DC through transendothelial migration in which peripheral blood monocytes differentiate into tissue DC after crossing the vascular endothelium. CCR2 is a critical receptor in the recruitment of DC during inflammatory responses. CCR6 mediates recruitment of DC specifically to the airways and alveolar space in response to macrophage inhibitory protein (MIP)-3α secreted by respiratory epithelial cells.

DC maturation is dependent on sensing of infection which may occur either directly by detection of pathogen products using TLRs or indirectly through exposure to endogenous danger signals such as material released from damaged cells. Ingested antigens are rapidly processed by one of two pathways. The endocytic pathways processe protein antigens obtained from the extracellular space in phagolysosomes converting them to small polypeptides. The polypeptides are loaded on to MHC class II molecules to prime DC for further presentation to MHC class II restricted, CD4+ T helper lymphocytes. The endogenous pathway processes peptides from the intracellular environment and loads them onto MHC class I molecules for presentation to MHC class I restricted, CD8+ T cells. Mature DC up regulate MHC class II and costimulatory molecules allowing a phenotype focused on antigen presentation and the stimulation of naïve T cells.

DC maturation is accompanied by changes in the expression of chemokine receptors. CCR1, CCR2, CCR5, and CCR6 are down regulated. CCR7 expression is enhanced allowing DC to respond to chemokine gradients of secondary lymphoid tissue chemokines (SLC/CCL21) and Epstein-Barr virus–induced molecule1 ligand chemokine (ELC/CCL19) emanating from local lymphatics and draining lymph nodes. Mature DC leave the local inflammatory environment carrying their antigenic load to draining lymph nodes. DC–T-cell interactions within the draining lymph node are complex.

T-cell stimulation, proliferation, and activation result if antigen recognition occurs. Induction of Th1, Th2, Th17, or T-regulatory responses may be the end result.

The engagement of TLRs on DCs leads to increased expression of MHC-peptide complexes and co-stimulatory molecules as well as the production of immunomodulatory cytokines, all of which have a profound effect on T-cell priming and differentiation. Triggering of the T-cell receptor (TCR) occurs following an interaction with an antigen/MHC complex and provides "signal one" to the T cell. T-cell maturation results in upregulation of important co-stimulatory molecules. Specifically, DC increase the expression of B7.1 (CD80) and B7.2 (CD86), which bind CD28 on T cells providing "signal two" to activate antigen specific T cells.

T-cell responses to pathogens are heterogeneous; three subsets of CD4 T helper cells have been defined on the basis of the cytokines they produce. Interleukin-12 (IL-12) is an innate immune response cytokine that drives Th1 polarization. IL-12 production by DC is tightly controlled, requiring a priming signal provided by microbial products or IFN-γ and an amplifying signal provided by T cells through CD40 ligand (CD40L). Cues other than IL-12 drive T-cell differentiation. IL-23, which shares the p40 chain with IL-12 but pairs with a unique p19 chain, drives differentiation of inflammatory T cells capable of secreting large amounts of TNF and IL-17. TLR3 and TLR4 potently act in synergy with endosomal TLR7, TLR8, and TLR9 in the induction of IL-12 p70 and IL-23. The amounts of IL-12 and IL-23 induced by synergistic signaling are 50- to 100-fold higher than those induced by optimal concentrations of single agonists, leading to enhanced and sustained Th1-polarizing capacity. Since pathogens express several TLR agonists that may engage different TLRs at different times and in distinct cellular compartments, it is likely that "combinatorial codes" may exist by which DC discriminate pathogens for which a Th1 response is desirable. IL-12 activation of STAT4 is necessary for differentiation of naive T cells into IFN-γ–producing Th1 cells. IFN-γ activates STAT1 and subsequently T-bet. T-bet activation is required for IL-12Rβ_2 expression and IL-12 responsiveness. Th1 responses are characterized by the strong expression of IFN-γ, IL-2, and TNF-α. These cytokines in concert with simultaneous interactions between DC, Th1 cells, and CD8+ T cells result in the generation of antigen specific cytoxic T lymphocytes. The net result of the Th1 response is the generation of activated Th1 and cytotoxic T lymphocytes necessary for macrophage activation and effective cell-mediated immunity against predominantly intracellular pathogens.

Th2 responses are characterized by T-cell production of IL-4, IL-5, IL-10, and IL-13 as well as systemic IgE production and tissue eosinophilia. This response results in humoral immunity–mediated through interactions among DC, Th2 cells, and B cells. Th2 cell development is dependent on the transcription factors GATA3, STAT6, and IL-4.

It is increasingly evident that IL-23 has unique roles in regulating immunity. Whereas IL-12 drives classic Th1 responses characterized by IFN-γ production, IL-23 drives a T-cell population that produces IL-17 (Th17 cells). IL-17 is a proinflammatory cytokine that induces G-CSF, GM-CSF, monocyte chemoattractant protein 1 (MCP-1), macrophage-inflammatory protein-2 (MIP-2), IL-6, IL-8, neutrophil chemokine growth-related oncogene-α and PGE_2. The production of IL-17 by antigen-specific Th17 cells within a local tissue environment is important for both rapid recruitment of neutrophils to sites of acute infection and for continuous neutrophil recruitment. IL-23 induces IL-17 production in both CD4+ and CD8+ T cells.

Regulatory T Cells

The immune system possesses various mechanisms to control and regulate the immune system to prevent and minimize reactivity to self-antigens or an overexuberant response to a pathogen. Avoidance of damage to the host is achieved by active suppression mediated by regulatory T (Treg) cell populations. Naturally occurring CD4+ CD25+ T reg cells are the best characterized subset. These cells represent 5 to 10 percent of the CD4+ T lymphocytes in healthy adult mice and humans. No characteristic stable surface marker has been ascribed to Treg cells. The forkhead/winged helix transcription factor, Foxp3, is specifically expressed by CD25+ Treg cells as well as CD25– T cells with regulatory activity. Foxp3 is thought to program the development and function of this subset of T cells. Naturally occurring Tregs suppress T cell proliferation by cell contact, membrane or soluble TGF-β and by secreted IL-10. A second population of regulatory T cells that produce IL-10 and secrete TGF-β have been described (IL-10 T reg). These cells are derived in culture and also express CD25. This second type of regulatory T cell also inhibits naïve T-cell proliferation in vitro and suppresses experimentally induced autoimmune disease. These cells are Foxp3 negative. IL-10 Tregs suppress T cells via cell contact mediated mechanisms and secreted IL-10.

Efferent Immune Responses

Migration of Effector Cells to the Lung

Antigen specific T cells must migrate via the blood stream to peripheral sites of ongoing infection (Fig. 111-5). Chemokine receptors are used, some of which are specific for Th1 cells. A subset of recruited DC remains in the lung rather than migrating to draining lymph nodes. These recruited nonmigratory pulmonary DC present antigen to newly recruited T cells to drive T-cell polarization and stimulate cytokine release. Cytokines produced by specific CD4 and CD8 lymphocytes play a central role in the recruitment of inflammatory mononuclear phagocytes and other effector lymphocytes. Monocytes and NK cells are recruited into the complex peripheral infectious environment.

Efferent T Cell Mediated Responses in the Lung

Viral Infection

Viruses including influenza, parainfluenza, respiratory syncytial virus, Hantavirus, coronavirus (severe acute respiratory

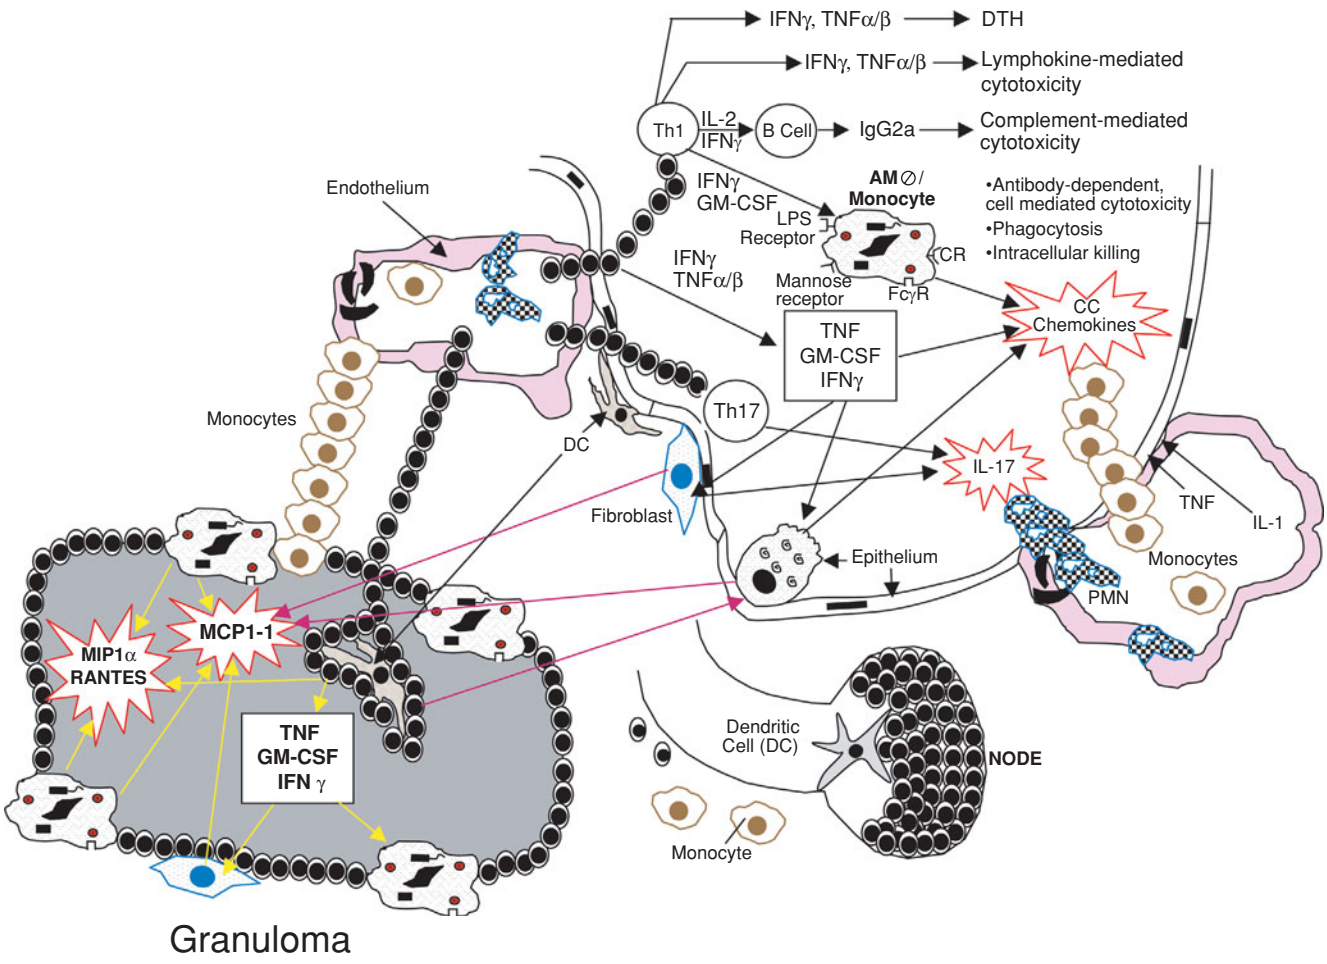

Figure 111-5 Expression of specific immune responses in the lower respiratory tract. Activated T lymphocytes recirculate from draining regional lymph nodes and enter sites of microbial multiplication via a series of highly regulated events involving cytokines and adherence molecules expressed on both lymphocytes and endothelial cells. Activated Th0 or Th1 lymphocytes are stimulated by resident antigen-presenting cells to produce high levels of IFN-γ, GM-CSF, and TNF, which recruit and activate monocytes from the circulation. Adherence receptor ligand interactions between monocytes and endothelial cells are important in their recruitment. A unique subset of mononuclear cell chemotaxins (MIP-1α, MCP-1) are probably active in recruitment of mononuclear phagocytes. Recruited, activated mononuclear phagocytes are crucial to the clearance of certain pathogens. Th17 cells produce IL-17, which induces parenchymal cells to produce TNF-α, IL-1, IL-6, and CXC chemokines. These proinflammatory cytokines are important for continuous neutrophil recruitment during chronic infections.

syndrome), herpesvirus, and CMV cause significant pulmonary disease. Viruses are intracellular pathogens; the killing of virally infected cells by MHC class I restricted cytotoxic CD8 T lymphocytes (CTL) is required. CTL kill target cells by two mechanisms. Cytolytic mediators, including perforins and granzymes, are released from cytoplasmic granules. Perforins induce pore formation and osmotic cell lysis and granzymes are proteases that activate cell caspases, resulting in apoptosis. Killing of virally infected cells can also result from the direct induction of apoptosis by ligation of Fas by Fas ligand, which is up regulated and present on CTL.

The development of cell-mediated immunity to viral infections precedes by mechanisms presented earlier, but may also precede locally within the lung. Lymphotoxin knockout mice that lack lymphoid organs are capable of generating antigen-specific CD4+ T-cell responses. Priming occurred in bronchus-associated lymphoid tissue (BALT), a submucosal lymphoid tissue found in the major bronchi. Localized priming of the cell-mediated immune response may play a crucial role in viral host defense.

Memory T-cell responses are important in certain viral illnesses and following administration of antiviral vaccines. Two subsets of memory T cells have been defined. Effector memory T cells are found within the lung, are short lived, retain markers of activation, and have effector functions; these cells lack expression of lymphoid trafficking molecules CCR7 or CD62L. Central memory T cells reside predominantly within lymphoid organs, persist for long periods of time, and express CCR7 and CD62L.

Intracellular Pathogens

Numerous strains of bacteria and certain fungi have evolved the capacity to invade and survive within host leukocytes, primarily macrophages, to evade recognition and elimination by innate immune responses. Cell-mediated immunity is required to successfully eradicate these microbes. Cytokines produced by CD4 and CD8 T lymphocytes play a central role in the activation of microbicidal function in phagocytic cells (see Fig. 111-5). IFN-γ produced by both CD4 and CD8 T lymphocytes is the most important macrophage activating factor. Macrophage activation is further enhanced by TLR stimulation and by inflammatory cytokines such as TNF-α and GM-CSF. Activated macrophages kill microbes. Intracellular microbes are exposed to toxic acid hydrolysis and cationic peptides in phagolysosomes. Expression of inducible nitric oxide synthase results in enhanced nitric oxide synthesis and the synthesis of reactive nitrogen intermediates that have antimicrobial properties. Induction of the respiratory burst results in generation of superoxide, hydrogen peroxide, and toxic reactive oxygen intermediates. The induction of macrophage apoptosis in response to intracellular infection has been shown to be of importance in blocking cell-to-cell spread of certain intracellular infections.

Granuloma formation is an important mechanism of host defense to intracellular microbes (see Fig. 111-5). The recruitment of monocytes and lymphocyte populations to the site of infection is required for granuloma formation. Macrophages coalesce into large, epithelioid and multinucleated giant cells. DC, CD4+ T lymphocytes, and CD8+ lymphocytes form a loose meshwork that serves to contain microorganisms. Granulomas are sites of ongoing production of inflammatory cytokines, including TNF-α, IFN-γ, and chemokines capable of recruiting additional effector cells.

Efferent B Lymphocyte–Mediated Immune Responses in the Lung

Immunoglobulins are a major protein constituent of the fluid that lines the luminal surface of conducting airways and alveolar lining fluid. Effector functions for antibodies include opsonization, complement fixation, antibody-dependent cellular cytotoxicity (ADCC), agglutination and neutralization (Fig. 111-6). Approximately 20 percent of the total protein

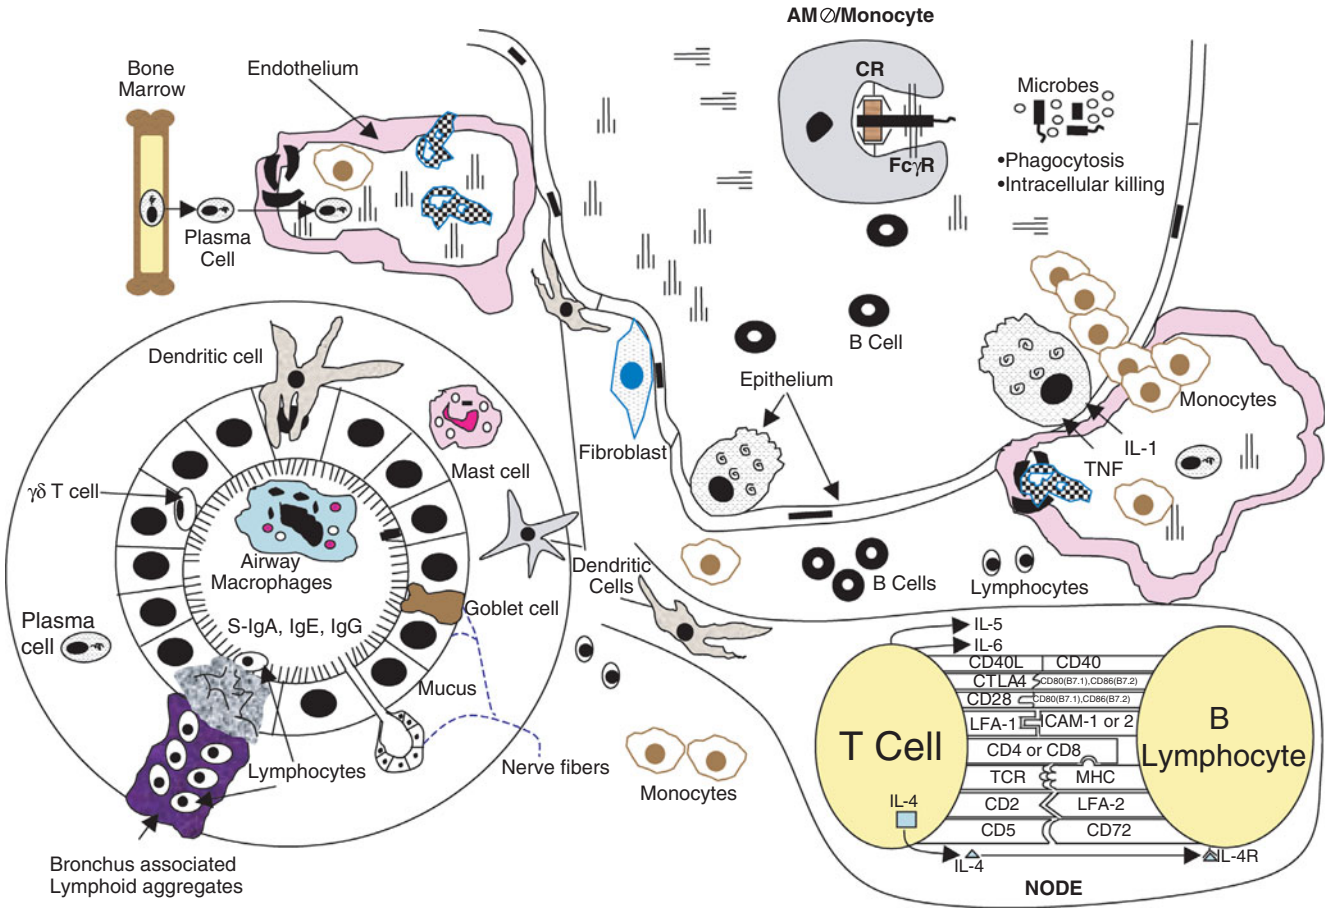

Figure 111-6 Expression of B lymphocyte–mediated immune responses in the lower respiratory tract. Initial events in B-lymphocyte proliferation and differentiation occur in T lymphocyte–dependent areas of regional lymph nodes. Proliferation, somatic hypermutation, and selection occur within the lymphoid follicle. B lymphocytes then migrate to bone marrow and to the lung, where they undergo differentiation to mature antibody-producing plasma cells. Serum antibody that gains access to the alveolar spaces of uninflamed lungs is present in large amounts during intra-alveolar infections processes. Antibodies neutralize pathogens and their toxins, activate complement, and function as opsonins to enhance macrophage recognition and ingestion of extracellular pathogens.

present in bronchoalveolar lavage fluid consists of IgG, IgM, and IgA. IgA is the predominant immunoglobulin in secretions of the trachea and major bronchi while both IgG and IgE are present as well. IgG is the predominant immunoglobulin in alveolar lining fluid.

Humans produce more IgA than any other Ig class. The secretory IgA found in external secretions consists of two molecules of IgA that are held together by a joining chain and by a secretory component, a glycoprotein produced by epithelial cells. The role of IgA in pulmonary defenses remains enigmatic. The usual specificity of IgA antibodies is antiviral. Specific IgA antibodies against hemagglutinating antigen have been isolated from patients infected with influenza A. IgA may also be important in inhibiting bacterial adherence to the respiratory epithelium; it may also serve as an antitoxin, since specific IgA against *Bordetella pertussis* toxin has been isolated from the respiratory secretions of patients with pertussis. Although IgA is believed to fix complement poorly, IgA1 antibodies from volunteers vaccinated with meningococcal polysaccharide vaccine induced classic complement pathway–mediated killing of group C *Neisseria meningitis*. Finally, IgA may also have a role as an opsonin, since human alveolar macrophages bear Fc receptors that bind either IgA1 or IgA2. Certain bacteria elaborate proteases that digest IgA; these proteases may provide a selective colonization advantage to the microbes.

Specific antibody is an important ingredient in lower respiratory tract defenses against extracellular microbes. Extracellular bacteria possess polysaccharide capsules that allow them to evade phagocytic cells. Antibodies function as: (a) opsonins that allow phagocytes to recognize and ingest microbes via the involvement of Fc receptors; (b) activators of complement, which enhances opsonization and leads to direct lysis of some bacteria; and (c) as neutralizing antibodies that neutralize pathogens or their toxins by binding to microbes or their products, thereby preventing injury to cells.

The role of antibody in resident bacterial defenses in the lower respiratory tract is uncertain. Immunoglobulins are clearly present in the epithelial lining fluid of the lower respiratory tract. Systemic immunization enhances pulmonary clearance of *P. aeruginosa, P. mirabilis,* and *H. influenzae*. Enhanced clearance correlates with the appearance of antibodies in serum and bronchoalveolar lavage fluid, which are directed against the organisms. Antibody specificities of serum and alveolar antibodies are identical. Thus, it seems likely that alveolar antibodies are derived in large part from serum.

Serum IgG can clearly gain access to the alveolar space in normal subjects and during inflammation when large changes in alveolar permeability occur. Serum IgG can clearly and directly enhance bacterial clearance from the lower respiratory tract, since intravenous injection of a murine IgG monoclonal antibody specific for a cell surface–exposed epitope of nontypable *H. influenzae* resulted in enhanced pulmonary clearance. Accordingly, it seems likely that direct airway immunization would not be required to obtain protective antibodies in the lung.

CONCLUSION

Infections are the most likely evolutionary driving force for the development of a complex system of pulmonary host defenses. A coordinated response of many different cells is required for the lung to clear pulmonary pathogens. An increasingly complex and potentially injurious cascade of host responses is mobilized following pulmonary microbial challenges (Table 111-2). Although the interactions of microbes

Table 111-2

Pulmonary Host Defense-Microbe Interactions

Host Mood	Defense Mechanism	Timing	Microbial Behavior
Content	Mechanical: Epithelial barrier Mucociliary escalator	Continuous	Commensal
Irritated	Innate Immunity: Macrophages, NK cells, γ/δ T lymphocytes	Hours–days	Replication in the airway and alveolar space
Interested	Inflammation: Macrophages/PMN	Minutes–hours	Invasion
Angry	Antigen-specific immunity: DC; CD4, CD8 T lymphocytes; B lymphocytes	3–7 days	Tissue invasion/replication in phagocytes
Hysterical	Immunopathology: Macrophages; CD4, CD8 T cells; NK cells, B cells		Dissemination to many tissues

in the host are invariably complex, models of pulmonary infection have provided crucial information regarding the regulation of inflammatory and immune responses. These insights should eventually allow the development of rational strategies regarding vaccination and immunotherapy. The use of animal models offers the possibility of understanding the mechanisms that regulate immune responses sufficiently well so that the response to a specific antigen could be controlled. A more complete understanding of host defense would allow the stimulation of deficient responses and the suppression of harmful responses to microbial pathogens and other antigens that enter the lung.

Approach to the Patient with Pulmonary Infection

Jay A. Fishman

I. THE PATIENT WITH PNEUMONIA

Pneumonia is a common cause of infection-related mortality and is one of the most important challenges in clinical medicine. Inappropriate treatment of pulmonary infection contributes to poor clinical outcomes and to the emergence of antimicrobial resistance. Pneumonia is defined as inflammation of the pulmonary parenchyma caused by an infectious agent. The clinical syndrome of pneumonia may include fever or hypothermia, sweats, rigors or chills, and pulmonary symptoms such as cough, sputum production, dyspnea, pleurisy or pulmonary lesions observed on radiographic examination. The diagnosis and management of pneumonia has been complicated by the discovery of newer pathogens, expanded antimicrobial resistance, increased populations of immunocompromised patients, and by newer diagnostic tools and antimicrobial agents.

Pneumonitis may be due to both infectious and noninfectious causes and only reflects inflammation. A variety of eponyms have been applied to various forms of pneumonia that *may* reflect the epidemiology of the process and the likely causative organisms: aspiration pneumonia, community-acquired, nosocomial pneumonia, immunocompromised host, and atypical pneumonia (Table 112-1). These descriptions coupled with the radiologic appearance are useful in considering empiric therapy while awaiting microbiologic data. Consideration of potential immune deficits in each host will help to define the urgency of empiric antimicrobial therapies. These categories may be misleading, emphasizing the importance of definitive microbiologic diagnosis in optimizing clinical care (Table 112-2). Physical findings may also be unreliable—particularly since reliance on radiologic techniques has displaced the physical examination as an art form. Further, dual processes are common and physical findings are often muted in the immunocompromised host. "Crackles" and rales are "heard" much more often than the actual frequency of pulmonary consolidation. Commonly, radiographic appearances are misconstrued as etiologic diagnoses: consolidation, bronchopneumonia, miliary patterns, nodules, abscesses, fluid collections, pleural effusions, interstitial pneumonitis, and lymphadenopathy. The goal of the

Table 112-1

Categorization of Pneumonia by Clinical Setting

Community-Acquired Pneumonia
- Typical (i.e., classic) pneumonia
- Atypical pneumonia
- Aspiration pneumonia

Pneumonia in the Elderly
- Community-acquired
- Nursing home residents

Nosocomial Pneumonia
- Hospital-associated pneumonia
- Ventilator-associated pneumonia
- Health care facility associated pneumonia

Pneumonia in Immunocompromised Hosts
- Immunoglobulin and complement deficiencies
- Granulocyte dysfunction or deficiency (cyclic neutropenia, chronic granulomatous disease)
- Cellular and combined immune deficiencies
  - Neoplastic disease
  - Solid organ and hematopoietic transplant recipients
  - Untreated HIV infection
  - Immune reconstitution syndromes (AIDS, neutropenia)
  - Severe combined immunodeficiency (SCID) and congenital deficiencies
  - Autoimmune and connective tissue disorders
  - Other immunocompromised patients

Cystic Fibrosis and Anatomic Disorders
- Bronchopulmonary sequestration

Table 112-2

Routine Evaluation of Patients with Suspected Pneumonia

History
- Age
- Community (respiratory viruses, antimicrobial resistance) vs. hospital (ventilator)
- Pace of onset, dyspnea
- Recent infections (postviral pneumonia, endocarditis, aspiration)
- Recent hospitalization or exposure to medical facilities (extended care)
- Underlying conditions (mental status, immunity, cardiopulmonary, medications)
- Exposures (illness, children, institutions, animals, gardens, travel)
- Antimicrobial therapies, home infusion therapy, vaccinations
- Duration of hospitalization or endotracheal intubation

Physical Examination

Laboratory
- Complete blood count with differential counts
- Electrolytes, liver function tests, blood urea nitrogen, creatinine

Radiology
- PA and lateral chest radiograph
- *Consider need for:* Chest CT with contrast, echocardiogram, thoracentesis

Microbiology
- Sputum Gram's is stain, culture and sensitivity (susceptibility)
- Nasal swab (direct immunofluorescence) for respiratory virus panel (influenza, respiratory syncytial virus, parainfluenza, adenovirus)
- Blood cultures (2)

Consider in appropriate setting:
- Pneumococcal urinary antigen
- *Legionella* urinary antigen
- *Histoplasma* urinary antigen
- Acid-fast smear (modified acid-fast smear) and culture
- Acute and convalescent sera *(Mycoplasma, Chlamydophila*, Q fever (*Coxiella burnetti*), *Histoplasma, Coccidioides, Tularemia*)
- HIV status
- Molecular assays (cytomegalovirus, Epstein-Barr virus)

clinician is to define the etiology of pulmonary processes as rapidly as possible so as to facilitate management.

Host Defenses

The presence of pneumonia should be taken as evidence of an immune defect relative to the epidemiological pressure of the microorganisms. A small inoculum of an organism of high intrinsic virulence (adhesion, invasive enzymes, motility, intracellular pathogens) may cause infection in a relatively normal host. Organisms of low virulence should cause infection only if there is an immune or anatomic predisposition to infection or with a high burden of organisms. Microorganisms may reach the lungs via the airways, bloodstream, or lymphatics. Defects in specific components of the immune system (innate and acquired) predispose to specific types of infection (Table 112-3). An important first step in many infections is colonization of the upper airway via adhesion of organisms to

Table 112-3

Infections Associated with Specific Immune Defects

Defect	Common Causes	Associated Infections
Granulocytopenia	Leukemia, cytotoxic chemotherapy, AIDS, drug toxicity, Felty syndrome	Enteric gnr, *Pseudomonas, S. aureus, S. epidermidis,* streptococci, *Aspergillus, Candida* and other fungi
Neutrophil chemotaxis	Diabetes, alcoholism, uremia, Hodgkin's disease, trauma (burns), lazy leukocyte syndrome, CT disease	*S. aureus*, Candida, streptococci
Neutrophil killing	CGD, myeloperoxidase deficiency	*S. aureus, E. coli, Candida, Aspergillus, Torulopsis*
T-cell defects	AIDS, congenital, lymphoma, sarcoidosis, viral infection, CT diseases, organ transplants, steroids	Intracellular bacteria (*Legionella Listeria*, mycobacteria), HSV, VZV, CMV, EBV, parasites
B-cell defects	Congenital/acquired agammaglobulinemia, burns, enteropathies, splenic dysfunction, myeloma, ALL surgery, sickle cell disease, cirrhosis	(*Strongyloides, Toxoplasma*), fungi (*P. carinii, Candida, Cryptococcus*) *S. pneumoniae, H. influenzae, Salmonella* and *Campylobacter spp, Giardia lamblia*
Splenectomy		*S. pneumoniae, H. influenzae, Salmonella spp, Capnocytophaga*
Complement	Congenital/acquired defects	*S. aureus, Neisseria spp, H. influenzae, S. pneumoniae*
Anatomic	IV/foley catheters, incisions, anastomotic leaks, mucosal ulceration, vascular insufficiency	Colonizing organisms, resistant nosocomial organisms

HSV, herps simplex virus; VZV, Varicella zoster virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus.

the epithelial surfaces. These surfaces are normally protected against infection by mechanical clearance of organisms via the nose or oropharynx, local production of complement and immunoglobulin A (IgA), saliva, sloughing of epithelial cells, and bacterial interference by "normal flora". Changes in these surfaces (diminished IgA secretion, changes in production of adhesins, fibronectin, altered lectin binding) predispose to adhesion of microorganisms. Organisms carrying enzymes that can degrade IgA exotoxins, adhesion proteins, or pili are favored in colonizing the respiratory epithelium. Mucociliary clearance may be disrupted by cigarette smoking, viral infection, *Haemophilus influenzae*, or *Mycoplasma pneumoniae* infection. Aspiration can result from altered closure of the glottis (neurological injury, sleep apnea, intubation, alcohol, anesthesia). Once past the glottis, most bacteria and viruses are small enough (up to 2 microns) to reach the alveoli unless impeded by alveolar lining fluid containing surfactant, immunoglobulin G (IgG), complement, and other proteins. Surfactant includes a variety of components that serve to activate alveolar macrophage and neutrophil functions and may serve as an opsonin (SP-A and SP-D) for many types of organism. Organisms surviving the defenses of the upper airway are left to the cellular components of the lower airways including T- and B-lymphocytes, macrophages, and dendritic cells.

Pulmonary defense mechanisms are also disrupted by systemic infections (sepsis), acidosis, hypoxemia, pulmonary edema, malnutrition, uremia, age, and lung injury (acute respiratory distress syndrome, ARDS). Endotoxin and lipopolysaccharide diminish clearance of bacteria from the lungs. Viral infections may diminish neutrophil and macrophage functions, including phagocytosis, chemotaxis, and oxidative metabolism.

General Guidelines for Management of Pneumonia

The individual with pulmonary infection often presents in an ambulatory setting. The evaluation of the patient with possible pneumonia depends on a series of questions that provide clues to management, including the need for hospitalization and selection of antimicrobial agents. Subsequently,

microbiologic data provide the basis for adjusting antimicrobial therapy. The questions include:

1. *Is the process life-threatening?*
   a. Does the patient need to be admitted to the hospital? *Does the patient have supports in the community?* Can he/she manage oral medications, other therapies, and follow-up visits from home?
   b. What is the time course of the process? Is the infection rapidly progressive or gradual? Is there time to delay therapy or diagnostic procedures?
   c. Does the patient need supplemental oxygen, assisted ventilation, surgery, blood products, monitoring, or isolation?
2. *Does the patient have immune deficits?* Could the process be underestimated based on the absence of normal inflammatory responses?
3. *What are the most common infections in the community or hospital or institution where this "infection" was acquired?* In this appraisal, it is helpful to resort to clinical groupings: community-acquired, nosocomial (hospital, ventilator, health care facility), and pneumonia in the immunocompromised patient. Such groupings provide a guide to empiric therapy while evaluation is underway. It is important to understand the incidence of tuberculosis, acquired immunodeficiency syndrome (AIDS), respiratory viral infections, and antimicrobial-resistant organisms (*Pneumococcus, Staphylococcus*) in the community and of antimicrobial resistance in the institution.
4. *What are the gross pathological and pathogenetic features of the pulmonary process?* These may include frank pneumonia, focal infiltrate, lung abscess, chronic cavitary lesion, bronchiectasis, or miliary lesions. As a corollary, since pulmonary infections are occasionally generated by the hematogenous route, rather than by the bronchogenic route, consider possible extrapulmonary processes in the pathogenesis of pulmonary infection.
5. *History:* Are there clues to a specific etiology of infection and to the severity of the illness?
   a. Underlying clinical conditions: Chronic obstructive pulmonary disease (COPD), immune deficits, altered mental status, prior infections.
   b. Epidemiological history (i.e., travel, contacts, exposures, vaccines, medications, prior infections or hospitalizations): Has the patient traveled or does he/she have any hobbies (gardening, hiking, cooking) that might provide an epidemiological clue (Table 112-4)?
   c. Symptoms: Rate of progression, other systemic signs. Prior mild respiratory illness ("the flu") with improvement and then rapid deterioration is suggestive of bacterial superinfection of viral pneumonitis, consistent with *Staphylococcus*

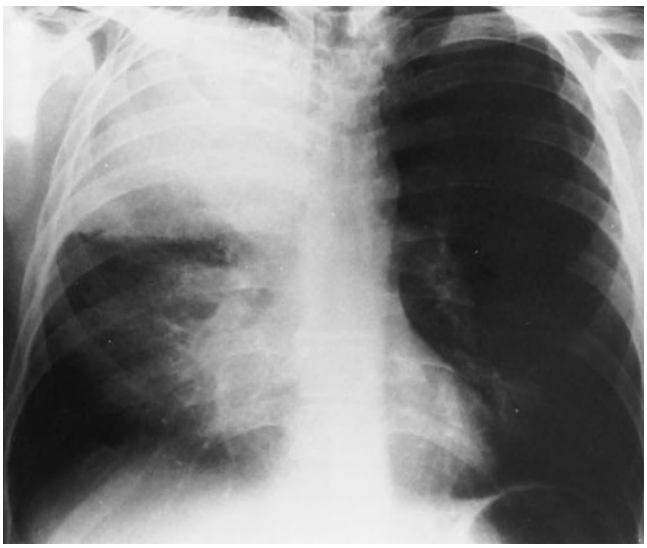
Table 112-4

Epidemiologic Exposures Associated with Pneumonia

Pathogen	Epidemiology
Anthrax	Bioterrorism; animals, hides, raw wool, goat hair
Brucella sp.	Domestic animals, dairy products, abattoir, veterinarian
Chlamydophila psittaci	Birds: parrots, budgerigars, cockatoos, pigeons, turkeys
Coccidioidomycosis	Southwest United States, Southern California, San Joaquin Valley
Coxiella burnetii	Cattle, domestic animals, cats
Hantavirus	Rodent droppings/urine (virtually all states)
Histoplasmosis	Bird/bat droppings
Legionella	Contaminated aerosols
Leptospirosis	Rodents, animals, water contaminated by animal urine
Melioidosis	West Indies, Australia, Southeast Asia, South Central America—delayed onset post-exposure
Pasturella multocida	Dogs, cats
Plague (*Yersinia, pestis*)	Bioterrorism; squirrels, chipmunks, rabbits, prairie dogs, rats
Paracoccidioides	South America (Brazil)
Q fever	Goats, sheep, cattle, domestic animals (feces, amniotic fluid, placenta, milk)
Rhodococcus	Horses, soil, farms
Severe acute respiratory syndrome/ (SARS)	Endemic regions, nosocomial exposures

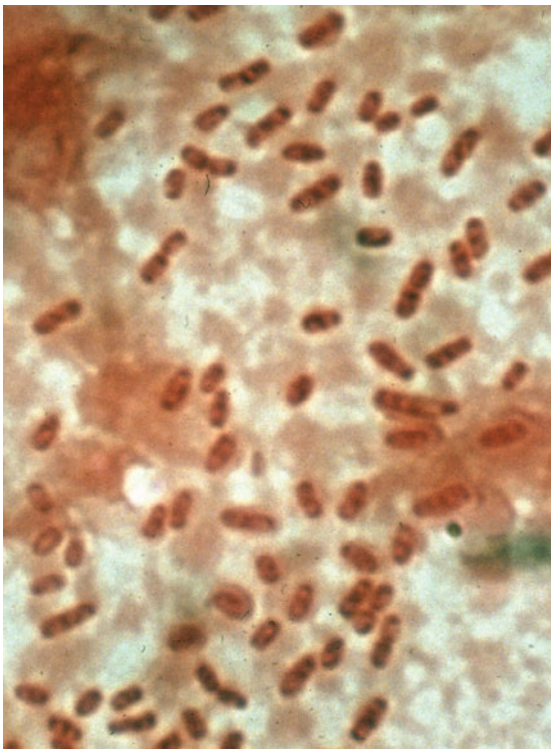
aureus or other bacterial infection. The abrupt onset of illness with recurrent (over several days) shaking chills, particularly if associated with mild diarrhea for 1 or 2 days, may suggest Legionnaires' disease. Pneumococcal pneumonia may be associated with a single severe rigor with fever, often with symptomatic herpes labialis. Gastrointestinal symptoms and confusion may occur with any infection but are often notable with pneumococcal pneumonia and Legionnaires' disease. The presence of extrapulmonary signs or symptoms is often a better clue to the nature of infection than are pulmonary symptoms.

6. *Physical examination:* Skin lesions (e.g., furuncles, endocarditis, or gram-negative sepsis), lymph nodes (symmetrical or regional), retinal examination, ear examination (bullous myringitis with *Mycoplasma* infection), periodontal disease or absent gag reflexes (with aspiration pneumonia), ipsilateral chest splinting, and neurological disease (pulmonary-brain syndromes) are often ignored but provide valuable clues. Dullness to percussion, bronchial breath sounds, and egophony (E to A changes) are suggestive of pulmonary consolidation but may be absent. Patients infected with *Pneumocystis carinii*, *Mycoplasma*, or viruses (or severe immune compromise) may have normal chest examinations despite abnormal chest radiographs and marked hypoxemia.
7. *Basic laboratory data:* Many systemic processes are reflected in abnormalities of blood counts, urinalysis, and routine blood chemistries. For example, the presence of mild liver function abnormalities might suggest Q fever, tularemia, miliary tuberculosis, or Legionnaires' disease. The presence of pigmented casts in the urine and markedly elevated serum levels of creatine phosphokinase might focus attention on the possibilities of influenza virus pneumonia, Legionnaires' disease, or a pulmonary infiltrate associated with intravenous drug abuse. Rapid screening tests (e.g., for respiratory viruses) are useful, but have limitations in terms of sensitivity.
8. *Radiology:* All patients with pneumonia merit chest radiography, preferably posterior-anterior and lateral views since portable films are often of limited value. Radiographs allow the physician to assess the severity of pneumonia and to distinguish this process from acute bronchitis; the latter, when infectious, is often viral in etiology. No radiographic findings are specific enough to define the microbial origin of a given pneumonia or pulmonary infiltrate. The only definitive way to obtain a specific etiologic diagnosis is through demonstration of the infecting organism—i.e., by examination of stained smears of sputum and pleural fluid or other biologic materials, by culture of respiratory secretions and blood, by demonstration of nucleic acids or proteins from an infecting microorganism, or by demonstration of an increase in antibody titer against the infecting microorganism. Nonetheless, the radiographic picture, taken along with other clinical information, can favor one or several etiologic agents. Involvement of multiple pulmonary lobes in the process and the presence of a pulmonary effusion are poor prognostic features.
   a. Define the radiographic pattern as either lobar (Fig. 112-1) or segmental consolidation, patchy bronchopneumonia, nodules (large, small, or miliary) (Fig. 112-2), or an interstitial process (Table 112-5). For example, many large, round pulmonary densities in a renal transplant recipient suggest *Nocardia* infection rather than *Pneumocystis* pneumonia, whereas in a heroin addict with cough, fever, and pleuritic chest pain, such densities suggest acute right-sided endocarditis rather than pneumococcal pneumonia.
   b. Compare with prior radiographs: Is the process old or new? Are there multiple processes? Has the patient had surgery in the intervening period? Is the spleen enlarged or absent?
   c. Confounding variables: Is it too early in the process to detect radiologic changes (first 18 to 24 h)? Is the patient neutropenic (early viral or fungal pneumonitis) or otherwise immunocompromised (*P. carinii* pneumonia often occurs with minimal or no findings on plain chest radiographs)? Dehydration is commonly cited as a cause of false-negative radiographs, but, in general, this concept is probably overrated.
   d. Computed tomography (CT) scanning is sensitive to changes unrecognized in plain radiographs and may be useful in guiding invasive procedures.
9. *How can a diagnosis be achieved most expeditiously?* Is this likely to be a viral process that can be diagnosed in the office? Which invasive procedures are done well at your institution?
10. *Examination of clinical specimens* (appropriately stained smear of sputum or pleural fluid, blood buffy coat, skin lesions, throat swabs) often provides a provisional diagnosis. Examination of an appropriately stained smear of sputum can provide a shortcut to diagnosis if the findings are reasonably definitive.
    a. Gram-stained smears provide valuable information regarding the morphology and the tinctorial properties of bacteria (and some fungi) but also about the presence of polymorphonuclear leukocytes and squamous epithelial cells, the latter indicating that the specimen originated in the upper, rather than the lower, respiratory tract (Fig. 112-3).
    b. Other special staining methods, including Kinyoun and modified acid-fast stains for



A

B



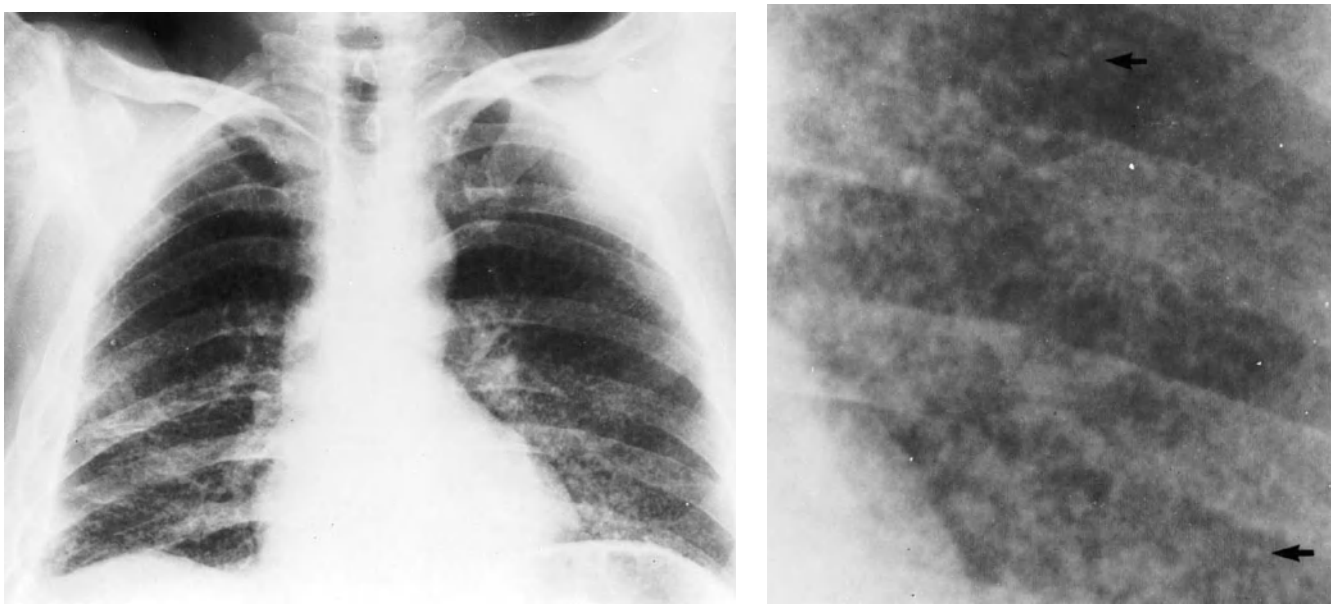
C

Figure 112-1 *A*. Dense lobar consolidation involving right upper lobe and right middle lobe in an alcoholic patient with *Klebsiella pneumoniae* pneumonia. The minor fissure is bulging downward. *(Courtesy of Dr. R. Greene.) B*. Same patient 7 days later. Despite antibiotic therapy, *K. pneumoniae* pneumonia progressed to become a necrotic process with formation of multiple abscesses. *(Courtesy of Dr. R. Greene.) C*. Sputum Gram's stain from patient with *K. pneumoniae* infection reveals gram-negative rod forms with trace of a surrounding capsule.

mycobacteria can provide additional data. *Actinomyces* or *Nocardia* species and Wright-Giemsa or a variant such as Diff-Quik or direct fluorescent antibody staining of induced sputum samples for *P. carinii* or *Legionella pneumophila* may provide a diagnosis.

c. Culture of sputum or blood or other bodily fluids may provide a specific etiologic diagnosis when evaluation of a sputum smear has not supplied a provisional diagnosis. The failure may be caused either because the infecting agent cannot be distinguished from components of the normal upper-respiratory-tract flora which are incorporated in the specimen or because the particular microorganism is not visible on Gram-stained smear (e.g., *Aspergillus* species or *M. pneumoniae*).

d. In some patients, an etiologic diagnosis cannot be made on the basis of initial smears or cultures. In such circumstances, a definitive diagnosis can sometimes be made by alternative means—e.g., urinary antigen tests for *Legionella* or *Histoplasma* infections, antigenemia or nucleic acid polymerase chain reactions for viral processes



A *B*

(Tables 112-2 and 112-6) or, retrospectively, by serologic means, as in psittacosis, Q fever, or adenovirus pneumonia. Screening tests are highly useful for respiratory viruses (nasal swab coupled with immunofluorescence). Induced sputum examinations have a high yield for *Pneumocystis* and mycobacteria.

e. Invasive diagnostic procedures: In patients who are critically ill or unlikely to tolerate invasive infections (immunocompromised hosts, recent major surgery, heart failure, COPD) it is reasonable to consider more invasive diagnostic procedures early in the clinical course. In such patients, only specific etiologic diagnoses can direct appropriate therapy. However, this observation illustrates the tension between empiric therapies and the risks inherent in invasive tests. Empiric antimicrobial therapies carry the risk of obscuring a specific microbiologic diagnosis as well as evoking drug-associated toxicities. Invasive diagnostic procedures are used to obtain uncontaminated lower-respiratory-tract secretions or pulmonary tissue for microbiologic and histologic analysis. The selection of an invasive procedure should be based on the nature of the illness and the likelihood of success for each procedure afforded by the institution. Among the invasive procedures that are available are:

(1) protected specimen brushing (PSB)
(2) plugged telescoping catheter (PTC) sampling
(3) standard bronchoalveolar lavage (BAL)
(4) protected bronchoalveolar lavage (P-BAL or PTC-BAL)
(5) transtracheal aspiration (now uncommon)
(6) fiberoptic bronchoscopy with transbronchial biopsy
(7) needle biopsy of the lung
(8) open lung biopsy via limited or video-assisted thoracotomy.

Important considerations in selecting an invasive procedure include the type and location of the pulmonary lesion, the ability of the patient to cooperate with the required manipulations, the presence of coagulopathies, and experience at the particular hospital in performing the particular procedure.

11. *Antimicrobial therapy:* In practice, initial therapy is empiric and based primarily on clinical clues. The selection of drug(s) for empiric therapy depends on the clinical setting and on the gravity of the pulmonary process. The selection of specific antimicrobial agents is considered in subsequent chapters.

PULMONARY INFECTIONS: PATHOLOGICAL AND PATHOGENETIC FEATURES

Pulmonary infections can be categorized according to distinctive pathological, anatomic, and radiologic features. Some general patterns are presented below for their value in

Table 112-5

Radiographic Features and Differential Diagnosis of Pneumonia in an Immunocompetent Host

Consolidation/Focal opacity	*S. pneumoniae, M. pneumoniae, H. influenzae, C. pneumoniae, Legionella* sp., *S. aureus, M. tuberculosis*, and "atypical" mycobacteria (*M. avium* complex)
Cavitation	*S. aureus*, anaerobic bacteria, *M. tuberculosis*, gram-negative aerobic bacteria, *Aspergillus sp.*, geographic/endemic fungi (*H. capsulatum, C. immitis, B. dermatitidis*)
Interstitial infiltrates	Viruses, *M. pneumoniae, M. tuberculosis*, geographic/endemic fungi, *C. psittaci*
Miliary	*M. tuberculosis*, geographic/endemic fungi, viruses, *M. pneumoniae*
Lymphadenopathy	*M. tuberculosis*, viral , Epstein-Barr virus, cytomegalovirus, rubella), geographic/endemic fungi, *C. psittaci*, cat-scratch disease.

differential diagnosis and are discussed in detail in subsequent chapters.

Bacterial Pneumonia

Bacterial pneumonia commonly results from bronchogenic spread of infection following microaspiration of pharyngeal secretions. Such particles reach terminal airways and alveoli where they initiate infection, which has the anatomic distribution and radiologic appearance of subsegmental, segmental, or lobar consolidation. Pneumonia may be patchy, with a peribronchial and multifocal distribution, and occur in association with aspiration and bronchial plugging, superinfection of preexisting chronic bronchitis, diffuse acute tracheobronchial inflammation (e.g., influenza, parainfluenza), and with specific infecting microorganisms (e.g., oral anaerobic bacteria). The progression of a pulmonary infiltrate or lobar consolidation to parenchymal destruction (necrotizing pneumonia or lung abscess) is usually the consequence of one or more of three factors: the intrinsic virulence of the infecting organism(s), the presence of bronchial obstruction

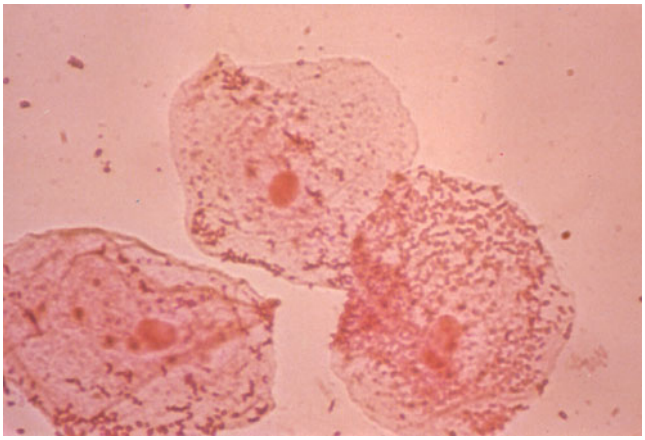

Figure 112-3 Three large oropharyngeal epithelial cells from a specimen of "sputum" that is inadequate for Gram's stain analysis and culture because of its origin in the upper respiratory tract. Note the large number of organisms agglutinated on the surface of the squamous epithelial cells (×400).

or other anatomic abnormality, or immune compromise of the host (Fig. 112-1).

Pneumonia may develop via the bacteremic route rather than the bronchogenic route. The clinical setting and the radiographic pattern usually suggest this type of pathogenesis. The intravenous drug abuser with *S. aureus* bacteremia and acute right-sided endocarditis presents with fever, cough, purulent sputum, a murmur of tricuspid insufficiency, numerous irregular infiltrates, and rounded densities on chest radiograph. Similarly, burn patients with *Pseudomonas aeruginosa* bacteremia and multiple nodular pulmonary densities are apt to have bacteremic *Pseudomonas* pneumonia with pulmonary bacterial arteritis. Septic pulmonary emboli, arising from septic thrombosis of the jugular vein may cause a clinical and radiographic picture suggestive of multifocal bronchopneumonia. On the chest radiograph, however, the lesions are nodular; histologically, they represent septic pulmonary infarcts (following emboli) upon which are engrafted pyogenic infection and abscess formation.

Lung Abscess

A lung abscess is an area of pulmonary infection with parenchymal necrosis. Lung abscesses may be solitary or may occur as multiple discrete lesions. Most often a lung abscess is secondary to aspiration of anaerobic or anaerobic and aerobic organisms which have colonized the upper-respiratory tract and may be associated with periodontal disease (Fig. 112-4). Superinfection of damaged or infarcted lung tissue (e.g., as occurs in aspirational pneumonia after chemical injury and anaerobic superinfection or primary anaerobic infection) progresses to necrosis and to microscopic foci of abscess formation. Confluence of small necrotic foci can either create one or more lung abscesses or lead to a progressively fibrotic, shrunken, and destroyed lobe. *Pulmonary gangrene* is an unusual consequence of severe pulmonary infection characterized by sloughing of a pulmonary segment or lobe. This

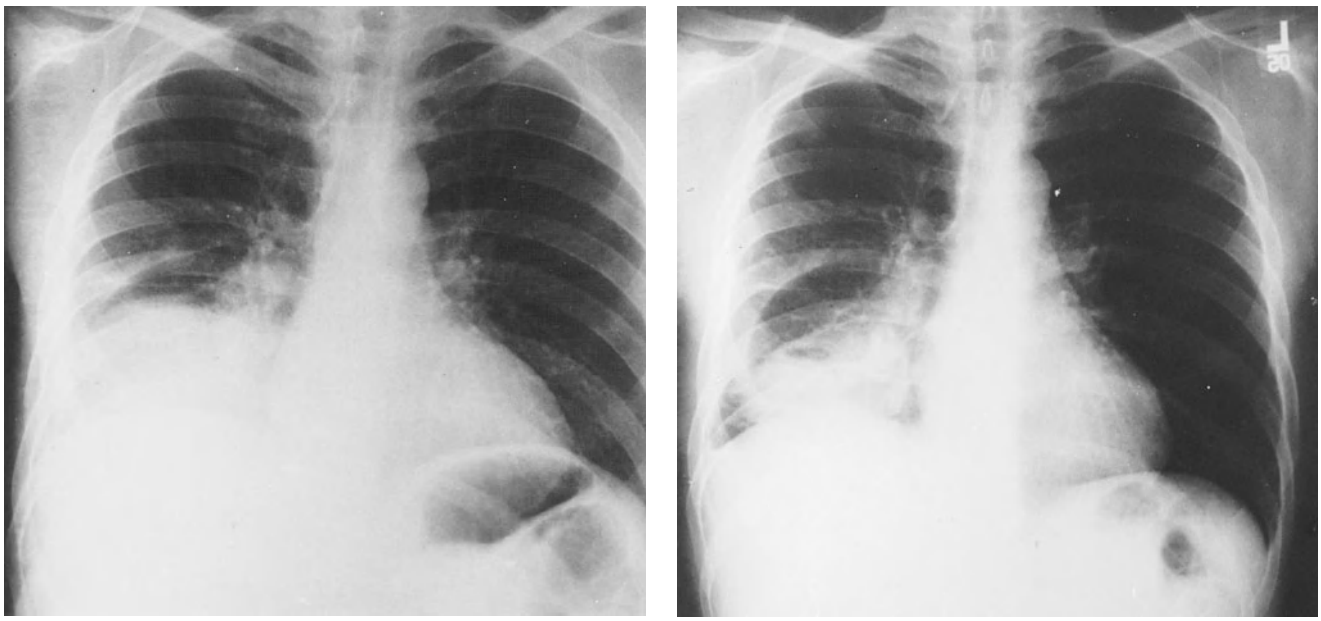
process affects an entire segment or lobe secondary to thrombosis of both bronchial and pulmonary arteries followed by pulmonary infarction. The organism most commonly implicated has been *Klebsiella pneumoniae*, but others which have been implicated include *Streptococcus pneumoniae*, *Escherichia coli*, mixed anaerobes, *H. influenzae*, and *S. aureus*. If there is some degree of ball-valve bronchial obstruction, air may enter while contained pus may fail to drain, producing the radiographic picture of an air-fluid level.

Other causes of lung abscess are (1) progression of a bronchogenic pneumonia due to a pathogen with necrotizing potential (e.g., *K. pneumoniae*, Fig. 112-1) or *Nocardia asteroides* in an immunocompromised patient, (2) bacteremic spread of infection, and (3) septic pulmonary emboli. Lung abscesses complicating necrotizing pneumonia should be distinguished from pneumatoceles; the latter are thin-walled, air-filled structures that often develop early in the course of staphylococcal pneumonia, particularly in infants and young children, and usually disappear over the course of a few months.

Bronchitis and Bronchiectasis

Acute bronchitis is an inflammatory process, usually of viral origin, confined to the bronchi and bronchioles; it does not extend appreciably to surrounding pulmonary parenchyma



A *B*

Figure 112-4 Necrotizing pneumonia, probably secondary to aspiration in a 39-year-old man, smoker and drinker, previously healthy. Onset was with cough, shortness of breath, fever, and right-sided pleuritic pain. Despite antibiotics, signs and symptoms progressed to include high fevers, night sweats, greenish sputum, leukocytosis, and manifestations of hypertrophic osteoarthropathy. *A*. On admission, there was consolidation of right lower lobe, a right hilar mass (or adenopathy), and right pleural effusion. Mediastinoscopy and bronchoscopy revealed no tumor. *B*. Three months later, the process in the right lower lobe is more circumscribed. Right lower lobectomy revealed extensive necrotizing pneumonia, multiple abscesses, and ''reactive" lymph nodes. Postoperatively, the patient was free of signs and symptoms, including hypertrophic osteoarthropathy.

and is not evident on radiographic examination. Purulent inflammatory secretions are common even though there may be no discernible bacterial infection. Such purulent secretions represent bacterial superinfection. The diagnosis of an acute exacerbation of chronic bronchitis is based solely on clinical grounds; the manifestations are increased cough, dyspnea, and enhanced production of purulent sputum, with or without fever, in a patient with COPD. Bacteriologic examination generally reveals large numbers of pneumococci or nontypeable *H. influenzae*, either as infecting organisms or as chronic colonizers of the bronchial tree. Patients with acute exacerbations of chronic bronchitis tend to improve with antimicrobial treatment while those with chronic bronchitis are less likely to improve with therapy.

Bronchiectasis is characterized by destruction of epithelial, elastic, and muscular elements of bronchi, resulting in their irreversible dilatation. The major proximate cause is repeated or chronic bacterial infection. However, predisposition to such infections may be a consequence of a variety of factors, including certain types of prior infection (pertussis, adenovirus, or rubeola infections, necrotizing pneumonia), bronchial obstruction, immunodeficiencies, congenital anatomic lung disease (e.g., congenital tracheobronchomegaly), and other hereditable disorders, such as ciliary dysfunctional states and α_1-antitrypsin deficiency. Currently, cystic fibrosis is the most common predisposing factor for bronchiectasis. As a result of repeated infections, stasis of secretions, and peribronchial fibrosis, bronchi are grossly distorted or completely destroyed. Although pneumonia or lung abscess may accompany recurrent acute infections, exacerbations are usually confined to bronchial and peribronchial tissues.

Chronic Cavitary Disease

Chronic cavitary pulmonary disease is most often due to tuberculosis, but may be seen in α_1-antitrypsin deficiency, echinococcal disease, Wegener's granulomatosis, and other structural disorders. Tuberculosis commonly begins with a focus of pneumonitis, usually in the subapical posterior portion of an upper lobe. This patch of pneumonitis occurs at a latent site of earlier metastatic infection (Simon focus) produced by lymphohematogenous spread from primary pulmonary tuberculous lesions. Progressive caseation necrosis at this site, followed by drainage of caseous material through the bronchial tree, produces a cavity (Fig. 112-5). The cavity is encased in a rigid wall of fibrous tissue.

In addition to pyogenic lung abscess and pulmonary tuberculosis, other pulmonary infections can produce chronic cavities. These include *Nocardia* infections, *Rhodococcus equi* infections, actinomycosis, and chronic primary pulmonary mycoses (particularly histoplasmosis, occasionally coccidioidomycosis, uncommonly blastomycosis). Sporotrichosis can affect the lung and produce thin-walled cavities. Parasitic

Spread from original involvement of right upper lobe.

infestation of the lung (paragonimiasis, echinococcosis) can also form cavities.

Pulmonary cavities may also occur in noninfectious disorders (e.g., Wegener's granulomatosis, lymphoma or bronchogenic carcinoma, bland pulmonary infarcts, and intrapulmonary nodules of rheumatoid lung disease) (Fig. 112-6). Such cavitary lesions, as well as the cystic lesions that occur in chronic pulmonary sarcoidosis (Fig. 112-7) and in the markedly dilated bronchi of saccular bronchiectasis, can be the sites of *fungus balls.* These represent tangled masses of fungal hyphae and debris lying freely within pulmonary cavities generally as noninvasive saprophytic growths in the immunologically normal host. Most often the mycotic agent is an *Aspergillus* species (usually *A. fumigatus*), and the fungus balls are called *aspergillomas.* Hemoptysis originating from the cavity wall is common and may be severe.

Miliary Lesions

Hematogenous dissemination of tuberculosis can follow initial infection in children or adults. It also can result from breakdown of formerly quiescent sites of pulmonary or extrapulmonary infection. Clinically unexplained fever may be accompanied by miliary lesions (which resemble millet seeds and are very small and uniform in shape) on the chest radiograph; histologically, these lesions are foci of granulomatous reaction (Fig. 112-2). Similar radiographic lesions also occur in the course of hematogenously disseminated bacterial and mycotic infections including cryptococcosis and histoplasmosis.

Viral Infections of the Respiratory Tract

Respiratory viral infections are a major cause of morbidity worldwide. Patients present with cough, sore throat, bronchoconstriction, fever, rhinitis, and suffusion of mucous membranes. The majority of these infections are upper respiratory infections and of significance only as causes of discomfort and as predisposing conditions for infection of the lower respiratory tract. Spread is via aerosolized droplets and hand contamination. The most prominent viral pathogens include rhinovirus and coronavirus for which no specific antimicrobial therapies are available. Commonly, adenovirus,

parainfluenza virus, respiratory syncytial virus (RSV), and influenza virus may also cause this syndrome. Infections with respiratory viruses occur predominantly in the winter and early spring. Less commonly, reovirus, enteroviruses, metapneumoviruses, and picornaviruses may cause the same symptoms. Of nonviral etiologies, treatable infections with *M. pneumoniae* and *Chlamydophila* (formerly *Chlamydia*) *pneumoniae* also cause significant upper- as well as lower-respiratory infections. The predominant differential diagnoses for these infections include allergic, vasomotor, or atrophic rhinitis or nasal polyposis. These syndromes should be considered in patients with an atopic history and recurrent

(Original magnification ×10.)

upper-respiratory infections. Although these infections are generally self-limited, common complications include sinusitis, otitis and bronchitis, exacerbations of chronic pulmonary disease (chronic bronchitis), asthma, and bacterial superinfection with pneumonia.

Viral Infections of the Lower-Respiratory Tract

Influenza virus is an agent of the family Orthomyxoviridae that may be associated with sizable outbreaks or major epidemics of upper-respiratory infections. Influenza is classified into three subtypes based on antigenic differences: influenza

A, B, and C. Primary influenza viral pneumonia usually occurs in the setting of an outbreak of influenza A infections. It impacts disproportionately on patients with underlying heart disease (mitral stenosis), chronic pulmonary disease, pregnancy, and immunocompromised individuals. Unlike secondary bacterial pneumonia after influenza—a complication that occurs after a period (1 to 4 days) of improvement following typical upper-respiratory illness—primary influenza pneumonia immediately follows typical influenza. Two classes of drugs are available to treat influenza A including M2 matrix protein inhibitors (amantadine and rimantadine) and neuraminidase inhibitors (zanamivir and oseltamivir). Resistance is emerging to both groups. Influenza A infects a wide range of species as hosts, including humans, pigs, birds, horses, and marine animals, whereas influenza B and C are generally restricted to humans. As a result, influenza A may move between host species, risking recombination, mutation (drift), and geographic spread. Pandemic influenza (e.g., avian influenza, H5N1) is most likely to arise in birds as all of the hemagglutinin and neuraminidase variants are carried in that population with viral replication in the gastrointestinal tract and secretion in high titers in feces. The spread of mild variants of H5N1 influenza is common in some Asian populations.

Rarely, viral pneumonia develops in an otherwise healthy person in the course of systemic infection with viruses whose principal impact is extrapulmonary. Pulmonary infiltrates occur in 16 percent of young adults with varicella, but only 2 to 4 percent have clinical manifestations suggestive of pneumonia. Some cases of mild pneumonitis have been observed in patients receiving live varicella vaccine. Pneumonia in children with varicella is more likely to represent bacterial superinfection than primary viral pneumonia. On rare occasions, pulmonary infiltrates develop in patients with clinical infectious mononucleosis; the infiltrates represent atypical pneumonia due to Epstein-Barr virus (EBV).

A novel Hantavirus, Sin Nombre virus, emerged acutely in 1993, in the Four Corners area of New Mexico, Arizona, Colorado, and Utah. Cases had previously been reported worldwide but primarily in the west and southwestern United States. The Hantavirus pulmonary syndrome begins with a 3- to 6-day prodromal period consisting of myalgias and fever, sometimes accompanied by gastrointestinal symptoms. The prodrome is followed by progressive cough, dyspnea, tachycardia, and hypotension. Bleeding may occur. Laboratory findings include hemoconcentration, leukocytosis, and thrombocytopenia. The chest radiograph demonstrates interstitial edema, peribronchial cuffing, and bilateral airspace (bibasilar and perihilar) disease. The picture of pulmonary edema (interstitial and alveolar) is consistent with a diffuse pulmonary capillary leak syndrome. The case fatality rate for the Hantavirus pulmonary syndrome is 50 percent. The principal host for Sin Nombre virus is the deer mouse, and infection is acquired through exposure to this rodent, to rodent excreta, or to contaminated dust.

Severe acute respiratory syndrome (SARS) is a viral respiratory illness that first appeared in southern China in November 2002 before spreading globally. SARS is caused by a previously unrecognized coronavirus, called *SARS-associated coronavirus* (SARS-CoV). SARS-CoV is thought to be transmitted most readily by respiratory droplets. Illness usually begins with a high fever (measured temperature greater than 38.0°C with chills and malaise). Diarrhea occurs in approximately 10 to 20 percent of patients. After 2 to 7 days, SARS patients may develop a dry, nonproductive cough that may be accompanied by hypoxemia or progress to hypoxemia. Ten to 20 percent of cases require mechanical ventilation. Most patients develop pneumonia. The incidence of pneumonia is greatest in immunocompromised individuals. Between November 2002 through July 2003, 8098 people worldwide developed SARS and 774 died. No new cases were reported after July 2003.

Human metapneumovirus (HMPV) is a recently described but ubiquitous virus (Pneumovirinae subfamily, Paramyxoviridae family) which is recognized to be a major cause of acute respiratory infection, particularly in children and in immunocompromised individuals. The virus has phenotypic and clinical characteristics similar to those of RSV, often presenting with bronchiolitis. This virus may co-infect individuals with RSV.

In the immunocompromised host, viral infection is most often due to cytomegalovirus (CMV) or community-acquired respiratory viruses, although varicella zoster and herpes simplex viral pneumonias do occur. In this population, the frequency, duration, and severity of viral illness exceed that of the general population. In the solid-organ transplant recipient CMV pneumonia occurs most often in seronegative (naïve) recipients of donor organs from seropositive (latently infected) individuals. Conversely, in hematopoietic stem cell recipients, the seropositive recipient of seronegative cells is at greatest risk. The syndrome of hypoxia with diffuse, interstitial infiltrates may predispose to, or coexist with, a similar syndrome due to *P. carinii*. This syndrome is most severe in the lung transplant recipient. In contrast, CMV pneumonitis in the hematopoietic transplant recipient (bone marrow transplant) occurs with the activation of CMV in the seropositive recipient of cells from a seronegative donor. With engraftment, the naïve immune system reacts against CMV antigens expressed in the lungs. Superinfection is common; graft-versus-host disease may complicate the differential diagnosis.

Fungal Pneumonia

Fungal pneumonia occurs most often in immunocompromised hosts. However, in the normal host, infection due to the endemic or geographic fungi (*Histoplasma capsulatum, Coccidioides immitis*) or to *Cryptococcus neoformans* may be asymptomatic or may present with systemic signs often confused with acute bronchitis, viral infection, mycobacterial infection, or aseptic meningitis. Otherwise, fungal infection of the lungs is most common with anatomic defects (aspergilloma) or aspiration (*Candida* species) but is otherwise rare in individuals without immune defects. A few syndromes

merit consideration. *P. carinii* causes pneumonia with prominent hypoxia and often few physical or radiologic findings in immunocompromised individuals, particularly those on corticosteroids. Since this infection is easily prevented, consideration should be given to prophylaxis in any individual receiving chronic immunosuppressive therapy or with human immunodeficiency virus (HIV) infection or AIDS unresponsive to antiretroviral therapy.

Aspergilloma was traditionally considered to be a noninvasive colonization of pulmonary cavities. However, gross hemoptysis may complicate management and dissemination may occur at the time of surgical resection. Immune suppression may convert benign disease into invasive infection. Mucormycosis (due to the Mucoraceae family) causes rapidly progressive sinus and lung infection that requires surgical resection for cure. This infection is most common in diabetics. *Fusarium* species typically disseminate via the bloodstream, producing diffuse infiltrates.

Parasitic Pneumonia

Parasitic pneumonia is uncommon without endemic exposures. Pneumonia generally occurs when the normal life cycle of the organism includes the lungs. Infection by *Entaboeba histolytica* causes pleuropulmonary disease as a result of (1) *sympathetic* reaction to an unruptured abscess within the liver; (2) empyema, after rupture of the liver abscess into the pleural space; or (3) parenchymal involvement with abscess, consolidation, or hepatobronchial fistula after rupture of a liver abscess. Amebae that have broached the mucosal barrier are thought to gain entry to the liver via the portal vein. Subsequent liver abscesses can be either purely amebic or mixed bacterial and amebic. Other less common routes exist, including hematogenous spread that can lead to metastatic abscesses of brain, lung, and other organs. *Acanthamoeba* species cause subacute meningoencephalitis or secondary keratitis often after hematogenous spread of dermal or pulmonary disease. Some form of pulmonary complication occurs in 3 to 10 percent of patients with falciparum malaria. Noncardiogenic pulmonary edema can develop suddenly, even after appropriate antimalarial therapy has been instituted and even after parasites are no longer detected on blood smears. Acute acquired infection due to *Toxoplasma gondii* in the immunocompetent host is generally asymptomatic, with cervical lymphadenopathy as the hallmark of disease. It may be confused with mononucleosis caused by EBV or CMV. Fever, malaise, sore throat, and hepatosplenomegaly also occur, and the peripheral blood may manifest atypical lymphocytosis. Rarely, acute acquired disease may present with severe dissemination, marked by pneumonitis, hepatitis, encephalitis, polymyositis, or myocarditis. In the immunocompromised host, acute toxoplasmosis is most often associated with necrotizing encephalitis as a result of brain cyst reactivation, although myocarditis, hepatosplenomegaly, fever, and interstitial pneumonitis are also common. Pulmonary infections due to migrating worms include a Loeffler-like syndrome with *Ascaris lumbricoides*, postobstructive pneumonitis and systemic sepsis due to *Strongyloides stercoralis*, cysts and nodules due to *Echinococcus granulosus*, *Paragonimus westermani*, *Schistosoma* species, and pulmonary eosinophilia in filariasis.

RADIOGRAPHIC FEATURES OF PNEUMONIA

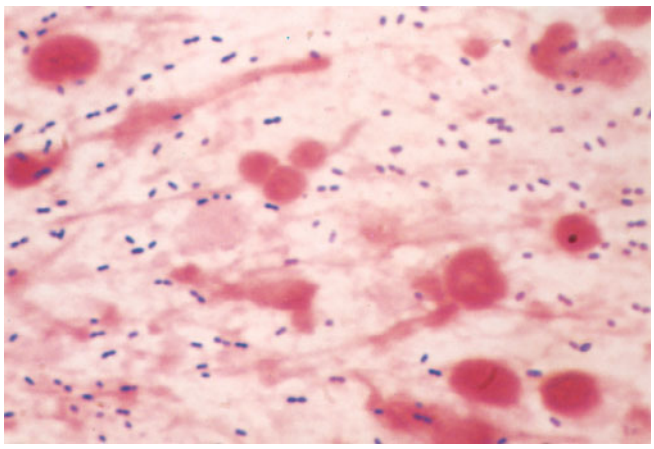
The radiographic features of pneumonia are discussed in detail elsewhere. No radiologic pattern provides a specific etiologic diagnosis. However, the radiographic pattern, combined with clinical and epidemiological information, can narrow diagnostic considerations while microbiologic data are being assembled. Several radiographic patterns can be helpful in categorizing infectious and noninfectious causes: (1) airspace or alveolar pneumonia, (2) broncho- or lobular pneumonia (Fig. 112-1), (3) interstitial pneumonia, and (4) nodular infiltrates. Although the chest radiographs of a particular patient may not fit neatly into one or another of these categories, identification of a predominant pattern can be helpful in directing attention to certain causes.

Alveolar Pneumonia

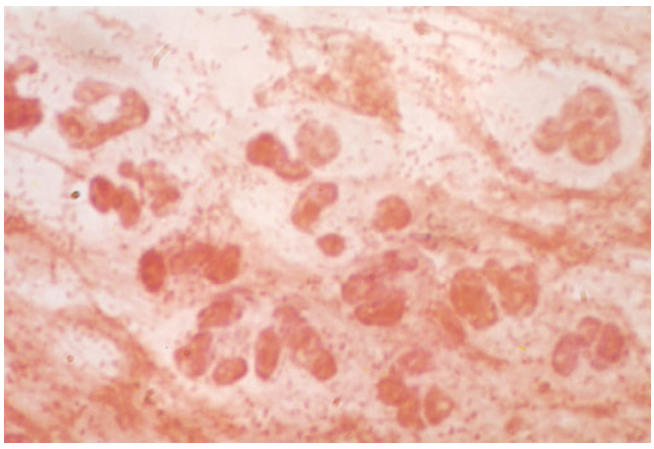
This form of infiltrate occurs when certain organisms, notably *S. pneumoniae*, induce inflammatory edema in peripheral alveoli. When the extent of the consolidation involves an entire lobe, this is the classic *lobar pneumonia*. But more often the process is not that extensive, although the pathogenesis is the same. An air bronchogram is characteristic. Loss of volume is absent or minimal during the acute stage of consolidation, but some atelectasis may develop owing to obstruction of bronchi by exudate during resolution of the process.

K. pneumoniae is another common cause of community-acquired pneumonia (CAP), which, like pneumococcal pneumonia, shows homogeneous parenchymal consolidation containing air bronchograms. Although *K. pneumoniae* pneumonia classically affects the right upper lobe and produces a dense, homogeneous lobar consolidation with bulging of the fissure, these features are not pathognomonic and cannot be relied on for diagnosis without supportive bacteriologic data (Fig. 112-1). The propensity for *K. pneumoniae* to produce tissue destruction and abscess formation may, in fact, result in a shrunken, rather than an expanded, lobe. Pneumococcal pneumonia may also cause bulging of the fissure, albeit less commonly and less prominently. Extensive alveolar consolidation may occur with a variety of other bacterial causes of pneumonia, including mixed anaerobes of aspiration pneumonia and a variety of gram-negative bacilli implicated in nosocomial pneumonias. Occasionally, an unusual configuration of airspace consolidation, *spherical pneumonia*, occurs, particularly in children, with pneumococcal or *H. influenzae* pneumonia. It has also been reported with Q fever.

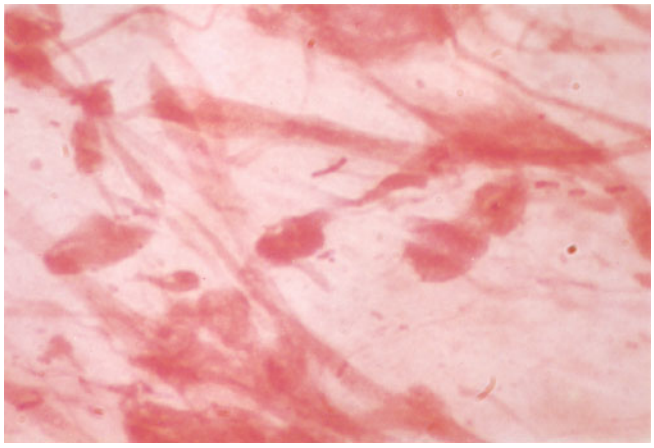
In the immunocompromised host, alveolar consolidation on the plain chest radiograph may be delayed and appreciated only by chest CT scan. Among infectious causes, bacterial agents are a major consideration. Common pathogens, such as *S. pneumoniae*, cause infection in this group of patients



A



B



C

Figure 112-8 *A*. Gram-stained smear of sputum from patient with pneumococcal lobar pneumonia (×1000). In this field there are numerous gram-positive, lancet-shaped diplococci and polymorphonuclear leukocytes. *B*. Gram-stained smear of sputum from patient with bronchopneumonia superimposed on chronic bronchitis. This field (×1000) is teeming with gram-negative coccobacilli. Many polymorphonuclear leukocytes are present. *Haemophilus influenzae* was isolated from sputum as the predominant organism. *C*. Gram-stained smear of sputum from patient with lobar pneumonia due to *K. pneumoniae*. which is often of greater severity than in the normal host and with less radiologic evidence for infection. Bacterial superinfection of viral processes (e.g., influenza, CMV) is also common. However, if the consolidation is lobar or multilobar, *L. pneumophila* is an important possibility. Other likely infectious agents are fungi (e.g., *Aspergillus*), *Nocardia*, and *M. tuberculosis*. Less often, viruses alone (e.g., CMV) elicit a predominantly alveolar pattern. Bilateral diffuse involvement with an airspace pattern resembling pulmonary edema is not uncommonly a feature of *P. carinii* pneumonia, but may also reflect viral or noninfectious etiologies.

Bronchopneumonia

In bronchopneumonia, the focus of infection and the inflammatory response is in the bronchi and surrounding parenchyma. Consolidation is segmental in distribution, and involvement is patchy; segmental involvement may become confluent to produce a more homogeneous pattern. Bronchopneumonic patterns are commonly observed in pulmonary infections due to *S. aureus* or nonencapsulated *H. influenzae*. With *S. aureus* infections, macro- and microabscess formation may occur rapidly. Also, pneumatoceles occur during the first week of lung involvement in about half the children with *S. aureus* pneumonia. These cystic spaces are believed to be the consequence of a check valve opening between a peribronchial abscess and an adjacent bronchus.

A bronchopneumonic pattern of consolidation is commonly observed when pneumonia is engrafted on underlying bronchiectasis or chronic bronchitis. In such predisposing circumstances, *S. pneumoniae* infection may produce a bronchopneumonic pattern rather than its usual lobar consolidation (Fig. 112-8). In the presence of underlying emphysema, the radiographic pattern of pneumococcal pneumonia may also be altered from its usual homogeneous pattern to one that contains multiple radiolucencies (representing unconsolidated emphysematous areas) that may be misinterpreted as abscesses.

Segmental bronchopneumonia is the radiographic picture in pneumonia due to *C. pneumoniae* (strain TWAR) or *M. pneumoniae,* and in many viral pneumonias. Any of the bacterial species that cause nosocomial pneumonia can produce a radiographic pattern of bronchopneumonic consolidation.

Interstitial Pneumonia (Peribronchovascular Infiltrate)

A reticular or reticulonodular pattern of infiltration is the radiographic representation of interstitial inflammation—i.e.,

a peribronchovascular infiltrate. In otherwise healthy persons, *M. pneumoniae* is high on the list of community-acquired causes of a radiographic pattern of interstitial pneumonia. In some instances, interstitial infiltration progresses to produce patchy consolidation of airspaces, most often in the lower lobes. Pneumonias due to respiratory viruses sometimes have an interstitial pattern that progresses to patchy segmental consolidation or to diffuse airspace disease that resembles pulmonary edema. A variety of noninfectious causes of interstitial lung disease (e.g., hypersensitivity lung disease, collagen vascular disease, and sarcoidosis) may also produce a reticular pattern on the chest radiograph (Fig. 112-6).

In immunocompromised patients, particularly in those with AIDS, the infectious causes of interstitial pneumonia are broadened to include early *P. carinii* pneumonia and additional opportunistic viral agents (CMV, varicella-zoster, herpes simplex, and probably EBV and possibly HIV). Noninfectious causes of a reticular pattern on chest radiography in an immunocompromised host include drug-induced (bleomycin, methotrexate, etc.) pneumonitis, early radiation pneumonitis, and pulmonary edema.

Nodular Infiltrates

Nodular infiltrates are considered here as well-defined large (greater than 1 cm on the chest radiograph), round focal lesions. Such a lesion may represent small aspirational abscesses (without air-fluid levels), a fungal or tuberculous granuloma, or a lesion of pulmonary nocardiosis. Multiple nodular infiltrates may also represent the necrotic lesions that develop in the lung secondary to the septic vasculitis produced by *P. aeruginosa* bacteremia or the consequences of fungemic spread of candidal infection from an infected intravascular catheter. Infected nodular pulmonary lesions are sometimes caused by septic pulmonary infarcts produced by infected emboli that originate from right-sided bacterial endocarditis, septic thrombophlebitis of pelvic veins, or septic jugular vein phlebitis. On rare occasions, similar nodular lesions are produced by necrotic (but not infected) pulmonary infarctions; primary or metastatic neoplastic lesions may have a similar appearance. Nodular lesions that undergo rapid necrosis with cavity formation can be a feature of Wegener's granulomatosis (Fig. 112-5).

In the immunocompromised patient, nodular infiltrates may be due to bacteremic or fungemic spread of infection, most often as a result of nosocomial infection caused by an infected intravenous catheter. In this type of patient, nodular lesions should bring to mind the possibilities of pulmonary nocardial infection, aspergillosis, or other fungal infections. Tuberculous granulomas in the lungs may develop or enlarge in the immunosuppressed patient. Metastatic neoplasm or lymphoma sometimes presents a similar radiologic picture. Multiple small nodules, larger than miliary lesions but smaller than the gross nodular lesions described above, raise the possibility of varicella-zoster or CMV infection of the lung.

Miliary Pulmonary Disease

Disseminated miliary lesions of infectious nature suggest miliary tuberculosis, histoplasmosis, or blastomycosis in either the normal or immunosuppressed host. In the immunosuppressed patient, a miliary pattern may also occur in disseminated cryptococcal infection or bacteremic spread of bacterial or candidal infection (Figs. 112-2 and 112-4).

Computed Tomography Scanning

In patients with pulmonary infections, CT scanning of the chest may be helpful in certain situations in determining whether pneumonia is necrotizing, consolidation secondary to bronchial obstruction (as by hilar lymphadenopathy or by endobronchial tumor), or if there is a relationship between a pleural effusion or an empyema or loculated fluid collections to parenchymal infections, if bronchiectasis is present, or whether circumscribed pulmonary densities represent a fungus ball within a cavitary lesion, and so forth. When small granulomatous lesions are present, CT scanning can provide information on the extent of the process. When a single nodule is present, CT scanning can assist in determining the best invasive diagnostic approach (needle, open biopsy). In particular, in immunocompromised individuals in which infiltrates are not appreciated on ordinary radiographs (e.g., *P. carinii*) may be demonstrated by CT scanning. This information greatly facilitates invasive procedures such as needle biopsy, video-assisted thoracoscopy, or bronchoscopy.

Noninvasive Diagnostic Studies

Noninvasive studies can provide information indicating the specific microbial cause of a pulmonary infection or can narrow the field of likely etiologic agents.

Direct Examination of the Sputum

Cytologic Examination

Examination of Gram-stained sputum smears can be of major value in pinpointing a bacterial cause of pneumonia and guiding initial and subsequent therapy. The quality of a sample of expectorated or induced sputum sample determines the value of the results that can be expected. Culture of sputum or nasopharyngeal secretions that consists principally of saliva is worthless. Cytologic examination provides an evaluation of the quality of the sample and its suitability for culture and interpretation of a Gram-stained smear made from it. Scanning of Gram-stained smears or application of specific quantitative criteria is helpful in selecting meaningful specimens for bacteriologic evaluation by smear and in culture. Squamous epithelial cells (normally exfoliated from the oropharynx), when present in numbers of 10 or more per low-power ($\times 100$) magnification field, indicate that the specimen is unsatisfactory; culture of such a specimen correlates poorly with results from culture of a transtracheal aspirate (Fig. 112-3). The presence of numerous polymorphonuclear neutrophils on Gram-stained smear (10 to 25 or more per

low-power microscopic field) in the absence of an excessive number of squamous cells (see above) is indicative of a good specimen for bacteriologic evaluation.

Examination of Gram-Stained Smears for Bacteria

The oil immersion fields examined, and the immediately adjacent fields should not contain any squamous cells; each should also contain at least three or four neutrophils (in non-neutropenic hosts). The presence of squamous cells not only indicates that the specimen is derived from the upper-respiratory tract but also may be confusing to the uninitiated because of the large number of bacteria, often gram-positive diplococci, which might be mistaken for *S. pneumoniae*, adherent to the surface of these cells.

A variety of bacterial respiratory tract pathogens have rather characteristic morphologies and strongly suggest an etiologic role when present in a suitable specimen of sputum (or in a transtracheal aspirate) that contains the proper numbers of inflammatory cells. Such organisms include *S. pneumoniae* (gram-positive oval or lancet-shaped diplococci), *H. influenzae* (small, pleomorphic gram-negative bacilli), *Moraxella catarrhalis* (gram-negative, biscuit-shaped diplococci), or the similar-appearing *Neisseria meningitis*, enteric gram-negative bacilli (not distinguishable from one another with respect to species except for large encapsulated rods that are suggestive of *Klebsiella*), and *S. aureus* (large gram-positive cocci in small groups or clusters (Fig. 112-9). Since normal oral flora includes a variety of streptococcal species that are morphologically somewhat similar to *S. pneumoniae*, sputum smears may be misinterpreted. Thus, a definite predominance of gram-positive diplococci in multiple appropriate oil immersion fields needs to be observed in order to implicate *S. pneumoniae* (Fig. 112-7). A quantitative aspect to the evaluation has been suggested: at least 10 gram-positive lancet-shaped diplococci per oil immersion field predict the isolation of *S. pneumoniae* from sputum cultures. With use of these criteria (numbers of polymorphonuclear leukocytes, absence of epithelial cells, and numbers of gram-positive lancet-shaped diplococci), the specificity of Gram's stain for identifying *S. pneumoniae* is 85 percent, with a sensitivity of 62 percent.

Gram-stained smears can be helpful not only in the etiologic diagnosis of community-acquired bacterial pneumonia due to the usual respiratory pathogens but also in supporting a diagnosis of atypical pneumonia when sputum examinations repeatedly show neither neutrophils nor bacteria. Uncommon bacterial species may be implicated in a pulmonary infection on the basis of unusual morphology on Gram-stained smear. For example, irregularly staining, beaded, delicate gram-positive branching filaments suggest either *Nocardia* or *Actinomyces* (Fig. 112-10).

Several organisms, uncommon causes of pulmonary infection, have morphologic characteristics that may mimic other, more common respiratory pathogens. *Pasteurella multocida* and *Acinetobacter* species, both small gram-negative coccobacilli, have each been mistaken in sputum of patients with pulmonary infections for either *H. influenzae* or *M. catarrhalis*, or for a mixture of the two.

Sputum or pleural fluid with foul odor provides evidence of activity of anaerobic organisms in infective processes such as lung abscess, aspiration pneumonia, empyema, and, occasionally, bronchiectasis. In these settings, the findings on Gram-stained smear may corroborate the preliminary diagnosis. Organisms of the *P. melaninogenicus-asaccharolyticus* group are small, gram-negative coccobacilli. *Fusobacterium nucleatum* is a long, tapering, pale-staining gram-negative bacillus with irregularly staining gram-positive internal granules. Purulent secretions or pus from such anaerobic infections contain numerous neutrophils and usually a mixture

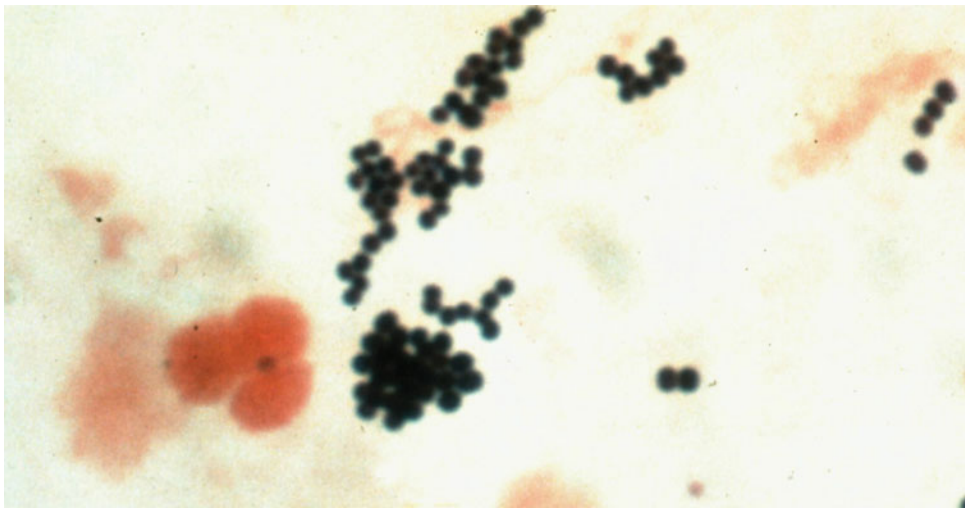

Figure 112-9 *Staphylococcus aureus* on Gram-stained smear from a drug addict with right-sided bacterial endocarditis. In this field (×1000) there are polymorphonuclear leukocytes and clusters of gram-positive cocci. (*Courtesy of H. Provine.)*

Figure 112-10 Actinomycosis in a 54-year-old chronic alcoholic man with pyorrheic gums who was admitted with signs of brain tumor. Chest radiograph shows mass in left lower lobe. Computed tomography is consistent with brain metastasis. Transthoracic needle aspirate revealed *Actinomyces israelii*.

of bacterial species, including anaerobic and microaerophilic streptococci on stained smear.

Examination of Ziehl-Neelsen or Fluorochrome-Stained Smears for Mycobacteria

The number of new cases of tuberculosis in the United States steadily declined over past decades, reaching a nadir in 1995. During the period 1985 to 1991, the rate of development of new cases (often due to multidrug-resistant strains of *M. tuberculosis*) increased, primarily associated with microepidemics among the urban poor, racial and ethnic minorities, drug abusers, hospital and correctional facility populations, and patients with HIV infection. In patients with AIDS who have access to HAART (highly active antiretroviral therapies), the incidence of tuberculosis is decreasing. Pulmonary tuberculosis in the aforementioned settings may take the form of chronic cavitary tuberculosis or of forms more suggestive of pyogenic or atypical pneumonia—i.e., progressive primary tuberculosis and tuberculous pneumonia. Acid-fast smears of sputum can provide the very first evidence of this disease. Mycobacteria are seen on smears of about 50 percent of specimens that subsequently prove to contain *M. tuberculosis*. Most laboratories currently employ a fluorochrome stain with auramine-rhodamine (mycobacteria fluoresce orange-yellow) for initial examination of sputum or other body fluids. Atypical mycobacteria may be demonstrated on sputum smears of patients, usually older people, with slowly progressive pulmonary disease. In patients with AIDS, disseminated *Mycobacterium avium-intracellulare* infection is usually diagnosed by isolation of the organism from blood culture (lysis centrifugation method) or by histopathological diagnosis on biopsy. However, the organism can be demonstrated on acid-fast smears and culture of respiratory secretions even though there may be little radiographic evidence of pulmonary infection directly attributable to its presence. Modified Ziehl-Neelsen–stained smears are helpful in detecting *Nocardia*.

Fungal Wet Mounts (Potassium Hydroxide, KOH Preparations)

Fungal wet mounts, smears stained with Calcofluor white chemofluorescent agent or phase-contrast microscopy, are employed when epidemiological considerations suggest community-acquired pulmonary mycoses (particularly coccidioidomycosis and blastomycosis). They should be a routine part of evaluation of respiratory secretions and lung biopsy materials from immunocompromised patients in whom additional fungal pathogens (e.g., *Aspergillus* and *Mucor*) may be active. In patients with allergic bronchopulmonary aspergillosis, or with the unexpected detection of *Aspergillus* in sputum, fungal hyphae must be considered in the clinical context of each patient.

Direct Immunofluorescent Microscopy

Direct fluorescent antibody (DFA) staining can be useful in rapid diagnosis of respiratory tract pathogens. DFA staining reagents for *L. pneumophila* are commercially available. Their use is not recommended in examination of sputum specimens because of the presence of cross-reacting species (*Bacteroides* species, *Pseudomonas* species, *Bordetella pertussis*) in the upper-respiratory tract. However, biopsy specimens of lung (needle, bronchoscopic, or surgical), bronchoscopic aspirates, BAL washings, and pleural fluid samples are suitable for DFA staining for *L. pneumophila*. Although a variety of stains (toluidine blue O, methenamine silver, Wright-Giemsa, Diff-Quik, Calcofluor) are useful in identifying *P. carinii* in induced sputa or BAL specimens, or on imprint smears of tissue specimens, the most widely used diagnostic technique utilizes immunofluorescence with monoclonal antibodies against *P. carinii*. Rapid viral diagnosis (RSV, influenza, parainfluenza, adenovirus) by DFA can be applied to specimens from bronchial lavage or brushings or from nasopharyngeal swabs or washings. Anti–*B. pertussis* DFA may be used on nasopharyngeal aspirate smears in the presumptive diagnosis of pertussis.

Giemsa and Other Special Stained Smears for Diagnosis of Pneumocystis Infection

Since *P. carinii* pneumonia is an alveolar process, examination of routinely collected expectorated sputa for *P. carinii* is generally not regarded as rewarding in immunosuppressed patients with neoplastic disease or transplant recipients. In these patients, fiberoptic bronchoscopy and transbronchial biopsy, combined with BAL, provide the highest diagnostic yield. In patients with AIDS, however, induced sputum

examination for *P. carinii* may be helpful. Sputum induction employing aerosolized, hypertonic saline provides a diagnosis in up to 80 percent of patients, particularly if coupled with microscopy of antibody-stained cytocentrifuged specimens. Immunofluorescent assays, with monoclonal antibodies to *P. carinii*, of induced sputum have a sensitivity of 69 to 92 percent, compared with that of 28 to 80 percent for tinctorial stains. Toluidine blue O and methenamine silver stains stain only the cyst (less than 10 percent of the organism burden) and not the trophozoite forms of *P. carinii*. Giemsa and Diff-Quik stain trophozoites and intracystic sporozoites. If results of examination of induced sputum are negative and clinical circumstances warrant further attempts at diagnosis, follow-up bronchoscopy with transbronchial biopsy or BAL is performed. The sensitivity of each of these procedures for diagnosis of *P. carinii* pneumonia is more than 90 percent.

Special Microscopic Examinations

Occasionally, in the setting of apparent pulmonary inflammation with features atypical for infection, microscopic examinations using stains other than Gram's stain may be indicated. For example, Wright-stained smears may show the presence of eosinophils in allergic pulmonary aspergillosis or other causes of pulmonary infiltrates that are accompanied by eosinophilia. Cytologic examination of exfoliated sputum using Papanicolaou's stain may reveal a pulmonary neoplasm. Birefringent calcium oxalate crystals (needlelike in rosettes or arranged like sheaves of wheat) in sputum cytologic specimens have been reported as suggesting pulmonary infection with *Aspergillus* (aspergilloma and, occasionally, invasive aspergillosis).

In the intubated or tracheotomized patient, whose tracheobronchial secretions commonly contain neutrophils and often some bacteria on Gram-stained smears, it may be difficult to distinguish between colonization and nosocomial pneumonia. The presence on light microscopy (×400) of characteristic elastin fibers with split ends (in a drop of tracheal aspirate to which a drop of 40 percent KOH has been added), in the appropriate clinical setting, is a strong indicator of a necrotizing pulmonary infection.

Intense bacteremia sometimes accompanies pulmonary infections, and the etiologic agent may be demonstrable on stained smears of the buffy coat of centrifuged blood: pneumococci have been identified in Gram-stained or Wright-Giemsa–stained smears of buffy coats from splenectomized patients; occasionally, *M. avium-intracellulare* has been found intracellularly in acid-fast stains of buffy coats from patients with AIDS.

Additional special microscopic examinations may be indicated for immunocompromised patients who have patchy pulmonary infiltrates on the chest radiograph. For example, the presence of the hyperinfection syndrome of strongyloidiasis (often accompanied by *E. coli* bacteremia) can be established by the finding of filariform larvae in the sputum and in the stool after the latter is suitably prepared by concentration techniques. Although eosinophilia is often present in patients with strongyloidiasis, it may be absent in the hyperinfection syndrome.

Sputum Cultures

In most patients with the common types of community-acquired and nosocomial bacterial pneumonia, the etiologic diagnosis can be made on the basis of the combined results of a Gram-stained smear of sputum and a proper culture of a suitable exudative portion of a freshly obtained sputum specimen. The criteria for a proper sample of sputum have been noted above. Culture entails streak dilution on blood agar and MacConkey media. Expectorated sputum should not be cultured anaerobically, since contamination with oral anaerobes is inevitable. Because patients with Legionnaires' disease often have little sputum production, most attempts to isolate *Legionella* are limited to specimens obtained either by induced sputum samples, fiberoptic bronchoscopy or lung biopsy, or at thoracentesis. Cultures of such materials are plated on buffered charcoal-yeast extract (BCYE) agar. Occasionally, *Legionella* species can be isolated from sputum with the use of a semi-selective medium, either BCYE or BCYE-containing cefamandole, polymyxin B, and ansamycin. Culture is the most definitive method for diagnosis of *Legionella* infection. Unfortunately, it may take 5 or more days for colonies to appear.

Cultures for mycobacteria are undertaken when clinical circumstances raise the possibility of pulmonary infections due to *M. tuberculosis* or atypical mycobacteria. Similarly, cultures of sputum for primary invasive mycotic agents (e.g., *H. capsulatum*, *Blastomyces dermatitidis*, and *C. immitis*) are dictated by clinical and epidemiological circumstances. In immunosuppressed patients, cultures of sputum are also directed toward uncovering a variety of opportunistic fungi, including *Cryptococcus neoformans*, *Aspergillus* species, and Mucoraceae.

Most hospitals do not have facilities for isolating viruses by tissue culture. This lack poses little problem in dealing with most community-acquired viral pneumonias, for which viral isolation is not necessary and the cost is prohibitive. However, viral isolation from throat washings is warranted in certain circumstances (e.g., to prove the presence of an outbreak of influenza), to establish that an outbreak among young children is due to RSV, and to identify a specific viral agent, such as an adenovirus, as the cause of a serious pneumonia that is not responding to antibacterial therapy. In immunosuppressed patients with pneumonia, a variety of opportunistic viral infections (CMV, RSV, varicella-zoster virus, herpes simplex) are diagnostic considerations. In vitro testing of CMV may provide data regarding susceptibility to antiviral agents. Most viral cultures and susceptibility (for CMV in particular) tests have been replaced by quantitative molecular amplification assays (polymerase chain reaction, PCR) or antigen detection systems (Table 112-6) that are more rapid and cost-efficient than culture systems.

Cultures are grown in cell lines susceptible to the viral infections under consideration in either standard

"tube cultures" or "shell vial" cultures (rapid culture achieved by centrifugation of specimens against the cultured cells). Viral replication in the tissue culture can be confirmed within 48 h after inoculation with use of fluorescent monoclonal antibodies. Because CMV and herpes simplex are frequently present in the oral secretions of immunosuppressed patients, isolation of these viruses is apt to be meaningful only if the materials used for the isolation procedure were obtained either by bronchoscopy with protected specimen brushing (PSB) or with BAL, lung biopsy, or transtracheal aspiration.

Blood Cultures

Blood cultures should always be performed in patients with suspected bacterial pneumonia. Bacteremia occurs in approximately 30 percent of patients with pneumococcal pneumonia. Demonstration of bacteremia in other patients with pneumonia may indicate that the pulmonary infection is secondary to a focus of infection elsewhere (e.g., acute right-sided *S. aureus* endocarditis or *P. aeruginosa* infection of thermal burns). In patients with AIDS and disseminated *M. avium-intracellulare* infection, mycobacterial blood cultures are almost always positive. The lysis centrifugation technique permits ready and rapid isolation of the mycobacterium and quantifies the intensity of the bacteremia. *L. pneumophila* has been isolated with some frequency from automated radiometric blood culture bottles, but blind subculture onto BCYE agar is necessary because growth in the liquid medium does not achieve detectable levels.

Bacterial Antigen Detection in Sputum and Urine

The quellung reaction was extensively used in the pre-antimicrobial agent era to identify *S. pneumoniae* in sputum. It entails the use of light microscopy to detect capsular swelling after pneumococcal antiserum has been added to a loopful of sputum. The occurrence of the quellung reaction was shown to correlate closely with the presence of *S. pneumoniae* in sputum culture—in about 90 percent of the patients.

Pneumococcal antigens may be detected in the sputum of patients with pneumococcal pneumonia by enzyme-linked immunosorbent assay (ELISA), latex particle agglutination, or counterimmunoelectrophoresis. The first two are more readily available. ELISA is the most sensitive method. Antigen detection in sputum may have as high a sensitivity as 70 to 90 percent; but specificity is a problem, with about 20 percent false-positives, probably due in part to the difficulty in distinguishing oropharyngeal contamination and colonization (e.g., in patients with chronic bronchitis without pneumonia). Antigen detection in the urine has been less sensitive, and the sensitivity of antigen detection in the serum has been even lower.

A radioimmunoassay and an enzyme-linked immunoassay for *L. pneumophila* antigenuria are commercially available and provide a means of rapid (under 24 h) diagnosis of *Legionella* pneumonia, particularly in patients without sputum production. The sensitivity of the radioimmunoassay is 89 to 95 percent, and the specificity is very high (estimated at 99 percent). The test is positive despite antimicrobial agent administration, and antigenuria may persist for weeks or months after recovery from pneumonia. It must be remembered that the assay is available only for *L. pneumophila* serogroup 1, and this serogroup is responsible for only 80 percent of *L. pneumophila* infections.

Rapid Viral Diagnosis by Antigen Detection

The need for methods that can rapidly identify viruses stems from the introduction of effective antiviral chemotherapy for several common viral agents. As noted earlier ("Direct Immunofluorescent Microscopy"), DFA can be used to detect viral antigens (adenovirus, influenza A and B, parainfluenza, and RSV, as well as CMV and herpes simplex virus [HSV]) in specimens of bronchial brushings, BAL, or nasopharyngeal washings. Enzyme immunoassay can also be used to detect viral antigens in respiratory secretions. The CMV antigenemia assay detects matrix protein pp65 and can be detected with the use of fluorescent or peroxidase-labeled antibody staining of peripheral blood neutrophils. This assay is semiquantitative. Quantitative and sensitive PCR assays are available for most clinically important viruses (see below, Table 112-6). These are positive days in the advance of antigenemia assays, which are useful in management as well as diagnosis of acute infection. Strict criteria for CMV pneumonia include demonstration of the virus, typical cytologic changes, and absence of other evident pathogens. This is applicable in patients with AIDS, in whom CMV is frequently isolated but in whom CMV rarely causes pneumonia. In contrast, isolation of CMV from BAL fluid in blood or bone marrow transplant recipients with pneumonia is sufficient evidence to make the diagnosis and institute treatment, in view of the high frequency and mortality of CMV pneumonia in these patients.

Serologic Tests

Serologic tests are sometimes of considerable help in establishing the causes of a number of pulmonary infections when the causative agents are difficult to isolate. However, this approach, requiring the demonstration of a fourfold or greater rise in titer between acute and convalescent samples, neither enables rapid diagnosis nor provides assistance in initial selection of antimicrobial therapy. Microimmunofluorescence serologic tests are of value in the diagnosis of psittacosis (*Chlamydophila psittaci*). A fourfold rise in IgG or the presence of IgM antibody indicates recent infection. The indirect immunofluorescent antibody test (fourfold titer rise to 1:128 or higher indicates recent infection) may provide a retrospective diagnosis of Legionnaires' disease, but the antibody rise occasionally may not be demonstrable for 4 to 6 weeks after the clinical onset. Antibodies may persist for months or up to a year or more. Thus, a single titer of 1:256 or higher may reflect a prior *Legionella* infection. Cold agglutinins develop in about half the patients with *M. pneumoniae* pneumonia, but such antibodies occur in other conditions; complement fixation testing is the preferred diagnostic procedure. The

most sensitive and specific serologic test for infection with *C. pneumoniae* is the microimmunofluorescence test. A fourfold rise in IgG titer or an IgM titer of 1:16 or more reflects an acute infection. The complement fixation test is usually used to confirm a diagnosis of Q-fever pneumonia, but microimmunofluorescence, microagglutination, and ELISA have been used to diagnose acute *Coxiella burnetii* pulmonary infection. Tularemic pneumonia can be diagnosed serologically with an agglutination test for *Francisella tularensis*.

Serologic tests are also helpful in the diagnosis of invasive infection due to the primary pulmonary mycotic pathogens. Serum IgM precipitins (latex agglutination, immunodiffusion) appear with primary coccidioidomycosis. Abnormally high complement fixation titers (at least 1:32) are present in most patients who have disseminated infection due to *C. immitis*. A fourfold increase in complement fixation titer to yeast and to mycelial phases of *H. capsulatum* (or possibly a single titer of 1:64 or higher) and the presence of H and M precipitin bands strongly suggest histoplasmosis. Complement fixation tests for blastomycosis lack sensitivity and specificity: titers of at least 1:8 suggest recent or active disease, particularly if precipitins to the A antigen are also present. Cryptococcal antigenemia is detectable from latex particle agglutination in patients with cryptococcal pneumonia or disseminated cryptococcal infection. Sporotrichosis can be diagnosed with a serologic agglutination test when the titer is 1:80 or greater. Pulmonary toxoplasmosis is uncommon in seronegative individuals although acute toxoplasmosis is seen in endemic regions (the Caribbean, France) and after organ transplantation.

Serologic tests (paired acute and convalescent sera) may be helpful for the retrospective diagnosis of infections due to influenza A and B, RSV, adenoviruses, and parainfluenza viruses.

Molecular Diagnostic Testing

A variety of nucleic acid target amplification tests (often PCR) are available for the direct detection of pulmonary pathogens. PCR tests approved by the U.S. Food and Drug Administration can detect *M. tuberculosis* (as distinct from nontuberculosis mycobacteria) directly from sputum and BAL specimens. These tests have shown a sensitivity of 90 to 100 percent in specimens that are acid-fast bacillus (AFB) smear–positive but a sensitivity of only 65 to 85 percent for specimens that are smear negative. Consequently, these PCR assays have been approved for use only on AFB smear–positive specimens. In some major medical centers, PCR assays for detection of *C. pneumoniae* and *M. pneumoniae* on nasopharyngeal or throat swab specimens are available to markedly shorten (by 1 to 2 days) the time required to isolate these organisms by culture (up to 3 weeks). Molecular detection of HSV, adenovirus, CMV, EBV, and other pathogens are used primarily with blood specimens but may also be used in BAL or cerebrospinal fluid samples. The interpretation of such assays used with respiratory secretions is nonstandardized and blood studies are preferred. Molecular amplification is under development for many common pulmonary pathogens including *P. carinii, L. pneumophila,* and *Candida* and *Aspergillus* species. PCR tests are also under development for agents of bioterrorism.

Skin Tests of Delayed Hypersensitivity

The tuberculin skin test is of great importance in the evaluation of a pulmonary infection of unknown origin. The intermediate (5 tuberculin unit) purified protein derivative (IPPD) test should be used if no information is available about previous testing. A positive test does not distinguish between prior and current infection, but in persons who are either less than 35 years old or members of high-risk groups (immigrant, HIV-positive), a positive reaction carries considerable diagnostic weight.

A negative second-strength PPD skin test in a patient who is not anergic is strong evidence against a tuberculous origin of a pulmonary process. However, several caveats are noteworthy: since it may take 4 to 6 weeks for the skin test to become positive, the tuberculin skin test may be initially negative in progressive primary pulmonary tuberculosis, and in the patient who was infected long ago, cutaneous hypersensitivity may wane; in the elderly person, in whom waning has occurred, repeat testing several weeks later may show a positive result (booster effect) even if the original IPPD skin test was negative.

Fungal skin tests do not distinguish between current and past infection; indeed, active disease is often accompanied by a negative skin test. The coccidioidin skin test is the best of the available tests, but the diagnosis of coccidioidomycosis is not excluded by a negative test. Blastomycin and histoplasmin skin tests are of little value because of frequent false-negative results and cross-reactions. Also, the performance of the histoplasmin skin test may falsely elevate antibody levels to the *H. capsulatum* mycelial antigen.

A negative skin test response to a specific antigen must be interpreted in light of possible anergy. A battery of control antigens (mumps, *Candida*, *Trichophyton*, streptokinase-streptodornase) serves to detect such anergy, but these reagents are increasingly unavailable and costly.

Invasive Diagnostic Procedures

In certain circumstances, a more aggressive approach is required to uncover the etiology of pneumonia. This should be considered in any patient with immune deficiency or who is critically ill in whom rapid therapy is critical or in whom drug toxicity may be a major concern (e.g., renal transplant recipients). Such procedures are best done prior to the initiation of antimicrobial therapy. Such an approach may also be required if the patient's condition continues to deteriorate despite empiric antimicrobial therapy. In the immunocompromised patient, early invasive diagnostic approaches are mandated by the large number of etiologic agents that may be responsible, the frequent involvement of many infectious or noninfectious agents in the pulmonary process, the multiplicity of antimicrobial choices available against different organisms, and the rapidity with which clinical deterioration may

preclude further diagnostic and therapeutic actions. Among such invasive diagnostic procedures are bronchoscopy, BAL, open lung biopsy, transthoracic needle aspiration, and video-assisted thoracoscopy (VATS). A choice has to be made for one of several invasive procedures. The choice depends on the experience and skill with the different procedures at a given hospital. Also important in determining the proper procedure are the location and radiographic appearance of the pulmonary lesions. Fiberoptic bronchoscopy using specialized devices to shield against oropharyngeal contamination (protected specimen brushing) is used at some institutions to obtain tracheobronchial secretions for culture in certain acute bacterial pneumonias. A peripheral nodule or cavity (more than 1 cm in diameter) that is readily visualized on conventional (posteroanterior and lateral) radiographs and fluoroscopy, and is in an accessible location, may be aspirated and biopsied by a needle introduced percutaneously. A nodule that is inaccessible to needle aspiration, or a process placed peripherally, where the need for histopathology is not apt to be met by needle aspiration and biopsy, is best approached by open lung biopsy.

Flexible Fiberoptic Bronchoscopy with Lung Biopsy

Fiberoptic bronchoscopy in conjunction with transbronchial lung biopsy provides an etiologic diagnosis in about 50 to 80 percent of immunosuppressed patients who do not have AIDS and in 60 to 90 percent of patients who do have AIDS, in whom *P. carinii*, CMV, and *M. avium-intracellulare* infections are common. Contraindications to transbronchial biopsy include inability of the patient to cooperate, marked hypoxemia, bleeding disorders (particularly those associated with hypoprothrombinemia, thrombocytopenia refractory to platelet transfusion, and uremia), and pulmonary hypertension. In such patients, correction of bleeding tendency and/or open procedures may be preferred. Fiberoptic bronchoscopy combined with transbronchial biopsy and segmental BAL is the usual initial invasive diagnostic procedure in the immunocompromised patient with an undefined diffuse pulmonary process. If this fails to provide a diagnosis, open lung biopsy is indicated.

Tissue specimens are processed for histopathological examination (hematoxylin and eosin stain, tissue acid-fast stains, Gomori's methenamine-silver stain, periodic acid–Schiff stain, tissue Gram's stain, and Dieterle silver stain). Impression smears from tissues are made with sterile slides, which, after appropriate fixation, are stained with Giemsa, Gram, Ziehl-Neelsen, and methenamine silver (for *P. carinii*) stains, as previously described. As indicated, DFA staining for *Legionella* and monoclonal antibody staining for *P. carinii* are performed on separate impression smears. Appropriate cultures are made with tissue obtained either transbronchially or at open lung biopsy.

Bronchoalveolar Lavage

In patients with AIDS, fiberoptic bronchoscopy coupled with wedged, terminal, subsegmental BAL has proved particularly useful, providing a diagnosis in more than 95 percent of cases of *Pneumocystis* pneumonia. BAL alone, without transbronchial biopsy, is often substituted in patients who are thrombocytopenic, on mechanical ventilation, or severely hypoxemic. It should be noted that the yield in non-AIDS immunocompromised hosts is significantly less than in AIDS. Biopsy is often needed in this population. The material obtained by BAL is processed for smear and culture. As indicated earlier, a variety of stains are available for demonstrating the presence of *Pneumocystis* in the cytocentrifuged material. Stained cytocentrifuged BAL specimens can also be helpful in establishing other diagnoses: Papanicolaou's stain is useful in detecting neoplastic cells and in identifying viral cytopathic effects in epithelial cells.

In at least two-thirds of immunosuppressed patients with CMV pneumonia, the diagnosis can be made from the finding of inclusion bodies in cytocentrifuged BAL specimens and with immunofluorescent monoclonal antibody staining. CMV is isolated more often on culture in these patients, but culture alone is not sufficient to establish the diagnosis, since viral isolation may represent only viral shedding in the presence of pulmonary disease due to other causes.

Invasive Diagnostic Testing in Ventilator-Associated Pneumonia

Protected specimen brushing (PSB) with quantitative culture and protected-catheter BAL, also with quantitative culture, have been employed to obtain bacteriologic information while minimizing opportunity for contamination from colonization of the upper airway in patients with ventilator-associated pneumonia (VAP). The role of quantitative diagnostic techniques in the evaluation of patients with hospital-acquired pneumonia (HAP) and VAP remains controversial (discussed below) because of questions of reproducibility and the optimal threshold concentration of bacteria. In at least one study, tracheal aspirate cultures correlated with PSB cultures in patients with VAP, suggesting no added value to use of such an invasive procedure to direct initial therapy. The routine use of such tests requires standardization of techniques at the institutional level.

Percutaneous Transthoracic Needle Lung Biopsy

Percutaneous needle biopsy is often the invasive diagnostic procedure of choice for a sizable (greater than 1 cm) pulmonary nodule or cavity that is located peripherally. The use of smaller-gauge needles has reduced the frequency of pneumothorax as a complication. Diagnostic yields of 60 to 80 percent have been obtained in immunocompromised patients with pneumonia. This procedure has also provided the diagnosis in 70 percent of patients in whom the underlying lesion was granulomatous. The small core of tissue and aspirated fluid is examined by stained smear and culture for various infectious agents (see "Flexible Fiberoptic Bronchoscopy with Lung Biopsy"). Cytologic examination should be done for neoplastic cells. Because of the nature of the specimen, however, histopathological examination is generally fruitless. In patients in whom respiratory status is tenuous, or in whom

lymph node biopsy or sampling of pleural fluid may be desired, VATS or open biopsy may be preferable.

Open Lung Biopsy

Open lung biopsy and more recently VATS, provides the most definitive procedure for histopathological diagnosis in the immunocompromised host. It provides sufficient lung tissue for diagnosis and also makes it possible to sample several different sites. It is particularly suitable for evaluating processes that may not be infectious (e.g., neoplasm such as Kaposi's sarcoma, antineoplastic drug toxicity, drug hypersensitivity, and lymphocytic interstitial pneumonia). Open lung biopsy has provided a specific diagnosis in 60 to 90 percent of non-AIDS immunocompromised patients. Major advantages include specimen size and the ability to control bleeding, air leaks, and the airway. Its disadvantages relate to the thoracotomy: the need for general anesthesia, the inherent delay in preparing the patient for the surgical procedure, the need for intubation, the usual placement of a chest tube, and postoperative splinting due to incisional pain. Some of these complications are decreased in VATS. The mortality from the procedure is about 1 percent. Bleeding is a complication in about 1 percent of patients and delayed pneumothorax in about 9 percent. For the patient in whom the pace of the illness does not allow this sequential approach, open lung biopsy may have to be the first choice. It is also preferred in the patient who is unable to cooperate with fiberoptic bronchoscopy or in whom thrombocytopenia or hypoxemia pose additional problems for transbronchial biopsy.

Processing of lung biopsy specimens should include special stained imprint smears for *P. carinii*, bacteria (including *Nocardia* and mycobacteria), fungi, and viral inclusion bodies; cultures for bacteria, viruses, fungi, and mycobacteria; and tissue sections stained for histology and for infectious agents.

MAJOR CLINICAL SYNDROMES

Community-Acquired Pneumonia

Approximately 1 million people are admitted to the hospital each year for pneumonia. Initial evaluations of pulmonary processes in the outpatient setting revolve around an assessment of whether the individual merits admission to the hospital for management. Clinical judgment is the most important guide to appropriate care. This judgment is based on whether the patient can manage at home (needs oxygen or intravenous antimicrobials, weakness, cannot eat independently or take oral medications, other preexisting medical or psychiatric conditions, substance abuse, home supports) and whether the patient is at risk for disease progression. Many factors have been implicated in risk for death due to pneumonia. These include both common (alcoholism) and less common (immune deficiency) underlying conditions (Table 112-7). The PORT (Pneumonia Outcomes Research Team) Severity Index (PSI) is a quantitative tool that assesses the severity of a patient's illness, prognosis, and the need for hospitalization. This index provides the basis of North American practice guidelines for community-acquired pneumonia (CAP).

Table 112-7

Underlying Conditions Contributing to Adverse Outcomes from Pneumonia

Alcohol consumption
Increasing age
Leukopenia
Congestive heart failure
Coronary artery disease
Diabetes mellitus
Immune compromise
Neurological disease
Active malignancy
Clinical signs including: dyspnea/tachypnea, hypothermia, chills, hypotension, confusion or altered mental status
Laboratory tests: hyponatremia, hyperglycemia, azotemia, hypoalbuminemia, liver function test abnormalities
Radiographic infiltrates and pleural effusions, post-obstructive pneumonia
Microbiology: gram-negative bacilli, *S. aureus*, mixed flora (aspiration), bacteremia

For more than half of the patients with CAP, no causative pathogen can be identified. Up to 15 percent of CAP cases are due to aspiration or mixed bacteria. In most series, 20 to 65 percent are due to *S. pneumoniae* (pneumococcus). Approximately 15 percent of patients have definable, nonbacterial etiologies such as *M. pneumoniae*, *C. psittaci*, or viruses. These atypical pathogens are difficult to diagnose (and therapy, while universal, is often of less than certain value). The atypical pathogens, the pneumococcus and *Legionella* species, and aspirational events account for many of the undiagnosed cases of CAP. Certain uncommon causes may be endemic, in particular geographic niches, including *Coxiella burnetii* (in Nova Scotia) or *Francisella tularensis* in Little Rock, Arkansas. Thus, a major variable is the regional incidence of endemic infections including tuberculosis, and the episodic occurrence of epidemic infections such as outbreaks of influenza virus or Hantavirus.

CAP is a major cause of infectious morbidity and mortality. Depending on the causative organisms, the mortality of CAP ranges from 10 to 15 percent for pneumococcal infection to 60 percent for *P. aeruginosa*. Adverse clinical prognostic factors included co-morbid conditions (neurological or neoplastic disease, cirrhosis, congestive heart failure, respiratory compromise, diabetes, hepatic and renal dysfunction, immune deficiency), bacteremia, and multilobar involvement. *S. pneumoniae* is the preeminent bacterial cause of CAP. *H. influenzae*, usually unencapsulated strains, may produce pneumonia in patients with chronic bronchitis or in the chronic alcoholic. Apart from *S. pneumoniae*, however, the most important pathogen in this type of patient, by virtue of its virulence and special antimicrobial agent susceptibilities, is *K. pneumoniae*. During an outbreak of influenza viral infections, bacterial superinfections often occur, usually in the elderly or in patients with chronic cardiopulmonary disease. Patients with secondary bacterial pneumonia often have up to 4 days of clinical improvement after the initial influenzal illness before the onset of overt pulmonary infection. The superinfecting microorganisms are the pathogens that would ordinarily colonize the upper airways but opportunistically invade a tracheobronchial tree that has been recently damaged. These organisms include *S. pneumoniae*, *H. influenzae*, *S. aureus*, *Streptococcus pyogenes*, *M. catarrhalis*, and *K. pneumoniae*. The use of antimicrobial agents at the time of the initial respiratory infection not only is useless against viral influenza but also may selectively promote the emergence of a more resistant bacterial flora in the respiratory tract. *S. aureus* is a very uncommon cause of CAP. Indeed, the occurrence of several cases of *S. aureus* pneumonia in the community during the winter months is usually a good indicator of the presence of an ambient influenza outbreak. Pneumonia due to *S. pyogenes* is quite uncommon. Usually it occurs as a superinfection in a patient with influenza or as a primary pneumonia in the course of a regional outbreak of group A streptococcal infections (as still occurs from time to time when a new M-antigenic type appears in a community).

Atypical Pneumonia Syndromes and Endemic Mycoses

In the evaluation of patients with CAP, it is often helpful to consider separately a group of patients whose illness is characterized by minimal sputum that does not reveal a predominant microbial etiology on routine smears (Gram's stain, Ziehl-Neelsen) or cultures (including for mycobacteria and *Legionella*). The clinical onset of illness is generally subacute with a radiologic picture consisting of patchy infiltrates or an interstitial pattern than a lobar consolidation. Fever and peripheral leukocytosis are less common or intense than in common bacterial pneumonias. For convenience, this grouping has been designated *atypical pneumonia*.

The entities in the category of atypical pneumonia are heterogeneous (Table 112-8). The syndrome may account for up to 60 percent of cases of CAP. *M. pneumoniae* is the causative agent in about 25 percent of the cases of atypical pneumonia. Respiratory viruses are responsible for about another 30 percent. However, the predominant etiologic agent varies with the season and the prevalence of influenza viruses in the community. This information should direct the initial evaluation (e.g., nasal swab for respiratory viruses).

Chlamydophila pneumoniae (formerly known as *Chlamydia* strain TWAR) is an infectious agent that can be spread from person to person and appears to be responsible for 12 to 21 percent of cases of atypical pneumonia. This form of pneumonia typically occurs in young adults as a sporadic mild pneumonia, but may have enhanced severity when co-infecting individuals with pneumococcal infection. In adults, *M. pneumoniae* pneumonia, in contrast to bacterial pneumonia, often begins insidiously with malaise, fever, and prominent headache. Sore throat is common, but coryza is minimal or absent. Nonproductive cough develops over the next few days and is the hallmark of this disease. Skin rash (erythema multiforme) and bullous myringitis, usually appearing late in the course of illness, are uncommon findings but, when present, do suggest the diagnosis. Mini-outbreaks of *M. pneumoniae* infection in households, schools, and military camps may not be appreciated because of the long incubation period (3 weeks) and variation in clinical presentation.

Q fever, due to *C. burnetii*, is suspected on the basis of epidemiological clues. Transmission of this disease to humans occurs as a result of inhalation of aerosols from surroundings

Table 112-8

Causes of "Atypical Pneumonia"

Mycoplasma *M. pneumoniae*
Chlamydophila *C. psittaci* (psittacosis), *C. pneumoniae*
Respiratory tract viruses Influenza, adenovirus, respiratory syncytial virus, parainfluenza virus
Bacteria *Legionella, F. tularensis, Y. pestis, B. anthracis*
Fungi *Histoplasma, Blastomyces, Coccidioides, Pneumocystis*
Aspiration pneumonitis Sterile or mixed upper respiratory and oral flora
Other viral agents Varicella-zoster, measles, Epstein-Barr virus, cytomegalovirus, metapneumovirus, Hantavirus
Rickettsia *C. burnetii* (Q fever)

contaminated by placental and birth fluids of infected livestock (cattle, sheep, goats), wild rabbits, and domestic animals (cats). Veterinarians, ranchers, taxidermists, and others who handle livestock are at particular risk. Since the incubation period of Q fever is approximately 20 days, a source of exposure may be overlooked. Although the clinical picture resembles that of *M. pneumoniae* pneumonia, the onset may be more abrupt, with chills and high fever. Liver function abnormalities or clinical hepatitis in a patient with atypical pneumonia is suggestive of Q fever. In some geographic areas (Australia, France), hepatitis has been the most frequent clinical presentation of *C. burnetii* infection; in others (Spain, Nova Scotia), pneumonia has been the major presenting sign.

Chlamydia trachomatis causes pneumonia in the newborn but has not been proved to be a cause of pneumonia in adults. *C. psittaci*, the causative agent of psittacosis, is spread to humans by avian species. Although psittacine birds (parakeets, parrots) are the major reservoir, human infection can be acquired from pigeons, sparrows, and turkeys. In a patient with atypical pneumonia, the clinical features that raise the possibility of this etiology are relative bradycardia, splenomegaly and hepatomegaly, and hepatic dysfunction. *C. pneumoniae* produces atypical pneumonia without the usual bird-to-human transmission of *C. psittaci* infection.

Legionella infections (due to *L. pneumophila* and other *Legionella* species) account for 2 to 4 percent of cases of atypical pneumonia. Although *Legionella* is an important nosocomial pathogen, it is also responsible for community-based sporadic cases and major outbreaks. The occurrence of summer outbreaks associated with the use of air conditioners, pooled water, and evaporative condensers should call attention to this possible cause of pneumonia. Various extrapulmonary manifestations are common with Legionnaires' disease including relative bradycardia, diarrhea for 24 h at the onset of illness, confusion and obtundation, mild renal dysfunction (azotemia, microscopic hematuria, proteinuria), acute rhabdomyolysis, and mild hepatic dysfunction. Although many of these manifestations also occur with other pneumonias, the coincidence of several of these features should raise the possibility of *Legionella* infection. This is particularly important in view of the fact that the antimicrobial therapy (macrolides, fluoroquinolones) for Legionnaires' disease differs from that for the more common bacterial pneumonias. The mortality from Legionnaires' disease, if inadequately treated, can be as high as 15 percent. Recurrent chills, which occur over several days in Legionnaires' disease, are rare in pneumococcal pneumonia unless septic complications (e.g., endocarditis and pericarditis) develop. Although the initial radiographic picture of *Legionella* pneumonia is often that of an interstitial, segmental, or bronchopneumonic pneumonia, if the disease is untreated, it progresses to lobar or multilobar consolidation, a picture that mimics pneumococcal or *Klebsiella* pneumonia.

The other noteworthy bacterial types of atypical pneumonia are those due to *F. tularensis* (tularemic pneumonia), *Yersinia pestis* (plague pneumonia), and *Bacillus anthracis* (anthrax pneumonia). These are all singularly uncommon causes of pneumonia, and the principal clues to diagnosis again derive from epidemiological considerations. Exposure to *F. tularensis* comes through contact with tissues of an infected animal (rabbit), animal bites (coyote, cat), inhalation of infectious aerosols, tick or deerfly bites, or ingestion of contaminated water or poorly cooked meat from an infected animal. Ulceroglandular tularemia, or the typhoidal form of tularemia, may be complicated by patchy pulmonary infiltrates. Indeed, it is likely that typhoidal tularemia often represents infection initially acquired via the bronchogenic route. Plague is less common than tularemia in the United States and is strictly localized to southwestern states, including California. The diagnosis should be considered in a person from an endemic area who has a septic illness (septicemic plague) or painful localized lymphadenopathy with fever (bubonic plague) and a history of bites by rodent fleas or of handling tissues of infected animals, such as prairie dogs or coyotes. Pneumonia occurs as a complication in 10 to 15 percent of patients with bubonic or septicemic plague. Primary (inhalation) pneumonic plague is extremely rare and occurs only as a result of exposure to aerosolized particles from an infected animal or following close contact with cases of plague pneumonia. Anthrax pneumonia (inhalation anthrax) is also extremely rare in this country; it is a consequence of the inhalation of anthrax spores during the processing, or use, of goat skin, hair, or wool (usually imported from the Middle East, Asia, or Africa).

The principal clues to the presence of pulmonary mycoses are epidemiological. Thus, the principal endemic areas for histoplasmosis in the Western Hemisphere are in the midwestern United States and Central America. However, disease can be found in other locales and after travel. The organism is present in high concentrations in soil sites where avian, chicken, or bat excrement has accumulated. Movement of soil in such endemic areas by cleaning chicken coops, knocking down old starling roosts, or cleaning out old attics or basements can expose people to high concentrations of airborne spores that, when inhaled, produce an acute pneumonia. Atypical pneumonia in a person with this type of geographic exposure, or in a spelunker, should automatically raise the possibility of histoplasmosis. Blastomycosis occurs throughout most areas of the United States, but the endemic area is principally in the southeastern and south central areas. Rural exposure to soil contaminated with animal excrement appears to be a risk factor. Skin lesions, either verrucous or ulcerative, are the most common extrapulmonary manifestations of blastomycosis and afford a clinical clue to diagnosis. Coccidioidomycosis is endemic in the southwestern United States (California, particularly the San Joaquin Valley, and Arizona) and in neighboring portions of Mexico. Infection is usually acquired in these areas by inhalation of highly infectious arthrospores. Occasionally, major dust storms carry the arthrospores considerable distances from their soil source and produce unexpected outbreaks of infection. Archeological digs sometimes cause infection in those living elsewhere who receive an artifact uncovered in the explorations. Erythema nodosum may be associated with any of the primary

pulmonary mycoses, but most often with coccidioidomycosis. The coincidence of this hypersensitivity skin lesion and an atypical pneumonia syndrome in a person from an endemic area suggests the possibility of one of these pulmonary mycoses.

Paracoccidioidomycosis (South American blastomycosis) is endemic to Brazil (predominantly), and in Colombia, Venezuela, and Argentina. This disease is caused by *Paracoccidioides brasiliensis*. In adults, the manifestations of this disease are mainly pulmonary; radiographs show patchy or confluent areas of consolidation, often bilateral. Cases have occurred in North America and Europe, but in those instances, the patients had previously resided in endemic areas where initial infection presumably had been acquired.

Aspiration Pneumonia

Aspiration pneumonia may occur after an overt episode of aspiration (e.g., of gastric contents) or of bronchial obstruction by a foreign body. More often the predisposing circumstances are clear-cut (e.g., alcoholism, nocturnal esophageal reflux, pyorrhea, a prolonged session in the dental chair, epilepsy, or chronic sinusitis in a patient with absent gag reflex). In these circumstances, since the pneumonia may develop more insidiously than after overt aspiration, the relationship of the developing pneumonia to the predisposing circumstances may not be appreciated at the time. For this reason, specific questioning regarding such possible pathogenetic factors and evaluation of the gag reflex should be part of the examination of any patient with pneumonia.

If untreated, aspiration pneumonia may progress rapidly to a necrotizing process that is usually due to anaerobic organisms. The process may involve a pulmonary segment, a lobe, or an entire lung, with ultimate extension to the pleura ("putrid empyema"); in some patients, the necrotizing pneumonia culminates in lung abscesses. In others, aspiration produces an illness of several weeks' duration that is characterized by malaise, productive cough, and low-grade fever. If a chest radiograph is first taken after several weeks of untreated illness, it may show little, if any, evidence of pneumonia but will clearly identify a well-formed lung abscess.

In community-acquired aspiration pneumonia, bacteriologic studies provide a statistical basis for selecting initial antimicrobial therapy. Anaerobic bacteria are etiologically implicated in about 90 percent of community-acquired aspiration pneumonias and lung abscesses. In 40 to 65 percent of these patients, anaerobic organisms are the sole infecting agents; in 40 to 45 percent, the cause is a mixture of anaerobes and aerobes. The most common anaerobes are *Prevotella melaninogenica*, *Bacteroides* species, *Porphyromonas* species, *Fusobacterium* species, peptostreptococci, peptococci, and microaerophilic streptococci. β-Lactamase–producing *Bacteroides* species, *P. melaninogenica*, and members of the *Bacteroides fragilis* group are present in about 15 percent of cases. *P. melaninogenica* may be the most important contributor in such mixed infections. The aerobic indigenous flora in mixed aerobic-anaerobic infections are *Streptococcus viridans*, *M. catarrhalis*, and *Eikenella corrodens*. A rare form of anaerobic aspiration pneumonia (actinomycosis) that is community-acquired is that due to *Actinomyces israelii*, part of the normal flora in the gingival crevice or may contribute to chronic sinus infection. The direct extension of such a necrotizing pneumonia to the pleura and chest wall is a characteristic finding that strongly suggests the diagnosis of actinomycosis.

Although anaerobic members of the oropharyngeal flora have a preeminent role in community-acquired aspiration pneumonia and lung abscess, occasionally colonizing gram-negative enteric bacilli such as *K. pneumoniae*, *E. coli*, and *Proteus* species may be the cause (notably in alcoholics). Persistence of a necrotizing pneumonia or lung abscess despite antimicrobial therapy that would be expected a priori to be effective raises the possibility of an underlying obstruction, often in the form of bronchogenic carcinoma, particularly if the patient is edentulous.

Pneumonia in the Elderly

CAP in the elderly (over 60 years) primarily affects two populations: one that lives at home and another residing in nursing homes. The latter, from the point of view of oropharyngeal flora and the extent of exposure to antimicrobial agents, is generally considered as a part of "Health Care–Associated Pneumonia" (HCAP), with a predisposition to nosocomial infection (see below) with an increased rate of antimicrobial resistance. The clinical features of pneumonia in the elderly may differ in presentation from that in younger people. Infection has a more gradual onset, with less fever and cough, often with a decline in mental status or confusion and generalized weakness, often with less readily elicited signs of consolidation on examination. Eliciting a deep breath from the patient may be helpful in demonstrating a localized wheeze or rales that might otherwise be undetectable. Among the bacterial causes of CAP in the elderly, *S. pneumoniae* is the most frequent, accounting for 30 to 60 percent of cases. *H. influenzae*, primarily nontypeable strains, is the second most common cause (about 20 percent). *M. catarrhalis* is another cause of pneumonia in this age group, primarily in patients with chronic bronchitis. Aspiration pneumonia due to mixed aerobic-anaerobic flora occurs in this age group, particularly because of the presence of a diminished gag reflex or impaired pharyngeal motor function.

In nursing home residents or persons with recent hospitalizations, increased oropharyngeal colonization with gram-negative bacilli occurs, due to antimicrobial exposure, or exposure to the hospital environment or to other recent patients. Microaspirational events predispose to pneumonia due to species such as *K. pneumoniae, E. coli* and other Enterobacteriaceae, and *P. aeruginosa*. Such gram-negative bacilli have been implicated as the cause in 25 to 40 percent of elderly nursing home residents with pneumonia. *S. aureus* is responsible for 2 to 10 percent of cases of CAP in the elderly overall, more commonly in nursing home residents and during community outbreaks of influenza. Common forms of CAP are also seen in the elderly.

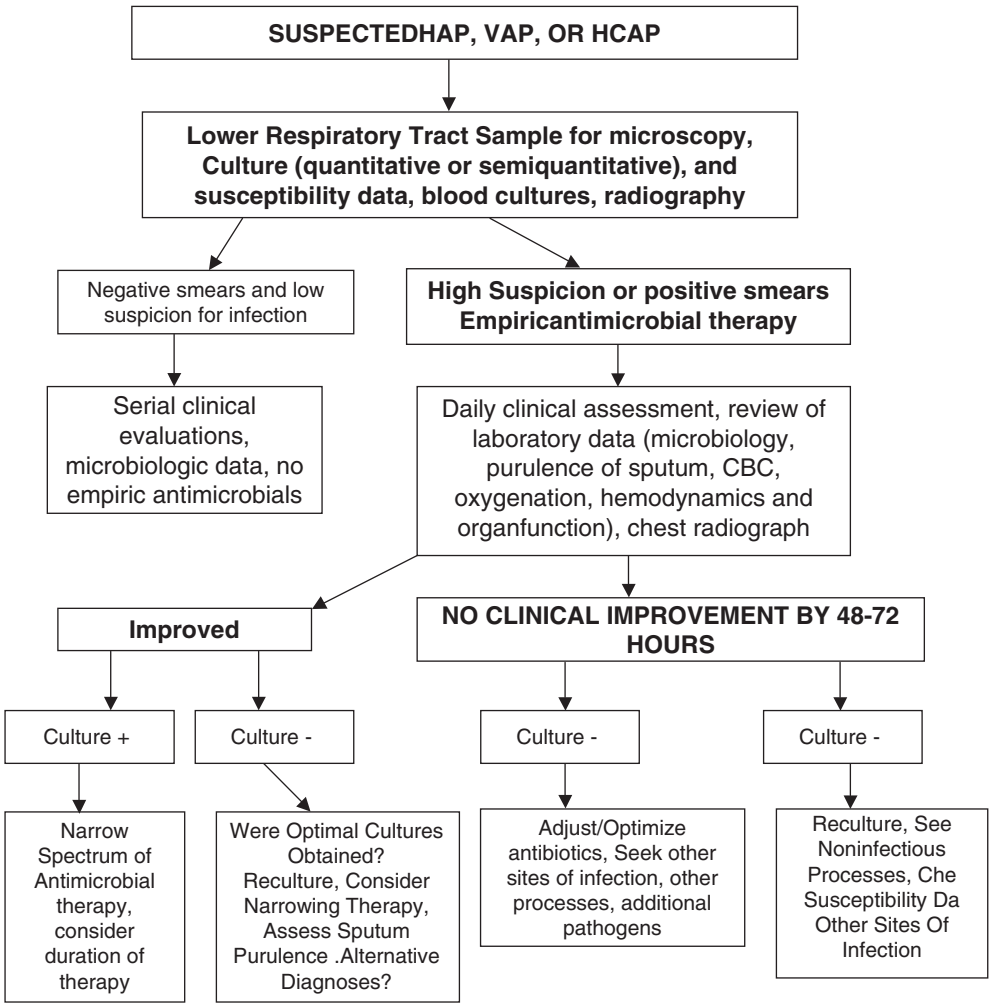

Figure 112-11 Paradigm for the evaluation of patients with nosocomially acquired pneumonia. Careful reassessment of patients on a daily basis is needed to assure an adequate response to therapy. Clinical judgment is the best guide to the use of empiric therapy.

Hospital-Acquired, Ventilator-Associated, and Nonresolving Pneumonias

The hospitalized patient with pneumonia poses the dual challenge of infection with nosocomial pathogens and the presence of concomitant processes—the "sick" patient (Fig. 112-11). Nosocomial pneumonia occurs at a rate of 5 to 10 cases per 1000 hospital admissions. The incidence increases 6- to 20-fold in patients receiving assisted ventilation. Hospital-acquired pneumonia (HAP) develops over 48 hours into hospitalization while VAP occurs more than 48 to 72 hours after endotracheal intubation. HCAP includes patients with infection developing within 90 days of hospitalization, residents in a nursing home or long-term care facility, or those who have had recent exposure to hemodialysis, intravenous antimicrobial therapy, chemotherapy, wound care, or hospital-associated clinics. HAP accounts for up to one-fourth of intensive care unit infections. VAP occurs in up to one-fourth of intubated patients in some series, generally in the first 4 days of intubation.

Early-onset (first 3 days) nosocomial pneumonia is more often due to organisms without antimicrobial resistance including *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Community-acquired atypical pathogens (*Mycoplasma, Chlamydophila*) may also lead to early hospitalization. Beyond 5 days of hospitalization, or in those with recent hospitalization or with prior antimicrobial therapy, infection is more often due to multidrug-resistant (MDR) organisms (*K. pneumoniae*, other Enterobacteriaceae, *Acinetobacter* species, and *P. aeruginosa*) and mortality is increased. Attributable mortality for nosocomial pneumonia approaches 50 percent.

In practice, pneumonia is defined as the presence of a new or progressive radiologic infiltrate coupled with evidence that the infiltrate is infectious in origin—fever higher than 38°C, leukocytosis or leukopenia, and/or purulent secretions. Two out of three criteria are generally considered adequate. Tracheal aspirates will generally contain the offending organism(s) but may be contaminated by upper-tract flora, notably flora associated with tracheobronchitis.

Semiquantitative cultures are used to discriminate between pathogens and commensals. Gram staining of such specimens provides added information about host response (neutrophils and macrophages) and predominant bacterial forms. In immunocompromised hosts, fungal smears and cultures, cultures and microscopy for *Legionella, Nocardia*, and mycobacteria should also be obtained. A good sputum specimen or an aspirate lacking bacteria or inflammatory cells (in a non-neutropenic host) should suggest other diagnoses (nonbacterial or noninfectious). While the majority of HAPs are bacterial, nosocomial infection due to respiratory viruses and *Legionella* species are common. A negative Gram's stain of a good tracheal aspirate has a strong negative predictive value (approximately 94 percent) for VAP.

Some friction exists between strict advocates of microbiologic evaluations and care which is based on clinical expertise. In practice, neither is sufficient, per se. Lower respiratory tract cultures must be obtained prior to the initiation of antimicrobial therapy, but should not delay the initiation of therapy in critically ill patients or in those with evidence of sepsis. Respiratory specimens may be obtained bronchoscopically or nonbronchoscopically, and cultured semiquantitatively or quantitatively, based on local expertise and availability. All patients with nosocomial pneumonia should also have blood cultures, chest radiography, arterial oxygenation levels, and diagnostic thoracentesis if large pleural effusions are present.

The use of semiquantitative cultures and clinical judgment results in the inappropriate use of broad-spectrum antimicrobial therapy in some patients with either minor infections or colonization in the setting of other pulmonary inflammatory processes: drug reactions, cancer, ARDS, congestive heart failure, pulmonary thromboembolus, hemorrhage, or even viral infection. However, depending on the patient mix of the institution (acuity, immune deficits) this approach is generally appropriate.

A narrower spectrum of initial antimicrobial therapy is possible by using quantitative cultures of invasive (endotracheal aspirates, BAL, or PSB specimens) specimens from the lower respiratory tract. Bacterial growth above a predetermined threshold (e.g., 10^4 to 10^5 cfu/ml in BAL or 10^3 cfu/ml for PSB specimen) provides a basis for treatment. Quantitative approaches may suffer from poor reproducibility and the impact of recent antimicrobial therapies (e.g., the use of empiric antimicrobial agents entails the risk of false-negative cultures and under-treatment of specific pathogens or patients). Pneumonia "in evolution" or patchy processes may confound quantitative approaches. This approach risks delays in therapy while awaiting culture data. This reservation is addressed in part by using detection of intracellular organisms (in 2 to 5 percent of cells) on Gram's stained smear as a basis for empiric therapy. Sensitivity and specificity of various methods of collection and analysis vary greatly—but can be standardized within an institution.

Use of appropriate antimicrobial agents initially has a major beneficial impact on patient survival. Prior antimicrobial therapy and colonization patterns must be considered as risk factors for antimicrobial-resistant pathogens. The major pathogens in "hospital-acquired" pneumonia vary among institutions and within hospitals. Thus, empiric therapies must be individualized by institution as well by patient. Initially, broad-spectrum antimicrobial therapy directed at the likely pathogens (by clinical assessment) and at the predominant resistant flora of the given institution is likely to avoid inappropriate selection of agents. This approach must be coupled with "de-escalation" of therapy based on culture data. Initial therapy should utilize appropriate doses of bactericidal therapies (including loading doses). If the patient has recently received antimicrobial therapy, drugs from a different class should be used in initial therapy. In normal hosts, sputum Gram's stains are useful in gauging response to therapy (disappearance of neutrophils) while chest radiographs and oxygenation are helpful in evaluating response to therapy. Reevaluation of antimicrobial selections must be made as microbiologic data become available and the clinical progress of the patient is observed.

MDR pathogens provide special challenges. Risk factors for MDR-infection include recent hospitalization or antimicrobial therapy, exposure to certain clinical environments (dialysis, clinic, home IV therapy), and to immune compromise (Table 112-9). In intensive care units, *Burkholderia* (formerly *Pseudomonas*) *cepacia*, *Stenotrophomonas* (formerly *Xanthomonas*) *maltophilia*, and *Acinetobacter baumannii* (formerly *Acinetobacter calcoaceticus* variant *anitratus*) have been implicated in localized outbreaks of nosocomial pneumonia. Combination therapy for gram-negative bacterial pneumonia is generally reserved for two situations: suspected *Pseudomonas* pneumonia or for the initial therapy of nosocomial pneumonia while susceptibility data are pending. Community- and hospital-acquired *Staphylococcus aureus* is increasingly resistant to methicillin (MRSA). Both vancomycin and linezolid are reasonable alternatives for MRSA in this setting and some preliminary data suggest that linezolid may be advantageous in ventilator-associated infection. Strategies for empiric therapy are discussed in Chapter 115.

Nonresolving pneumonia occurs as a result of inappropriate antimicrobial therapy, superinfection, inadequate host response, obstruction, empyema, noninfectious processes, or recurrent infection. Inappropriate antimicrobial therapy includes inadequate dosing, agents that fail to penetrate infected lung tissue (often aminoglycosides), or the use of agents to which the organisms are or have become resistant. Empyema or loculated infection may occur during the course of appropriate therapy for pneumonia. Relapsed infection is common in intubated patients colonized with resistant microorganisms. Superinfection with resistant organisms (including fungi, *Mycobacterium tuberculosis*) may occur in the hospital setting as well as viral co-infection with community-acquired respiratory viruses. Untreated bacteremia (due to endocarditis, abdominal abscess, catheter-associated infections) or septic pulmonary emboli may cause persistent lung infections. In the compromised host, repletion of antibodies, neutrophils (colony-stimulating factor), treatment of concomitant viral

Table 112-9

Factors in the Emergence of Antimicrobial Resistance

Increase in "high-risk" (immunodeficient) population
Prolonged survival of persons with chronic diseases
Greater severity of illness of hospitalized patients
Newer devices and procedures in use
Increased introduction of resistant organisms from the community
Congregate facilities (e.g., jails, day care centers)
Increased use of antibiotics in animals and agriculture
Physician practices that contribute to inappropriate antibiotic use
Providing antibacterial drugs to treat viral illnesses
Using inadequate diagnostic criteria for infections that may have a bacterial etiology
Providing expensive, broad-spectrum agents that are unnecessary
Prescribing antibiotics at an improper dose or duration • Lack of rapid, accurate diagnostic tests to distinguish between viral and bacterial infections
Selection of antibiotic-resistant genes via abuse of antimicrobial agents • Ineffective infection control and isolation practices and compliance

infections (HIV, CMV), and repeat culturing may assist in management. Obstruction or empyema must resolve to allow resolution of infection. Recurrent infection may be observed if the patient is aspirating, has sinusitis, has a misplaced feeding tube, has airway compromise, or has pulmonary infarction. Additional cultures and radiologic studies (CT scans, decubitus films) may assist in defining lung processes which fail to respond to therapy. Bronchoscopic evaluation and, in selected patients, lung biopsy may assist in management.

NONINFECTIOUS PROCESSES MIMICKING PULMONARY INFECTIONS

The list of noninfectious disorders that mimic pulmonary infections is extensive (Table 112-10). These should be considered in the course of taking the initial history. The likelihood of noninfectious etiologies of pulmonary disease increases if the Gram-stained smear and culture of sputum are unrevealing, if the initial response to empiric antimicrobial therapy proves unsatisfactory, or if radiographic findings are atypical. Similar histologic appearances result from both infectious and noninfectious etiologies. The presence of a maculopapular skin rash, generalized lymphadenopathy, joint or rheumatologic symptoms, and/or peripheral eosinophilia should suggest hypersensitivity. However, as noninfectious and infectious processes often coexist, it is essential to exclude infectious causes of pulmonary dysfunction before treating hypersensitivity reactions. Immunosuppressive agents, notably corticosteroids, reduce inflammation due to both infectious and noninfectious causes.

Drug-Induced Pneumonitis

Noncytotoxic Drugs

Drugs producing pulmonary reactions may be considered in two categories: noncytotoxic and cytotoxic drugs. Noncytotoxic drugs that cause hypersensitivity pneumonitis include antimicrobials, anticonvulsants, diuretics, antiarrhythmics, tranquilizers, and antirheumatic agents (Table 112-11). Among the most common pulmonary reactions are those due to sulfa drugs, phenytoin, nitrofurantoin, and amiodarone. Sulfasalazine (and other sulfonamides) can produce hypersensitivity lung disease that includes cough, fever, dyspnea, and peripheral hazy acinar or diffuse reticular infiltrates on the chest radiograph. Phenytoin can produce hypersensitivity responses in the lungs 3 to 6 weeks after initiation of therapy. Fever, cough, and dyspnea are accompanied by radiographic findings of bilateral acinar, nodular, or reticular infiltrates. Nitrofurantoin can produce two patterns of pulmonary reaction: (1) acute, which occurs within 2 weeks after starting therapy and consists of dyspnea, nonproductive cough, chills, fever, crackles, eosinophilia, and diffuse interstitial or patchy infiltrates (often with pleural effusion); and (2) chronic, which is less common and occurs after months to years of continuous treatment. The picture of the chronic form is one in which exertional dyspnea and nonproductive cough appear gradually and are unaccompanied by fever; the pattern is not that of an acute pulmonary infection but, rather, the pattern of diffuse interstitial pneumonitis or pulmonary fibrosis. Amiodarone may be associated with pulmonary side effects that often occur after 5 to 6 months of therapy. Exertional dyspnea, nonproductive cough, malaise, and fever (in about half the patients) are gradual in onset, over weeks to several months. The radiographic findings include peripheral areas of consolidation that primarily affect the upper lobes. In some instances, coarse reticular interstitial infiltrates are present. Withdrawal of the medication, coupled with the administration of corticosteroids, usually leads to complete resolution. Other common forms of drug-induced hypersensitivity pneumonitis include those due to hydrochlorothiazide and gold salts. Hydralazine, procainamide, and isoniazid are capable of inducing a lupus-like syndrome which may include pleuropulmonary involvement.

Table 112-10

Noninfectious Causes of Febrile Pneumonitis Syndrome (Mimics of Pulmonary Infection)

- Drug-induced pulmonary disease
- Extrinsic allergic alveolitis
- Injury due to inhaled toxic gases, dusts, chemicals
- Acute eosinophilic pneumonia
- Pulmonary infiltrate with eosinophilia ("PIE syndrome")
- Chronic eosinophilic pneumonia
- Interstitial lung disease associated with autoimmune/connective-tissue disorders
  - Systemic lupus erythematosus
  - Polymyositis-dermatomyositis
  - Mixed connective-tissue disease
- Interstitial lung disease associated with pulmonary vasculitis
  - Wegener's granulomatosis
  - Lymphomatoid granulomatosis
  - Churg-Strauss syndrome (allergic angiitis and granulomatosis)
  - Polyangiitis overlap syndrome
- Intersititial lung disease associated with pulmonary airway disease
  - Allergic bronchopulmonary aspergillosis
  - Bronchocentric granulomatosis
  - Bronchiolitis obliterans and bronchiolitis obliterans with organizing pneumonia
- Acute or subacute interstitial pulmonary fibrosis (IPF, Hamman-Rich syndrome)
- Chronic interstitial pneumonias of unknown origin
  - Usual interstitial pneumonia (UIP)
  - Lymphocytic interstitial pneumonia (LIP)
  - Desquamative interstitial pneumonia (DIP)
  - Giant-cell interstitial pneumonia (GIP)
- Pulmonary neoplasms
  - Carcinoma or lymphoma
  - Kaposi's sarcoma in AIDS
- Sarcoidosis
- Pulmonary infarction
- Acute chest syndrome in sickle cell crisis
- Radiation pneumonitis
- Lipoid pneumonia (exogenous or endogenous)
- Acute respiratory distress syndrome (ARDS) associated with:
  - Extrapulmonary sepsis
  - Oxygen toxicity, chemical inhalation or aspiration, or aspiration of gastric contents
  - Pancreatitis
  - Fat embolization
  - Shock of various etiologies
  - Drug overdose
  - Chest trauma
- Pulmonary leukoagglutinin transfusion reactions
- Miscellaneous
  - Pulmonary alveolar proteinosis
  - Plasma cell granuloma
  - Histiocytosis X
  - Idiopathic pulmonary hemosiderosis
  - Goodpasture's syndrome
  - Rheumatic pneumonia (in acute rheumatic fever)

Cytotoxic Drugs

Three clinical and pathological patterns characterize cytotoxic drug–induced pulmonary disease: chronic pneumonitis with pulmonary fibrosis, acute hypersensitivity lung disease, and noncardiogenic pulmonary edema (Table 112-12). A variety of predisposing factors may contribute to the development of these reactions. The cumulative dose of certain drugs (e.g., bleomycin, busulfan, and carmustine) appears to be particularly important. Combined exposures (e.g., Adriamycin and bleomycin) with dual patterns (cardiac failure and pulmonary injury) are common.

Syndrome of Acute or Chronic Pneumonitis with Fibrosis

All cytotoxic drugs capable of inducing pulmonary disease can produce pneumonitis with fibrosis. The clinical manifestations develop over weeks to months and include nonproductive cough, progressive dyspnea on exertion, fatigue, and malaise. End-inspiratory crackles are audible on examination. The radiographic findings are consistent with those of an interstitial inflammatory process and pulmonary fibrosis. Fever is not common in this process except for the disease due to cyclophosphamide; over 50 percent of patients with pulmonary fibrosis due to cyclophosphamide exhibit fever.

Table 112-11

Noncytotoxic Drugs Capable of Inducing a Picture Resembling Pulmonary Infection

Antimicrobial agents
- Nitrofurantoin
- Penicillins, cephalosporins
- Sulfasalazine, other salfonamides
- Minocycline, tetracycline
- Amphotericin B (acting with leukocyte transfusions)
- Para-aminosalicylic acid

Anticonvulsants
- Phenytoin
- Carbamazepine

Diuretics
- Hydrochlorothiazide

Antiarrhythmics
- Amiodarone
- Tocainide

Narcotics
- Heroin
- Methadone
- Propoxyphene
- Cocaine

Anti-rheumatic agents
- Gold salts
- Penicillamine
- Naproxen

Drugs that can induce a lupus erythematosus-like syndrome
- Hydralazine
- Procainamide
- Isoniazid
- Chlorpromazine

Others: Sirolimus

Distinguishing between the effect of the drugs and the underlying disease process is often difficult.

Syndrome of Hypersensitivity Lung Disease

Methotrexate, bleomycin, and procarbazine cause an acute syndrome of dyspnea, nonproductive cough, fever, and occasionally pleuritic chest pain. The presence of blood eosinophilia and a skin rash suggests a hypersensitivity reaction. The radiographic findings include a diffuse reticular pattern and, in some patients, bilateral acinar infiltrates.

Table 112-12

Cytotoxic Drugs Capable of Inducing a Picture Resembling Pulmonary Infection

Acute or Chronic Pneumonitis with Pulmonary Fibrosis
- Antimicrobial agents
  - Bleomycin, mitomycin, neocarzinostatin
- Alkylating agents
  - Busulfan, cyclophosphamide, chlorambucil, melphalan, chlorozotocin
- Nitrosoureas
  - Carmustine (BCNU), semustine (methyl CCNU), lomustine (CCNU), chlorozotocin
- Antimetabolites
  - Methotrexate, azathioprine, mercaptopurine, cytosine arabinoside, 6-thioguanine
- Miscellaneous
  - Vinblastine, VM-26, vindescine

Hypersensitivity Lung Disease
- Antimetabolites
  - Methotrexate
- Antimicrobial agents
  - Bleomycin
- Miscellaneous
  - Procarbazine

Noncardiogenic Pulmonary Edema
- Antimetabolites
  - Methotrexate, cytosine arabinoside
- Alkylating agents
  - Cyclophosphamide
- Miscellaneous
  - VM-26

Extrinsic Allergic Alveolitis (Hypersensitivity Pneumonitis)

Inhalation of organic dusts may produce chills, fever, nonproductive cough, dyspnea, and pulmonary crackles within hours of exposure to organic dusts or vapors. The chest radiograph usually shows bilateral patchy acinar infiltrates, suggestive of pulmonary infection. The history of a specific exposure provides the clue to diagnosis, particularly when such episodes have been recurrent. Farmer's lung is due to hypersensitivity to moldy hay containing *Thermoactinomyces* species and *Micropolyspora faeni*. "Air-conditioner" or "humidifier" lung is associated with exposure to similar moldy antigens stemming from occult microbial growth on air-exchanging systems in offices and homes. In other hypersensitivity pneumonitides, the offending antigens may be avian in origin (pigeon breeder's disease) or due to other environmental fungi which contaminate natural products in industry (e.g., maple bark stripper's lung; moldy sugar cane in bagassosis).

INJURY DUE TO INHALED TOXIC GASES, DUSTS, CHEMICALS Silo-filler's disease is an acute syndrome that mimics acute bacterial or viral pneumonia clinically and radiologically following exposure to nitrogen dioxide. A degenerative interstitial pneumonitis–like picture may result from exposure to organic (e.g., wood, mycotoxin-containing) and inorganic (e.g., silicates, tungsten carbide) dusts. Severe interstitial disease and organizing pneumonia have occurred among workers exposed to aerosols of organic chemicals (designed to polymerize on mixing) used in textile dyeing.

CHRONIC AND ACUTE EOSINOPHILIC PNEUMONIA Chronic eosinophilic pneumonia usually has a course of weeks to months, characterized by fever, night sweats, nonproductive cough, and dyspnea. Pulmonary crackles are variably present. Chest radiographs show a characteristic pattern of peripheral acinar infiltrates that usually involve the upper lobes and resemble the appearance of butterfly pulmonary edema. Peripheral blood eosinophilia is common. Occasionally, chronic eosinophilic pneumonia has an acute onset. Even though the onset in such instances is acute, the course, if untreated (corticosteroids), is prolonged, as in typical chronic eosinophilic pneumonia. Acute eosinophilic pneumonia was initially described as an acute febrile illness with severe hypoxemia, diffuse pulmonary infiltrates, increased numbers of eosinophils in BAL fluid, and prompt response to corticosteroid therapy without relapse. Drug hypersensitivity may be the cause in some instances. A subset has been described with the same acute onset with high fever, a radiologic picture of micronodular and diffuse ground-glass infiltrates, and spontaneous improvement without relapse.

PULMONARY INFILTRATE WITH EOSINOPHILIA The term *pulmonary infiltrates with eosinophilia* (PIE syndrome) is used to encompass a wide range of definable clinical entities such as acute eosinophilic pneumonia, chronic eosinophilic pneumonia, allergic pulmonary aspergillosis, and Churg-Strauss vasculitis (see below). However, PIE syndrome should be used to refer to a syndrome consisting of fleeting pulmonary infiltrates, dry cough and mild wheezing, low-grade fever, and blood and pulmonary eosinophilia. Loeffler's syndrome, a form of PIE, may be associated with parasitic infestation (migration or hypersensitivity) with *Ascaris lumbricoides, Strongyloides stercoralis, Ancylostoma duodenale, Toxocara canis,* and others, or due to drug hypersensitivity. Tropical eosinophilia is a similar syndrome, endemic in India and southern Asia, Africa, and South America, and most likely due to filarial infection.

INTERSTITIAL LUNG DISEASE ASSOCIATED WITH CONNECTIVE TISSUE DISORDERS AND PULMONARY VASCULITIS A variety of connective tissue disorders and vasculitides mimic pulmonary infections. Systemic lupus erythematosus may be associated with transitory infiltrates, interstitial disease, or frank consolidation of a noninfectious nature. Interstitial pneumonitis occurs in 5 to 10 percent of patients with polymyositis and may be mistaken for a pulmonary infection, since pulmonary manifestations and fever may precede muscle weakness.

Three types of vasculitis commonly mimic pulmonary infection. Wegener's granulomatosis involves the lung in approximately 95 percent of cases. Radiologically, the lesions appear as patchy infiltrates or as nodular lesions that may progress to cavities or lung abscesses. Superinfection of Wegener's granulomatosis of the lungs is common. Allergic angiitis and granulomatosis (Churg-Strauss syndrome) occurs in the setting of asthma and peripheral eosinophilia. It characteristically involves the lungs, producing pulmonary infiltrates associated with granulomatous and vasculitic lesions. The polyangiitis overlap syndrome combines some of the characteristic features of classic polyarteritis nodosa and of allergic angiitis and granulomatosis; in some instances pulmonary impairment is a prominent feature.

INTERSTITIAL LUNG DISEASE ASSOCIATED WITH PULMONARY AIRWAY DISEASE Allergic bronchopulmonary aspergillosis, characterized by cough, bronchospasm, fever, and intermittent pulmonary infiltrates, can suggest pulmonary infection, although an accompanying eosinophilia provides a clue to the true nature of the process. Eosinophilia may be absent in patients receiving corticosteroid therapy. Bronchocentric granulomatosis, a necrotizing process of unknown cause affecting small bronchi may be associated with fever in some patients. The pulmonary lesions vary from mucoid impaction to diffuse and nodular infiltrates.

Bronchiolitis obliterans is an occasional complication of pulmonary viral or bacterial infections, cocaine toxicity, drug hypersensitivity, connective tissue disease, inhalation of chemical irritants; or the disease can occur without apparent cause. It is a common presentation of lung injury and chronic rejection of transplanted lungs. It may present with patchy areas of pneumonitis, necrosis of bronchiolar epithelium, and occlusion of terminal airways by granulation tissue. Bronchiolitis obliterans-organizing pneumonia (BOOP) refers to instances in which the presence of organizing inflammatory polypoid masses in distal bronchioles and alveolar ducts is accompanied by a chronic pneumonitis with lipid-laden macrophages. Although many patients with BOOP respond promptly to corticosteroids, occasional patients undergo a rapidly progressive course even with intensive therapy.

CHRONIC INTERSTITIAL PNEUMONIAS OF UNKNOWN CAUSE A variety of interstitial pneumonias, known as usual interstitial pneumonia (UIP), lymphocytic interstitial pneumonia (LIP), desquamative interstitial pneumonia (DIP), and giant cell interstitial pneumonia (GIP), are conditions of unknown origin that are defined on histologic grounds. Most often they present clinically as subacute or chronic processes characterized by progressive dyspnea, cyanosis, nonproductive cough, pulmonary crackles, and a radiographic picture of diffuse reticulonodular infiltrates (more prominent at the lung bases) or a "ground-glass" pattern without fever. Thus, the clinical picture may not suggest pulmonary infection. In some patients, the onset is rapid and accompanied by fever suggesting an acute respiratory infection.

PULMONARY NEOPLASMS Bronchial obstruction by a bronchogenic carcinoma may produce obstructive pneumonia ("drowned lung") or atelectasis. Fever and signs of consolidation/atelectasis may fail to respond to antimicrobial therapy. Recurrent pneumonia in the same portion of the lung should suggest this possibility. Hodgkin's disease and non-Hodgkin's lymphoma may present with fever, cough, dyspnea, and pulmonary lesions suggesting infection. In Hodgkin's disease, a single mass lesion may be present and cavitate, suggesting a lung abscess.

SARCOIDOSIS In the patient with sarcoidosis and interstitial lung disease, fever is uncommon unless hilar adenopathy or other features, such as erythema nodosum, are also present. Consequently, this process is usually not mistaken for a primary pulmonary infection.

PULMONARY INFARCTION Fever, dyspnea, pleuritic chest pain, leukocytosis, and segmental pleural-based infiltrates (and possibly accompanying pleural effusion) of pulmonary infarction suggest the presence of pulmonary infarction due to pulmonary embolus or septic emboli. Similar features are observed with pneumococcal pneumonia. The presence of blood-streaked sputum in this syndrome may suggest the possibility of *S. pyogenes* pneumonia with hemorrhagic tracheobronchitis. Occasionally, multiple round radiographic infiltrates in the lungs of a febrile, dyspneic patient with pulmonary emboli may suggest lung abscesses due to aspiration or septic emboli.

LIPOID PNEUMONIA Exogenous lipoid pneumonia results from inhaling or aspirating fatty materials (oily nose drops, mineral oil). Endogenous lipoid pneumonia (often called "*cholesterol* pneumonia") consists of chronic inflammatory foci containing cholesterol and its esters, derived from destroyed alveolar walls located either behind a bronchial obstruction or in lung parenchyma at a site of chronic suppuration. Sputum, fine-needle aspirates, or BAL specimens may reveal macrophages containing lipoid vacuoles, as demonstrated by fat stains (Sudan, oil red O).

RADIATION PNEUMONITIS The acute phase of radiation pneumonitis usually develops within 3 or 4 months after initiation of radiation therapy. It is characterized by fever, dyspnea, cough, and radiographic changes (infiltrates or ground-glass density) sharply demarcated geometrically to the portal of irradiation rather than to natural pulmonary anatomic divisions. This reaction might be mistaken for a bacterial pneumonia. The late phase of radiation pneumonia, characterized by pulmonary fibrosis, occurs 9 months or more after radiation therapy and is not accompanied by fever.

MISCELLANEOUS MIMICS OF PULMONARY INFECTION Pulmonary alveolar proteinosis usually begins slowly, with dyspnea as the principal symptom. Radiographic features are those of a bilateral diffuse, predominantly perihilar airspace disease. The radiographic, but not the clinical, manifestations may suggest pulmonary infection. Fever is usually absent. However, pulmonary alveolar proteinosis may be associated with hematologic malignancies, which are associated with fever including lymphoma or acute leukemia. In addition, pulmonary alveolar proteinosis is sometimes complicated by pulmonary infections—e.g., nocardiosis (most frequently), cryptococcosis, aspergillosis, tuberculosis, pneumocystosis, and histoplasmosis.

Plasma cell granuloma is a postinflammatory pseudotumor of the lung. The combination of cough, fever, and radiologic changes of atelectasis and consolidation suggests the diagnosis of pulmonary infection associated with bronchial obstruction. This process is very similar to the previously described cholesterol pneumonia.

Eosinophilic granuloma of the lung (pulmonary histiocytosis X) usually is manifested as a noninfectious interstitial pulmonary process with dyspnea and nonprogressive cough. In about 15 percent of patients, however, fever does occur, suggesting the possibility of pulmonary infection. The radiographic findings are those of small nodules and reticulation or honeycombing; these findings in the febrile patient may suggest the diagnosis of miliary tuberculosis, invasive mycotic infection, *Rhodococcus equi*, or viral disease (e.g., varicella-zoster).

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS) Many unrelated conditions involving the lungs primarily or having their initial impact elsewhere have in common the capacity to cause diffuse damage to the alveolar-capillary membrane and produce noncardiogenic pulmonary edema. The process progresses rapidly with inflammatory cell infiltration and pulmonary fibrosis. Extensive pulmonary infiltrates are evident on chest radiographs. Superinfection of lungs injured by ARDS, often by nosocomial pathogens, is common. Many of the underlying processes that produce ARDS are associated with fever, including pancreatitis, peritonitis, endocarditis, severe thermal injuries, as well as fulminant bacterial or viral infections.

PULMONARY LEUKOAGGLUTININ TRANSFUSION REACTIONS An acute pulmonary reaction may follow receipt of a blood transfusion with which there has been passive transfer of leukoagglutinins and antibodies cytotoxic to recipient lymphocytes. The clinical picture of an abrupt onset of chills, fever, tachycardia, cough, and dyspnea, accompanied by numerous fluffy and nodular perihilar infiltrates on radiograph, may easily be mistaken for an acute pulmonary infection. Pulmonary hemorrhage may also affect such patients, particularly after hematopoietic transplantation.

The Radiology of Pulmonary Infection

Reginald E. Greene

This chapter aims to provide clinicians with a framework for analyzing images of pulmonary infection by focusing on generic pathogenetic categories that can be identified on computed tomography (CT). The focus is on the role of chest imaging in the diagnosis of pneumonia, the identification of common etiologic classes of infection, and notation of pertinent non-infectious differential diagnoses. A detailed examination of the imaging findings of the entire range of potential causes of lung infection is beyond the scope of this chapter.

IMAGING MODALITIES

Imaging is an essential tool in the management of patients with pneumonia. The main roles of imaging are to independently detect, corroborate, and localize clinically suspected pneumonia, estimate the severity and extent of disease, identify categorical abnormalities that can narrow the range of likely etiological infectious agents, and differentiate pneumonia from non-infectious etiologies that may be responsible for the clinical and imaging findings. Follow-up imaging is used to estimate response to treatment, exclude complications of pneumonia, and document clearing of the initial imaging abnormality. Pneumonias that respond clinically to treatment can often take 8 weeks or more to clear on plain film radiography, and even longer on CT, usually long after the clinical status has returned to normal. Return to an imaging baseline condition is particularly slow in patients with co-morbidity or severe infections.

Plain chest radiography is the basic tool for imaging patients with suspected pneumonia. The findings can justify a working clinical diagnosis and help form the basis for initial management. In some cases atypical or otherwise worrisome findings of plain film radiography point to a need for supplementary CT to rule out complicated infection or other disease. This sequence occurs more often in older patients, and those with co-morbidities than in previously healthy young patients.

CT is the imaging gold standard for evaluation of lung disease in general, and chest infection in particular. It provides the highest level of global specificity and sensitivity for the diagnosis of pneumonia. In a few specific circumstances CT findings may warrant the start of preemptive antimicrobial therapy when etiological, microbiological, or histopathological proof of diagnosis is lacking. The present generation of 4- to 64-slice multidetector CT scanners can provide high-speed, single-breath, volume acquisitions that can be viewed as 2.5 mm or finer reconstructed sections. If these images are obtained after delivery of intravenous iodinated contrast medium, and there is careful control of the patient's breath-hold during the scan, then adequate anatomic detail can be obtained to evaluate the lung, pleura, mediastinum, and great vessels for infection. The categories of imaging findings discussed in this chapter may at times be identifiable on plain film radiography when fully developed, but the basis for their discussion relies on the CT technique.

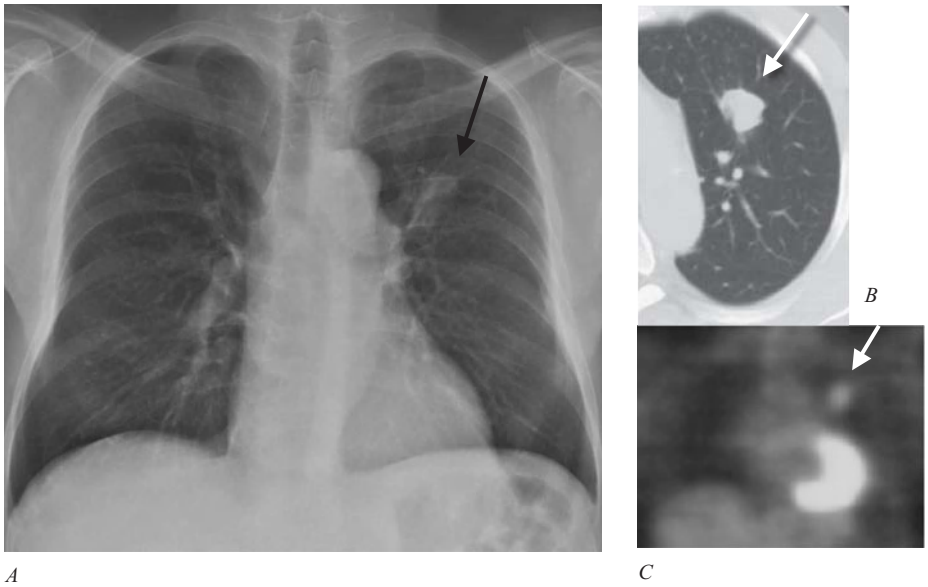

Figure 113-1 18FDG-avid macronodular C. neoformans infection. *A*. Plain chest radiograph with a macronodular opacity in the left upper lobe (arrow) in an asymptomatic mildly immunosuppressed solid organ transplant recipient. *B*. CT scan confirms a well defined macronodule in the left upper lobe (white arrow). *C*. Positron emission tomography (PET) with 18 fluorodeoxyglucose (18FDG) shows normally high metabolic avidity of the cardiac ventricular musculature, and moderate avidity of the left upper lobe nodule due to *Cryptococcus neoformans*.

Other imaging modalities are at present used infrequently for evaluation of suspected pneumonia. Ultrasound is a standard modality for detecting and tapping pleural effusions, but it is not employed in the diagnosis of pneumonia. Magnetic resonance imaging (MRI) is rarely employed to detect or further assess patients with a clinical diagnosis of infection except when critical extension or dissemination is suspected. Positron emission tomography (PET) with 18 fluorodeoxyglucose (18FDG) is increasing used as a sensitive method of detecting metabolically active tumor lesions, but it has yet to find a definable role in clinical evaluation of inflammation and pneumonia. Anecdotal studies of patients with chronic and acute inflammatory lesions and infections have identified a wide spectrum of lung lesions that are 18FDG-avid (Fig. 113-1).

GENERIC LUNG FINDINGS ASSOCIATED WITH PNEUMONIA

Six common imaging categories of pneumonia are discussed, each of which has a distinctive pathogenesis, typical gross pathology, and characteristic imaging findings: the first two are most common: (1) peripheral airspace consolidation pneumonia (lobar pneumonia); and (2) centrilobular and peribronchiolar opacity pneumonia (bronchopneumonia). The next three categories are less common but no less important: (3) nodular pneumonia; (4) micronodular pneumonia (miliary pneumonia); and (5) diffuse lung opacification pneumonia.

Several factors that limit this type of categorical analysis must be recognized; imaging findings vary between patients with pneumonia of the same etiology; imaging findings vary over time as pneumonias evolve, and different categories of imaging findings may be encountered in any single snapshot of a patient with pneumonia. Although no single imaging category can completely characterize a single etiologic kind of pneumonia, it is useful to think in terms of the predominant imaging finding when evaluating the likely pathogenesis and etiology of a likely pneumonia while taking into account the clinical context in which it occurs. One or more types of etiologic agents are more likely than others in each category of pneumonia when the clinical background is taken into account: immunocompetent versus immunocompromised, previously healthy versus having co-morbidity, acquisition of infection inside of the hospital, i.e., nosocomial pneumonia (NP) versus acquisition in the wider community, i.e., community-acquired pneumonia (CAP), and the presence of local epidemic infections.

Peripheral Airspace Consolidation Pneumonia (Lobar Pneumonia)

Overview and Pathogenesis

Peripheral airspace consolidation is a characteristic imaging category of pneumonia that is commonly encountered in all patient groups. It is an especially common primary pneumonia caused by bacteria in previously healthy patients with CAP. It is also called lobar pneumonia because it is often essentially confined to a single peripheral lung region without prominent involvement of the bronchial tree.

The pathogenesis and imaging of peripheral airspace consolidation pneumonia is unique. It is the result of airborne infection initiated by microbes that reach and settle in the peripheral alveolar airspaces. From there the pneumonia spreads into adjacent alveoli by traversing collateral channels of ventilation, such as the pores of Kohn and canals of Lambert. Spread by this way from alveolus to alveolus results in characteristic involvement that parallels the pleural surface, and ultimately extends toward the more central regions of the lung in centripedal fashion. As the infection progresses, gas in the peripheral airspaces is replaced by exudate. This process of accretion tends to preserve or slightly expand without distorting the normal anatomic contours of the affected lung. The relatively unaffected bronchi remain relatively gas filled, and become surrounded by consolidated alveoli. At the leading edge of a consolidation there is generally a patchwork of individually spared and affected lung.

Etiologies

Outside of neonates, *Streptococcus pneumoniae* is the most common bacterial etiology of peripheral airspace consolidation pneumonia, as well as the most common cause of bacterial pneumonia acquired outside of hospitals in previously healthy patients (Fig. 113-2). It accounts for a large fraction of the etiologically proven, bacteremic, life-threatening pneumonias. In CAP and NP of patients with co-morbid conditions, peripheral airspace consolidation may be caused by opportunistic gram-negative enteric bacteria of the Enterobacteriaceae *family* such as, *Klebsiella, Enterobacter*, *Escherichia*, *Citrobacter,* and *Serratia*, as well as by *Legionella pneumophila* (Fig. 113-3). Large peripheral airspace consolidation is also a presenting imaging category in primary tuberculosis, in which case it affects primarily the lower lobes, middle lobes, and/or anterior segments of the upper lobes. It is usually associated with mediastinal lymphadenopathy,

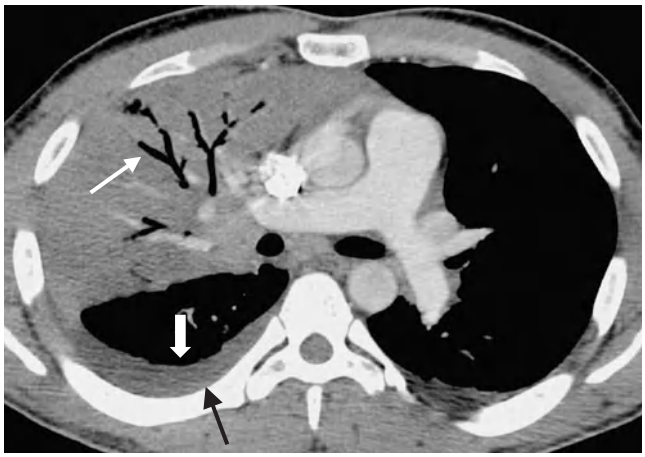

Figure 113-2 Lobar pneumonia due to *S. Pneumoniae* in previously normal host. Severe community-acquired lobar pneumonia with bacteremia due to *S. pneumoniae* in a previously healthy 30-year-old man. There is dense consolidation of the right upper lobe with prominent air bronchograms (white arrow). Layered pleural fluid is present along the right posterior chest wall (black arrow).

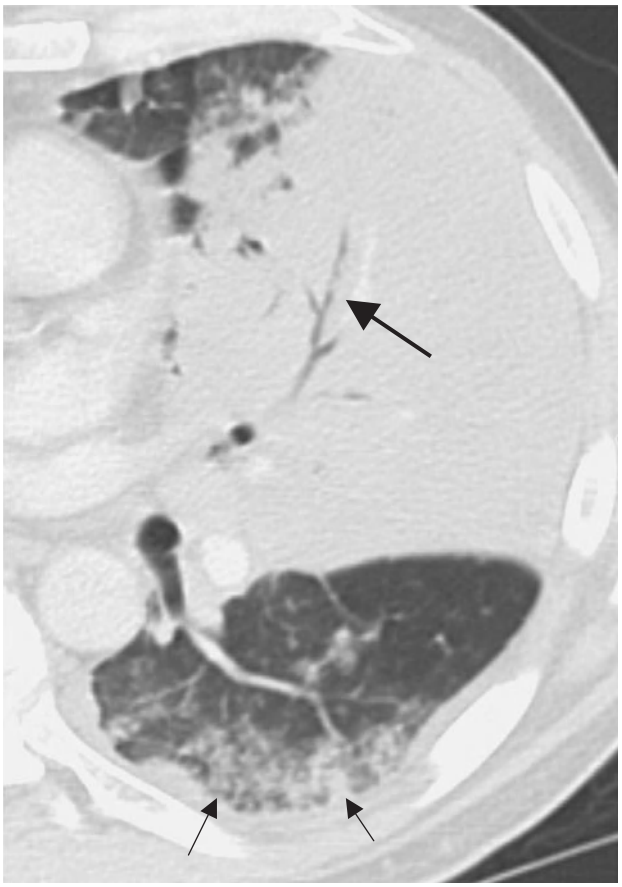

Figure 113-3 Community-acquired lobar pneumonia caused by *Legionella pneumoniae* in patient with co-morbidity. Community-acquired lobar pneumonia caused by *Legionella pneumoniae* in patient with co-morbidity due to chronic granulomatous vasculitis. There is peripheral airspace consolidation (lobar) pneumonia containing prominent air bronchograms (black arrow). There is also patchy "spillover" pneumonia associated with ground glass and tree-in-bud opacities along the posterior chest wall (small black arrows), as well as a small layering pleural effusion.

especially in pediatric patients. Lobar pneumonia can also be a component of the imaging findings in endemic fungal infections, and in immunocompromised patients with invasive fungal infection. Less commonly it can result from a wide variety of viral infections such as adenovirus, Hantavirus, and the coronavirus of severe acute respiratory syndrome (SARS).

Imaging

The characteristic imaging finding of peripheral airspace consolidation pneumonia is opacification of the peripheral airspaces often with visible air-filled proximal conducting airways, i.e., "air bronchograms." Where fully developed, exudate causes complete opacification of the involved lung such that all the underlying pulmonary vasculature of the affected region is totally obscured. Where the consolidation is incomplete the affected lung may exhibit ground-glass opacification, in which case it does not completely obscure underlying vasculature. At the leading edge of spread of infection, there

is generally a patchwork of affected and spared secondary lobules, i.e., lung regions of 10 to 25 mm on a side that are marginated by pulmonary septations. Specific identification of peripheral airspace consolidation is facilitated by recognition of internal air bronchograms that are in most cases identifiable. Atelectasis and significant local loss of lung volume are usually absent.

Peripheral consolidative pneumonia differs notably from bronchopneumonia (which will be described subsequently) in that it primarily affects peripheral airspaces rather than bronchi/bronchioles and peri-bronchial airspaces, and is not usually associated with loss of volume or atelectasis of the affected lung. It differs also from macronodule pneumonia (which will be described subsequently) in that even when large its lung opacification does not tend to substantially distort the pre-infection anatomic shape of the involved area.

The absence of air bronchograms does not per se exclude consolidation; air bronchograms may be absent when consolidation results from central bronchial occlusion or causes exudative impaction of proximal bronchi within the affected lung. Cavitation, necrosis, and pleural effusion are sometimes features of peripheral airspace consolidation pneumonia, particularly when the infection is caused by aggressive or necrotizing bacterium, such as *Staphylococcus aureus*, mycobacteria, and anaerobic enteric bacilli such as *actinomycetes*. The association of lymphadenopathy is common in mycobacterial, endemic fungal, and other less common infections such as tularemia.

Non-Infectious Etiologies

Non-infectious simulators and etiologies of peripheral consolidation include localized aspiration, atelectasis, hemorrhage, hydrostatic edema, alveolar-capillary leak edema, post-obstructive pneumonitis, bronchiolo-alveolar cell carcinoma, lymphoma, and bronchiolitis obliterans organizing pneumonia (BOOP). Air bronchograms are often present in non-obstructive atelectasis in the absence of infection. In such cases of atelectasis is recognized by crowding together of the air-filled bronchi that are be visible within the atelectatic lung. The air bronchograms of pure airspace consolidative pneumonia are normally distributed or splayed apart. Bronchioloalveolar cell carcinoma is suspected by atypical clinical presentation and failure to respond to antibiotic therapy.

Centrilobular and Peri-bronchiolar Opacity Pneumonia (Bronchopneumonia)

Overview and Pathogenesis

Like lobar pneumonia, centrilobular and peribronchiolar opacity pneumonia (bronchopneumonia), a characteristic imaging category of pneumonia that is commonly encountered in all patient groups. It is an especially common imaging category in CAP that follows viral infection. It is also called bronchopneumonia because it is associated with acute infection of the walls of bronchioles that spreads into the peribronchiolar alveoli, and often involves the lung in a patchy multifocal distribution (Fig. 113-2).

Etiologies

Many patients with community-acquired bronchopneumonia have mild and self-limited disease attributable to respiratory viruses, including epidemic influenza, adenovirus, rhinovirus, and respiratory syncytial viruses (RSV) (Fig. 113-3). Some of these viruses can produce more serious primary pneumonia, as well as set the stage for bacterial or other etiology superinfection pneumonia, especially when there are co-morbid conditions. Severe acute respiratory syndrome (SARS), a newly identified coronavirus infection, can produce severe viral pneumonia with a broad spectrum of imaging findings, including bronchopneumonia. Other organisms that commonly cause bronchopneumonia include *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Haemophilus influenzae,* and *Neisseria catarrhalis (Moraxella catarrhalis)*. *Klebsiella pneumoniae, Escherichia coli,* and *Pseudomonas aeruginosa* are also common causes of nosocomial (and ventilator-associated) bronchopneumonia, and of community-acquired bronchopneumonia in patients with co-morbid conditions. These latter pneumonias are associated with necrosis, abscess formation and pleural effusion.

The role of *Staphylococcus aureus* in the etiology of bronchopneumonia in the ventilator-associated milieu pneumonia (VAP) is controversial because airway recovery of the organism is not usually associated with the characteristic imaging signs of CAP caused by that organism in patients without co-morbid conditions, i.e., rapid development and necrosis. The organisms that cause peripheral airspace consolidation pneumonia are not restricted from also causing bronchopneumonia when bronchioles are already inflamed by recent infection.

Imaging

On initial imaging bronchopneumonia is different from lobar pneumonia; it causes centrilobular opacities, as well as peri-bronchiolar opacities rather than affecting subpleural lung as in lobar pneumonia, and it tends to be multifocal and patchy in distribution rather than localized to any one lung region. Centrilobular opacities include centrilobular nodules, and small branching tubular opacities (tree-in-bud opacities), each of which is found within the center of the secondary pulmonary lobule (Fig. 113-4).

Centrilobular nodules are very small well- or ill-defined rounded opacities situated in the center of a secondary lobule (defined by its arterial/bronchial core, and/or straight septal walls with pulmonary veins at its corners). The nodules are usually only in (2–3 mm) in diameter but may grow large enough to fill entire lobules (10–24 mm), at which size they are often considered to be macro-nodules. Because small centrilobular nodules are located at the center rather than at the periphery of the secondary pulmonary lobule, they do not normally abut the visceral pleural surface, but usually stand off about 5 mm from it. Centrilobular nodules are considered

Figure 113-4 Viral bronchopneumonia. Centrilobular and peribronchial opacity pneumonia (bronchopneumonia) after a 1-week viral type prodrome with fever and cough. One of many bilateral patches of bronchopneumonia in the left lower lobe is characterized by branching small tubular opacities (black arrow) attributed to thickened, dilated and impacted bronchioles (tree-in-bud opacities) that simulate game "Jacks," i.e., six-pronged three-dimensional metal crosses with bulbous ends. There is also a thickened bronchial wall leading to, and surrounded by the same tubular bronchiolar opacities (white arrow).

to be axial views of bronchiolar wall thickening, impaction and distention at bifurcations, and may present in clusters. Branching centrilobular tubular opacities (tree-in-bud opacities) are very small cylindrical, branching structures with bulbous ends that equate to longitudinal projection of the bronchiolar thickening, exudative filling, and distention.

Peribronchial and peribronchiolar lung opacities are much larger than centrilobular opacities that develop from the coalescence of affected alveoli that open directly into respiratory bronchioles (Fig. 113-5). When secondary lobular involvement is complete, there is total opacification of a secondary lobule. When local alveolar involvement is incomplete, there may be ground-glass opacification of the lobule such that background vasculature is still visible. In lobar pneumonia, progression of infection tends to spread subpleurally and centripetally. In bronchopneumonia, progression of infection tends to spread centrifugally to affect secondary lobules distributed axially along bronchovascular bundles.

In most cases centrilobular nodules and tree-in-bud opacities are seen in combination. Common infectious etiologies of centrilobular opacities include a wide range of bacterial, mycobacterial, viral, and fungal etiologies that are caused by acute or chronic bronchiolar inflammation/infection.

Figure 113-5 Peribronchial consolidation due to viral pneumonia. CT scan one week after onset of fever; cough with a confirmed diagnosis of *Influenza B* and *Mycoplasma pneumoniae*. There are multifocal, bilateral peribronchial consolidations, one of which is in the right lower lobe (large black arrows) with prominent air bronchograms and bronchial wall thickening (curved white arrows). Centrilobular opacities, including nodules (short arrow) and branching tree-in-bud opacities, are also present.

They are also often seen in infectious pneumonias associated with bronchiectasis or cystic fibrosis. In *Mycoplasma pneumoniae* infection, tree-in-bud opacities are a common feature, and are often found in association with centrilobular nodules. In some infections tree-in-bud opacities may be seen as a predominant feature, as in acute bronchiolitis, bronchogenic tuberculosis, and infections by atypical mycobacteria (Fig. 113-6). In patients with HIV infection (CD4 T-lymphocyte count less than 200/mm^3), disseminated bronchogenic tuberculosis, and disseminated atypical mycobacterial infection may be manifested by diffuse tree-in-bud opacities. The high CT attenuation of these opacities is ascribed to caseous necrosis material impacted within bronchioles (Fig. 113-7). In progressive primary or post-primary tuberculosis bronchogenic spread into other regions of the lung occurs when infected liquefied caseous material gains access into bronchial tree to be coughed or expectorated into other lung regions. In addition to centrilobular nodules, tree-in-bud opacities, multiple fluffy 5- to 10-mm "acinar" nodules may be detected adjacent to a source consolidation or cavity.

Regional atelectasis is common imaging finding in bronchopneumonia due to multiple small airway occlusions by exudates. Some infections may produce necrosis, cavitation, pleural effusion, bronchopleural fistula, and empyema.

Post-primary tuberculosis is a centrilobular process that when latent may include scarring, atelectasis, bronchial wall thickening, bronchiectasis, architectural distortion, and local pleural thickening, especially in the lung apices or superior segments of the lower lobes. Active post-primary tuberculosis usually results from reactivation of a dormant

Figure 113-6 Bronchogenic tuberculosis. CT scan with disseminated bilateral high density tree-in-bud opacities (white arrow), centrilobular nodules (black arrow), and bronchial wall thickening (curved arrow) in a patient with advanced HIV infection and bronchogenic tuberculosis.

focus when cellular immunity deficiency lowers specific cellular immunity to tuberculosis, such as in debility or advanced AIDS. Active post-primary tuberculosis begins with ulceration of one or more bronchioles (2- to 4-mm diameter) that progress by coalescing into larger bronchocentric cavities.

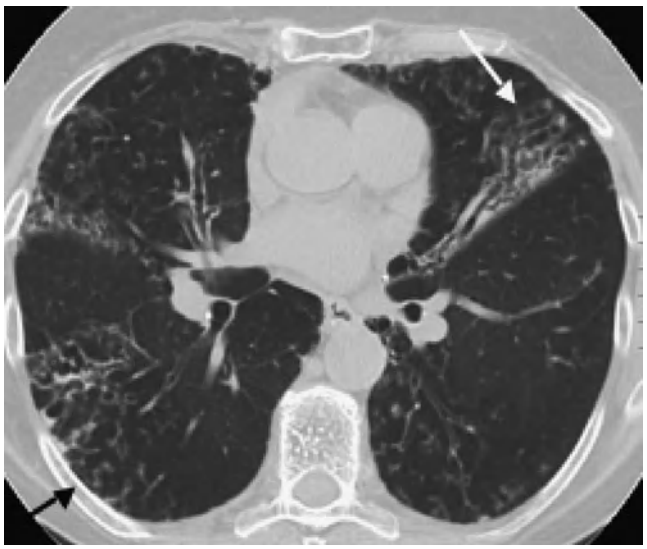

Figure 113-7 Widespread centrilobular opacities and bronchiectasis in chronic *Mycobacterium avium* complex (MAC) infection. CT scan of elderly female with widespread centrilobular opacities, including tree-in-bud opacities (black arrows), and lingular bronchiectasis (white arrow) due to chronic *Mycobacterium avium* complex (MAC) infection.

These cavities indicate activated latent post-primary tuberculosis, and can be detected twice as often, and more accurately differentiated from paracicatricial emphysema and fibrosis by CT than by plain film radiography (Fig. 113-8). Other findings in active post-primary tuberculosis include poorly defined centrilobular 5- to 8-mm nodules, consolidation, and granulomas.

Non-Infectious Etiologies

Non-infectious simulators and etiologies of centrilobular and peri-bronchial opacities include aspiration pneumonia, itself a frequent non-infectious cause of bronchopneumonia, as well as a facilitator of superinfection. Other causes include bronchiolo-alveolar cell carcinoma, non-infectious granulomas due to pneumoconiosis, sarcoidosis, respiratory bronchiolitis, hypersensitivity pneumonitis, bronchiolitis obliterans organizing pneumonia (BOOP), asthma, autoimmune disease, and bronchiolitis obliterans. They can also be found in patients with small mucous airway plugs and other endobronchial disease.

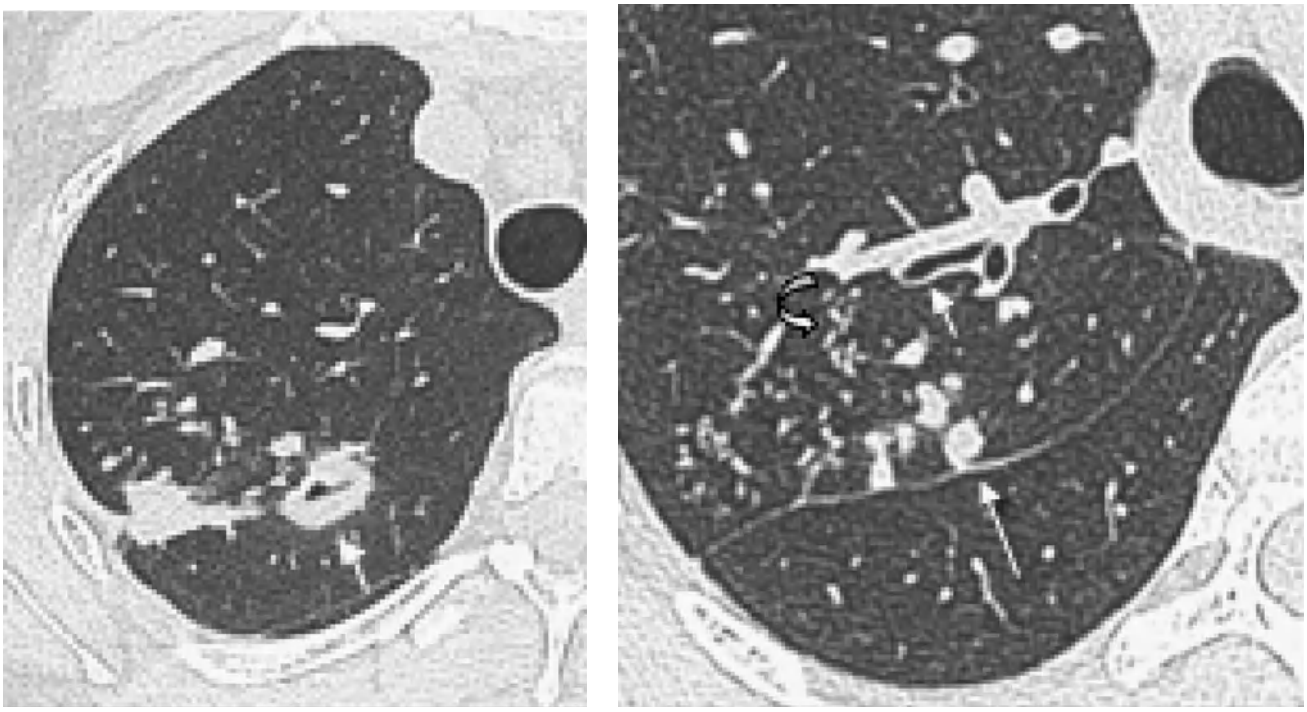
Nodular Pneumonia (Round Pneumonia)

Overview and Pathogenesis

Nodular pneumonia is predominantly made up of circumscribed, ovoid opacities greater than or equal to 1 cm diameter that may at times be quadrilateral shaped and marginated by septal walls. This imaging type of is not as common as the two previously discussed types of pneumonia, but its finding as acute pneumonia may portend aggressive, potentially life-threatening pneumonia. The nodules may be bronchocentric in location, but are often are subpleural whether the portal of entry is by way of the vascular route such as in septic emboli, or via the inhalational route, as in *Staphylococcus aureus* pneumonia and invasive pulmonary aspergillosis (Fig. 113-9). They represent circumscribed foci of pneumonia forming in the distal airspaces or foci of pneumonia forming at the termination of pulmonary arteries.

Etiologies

In a CAP setting, nodular pneumonia is often caused by *Staphylococcus aureus* in which case the lesions tend to enlarge rapidly and cavitate (Fig. 113-10). *S. aureus* is relatively more common among children and infants than among adults. Other causes of round pneumonia include *Actinomycetes*, *Nocardia*, *Aspergillus, Legionella* spp., Q fever, *M. tuberculosis,* and viruses. Among pediatric-aged patients, nodular pneumonia may be due to measles virus. In the nosocomial setting, and in the immunocompromised patient, nodular pneumonia may be due to inhaled or bacteremic seeding of the lungs by gram-negative opportunistic intestinal organisms, opportunistic gram-negative enteric bacteria of the Enterobacteriaceae *family* such as, *Klebsiella, Enterobacter*, *Escherichia*, *Citrobacter,* and *Serratia,* especially when there is bowel distention or obstruction. In patients with mild reduction in defense against infection, such as that due in alcoholism, liver dysfunction, diabetes, wasting or chronic lung



A *B*

Figure 113-8 Centrilobular opacities and cavity in reactivation of latent post-primary tuberculosis. *A*. Non-immunocompromised patient with abnormal nodular opacities characteristic of latent post-primary tuberculosis in the posterior segment of the right upper lobe. The presence of new cavitation of a "tuberculoma" indicates reactivation of latent tuberculosis (white arrow). *B*. More caudally in the same lobe, there are multiple centrilobular opacities indicative of endobronchial spread from the cephalad thick-walled cavity identified in Fig. 113-3*A*. There is a very large centrilobular nodule that approaches the major fissure (long arrow), bronchial wall thickening (short arrow), and many branching centrilobular tubular opacities (tree-in-bud) indicative of bronchiolar thickening, dilatation, and impaction (curved arrow).

Figure 113-9 Macronodular pneumonia. Multiple subpleural macronodular opacities (arrows) in a patient with acute onset of fever, shaking chills, fever, and cough productive of green sputum likely due to bacterial pneumonia that responded promptly to vancomycin therapy. Respiratory secretions and blood were culture-negative.

disease, and in AIDS patients with CD4+ greater than 200 c/ml, nodular pneumonia is often due to bacterial pneumonia. In severely immunosuppressed AIDS patients with CD4+ less than 200 c/ml, and in solid organ transplant recipients, nodular pneumonia may also be due to mycobacterial or fungal infection, including *Mycobacterium avium complex*

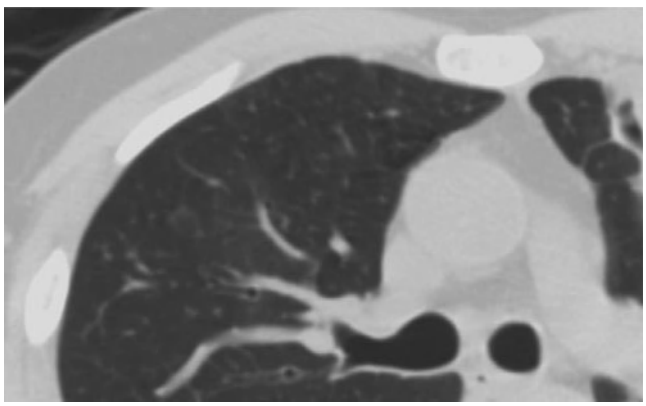


Figure 113-10 Cavitating *Staphylococcal aureus* macronodular pneumonia. Large subpleural mass-like macronodule with multiple gas pockets in this previously normal 39-year-old patient with sputum positive for *S. aureus*. The findings are characteristic of lung abscess before complete excavation.

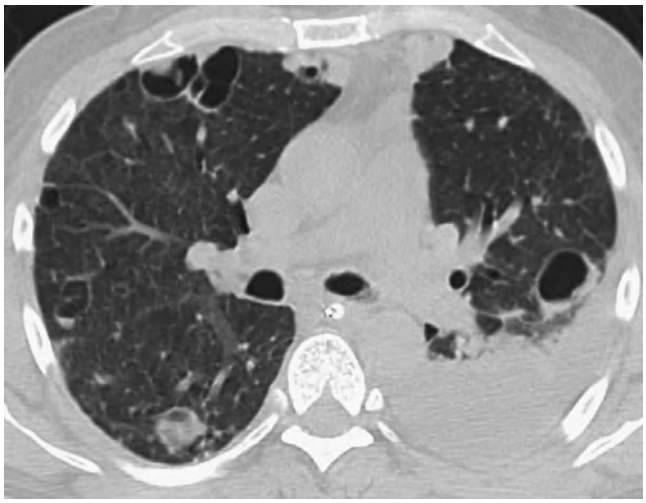

Figure 113-11 Septic emboli. Multiple predominately subpleural nodular opacities of varying sizes and stages in a patient with positive blood cultures for methicillin-resistant *S. aureus* (MRSA) and beta hemolytic *Streptococcus*. These findings are characteristic of septic emboli. There is a wide disparity in the size and stage of infection; some nodules are three times the diameter of others; some nodules are partially solid; others are partially fluid filled; and others are totally gas-filled, and have thin walls. There is a layered left pleural effusion likely due to unroofing of an infected cavity, a common feature.

(MAC), *M. tuberculosis*, *Cryptococcus* sp., *Blastomyces* sp., *Histoplasma capsulatum*, *C. immitis*, or *Aspergillus* spp. (Fig. 113-1). In heart, lung, and other solid organ transplant recipients, nodular pneumonias found shortly after surgery nodular pneumonia is most often due to bacterial infection, especially gram-negative intestinal bacteria. During the initial 3 months after lung transplantation, the risk of CMV pneumonia is high enough that even an uncharacteristic nodular presentation must be considered as possible CMV pneumonia.

Imaging

In intravenous drug abusers nodular pneumonia can indicate septic emboli, particularly when the nodules are multiple, subpleural, and of varying size often from less than 10 mm in diameter to greater than 3 cm. Ultimately, the nodules cavitate late in the course of disease. Sometimes a feeding vessel can be seen extending to a nodule (Fig. 113-11).

Among severely immunocompromised patients with a compatible illnesses suffering from hematological malignancy with severe or prolonged neutropenia, or allogeneic hematopoietic stem cell transplant recipients, the presence of one or "halo signs," i.e., macronodules (greater than or equal to 1 cm) with perimeter of ground-glass, is virtually diagnostic of early angio-invasive pulmonary aspergillosis (Fig. 113-12). Pre-emptive targeted treatment of such patients based on the presence of a halo sign is associated with improved treatment response and outcome. It is notable that 90 percent of such patients with angioinvasive aspergillosis have one or more macronodular lesions with or without halo signs at

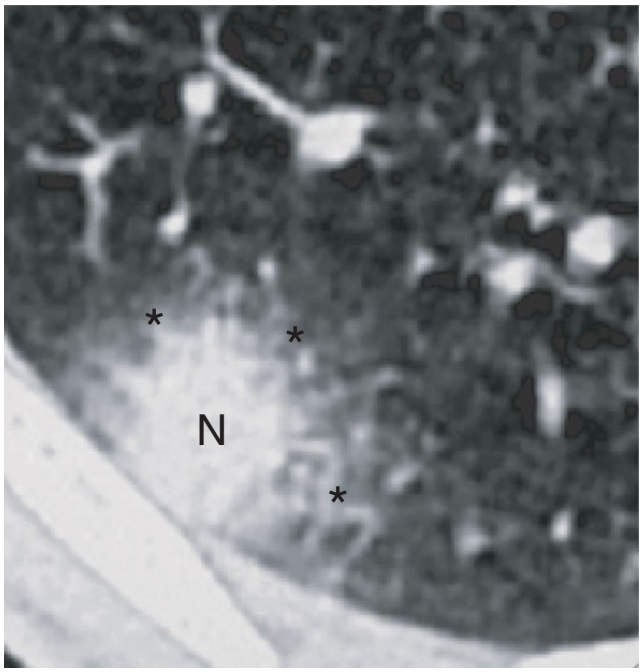

Figure 113-12 Halo sign in angioinvasive aspergillosis. CT scan of patient with hematopoietic malignancy and prolonged neutropenia demonstrating a macronodule (N) surrounded by a halo of ground-glass opacity (*) in a patient with angioinvasive aspergillosis.

presentation. Thus, the absence of at least one macro-nodule argues against the diagnosis of angioinvasive aspergillosis. Although other etiologies, such as mucormycosis, may cause halo signs in this group of patients, the prior probability of such infections is very much lower. The air crescent sign is an indicator of late angioinvasive pulmonary aspergillosis, usually after recovery from neutropenia (Fig. 113-13).

Non-Infectious Etiologies

The most common simulators and non-infectious etiologies of nodular pneumonia include bland pulmonary infarcts, granulomatous vasculitis, primary lung cancer, and pulmonary metastases. Often a biopsy is necessary to make the diagnosis.

Micronodular Pneumonia

Overview and Pathogenesis

Micronodular pneumonias are an uncommon but important group of pneumonias. Micronodules are nodules 9 mm or less in diameter, ill- or well-defined, and of random distribution. The most important infectious etiologies of micronodular pneumonia include: (1) miliary pneumonia; and (2) intermediate micronodular pneumonias. These micronodules are generally diffuse, bilateral, and widely distributed. They are variously distributed along the bronchovascular bundles, interlobular septal walls, and costal and interlobar fissural pleural surfaces.

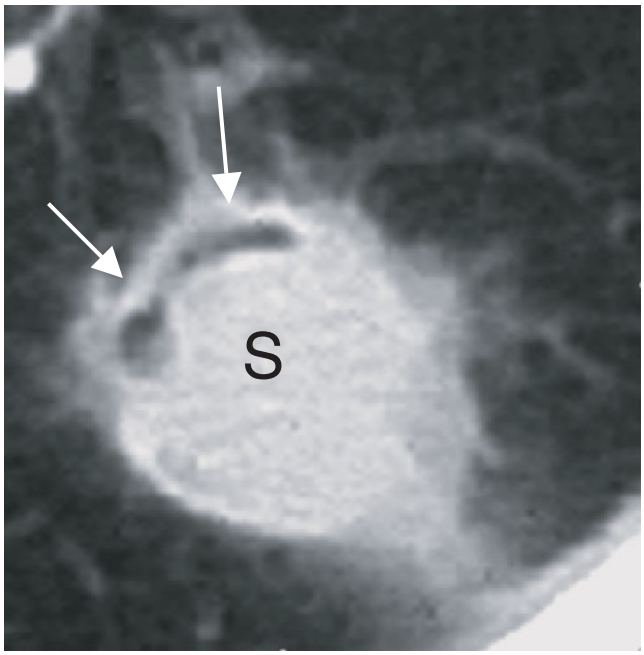

Figure 113-13 Air crescent sign in late angioinvasive aspergillosis. CT scan of patient with hematologic condition late in the course of angioinvasive aspergillosis after recovery from neutropenia demonstrates a cavitary macronodule with an air crescent at 10 to 1 o'clock (arrows) outlining a central necrotic sequestrum (S).

Etiologies

Miliary nodules are random micronodular opacities (1–5 mm) that are associated with a small but important group of disseminated miliary infections, including those caused by disseminated *M. tuberculosis*, non-tuberculous mycobacteria, and fungi (Fig. 113-14).

Imaging

Miliary Nodules

Miliary tuberculosis is the prototypical example of miliary pneumonia that results from lymphohematogenous dissemination. Like bronchogenic tuberculosis, miliary tuberculosis can result from either progressive primary or re-activated post-primary tuberculosis. The numerous 1- to 5-mm randomly distributed nodules of military tuberculosis can usually be detected 3 to 6 weeks after lymphohematogenous dissemination. Some nodules are subpleural in location; some are septal thickening, and some are bronchovascular. Ground-glass opacities may be seen. As the infection progresses, the nodules tend to increase in size and coalesce.

The primary non-infectious etiologies include disseminated hematogenous metastases from cancers of the thyroid, kidney, or the breast. Under other clinical circumstances, miliary nodules may be identified in coal workers pneumoconiosis, silicosis, berylliosis, sarcoidosis and Langerhans' cell histiocytosis, and silicosis, but such nodules tend not to be randomly distributed.

Intermediate Micronodular Pneumonia

These are micronodules are of intermediate size and somewhat larger than those most characteristic of early miliary nodules. They range in average size from 5 to 7 mm. These are often ill-defined. The prototypical viral causes of intermediate micronodule pneumonia are herpes simplex and varicella zoster pneumonias. In the patient with varicella skin lesions, intermediate-sized random lung nodules are virtually diagnostic of varicella pneumonia (Fig. 113-15). This appearance can also be found in hematogenous dissemination of fungal pneumonias, and other late disseminated infections. Intermediate nodules can be caused by bronchogenic tuberculosis, but these are restricted to centrilobular location. Non-infectious causes most often are due to metastatic neoplasms.

Diffuse Opacification Pneumonia

Overview and Pathogenesis

Diffuse opacification pneumonia is a group of pneumonias of variable etiology that may have a diffuse or widespread multifocal bilateral distribution associated with ground-glass opacification, septal widening and/or frank consolidation. Sometimes the lesions are limited to discrete secondary lobules leaving multiple areas of spared lung (Fig. 113-16).

Etiologies

This type of pneumonia can be caused by *Mycoplasma pneumoniae* pneumonia, *Respiratory syncytial virus (RSV), Ebstein-Barr virus (EBV), Herpes Simplex virus (HSV), adenovirus,* and other viruses. These viruses may also cause a wide variety of other imaging types of findings. In pneumonias caused by *Cytomegalovirus (CMV)* diffuse ground-glass opacification heralds a poor prognosis (Fig. 113-17). In *Pneumocystis jiroveci* pneumonia, patchy diffuse ground-glass opacities often demonstrate spared regions, prominent septal thickening, bulla, and thin-walled cysts (Fig. 113-18). Less common causes of diffuse ground-glass attenuation, include infections due to fungi which most often focal or multifocal.

Imaging

The imaging elements of diffuse lung opacification include ground-glass opacification, septal thickening, and a variety of centrilobular airspace opacities. Ground-glass attenuation is intermediate lung opacification that unlike consolidation does not completely obscure underlying pulmonary vasculature. This can result from parenchymal abnormalities that are beyond the spatial resolving power of CT, i.e., alveolar wall inflammation, alveolar wall thickening, partial airspace filling, or a combination of multiple causes, in which extensive bilateral ground-glass opacities progress into complete consolidation. Most infectious causes of diffuse lung opacification may also at different times be multifocal, and less commonly be localized.

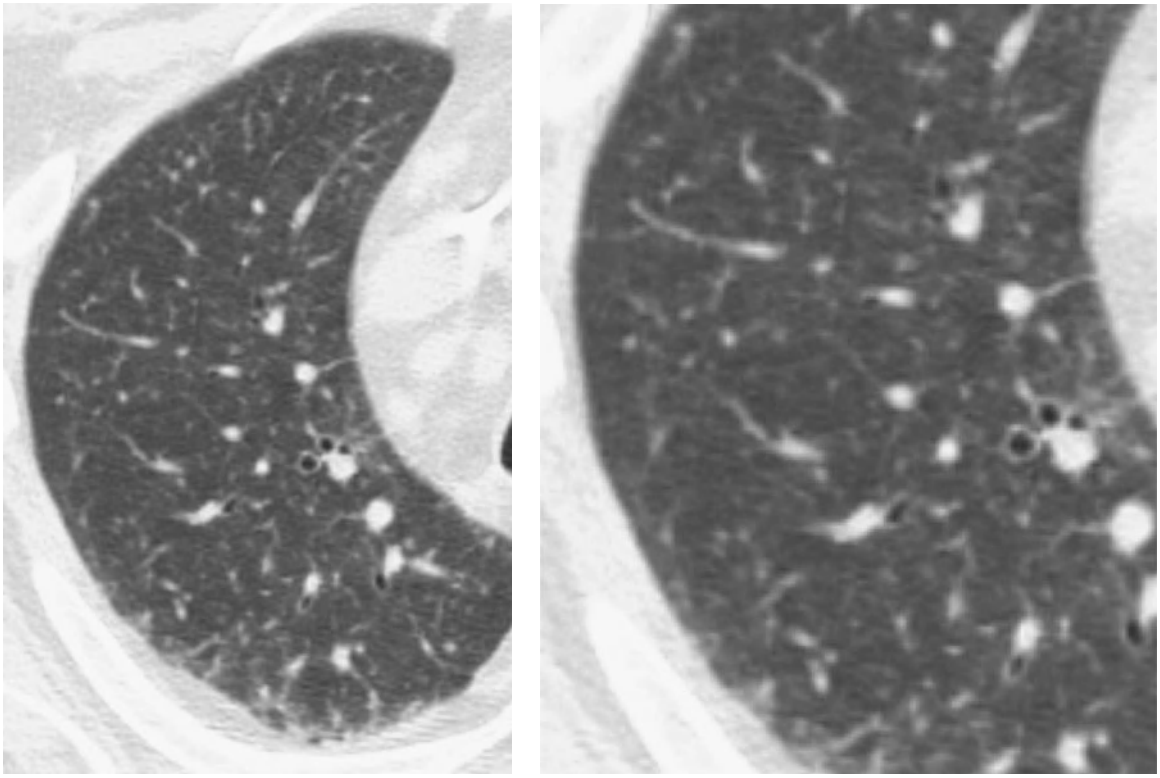

Figure 113-14 Miliary cryptococcal pneumonia. Immunosuppressed 62-year-old man under chemotherapy for metastatic pancreatic carcinoma. Disseminated cryptococcal infection was diagnosed by isolating cryptococcus from bronchoalveolar lavage, and detecting cryptococcus antigen in cerebrospinal fluid. CT scan demonstrates myriad randomly distributed 1- to 3-mm micronodules distributed throughout both lungs. Such miliary micronodules, although not easily distinguished from small end-on vessels on a single CT section, are more obvious when a stack of sections are viewed in rapid succession at which time the micronodules are found to be small spheres, not part of a longitudinal vascular structure.

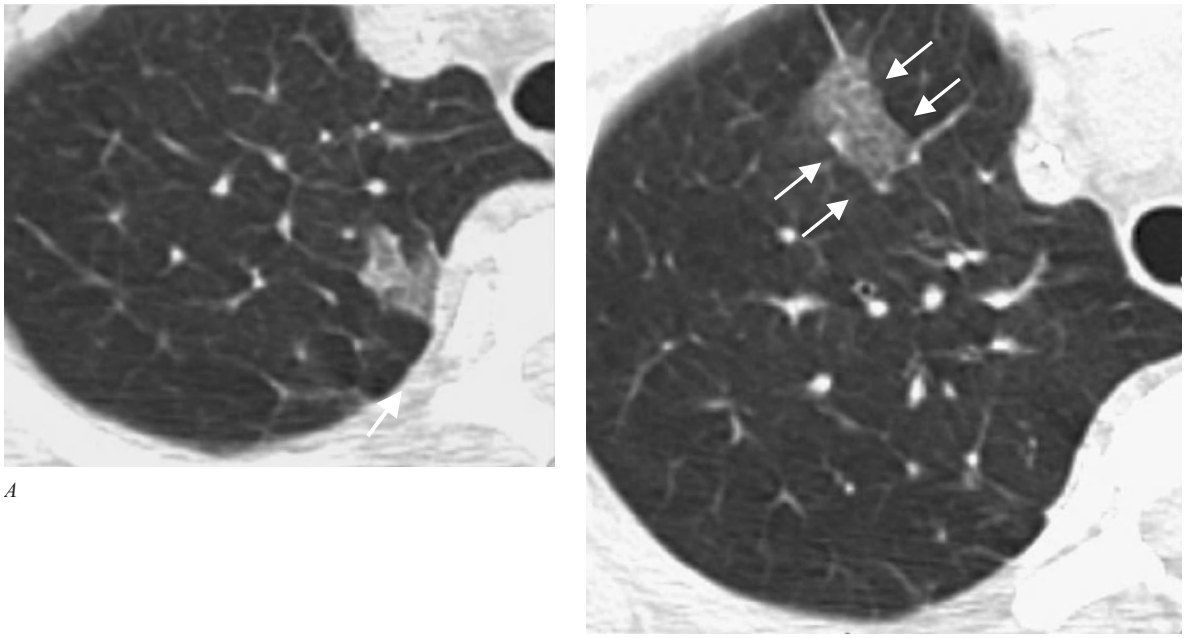
Figure 113-15 Diffuse small nodules in varicella virus pneumonia. Thirty-nine-year-old woman whose son had chickenpox 2 weeks before she developed a new chickenpox lesion on her neck, cough, nausea, vomiting, headache, chills, and malaise. Chest radiograph demonstrates widespread small nodular opacities approximately 5 to 7 mm in diameter. A CT scan was not deemed necessary because of the characteristic radiographic findings of varicella zoster virus (VZV) pneumonia, the skin lesions, and the high clinical likelihood of varicella zoster virus (VZV) infection. The patient rapidly responded to intravenous acyclovir therapy.



A

B

Figure 113-16 Lobular ground-glass opacities in viral pneumonia. Multifocal, bilateral patchy lobular ground glass opacification of secondary pulmonary nodules in the right upper lobe attributed to respiratory syncytial virus (RSV) pneumonia in immunocompromised patient under treatment for metastatic breast cancer. CT scan of the chest demonstrates two of many ground glass opacified secondary pulmonary lobules (*A* and *B*). The flat sides of the lobules indicate the sites of the septal margins of the lobules (arrows). The ground-glass opacity only partly obscures the underlying lung parenchyma.

Non-infectious Etiologies

Non-infectious causes of diffuse opacification include pulmonary edema, drug-induced lung disease, hypersensitivity pneumonia; pulmonary hemorrhage, diffuse aspiration, diffuse alveolar damage, and other diffuse interstitial lung diseases, such as lymphocytic interstitial pneumonia and pulmonary alveolar proteinosis.

Ancillary Findings Associated with Pneumonia

A wide variety of ancillary imaging findings may provide useful additional clues to etiologic causes of pneumonia. These include: atelectasis or other evidence of reduced lung volume; cavitation (which is suggested by lucency within lung

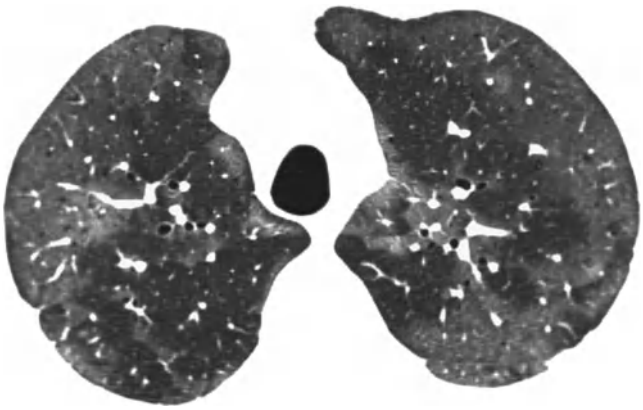


Figure 113-17 Diffuse ground-glass opacity in cytomegalovirus pneumonia. Widespread ground-glass opacity with prominent inter- and intra-lobular septal thickening sparing the anterior lung in an elderly patient with cytomegalovirus pneumonia (CMV) while under radiotherapy for residual chordoma.

Figure 113-18 Diffuse ground-glass opacity *Pneumocystis jiroveci* pneumonia. Diffuse ground-glass opacification predominantly involving the subpleural (cortical) lung sparing the central lung at the time of first detection of *Pneumocystis jiroveci* pneumonia in a patient with advanced AIDS.

opacity); or pleural effusion (which is suggested by a meniscus contour or smooth thickening of the pleural space); pericardial effusion or pericarditis (which is suggested by pericardial widening or enlargement of the cardiac silhouette); and mediastinal and/or hilar or perihilar lymphadenopathy.

Atelectasis

Atelectasis refers to airlessness of a portion of lung. Crowded air-filled bronchi, and appropriate shift of lung contours toward the area of atelectasis may be diagnostic, e.g., pleural fissures, mediastinum, and diaphragm. When atelectasis is due to total airway occlusion, such as in proximal bronchogenic carcinoma, mucous plug, or aspirated foreign body, air bronchograms are usually absent. Atelectasis is a common feature of bronchopneumonia; it is not usually a prominent feature of peripheral airspace consolidation pneumonia. Atelectasis per se needs to be differentiated from pneumonia.

Bronchiectasis/Bronchiolectasis

Bronchiectasis/bronchiolectasis refers to abnormal dilatation of the airway. It implies air- or fluid-filled and widened tubular, varicose, or cystic. Bronchiectasis is recognized by an airway diameter significantly greater than its paired pulmonary artery. Varicose and cystic bronchiectasis implies destructive pneumonia or other inflammation, such as due to granulomatous pneumonia, or prior radiation therapy. In acute pneumonia, cylindrical, often "reversible" bronchiectasis may be identified.

Cavitation

Cavitation refers to abnormal non-anatomic lucency of lung usually within a lung opacity that makes up its wall. It is often devoid of normal internal vasculature. In uncomplicated bullous lung disease no significant wall thickness is present, and residual internal vasculature may be identified. Necrotizing cavitation may be caused by aspiration or pneumonia due to gram-negative intestinal bacteria, and mixed anaerobic oral flora. Cavitation suggests aggressive bacterial infections infection by bacteria such as *S. aureus* and gram-negative bacilli, and granulomatous infections, such as due to mycobacteria and fungi.

Lymphadenopathy

Lymphadenopathy is inferred on plain film radiography by unilateral or bilateral nodular enlargement of the mediastinum and hilar regions. On plain film radiography these findings often cannot be differentiated from vascular enlargement. Contrast-enhanced CT is much more sensitive than non-contrast CT scan in the detection of lymph node enlargement.

In general, mediastinal adenopathy can be found in a wide variety of different types of pneumonia associated with sympathetic or complicated effusions, but it is especially common in patients with primary infection due to *M. tuberculosis*. The absence of acquired specific cellular immunity to *M. tuberculosis* is responsible for the peripheral airspace consolidation and lymphadenopathy that are characteristic of primary tuberculosis. Lymphohematogenous dissemination results in characteristic mediastinal and hilar adenopathy with low-density necrotic centers, and rim enhancement in contrast-enhanced CT. Lymphadenopathy is also found in atypical mycobacterial infection; fungal infection due to *Histoplasma capsulatum* and *Coccidioidomycosis immitis*; viral infection due to HIV, CMV, and EBV; and bacterial infection associated with sepsis, e.g., pneumonia due to staphylococci, beta-hemolytic streptococci, and tularemia. In *P. jiroveci* pneumonia, lymphadenopathy often calcifies.

Non-infectious causes of hilar and mediastinal lymphadenopathy include bronchogenic carcinoma, lymphoma, sarcoidosis, metastatic cancer, lymphatic spread of tumor, pneumoconiosis, such as due to silica (in which case "eggshell" calcification, small lung nodules, and conglomerate masses may be seen), and interstitial pulmonary fibrosis. In congestive heart failure non-pathologic lymph nodes can significantly enlarge, and reduce in size after diuresis.

Pleural and Pericardial Abnormality

Pleural fluid is identified by abnormal fluid separation of the visceral and parietal pleural surfaces. It is likely to be free flowing if it is gravitationally dependent, and tapers out smoothly against gravity. Uniform meniscal opacity is usually identified in gravitationally dependent lung regions, where it tends to separate the lung from the ribcage. Loculation is suspected when the fluid localizes in non-gravitational regions of the pleural space. Pleural fluid is the only radiographic finding that has thus far been found to be an independent predictor of outcome of CAP pneumonia. For this reason pleural effusion has been incorporated into a Pneumonia Severity Index. Pleural fluid accumulation is more likely to indicate progressive and/or necrotizing pneumonia.

Pleural thickening and empyema are higher than water density on CT. Abnormal enhancement of both the visceral and parietal pleura is an imaging sign of active pleuritis. Empyema fluid may have near-normal water density or increased density. Pleural hemorrhage tends to have high density on non-contrast–enhanced CT studies.

Pneumothorax in the context of pneumonia implies a bronchopleural fistula (BPF) usually from cavitating pneumonia. CT scan can help localize the source of a BPF, as well as detect a small pneumothorax.

Pericardial effusion, when large, can be suspected on plain-film radiography by a new globular cardiac silhouette, short-interval cardiac enlargement, or abnormal fluid density thickness between the visceral and parietal pericardium on the lateral chest radiograph. On CT pericardial fluid can be identified by fluid density (or higher than fluid density in the case of empyema or hemorrhage) within the pericardial sac. Active pericarditis is indicated by abnormal thickening and enhancement of the visceral and parietal pericardium.

CONCLUSIONS

Radiologic imaging is an essential diagnostic tool for the diagnosis and management of pneumonia. Uncommonly, under special clinical circumstances, imaging findings can be virtually diagnostic of a specific etiology of infection. However, in most cases imaging only narrows the range of likely etiologies of pneumonia, and provides insight into its pathogenesis by categorizing its predominant imaging features and integrating these findings into the prior clinical probabilities. Radiologists need to be aware of each patient's pertinent background information to provide insightful opinions regarding imaging findings.

The Pathology of Pulmonary Infection

Richard Kradin

The pathology of lung infection reflects a composite of host-pathogen interactions. Distortions in pulmonary anatomy, decreased mucocilary clearance, and local and systemic abnormalities in cellular and humoral immune response all predispose to pulmonary infection. Although clinical history, radiographic findings, and noninvasive sampling of secretions often establish a diagnosis of infection, only tissue sampling affords the possibility of directly assessing pulmonary infection. As biopsy procedures have become progressively less invasive, there has been a tendency to focus primarily on the identification of the causative infectious agent as the sole end point of the diagnostic process. However, this goal potentially ignores the benefits of evaluating host-pathogen interactions.

This chapter reviews the basics that clinicians and pathologists must know about lung tissue sampling, the optimal diagnostic work-up of the lung biopsy, and the histopathology of infection.

I. THE APPROACH TO TISSUE SAMPLING

The optimal method of sampling infection (Table 114-1) is a function of host immune status, where the infection is located in the lung, and on whether it is localized or diffuse. Infections that cause diffuse pulmonary infiltrates in an immunosuppressed patient with HIV-1 infection often can be accurately diagnosed by the induction of sputum or by bronchoalveolar lavage (BAL). This is particularly true when the microbial burden is large, as it often is in *P. jirocevi* and mycobacterial infections. Noninvasive procedures are less sensitive than biopsy in diagnosing pulmonary fungal infections, e.g., aspergillosis, and do not differentiate between noninvasive and invasive disease. Lung biopsy is also indispensable in distinguishing infection from noninfectious lung injury in patients receiving chemotherapy, radiation, or immunosuppressive agents. Whereas clinicians tend to favor minimally invasive

Table 114-1

Approach to the Isolation of Pulmonary Microorganisms

Expectorated sputum
Induced sputum
Bronchoalveolar lavage
Fine-needle aspirate (1 mm)
Bronchial biopsy (1–3 mm)
Transbronchial biopsy (1–3 mm)
Transbronchial needle biopsy (1 mm)
Video-assisted thoracoscopic biopsy (2–3 cm)
Open-lung biopsy (2–3 cm)

techniques in the sampling of lung tissue, most pathologists favor generous tissue samples. In support of the latter preference, it may be argued that diagnoses based on larger tissue samples are more reliable, afford the opportunity to establish additional treatable diagnoses, and lead to more finely crafted therapeutic interventions.

Transbronchial Biopsy

The optimal approach to lung biopsy depends on the specific clinical features of the case. Sampling error is a serious pitfall in pulmonary pathology. Since the lungs have roughly the surface area of a tennis court, diagnostic accuracy is inversely related to the size of the biopsy. Transbronchial biopsy (TBB) yields tissue fragments of 1 to 3 mm in diameter and preferentially samples peribronchiolar parenchyma of the lung. The TBB is particularly effective in sampling diffuse peribronchiolar granulomatous and neoplastic disorders. Despite limitations imposed by its size, it has a high yield in identifying infection when pulmonary infiltrates are diffuse, e.g., in diffuse alveolar damage due to viral pneumonia but is far less reliable in the diagnosis of localized parenchymal infections.

Despite its advantages, the findings in TBBs are often nonspecific and even misleading. Peripheral lesions in the lung are difficult to sample by TBB and samples obtained by this approach often prove to be nondiagnostic or nonrepresentative. For example, an area of organizing pneumonia can represent a tissue response to a focus of infection or it may reflect noninfectious etiologies, including treatment effects, aspiration, or cryptogenic organizing pneumonia. The findings in a TBB must always be carefully correlated with clinical and radiographic data, but even then there is risk that they will be inaccurately interpreted.

Fine-Needle Aspiration Biopsy

CT-guided fine needle aspiration biopsies have a high yield in the diagnosis of peripheral nodular infiltrates. Samples may be semi-liquid or include a 1-mm core of tissue. The procedures are generally performed with the assistance of a cytotechnologist, so that rapid diagnoses can be proffered at the bedside from the preparation and examination of stained smears. FNA is helpful in isolating the cause of infection and may enable the cytopathologists to suggest the pattern of inflammation based on the types of inflammatory cells, and the presence or absence of fibrin, necrosis, and elastic fibers in the sample. However, the limited sampling often does not provide sufficient tissue to reliably assess the inflammatory response of the host.

Transbronchial Needle Aspiration Biopsy

Transbronchial needle aspiration biopsies of regional lymph node groups generally add little to the diagnosis of pulmonary infection, in part, because nonspecific reactive lymphadenitis is common but also because the procedure yields artifacts that can present diagnostic difficulties for the surgical pathologist. However, they may have a role in diagnosing infection in patients with AIDS, since approximately 50 percent of patients with tuberculous lymphadenitis were successfully diagnosed using this approach.

Video-Assisted and Open Thoracoscopic Biopsy

Video-assisted thoracoscopic lung biopsies have largely replaced procedures involving open thoracotomy. This approach is associated with less overall morbidity and allows direct access to widely separated lung segments. The procedure yields wedge biopsies of 2 to 3 cm with little artifactual distortion. Although it may be bucking the current clinical tide to argue for larger rather than smaller biopsies, the slight potential increase in morbidity associated with VATS lung biopsy is often counterbalanced by less discomfort than TBB, increased diagnostic accuracy, and less doubt concerning the subsequent treatment.

HANDLING OF BIOPSY TISSUES

Proper handling of the lung biopsy is critical for obtaining the highest diagnostic yield from tissue samples (Fig. 114-1). The examination of touch imprints of lung biopsy tissue is a simple way for identifying organisms rapidly. At least 10 touch imprint slides should be prepared from areas of pulmonary consolidation. These can be stained rapidly for bacteria, mycobacteria, and fungi, in the surgical pathology suite or the microbiology laboratory. Concomitantly, portions of

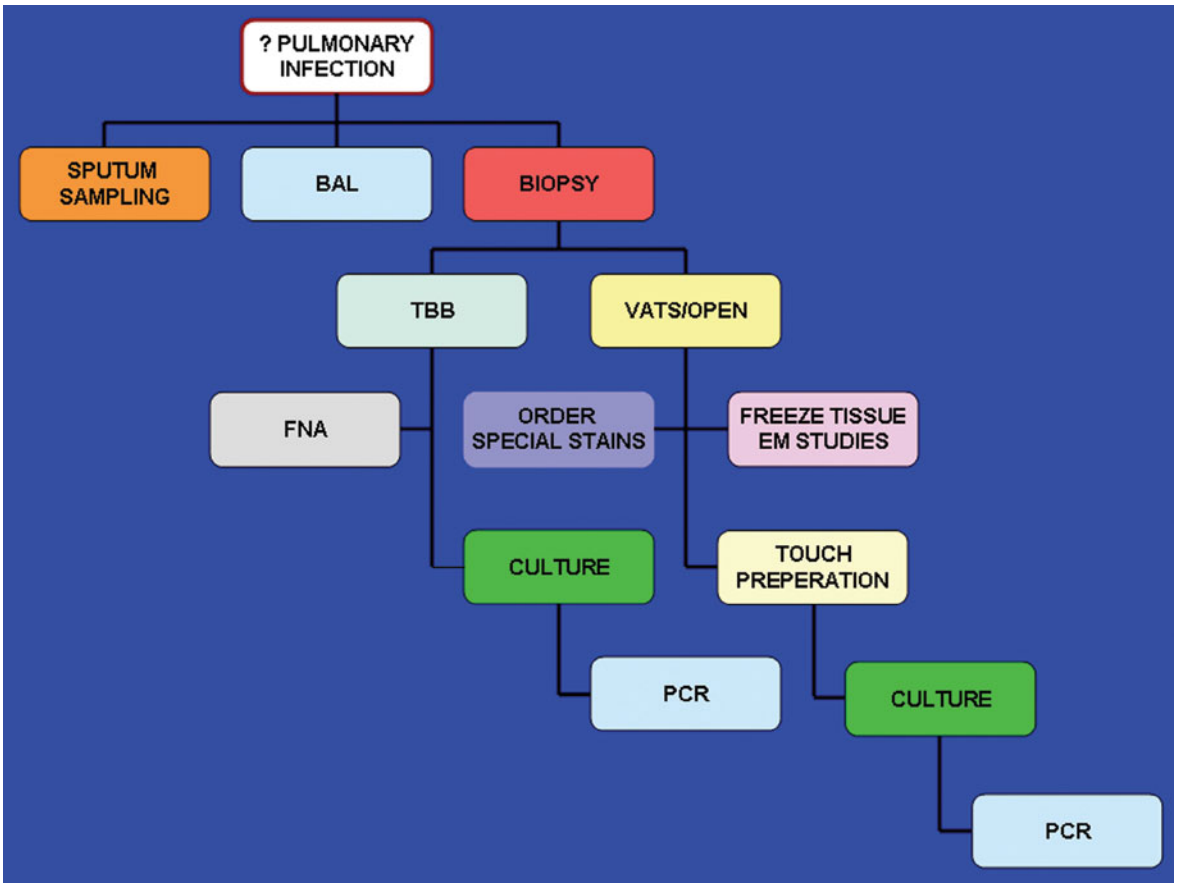

Figure 114-1 The diagnostic work-up of pulmonary infection.

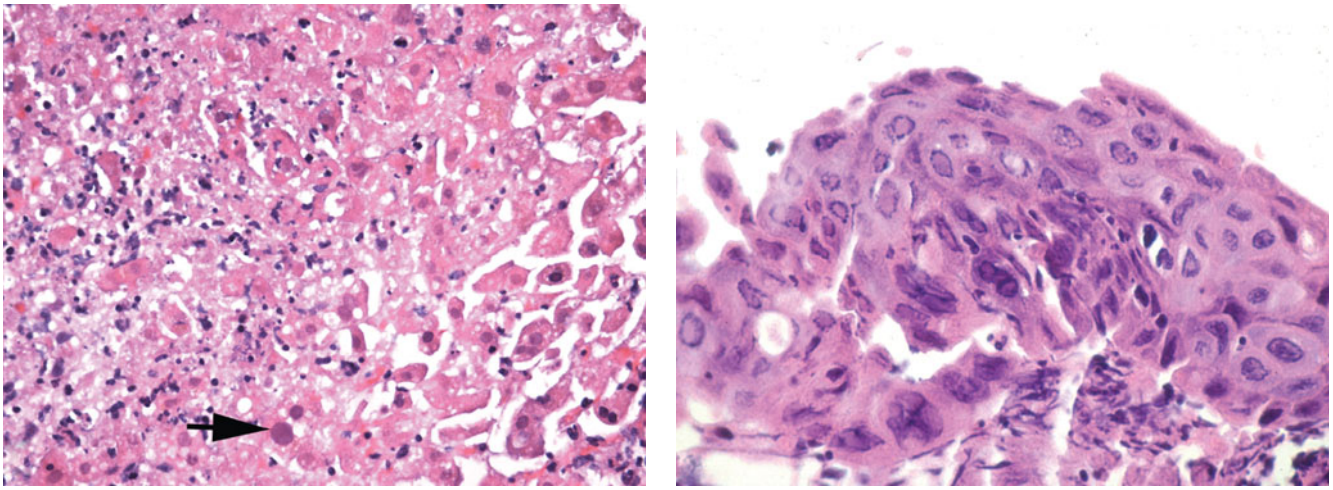
a large biopsy (VATS or open) or separate biopsies (TBB or FNA) should be harvested for culture, ultrastructural analysis, and polymerase chain reaction (PCR) assays. In preparing lung tissue for culture, it should be finely minced rather than crushed, since some hyphal fungi, e.g., *Zygomyces* sp., fail to grow in culture after the tissue has been macerated. For VATS or open lung biopsies, the lung should subsequently be inflated with 5 percent formalin via a 23- to 25-gauge needle, in order to optimize the histology of the paraffin-embedded lung sections.

The pathologist who receives the lung biopsy for processing must ascertain which diagnostic tests were sent by the surgeon and be prepared to harvest additional samples for tests that may have been overlooked. It is substandard care for either a surgeon or a pathologist to place a lung biopsy directly into formalin fixative, without first considering the possibility of infection. If there are doubts concerning which diagnostic tests to order, the amount of tissue required for a test or how best to transport the specimen to the laboratory, brief discussions with the hospital microbiology laboratory or an infectious disease specialist will promptly eliminate them.

Preparing Histopathology Sections

The scarcity of microorganisms in tissue biopsies creates a diagnostic challenge for the pathologist. In addition, previous antibiotic treatment can sterilize inflamed tissues, making it difficult to identify the original cause of the infection in situ. For these reasons, an adequate sample of tissue obtained by biopsy is critical for the microscopic identification of infectious agents. The surgical pathologist must be prepared to review multiple sections in the routine assessment of infection. In some instances, it may be necessary to examine literally scores of sections in order to identify an organism in situ. Too often, busy surgical pathologists may conclude that the diagnosis of infection is primarily in the realm of the microbiology laboratory or that the labor-intensive effort required to identify organisms in situ is not cost effective. This attitude is to be discouraged, since it is incorrect and limits the practice that is required in order to acquire expertise in the identification of microorganisms in situ.

Certainly, if the microbiology laboratory has previously identified the offending pathogen, it may not be necessary to go to extraordinary lengths in order to duplicate its results. But in instances in which cultures were not obtained, or when pathogens require weeks to grow in culture, e.g., mycobacteria, or the organism isolated in the laboratory may represent a commensal or contaminant, the pathologist must be ready to undertake a detailed examination of multiple tissue sections. Since antimicrobial drugs have become increasingly selective, it is currently suboptimal to render a nonspecific



A B

Figure 114-2 *A*. The lung shows a miliary focus of necrosis and fibrin deposition. Intranuclear inclusions (arrow) of herpesvirus-1 are present. *B*. Note the presence of multiple amphophilic intranuclear inclusions of Herpesvirus-1 infection in the trachea of a patient receiving chronic ventilator support.

diagnosis of, e.g., "necrotizing granulomatous inflammation," without a concerted effort to identify the offending pathogen.

The pattern of pulmonary inflammation suggests the primary route of infection in the lung. For example, *Herpesvirus-1* may either show a miliary pattern of fibrinoid necrosis (Fig. 114-2) in patients with viremia, or primarily affect the tracheobronchial epithelium in patients who have been intubated for prolonged periods. Microbes tend to be compartmentalized in inflamed tissues, and substantial effort can be wasted in searching for organisms at high magnification, in areas of the tissue section where they are not likely to be found. For example, mycobacteria and fungi are almost always localized in areas of necrotic tissue, and it is unusual to find them elsewhere in the biopsy. Organisms, such as *Rickettsia* sp. and *Bartonella* sp. are angiotropic, and attention should be focused on foci of perivascular inflammation. Virus tends to target specific areas of the lung and certain types of cells.

Histochemical Stains

A number of histochemical stains are available for the demonstration of microbes in situ and their proper application can yield accurate and specific diagnoses in many cases (Table 114-2). However, the limits of this approach must be recognized, and the gold standard, in most cases, remains the isolation and biochemical or molecular identification of an organism.

Hematoxylin & Eosin

Most of the stains to be discussed in this chapter are widely available in pathology laboratories. However, if only one was to be chosen, it would be the standard hematoxylin and eosin (H&E) stain. Table 114-3 lists the diagnoses that can be established reliably by H&E staining, without the benefit of additional methods. They include cytopathic viral infections, most fungal infections, and all parasites.

Although it is not possible to speciate bacteria into gram-positive or -negative subsets by the H&E stain, bacterial colonies often can be identified by this approach. Most fungi are visible by H&E, with the notable exception of *Histoplasma capsulatum;* and the tinctorial properties of the fungi can be helpful in speciating. For example, the cell walls of *Zygomyces* sp. stain intensely basophilic with H&E (Fig. 114-3), and the yeast of *Candida glabrata* show prominent amphophilic staining.

Tissue Gram Stain

The tissue gram stain (Brown-Hopps and Brown-Brenn) identifies most bacteria and some fungi in tissue sections. It also can be used to demonstrate the spores of microsporidia. Gram-positive organisms stain a deep magenta, whereas gram-negative bacteria are pale pink (Fig. 114-4). For this reason, gram-negative organisms can easily be missed in a low-power cursory screening of gram-stained sections. The phenomenon of gram stain-variability, in which colonies of gram-positive organisms show a range of staining from dark blue to pink, is common and can give the false impression of "mixed flora." In such instances, only culture can reliably distinguish the actual additional presence of gram-negative bacteria. Although most fungi are weakly gram positive, most *Candida* sp. stain intensely positive, a fact that can be used to advantage in their identification.

Gomori Methenamine Silver

Gomori methenamine silver (GMS) is the stain of choice for identifying fungi in tissue sections. Both fungal yeast and

Table 114-2

Histochemical Staining Characteristics of Microbes

Organism	Staining Characteristics
Virus	
Influenza	No cytopathic change
SARS (Coronavirus)	No cytopathic change
Adenovirus	H&E (smudge cells), IHC
Cytomegalovirus	H&E (intranuclear and cytoplasmic inclusions) IHC; PAS and GMS (intracytoplasmic inclusions)
Herpes virus	H&E (intranuclear inclusions); IHC
Measles	H&E (intranuclear inclusions, polykaryons)
Respiratory	H&E (polykaryons); IHC syncytial virus
Parainfluenza	H&E (intracytoplasmic inclusions)
Bacteria	
Gram-positive	Tissue gram, GMS (all)
Gram-negative	Tissue gram, GMS (some)
Legionella	Silver impregnation
Nocardia	Tissue gram, GMS, modified ZN
Actinomyces	Tissue gram, GMS
Mycobacteria tuberculosis	ZN and mod ZN, PCR
Atypical mycobacteria	Mod ZN, ±ZN, PCR
Fungi	
Histoplasma	GMS, PAS
Cryptococcus	H&E, GMS, PAS, mucicarmine; Fontana, IHC
Blastomyces	H&E, GMS, PAS, mucicarmine (weak)
Coccidioidomycosis	H&E, GMS, PAS
Candida	H&E, GMS, PAS, gram-stain; IHC
Aspergillus	H&E, GMS, PAS, IHC
Zygomyces	H&E, GMS, PAS
Pseudeallescheria	H&E, GMS, PAS
Alternaria and dermatiacious fungi	H&E, GMS, PAS, Fontana
Parasites	
Protozooa	H&E, PAS, gram stain (microsporidia); IHC (toxoplasma)
Metazoa	H&E, trichrome stain
Echinococcus	GMS in chitinous wall, modified ZN (hooklets)
Paragonimiasis	Ova birefringent
Schistosomiasis	Lateral and terminal spines stain with modified ZN

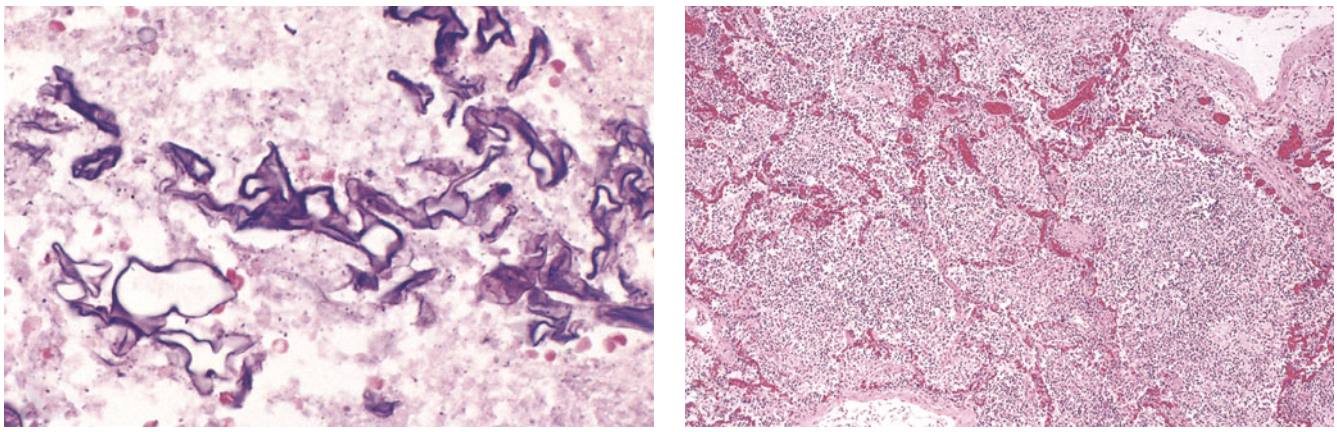
hyphae stain intensely with GMS (Fig. 114-5). However, identification of speciating fungi in tissue sections is a challenging morphologic task (Table 114-4). Identification is based primarily on size, branching pattern, and mode of reproduction. Hyphal organisms, e.g., *Aspergillus* sp., *Pseudallescheria* sp., *Fusarium* sp., and the *Zygomyces* sp. are particularly difficult to distinguish based solely on morphology, especially when fragmented, and immunohistochemical methods or culture confirmation are required (Fig. 114-6). Yeast forms are distinguished by size, pattern of budding, and affinity for special stains.

The GMS stain is generally counterstained with methyl green, which highlights the grey-black staining of fungi.



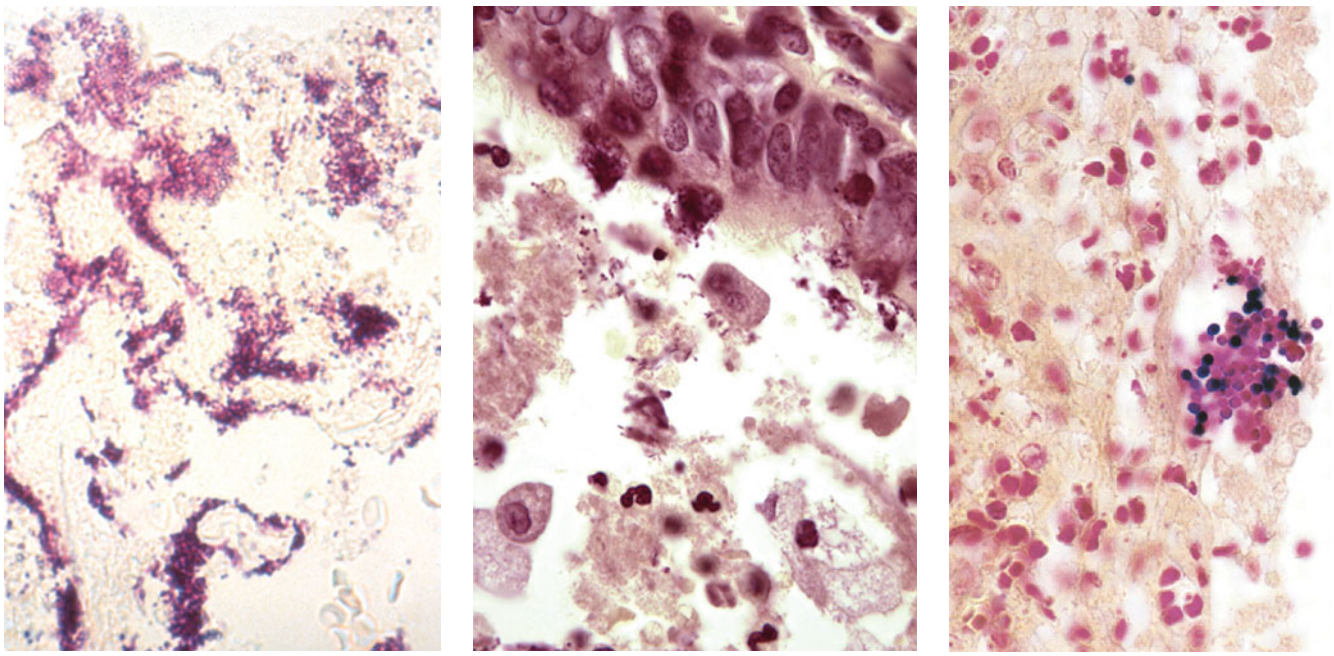
A *B*

Figure 114-3 *A*. The broad pauciseptate ribbon-like hyphae of *Zygomyces* (mucor) stain intensely basophilic with H&E. *B*. The 3 to 4 μM yeast of *C. glabrata* (torulopsis) show amphophilic staining with H&E.

However, this does not allow for optimal visualization of pulmonary anatomic structures or assessment of the inflammatory response of the host. When desirable or necessary, the GMS can be counterstained with H&E. This technique diminishes modestly the sensitivity of fungal identification in situ, but greatly facilitates localization within the lung (Fig. 114-7).

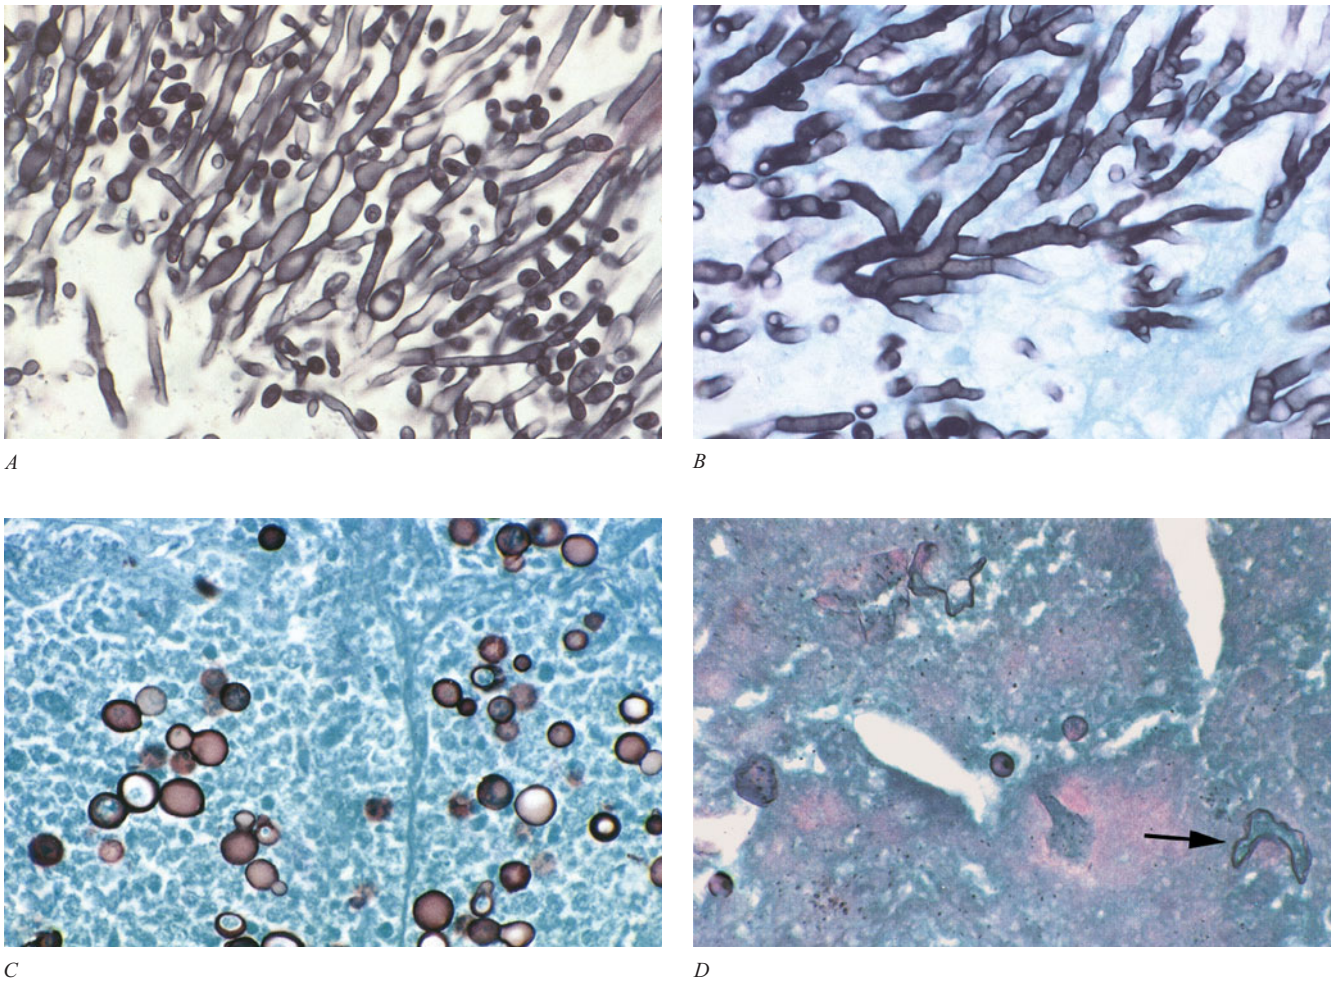
In addition to staining fungi, GMS blackens gram-positive bacteria and some encapsulated gram-negative bacteria, e.g., *Klebsiella* sp. and *H. influenzae*. Unfortunately, the stain also reacts with anthracotic pigment, microcalcifications, and hemosiderin, complicating the distinction between bacteria and nonbacterial structures. The identification of bacteria by GMS should be confirmed and complemented by tissue gram stain.

Most pathologists recognize that GMS reacts with both *Actinomyces* sp. and *Nocardia* sp.; however, this is not a specific feature of these organisms but instead reflects the fact that they are gram-positive filamentous bacteria. The GMS stain adds little to their specific identification but does enhance



A *B* *C*

Figure 114-4 *A*. Colonies of magenta staining gram-positive cocci line the alveoli in a lethal case of streptococcal pneumonia. *B*. Gram-negative rods are seen in the lumen of a bronchiectatic airway in a patient with cystic fibrosis and *Burkholderia cepacia* infection. *C*. The yeast (blastoconidia) of *C. parapsilosis* show gram-variable staining.



A *B*

C *D*

Endosporulation is not obvious.

their visibility in tissue sections. *Actinomyces* sp. are invariably seen within granules lined by granulohistiocytic inflammation, often highlighted by the eosinophilic staining of the Splendore-Hoepllei phenomenon (Fig. 114-8). *Nocardia* in the lung are rarely localized to granules, and unlike *Actinomyces* sp., they are generally weakly acid-fast positive. GMS reacts variably with mycobacteria. The intracellular inclusions of cytomegalovirus (CMV)-infected cells are GMS-positive and must not be confused with intracellular *Histoplasma capsulatum*.

Periodic Acid Schiff

Many pathologists prefer the periodic acid Schiff (PAS) stain with diastase digestion for the identification of fungal forms. However, PAS should be used primarily to complement GMS, and not as a first-line screening tool, since the latter is more sensitive. However, PAS can add important morphologic details that assist with identification of fungi (Fig. 114-9). PAS stains the cytoplasm of *Entamoeba* intensely but obscures the karyosome, a feature that is required for accurate diagnosis. The PAS stain also demonstrates the intracellular bacilli of *Trophyrema whipelli* (Whipple's disease bacillus).

Silver Impregnation Techniques

Silver impregnation techniques, including the Warthin-Starry, Steiner, and Dieterle stains, are distinguished by their capacity to blacken *all* eubacteria, including mycobacteria. In practice, this stain is used to identify bacteria that cannot be visualized by tissue gram stain. This includes *Legionella* sp., *Bartonella* sp., and spirochetes (Fig. 114-10).

Mucin Stains

Mucicarmine stains *Cryptococcus* sp. (Fig. 114-11). The central organism does not stain and the capsule is stained red. Capsule-deficient variants generally infect hosts who can mount a granulomatous response. When yeast forms meet the

Table 114-4

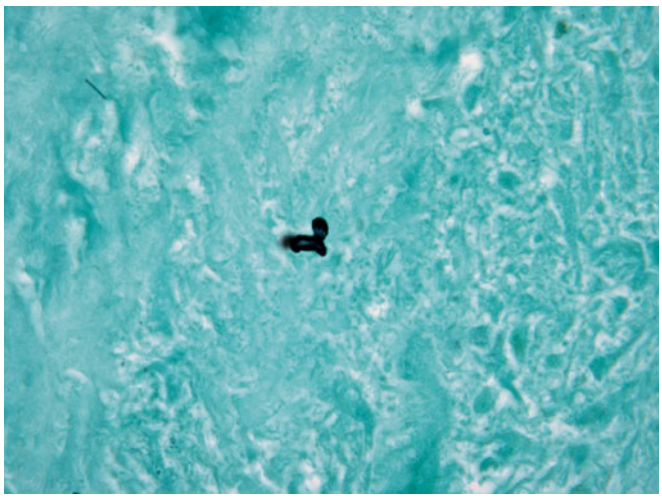
Fungal Identification in Tissue

Organism	Size (Width μM)	Defining Morphology
Histoplasma capsulatum	2–5	Narrow-neck bud
Cryptococcus neoformans	5–20	Narrow-neck bud
Blastomyces dermatitides	15–30	Broad-based bud
Candida glabrata	3–5	Budding, no pseudohyphae
Candida sp.	2–3	Yeast, pseudohyphae, hyphae
Aspergillus sp.	3–5	Acute-angle branching, septate, conidial head
Zygomyces spp.	5–8	Right-angle branching, ribbons, pauciseptate
Pseudallescheria sp.	3–4	Acute-angle branch, septate, terminal chlamydospore, pigmented conidia
Fusarium sp.	4–5	Acute and right-angle branch, septate, narrowed branch points
Coccidioides immitis	20–200	Endosporulation

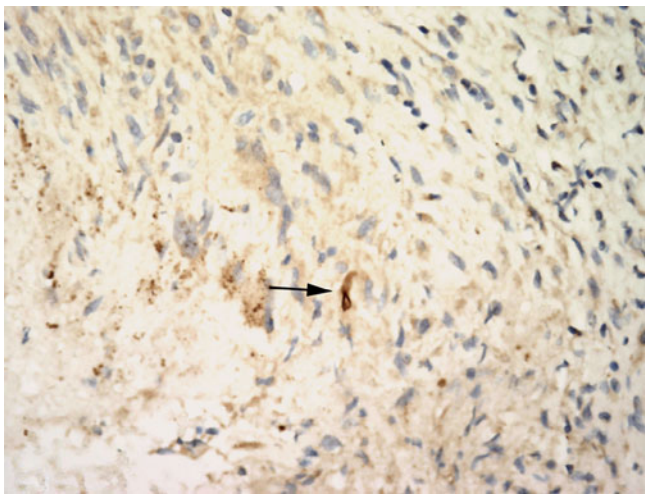
size and morphologic criteria of *Cryptoccocus* on the GMS and PAS stains but do not react well with mucin stains. A Fontana-Masson stain will demonstrate the premelanin substances expressed within the cell wall by all cryptococci. A careful examination of the mucicarmine stain will generally reveal a rim of weak staining, even in the capsule deficient organisms. Fontana-Masson is helpful in demonstrating dermatiacious fungi, when pigment is not convincingly discerned with H&E.

Acid-Fast Stains

The Ziehl-Neelsen (ZN) stain and its modifications are useful in the identification of mycobacteria in tissue sections.



A



B

Figure 114-6 A patient with chronic granulomatous disease and lung nodule. Lung biopsy showed (*A*) fragmented hyphal form with stubby right angle buds that were impossible to speciate with confidence with GMS. *B*. Immunostain for *Aspergillus sp.* was positive (arrow) and the microbiology laboratory isolated *A. terreus*.

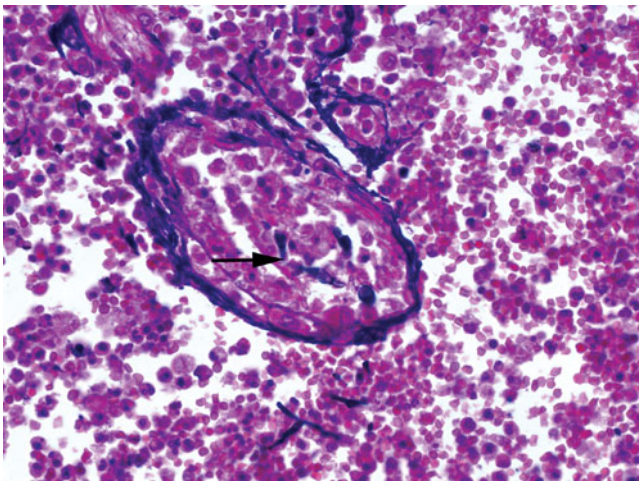


Figure 114-7 Patient with disseminated trichosporon infection. GMS-H&E shows hyphae (arrow) in a blood vessel with surrounding hemorrhage. This preparation is helpful when there is doubt concerning the localization of organisms in the routine GMS-methyl green preparation.

M. tuberculosis stains avidly with ZN. Mycobacterial organisms vary in length and are often curved and beaded (Fig. 114-12). Modifications of the ZN (Fite-Farraco or Putt) can help to identify organisms that fail to stain following strong decolorization by acid. This includes some atypical mycobacteria and *M. leprae.* The morphology of the mycobacteria is generally not diagnostic; however, *M. kansasii* characteristically shows prominent "cross-linking" due to variable uptake of stain. As noted, *Nocardia* sp. generally stain with the modified ZN, a feature that can help to differentiate this organism from *Actinomyces* sp. The hooklets of *Echinococcus* sp. stain with the modified ZN; so do the shells or spines of *Schistosoma* sp.

Immunohistochemical Techniques

A variety of immunohistochemical techniques are currently available for the identification of organisms in tissue (Table 114-5). Unfortunately, the number of commercially available stains for specific organisms is limited. A large panel of specific reagents is available through consultation with the Pathology Division of the Center for Disease Control in Atlanta, GA, or other regional medical centers. Most antimicrobial immunostains can be applied to either frozen or formalin-fixed and paraffin-embedded tissues. Protein nucleotide agglutination (PNA) represents a new and potentially important breakthrough in the localization of microorganisms in tissue sections.

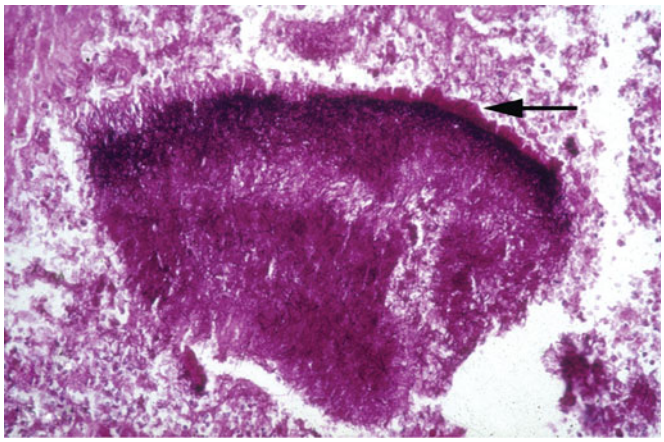
Electron Microscopy

Ultrastructural examination can be adopted for the identification of microbes in tissue. The limiting factors in this approach include sampling and expense. Whereas ultrastructural examination has largely been replaced primarily by immunohistochemistry, it can still assist in the morphologic identification of virus and other organisms. In addition, when questions remain concerning the veracity of light microscopic findings, areas of interest can be excised from the paraffin block and examined by electron microscopy. Most organisms can be identified even though fixation and paraffin embedding procedures may be suboptimal.

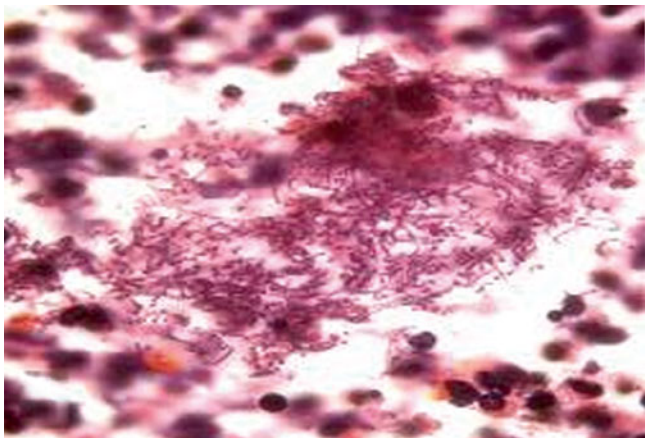
PATTERNS OF PULMONARY INJURY IN INFECTION

Pulmonary Host Response

Before examining the patterns of inflammation that occur in pulmonary infection, it may be helpful to summarize the basic

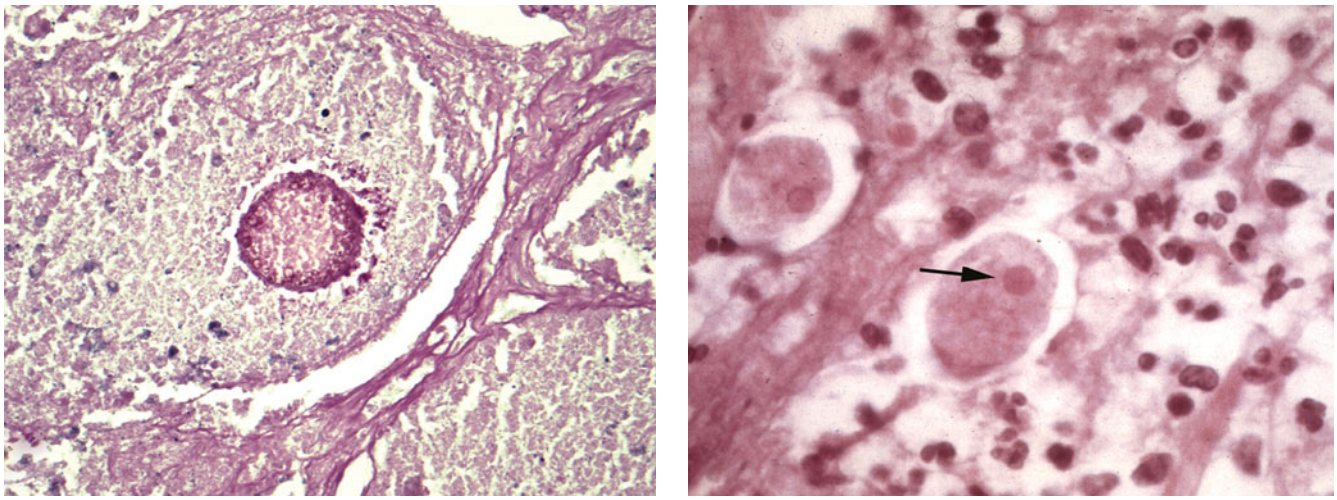


A



B

Figure 114-8 *A.* Granule in patient with *Actinomyces israelli.* To the naked eye, these granules are bight yellow (sulfur granules). Microscopically the gram-positive filamentous organisms are coated with eosinophilic PAS+ material that is deposited on the surface of the granule, i.e., the Splendore-Hoepllei phenomenon. *B.* Loosely adherent gram-positive filamentous organisms are seen *in Nocardia asteroides* pneumonia. *Nocardia* in the lung rarely forms true granules.

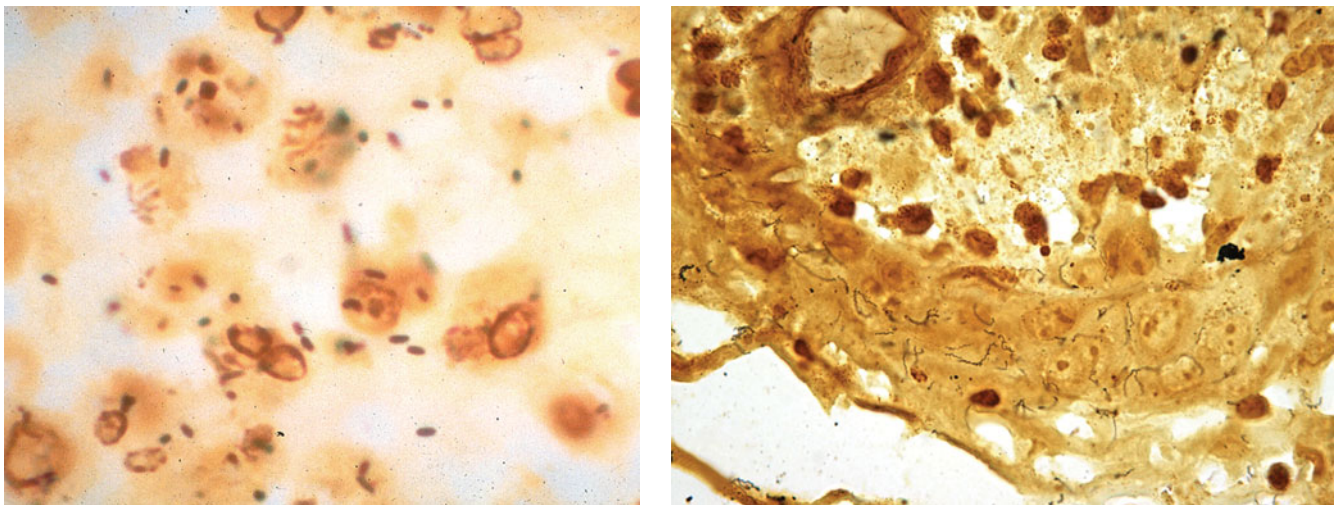


A *B*

Figure 114-9 *A*. PAS shows the cyst wall and endospores of *Coccidioides immitis* to excellent advantage. *B*. The karyosome (arrow) of *Entamoeba histolytica* is well seen in this H&E preparation but can be obscured by PAS.

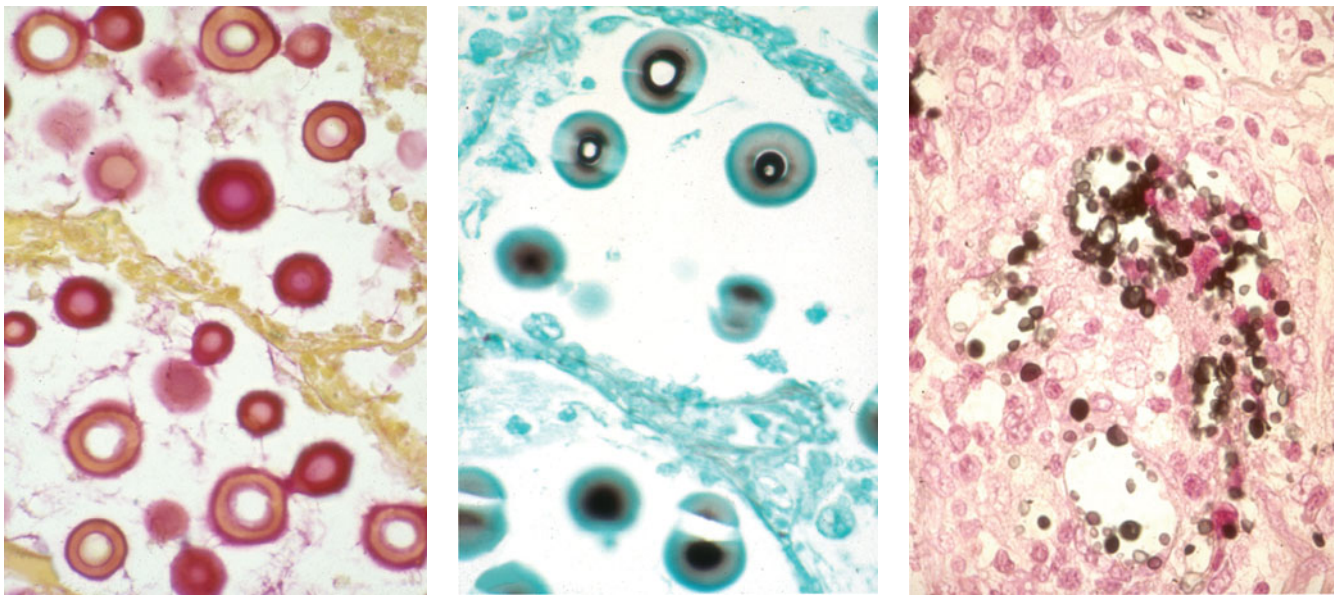
mechanisms of pulmonary host defense. The pulmonary response to infection includes generic elements of both innate and adaptive immunity that are shared by all tissues in their response to a particular infectious agent. However, the morphology of immune responses is modified by the specific microanatomy of the lung.

The lung is an elastic organ, composed of asymmetric dichotomously branching conducting airways that lead to the gas-exchange surfaces. The airways and the alveoli are embedded in a connective tissue matrix that is supplied by two blood circulations. The pulmonary circulation arises from the right side of the heart and carries deoxygenated blood at low mean arterial pressures to the alveolated surfaces, whereas the bronchial circulation arises from branches of the aorta and nourishes the airways and connective tissue stroma of the lung with oxygenated blood at systemic arterial pressures. All new growths within the lung, including fibroinflammatory responses to pulmonary infection, evoke neoangiogenesis from the bronchial circulation, so that areas of infected bronchiectasis, abscesses, and tuberculous cavities are all supplied by the systemic circulation. Deep and superficial systems of pulmonary lymphatics drain the lung from the level of the respiratory bronchioles, respectively, either toward lymph nodes at the hilum or centripetally along



A *B*

Figure 114-10 *A*. The coccobacilli of *Legionella pneumophila* are demonstrated by silver impregnation (Steiner). *B*. A pulmonary syphilitic gumma shows numerous spirochetes with silver impregnation (Warthin-Starry).



A *B* *C*

Figure 114-11 *A*. The true capsule of *Cryptococcus neoformans* stains red with mucicarmine. *B*. GMS shows the staining of the organism but does not demonstrate the capsule. *C*. Capsule-deficient cryptococci stain with Fontana-Masson. In most cases, careful examination, in retrospect, will reveal a faint mucicarminophilic capsule.

the pleural surfaces before emptying at the hilum. Lymphatic drainage plays an important role in the mechanism of disease. Streptococcal infections rapidly invade the pulmonary lymphatics, which transport bacteria to the pleural spaces to produce empyema. Inhaled anthrax bacilli drain rapidly to the local lymph nodes and lead to rapid dissemination of infection. Mycobacteria and fungi drain to the hilar nodes and, from there, disseminate to extrapulmonary tissues via the blood circulation.

The primary defenses of the airways include the olfactory hairs of the nasal passages and the mucociliary clearance mechanisms of the lower airways. Most microbes are

Table 114-5

Immunohistochemical Stains Commercially Available for Microbe Identification in Paraffin-Embedded Tissues

Fungi	Virus
Aspergillus (genus only)	Herpesvirus-1 (cross-reacts Herpesvirus-2)
Cryptococcus	Varicella-Zoster
Histoplasma	Cytomegalovirus
Candida sp.	Respiratory syncytial virus
Coccidioides immitis	Adenovirus
Pneumocystis jiroveci	Ebstein-Barr (EBER)
Pseudallescheria boydii	*Actinomycetes*
Zygomyces (genus only)	*Actinomyces israelii*
Sporothrix schenkii	*Actinomyces naeslundi*
Trichosporon	Arachnia propionica

small enough (less than 5 μM) to penetrate to the distal gas-exchanging surfaces of the lung. However, the vast majority are excluded by the defenses of the upper airways or deposit along the conducting airways, and are cleared by the mucociliary escalator. Humoral factors, including sIgA and defensins that are released into the airways, limit penetration by microbes. Mucosal dendritic cells trap microbial antigens and carry them to the regional lymph nodes, where they are processed and presented to both T- and B-lymphocytes (Fig. 114-13), affording the potential for specific adaptive anamnestic responses

The gas-exchange surface consists of a fused epithelial-endothelial basement membrane. Disruption or thickening of the gas-exchange surface is deleterious with respect to the diffusion of oxygen and carbon dioxide. For this reason, the surfaces of the alveoli are kept sterile by scavenging alveolar macrophages. These resident alveolar macrophages have the capacity to ingest inhaled particulates and to secrete monokines, including IL-10, that actively suppress local inflammation. Under conditions of health, the prevailing response is one of immunotolerance. However, when the alveolar lining is injured, or the number of invading organisms overwhelms the phagocytotic capacities of resident alveolar macrophages, neutrophils and exudate monocytes are recruited to the sites of inflammation. Even small numbers of virulent pathogens can greatly amplify inflammation via the release by the host of chemokines, cytokines, and complement components. Although this response may increase the clearance of infection, the damage evoked by these factors can injure the lung irreversibly, leading to fibrosis. The lung biopsy affords a unique opportunity to assess the host inflammatory response, in addition to identifying the cause of infection (Table 114-6). It is ultimately, the most accurate mode of determining host immune competence in patients with immune deficits.

Diffuse Alveolar Damage

A number of patterns of inflammation are unique to the lung. The *sine qua non* of acute injury to the alveolar wall is the development of the *hyaline membrane*, composed of an extravascular fibrin coagulum admixed with the necrotic alveolar cell debris. Diffuse alveolar damage (DAD) is the most frequent pathological correlate of the adult respiratory distress syndrome (ARDS), although confluent bronchopneumonia can also yield this syndrome since it is impossible to distinguish DAD from localized acute lung injury in small biopsy specimens, radiographic and clinical confirmation always should be sought.

Virtually all viruses cause DAD. *Influenza* and *coronarvirus* are RNA viruses that yield DAD with no diagnostic cytopathic features (Fig. 114-14). *Herpesvirus, adenovirus, varicella-zoster, measles* and *cytomegalovirus* cause DAD, but also exhibit cytopathic changes that are diagnostic. Immunohistochemical techniques can be used to localize viral proteins within infected cells in situ.

Bacterial, fungal, or parasitic infections rarely cause DAD primarily, although *Pneumocystis jiroveci* is a well-recognized cause. However, the presence of DAD is not limited to infection. Many inhaled toxins also produce DAD, and in patients who are immunosuppressed due to cancer therapy or organ transplantation, distinction can be difficult between DAD due to infection versus radiation, cytotoxic drug therapy, lung implantation injury, and diffuse gastric acid aspiration. Pulmonary infection can complicate DAD due to other causes, and the septic complications of extrathoracic infections can cause DAD.

Bronchopneumonia

Bronchopneumonia is the most common pattern of inflammation caused by inhaled pathogens. Bronchopneumonia begins as infection with inflammation of the membranous small airways and then extends into the surrounding alveolar spaces. Bacterial bronchopneumonia due to pyogenic bacteria, including *S. pneumonia*, *S. aureus*, and *Streptococci* sp., often complicate viral tracheobronchitis, probably reflecting an acquired postviral defect in mucociliary clearance and barrier defense. Virtually all bacteria and fungi and many viruses can cause bronchopneumonia. The inflammatory response evoked by the pathogen is helpful in limiting the differential diagnosis. Both gram-positive and -negative bacterial infections evoke a brisk pyogenic neutrophilic response

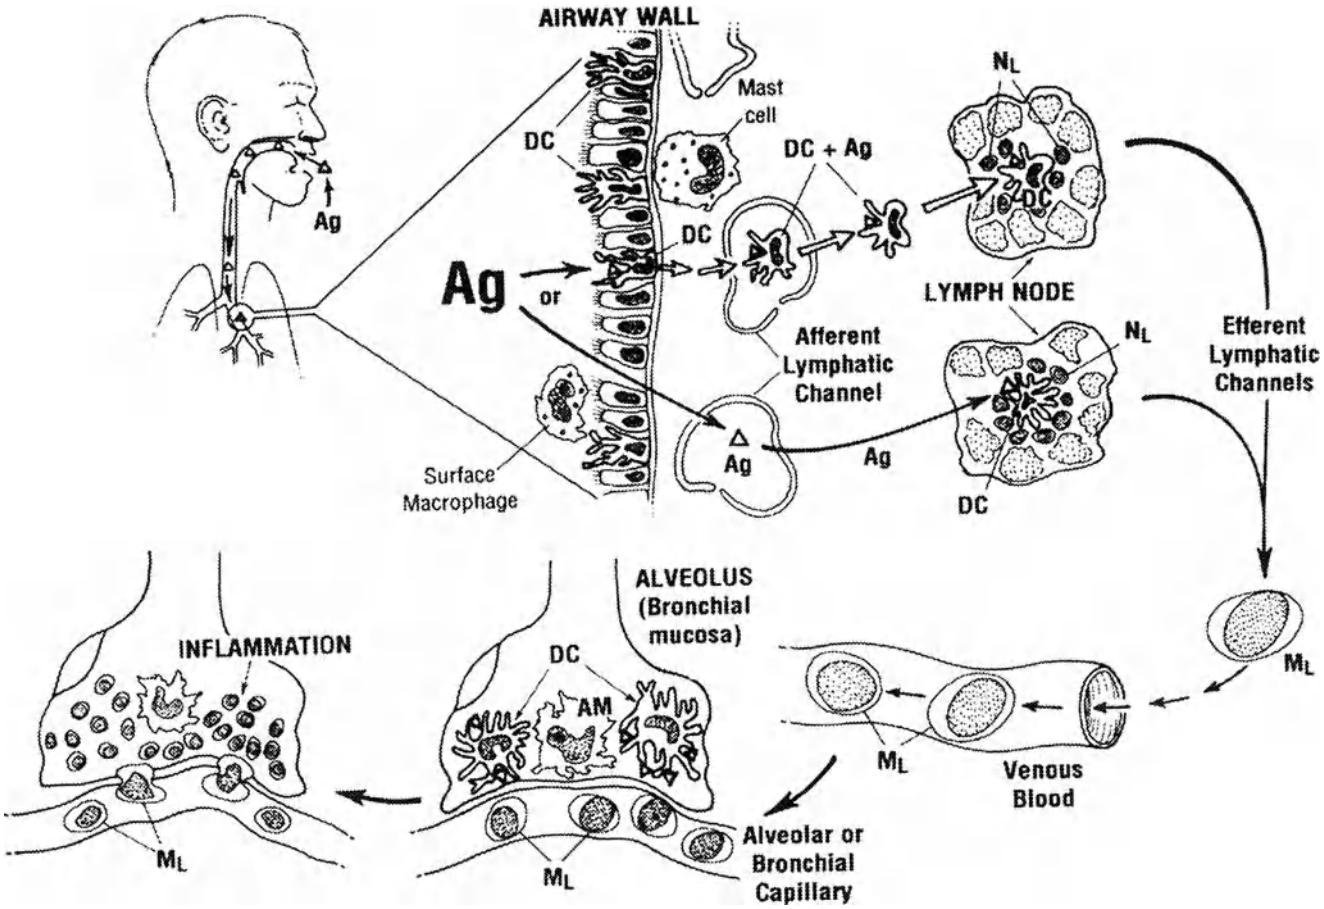

Figure 114-13 The cartoon shows the afferent and efferent pathways of adaptive pulmonary immunity via which entrapped antigens (Ag) are transported by dendritic cells (DC) to regional lymph nodes, presented to T- and B-lymphocytes, and subsequently evoke a cellular anamnestic response by memory lymphocytes (M_L) upon rechallenge. (Adapted from Kradin RL, Robinson BWS (eds.): *Immunopathology of the Lung.* Boston: Butterworth-Heinemann, 1996.)

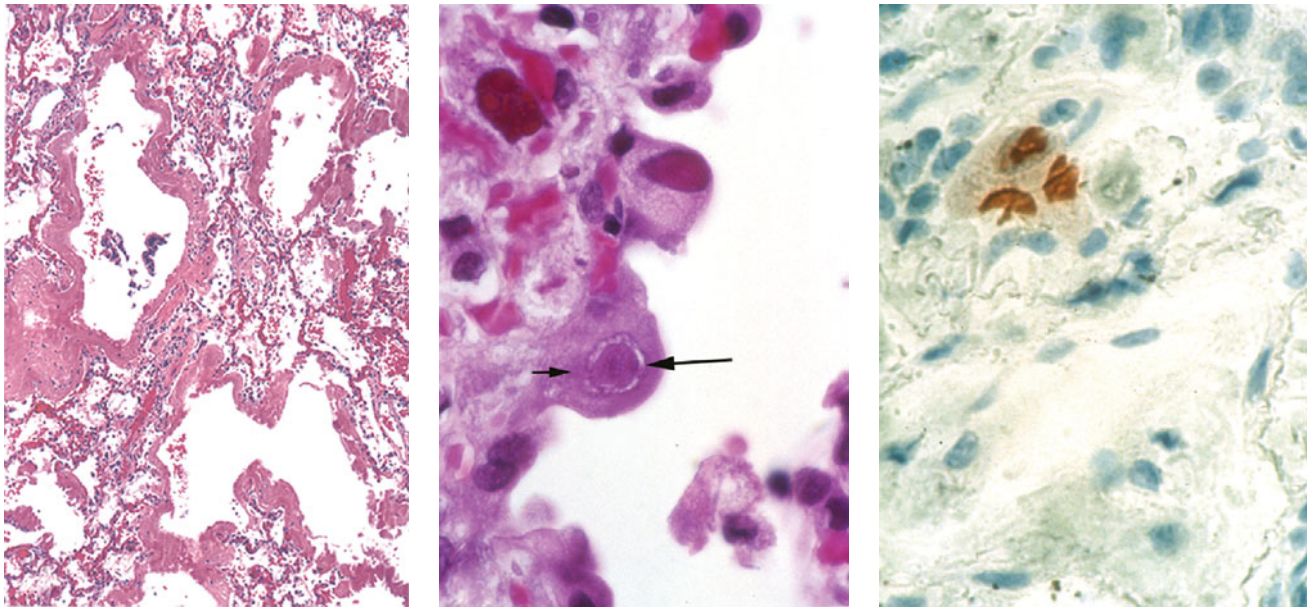
Table 114-6

Tissue Responses to Infection

Type of Inflammation	Example
Exudative inflammation	Pyogenic bacteria
Necrotizing inflammation	Gram-negative bacteria, amebiasis
Granulomatous inflammation	Mycobacteria, fungi
Histiocytic inflammation	*Rhodococcus, Legionella*, Whipple's
Interstitial inflammation	Pneumocystis
Cytopathic changes	Virus
No response	Host anergy

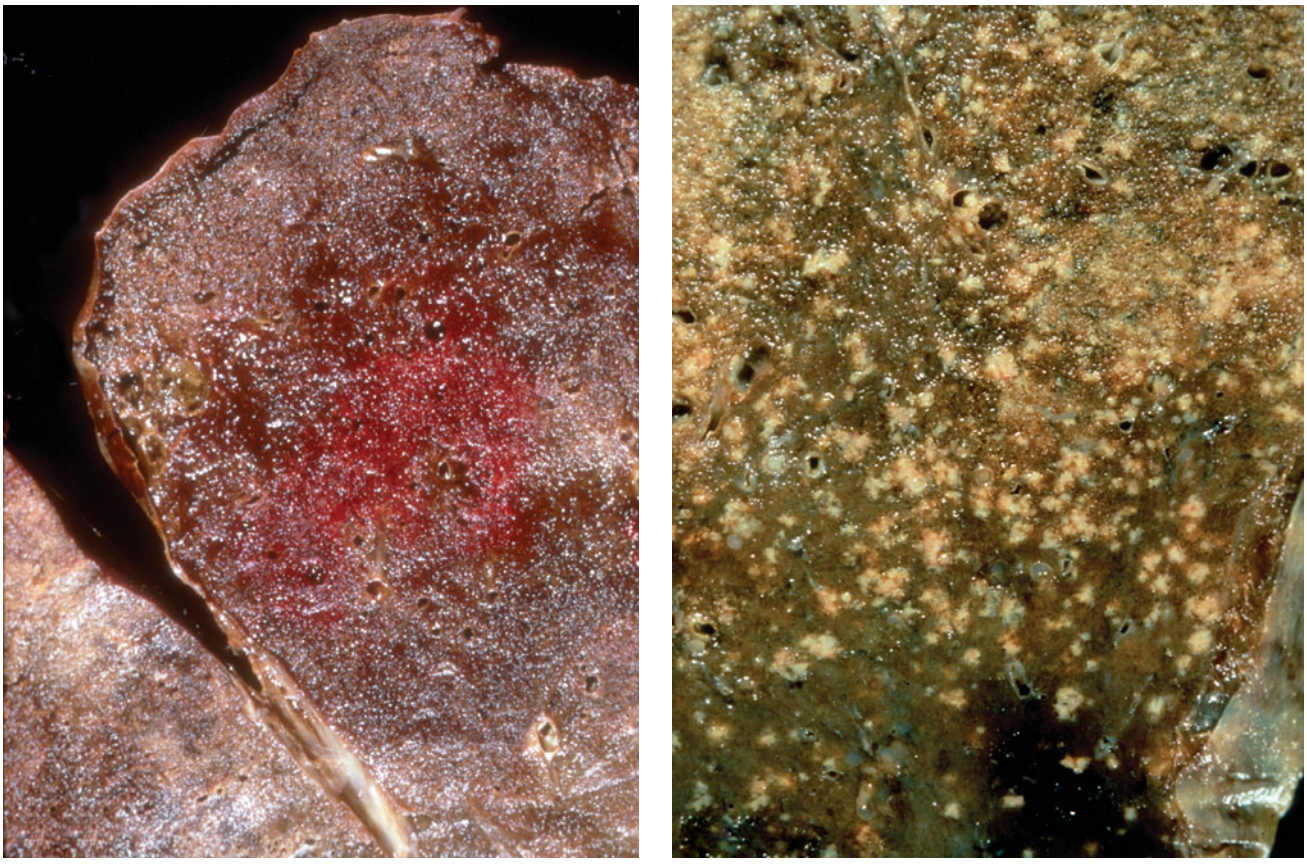
in the lung. *Streptococcal pneumonia* is distinguished by its tendency to produce a non-necrotizing lobar pneumonia, although in the current age of antibiotic treatment, bronchopneumonia is more common. *Klebsiella* sp. classically produces a hemorrhagic lobar pneumonia, with upper lobe predominance (Fig. 114-15). Necrosis of lung tissue with microabscess formation proceeding to cavitation can follow due to infection by aspirated mixed oral flora, *Staphylococcal* sp., *Streptococcal* sp., or gram-negative bacilli.

Herpes simplex virus evokes dense neutrophilic infiltrates in the airways with fibrinoid necrosis and karyorrhexis that histologically mimics bacterial bronchopneumonia (Fig. 114-16). But the presence of characteristic intranuclear viral inclusions distinguishes herpetic from bacterial infection. *Adenovirus* has a propensity to produce ulcerative bronchiolitis and bronchiolitis obliterans organizing pneumonia (BOOP). The characteristic nuclear inclusions disrupt the nuclear membrane to produce diagnostic "smudge cells." Influenza, respiratory syncytial virus (RSV) and parainfluenza viruses can all present as bronchopneumonia with a lymphohistiocytic inflammation or progress to DAD. Mycoplasma and nonvirulent *Chlamydia* produce acute bronchiolitis with



A *B* *C*

Figure 114-14 *A*. The lung in a lethal case of severe acute respiratory syndrome (SARS) shows diffuse alveolar damage with no cytopathic changes. *B*. Cytomegalovirus infection (CMV) with enlarged cell bodies, intranuclear (long arrow) and intracytoplasmic inclusions (small arrow), which are well seen with H&E. *C*. Confirmation can be established by immunohistologic demonstration of nuclear antigen. CMV can produce DAD, bronchopneumonia, or patchy nodular interstitial pneumonitis.



A *B*

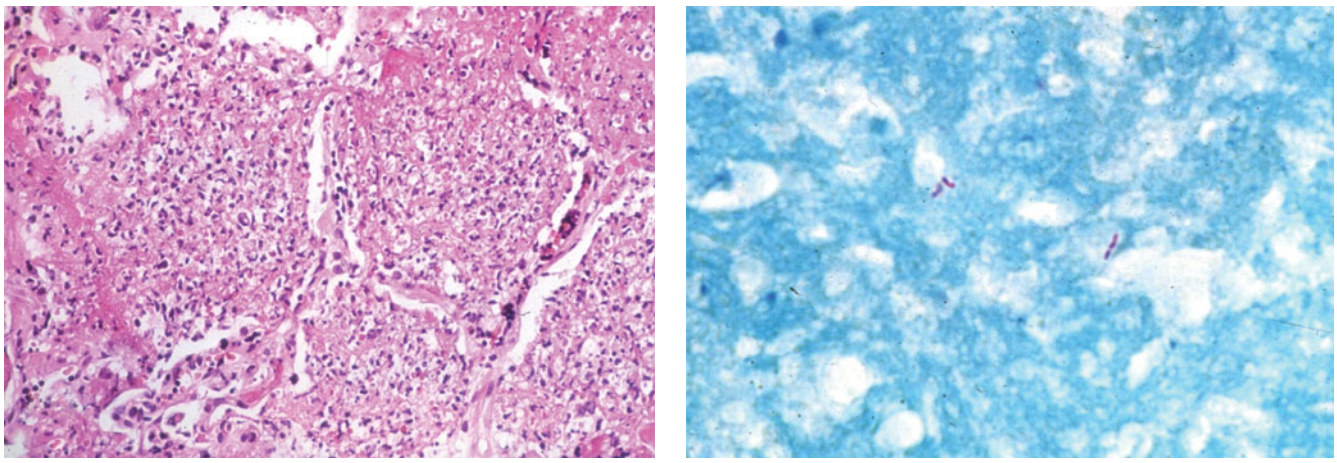
Figure 114-16 *A. Herpesvirus-1* bronchopneumonia produces a pyogenic and necrotizing response. Viral inclusions are present (arrow). *B. Adenovirus* causes necrotizing bronchiolitis with surrounding fibrinous pneumonia. A diagnostic "smudge cell" is shown in the inset.

interstitial lymphohistiocytic infiltrates. *Legionella sp.* characteristically exhibits a necrotizing bronchopneumonia with alveolar filling by fibrin and histiocytes (Fig. 114-17). The demonstration of this weakly gram-negative coccobacillus in tissue requires either silver-impregnation techniques or immunohistochemical staining. *L. micdadei* shows positivity on modified Ziehl-Neelsen stains.

Confluent bronchopneumonia mimicking lobar consolidation is a common finding at autopsy in immunosuppressed patients with fungal infection. Opportunistic molds such as *Aspergillus, Zygomyces, Pseudoallescheria,* and *Fusarium* (Fig. 114-18), often begin as airway infections and then rapidly invade blood vessels. This produces the characteristic gross appearance of a "targetoid" lesion, comprised of central vascular plugging by organisms and surrounding necrotizing fungal pneumonia (Fig. 114-19). Fungal infection due to fungemic spread to the lungs from extrathoracic sites yields a lesion in which the fungi grow radially from a plugged pulmonary arteriole, producing a "sunburst" appearance.

Nematodes that have a larval developmental phase in the lung, e.g., *Ascaris and Strongyloides*, migrate through the airways toward the mouth, where they are either swallowed or expectorated. This process may be associated with wheezing, migratory pneumonia, and blood eosinophilia, a complex of findings termed Loeffler syndrome (Fig. 114-20). The presence of track-like necrotizing granulomatous bronchitis and bronchopneumonia with prominent eosinophilic infiltrates



A *B*

Figure 114-17 *A. Legionella pneumophila* characteristically yields a fibrinous and histiocytic bronchopneumonia. Coccobacilli organisms are generally numerous but require silver impregnation for demonstration. *B. L. micdadei* stains with modified Ziehl-Neelsen.

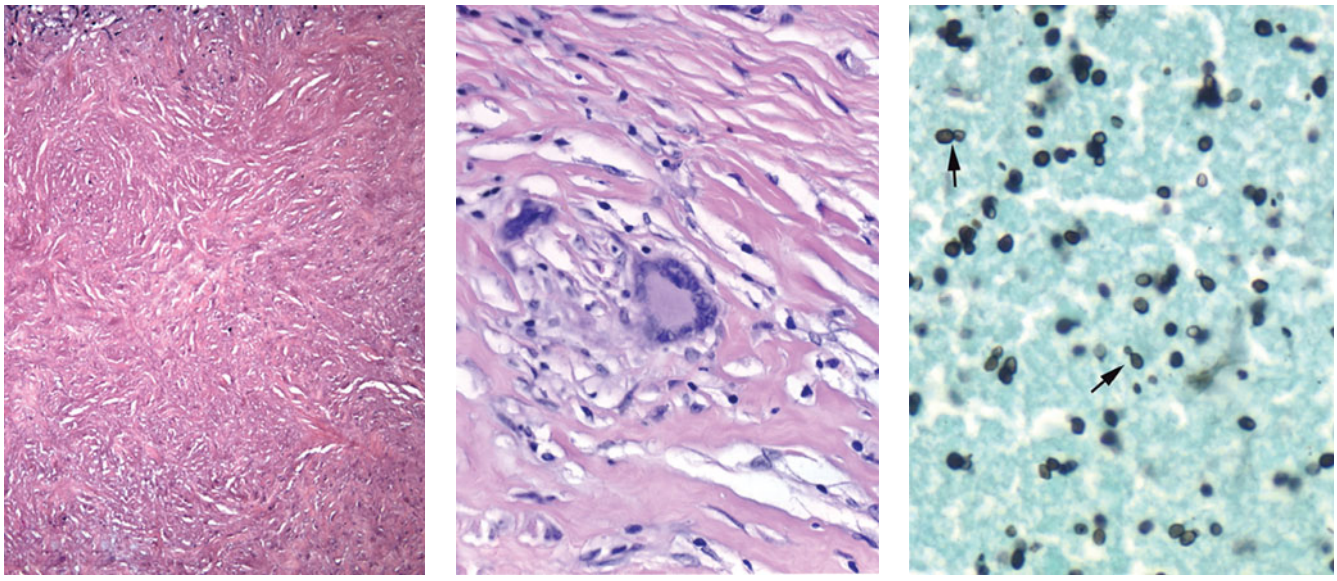
Figure 114-21 *A*. The lung in *Pneumocystis jiroveci* pneumonia shows filling of alveolar spaces by eosinophilic frothy material due to the presence of trophozoites. *B*. This appearance can be confused with pulmonary alveolar proteinosis or with fibrinous pulmonary edema (not shown). The organisms of *P. jiroveci* are demonstrated with GMS. Characteristic features include size (4 to 6 μM), absence of budding, "boat"-shaped cysts (white arrow), and pericapsular accentuations (red arrow).

should alert the diagnostic pathologist to the presence of a parasitic pulmonary infection.

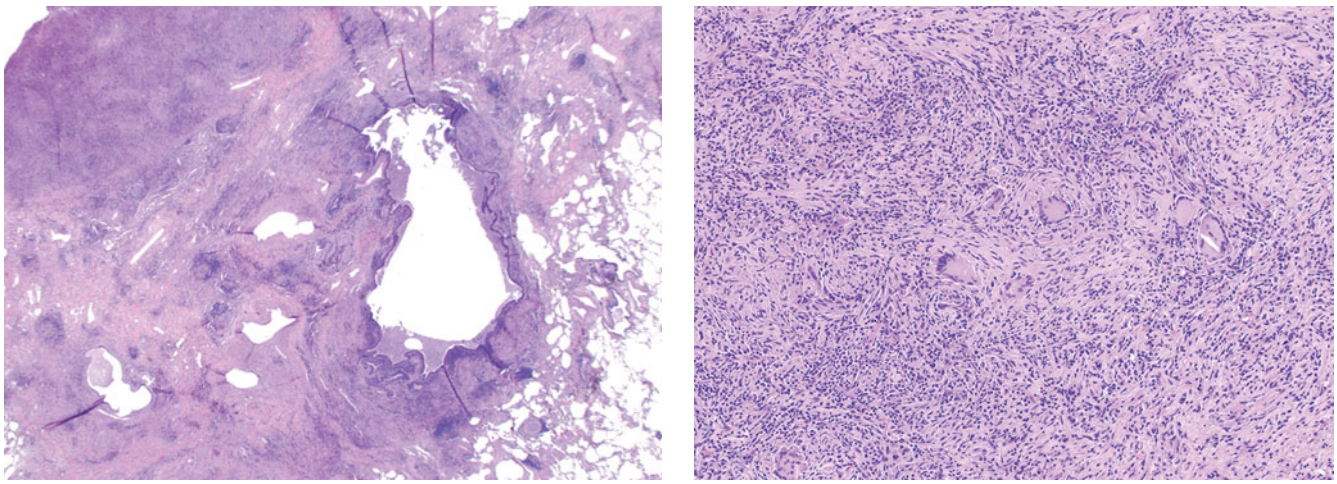
Other Patterns of Inflammation

A variety of other inflammatory reactions are seen in response to infection. *Pneumocystis jiroveci* pneumonia generally shows alveolar filling by a foamy exudate that contains innumerable trophozoites (Fig. 114-21). *Pneumocystis* pneumonia must be morphologically distinguished from pulmonary alveolar proteinosis that also can occur in the immunosuppressed host, as well as from fibrinous pulmonary edema. Necrotizing granulomas and cystic lesions also may be caused by *Pneumocystis* and can easily be mistaken for fungal yeast forms.



A *B* *C*

Figure 114-22 *A*. Chronic infection with *Histoplasma capsulatum* shows a necrotizing granuloma with mummification. *B*. The wall shows a multinucleate giant cell and characteristic paucicellular hyaline fibrosis. The GMS stain reveals multiple 2- to 4-μM yeast, some of which have single narrow-necked buds (arrow).



A *B*

Figure 114-23 *A*. A bronchiectatic lung is infected with *Mycobacteria avium/intracellulare* complex (MAC). *B*. The inflammatory response in the non-immunosuppressed host includes primarily non-necrotizing granulomatous inflammation. When areas of necrosis are more prominent, *M. tuberculosis*, or other more virulent atypical mycobacteria, e.g., *M. kansasii*, or an abnormal host response, should be considered.

Granulomatous Inflammation

Most necrotizing granulomas in the lung are caused by chronic mycobacterial or fungal infections. However, noninfectious diseases, e.g., Wegener's granulomatosis and rheumatoid nodules, can show comparable morphologic features. *M. tuberculosis* can affect the airways, lung parenchyma, and pleura. Miliary tuberculous granulomas in the lung indicate spread through the pulmonary blood circulation. Tuberculous necrosis destroys the underlying elastic framework of the lung and is generally referred to as "caseous" necrosis, but this term should be restricted to describe the cheesy appearance of the gross lesion. Chronic pulmonary infection with *Histoplasma capsulatum* yields an unusual form of mummifactive necrosis, as well as a dense paucicellular fibrotic response that can, in most instances, be distinguished from tuberculosis (Fig. 114-22). Involvement of regional lymph nodes by *H. capsulatum* can lead to the development of broncholiths or to immune-mediated mediastinal fibrosis.

Atypical mycobacterial infection in the emphysematous or bronchiectatic lung is characterized by a considerable number of non-necrotizing granulomas centered on distorted airways (Fig. 114-23). Necrotizing granulomatous changes

In this case, the morphology is diagnostic of *Aspergillus fumigatus*.

suggest a more virulent atypical mycobacterial infection, e.g., *M. kansasii* or *M. abscessus*. *Rhodococcus equi*, a gram-positive, weakly acid-fast coccobacillus, can yield necrotizing histiocytic pulmonary inflammation, usually in the immunocompromised host. The host response is distinguished by the presence of microcalcifications termed Michaelis-Guttmann bodies (Fig. 114-24). Amebic pulmonary infection is virtually always the result of extension of a hepatic abscess through the diaphragm. The organisms produce liquefactive necrosis with granulohistiocytic inflammation but no tissue eosinophilia.

Fungus Balls

Aspergillus, *Pseudallescheria*, and the *Zygomyces* can produce fungus balls within pre-existing areas of lung cystification due to emphysema, old mycobacterial infection, or sarcoidosis (Fig. 114-25). The diagnostic morphologic features of the organisms are distorted by the mycelial growth so that either immunohistological staining or culture is required to establish the specific cause. Occasionally, a conidial fruiting body, which develops only in areas of high oxygen tensions, e.g., a cavity, enables accurate speciation of aspergillus in situ or

helps to identify the pigmented conidia of *Pseudallescheria boydii*. The presence of birefringent oxalate crystals is particularly common with *A. niger*.

Vascular Inflammation

Blood vessel involvement can occur as a necrotizing vasculitis associated with acute pneumonia in *Pseudomonas* and other gram-negative bacterial infections (Fig. 114-26). Penetration of blood vessels is a dreaded complication of infections by molds, such as *Aspergillus, Pseudallescheria, Fusarium,* and *Mucor* sp., *Rickettsiae* sp., *Bartonella* sp., and spirochetes target blood vessels where they cause endothelialitis. Granulomatous arteritis may be evoked in response to either the ova or larval forms of schistosomes. Unlike the ova of *Paragonimus* sp., schistosome eggs are not birefringent. Pulmonary arterial occlusion with distal ischemic infarction may be caused by the heartworm *Dirofilaria immitis*.

Pleural Infection

Parapneumonic effusions may complicate bacterial pneumonias but are rarely biopsied, unless they lead to empyema or the production of a restrictive rind around the underlying lung. In most instances, an infectious cause has been identified and treated previously, so that identifying viable organisms in situ is uncommon. Mycobacteria, fungi, and parasites yield exudative effusions and necrotizing granulomatous inflammation, and their presence helps to narrow the differential diagnosis, even if organisms are not identified (Fig. 114-27). Tissue eosinophilia may be a clue to the presence of a parasitic infection, but can also occur in fungal and mycobacterial infections, in response to pleural metastases, and following pneumothorax.

Principles of Antibiotic Use and the Selection of Empiric Therapy for Pneumonia

Michael S. Niederman

Antibiotics are the foundation of therapy for respiratory tract infections, but the approach to their use varies with the type of pneumonia present (community acquired, health care–related, or nosocomial), as well as the age of the affected patient, the presence of various co-morbid illnesses and risk factors for infection by specific pathogens, and the severity of the acute illness. For most patients, initial therapy is aimed at a broad spectrum of potential pathogens and is empiric because the infecting pathogen is often not known. Therapy can be more specifically focused on the basis of results of diagnostic tests. In some cases, initial empiric therapy must be continued because no etiologic pathogen is identified. When a pathogen is defined, the term "appropriate" refers to the use of at least one antimicrobial agent that is active in vitro against the etiologic pathogen. The term "adequate" includes not only appropriate therapy, but also the use of that agent in the correct dose, via the right route, given in a timely fashion and with penetration to the site of infection.

Timely and appropriate antibiotic therapy can improve survival in patients with community-acquired pneumonia (CAP) and nosocomial pneumonia [hospital-acquired pneumonia (HAP)], and the benefits are most evident in patients who are not otherwise terminally ill. The term HAP includes pneumonia in nonventilated patients, ventilated patients (VAP), and a new entity health care–associated pneumonia (HCAP). HCAP includes patients coming from nursing homes, those in the hospital for more than 2 days in the past 90 days, those from dialysis centers, or those getting home wound care. Because of their exposure to the health care environment, those with HCAP are at risk for infection with drug-resistant pathogens, and the presence of this entity has blurred the distinction between CAP and HAP, since HCAP patients may reside in the "community," but be infected with organisms very similar to those present in patients with HAP.

In the setting of CAP, effective initial antibiotic therapy is associated with a marked improvement in survival,

compared with ineffective initial therapy, particularly in patients with severe illness. Data on patients with severe CAP provide the most convincing argument for the use of empiric therapy. In several studies, identification of the pathogens causing severe CAP did not lead to an improved survival rate, whereas the use of a broad-spectrum, empiric regimen directed at likely pathogens reduced mortality. In patients with HAP and VAP, survival is improved with the use of antibiotics to which isolated pathogens are susceptible, compared with empiric, nonspecific therapy. In both forms of respiratory infection, the timing of appropriate therapy has also been identified as a determinant of outcome. Patients with CAP have a reduced mortality if initial antibiotic therapy is provided within 4–6 hours of arrival to the hospital. In the treatment of VAP, data show that appropriate therapy should be given as soon as the infection is clinically identified and lower respiratory tract samples have been collected for culture. A delay of at least 24 hours in starting therapy is an important mortality risk factor in VAP.

Even with the use of the correct agents, not all patients recover. The fact that some patients with HAP die in spite of microbiologically appropriate therapy is a reflection of the degree of antibiotic efficacy, as well as a reflection of host response capability (which may have a genetic determination in part), and the fact that not all deaths are the direct result of infection. In some patients with HAP, death is the result of underlying serious illness; the percentage of deaths that occur because of infection, termed the "attributable mortality" of HAP, has been estimated to be as high as 50 to 60 percent. However, the use of timely appropriate antimicrobial therapy can reduce attributable mortality to as little as 20 percent.

In recent years, a number of paradigms for empiric therapy, in the form of guidelines for both CAP and HAP have been developed, but several caveats should be remembered. First, although current guidelines for empiric therapy are evidence based, outcome studies are required to demonstrate their utility in clinical practice.Second, guidelines must be re-evaluated relative to local patterns of antibiotic susceptibility. In the case of CAP, the emergence of penicillin-resistant pneumococcus, community-acquired methicillin-resistant *S. aureus*, and epidemic viral illness (influenza, severe acute respiratory syndrome) may affect the selection of initial therapy, particularly if resistance is prevalent in a specific community. In the setting of HAP, each hospital has its own unique flora and antibiotic susceptibility patterns; a knowledge of such patterns is essential.

This chapter examines the principles underlying antibiotic use, and then discusses the commonly used antibiotics for respiratory tract infections and the principles of empiric therapy for patients with both CAP and HAP.

PRINCIPLES OF ANTIBIOTIC USE

Mechanisms of Action

Antibiotics interfere with the growth of bacteria by undermining the integrity of their cell wall or interfering with bacterial protein synthesis or common metabolic pathways. The terms *bactericidal* and *bacteriostatic* are broad categorizations, and may not apply for a given agent against all organisms, with certain antimicrobials being bactericidal for one bacterial pathogen but bacteriostatic for another. Bactericidal antibiotics kill bacteria, generally by inhibiting cell wall synthesis or interrupting a key metabolic function of the organism. Agents of this type include the penicillins, cephalosporins, aminoglycosides, fluoroquinolones, vancomycin, daptomycin, rifampin, and metronidazole. Bacteriostatic agents inhibit bacterial growth, do not interfere with cell wall synthesis, and rely on host defenses to eliminate bacteria. Agents of this type include the macrolides, tetracyclines, sulfa drugs, chloramphenicol, linezolid, and clindamycin. The use of specific agents is dictated by the susceptibility of the causative organism(s) in a given location to individual antibiotics. However, when neutropenia is present, or if there is accompanying endocarditis or meningitis, the use of a bactericidal agent is preferred. Thus, for most patients with pneumonia, it is not essential to choose a bactericidal agent. One additional consideration is that certain organisms, such as *S. aureus,* can produce toxins, and the optimal agent must be able to not only kill the bacteria, but also inhibit the production of disease-mediating toxins.

Antimicrobial activity is often described by the terms MIC and MBC. The term MIC defines the minimum concentration of an antibiotic that inhibits the growth of 90 percent of a standard-size inoculum, leading to no visible growth in a broth culture. At this concentration not necessarily all the bacteria have been killed. The term MBC refers to the minimum concentration needed to cause a 3-logarithmic decrease (99.9 percent killing) in the size of the standard inoculum, and generally all pathogenic bacteria are killed at this concentration. The MIC is used to define the *sensitivity* of a pathogen to a specific antibiotic, under the assumption that the concentration required for killing (the MIC) can be reached in the serum in vivo. However, these terms must be interpreted cautiously in the treatment of pneumonia, because the clinician must consider the MIC data in light of the penetration of an agent into lung tissues, with some agents achieving higher than serum levels at respiratory sites of infection, and others reaching lower levels.

In recent years, most respiratory infections have been dominated by concerns of antimicrobial resistance, and a new term has emerged, the mutant prevention concentration (MPC). The MPC is defined as the lowest concentration of an antimicrobial that prevents bacterial colony formation from a culture containing greater than 10^{10} bacteria. At lower than MPC concentrations, spontaneous mutants can persist and be enriched among the organisms that remain during therapy. The concept has been most carefully studied with pneumococcus and the fluoroquinolones. In general the MPC is higher than the MIC, implying that it is possible to use an antimicrobial to successfully treat an infection, but not to prevent the remaining organisms (which are not causing illness) from emerging as resistant, and persisting and spreading to other patients.

Penetration into the Lung

The concentration of an antibiotic in the lung depends on the permeability of the capillary bed at the site of infection (the bronchial circulation), the degree of protein binding of the drug, and the presence or absence of an active transport site for the antibiotic in the lung. In the lung, the relevant site to consider for antibiotic penetration is controversial and not clearly defined. Sputum and bronchial concentrations may be most relevant for bronchial infections, whereas concentrations in lung parenchyma, epithelial lining fluid, and cells such as macrophages and neutrophils are probably more important for parenchymal infections. The localization of the pathogen also may be important, and intracellular organisms such as *Legionella pneumophila* and *Chlamydophila pneumoniae* may be best eradicated by agents that achieve high concentrations in macrophages. Local concentrations of an antibiotic must be considered in light of the activity of the agent at the site of infection. For example, antibiotics can be inactivated by certain local conditions. Aminoglycosides have reduced activity at acidic pHs, which may be present in infected lung tissues. In addition, certain bacteria develop resistance by producing destructive enzymes (e.g., β-lactamases), altering the permeability of the outer cell wall, changing the target site of antimicrobial action, or pumping (efflux) of the antimicrobial from the interior of the cell. In all of these conditions, a high local concentration of antimicrobial may help offset the bacterial resistance mechanisms.

The concentration of an antibiotic in lung parenchyma depends on its penetration through the bronchial circulation capillaries. The bronchial circulation has a fenestrated endothelium, so antibiotics penetrate in proportion to their molecular size and protein binding, with small molecules that are not highly protein bound passing readily into the lung parenchyma. When inflammation is present, penetration is further improved. For an antibiotic to reach the epithelial lining fluid, it must pass through the pulmonary vascular bed, which has a nonfenestrated endothelium. This presents an advantage for lipophilic agents, which are generally not inflammation dependent. Agents that are lipophilic and thus inflammation independent for their entry into the epithelial lining fluid include chloramphenicol, the macrolides (including the azalides and ketolides), linezolid, clindamycin, the tetracyclines, the quinolones, and trimethoprim-sulfamethoxazole. Agents that are poorly lipid soluble are inflammation dependent for their entry into the epithelial lining fluid and include the penicillins, cephalosporins, aminoglycosides, vancomycin, carbapenems, and monobactams.

The volume of distribution of an antibiotic reflects the compartment size of its distribution. If this value exceeds 3 L it implies distribution outside of the plasma. The poorly lipid soluble (hydrophilic) drugs diffuse freely into interstitial fluid, but do not penetrate cells. For these agents, only the free, non–protein-bound drug can be distributed out of the plasma. Some lipophilic agents, such as the macrolides and quinolones, are distributed extensively to body tissues, and the serum levels underestimate their effect at sites of infection, an observation that can explain the efficacy of azithromycin, which achieves high intracellular concentrations in phagocytes, can treat pneumonia, but achieves relatively low serum levels. Volume of distribution also can be increased by obesity, and dosing based on ideal body weight may lead to underdosing, although basing doses of hydrophilic antibiotics on total body weight may result in overdosage.

Active transport can facilitate antibiotic entry into lung tissue and phagocytes. Agents that are concentrated in phagocytes in this manner include the macrolides, clindamycin, and the fluoroquinolones. Antibiotics, such as the β-lactams, that are not concentrated in phagocytes by active transport remain in the extracellular space, which constitutes 40 percent of the weight of bronchial tissue; thus, penicillins achieve only about 40 percent of their serum level in lung tissue. Considering all of these factors, some general categories can be established (Table 115-1). Drugs that penetrate well into the sputum or bronchial tissue include the quinolones, newer macrolides and azalides (azithromycin and clarithromycin), ketolides (telithromycin), tetracyclines, clindamycin, and trimethoprim-sulfamethoxazole. On the other hand, the aminoglycosides, vancomycin, and to some extent the β-lactams penetrate less well into these sites. With the use of once-daily aminoglycoside dosing, high peak serum concentrations can be achieved, but the alveolar lining fluid concentration in patients with pneumonia is only 32 percent of the serum level over the first 2 hours, but the two sites have more similar concentrations later in the dosing interval. Since aminoglycosides require high peak concentrations for optimal killing (below), their poor penetration with systemic administration often makes this impossible, suggesting a potential role for delivery by the aerosol route (discussed below).

Table 115-1

Penetration of Antibiotics into Respiratory Secretions

Good Penetration: Lipid Soluble, Concentration Not Inflammation Dependent
Quinolones
New macrolides: azithromycin, clarithromycin
Ketolides (telithromycin)
Tetracyclines
Clindamycin
Trimethoprim/sulfamethoxazole
Poor Penetration: Relatively Lipid Insoluble, Inflammation Dependent for Concentration in the Lung
Aminoglycosides
β-lactams
Penicillins
Cephalosporins
Monobactams
Carbapenems

Antibiotic Pharmacokinetics and Pharmacodynamics

Pharmacokinetics is the study of the absorption, distribution, and elimination of a drug in the body, and the information can be used to describe the concentration in serum. Pharmacokinetics also includes the study of the concentration at other sites of the body, including the site of infection and the relationship between drug concentrations and their pharmacologic or toxic effect. For antibiotics, this means the relationship of antibiotic concentrations at the site of infection, compared with the MIC of the target organism. Pharmacodynamics refers to the action of a drug on the body, including its therapeutic effect.

The way in which an antibiotic reaches the site of infection, considering the frequency of administration and dose administered, can affect its ability to kill bacteria, thus defining a close relationship between pharmacokinetics and pharmacodynamics. Some agents are bactericidal in relation to how long they stay above the MIC of the target organism (time-dependent killing), whereas others are effective in relation to the peak concentration achieved (concentration-dependent killing). If antibiotic killing is time dependent, dosing schedules should be chosen to achieve the maximal time above the MIC of the target organism. Antibiotics of this type include the β-lactams (penicillins and cephalosporins), carbapenems, aztreonam, macrolides, and clindamycin. The rate of killing is saturated once the antibiotic concentration exceeds four times the MIC of the target organism. Therefore, the optimal dosing strategy is to dose often and not let trough concentrations fall below the MIC of the target organism. With these considerations in mind, continuous infusion of β-lactams is under study to optimize treatment with β-lactam agents. In spite of these considerations, for many organisms, the concentration of the antibiotic only needs to be above the MIC for 40 to 50 percent of the dosing interval, and possibly as little as 20 to 30 percent of the interval in the case of carbapenems. For the time-dependent killing drugs listed above, the pharmacodynamic parameter that best predicts clinical efficacy is the time above the MIC.

When killing is concentration dependent, activity is related to how high a concentration is achieved at the site of infection and how great is the AUC, or the "area under the curve" (of drug concentration plotted versus time) in relation to the MIC of the target organism. Alternatively, the action of these agents can be described by how high the peak serum concentration (Cmax) is in relation to the organism MIC. Classic agents of this type include the aminoglycosides and fluoroquinolones, but the ketolides are also concentration-dependent antibiotics. For these types of agents, the optimal killing of bacteria is defined by the ratio of AUC to MIC, often referred to as the area under the inhibition curve, or the AUIC. The target AUIC for gram-negative bacteria is 125 or greater, whereas for most antibiotics that treat pneumococcus, the target value is at least 30. For both the aminoglycosides and quinolones, some studies have shown that efficacy also can be defined by the ratio of peak serum concentrations to MIC (Cmax/MIC), aiming for a target of 12 for quinolones against pneumococcus. Optimal use of these agents would entail infrequent administration but with high doses—the underlying principle behind the once-daily administration of aminoglycosides. With once-daily aminoglycoside dosing regimens, the patient achieves a high peak concentration (maximal killing), and a low trough concentration (minimal nephrotoxicity), relying on the "postantibiotic effect" (PAE) to maintain the efficacy of the antibiotic after the serum (or lung) concentrations fall below the MIC of the target organism. If an antibiotic has a PAE, it is capable of suppressing bacterial growth even after its concentration falls below the MIC of the target organism.

Although most agents exhibit a PAE against gram-positive organisms, a prolonged PAE against gram-negative bacilli is achieved by the aminoglycosides and fluoroquinolones For pneumococcus, a PAE exists for the macrolides/azalides, clindamycin, vancomycin, quinupristin/dalfopristin, tetracyclines, and the oxazolidinones (e.g., linezolid) Most of the agents that kill in a concentration-dependent fashion have a prolonged PAE. Agents with little or no PAE against gram negatives are generally also agents that kill in a time-dependent fashion; thus, they are given several times daily. The β-lactams (including penicillins, cephalosporins, and monobactams) generally have little or no PAE against gram-negatives; one notable exception is imipenem, which has a modest PAE against *Pseudomonas aeruginosa*. In clinical practice, the use of once-daily aminoglycoside dosing has had variable benefits in both efficacy and toxicity, but the advent of this type of dosing regimen follows from an understanding of pharmacodynamic principles.

A phenomenon similar to PAE is termed *postantibiotic leukocyte enhancement* (PALE), which refers to the ability of functioning white blood cells to kill organisms while they are in the postantibiotic phase of growth. Thus, when the patient has functioning neutrophils, the PAE of some agents is extended by their PALE.

Recently, some investigators have suggested that antibiotic therapy be chosen on the basis of another property of certain agents: their ability to stimulate inflammation and cytokine production in response to the presence of the bacterial cell wall lysis products that they generate. It has been known for many years that certain antibiotics liberate bacterial cell wall products that can interact with cytokine-producing cells, stimulating the production of high levels of cytokines such as tumor necrosis factor. In theory, this could lead to the development, or worsening, of the sepsis syndrome in patients immediately after therapy for pneumonia is started, a phenomenon seen in the therapy of *Pneumocystis jiroveci* pneumonia and pneumococcal meningitis, leading to recommendations to use corticosteroids with antibiotics when treating these infections. Other than in these situations, it is unclear if cytokine release is clinically relevant, but bactericidal antibiotics lead to more of a host inflammatory response than bacteriostatic agents; antibiotics that are cell wall active, and kill slowly, have been associated with the greatest cytokine

release. In particular, if an antibiotic has a high affinity for bacterial penicillin-binding protein 3, it may kill slowly and lead to filamentous cell wall products that are potent stimuli for cytokine release. On the other hand, agents that kill rapidly and do not interact with penicillin-binding protein 3 are associated with lower levels of in vitro stimulation of cytokine production by host inflammatory cells. In addition to these considerations, the use of antibiotics that inhibit protein synthesis (linezolid, clindamycin) may have an advantage in toxin-mediated illnesses, such as those caused by certain strains of *S. aureus*, when compared with cell-wall active bactericidal antibiotics.

FEATURES OF SPECIFIC ANTIMICROBIALS USED IN THE THERAPY OF RESPIRATORY TRACT INFECTIONS

Macrolides (Including Azalides) and Tetracyclines

Macrolides are bacteriostatic agents that bind to the 50S ribosomal subunit of the target bacteria and inhibit RNA-dependent protein synthesis. The macrolides traditionally have had good activity against pneumococci, as well as atypical pathogens (*C. pneumoniae, M. pneumoniae, Legionella*), but the older erythromycin-like agents are not active against *H. influenzae*, and have poor intestinal tolerance, so prolonged therapy is difficult. The new agents in this class include azithromycin (also referred to as an azalide) and clarithromycin. These agents have enhanced activity against *H. influenzae* (including β-lactamase–producing strains), although on an MIC basis, azithromycin is more active. Erythromycin is active against *Moraxella catarrhalis,* although the new agents have enhanced activity against this pathogen. Among the new macrolides, azithromycin is more active against not only *H. influenzae* and *M. catarrhalis*, but also *M. pneumoniae* than clarithromycin. On the other hand, clarithromycin is more active against *S. pneumoniae, Legionella,* and *C. pneumoniae.*

Both of the newer agents have better intestinal tolerance than erythromycin and penetrate well into sputum, lung tissue, and phagocytes. Clarithromycin, which has an active 14-hydroxy metabolite that is antibacterial, is administered twice a day orally at a 500 mg dose for 7 to 10 days in the treatment of CAP and acute exacerbations of chronic bronchitis (AECB). A new preparation of extended-release clarithromycin is administered as a 1000 mg dose once daily and has been effective as a 7-day course of therapy for AECB. Azithromycin has a longer half-life than clarithromycin, and concentrates in tissues, achieving very low serum levels when administered orally. The dosing regimen for CAP is usually 500 mg daily for 3 days in outpatients, but a recent extended release preparation allows the administration of 2000 mg as a one-time dose for CAP. For the hospitalized patient, an intravenous preparation of azithromycin is available and is dosed as 500 mg daily, with the duration defined by the clinical course of the patient, but usually for 7 to 10 days. Because of its intravenous administration, the serum levels achieved have been adequate for the therapy of bacteremic pneumococcal pneumonia.

Clinical studies of CAP have consistently shown a benefit of using macrolide therapy, usually in conjunction with a β-lactam, but the mechanism for this favorable effect is not known. Speculation has included the possibility of atypical pathogen co-infection, a possibility supported by studies that have found the benefit of the addition of macrolides to vary over the course of time. Another explanation has been that macrolides have anti-inflammatory effects, which may explain their benefit in improving quality of life in patients with cystic fibrosis. Macrolides have a myriad of other effects, including the interference with "quorum sensing" between bacteria, which could inhibit the in vivo proliferation of *Pseudomonas aeruginosa* after colonization has occurred.

Although macrolides remain an important therapeutic option for community respiratory tract infections, pneumococcal resistance is becoming increasingly common, being present in as many as 35 to 40 percent of all pneumococci, especially in patients who have received an agent of this class in the past 3 months. In addition, macrolide resistance also can co-exist with penicillin resistance, and as many as 30 to 40 percent of penicillin-resistant pneumococci are also erythromycin resistant. The clinical relevance of these in vitro findings remains to be defined. However, there are two forms of pneumococcal macrolide resistance, one involving efflux of the antibiotic from the bacterial cell, and the other involving altered ribosomal binding of the antibiotic. The former mechanism is associated with much lower levels of resistance than the latter, and is present in two-thirds of the macrolide resistant pneumococci in the United States. The latter form of resistance is fortunately less common, because if present, it is unlikely that macrolide therapy for pneumococcal infection would be effective.

The tetracyclines are also bacteriostatic agents that act by binding the 30S ribosomal subunit and interfering with protein synthesis. These agents can be used in CAP because they are active against *H. influenzae* and atypical pathogens, but in the United States pneumococcal resistance to tetracyclines may be approaching 20 percent, and may exceed 50 percent among organisms with high-level penicillin resistance. Photosensitivity is the major side effect, limiting the use of these agents in sun-exposed patients.

Ketolides

This new class of antimicrobials is a semisynthetic derivative of the macrolides, with a 14-member ring structure, and substitution of a keto group at the C3 site. These agents act to inhibit ribosomal protein synthesis in bacteria, by binding to two different sites on the 50S ribosomal subunit, and because of enhanced binding affinity and the binding to multiples sites, may be able to avoid some of the resistance problems associated with the macrolides. In addition, this class

of antibiotics has a poor affinity for the pneumococcal efflux pump. Because of these characteristics, ketolides are active against pneumococci that are macrolide resistant by either the efflux or ribosomal mechanism. Ketolides are also active against *H. influenzae*, but in vitro activity is not quite as high as with azithromycin, and efficacy in AECB is an area that requires further data. In addition, these agents have activity against the atypical pathogens. In clinical trials, one ketolide, telithromycin, has been evaluated and has been dosed at 800 mg daily for 5 days in the therapy of AECB and 7 to 10 days for CAP, with good efficacy. Side effects are primarily intestinal, with nausea and diarrhea occurring in some patients, but visual disturbances, liver function abnormalities (including rare cases of liver failure), and electrocardiographic QT prolongation have been reported.

Trimethoprim-Sulfamethoxazole (TMP-SMX)

This combination antibiotic has been used as a mainstay for the therapy of *P. jiroveci* pneumonia, and in the past was an effective agent for CAP and AECB because of its antimicrobial spectrum, ease of use, and low cost. It has bactericidal activity against pneumococcus, *H. influenzae,* and *M. catarrhalis*, but not against atypical pathogens. Recently, it has become less popular because of the emergence of pneumococcal resistance at rates of at least 30 percent, since 80 to 90 percent of organisms that are penicillin resistant are also resistant to TMP-SMX. The sulfa component of the drug inhibits the bacterial enzyme responsible for forming the immediate precursor of folic acid, dihydropteroic acid. Trimethoprim is synergistic with the sulfa component because it inhibits the activity of bacterial dihydrofolate reductase. TMP-SMX is available in a fixed combination of 1:5 (TMP:SMX), and is dosed as either 80/400 mg or 160/800 mg orally twice a day for 10 days, but the dosage should be adjusted in renal failure. An intravenous preparation is also available. Side effects generally result from the sulfa component and include rash, gastrointestinal upset, and occasional renal failure (especially in elderly patients).

β-Lactam Antibiotics

These bactericidal antibiotics have in common the presence of a β-lactam ring, which is bound to a five-membered thiazolidine ring in the case of the penicillins and a six-membered dihydrothiazine ring in the case of the cephalosporins. Modifications in the thiazolidine ring can lead to agents such as the penems (imipenem, ertapenem, and meropenem), whereas absence of the second ring structure characterizes the monobactams (aztreonam). These agents also can be combined with β-lactamase inhibitors such as sulbactam, tazobactam, or clavulanic acid, to create the β-lactam/β-lactamase inhibitor drugs. These agents extend the antimicrobial spectrum of the β-lactams by providing a substrate (sulbactam, clavulanic acid, tazobactam) for the bacterial β-lactamase, thereby preserving the antibacterial activity of the parent compound. β-Lactam antibiotics work by interfering with the synthesis of bacterial cell wall peptidoglycans by binding to bacterial penicillin binding proteins.

The penicillins used for respiratory tract infections include the natural penicillins (penicillin G and V), aminopenicillins (ampicillin, amoxicillin), anti-*Staphylococcal* agents (nafcillin, oxacillin), anti-*Pseudomonal* agents (piperacillin, ticarcillin), and β-lactam/β-lactamase inhibitor combinations (ampicillin/sulbactam, amoxicillin/clavulanate, piperacillin/tazobactam, and ticarcillin/clavulanate). Among the anti-*Pseudomonal* penicillins, piperacillin is the most active agent.

The cephalosporins span from first to fourth generation. The earlier agents generally were active against gram-positives, but did not extend activity to the more complex gram-negatives, or anaerobes, and were susceptible to destruction by bacterial β-lactamase. The newer generation agents generally are more specialized, with broad-spectrum activity, and more mechanisms to resist breakdown by bacterial enzymes. The second generation and newer agents are resistant to bacterial β-lactamase, but recent data suggest that cefuroxime may not be an optimal pneumococcal agent if resistance is present. On the other hand, the third generation agents such as ceftriaxone and cefotaxime are reliable and active against penicillin resistant pneumococci, whereas ceftazidime is not reliable against pneumococcus, but is active against *P. aeruginosa*. The third-generation agents may induce β-lactamases among certain gram-negatives (especially the *Enterobacteriaceae* spp.), and thus promote the emergence of resistance during monotherapy. The fourth-generation agent, cefepime, is active against pneumococci and *P. aeruginosa*, but is also less likely to induce resistance among the *Enterobacteriaceae* than the third-generation agents.

Imipenem and meropenem are the broadest spectrum agents in this class, being active against gram-positives, anaerobes, and gram-negatives, including *P. aeruginosa*. They have shown efficacy for patients with severe pneumonia, both community-acquired and nosocomial. A non-*Pseudomonal* carbapenem, ertapenem, is also available and has been used effectively in the therapy of CAP. Aztreonam is a monobactam that is so antigenically different from the rest of the β-lactams that it can be used in penicillin-allergic patients. It is only active against gram-negative organisms, having a spectrum very similar to the aminoglycosides.

Fluoroquinolones

These bactericidal agents act by interfering with bacterial DNA gyrase and/or topoisomerase IV, leading to impaired DNA synthesis repair, transcription, and other cellular processes, resulting in bacterial cell lysis. DNA gyrase is only one form of a bacterial topoisomerase enzyme that is inhibited by quinolones, and activity against other such enzymes is part of the effect of a variety of quinolones. The earlier quinolones (e.g., ciprofloxacin and ofloxacin) are active primarily against DNA gyrase, which accounts for their good activity against gram-negatives. The newer agents (gemifloxacin, levofloxacin, and moxifloxacin) bind both DNA

gyrase and topoisomerase IV, and have extended their activity to gram-positives, including drug-resistant *Streptococcus pneumoniae* (DRSP). Resistance to quinolones can occur through mutations in the topoisomerase enzymes, by altered permeability of the bacterial cell wall, or efflux of the antibiotic from the inside of the bacteria. The quinolones kill in a concentration-dependent fashion, and thus optimal antibacterial activity can be achieved with infrequent dosing, and high peak concentrations and high ratios of either AUC/MIC or Cmax/MIC. In addition, because quinolones have a postantibiotic effect (PAE) against both gram-positive and -negative organisms, they can continue to kill even after local concentrations fall below the MIC of the target organism. These properties make the quinolones well suited to infrequent dosing, with the ideal being once-daily dosing, particularly given the relatively long half-life of the newer compounds. The only factor limiting a switch to once-daily dosing for all quinolones is the toxicity associated with high doses of some agents (e.g., ciprofloxacin), particularly concerns related to neurotoxicity and possible seizures.

Two features of quinolones make them well suited to respiratory infections. First, they penetrate well into respiratory secretions and inflammatory cells within the lung, achieving local concentrations that often exceed serum levels. Thus, these agents may be clinically more effective than predicted by MIC values. This may explain the observation that quinolones are often better than other agents in prolonging the "disease-free" interval between exacerbations of COPD, a finding that has been demonstrated for moxifloxacin and gemifloxacin. Second, these agents are highly bioavailable with oral administration and thus similar serum and tissue levels can be reached if administered orally or intravenously. This allows for some "borderline" patients (e.g., nursing home patients) with pneumonia to be managed with outpatient oral therapy and maintain high therapeutic levels in the serum. In addition, the high bioavailability of these agents permits an easy transition from intravenous to oral therapy of inpatients with pneumonia, facilitating early discharge when the patient is clinically improving, and permitting ongoing oral therapy with maintenance of high serum levels.

The fluoroquinolones have excellent antimicrobial activity against β-lactamase–producing *H. influenzae* and *M. catarrhalis,* making them very useful for patients with AECB. However, the newer agents (gemifloxacin, levofloxacin, and moxifloxacin) extend the activity of the quinolones by having enhanced gram-positive activity, as well as by being more active against *C. pneumoniae* and *M. pneumoniae*, compared with older agents. The new agents are also highly effective against *L. pneumophila* and may be the drug of choice for this organism. However, if *P. aeruginosa* is the target organism (as it is in certain patients with CAP, AECB, and HAP), then only ciprofloxacin (750 mg twice-daily orally or 400 mg every 8 hours intravenously) or levofloxacin (750 mg orally or intravenously daily) are active enough for clinical use. Since the older agents, ciprofloxacin and levofloxacin, have borderline activity against the pneumococcus, if they are used for AECB or CAP, the dose probably should be optimized to either 750 mg twice daily of ciprofloxacin for AECB or 750 mg once daily of levofloxacin for CAP or AECB.

Among the newer agents, their in vitro activity against pneumococcus is variable, with the agents listed in the order of most to least active (on an MIC basis) as gemifloxacin, moxifloxacin, and levofloxacin. All of these agents also have long half-lives, generally allowing for once-daily dosing, although the half-lives of these drugs vary from as short as 6 hours for levofloxacin, to as long as greater than15 hours for moxifloxacin and gemifloxacin. The agents also differ in the degree of protein binding, with agents that have a low degree of binding having higher free concentrations in the serum. The relevance of this feature to clinical outcome is uncertain, but agents like levofloxacin and moxifloxacin are not highly protein bound. Although the new agents are highly active against pneumococci, both penicillin-sensitive and -resistant organisms, there is some concern that with widespread use, pneumococcal resistance to these agents will increase, especially since recent data show that many pneumococci (up to 20 percent) have quinolone-resistance determinant genes present, but have not yet developed full resistance. However, with continued selection pressure due to widespread use, this may become an important clinical problem. With this in mind, pneumococci are more likely to be resistant to the agents with the lowest pneumococcal activity, and in parts of Asia pneumococcal resistance to quinolones has already developed at much higher rates than in North America, particularly to levofloxacin, and especially among patients who have been given repeated courses of therapy with this agent. Other risk factors for quinolone resistance among pneumococci are recent hospitalization and residence in a nursing home.

One major distinction among these new quinolones is their profile of toxic side effects. A number of agents have been removed from clinical use because of toxicities such as QT prolongation (grepafloxacin), phototoxicity (sparfloxacin), and liver necrosis (trovafloxacin). The side effects of the other new agents have been acceptable generally, but as with any therapy, the risks of use should be weighed against the benefits. There have been reports of drug-induced hypoglycemia, which may be a quinolones class-effect, but this problem is most common with gatifloxacin and has led to removal of this agent from clinical use. A recent study comparing moxifloxacin with levofloxacin in elderly hospitalized patients with CAP, and a high frequency of heart disease, showed comparable safety, including a low frequency for both drugs, of cardiac arrhythmias and *Clostridium difficile* diarrhea.

In clinical trials, all of the newer agents have been effective in the therapy of AECB with 5 days of therapy. In CAP, therapy is usually for 7 to 14 days, but levofloxacin at 750 mg daily can be used for 5 days. Levofloxacin, but not moxifloxacin, is renally excreted, and thus need dosage adjustment in patients with renal insufficiency. Currently there are no good studies of severe CAP showing efficacy of any of the quinolones as monotherapy, although in both nosocomial pneumonia and AECB, monotherapy has been tested and shown to be effective.

Aminoglycosides

These bactericidal agents act by binding to the 30S ribosomal subunit of bacteria, thus interfering with protein synthesis. Aminoglycosides have primarily a gram-negative spectrum of activity and are usually used in combination with other agents targeting difficult organisms such as *P. aeruginosa* or other resistant gram-negatives. When combined with certain β-lactam agents they can achieve antibacterial synergy against *P. aeruginosa.* Amikacin is the least susceptible to enzymatic inactivation by bacteria, whereas tobramycin is more active than gentamicin against *P. aeruginosa.* Aminoglycosides penetrate poorly into lung tissue, and can be inactivated by acid pHs, which are common in pneumonic lung tissue. Thus, in a clinical trial of nosocomial pneumonia therapy, the use of an aminoglycoside with a β-lactam was no more effective than a β-lactam alone, and the combination regimen was not more effective in preventing the emergence of *Pseudomonal* resistance during therapy than was the monotherapy regimen with a β-lactam. In the treatment of bacteremic *Pseudomonal* pneumonia, aminoglycoside combination therapy may be more effective than monotherapy. Recent meta-analysis has suggested that the use of combination therapy with an aminoglycoside is of limited value, and may simply add to the risk of nephrotoxicity.

As discussed, aminoglycosides kill in a concentration-dependent fashion, and can be dosed once daily to optimize killing while minimizing toxicity (primarily renal insufficiency). In clinical practice, this has not been proved to occur, and once-daily dosing is comparable in efficacy and nephrotoxicity to multiple-dose regimens. When aminoglycosides are used, it is necessary to monitor serum levels to minimize the occurrence of acute renal failure. Peak concentrations correlate with efficacy, but only have meaning with multiple daily doses, and their utility in once-daily regimens has not been established. Trough concentrations are monitored to minimize toxicity and probably should be followed regardless of dosing regimen.

Because of poor penetration into tissues, some investigators have used nebulized aminoglycosides for the therapy and/or prevention of gram-negative pneumonia. This approach is discussed below.

New Agents Active Against Methicillin-Resistant *S. aureus*

In the past several years, methicillin-resistant *S. aureus* (MRSA) has emerged as an important pathogen in patients with nosocomial pneumonia, particularly ventilator-associated pneumonia (VAP), and recently has been described as a potential pathogen in patients with necrotizing post-influenza pneumonia. In the past, vancomycin was the agent used most commonly for this pathogen. However, there have been concerns about the limited efficacy of vancomycin, primarily because of its poor penetration into respiratory secretions. Linezolid the first agent in a new antibiotic class, the oxazolidinones, is active against MRSA, and also may block the production of antibacterial toxins, such as the Panton-Valentine leukocidin, which can be produced by community MRSA strains. The oxazolidinones act to inhibit bacterial protein synthesis, by binding to the 50S ribosomal subunit, and preventing the binding of transfer RNA and the formation of the 70S initiation complex.

Linezolid is not only active against MRSA, but also drug-resistant *Streptococcus pneumoniae*, and vancomycin-resistant enterococci (VRE) (both *Enterococcus faecium* and *Enterococcus faecalis*). The agent has high bioavailability; thus, serum levels are the same with oral or IV therapy. Renal and nonrenal clearance occur, and dosing adjustment is not needed for patients with renal failure. Efficacy has been shown for nosocomial pneumonia and CAP, but one recent analysis suggested that linezolid may be superior to vancomycin for the therapy of VAP that is proved to be caused by MRSA. Side effects are not common and include nausea, diarrhea, anemia, and thrombocytopenia (especially with prolonged use). It is also a weak monoamine oxidase inhibitor.

Quinupristin/dalfopristin has been tested in patients with VAP and was not as effective against MRSA as vancomycin, in spite of good in vitro activity. Several other agents in various stages of development have activity against MRSA, but they are not yet proved to be useful for the therapy of respiratory tract infections. These include daptomycin, which has been shown to be inactivated by pulmonary surfactant, thus explaining its lack of efficacy in pneumonia therapy trials. Tigecycline is available for non-respiratory tract infections, and its efficacy in the therapy of pneumonia is not yet known, although it does have in vitro activity against MRSA and many gram-negatives, including *Acinetobacter* spp., but not *P. aeruginosa.* Other agents currently in development are dalbavancin and telavancin.

Aerosolized Antibiotics for Respiratory Tract Infections

Local administration of antimicrobials has been used in the therapy of bronchiectasis, especially in the setting of cystic fibrosis and the therapy of ventilator-associated pneumonia. This approach is used to enhance the delivery of agents to the site of respiratory infection, especially for antibiotics that penetrate poorly into the lung. Direct delivery of antibiotics is usually achieved by nebulization, and this approach not only achieves high intrapulmonary concentrations, but may do so with low systemic absorption, and thus a reduced risk of systemic toxicity. The majority of studies of inhaled antibiotics have been done in nonventilated patients with cystic fibrosis, and chronic bronchial infection with *Pseudomonas aeruginosa*, and have used nebulized tobramycin, which has been shown to both improve pulmonary function, as well as decrease the density of *P. aeruginosa* in sputum and thus reduce the risk of hospital admission. The use of this approach in mechanically ventilated patients has been proposed for patients with either infectious tracheobronchitis or VAP, since both infections can involve highly resistant gram-negative bacteria, and the local delivery of antibiotics may effectively treat some pathogens that cannot be eradicated by systemic therapy.

In mechanically ventilated patients, local antibiotic administration by instillation or nebulization has been used to prevent pneumonia. In general, this is not a recommended approach, because even when it has been successful, there has been concern about the emergence of multidrug resistant gram-negatives in those who subsequently do develop infection, and these organisms may be difficult to treat. Most studies in this population have involved either the aminoglycosides or polymyxin B. Only one prospective randomized trial has examined the impact of the adjunctive use of locally instilled tobramycin with intravenous agents in the management of VAP. Although the addition of endotracheal tobramycin did not improve clinical outcome compared with placebo, microbiologic eradication was significantly greater in the patients receiving aerosolized antibiotics.

In spite of these data, sporadic small and uncontrolled series have shown that when patients have VAP due to multidrug-resistant *Pseudomonas aeruginosa* or *Acinetobacter* spp., aerosolized aminoglycosides, polymyxin, or colistin may be helpful as adjunctive therapy to systemic antibiotics. One side effect of aerosolized antibiotics has been bronchospasm, which can be induced by the antibiotic or the associated diluents present in certain preparations. A specially formulated preparation of tobramycin for aerosol administration was designed to avoid this complication.

Although the optimal method of administration of aerosol therapy is unknown, most studies have shown that nebulization can be effective and achieve more uniform distribution than direct instillation. When aerosol therapy is used in mechanically ventilated patients, it must be carefully synchronized with the ventilator cycle, and the optimal delivery device is not yet defined. In an animal model, investigators found that using an ultrasonic nebulizer placed in the inspiratory limb of the ventilator circuit, proximal to the "Y-connector," up to 40 percent of the administered dose can be retained in the lung, achieving tissue concentrations ten times higher than can be achieved with comparable doses given systemically, and with minimal systemic absorption. To optimize delivery, inspiratory time may need to be as high as 50 percent of the ventilatory cycle and routine humidification should be stopped during antibiotic administration. In ventilated patients, the ventilator may need to be set with a tidal volume of 8 to 10 ml/kg, with no humidification system in use during the use of the ultrasonic nebulizer which should be set to deliver 8 L/min.

Table 115-2

Common Pathogens Causing CAP in Specific Patient Popoulations (in Order of Decreasing Frequency)

Outpatient, No Cardiopulmonary Disease or Modifying Factors *S. pneumoniae, M. pneumoniae, C. pneumoniae* (alone or as mixed infection), *H. influenzae*, respiratory viruses, others (*Legionella sp., M. tuberculosis*, endemic fungi)
Outpatient, with Cardiopulmonary Disease and/or Modifying Factors* All of the above plus: DRSP, enteric gram-negatives, and possibly anaerobes (with aspiration)
Inpatient, with Cardiopulmonary Disease and/or Modifying Factors* *S. pneumoniae* (including DRSP), *H. influenzae, M. pneumoniae, C. pneumoniae*, mixed infection (bacteria plus atypical pathogen), enteric gram-negatives (which can include *P. aeruginosa*), anaerobes (aspiration), viruses, *Legionella* sp., others (*M. tuberculosis*, endemic fungi, *Pneumocystis jerovici*)
Inpatient, with No Cardiopulmonary Disease or Modifying Factors All of the above, but DRSP and enteric gram-negatives are not likely. These patients are rarely admitted to the hospital.
Severe CAP, with no Risks for *P. Aeruginosa* *S. pneumoniae* (including DRSP), *Legionella* sp., *H. influenzae*, enteric gram-negative bacilli, *S. aureus, M. pneumoniae*, respiratory viruses, others (*C. pneumoniae, M. tuberculosis* endemic fungi)
Severe CAP, with Risks for *P. Aeruginosa* All of the pathogens above, plus *P. aeruginosa*

** Some patients in this category are now classified as having HCAP if they have risk factors such as: hospitalization in an acute care hospital for two or more days within 90 days of the infection; those residing in a nursing home or long-term care facility; those who have received recent intravenous antibiotic therapy, chemotherapy, or wound care within the past 30 days of the current infection; or individuals who have attended a hospital or hemodialysis clinic.*

PRINCIPLES OF THERAPY FOR RESPIRATORY TRACT INFECTIONS

Community-Acquired Pneumonia

Selection of Initial Therapy

Empiric therapy is selected by categorizing patients on the basis of place of therapy (outpatient, inpatient, intensive care unit), severity of illness, and the presence or absence of cardiopulmonary disease or specific "modifying" factors that make certain pathogens more likely (Table 115-2). In the current guidelines for CAP management, patient risk factors for infection with drug-resistant pneumococcus, enteric gram-negatives, and *P. aeruginosa* have been identified. By using these factors, a set of likely pathogens can be predicted for each type of patient and this information can be used to guide therapy. If a specific pathogen is subsequently identified by diagnostic testing, then therapy can be focused. Risk factors, or "modifying factors" that increase the risk of infection with DRSP are: age greater than 65 years, β-lactam therapy within

the past 3 months, alcoholism, immune suppressive illness (including therapy with corticosteroids), multiple medical comorbidities, and exposure to a child in day care. The modifying factors for enteric gram-negatives include residence in a nursing home, underlying cardiopulmonary disease, multiple medical comorbidities, and recent antibiotic therapy. The risk factors for *P. aeruginosa* infection are structural lung disease (bronchiectasis), corticosteroid therapy (greater than 10 mg prednisone per day), broad-spectrum antibiotic therapy for more than 7 days in the past month, and malnutrition. In addition, there are a number of other clinical conditions that are associated with specific pathogens, and these associations should be considered in all patients when obtaining a history. Examples include the association between *S. aureus* and post-influenza pneumonia, *H. influenzae* with underlying COPD, and oral anaerobes with the presence of poor dental hygiene.

Empiric therapy for outpatients with no cardiopulmonary disease or modifying factors should be with a new oral macrolide (azithromycin or clarithromycin) or a tetracycline. Although erythromycin has been used for these patients, its value is limited by its lack of coverage of *H. influenzae*, and a higher frequency of intestinal complications (nausea, vomiting) than with the newer macrolides. Therapy with an anti-pneumococcal quinolone (gemifloxacin, levofloxacin, or moxifloxacin) is not necessary in these outpatients, because they are not at risk for organisms, such as DRSP and enteric gram-negatives. However, outpatients with cardiopulmonary disease and/or modifying factors, should not receive macrolide monotherapy, but should be treated with either a selected oral β-lactam (cefpodoxime, cefuroxime, high-dose ampicillin [3 grams daily] or high-dose amoxicillin/clavulanate [up to 4 g daily]) combined with a macrolide or alternatively, they can receive monotherapy using an oral antipneumococcal quinolone (gemifloxacin, levofloxacin, or moxifloxacin). The ketolide telithromycin also can be used in this population as oral monotherapy for patients at risk for DRSP, but only if the patient has no risk factors for aspiration or for enteric gram-negatives but concerns about lung toxicity have limited its clinical utility.

For the non-ICU inpatient, therapy can be with an intravenous macrolide (azithromycin) alone, provided that the patient has no underlying cardiopulmonary disease, and no risk factors for infection with DRSP, enteric gram-negatives or anaerobes. Although very few patients of this type are admitted to the hospital, macrolide monotherapy has been documented to be effective in this patient population. Since the majority of inpatients have cardiopulmonary disease and/or modifying factors, they should treated with either a selected intravenous β-lactam (cefotaxime, ceftriaxone, ampicillin/sulbactam, or ertapenem) combined with a macrolide, or alternatively, monotherapy with an intravenous anti-pneumococcal quinolone (levofloxacin, or moxifloxacin) can be administered. From the available data, it appears that either regimen is therapeutically equivalent, and although not proved, it may be useful to use these two types of regimens interchangeably, striving for "antibiotic heterogeneity," but being sure to select an agent in a different class from what the patient received in the past 3 to 6 months. Recent data have shown that if patients have received a macrolide, quinolones, or penicillin in the past 3 months, then a subsequent infection with pneumococcus is more likely to be resistant to the agent received in the past, than to other agents. Although oral quinolones may be as effective as intravenous quinolones for admitted patients with moderately severe illness, most admitted patients should receive initial therapy intravenously to be sure that the medication has been absorbed. Once the patient shows a good clinical response, oral therapy can be started. Selected inpatients with mild to moderate disease can be treated initially with the combination of an intravenous β-lactam and an oral macrolide, switching to exclusively oral therapy once the patient shows a good clinical response.

In the ICU population, all individuals should be treated for DRSP and atypical pathogens, but only those with appropriate risk factors (see above) should have coverage for *P. aeruginosa*. As mentioned quinolone monotherapy has not been established as safe or effective for these patients, and monotherapy should not be used in any ICU admitted CAP patient. Those without *Pseudomonal* risk factors, should be treated with a selected intravenous β-lactam (cefotaxime, ceftriaxone, or ertapenem), combined with either an intravenous macrolide or an intravenous quinolone. For patients with *Pseudomonal* risk factors, therapy can be with a two-drug regimen, using an anti-*Pseudomonal* β-lactam (cefepime, imipenem, meropenem, or piperacillin/tazobactam) plus ciprofloxacin or high-dose levofloxacin, or alternatively, with a three-drug regimen, using an anti- *Pseudomonal* β-lactam plus an aminoglycoside plus either an intravenous non- *Pseudomonal* quinolone or macrolide.

Other Therapeutic Issues

In addition to the general approach to therapy outlined above, CAP patients need timely administration of initial antibiotic therapy. Retrospective data have shown a reduced mortality for admitted CAP patients who are treated within 4–6 hours of arrival to the hospital, compared with those who are treated later. However, it is uncertain if these outcomes are related to the timing of therapy or whether the timeliness of antimicrobial administration is a surrogate marker of other relevant factors. In the empiric therapy of CAP, there is a limited need for routine therapy against MRSA; however, a new strain of this organism has been described to cause a severe, necrotizing form of CAP after influenza. Although the frequency of this organism is still low, vigilance is needed to see how common it becomes in the future. The algorithms presented above suggest that all patients should receive empiric therapy that provides coverage for atypical pathogens. As mentioned, this recommendation is based on outcome studies, and may be explained by a high frequency of atypical pathogen co-infection. In fact, even with bacteremic pneumococcal pneumonia, mortality is reduced when a β-lactam is used with a macrolide, compared with when it is used as

monotherapy. Another emphasis of the recommendations for empiric therapy is to use a highly active agent in all patients with risk factors for infection with DRSP. The reason for this recommendation is because if a patient is at risk for infection with DRSP, the use of a highly active agent is not only likely to minimize the risk of treatment failure, but may also rapidly and reliably eradicate pneumococcal organisms that have even low levels of resistance, so that there is less selection pressure for the emergence of organisms with higher level of resistance.

Hospital-Acquired Pneumonia

How to Initiate Responsible Empiric Therapy (Table 115-3)

Many studies have documented that mortality in HAP is increased if initial empiric therapy is incorrect, or if there is a delay in the initiation of therapy. In the American Thoracic Society/Infectious Disease Society (ATS/IDSA)guideline for HAP, the terms "appropriate" and "adequate" therapy were defined. Appropriate refers to the use of an antibiotic that is active in vitro against the identified pathogen, the term "adequate" refers to not only using an antibiotic to which the organism is sensitive, but also using that therapy without delay, in the right doses, having it penetrate to the site of infection, and using combination therapy, if needed. For example, for critically ill patients with normal renal function who were effectively treated for nosocomial pneumonia in clinical trials, the correct doses, of common antibiotics include: cefepime 1 to 2 g every 8 to 12 hours; imipenem 500 mg every 6 hours, or 1 g every 8 hours; meropenem 1 g every 8 hours, piperacillin-tazobactam 4.5 g every 6 hours; levofloxacin 750 mg daily or ciprofloxacin 400 mg every 8 hours; vancomycin 15 mg/kg every 12 hours, leading to a trough level of 15 to 20 mg/L; linezolid 600 mg every 12 hours; and aminoglycosides of 7 mg/kg per day of gentamicin or tobramycin and 20 mg/kg of amikacin. However, it is still a challenge to use antibiotics adequately, without using them too widely, and

Table 115-3

Principles of Antibiotic Therapy for Hospital-Acquired Pneumonia

Prompt empiric therapy: Initiate when there is clinical suspicion of infection
Obtain a lower respiratory tract culture (sputum, tracheal aspirate, protected brush, BAL) prior to initiation of antibiotic therapy. Samples can be obtained bronchoscopically or nonbronchoscopically, cultured quantitatively or semiquantitatively.
Use a narrow spectrum agent for patients only at risk for infection with "core pathogens," and with no risk factors for MDR pathogens. Options include: ceftriaxone, ampicillin/sulbactam, ertapenem, levofloxacin, or moxifloxacin. For penicillin allergiy, use a quinolone or the combination of clindamycin and aztreonam.
Use combination therapy with a broad spectrum regimen, containing at least two antimicrobials in patients with risk factors for MDR pathogens. Specific choices should be guided by a knowledge of local microbiology patterns. Use an aminoglycoside or an antipneumococcal quinolone (ciprofloxacin or high dose levofloxacin), PLUS an anti-*Pseudomonal* β-lactam such as: cefepime, ceftazidime, imipenem, meropenem or piperacillin-tazobactam. If there is concern about MRSA, add either linezolid or vancomycin
Use the correct therapy in recommended doses (see text).
Choose an empiric therapy that uses agents from a different class of antibiotics than the patient has received in the past 2 weeks.
Try to de-escalate to monotherapy after initial combination therapy, after reviewing culture data and clinical response. If *Pseudomonas aeruginosa*, consider stopping the aminoglycoside after 5 days and finish with a single agent to which the organism is sensitive. If a non-*Pseudomonal* infection, switch to a single agent that the organism is sensitive to, using: imipenem, meropenem, cefepime, piperacillin/tazobactam, ciprofloxacin, or high-dose levofloxacin.
The drug of choice for *Acinetobacter* is a carbapenem, but colistin should be oonsidered if there is carbapenem resistance.
Consider linezolid as an alternative to vancomycin in patients with proven MRSA VAP, those with renal insufficiency, and those receiving other nephrotoxic medications (e.g., an aminoglycoside).
Consider adjunctive aerosolized aminoglycosides in patients with highly resistant gram-negative pathogens.

thus promoting antibiotic resistance, which is often driven by antibiotic use. Thus, the guideline emphasizes the need for a "de-escalation" strategy of usage, that generally urges prompt broad-spectrum empiric therapy whenever there is a clinical suspicion of infection, in order to avoid a delay of therapy, combined with a commitment to focus, narrow the spectrum, reduce the duration of therapy, or stop therapy once culture and clinical response information become available. Several studies have shown that it is possible to effectively treat VAP with 6 to 8 days of therapy, provided that the initial therapy is appropriate. The optimal duration of therapy for infections caused by *P. aeruginosa* and MRSA is still uncertain, but prolonged therapy may be no better than short duration therapy, in the absence of bacteremia.

Algorithms for Initial Empiric Therapy

Once there is a clinical suspicion of HAP, the antibiotic choice falls into either a narrow spectrum of therapy or a broad-spectrum regimen, directed at multi-drug resistant (MDR) pathogens. The narrow spectrum approach is used if the patient has a pneumonia that started in the first 4 days of hospitalization and there are no other risk factors for MDR pathogens. Risk factors include recent antibiotic therapy within the past 90 days, immunosuppressive illness or therapy (corticosteroids or chemotherapy), admission to a unit with a high rate of MDR organisms, recent hospitalization for two or more days within the past 90 days, residence in a nursing home or long-term care facility (i.e., the presence of HCAP); or regular visits to a hospital clinic or hemodialysis center. All others receive a broad-spectrum therapy approach.

The narrow spectrum therapy is directed at the "core pathogens," such as non-resistant enteric gram-negatives, pneumococcus,*H. influenzae*, and methicillin-sensitive *S. aureus*. Recommended regimens are usually monotherapy with ceftriaxone, ampicillin/sulbactam, ertapenem, levofloxacin, or moxifloxacin. If the patient is penicillin allergic, a quinolone can be used, or the patient can get the combination of clindamycin and aztreonam. When the patient has risk factors for MDR pathogens, therapy is directed at not only the core pathogens, but also *P. aeruginosa, Acinetobacter* spp., and in many instances MRSA. To provide this spectrum of coverage, patients need to receive at least two, and often three antibiotics. The recommended therapy is to use either an aminoglycoside or an anti-*Pseudomonal* quinolone (ciprofloxacin or levofloxacin) in combination with an anti-*Pseudomonal* β-lactam (cefepime, ceftazidime, imipenem, meropenem, or piperacillin-tazobactam). If there are concerns about MRSA because of risk factors, a high local prevalence, or the presence of gram-positives on a gram stain of lower respiratory tract secretions, then a third agent, either linezolid or vancomycin, should be added.

The use of combination therapy is controversial, and as mentioned, there are limited data to show that the use of an aminoglycoside with a β-lactam is more effective than β-lactam monotherapy. Dual therapy may have value if the patient is neutropenic, or if *Pseudomonal* bacteremia is present, but both situations are uncommon. Thus, the most compelling reason for using empiric combination therapy in patients with suspected MDR pathogens, is to provide a broad enough spectrum of agents to increase the likelihood that the initial therapy was appropriate. Once the organism is identified, it is possible to de-escalate, and if an aminoglycoside was used with a β-lactam, the maximal benefit may have been achieved after 5 days of dual therapy, and thus the aminoglycoside usually can be stopped at that point. Similarly, If a non-resistant gram-negative is identified, therapy can be with a single agent, and the ones that have been shown to be effective for critically ill mechanically ventilated patients are: ciprofloxacin, levofloxacin, imipenem, meropenem, piperacillin/tazobactam, and cefepime. Thus, it is usually possible to de-escalate to monotherapy with one of these agents as soon as culture data become available, or after 5 days of dual therapy with an aminoglycoside, if *P. aeruginosa* has been identified.

Other Principles of Antibiotic Usage for Hospital-Acquired Pneumonia

In general, it is necessary to use an agent as empiric therapy that is in a different class of antimicrobial than the patient has recently received. A number of studies of HAP have demonstrated that recent therapy with an antibiotic (within the past 2 weeks) predicts a greater frequency that pathogens such as *P. aeruginosa* will be resistant to the agents recently used. This applies to β-lactams, as well as to quinolones. In addition, some studies have shown that quinolones promote not only gram-negative resistance to quinolones, but also to β-lactams, and that their use can cause resistance to many types of β-lactam antimicrobials. With this in mind, it may be better not to use quinolones for a first episode of hospital infection, since it may make both β-lactams and quinolones less effective for a subsequent infection. If quinolones are not used for a first episode of infection, there will be more options available if the patient develops a second infection while in the hospital.

In the management of HAP, as clinical and microbiologic data become available, it is often possible to de-escalate therapy in the form of using less drugs, using agents of narrower spectrum, stopping therapy, or reducing the duration of therapy. The key decision point for manipulating therapy is on day 2 to 3 when a decision can be made about whether the patient is improving or not. This decision is made by assessing clinical features such as fever, leukocytosis, purulence of secretions, radiographic patterns, and oxygenation. In general, the best clinical predictor of response is improvement in oxygenation, which usually occurs by day 3 in survivors of VAP, but not in nonsurvivors. If the patient is improving, then cultures should be checked, and efforts made to de-escalate and shorten duration of therapy. In some instances, all signs of pneumonia are gone by day 2 to 3, respiratory cultures are negative and in retrospect, the diagnosis was heart failure or atelectasis, and antibiotics can be completely stopped.

Vaccination against Pulmonary Infections

Michael S. Simberkoff

Vaccines are an important, often recommended means of preventing pulmonary infections. There are several reasons to encourage their use.

1. Pulmonary infections, such as pneumonia, are associated with substantial morbidity. For example, recent data from the National Center for Health Statistics showed that respiratory diseases accounted for 11 percent of the hospitalizations in the United States during 2003. During that year, there were more than 1.4 million discharges from acute, non-federal health care facilities in the United States with pneumonia as the first diagnosis. The average length of stay for patients hospitalized with pneumonia was 5.5 days. Pneumonia disproportionately affects the elderly. In the study cited above, the rate of hospitalization for pneumonia for those who were 65 years of age or older was 224 per 10,000, over four times the rate in the population as a whole. In another population-based study conducted in the state of Washington, the rate of community-acquired pneumonia was 52.3 cases per 1000 person years among patients older than 85 years of age.
2. Pneumonia and influenza are, overall, the seventh leading causes of death in the United States, ranking behind heart, malignant, cerebrovascular, and chronic lower-respiratory tract diseases, accidents and diabetes mellitus. In 2003, the age-adjusted death rate for pneumonia in the United States was 21.4 per 100,000 population.
3. Pulmonary pathogens are increasingly resistant to commonly used antibiotics, even when acquired in the community. For example, investigators from the Centers for Disease Control and Prevention (CDC) recently reported that 24 percent of the bacteremic pneumococcal strains isolated during 1998 were resistant to penicillin and that 14 percent were resistant to multiple other antibiotics. Both of these numbers increased significantly during the period from 1995 to 1998. There was considerable variation in the prevalence of drug-resistant pneumococcal isolates from different parts of the United States, different age groups, and different racial backgrounds. Drug resistance was most common among the isolates from patients residing in Tennessee and Georgia, from patients who were very young and very old, and from white as compared to black patients.
4. Vaccines that are licensed for use in the United States are remarkably safe. Most produce transient local or mild and infrequent systemic reactions (described below).
5. The licensed vaccines are effective in preventing pulmonary infections and their complications. However, efficacy may vary in different patient populations. Specific examples will be discussed under individual vaccines.
6. Vaccines are generally inexpensive, whereas the pulmonary infections they prevent are often expensive to diagnose and treat. Further, infected patients are often unable to work for extended periods. Thus, use

of vaccines to prevent pulmonary infections is cost-effective for individual patients, employers, insurers, and society.

VACCINES AGAINST BACTERIAL PULMONARY PATHOGENS

A number of microorganisms infect the lungs including a diverse group of bacteria, mycobacteria, mycoplasma, chlamydia, viruses, and some fungi. *Streptococcus pneumoniae* is the most commonly recognized cause of severe community-acquired pneumonia (CAP), occurring in 20 to 50 percent of cases. *Haemophilus influenzae*, *Legionella* species, and *Moraxella catarrhalis* are isolated in 3 to 10 percent of cases.

Vaccines against four pulmonary pathogens are available (Table 116-1). These are the *S. pneumoniae* (pneumococcal) polysaccharide and protein-polysaccharide conjugate vaccines, the *H. influenzae*, type *b* protein-polysaccharide conjugate vaccines, the *Bordetella pertussis* vaccines (whole cell and acellular), and the live bacille Calmette-Guérin (BCG) vaccine.

Pneumococcal Vaccines

The pneumococcal vaccines are designed to elicit protective antibodies against the strains of *S. pneumoniae* that are commonly associated with invasive infection. At present, 83 pneumococcal serotypes are recognized by serological reactions with their capsular polysaccharide. Included among these are 19 serogroups consisting of 2 to 4 antigenically related serotypes. A 14-valent pneumococcal polysaccharide vaccine was licensed in the United States in 1977, a 23-valent polysaccharide vaccine was licensed in 1983, and a 7-valent protein-polysaccharide conjugate vaccine was licensed for use in infants and very young children in 2000.

The Advisory Committee on Immunization Practices (ACIP) recommended use of the 23-valent pneumococcal polysaccharide vaccine for immunocompetent individuals who are 65 years of age and older, for immunocompetent individuals who are between 2 and 64 years of age with chronic cardiac or pulmonary diseases, diabetes mellitus, cerebrospinal fluid leak, functional or anatomic asplenia, or those living in a chronic care facility. ACIP also recommended use of the vaccine for immunocompromised individuals 2 years of age and older, including those with human immunodeficiency virus (HIV) infection; leukemia, lymphoma, multiple myeloma or generalized malignancy; chronic renal failure or nephrotic syndrome; organ or bone marrow transplant recipients; and patients receiving immunosuppressive chemotherapy or corticosteroids. It recommended revaccination for those who were vaccinated at less than 65 years of age where 5 years or more have elapsed since last vaccinations.

Pneumococcal polysaccharides elicit a T-cell independent, B-cell response. Thus, responses to these vaccines are neither prolonged nor does revaccination elicit an anamnestic, booster response. Infants and young children (up to 5 years of age) respond poorly to the pneumococcal polysaccharide vaccine. Therefore, a 7-valent, protein-conjugate vaccine was developed to provide protection for them.

ACIP recommended use of the 7-valent pneumococcal vaccine for all children 23 months of age and younger and for children who are 23 to 59 months of age with chronic cardiac or pulmonary disease, cerebrospinal fluid leak, diabetes mellitus, renal failure or nephrotic syndrome, functional or anatomic asplenia, HIV infection, immuno- or complement

Table 116-1

Vaccines for Bacterial Pulmonary Pathogens

Pathogen	Vaccine	Targeted Population	Frequency
S. pneumoniae	23-valent polysaccharide	Elderly (>65 years of age) Asplenia; chronic pulmonary, cardiac or renal diseases; diabetes; HIV	Administer once; repeat once after 5 years
	7-valent protein-conjugate	Children 2 months to ≤5 years of age	2, 4, 6, and 12–15 months
H. influenzae, type *b*	Protein-conjugate	Children 2 months to <5 years of age	2, 4, 6, and 12–15 months
B. pertussis	Acellular purified	Children 2 months to <5 years of age	2, 4, 6, and 12–18 months
M. tuberculosis	Bacille Calmette-Guérin (BCG)	Not recommended in United States	Once in infancy

deficiency, or diseases associated with immunodeficiency or immunosuppressive therapy such as leukemia and lymphoma or those affecting transplant recipients.

Pneumococcal vaccines have proven to be effective in preventing invasive pneumococcal infections (proven bacteremia and/or isolation of the organism from normally sterile body fluids) in immunocompetent individuals. Their efficacy against noninvasive pneumococcal pneumonia and in immunocompromised individuals is more controversial.

Örtqvist et al reported the results of a randomized, double-blinded trial comparing pneumococcal vaccine and placebo in nonimmunocompromised patients 50 to 85 years of age who were being discharged from hospitals in Sweden with a diagnosis of CAP. A total of 693 patients were randomized: 340 received vaccine, 353 received placebo. In the vaccine group 63 patients developed recurrent pneumonia and in the control group 57 patients developed recurrent pneumonia (relative risk [RR] = 0.83; 95 percent confidence interval [CI] 0.58 to 1.2). Pneumococcal pneumonia was diagnosed in 16 and 19 of the patients in the placebo and vaccine groups, respectively (RR = 0.78; 95 percent CI 0.40 to 1.51). Thus, the pneumococcal vaccine did not appear to be protective against either pneumonia or pneumococcal pneumonia in this population.

Honkanen et al reported on a study in which patients 65 years of age and older living in Northern Finland were offered either a combination of influenza and pneumococcal vaccines (IPV, offered to those born in even years) or influenza vaccine (IV, offered to those born in odd years). Overall, 62 percent of the eligible populations decided to participate and there were 38,037 person-years of follow-up. There were 145 and 116 episodes of pneumonia in the IPV and IV groups, respectively (RR = 1.2; 95 percent CI 0.9 to 1.5). There were 52 and 40 episodes of pneumococcal pneumonia in the IPV and IV groups, respectively (RR = 1.2; 95 percent CI 0.8 to 1.9). There were 2 and 5 episodes of pneumococcal bacteremia in the IPV and IV groups, respectively (RR = 0.4; 95 percent CI 0.1 to 1.9). Thus, the pneumococcal vaccine appeared to offer incremental protection against bacteremic disease only.

Nichol et al reported on a retrospective cohort study (1993–1995) conducted among adults 65 years of age and older with a diagnosis of chronic lung disease who were enrolled in a health maintenance organization in Minnesota. Hospitalizations for pneumonia, influenza, and all deaths were assessed. Pneumococcal vaccination was associated with significantly lower risk of hospitalization for pneumonia (RR = 0.57; 95 percent CI 0.38 to 0.84) and for death (RR = 0.71; 95 percent CI 0.56 to 0.91). However, the authors noted that the patients who received pneumococcal vaccine were younger and had fewer co-morbid conditions than did the nonvaccinated cohort.

Jackson et al reported on a retrospective cohort study conducted between 1998 and 2001 among Group Health Cooperative member adults 65 years of age and older in Washington state. Pneumococcal bacteremia and CAP were the end points of the study. Receipt of pneumococcal vaccine was associated with a 44 percent reduction in the risk of pneumococcal bacteremia (RR = 0.56; 95 percent CI 0.33 to 0.93). However, receipt of the vaccine was not associated with a reduced risk of pneumonia (RR = 1.04; 95 percent CI 0.96 to 1.13).

French et al reported on the results of a trial of pneumococcal vaccine among untreated HIV-infected patients in Uganda. A total of 1392 HIV-infected patients were enrolled: 697 received the 23-valent pneumococcal vaccine; 695 received placebo. Invasive pneumococcal infection occurred in 15 and 7 patients in the vaccine and placebo groups, respectively (hazard ratio [HR] = 1.47; 95 percent CI 0.7 to 3.3). Pneumonia also was more frequent in the vaccine group (40 versus 21). Thus, pneumococcal vaccine offered no protection against invasive pneumococcal disease or pneumonia in this population of untreated HIV-infected patients.

Conaty et al conducted a review of cohort studies, case-control studies, and randomized clinical trials designed to study the efficacy of the pneumococcal polysaccharide vaccine in adult patients. Overall, these studies showed that the vaccine was effective against invasive pneumococcal diseases. The pooled efficacies of the randomized clinical trials, case-control studies, and observational studies reviewed were 0.62 (0.37 to 1.04), 0.45 (0.36 to 0.56), and 0.47 (0.41 to 0.54), respectively. Excluding studies done among young, high-incidence patients (e.g., South African gold miners), overall efficacy of the pneumococcal polysaccharide vaccine against all-cause pneumonia was less impressive. The efficacy of the vaccine in randomized, clinical trials was 0.97 (0.81 to 1.16), while its efficacy in the pooled cohort studies among the elderly was 0.68 (0.50 to 0.93).

Melegaro and Edmunds compared the published meta-analyses of pneumococcal polysaccharide vaccines in the elderly. These studies showed the vaccine to be effective against invasive disease in the general elderly populations (efficacy = 65 percent; 95 percent CI 49 to 92), far less effective in the high-risk elderly (efficacy = 20 percent; 95 percent CI −188 to −78), and generally ineffective against pneumonia (efficacy = 16 percent; 95 percent CI 50 to 53).

Fedson and Liss provided a critical analysis of the published results of trials and meta-analyses concerning pneumococcal polysaccharide vaccine efficacy and a counterpoint to some of their conclusions. These authors argued that many of the pneumococcal vaccine trials were underpowered and others used the wrong end points. For example, they contended that nonbacteremic pneumonia was a valid end point for studies because it could be diagnosed objectively by radiograph. However, they did not accept nonbacteremic pneumococcal pneumonia as a valid end point because recovery of pneumococcal isolates from sputum did not prove that this organism was present in the lung and causing the pneumonia seen on radiograph. Basically, they concluded (as did most authors) that pneumococcal vaccine is effective in preventing invasive complications of pneumococcal infection, but could make no firm conclusion about its efficacy against pneumonia. However, they contended that lack of proof of vaccine efficacy against pneumonia does not prove its lack of efficacy.

Data on efficacy of conjugate pneumococcal vaccines are less voluminous but point in the same general direction.

The seminal study on efficacy and safety of the protein conjugate vaccine was reported by Black et al. It was a randomized, double-blinded trial in which infants enrolled in the Kaiser-Permanente health system in Northern California were randomly assigned to receive the 7-valent conjugate-pneumococcal vaccine or meningococcal vaccine at 2, 4, 6, 12, and 15 months of age. Close to 38,000 infants were enrolled in the study and over 82 percent received 3 or more doses of the assigned vaccine. There were 40 cases of invasive disease caused by vaccine serotype *S. pneumoniae*. Thirty-nine of these were in the meningococcal vaccine recipients. The efficacy of the vaccine for fully vaccinated children was 97.4 percent (95 percent CI 82.7 to 99.9). The vaccine was highly effective against otitis media, reducing the number and severity of visits for this infection. The vaccine was well tolerated causing only slightly more local and systemic side effects than the meningococcal vaccine.

A conjugate pneumococcal vaccine also has been tested in developing countries. A trial conducted in The Gambia was reported by Cutts et al. In this trial, children 5 to 51 weeks of age were randomly assigned to receive 3 doses of a 9-valent conjugate pneumococcal vaccine or placebo. Over 8000 children were enrolled in each arm of the study. The primary end point of this study was radiologically confirmed pneumonia. Invasive pneumococcal disease, all-cause admissions, and death were secondary end points of this study. There were 333 children with radiologically confirmed pneumonia among the vaccine recipients and 513 among placebo recipients (vaccine efficacy [VE] = 37 percent; 95 percent CI 27 to 45). There were 9 and 38 cases of vaccine serotype-invasive pneumococcal infection among the vaccine and placebo recipients, respectively (VE = 77 percent; 95 percent CI 51 to 90). Compared to placebo the vaccine was 50 percent effective (95 percent CI 21 to 69) in reducing all invasive pneumococcal infection, 15 percent effective (95 percent CI 7 to 21) in reducing all-cause admissions, and 16 percent (95 percent CI 3 to 21) effective in reducing mortality in this patient population.

Use of the conjugate pneumococcal vaccine for children in the United States has yielded unanticipated benefits. Two publications have documented a declining rate of invasive pneumococcal disease that has occurred among older adults as well as children. Both of these publications used data from the Active Bacterial Core Surveillance (ABCS) Network. This network is situated in eight areas: San Francisco; the state of Connecticut; Atlanta; Baltimore; Minneapolis-St. Paul; Rochester, New York; Portland, Oregon; and Memphis-Nashville-Knoxville, Tennessee. The combined populations of these areas is approximately 19 million with approximately 5 million individuals who are 50 years of age or older.

In the first of these, Whitney et al reported on ABCS Network data during the first year (2001) following licensure of the conjugate vaccine compared to prior years. They found that there was a dramatic reduction in the rates of invasive pneumococcal infection in children under 2 years of age. They also found a small but significant reduction in invasive pneumococcal infections among adults.

The second report, by Lexau et al, provided follow-up data. In this study, the authors compared the rates of invasive pneumococcal disease in the ABCS Network populations during the pairs of years 2000–2001 and 2000–2003 following introduction of the vaccine compared to 1998–1999. They found that there was a 28 percent reduction in the rates of all serotype-invasive pneumococcal infections, a 55 percent reduction in the rates of the vaccine serotype invasive infections, and a slight increase in the rate of invasive disease caused by serotypes not in either the conjugate or pure polysaccharide vaccines in adults 50 years of age and older. A highly significant reduction in the rate of invasive pneumonia (pneumonia plus isolation of *S. pneumoniae* from blood or pleural culture) infections in the 50 years of age and older population was observed. However, not all older adults were benefited. The authors found that there was a significant increase in the rates of invasive disease among adults with HIV infection, diabetes mellitus, and immunosuppression such as Hodgkin's disease, leukemia, multiple myeloma, dialysis, nephritic syndrome, or transplantation recipients.

Appropriate use of the pneumococcal vaccine has become an indicator of quality of care in many large health care organizations in the United States including the Veterans Health Administration (VHA), the American Hospital Association, and the Joint Commission on Accreditation of Health Care Organizations. VHA was among the first to establish pneumococcal vaccination as a measure of quality of care and to measure vaccination rates by an external peer review of patient (EPRP) records program. Jha et al reported that the pneumococcal vaccination rate among VHA patient records reviewed in fiscal year (FY) 2000 was 81 percent compared to the rate of 27 percent in FY 1995 ($p < 0.001$), prior to the introduction of this measure.

In another study, Jha et al reported data on use of pneumococcal vaccine use in facilities that participated in the Hospital Quality Alliance Program (HQAP). Data were available from 3079 hospitals for 2004. They showed a lower rate of documented pneumococcal vaccine use than had the VHA study cited above. In 2004, less than 10 percent of the HQAP facilities had achieved a pneumococcal vaccination rate of 81 percent or more, the rate achieved by VHA facilities in 2000.

Finally, the National Health Interview Survey (NHIS) demonstrated that there are racial and ethnic disparities in receipt of pneumococcal vaccine. These NHIS data were collected in 2000 and 2001. They showed that both non-Hispanic blacks and Hispanics were significantly less likely to report receipt of pneumococcal vaccine than were non-Hispanic whites (odds ratio [OR] = 0.4; 95 percent CI 0.3 to 0.5 and OR = 0.4; 95 percent CI 0.3 to 0.5, respectively).

Pneumococcal vaccines are a remarkably safe and effective means of preventing invasive pneumococcal infections in children and adults. Their use is recommended for the very young, the elderly, and those at most risk from pneumococcal infections at all ages. Although it has not been proven that highly immunosuppressed patients respond to and are optimally protected by the vaccine, much broader use of these vaccines in the populations at risk should be encouraged.

Haemophilus influenzae, Type *b* Vaccine

H. influenzae is a common cause of pneumonia and bronchitis. Although many of the isolates from the respiratory tract are nontypeable, *H. influenzae,* type *b* (Hib) has been frequently associated with bacteremic pneumonia. For example, Farley et al found a total of 47 cases of invasive *H. influenzae* infection in patients 18 years of age or older in metropolitan Atlanta during the period from December 1, 1988 to May 31 1990 and calculated that the annual incidence was 1.7 cases per 100,000 population. Bacteremic pneumonia accounted for 70 percent of the cases and 44 percent of the 29 pneumonia-associated blood isolates that were serotyped were Hib. Twenty-two of the cases reported by Farley et al occurred in adults over 60 years of age (incidence 5.6 per 100,000 per year), and 21 of the 22 cases were associated with bacteremic pneumonia. Patients with HIV infection are another group at particularly high risk for bacteremic Hib infection.

Safe, immunogenic, protein-conjugate Hib vaccines (HibCV) exist. These have been licensed for use in the United States since 1987 and have proven to be remarkably effective in preventing invasive Hib infections. For example, the Centers for Disease Control (CDC) estimated that the rate of invasive Hib infections in U.S. children under 5 years of age was 100 per 100,000 prior to licensure of the vaccine in 1987, whereas in 2003 the rate of all serotype-invasive *H. influenzae* infections in this age group was 1.9 per 100,000 (376 reported cases), of which only 32 (9 percent) were serotyped to be Hib. Unfortunately, not all groups have benefited equally from wide use of the HibCV vaccines. The rate of invasive *H. influenzae* infections did not improve among the elderly (those who are 65 years of age and older). Further, American Indians and Native Alaskan children benefited less than other racial groups.

The HibCV program has virtually eliminated Hib meningitis, one of the most serious infections of early childhood, from the United States It also has dramatically reduced the number of Hib respiratory infections that occur. For example, Zhou et al estimated that HibCV prevents 1106 and 1567 cases per year of epiglottitis and pneumonia, respectively and prevents 663 deaths.

The ACIP recently added a footnote to its recommendations for adult immunization. This footnote pointed out that the HibCV are licensed for children 6 to 71 months of age and that, though data on their efficacy do not exist in older children and adults, the vaccines are safe and immunogenic in many high-risk populations (e.g., those with sickle cell disease, leukemia, and HIV infection). Administration of the vaccine to these patients is not contraindicated.

Pertussis Vaccine

Bordetella pertussis causes severe whooping cough in infants and young children. In recent years, however, clinical infections have been observed commonly in adolescents and young adults. For example, in the United States, a total of 11,647 *B. pertussis* infections were reported to the CDC in 2003, the highest number since 1964. Sixty-three percent of these infections occurred in persons who were 10 years of age and older. Currently, no pertussis vaccines are licensed in the United States for persons 7 years of age and older.

The typical features of *B. pertussis* infection in infants and young children are a persistent, paroxysmal cough followed by inspiratory gasps (whoops), vomiting, cyanosis, and apnea. Complications of *B. pertussis* infections (e.g., pneumonia, seizures, and encephalopathy) are most common in infants less than 1 year of age and are associated with inadequate vaccination. Death occurs in 0.4 percent of cases.

Recently, Lee et al reported on the morbidity and medical and societal costs of *B. pertussis* infections among adolescents and adults in Massachusetts. Two-thirds of the patients had severe, long-lasting cough with 31 percent of adolescents and 41 percent of adults reporting episodes of "whoops". Seventy-nine percent of adolescents and 81 percent of adults were still coughing at the time of interview, an average of 41 and 48 days, respectively, after onset of this symptom. Adolescents missed a mean of 5.5 days of school whereas working adults missed a mean of 9.8 days of work as a result of their pertussis infections. The medical costs of infection were approximately $275 per case (mean $242 for adolescents; $326 for adults). The nonmedical costs per case were $155 and $447 for adolescents and adults, respectively.

An acellular pertussis (aP) vaccine is available and is recommended for use in infants and young children in the United States. Acellular vaccines are composed of purified components of the bacteria that are thought to elicit protective immunity. They contain a combination of the filamentous hemagglutinin (FHA); detoxified pertussis toxin (PT); and pertactin, an outer-membrane protein. The aP vaccine is generally combined with diphtheria and tetanus toxoid vaccines and is given to children at 2, 4, 6, and 15 to 18 months of age with a final booster at 4 to 6 years of age or entry into kindergarten.

Pertussis vaccines can produce significant side effects. Local reactions include pain, tenderness, erythema, and induration at the inoculation site. Mild systemic reactions to pertussis vaccines include low-grade fever, drowsiness, fretfulness, and vomiting. Moderate to severe reactions include fever above 105°F, persistent inconsolable crying lasting at least 3 hours, and collapse (hypotonic-hyporesponsive episodes). Moderate to severe reactions are very uncommon with the acellular vaccine.

BCG Vaccine

Strains of the attenuated bovine tubercle bacillus, originally developed by Albert Calmette and Camille Guérin (bacille Calmette-Guérin, BCG), are among the most widely used and studied vaccines to prevent pulmonary infection. Worldwide, BCG has been in use since 1921, and over 3 billion individuals have been vaccinated. Despite this long history, use of the vaccine remains controversial, and it is not recommended for prevention of pulmonary tuberculosis (TB) in the United States.

Colditz et al reported on a meta-analysis of 15 prospective trials and 10 case-control studies of BCG. The efficacy of vaccine in preventing TB was 51 percent in the

prospective trials (RR = 0.49; 95 percent CI 0.34 to 0.70) for BCG recipients. The efficacy for preventing death was 71 percent (RR = 0.21; 95 percent CI 0.16 to 0.53). In case-control studies, the protective efficacy was 50 percent (RR = 0.50 (95 percent CI 0.39 to 0.64). Despite these data, use of the vaccine remains controversial.

One problem with BCG vaccine is that its observed efficacy varies greatly in different studies. Fine listed a number of possible reasons for the observed differences. These include: (1) differences in exposure of populations to nontuberculous mycobacteria (exposure to nontuberculous mycobacteria can affect the immune responses induced by BCG); (2) differences in the strains of BCG used (different strains elicit different immune responses); (3) differences in the age at which BCG was administered (BCG is most effective when given early in childhood and when protecting against primary infection); (4) differences in the time from vaccination to development of TB (protection can wane with time); and (5) differences in the nutritional status of the vaccine recipients (immune responses diminish as a result of malnourishment).

Recently, Aronson et al reported results of a 60-year follow-up study of the efficacy of BCG among American Indians and Alaskan Natives (subjects who have an unusually high risk of TB as well as other infectious diseases). This trial was originally conducted in Alaska, Arizona, North and South Dakota, and Wyoming between 1935 and 1938. It involved American Indian and Alaskan Native children and adults 1 month to 20 years of age who, prior to entry into the study, did not react to a second strength (250 TU) purified protein derivative (PPD) skin-test and who, upon entry, were given a single dose of BCG or saline placebo. The 60-year follow-up study showed that the overall incidence of TB was 66 and 138 per 100,000 person-years in the vaccine and placebo groups, respectively (efficacy 52 percent; 95 percent CI 27 to 69). Efficacy was observed for pulmonary and for extrapulmonary TB. Efficacy of BCG declined over time for men, but not for women.

BCG is *not* recommended for control of TB infection in the United States. Instead, a vigorous program of detection and treatment of latent and active TB is recommended for high-risk patients in high-risk settings (e.g., prisons, health care facilities) and for known contacts of patients (including infants and children) with active TB infection. However, research is recommended to develop an improved vaccine that would be effective in controlling latent TB infection.

VACCINES AGAINST VIRAL PULMONARY PATHOGENS

Although most viral respiratory infections are transient and benign, some can be associated with serious complications. Vaccines have been developed to prevent infections or limit the morbidity of some viral infections (Table 116-2). The most important of these are the vaccines against influenza, measles (rubeola), and chickenpox (varicella). An adenovirus vaccine was used exclusively in the military. However, it is no longer being manufactured and supplies have been exhausted.

Influenza Vaccine

Influenza viruses cause significant morbidity in all groups, but they are a particularly important cause of serious illness among aged and debilitated patients. For example, Thompson et al estimated that approximately 36,000 respiratory and circulatory deaths occur in the United States each year as a result of influenza virus infection. Over 90 percent of these occur in individuals 65 years of age and older. Further, the annual rates of influenza associated deaths in the United States increased steadily over the decade of the 1990s. This has increased the urgency for improving the influenza prevention and treatment programs.

Three distinct types of influenza virus exist: influenza A, influenza B, and influenza C. Influenza A viruses are

Table 116-2

Vaccines for Viral Pulmonary Pathogens

Pathogen	Vaccine	Targeted Population	Frequency
Influenza virus	Trivalent inactivated, whole or split	Persons ≥6 months of age	Annually
	Trivalent Live-attenuated	Healthy persons 5–49 years of age	Annually
Measles (rubeola)	Live-attenuated vaccine	All children Susceptible adolescents and adults	1st dose: 12–15 months 2nd dose: 4–6 years of age
Chickenpox (varicella)	Live-attenuated vaccine	All children Susceptible adolescents and adults	1st doses: 1–12 years of age 2nd doses: 6–8 weeks apart

classified into subtypes on the basis of two surface antigens: hemagglutinin (H0, H1, H2, H3, H4, H5, etc.) and neuraminidase (N1, N2, etc.). Immunity to these antigens, especially the hemagglutinin, reduces the chance and severity of infection. Influenza A and influenza B viruses undergo antigenic variation (drift and shift), although the latter has more stability. For the past two decades, two subtypes of influenza A and one of influenza B have circulated in the global community. However, an influenza A (H3N2) virus has been the predominant cause of morbidity and mortality.

Influenza virus infections can be prevented or controlled by annual vaccination. They also can be prevented or controlled by appropriate use of antiviral agents: amantadine or rimantadine for influenza A; oseltamivir and zanamivir for influenza A or influenza B. Two types of influenza vaccines exist: inactivated influenza vaccine and live-attenuated influenza vaccine (LAIV). Both are produced from egg-grown viruses that are highly purified. Inactivated virus vaccines are further divided into whole and split virus preparations. The latter are recommended for infants and children 6 months to 5 years of age because they are less likely to cause febrile reactions.

Every year, three influenza virus strains (usually two influenza A strains and one influenza B strain) are included in the vaccine preparations. For the past several years, the trivalent vaccine has consisted of an (H3N2), an (H1N1) influenza A, and an influenza B virus strain. These are chosen for the vaccine preparation on the basis of global monitoring by the World Health Organization (WHO) and anticipation that these viruses will circulate in the United States and other parts of the Northern Hemisphere during the late fall, winter, and early spring influenza season. For the 2006–2007 influenza season, the ACIP recommended vaccination for those at high risk of influenza and its complications as well as healthy adults over 50 years of age in October, November, and beyond throughout the influenza season.

Efficacy of the influenza vaccines has been difficult to assess because a number of agents can cause "flulike" symptoms and specific diagnostic tests (e.g., culture, serology) are rarely done in nonresearch, clinical situations. The ACIP estimated 70 to 90 percent efficacy of inactivated influenza vaccines in preventing illness in healthy adults over 65 years of age when the circulating viruses antigenically matched those used to prepare vaccine.

Bridges et al reported on a randomized, double-blind trial of inactivated influenza vaccine compared to placebo conducted among full-time, 18- to 64-year-old employees of the Ford Motor Company during the 1997–1998 and 1998–1999 influenza seasons. End points of this study were clinically defined influenza-like illnesses (ILI), days ill, associated physician visits, and time lost from work during the influenza season. During the 1997–1998 season, vaccine recipients reported more ILI, days ill, physician visits, and days lost from work than did placebo recipients. These differences were not significant. However, during the 1998–1999 season, vaccine recipients reported significantly fewer ILI, days ill, physician visits, and days lost from work than did the placebo recipients ($p = <0.001$ for each).

Demicheli et al reported results of a massive review and meta-analysis of the published literature on influenza control. Their analyses showed that parenteral vaccines had efficacies against virologically confirmed and clinical ILI cases of 68 percent (95 percent CI 49 to 79) and 24 percent (95 percent CI 15 to 32), respectively. They also reviewed data on LAIV, reporting efficacies of 48 percent (95 percent CI 24 to 64) and 13 percent (95 percent CI 5 to 13) against virologically confirmed and clinical ILI cases, respectively.

Influenza vaccination reduces the risk of hospitalization for cardiac disease and stroke as well as for respiratory disease among the elderly. For example, Nichol et al reported the results of a cohort study involving community-dwelling adults 65 years of age and older. They found that the risk of hospitalization for cardiac disease was reduced by 19 percent ($p = <0.001$) in vaccine recipients as compared to unvaccinated subjects. The risk of hospitalization for cerebrovascular disease was reduced by 16 percent ($p = 0.018$) in the 1998–1999 season and by 23 percent ($p = <0.001$) in the 1999–2000 season. The risk of death from all causes was reduced in vaccine recipients by 48 percent and 50 percent during the 1998–1999 and 1999–2000 seasons, respectively ($p = <0.001$).

Influenza vaccines are less effective in elderly, debilitated individuals. Therefore, the ACIP strongly recommends annual influenza vaccine administration to all health care workers (HCW). Studies have confirmed the benefits of this strategy in long-term care facilities. For example, Potter et al reported on a study in which patients and staff of geriatric, long-term care facilities were offered influenza vaccine. Facilities were divided into those where patients and HCW received vaccine, patient received vaccine but HCW did not, HCW received vaccine but patients did not, and facilities in which neither patients nor HCW received vaccine. Vaccination of HCW was associated in a reduction in mortality from 17 percent to 10 percent (OR = 0.56; 95 percent CI 0.40 to 0.80) and in ILI (OR = 0.57; 95 percent CI 0.34 to 0.94). Vaccination of patients was not associated with an effect on mortality (OR = 1.15; 95 percent CI 0.81 to 1.64). In another study, reported by Carman et al, the mortality of elderly patients in long-term care facilities was reduced from 22.4 percent to 13.6 percent (OR = 0.58; 95 percent CI 0.40 to 0.84) in facilities in which HCW were offered influenza vaccine.

The 2000 and 2001 NHIS data, referred to above, showed that non-Hispanic blacks were significantly less likely to report receipt of influenza vaccine than were non-Hispanic whites (OR = 0.7; 95 percent CI 0.6 to 0.8). However, there was no significant difference in the reported influenza vaccination rates for Hispanic and non-Hispanic whites (OR = 0.9; 95 percent CI 0.7 to 1.1).

Influenza vaccines are associated with relatively minor side effects. Local side effects of intramuscularly injected inactivated influenza vaccines, including soreness or swelling at the inoculation site, occur in 10 to 64 percent of patients, whereas systemic side effects (e.g., fever, malaise, and myalgia) are uncommon. Use of LAIV has been associated with runny nose or nasal congestion, headache, and low-grade fever. These were more often reported with the first dose of LAIV and were self-limited.

Occurrence of Guillain-Barré syndrome (GBS) following influenza vaccination has been of concern since an association between swine influenza vaccine use in 1976–1977 and GBS was first noted. As a result, the CDC established a Vaccine Adverse Event Reporting System (VAERS). During the 1993–1994 influenza vaccination season, an increase in the number of GBS cases reported to VAERS was noted. However, a careful study reported by Lasky et al showed that there was *not* an increase of vaccine-associated GBS during that period.

Two recent problems have refocused attention on control of influenza virus infections. The first is the shortage of influenza vaccine that occurred during the 2004–2005 season because of the problems of one vaccine manufacturer. As a result of that shortage, strategies to prioritize and stretch the use of available vaccine were developed. Two studies examined the immunogenicity of intradermal rather than the traditional intramuscular inoculation with influenza vaccine. These studies showed that a fraction of the conventional intramuscular dose elicited comparable seroconversion and presumed protective antibody titers when given intradermally. However, it was noted that reactions were more frequent following intradermal inoculations and that those over 60 years of age reacted less vigorously.

The second problem is the threat of avian influenza. WHO reported a total of 132 human cases of avian influenza A (H5N1) in Hong Kong, Vietnam, Thailand, Cambodia, Indonesia, and Fujian Province, China between 1997 and August 2005. Of these, 64 patients (48 percent) died. Most of the cases occurred in individuals who had exposure to infected poultry. However, there were clusters of infection within families. In addition, there were at least two incidents of apparent transmission of avian influenza from an infected 11-year-old girl to her 26-year-old mother and to a 32-year-old aunt with whom the child was living. The mother provided 16 to 18 hours and the aunt 12 to 13 hours of unprotected nursing care to the child. The child and her mother died from the infection, whereas the aunt survived.

The emergence of avian influenza as a human pathogen has raised concerns about the possibility of an influenza pandemic. A pandemic occurs when a highly contagious disease with novel antigens is introduced into a population with little immunity and spreads rapidly to cause worldwide disease. Influenza pandemics are known to have occurred in 1918, 1957, and 1968 when the H1N1, H2N2, and H3N2 influenza viruses were first introduced into the population, respectively. These prior pandemics were associated with approximately 40, 1, and 2 million deaths worldwide, respectively. The avian influenza (H5N1) has novel antigens for humans; there is little or no immunity to it. To date, avian influenza (H5N1) has not proven to be highly contagious either from fowl-to-humans or human-to-human. If, however, this virus acquires the genes that allow it to spread more efficiently, it could very well cause a pandemic associated with staggering morbidity and mortality.

At present there are no Food and Drug Administration (FDA)-approved, effective human vaccines against avian influenza (H5N1). The National Institute of Allergy and Infectious Disease (NIAID) has announced plans to test the immunogenicity of a candidate vaccine, but is unclear as to whether this will produce the desired antibody response, whether it will be approved without a clinical test of efficacy, or when it might be approved for use in humans.

Measles (Rubeola) Vaccine

Measles was a major cause of morbidity and mortality in the United States, and it remains an important pathogen in some other parts of the world. Before 1963, the year that a measles vaccine was introduced, approximately 400,000 cases of measles were reported annually in the United States, but as many at 3.5 million cases may have actually occurred. Prior to introduction of the vaccine, death occurred in 1 to 2 cases per 1000 measles cases in the United States. The risk of death was greater for infants, young children, and adults than it was for older children and adolescents. Death was usually associated with measles encephalitis or pneumonia. In 2003, there were only 56 cases of measles reported in the United States. Twenty-four of these were internationally imported cases, and an additional 19 were the result of exposure to internationally imported cases. In 2003, there were two measles-associated deaths in the United States.

Pneumonia is common in patients with measles. A study of 3220 U.S. Air Force recruits with measles showed measles pneumonia in 106 (3.3 percent) cases. Quiambao et al reported on 182 children with measles associated pneumonia who were admitted to the Research Institute for Tropical Medicine in Alabang, Philippines; 17 percent of these children died. Co-infection with bacteria (*Streptococcus pneumonia, Haemophilus influenzae, Staphylococcus aureus*) or other viruses was common and more likely to result in death.

Two doses of the live-attenuated measles virus vaccine are recommended for all children, adolescents, and adults without a true contraindication. These include severe allergic reaction after a previous dose or dose component, pregnancy, or severe immunodeficiency (congenital, hematologic malignancy, long-standing immunosuppression). A dose of the measles vaccine, generally combined with attenuated mumps and rubella vaccines (MMR) is recommended for children 12 to 15 months of age. A second dose should be given at 4 to 6 years of age prior to entry into kindergarten. Most colleges require documentation of two doses of measles vaccine before admission.

Measles vaccine can cause low-grade fever in 5 to 15 percent of recipients. This generally lasts 1 to 2 days. A transient rash may also occur.

Varicella Vaccine

The varicella-zoster virus (VZV) causes chickenpox in susceptible children and adults, and, as a result of latent infection in sensory ganglia, zoster in those who have had a previous case of chickenpox. Approximately 7 percent of healthy, young adults lack antibody to VZV.

Primary VZV was considered to be a relatively benign disease of childhood. However, it was associated with greater morbidity and mortality in adults. For example, Weber and Pellechia reported that 16 percent of military personnel with primary VZV infection had radiographic evidence of pneumonia. A number of factors increase the risk of developing VZV pneumonia including cigarette smoking, pregnancy, and prolonged use of nasal or inhaled steroids, immunodeficiency, malignancy, and transplantation. Meyer et al reviewed 2262 deaths that were ascribed to varicella during the 25-year period (1970–1994) prior to licensure of the vaccine in the United States. Adults had 25 times the risk and children under 1 year of age had 4 times the risk of dying compared to children 1 to 4 years of age with varicella. Pneumonia was the most common complication of the primary varicella infection in those who died.

Recently, Danovaro-Holliday et al reported on an outbreak of varicella involving 18 Mexican-born young adults residing in Alabama. Five of the cases were severe, requiring hospitalization. One patient developed pneumonia and another GBS. Fortunately, all of the patients survived. In an editorial commentary that accompanied this report, Gershon et al urged a more aggressive approach to identifying and vaccinating susceptible adults.

Live, attenuated varicella vaccine was approved for use in the United States in 1995. The number of varicella cases reported in the United States in 1984 and 2003 were 221,983 and 20,948, respectively.

Varicella vaccine is lyophilized and must be stored in a freezer at –15° to –20°C until use. It must be given within 30 minutes of thawing and reconstitution. Healthy children 12 months to 12 years of age should receive a single subcutaneous dose of the attenuated vaccine while adolescents and adults should receive 2 subcutaneous doses 4 to 8 weeks apart.

Approximately 15 percent of children inoculated with the attenuated varicella vaccine develop low-grade temperature elevations and 7 percent develop a transient, mild varicella-like rash.

Recently, a more potent version of the attenuated varicella vaccine was shown to be effective in preventing zoster infections in healthy adults over 65 years of age. However, it is not known whether this vaccine will be of any benefit in preventing the rare pulmonary infections that complicate zoster.

Adenovirus Vaccine

Adenoviruses cause respiratory infections in infants, children, adolescents, and young adults. They have been associated with pharyngitis, croup, bronchitis, and pneumonia. They are a particular problem in the military, where susceptible young men and women are brought together and where acute respiratory infections caused by adenoviruses types 4 and 7 are a leading cause of infirmary visits and hospitalization.

Inactivated vaccines, containing adenoviruses types 4 and 7 that were grown in monkey kidney tissue culture cells and then treated with formalin, were prepared and tested in military recruits in the 1950s and early 1960s. Randomized, controlled studies showed the inactivated vaccines to be more than 90 percent effective in reducing confirmed adenovirus infections.

Problems in production and contamination with simian viruses hampered further development of the inactivated adenovirus vaccine. Subsequently, Gutekunst et al tested a live, enteric, type 4 adenovirus vaccine in a placebo-controlled trial among marine recruits. The vaccine was 100 percent effective in preventing febrile respiratory disease in which adenovirus type 4 was recovered, 67 percent effective in preventing all febrile respiratory disease requiring hospitalization, and 77 percent effective in preventing all respiratory disease during the observation period.

For years, the enteric adenovirus vaccine was used by the military to protect recruits from adenovirus disease. Unfortunately, vaccine production was halted in 1995. The supply of adenovirus vaccine that remained was used by the military to vaccinate a limited number of recruits during 1996–1998 but was exhausted by 1999. By 1997, outbreaks of adenovirus infections had reappeared among military recruits. For example, Ryan et al reported an outbreak of 571 confirmed cases of adenovirus infection among recruits at a center in Great Lakes, Illinois that occurred in the fall of 1997. This outbreak was caused by adenovirus types 3 and 7. Similarly, Kolavic-Gray et al reported an outbreak of adenovirus type 4 infections that occurred in the fall of 1998 among U.S. Army recruits at Fort Jackson, South Carolina. This outbreak involved 678 recruits and caused 115 hospitalizations. In both of these outbreaks, respiratory symptoms were common.

CONCLUSIONS

Use of vaccines to prevent pulmonary infections has not been adequately emphasized in the past. Vaccines are a safe, effective, and relatively inexpensive means of preventing pulmonary infections that can be debilitating and, in some cases lethal. A number of vaccines are available and should be used in appropriate patients. These include the 23-valent polysaccharide and 7-valent conjugate pneumococcal vaccines, conjugate *H. influenzae*, type *b* vaccine, the acellular pertussis vaccine, the trivalent inactivated and live-attenuated influenza vaccines, and the live-attenuated measles and varicella vaccines.

A number of challenges to achieving a fully successful vaccination program exist. First, it is clear that there must be incentives for manufacturers to develop and maintain production of vaccines. A limited market for military recruits was an inadequate incentive for the manufacturer to sustain production of the adenovirus vaccine. Further, for many years, millions of doses of the inactivated trivalent influenza vaccines were unused. It is clear that manufacturers must have incentives to go through the costly process of preparing and maintaining supplies of vaccines. Subsidies may be necessary

to develop and sustain valuable vaccines with limited or unpredictable markets.

Second, there must be better incentives for health care providers to use or urge the use of existing vaccines. In 2006, Medicare will pay providers in New York City only $21.65 for administration of either the pneumococcal or trivalent influenza vaccines. This is less than the $23.08 that was paid for the same service in the same area in 2005. This cut in funding is not advisable. It is clear that there must be improvements in the financing of vaccination programs and/or development of alternate incentives (e.g., achievement of accreditation goals set by the Joint Commission on Accreditation of Healthcare Organizations, the American Hospital Association, and other organizations) to encourage provider participation in adult vaccination programs.

Finally, there must be better education of consumers and employers about the benefits of vaccination. Vaccination programs will be successful if there is demand for the vaccines. The most successful programs occur among our infants and children because parents demand and states or schools require evidence of vaccination. Consumers must be convinced that they need to be up-to-date with recommended vaccinations. Further, employers must be convinced that inexpensive vaccines can prevent illness and that healthy employees are more productive. Ultimately, patients are the beneficiaries of successful vaccination programs. Once this is recognized, they will demand the vaccines.

Microbial Virulence Factors in Pulmonary Infections

Gregory Priebe • Gerald B. Pier

Beginning at birth, microbial organisms enter and leave the body, primarily on external or mucosal surfaces. Some of these predominantly commensal organisms become resident; others are transient; and still others establish latent foci in otherwise sterile spaces. Over a lifetime, a person is the reservoir for hundreds of strains of viruses, thousands of bacterial species, and a scattering of fungi and parasites. When these organisms violate their niche, invade, or produce toxic products, virulent interactions take place and occasionally lead to disease. Thus, organisms can cause disease without entering or adhering to tissues by releasing toxic products. However, many infections are preceded by attachment of organisms to surfaces, followed by their entry into cells or otherwise sterile spaces. These processes of invasion are complex and involve factors present in both the host and the organism. Most organisms are cleared by a variety of nonspecific and specific mechanisms, with nonspecific mechanisms generally falling under the heading of innate immunity and the specific under adaptive immunity. In some situations, however, organisms are able to propagate and produce clinical symptoms. A number of pathological conditions in the host predispose to entry and survival of microbes, ranging from breaks in mucosal surfaces to defects in the immune system. Organisms become parasites when they express the requisite *virulence determinants* to gain entry and overcome or evade host defenses.

An important step in establishing infection occurs when the potential pathogen encounters the immune system. There are numerous mechanisms whereby the immune system detects and tries to limit the extent of microbial challenge, including inflammation (acute and chronic), phagocytosis (neutrophils and macrophages), complement, and humoral and cellular immune responses. The immune system also maintains surveillance for organisms that invade phagocytes, propagate, and resist killing, and also for organisms that invade nonphagocytic cells. Means by which microbes can be controlled range from physical clearance mechanisms to phagocytosis (followed by oxidative or nonoxidative killing) to nutritional depletion (e.g., sequestration of iron, which is an essential nutrient for bacterial growth).

Microbes have evolved a variety of strategies to overcome host defenses, evade the immune system, scavenge for nutrients, and survive to spread to other hosts. These processes can lead to tissue damage and even death of the host. However, ultimate survival of the microbe requires eventual spread to a new host. A new "generation" of microbes is established (by clonal division) approximately once an hour, whereas a new generation of humans occurs about once every 20 years. Thus, the microbes have a clear genetic advantage in selecting properties that enhance virulence and survival. In response, the human immune system has developed to present a variety of defenses against a broad range of pathogenic mechanisms. Infections can occur at specific sites on surfaces or within the body or involve local, distal (metastatic), or systemic spread. Infection can occur without damaging cells,

through direct cellular damage by microorganisms or their toxins, or as a consequence of the immune response. When physiological disruption or cellular damage occurs, the host needs to recover and repair. In addition, the immune system attempts to recognize the pathogen and prevent reinfection. Pathogens have also evolved a series of mechanisms to avoid immune detection, including local interference with immune processes, antigenic variation, and avoidance of inducing an immune response.

Organisms are constantly evolving to meet the demands and opportunities of modern society. Just as the cities of the Middle Ages brought together humans and rats and caused outbreaks of bubonic plague, the use of antibiotics, chemotherapy, and various medical devices has led to a number of new pathogenic interactions between microbes and humans. A key to understanding the pathophysiology of infectious diseases and appreciating the complexity of both the immune system and the microbial world is knowledge of the facts and processes of each; this knowledge base is necessary for an understanding of the ideas presented above and the conceptual basis of immunity and infection as related to respiratory tract infections.

GENERAL MECHANISMS OF INFECTIOUS PROCESSES IN THE RESPIRATORY TRACT

The pathogenesis of acute and chronic microbial infections of the lungs entails complex interactions between the microorganisms and a variety of host defense mechanisms. The general steps and molecular factors involved in the pathogenesis of microbes causing lung infections are summarized in Table 117-1. Although the alveolar spaces are generally sterile, low levels of microorganisms are continually inhaled into the lungs. Inoculation of the lungs can occur from a variety of sources, including aspirated upper-airway secretion or bacteria in small aqueous droplets inhaled directly via the nose or mouth. Most commonly, inhaled organisms, either alone or in association with particles of mucus, gain access to the lower airways. They are generally either cleared by mucociliary flow or scavenged by phagocytes (see Chapter 111). Particulates greater than 10 μm in diameter are deposited in the upper airways. Particles of less than 5 μm that are not cleared in the upper airways can be deposited in alveoli. Most particulate matter is not infectious, and only spores or organisms that remain viable can cause infection. Thus, the pathogenesis of microbial infection will initially depend on a microbe's ability to enter the respiratory system and avoid clearance by mechanical and innate immune mechanisms.

As noted above, microorganisms can reach the lower airways from various sources. Organisms in ambient air can be inhaled as droplet nuclei—particularly in closed environments, where density is great and infected individuals can deposit organisms into the air. Perhaps the most important source of organisms causing pneumonia is the flora of the upper respiratory tract. A large ecosystem of microorganisms that includes both pathogenic and nonpathogenic bacteria and fungi normally resides in the upper airways. The quantity and species diversity of many of these organisms can be stable over long periods, but transient colonization

Table 117-1

Steps and Molecular Factors for Infectious Microorganisms to Cause Lung Disease

Step	Molecular Factors	Result
Attachment to or entry into the body	Pili, flagella, surface proteins, lipopolysaccharide (LPS), specific ligands for receptors on host cells or mucins	Establish organisms in a host
Multiplication	Iron-binding factors; quorum-sensing signals, biofilm matrix	Increase microbial numbers; activate other virulence systems; initiate clinical symptoms
Local or general spread into the lungs	Capsular polysaccharides, antiphagocytic factors, motility (pili and flagella), toxins	Evade defenses and the natural barriers to spread
Damage to lung tissue	Exotoxins (including type III secretion system), LPS, cytotoxins, immunosuppressive factors	Inflict basic pathology due to the infectious agent
Shedding (exit) from the body	None identified	Leave body at site and on a scale that ensures spread to a new host

with a variety of microbes also occurs with some frequency, and these changes are often correlated seasonally and/or with concomitant infections with respiratory viruses. For example, *Streptococcus pneumoniae* and *Neisseria meningitidis* are more frequently isolated from the nasopharynx or throat during the winter months. In addition, organisms that make up the normal microbial flora in other parts of the body can be transferred to the lung, where they can cause infection. In early onset group B streptococcal pneumonia and sepsis in neonates, the organisms are transferred during birth from the vaginal canal of the mother to the respiratory tract of the infant.

Organisms causing infections at other body sites can spread to the lungs. Although not common, hematogenous spread from the bloodstream to the lungs can occur. The existence of heavy colonization or infection in the upper airways also increases the potential for infection in the lungs by a variety of mechanisms, mostly by a simple dose effect, whereby a large burden of potentially pathogenic organisms overwhelms the clearance mechanism of the lungs. Another mechanism for pneumonic infection can result from infections that perturb the specific and nonspecific defenses, leading to respiratory infection as a sequela of another pathogenic process. The most common example of this process is bacterial infection secondary to influenza virus. In fact, the neuraminidase of influenza virus has been shown to play a synergistic role in pneumococcal pneumonia models by cleaving the sialic acid residues on host glycoconjugates, thereby leading to increased adherence of the bacterium. Finally, any process that disrupts the physiological and physical barriers between the upper and lower airways can lead to infection—for example, the placement of an endotracheal tube or changes in normal clearance mechanisms associated with cystic fibrosis.

Once a microorganism gains access to the lower respiratory tract, it must be able to attach to tissue factors, remain viable, and multiply. Usually organisms will either multiply locally, resisting local defenses, or spread to other body sites by traversing epithelial barriers that normally inhibit microbial spread. In order for extracellular organisms to multiply, they must scavenge for nutrients. Of particular note is the universal requirement for iron, which must be extracted from iron-binding molecules such as transferrin. Many bacteria produce iron-binding substances known as siderophores that have an affinity for iron of greater than 10^{18} M and bind to high-affinity receptors on the bacterial surface. Organisms must also avoid or resist opsonophagocytosis or be able to survive and multiply within phagocytes. Subsequent to microbial growth and resistance of host defenses, damage to the host tissues occurs. This process is aided by a variety of pathogenic factors and results in invasion of tissues often with destruction of cells. Secreted toxins can act locally and/or be systemically spread to cause clinical symptoms. Many gram-negative bacilli possess a type III secretion system which can function like a hypodermic needle to inject toxins directly into host cells. The potential for inflammation to cause tissue destruction can be a devastating consequence of microbial growth in normally sterile lung sites. Finally, although not necessary for the pathological process to take place, most organisms that successfully multiply will have mechanisms with which to leave the body and transmit disease, thereby propagating their species.

MOLECULAR FACTORS AND PROCESSES IN RESPIRATORY INFECTIONS

The study of pathogenic microorganisms has benefited greatly from the ability to identify microbial factors that are at work to elicit a particular pathological process. Often these factors by themselves are responsible for a particular aspect of the infectious process, whereas at other times these factors act in consort to promote microbial colonization, growth, infection, and ultimately host responses and disease.

The success of the microorganism in establishing infection (the presence of a microorganism in a tissue where it is not normally found) and causing disease (the signs and symptoms of clinical illness) is predicated on the organism's ability to elaborate specific molecular factors that allow it to progress from the colonization to the disease state. Factors that inhibit or neutralize the host's response to eliminate the organism are also critical for pathogenesis. The ability of specific microorganisms to produce virulence or pathogenic factors is highly variable and is doubtless a major reason for the differences in pathogenicity among closely related strains of bacteria. Initially, most microbes that establish themselves in the respiratory tract will bind to host tissues, often in a specific manner. Pathogens will produce specific molecules to promote this process. Some potentially pathogenic microorganisms, such as *S. pneumoniae* and *N. meningitidis,* can establish colonization in the nasopharynx or throat without causing harmful effects. Almost everyone is colonized by these potential pathogens many times during life. Viruses and obligate intracellular parasites, such as *Chlamydia,* usually must find their way to the lower respiratory tract and invade a specific cell in order to start growing. Bacterial pathogens, such as *Legionella pneumophila* and *Mycobacterium tuberculosis,* need to encounter alveolar macrophages where they are ingested but resist destruction within these cells.

In some cases, as long as a potential pathogen confines itself to a local site, no disease will ensue. At other times, growth at the local site causes frank disease; this is the mechanism of group A streptococcal pharyngitis and whooping cough caused by *Bordetella pertussis.* In general, the nasopharynx and throat readily tolerate the presence of a dynamic bacterial population, comprising mostly nonpathogenic strains along with potential pathogens that do not spread to other tissues.

Most of the initial host response to pathogens in normally sterile sites, indicative of infection, involves the basic inflammatory responses of innate immunity. The microbes generally initiate this response by activating complement, binding quasi-specific host molecules such as mannose-binding

lectin, and generating other tissue signals via cell-associated pattern-recognition molecules such as toll-like receptors that lead to an influx of inflammatory cells and serum factors into the site of infection. Inflammation leads to clinical symptoms in the form of a sore throat, sneezing, coughing, feeling of malaise, etc. Some particularly virulent microbes can produce much more serious disease rapidly as the organisms spread and cause inflammation diffusely throughout the respiratory tract. Failure to control microbial growth and sustained inflammation lead to pathological tissue destruction. The balance between the host inflammatory response and microbial growth is the key factor in the disease process. As is often the case with microbial infection, inflammation is a double-edged sword, critically important for resolution of infection but also responsible for tissue damage.

SPECIFIC VIRULENCE MECHANISMS OF MICROBIAL PATHOGENS

Much of our knowledge in the area of molecular mechanisms that microbial pathogens use to establish and cause respiratory infections is derived from studies of bacteria. In the case of viruses, clear factors, such as the neuraminidase and hemagglutinin proteins on the coat of the influenza virus, are needed to expose cellular receptors and promote viral binding, subsequent cellular invasion, viral replication, inflammation, and disease. All viruses causing respiratory infections must enter cells in some manner that includes binding of a specific viral factor to a specific host cellular receptor. Intracellular nonviral microbes such as *Chlamydia* are probably taken into cells nonspecifically by phagocytosis or endocytosis.

A fairly good understanding of the molecular basis for the pathogenesis of *B. pertussis* infection has been established. *B. pertussis* binds exclusively to the cilia on ciliated respiratory epithelium using at least two bacterial cell-surface factors, designated pertactin and filamentous hemagglutinin (FHA). A fraction of the organism's cell wall, the muramyl dipeptide, is then extensively produced and secreted, and this factor is toxic to the ciliated tracheal cells. These cells are extruded from the epithelial surface, perhaps in an attempt to clear the bacteria from the respiratory tract. Secretion of pertussis toxin also contributes to the pathology. Pertussis toxin is composed of two subunits, designated A and B; the B subunit binds to receptors on host cells, allowing the A subunit to enter the cell. The A subunit transfers the ADP-ribosyl part of NAD to a membrane-bound GTP-binding protein that normally inhibits the enzyme adenyl cyclase. This leads to increased synthesis of cyclic adenosine monophosphate (cAMP). One recently described role of pertussis toxin is to inhibit neutrophil recruitment, thereby delaying antibody-dependent clearance of the bacterium even in immune hosts.

Other extracellular pathogens that cause lung infections establish themselves in tissues by binding to either cellular receptors or factors in the mucus, notably mucin. Krivan and colleagues report that several bacterial pathogens that frequently cause pneumonia—including *Pseudomonas aeruginosa, Haemophilus influenzae, Staphylococcus aureus, Streptococcus pneumoniae, Klebsiella pneumoniae,* and some *Escherichia coli*—bind specifically to terminal or internal Ga1NAc-β(1-4)-Gal sequences lacking sialic acid residues commonly found on cellular glycolipids in the respiratory tract. *P. aeruginosa* itself has been prominently studied in regard to binding to respiratory mucins as a mechanism to establish and maintain infection in the lung. Nontypeable *H. influenzae* also appears to use pilus-mediated adherence to human respiratory mucins to establish chronic infections in the lung.

Intracellular respiratory bacterial pathogens usually are ingested by alveolar macrophages and must resist phagocytic killing in order to establish infection and cause disease. *M. tuberculosis* enters these cells in the lower and middle airways with high airflow, as it is an obligate aerobic organism. Bacterial ligands and cellular receptors involved in this process are not fully characterized, although dendritic cell-specific intercellular adhesion molecule-3 grabbing nonintegrin (DC-SIGN) on dendritic cells and macrophages appears to play a role. Following inhalation, most individuals will effectively clear or contain the tubercle bacilli, while in a minority the bacteria escape from the macrophage phagolysosome, or prevent its formation in the first place, leading to bacterial growth and host inflammation and resulting in lesions typical of tuberculosis. On the opposite side of the time spectrum from *M. tuberculosis*, inhaled spores of *Bacillus anthracis* are phagocytosed by alveolar macrophages but within 6 hours can germinate, escape from the phagosome, replicate within the cytoplasm, and escape from the macrophage to enter the lymphatics or bloodstream.

Respiratory pathogens elaborate additional virulence factors beyond those needed to establish infection in normally sterile tissues. Many respiratory bacterial pathogens are encapsulated—a critical factor in promoting bacterial resistance to phagocytic killing. Neutralization of this antiphagocytic property by specific antibody results in high-level host immunity. Successful vaccines against *S. pneumoniae, H. influenzae* type b, and certain serogroups of *N. meningitidis* have been developed by engendering capsule-specific immunity via immunization, and comparable vaccines against *P. aeruginosa, K. pneumoniae,* group B streptococcus, and *S. aureus* are in various stages of development and testing in humans. Many studies support a role for the M protein capsule-like antigen of group A streptococcus in preventing phagocytosis of this organism, although recent studies suggest that the nonimmunogenic hyaluronic acid capsule plays a more prominent role as an antiphagocytic factor for group A streptococci.

Regulation of the expression of virulence factors is tightly controlled by the pathogen via complex networks of two-component regulatory systems and other systems. In *P. aeruginosa*, quorum sensing (cell-density–dependent gene expression) via small organic molecules called acyl homoserine lactones has been shown to be important for virulence in

pneumonia models both by regulating expression of secreted toxins and by inducing inflammation. *S. aureus* strains control virulence through regulatory peptides involved in activating and suppressing the accessory gene regulator (*agr*) network, with similar systems found in other gram-positive pathogens as well. Interfering with these systems with appropriate inhibitors holds promise for future therapeutic interventions in bacterial pneumonia.

Many respiratory pathogens, particularly *P. aeruginosa* and *S. aureus*, elaborate some very potent toxins. *P. aeruginosa* secretes an elastase that can interfere with innate immunity in the lung by cleaving surfactant protein D, thereby abrogating its role in bacterial clearance. In addition to secreted toxins, protein effectors of the type III secretion system of *P. aeruginosa* can be directly injected into host cells, injuring the alveolar epithelium and subsequently allowing the release of proinflammatory cytokines such as tumor necrosis factor–α (TNF-α) into the circulation, resulting in septic shock. The recent emergence of strains of community-acquired methicillin-resistant *S. aureus* (MRSA) that secrete the Panton-Valentine leukocidin, a pore-forming toxin specific for white blood cells, has been associated with severe cases of necrotizing pneumonia. The gram-negative endotoxin, also called lipopolysaccharide (LPS), can cause serious damage to lung tissues, although the lung seems relatively resistant to the effects of inhaled endotoxin when compared with the systemic response to circulating LPS.

EXAMPLES OF THE MOLECULAR PATHOGENESIS OF ACUTE AND CHRONIC BACTERIAL RESPIRATORY INFECTIONS

Pneumococcal pneumonia is the prototypic acute bacterial respiratory infection. As important a pathogen as *S. pneumoniae* is in the respiratory tract, the understanding of how it causes pneumonia and sepsis is not extensive. The capsular polysaccharide is a critical virulence factor, but beyond this, the role of other bacterial products in pathogenesis is mostly unknown. The cell-wall bacterial phosphorylcholine of virulent *S. pneumoniae* has been shown to bind to the G protein–coupled platelet-activating factor (PAF) receptor following inflammatory activation of human cells. This leads to invasion of epithelial and endothelial cells, indicating a mechanism whereby *S. pneumoniae* could escape through the lung epithelium via the vascular endothelium into the circulation to cause sepsis. The fact that lung inflammation increases PAF receptor levels is likely another reason for the hypersusceptibility of people with viral upper respiratory infections to secondary infection with *S. pneumoniae.*

Chronic lung infections can be caused by a variety of bacterial pathogens, many of which occur in persons with underlying lung disease. Patients with chronic obstructive pulmonary disease are particularly susceptible to chronic infection with nontypeable *H. influenzae,* although beyond the propensity of the organism to bind to respiratory mucins, the molecular bases for infection and disease are mostly unclear. Interestingly, co-colonization experiments with *H. influenzae* and *S. pneumoniae* in mice have found that *H. influenzae* predominates due to *H. influenzae*-induced complement-dependent phagocytic killing of *S. pneumoniae.*

Among patients with cystic fibrosis (CF), 80 to 90 percent will become chronically infected with *P. aeruginosa.* This infection is currently the major factor limiting their life expectancy. A large research effort has focused on understanding how this pathogen infects the vast majority of patients with a genetic defect that does not appear related to chronic bacterial lung infection. In patients with CF, mutations are found in the CF transmembrane conductance regulator (CFTR) gene which codes for a large protein that regulates chloride ion secretions directly and also appears to affect the flow of other ions, such as sodium. Ninety percent of people carry at least one mutant CFTR allele that lacks the codon for the phenylalanine at position 508 (ΔF508 mutation), and about two-thirds of affected persons are homozygous for this mutation. The lack of phenylalanine at position 508 leads to an inability of the mature protein to get into the cell membrane.

The relationship of mutant CFTR and hypersusceptibility to chronic *P. aeruginosa* infection is undergoing intensive study. Pier and colleagues have proposed that clearance of *P. aeruginosa* from the lung following inhalation of bacteria is critically dependent on CFTR-controlled internalization of the bacterium by lung epithelial cells followed by rapid activation of innate immunity involving nuclear factor (NF)-κB nuclear translocation and production of inflammatory cytokines such as interleukin (IL)-6, IL-8, and CXCL1. The combined effects of epithelial cell internalization and shedding along with rapid activation of innate immunity that most likely brings in neutrophils to phagocytose and eliminate any other extracellular bacteria can lead to efficient microbial clearance. Resolution of this response via apoptosis has also been shown to be important in the CFTR-dependent response of the lung to *P. aeruginosa.* The CFTR protein has been identified as the actual cellular receptor for clearance of *P. aeruginosa* from the lung. In a neonatal mouse model of clearance of *P. aeruginosa* from the lungs after nasal inoculation of bacteria, it was found that blocking of CFTR-mediated epithelial cell ingestion of *P. aeruginosa* led to higher bacterial burdens in the lung. Similarly, in transgenic CF mice there is reduced epithelial cell uptake of *P. aeruginosa* and increased overall bacterial burdens in the lung. Of note, there appears to be little to no binding of bacteria to tracheal epithelial cells in infected CF mice whereas extensive binding, ingestion, and shedding of *P. aeruginosa* by epithelial cells can be seen in tracheas of infected wild-type mice. Thus, in vivo, *P. aeruginosa* binding to CF epithelial cells is not observed, a situation completely consistent with results from histopathological examination of lungs taken at transplant or autopsy from CF patients, where *P. aeruginosa* also is not seen binding to the epithelium but rather encased in mucous plugs within the airways. Overall, the initial establishment of *P. aeruginosa* infections in the lungs of CF patients can be directly attributable

to the lack of functional CFTR in cell membranes to bind to this microbe and initiate appropriate innate immune responses, which prevents efficient bacterial clearance from the lung.

The pathogenesis of chronic *P. aeruginosa* lung infections in CF patients is more extensive. After avoiding initial clearance, the bacteria adhere to mucins and become embedded in mucous plugs within the airways and eventually undergo a phenotypic conversion wherein they lose both their ability to produce the long O polysaccharide side chains that are usually on the LPS and acquire the ability to elaborate copious quantities of a bacterial exopolysaccharide called alginate. The hypermutable phenotype seen in *P. aeruginosa* strains from CF patients likely speeds this adaptation. Alginate is unable to provoke a protective antibody response in the host and encases the bacteria in microcolonies within a hypoxic microenvironment in the lung. Within this protective coating, phagocytes such as neutrophils are unable to ingest and kill the microorganisms. This leads to a vicious cycle of additional but ineffective inflammation and bacterial growth, the result of which is tissue destruction subsequent to the chronic inflammatory process. Alterations in the lipid A structure of the *P. aeruginosa* LPS in strains isolated from CF patients appear to confer resistance to antimicrobial peptides and a hyperinflammatory response. For most of the patient's life, *P. aeruginosa* infection appears to remain confined to endobronchial surfaces, which become plugged with mucus while the airway tissues are being destroyed, although recently reported histopathological results from lungs of CF patients who died in the 1970s, prior to more modern medical management with aggressive antibiotic therapy used in some countries, also showed extensive alveolar involvement. The finding of quorum-sensing signals in the CF lung suggests that the *P. aeruginosa* may exist as a biofilm (defined as a structured community of bacteria encased in a self-produced matrix), which likely contributes to the recalcitrance of this infection to antibiotics. Thus, the pathogenesis of chronic *P. aeruginosa* infection in CF involves at least two components: an initial phase of hypersusceptibility to infection that is predicated on an inability of CF patients to kill or clear inhaled *P. aeruginosa* cells and a subsequent phase directly related to the bacterium's ability to elaborate alginate, which allows the organism to resist host defenses while continuing to provoke inflammation that damages lung tissues.

From these two examples we garner some important insights into mechanisms whereby bacterial pathogens cause lung infections. Many of the principles apply to other types of pathogenic microbes that follow the basic scenario of entry, attachment, multiplication and survival, elicitation of inflammation, and ultimately tissue damage and compromise of respiratory function. Although each of these steps can often be characterized at a highly specific molecular level, usually using isolated factors such as toxins to elicit clinical symptoms of disease, the overall pathogenesis of disease requires that elaboration of molecular factors of pathogenesis be coordinated and that each step in the process occur under the proper circumstances and at the right time. Research in identifying and understanding the microbe's genetic and molecular factors that control and coordinate pathogenesis is in its infancy. Presumably, greater understanding of particular factors and the interactions among both the factors and host tissues will lead to development of better vaccines and other therapies that will minimize the occurrence of microbial infections in the lung.

CHAPTER

Infections of the Upper Respiratory Tract

Marlene L. Durand

Upper respiratory tract infections are the most common infections and the most frequent reasons for office visits in the United States. Most upper respiratory infections are minor and self-limiting, but some (e.g., peritonsillar abscess, epiglottitis, invasive fungal sinusitis) may be life-threatening.

THE COMMON COLD

The common cold is a mild, self-limiting infection. Six major viral families are responsible: rhinovirus (30 to 40 percent of cases); influenza virus (25 to 30 percent); coronavirus (10 to 15 percent); adenovirus (5 to 10 percent); parainfluenza virus (5 percent); and respiratory syncytial virus (5 percent). Each virus has several serotypes; rhinovirus has 100. Adults have an average of two to four colds and children six to eight colds per year.

In the United States, the incidence of colds is seasonal, with most occurring fall through spring. Young children are the main reservoir of respiratory viruses, and adults with children have more colds than those without. Transmission probably occurs either by inhalation of infectious droplets or by hand-to-nose "self-inoculation" after touching infectious secretions. The pathogenesis of rhinovirus

infections is thought to include viral entry into the nose followed by infection of the epithelial cells of the upper airway. Symptoms (sneezing, nasal discharge and congestion, and a "scratchy" throat) develop 16 to 72 h after inoculation, and last for 1 to 2 weeks. The peak of rhinoviral excretion in nasal secretions coincides with the peak of clinical illness.

Complications of the common cold include bacterial superinfections of the upper respiratory tract, such as acute otitis media and acute sinusitis, and exacerbations of asthma. Recent studies have demonstrated that rhinoviruses may be present in the lower airways during the common cold, and are a major cause of asthma exacerbations in children and adults.

Treatment of the common cold is symptomatic, with nonsteroidal anti-inflammatory drugs (NSAIDs) and antihistamines providing some benefit. Development of a vaccine is unlikely given the number of viral pathogens and serotypes. Antiviral agents such as pleconaril have not provided sufficient benefit to outweigh risks or side effects. Herbal remedies, such as Echinacea, have shown no benefit. Careful handwashing and use of hand disinfectants may be the most effective preventive measures.

PHARYNGITIS

Over 6 million adults visit primary care physicians annually for sore throats, and three-fourths receive antibiotics. Most cases of acute pharyngitis occur as part of the common cold and are caused by viruses such as rhinovirus, coronavirus, and parainfluenza virus. These cases are mild, nonexudative, and self-limiting. Patients with primary human immunodeficiency virus (HIV) syndrome may also have a nonexudative pharyngitis. A severe, usually exudative pharyngitis occurs in about half of patients with either adenovirus infection or Epstein-Barr virus mononucleosis. The pharyngitis seen in herpangina, due to group A coxsackievirus, is characterized by a vesicular enanthem. Lesions (usually only two to six) begin as papules on the soft palate between the uvula and tonsils. These vesiculate, then ulcerate. Primary herpes simplex virus may cause a severe vesicular or ulcerative pharyngitis; when there is an overlying exudate, it may mimic streptococcal pharyngitis.

Group A streptococcus *(Streptococcus pyogenes)* is the most important bacterial cause of pharyngitis because of its suppurative (e.g., peritonsillar abscess) and nonsuppurative complications (e.g., rheumatic fever, acute poststreptococcal glomerulonephritis). It causes 15 to 30 percent of cases of pharyngitis in children and 5 to 10 percent in adults (likely higher in parents of school-age children). Symptoms and signs vary. Patients may have a severe exudative pharyngitis accompanied by fever, leukocytosis, and cervical lymphadenopathy, or they may have a mild pharyngitis that mimics that of the common cold. Some patients with mild disease have a viral pharyngitis but are colonized with group A streptococci. These patients must also be treated for presumed streptococcal disease. Features independently associated with group A streptococcal pharyngitis include tonsillar exudates, cervical lymphadenitis, lack of cough, and history of fever. Diagnosis of streptococcal pharyngitis is made by culture or by rapid antigen detection test (RADT). The latter is 95 percent specific but not as sensitive as culture. Therefore, a negative test requires culture confirmation in children and adolescents, while a positive test is sufficient for the diagnosis. In adults, practice guidelines suggest that a negative RADT may not require culture backup, as the incidence of streptococcal disease is lower than in the pediatric population and the risk of rheumatic fever extremely low. Treatment is with oral penicillin (or erythromycin in penicillin-allergic patients) for 10 days, or with a single intramuscular dose of benzathine penicillin. Cephalosporins are very effective in eradicating streptococci, and cefdinir and cefpodoxime have Food & Drug Administration (FDA) approval for 5-day treatment courses, as does the macrolide azithromycin.

Other bacteria may also cause pharyngitis. Group C and G streptococci may cause an exudative pharyngitis and may be endemic or related to foodborne outbreaks. *Arcanobacterium hemolyticum* may cause an exudative pharyngitis along with a maculopapular rash, and typically occurs in children and young adults. Diphtheria, caused by *Corynebacterium diphtheriae,* is rare in the United States. Sore throat is a common symptom (in 90 percent), and findings include mild pharyngeal injection and an overlying adherent gray membrane (especially over the tonsillar pillars) that bleeds if removal is attempted. *Yersinia enterocolitica* may cause an exudative pharyngitis; an associated enterocolitis is more common in children than in adults. *Neisseria gonorrhoeae* may cause a mild pharyngitis, although most cases are asymptomatic. *Neisseria meningitidis* has rarely been noted as a cause of pharyngitis, but it is often isolated from throat cultures because the meningococcal carrier state is common. Carriers are not treated except in epidemic situations or if they have had close contact with a case of invasive meningococcal disease. *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* may cause a mild pharyngitis.

A peritonsillar abscess (quinsy) may follow untreated streptococcal pharyngitis or may be due primarily to mouth anaerobes. Patients have severe sore throat and trismus, and may speak with a "hot potato" voice. There is marked unilateral peritonsillar swelling and erythema, causing deviation of the uvula. The abscess should be aspirated or incised and drained by an otolaryngologist, and antibiotics active against streptococci and mouth anaerobes (e.g., ampicillin-sulbactam) should be given.

ORAL CAVITY INFECTIONS

The oral cavity extends from the lips to the circumvallate papillae of the tongue. Various streptococci (e.g., *S. mutans, S. mitis, S. salivarius*) and anaerobes (e.g., *Peptostreptococcus, Veillonella, Lactobacillus, Bacteroides, Prevotella*) heavily colonize this area, and are the main pathogens in dental and oral cavity infections. *S. mutans* is a major pathogen in dental

cavities. Gingivitis and periodontitis are associated with anaerobic gram-negative rods such as *Prevotella intermedia* and *Porphyromonas gingivalis.* Mouth anaerobes are the major cause of Vincent's angina (acute necrotizing ulcerative gingivitis, or trench mouth). Patients have gingival pain, halitosis, cervical adenopathy, and ulcerations of the interdental papillae. Treatment is with oral clindamycin or penicillin plus metronidazole.

Ludwig's angina is a rapidly spreading cellulitis of the sublingual and submandibular spaces. It usually begins in the floor of the mouth from an infected mandibular molar tooth. The sublingual area becomes edematous, pushing the tongue to the roof of the mouth. The infection can cause acute airway obstruction. Patients present with fever, difficulty swallowing, drooling, and prominent submandibular and sublingual swelling. They should be admitted for airway monitoring, as intubation or tracheostomy may be necessary. Intravenous antibiotics active against streptococci and anaerobes should be given. Surgical incision of the infected soft tissue compartment may be necessary. Noma, or cancrum oris, is a rare infection caused by mouth anaerobes, especially fusospirochetal organisms such as *Fusobacterium nucleatum.* It occurs mainly in malnourished children, and begins as a gingival ulcer that rapidly spreads as a necrotizing cellulitis of the lips and cheeks. Therapy includes intravenous penicillin, debridement, and correction of dehydration and malnutrition.

Primary herpes simplex infection may cause painful vesicles on the buccal mucosa as well as the lips and tongue, and should be treated with hydration and acyclovir. The most common fungal infection of the oral cavity is thrush, usually due to *Candida* species. It occurs most often in immunocompromised patients, but may occur in normal hosts after prolonged antibiotic therapy or in patients with asthma using inhaled steroids. Treatment is with topical (e.g., nystatin) or oral (e.g., fluconazole) antifungal agents.

LARYNGITIS

Laryngitis, or inflammation of the larynx, is characterized by hoarseness. Acute laryngitis is usually caused by the same viruses that cause the common cold, and treatment is symptomatic. Hoarseness may accompany infections with human metapneumovirus, a virus identified in 2001 and primarily associated with bronchiolitis in young children. Herpes simplex virus may cause acute laryngitis; ulcerations or vesicles are typically seen. Streptococcal pharyngitis may be associated with laryngitis and should be treated with penicillin. *Corynebacterium ulcerans* has been a rare cause of a membranous laryngopharyngitis that may mimic diphtheria. Some studies from Sweden have found *Moraxella catarrhalis* to be more prevalent in cultures of patients with laryngitis than in controls, but a review of randomized controlled trials found that antibiotics appeared to have no benefit in the treatment of laryngitis. Fungi such as *Candida* and *Cryptococcus* are rare causes of laryngitis.

Patients with chronic hoarseness often have gastroesophageal reflux disease, but must be examined for laryngeal malignancies. In rare instances, fungi or mycobacteria may cause chronic laryngitis. In chronic progressive disseminated histoplasmosis, ulcers may occur on the larynx, as well as on the tongue, buccal mucosa, and gingiva. Blastomycosis may also produce laryngeal ulcers. Tuberculosis (TB) may cause laryngeal lesions that mimic a laryngeal neoplasm. Patients typically present with hoarseness but often lack systemic symptoms to suggest TB. They may have negative sputum smears for acid-fast bacilli and a clear chest radiograph. In a retrospective study of 22 patients with laryngeal TB, 9 had clear lungs and only 7 had active pulmonary TB. The patients with concurrent pulmonary TB characteristically had multiple ulcerative lesions on their vocal cords, while those with clear lungs had nonspecific, polypoid, single laryngeal lesions.

CROUP

Croup, or acute laryngotracheobronchitis, is characterized by subglottic edema and occurs most often in children ages 3 months to 3 years old, with peak incidence in the second year of life. It is rare in children over age 6. Most cases occur in fall, winter, and spring; the most common cause, parainfluenza type 1, has caused biennial epidemics in the fall in the United States. Croup is characterized by fever, inspiratory stridor, and a "seal's bark" cough. In severe cases, there is both inspiratory and expiratory stridor. There is typically a fluctuating course, and there can be alternating clinical improvement and worsening within an hour. Croup usually follows the onset of upper respiratory tract infection symptoms by 1 to 2 days. The cause is nearly always viral, with parainfluenza virus types 1 through 3 accounting for the majority of cases; type 1 is the most common cause in the United States. Influenza virus, particularly type A, also causes croup and may be more severe. Respiratory syncytial virus causes between 1 and 11 percent of cases, and typically affects children under age 1. Adenovirus, rhinovirus, enterovirus, and *M. pneumoniae* are rare causes.

The diagnosis of croup is based primarily on clinical grounds. A diagnosis of the viral etiology may be made by one of the rapid viral antigen detection techniques (e.g., RT-PCR) on nasopharyngeal swabs. The most important differential diagnosis in the acute clinical setting is epiglottitis (see below). Children with epiglottitis usually lack the characteristic seal's bark cough of croup, appear more toxic, and their illness worsens more rapidly.

Treatment of croup consists of nebulized racemic epinephrine, corticosteroids, and humidified air, although the value of humidified air has been questioned. A recent study of high vs. low humidity vs. mist therapy for croup in an emergency department found no difference in outcome between the three groups at 30 and 60 minutes, nor in the percentage of patients requiring hospitalization. Nebulized racemic epinephrine has a well-established role in treating croup, producing signs of clinical improvement within 30 minutes and with a duration of action of about 2 hours. Children should be

monitored for rebound edema for several hours after initiation of therapy. Corticosteroids are also beneficial, with onset of action within 6 hours and duration of benefit 12 hours. Oral or intramuscular dexamethasone has shown benefit for moderate to severe croup, and a single dose of oral dexamethasone is beneficial for mild croup.

EPIGLOTTITIS

Acute epiglottitis (supraglottitis) is a medical emergency, as it can rapidly lead to airway obstruction. It begins as a cellulitis between the base of the tongue and the epiglottis, pushing the epiglottis posteriorly. It then involves the epiglottis itself, with rapid swelling and airway compromise. Epiglottitis has become a rare disease in children since the advent of vaccination against *Haemophilus influenzae* type b (Hib) in 1985, which decreased the incidence of all types of invasive Hib disease by over 99 percent. In the prevaccine era, the incidence of epiglottitis was highest in children ages 2 to 4. Disease in children is due to rare cases of Hib vaccine failure or to other organisms, including nontypeable *H. influenzae*. The incidence in adults has been increasing in the past 20 years, from 0.8 cases per 10,000 in 1986 to 3.1 in 2000. Blood cultures are usually negative in adults and cultures of the epiglottis difficult or dangerous to obtain, so the etiology is often unknown. Pathogens isolated from throat cultures in adults with supraglottitis include *H. influenzae*, *H. parainfluenzae, Streptococcus pneumoniae,* group A streptococcus, and *Staphylococcus aureus*. Viral epiglottitis is very rare and poorly substantiated.

In children, the onset of symptoms occurs rapidly, usually within 6 to 12 h, and patients appear toxic. Patients are febrile, irritable, complain of sore throat and dysphagia, prefer to sit leaning forward, and may be drooling. Inspiratory stridor may occur, but the barking cough seen in croup is absent. Adolescents and adults usually have a less fulminant presentation, often with 2 to 3 days of symptoms. Severe sore throat, odynophagia, and fever are the main presenting symptoms, each occurring in 90 percent of adults in a recent study; muffled voice was present in 70 percent. In adults, diagnosis is made by direct flexible fiberoptic nasolaryngoscopy, a procedure that takes just minutes to perform in the emergency room by an otolaryngologist. A swollen, erythematous epiglottis is seen. Children suspected of having epiglottitis should be transported, sitting up, to the operating room for direct endoscopic visualization of the epiglottis. An uncuffed endotracheal (or nasotracheal) tube should be immediately inserted (or, if necessary, a tracheostomy performed) if a "cherry red" edematous epiglottis is seen. Lateral neck radiographs, used in the past to demonstrate the "thumb sign" of an edematous epiglottis, are rarely used now as they may be falsely negative and may cause a critical delay in securing the airway.

All patients with epiglottitis should be monitored in an intensive care unit. Children with epiglottitis should be intubated for airway protection, while adults whose endoscopic examination reveals no impending airway compromise may be managed with close observation. Broad-spectrum intravenous antibiotics with activity against *H. influenzae*, such as ampicillin-sulbactam, should be given. If the patient with epiglottitis due to *H. influenzae* has household contacts that include an unvaccinated child under age 4, the patient and all members of the household should receive rifampin prophylaxis to eradicate carriage of the organism.

BACTERIAL TRACHEITIS

This rare disorder, sometimes called membranous croup, presents acutely like epiglottitis but primarily involves the subglottic region like croup. It may represent bacterial superinfection of a viral tracheitis. It usually affects children between 3 weeks and 13 years of age, and is uncommon in adults. Patients present with the acute onset of high fever, stridor, and dyspnea after a viral prodrome. They do not respond to racemic epinephrine or corticosteroids. On endoscopy, patients have a normal epiglottis but the subglottic trachea is covered with a thick exudate. Inspissated secretions may produce a pseudomembrane. Cultures of tracheal secretions yield *S. aureus* in half of the cases; other organisms include group A streptococcus, *S. pneumoniae*, and *H. influenzae*. Gram-negative bacilli have been rarely described. Most patients require immediate intubation; some require tracheostomy. Up to 60 percent will have concurrent pneumonia. Broad-spectrum intravenous antibiotics active against *S. aureus* and *H. influenzae* should be given, along with airway humidification and aggressive pulmonary toilet. Inspissated or copious secretions may cause airway obstruction even in patients with an artificial airway; several patients have died because of this complication.

LARYNGEAL PAPILLOMATOSIS

Recurrent respiratory papillomatosis (RRP) is a rare disease caused by human papillomavirus that involves the larynx, but also may involve the trachea and lungs. Human papillomavirus types 6 and 11 are the types usually responsible; type 11 tends to produce more aggressive disease and carry a higher risk (3 percent) for eventual malignant transformation. Patients typically present with hoarseness, but may present with airway obstruction. Disease tends to be more severe in children than in adults, with extensive involvement of the airway and multiple episodes of recurrent disease. Treatment is with endoscopically directed surgical excision of the papillomas. In some young patients, rapid regrowth of the papillomas requires surgical excision on a nearly monthly basis. Intralesional injection of cidofovir at the time of surgery has been helpful in prolonging the time to relapse in some patients. Adjuvant systemic therapies with reports of some success in reducing the frequency of recurrences include oral indole-3-carbinol, subcutaneous injections of interferon-α,

and intravenous cidofovir. There are few randomized controlled trials of these agents, however, in this rare disease.

SINUSITIS

The paranasal sinuses develop as outpouches of the nasal cavity. The maxillary and ethmoid sinuses are present at birth, the frontal sinus develops after age 2, and the sphenoid sinus develops after age 7. The sinuses are lined with respiratory epithelium that includes ciliated cells and mucus-producing goblet cells. The cilia normally move the mucous blanket toward the sinus ostia (and then to the nasopharynx) at a speed of up to 1 cm/min. Inflammation causes a marked decrease in the beat frequency of the cilia, as well as narrowing or obstruction of the sinus ostia due to mucosal edema. The resulting disruption of mucociliary transport results in sinusitis.

The most common cause of inflammation leading to acute sinusitis is a viral upper respiratory infection. Most adults with common colds have computed tomographic (CT) evidence of ostial obstruction and sinus abnormalities, although only about 0.5 percent of all colds are complicated by acute sinusitis. Viral infections increase the amount of mucus produced and may damage ciliated cells. Another predisposing factor for sinusitis is allergic rhinitis, which may cause ostial obstruction by mucosal edema or polyps. Dental infections, especially of the upper teeth that abut the maxillary sinus (second bicuspid, first and second molars), may cause some cases of maxillary sinusitis. Anatomic obstruction of the sinus ostia due to a deviated septum, tumor, granulomatous disease (e.g., Wegener's granulomatosis), or nasotracheal or nasogastric tubes may also lead to sinusitis. Barotrauma from deep-sea diving or airplane travel, chemical irritants, and mucus abnormalities (e.g., cystic fibrosis) are other risk factors for sinusitis.

Acute Community-Acquired Bacterial Sinusitis

Symptoms of acute bacterial sinusitis include purulent nasal or postnasal drainage, nasal congestion, and sinus pain or pressure. The location of this pain depends on the sinus affected. Patients usually complain of pain in their cheek or upper teeth in maxillary sinusitis, the sides of the bridge of the nose in ethmoid sinusitis, supraorbital or frontal pain in frontal sinusitis, and retro-orbital, frontal, occipital, or vertex pain in sphenoid sinusitis. Fever occurs in about half of adults with acute sinusitis.

The diagnosis of acute bacterial sinusitis is often difficult on the basis of history and physical examination alone. Identical symptoms may occur in patients with viral upper respiratory infections, although bacterial sinusitis should be suspected if the patient has had persistent symptoms for more than 7 days. The sensitivity and specificity of individual symptoms such as facial pain when bending forward, purulent rhinorrhea, and sinus tenderness are less than 70 percent, making these features of limited diagnostic usefulness. In evaluating a patient for sinusitis, the routine physical examination is usually not helpful. Nasal endoscopy is helpful as it usually shows purulent secretions emanating from the sinus ostia in acute sinusitis, but this procedure is performed mainly by otolaryngologists. Plain films of the sinus are helpful in diagnosing sinusitis only if there is complete sinus opacification, an air-fluid level, or mucosal thickening of at least 4 mm; sinusitis, however, may be present without these findings. Sinus CT is much more sensitive than routine radiographs, particularly for ethmoid and sphenoid disease, but not specific for acute bacterial sinusitis as viral sinusitis may also show similar changes.

The bacteriology of sinusitis has been well defined only for acute, community-acquired maxillary sinusitis. Sinus puncture studies of adults with this infection have revealed that over 50 percent of cases are due to *S. pneumoniae* or nontypeable *H. influenzae*. Other pathogens include other streptococci, anaerobes, *Moraxella catarrhalis*, and rarely *S. aureus*. Anaerobes are more common in adults and *M. catarrhalis* is more common in children. Studies of sinuses other than the maxillary sinus are hindered by the difficulty of obtaining culture material that is not contaminated by nasal flora.

Treatment should be empiric and target the bacterial pathogens noted above. Oral therapy (e.g., amoxicillin-clavulanate, cefuroxime, levofloxacin) for 10 days is sufficient except in severe disease or in patients who also have a complication of sinusitis (e.g., orbital sinusitis).

Nosocomial Bacterial Sinusitis

Nosocomial bacterial sinusitis is usually seen in patients in the intensive care unit, and typically considered in those with fever of unknown origin. The incidence is higher in patients with nasotracheal tubes. It is also higher in patients with nasogastric tubes vs. those without, 20 vs. 12 cases per 1000 patient-days in one study. A sinus CT scan showing sinus opacification or an air-fluid level suggests the diagnosis. Bedside nasal endoscopy performed by an otolaryngologist may be helpful in obtaining cultures, either by endoscopically directed cultures of purulent meatal secretions or by maxillary sinus (antral) puncture. Antral puncture may not be indicated in all intensive care unit patients suspected of having sinusitis, however. One study found that only 8 percent of antral punctures yielded positive cultures in patients with normal endoscopic examinations. The pathogens in nosocomial sinusitis are usually *S. aureus* and gram-negative bacilli, and often include antibiotic-resistant organisms. Empiric treatment should be directed against these organisms (e.g., intravenous vancomycin plus cefepime) until culture results are known.

Chronic Bacterial Sinusitis

Chronic sinusitis is characterized by symptoms that last for weeks to months. Patients complain of persistent dull pain, postnasal drainage, foul odor and taste, and fatigue. True fever is rare, although many patients complain of having temperatures around 99°F. Most patients have stable, low-grade symptoms punctuated by episodes of acute sinusitis. These

episodes may be signaled by a change to purulent secretions and increased sinus pressure. A sinus CT scan is indicated in patients with chronic sinusitis, both to define the extent of disease and to exclude other causes of their symptoms. Patients should be evaluated by an otolaryngologist to exclude conditions that may be causing obstruction, such as a deviated septum, nasal polyps, Wegener's disease, or cancers such as adenocystic carcinoma.

The bacteriology of chronic sinusitis is not well defined. Most patients with chronic disease will have sinus cultures positive for bacteria, but whether these are colonizers or pathogens is not always clear. Patients without sinus disease also have positive cultures when cultures are obtained intranasally. Sinus cultures cannot be obtained without contamination by nasal flora, and since *S. aureus* is a nasal colonizer in 30 percent of the normal population, recovery of this organism is particularly difficult to interpret in the patient with chronic sinusitis. Coagulase-negative staphylococci are not sinus pathogens and should not be treated. Recently, there has been interest in fungi as the major pathogens in chronic sinusitis via a local allergic mechanism, since careful cultures of nasal mucus yield fungi in most patients. However, the same study that demonstrated the prevalence of molds in nasal mucus in patients with chronic sinusitis also recovered them in cultures from all of the normal controls, so causality has not been demonstrated. Studies of topical or oral antifungal agents for chronic sinusitis have been small or have not shown benefit over placebo.

Complications of Bacterial Sinusitis

Orbital Cellulitis

The most common complication of bacterial sinusitis is preseptal cellulitis or deeper orbital infection, conditions usually grouped under the heading "orbital cellulitis" (Fig. 118-1). Most cases are secondary to ethmoid sinusitis, since the ethmoid is separated from the orbit by only a very thin plate of bone, the lamina papyracea. Preseptal cellulitis only involves the eyelids and surrounding skin anterior to the orbital septum, but not the structures of the orbit. The lids appear red and edematous, but vision is normal and there are no orbital findings. In patients with orbital cellulitis, subperiosteal abscess, or orbital abscess, the eyelids are also red and swollen, but examination of the eye reveals one or more orbital findings as well. These include proptosis, which may be only detectable by using a Hertel's exophthalmometer, limitation of extraocular movements, and decrease in vision. In subperiosteal and orbital abscess, the abscess is almost always located medially or superomedially in the orbit (reflecting the involvement of the adjacent ethmoid sinus), and the eye looks "down and out." Abscess cultures demonstrate that the major pathogens are *S. pneumoniae*, group A streptococcus, nontypeable *H. influenzae*, and *S. aureus*, and these are presumably also the major pathogens in sinus-related orbital cellulitis and preseptal cellulitis. Antibiotics should be directed against these pathogens. Blood cultures are usually negative in adults, but are positive in 4 to 8 percent of young children

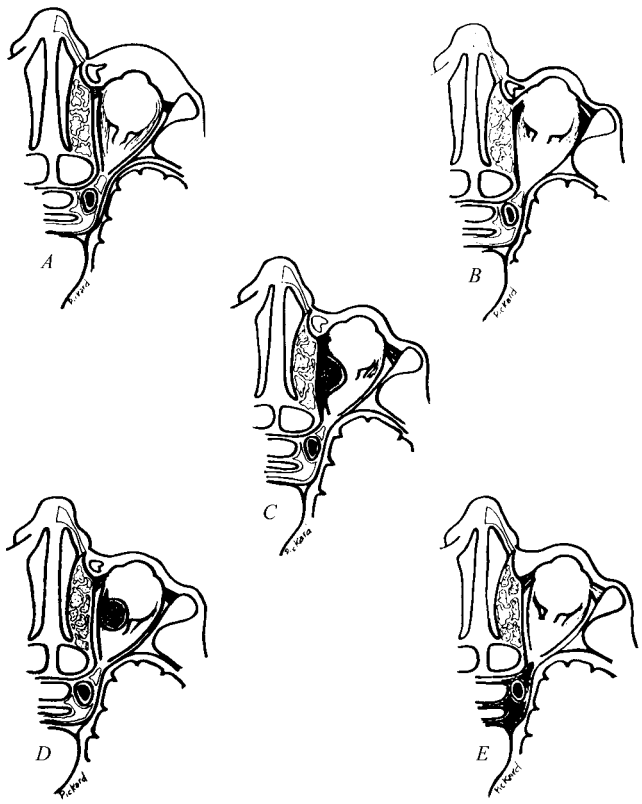

Figure 118-1 Orbital complications of sinusitis. *A.* Preseptal cellulitis. *B.* Orbital cellulitis. *C.* Subperiosteal abscess. *D.* Orbital abscess. *E.* Cavernous sinus thrombosis. *(From Chandler JR, Langenbrunner DJ, Stevens FR: The pathogenesis of orbital complications in acute sinusitis. Laryngoscope 1970; 80:1414–1428, with permission.)*

with preseptal cellulitis, in whom this condition may be secondary to bacteremic seeding by *S. pneumoniae*, other streptococci, or nontypeable *H. influenzae*. A CT scan should be performed on any patient with orbital findings, and an orbital or subperiosteal abscess usually requires emergency surgical drainage. Some authors also advocate a CT scan for children with apparent preseptal cellulitis, as some have a subclinical abscess.

"Pott's puffy tumor," or subperiosteal abscess of the frontal bone, is a complication of frontal sinusitis. Patients present with frontal pain and a tender, doughy swelling over the forehead. Treatment consists of 6 weeks of intravenous antibiotic therapy, and surgical drainage of the frontal sinus and subperiosteal abscess may be necessary. Intracranial complications of sinusitis usually result from frontal or sphenoid sinusitis. These include epidural abscess, subdural empyema, meningitis, cerebral abscess, and dural vein thrombophlebitis. Because of the proximity of the sphenoid sinus to the cavernous sinus, sphenoid sinusitis also may cause cavernous sinus thrombophlebitis.

Fungal Sinusitis

There are three forms of fungal sinusitis: allergic fungal sinusitis, sinus aspergilloma, and invasive fungal sinusitis.

Allergic fungal sinusitis (AFS) is characterized by the presence of "allergic mucin" in the involved sinuses and is thought to be due to a local hypersensitivity reaction to fungi. Mold spores are ubiquitous in the environment and in the nasal mucus, where they are trapped after being inhaled. Patients with AFS present with chronic sinusitis symptoms, and most have a history of nasal polyposis, aspirin allergy, and asthma. The CT typically shows inhomogeneous opacification of one or more sinuses, and there may be evidence of bony erosion of the sinus. Erosion is due to pressure necrosis, not fungal invasion. On magnetic resonance imaging (MRI), the affected sinus often appears black on T2 ("T2-weighted signal void"), a finding also seen in other types of fungal sinusitis. The diagnosis of AFS may be suspected at surgery because allergic mucin is tenacious, with the consistency of anchovy paste. It has histological features similar to that of mucin found in allergic bronchopulmonary aspergillosis, with many eosinophils and Charcot-Leyden crystals. Fungal hyphae are found in the mucus of half of the cases, but there is no evidence of tissue invasion. Only half of cases have positive fungal cultures, and these grow molds such as *Bipolaris, Curvularia, Alternaria,* and *Aspergillus.* Surgical removal of the inspissated mucus, along with intranasal steroids or short courses of oral steroids, seems to be effective. There is no proven role for antifungal agents.

Sinus aspergilloma is a noninvasive fungal disease that may cause symptoms of obstruction and chronic sinusitis. Usually only one sinus (most often maxillary) is affected, and symptoms are therefore unilateral. Surgical removal of the fungus ball is usually curative. Careful review of the pathological slides is required to verify that there is no tissue invasion.

Invasive fungal sinusitis carries a significant risk of mortality, in contrast to the other two benign forms of fungal disease. Estimates of mortality depend on the sinus affected and the immune state of the patient. In immunocompromised hosts, fungal disease presents acutely. Rhinocerebral mucormycosis is a life-threatening infection due to molds of the order Mucorales *(Rhizopus, Mucor, Absidia).* Approximately 70 percent of patients with mucormycosis have diabetes, while other risk factors include corticosteroid therapy or other immunosuppressant therapy, hematologic malignancies, and deferoxamine chelation therapy. Patients usually present with signs mimicking bacterial orbital cellulitis involving one eye, with swollen eyelids, proptosis, decreased extraocular movements, and decreased vision in that eye. In contrast with orbital cellulitis, eyelids may appear less red, unilateral frontal pain or temporal pain may be prominent, and there may be hypesthesia in the V_1 or V_2 distribution. If there are bilateral eye findings, involvement of the cavernous sinus should be suspected. Patients in whom the diagnosis is suspected should undergo immediate endoscopy by an otolaryngologist to look for a characteristic black eschar signifying infarcted intranasal or sinus mucosa. The eschar and adjacent tissue should be biopsied and examined for fungus on frozen section by a pathologist. On pathology, broad nonseptate hyphae are found invading tissue, often around blood vessels and nerves. In patients in whom the clinical suspicion for mucormycosis is high, the absence of a black eschar on clinical examination does not exclude the diagnosis, and biopsies of normal-appearing middle turbinate may yield the diagnosis. The absence of any evidence of sinusitis by CT scan also does not exclude the diagnosis. Treatment of mucormycosis requires a combination of aggressive surgical debridement and intravenous amphotericin or liposomal amphotericin therapy. Voriconazole is not active against mucormycosis. Posaconazole is a new agent that may be effective in patients who fail debridement and amphotericin therapy.

Aspergillus and other fungi (e.g., *Bipolaris, Curvularia, Exserohilum*) may also cause invasive fungal sinusitis. Immunocompromised patients, such as those who have received organ transplants, usually present acutely. Treatment is aggressive surgical debridement and systemic antifungal therapy. Normal hosts, in contrast, usually present subacutely, with weeks to months of symptoms. Fungi in the ethmoid and sphenoid sinuses may invade the orbital apex and cavernous sinus, affecting cranial nerves III, IV, V, and VI. Symptoms include headache, unilateral retroorbital pain, proptosis, ptosis, limitation of eye movement, decreased vision, and hypesthesia in the distribution of cranial nerve VI on the affected side. Symptoms of sinusitis are often absent. Diagnosis is suggested by the clinical findings and CT and MRI scans showing inflammation in the orbital apex or cavernous sinus. The diagnosis is made by demonstrating tissue-invasive fungi on pathology. Treatment is with appropriate systemic antifungal therapy (e.g., voriconazole for *Aspergillus*). Unlike immunocompromised patients with invasive fungal disease or patients with rapidly progressive mucormycosis, nonimmunocompromised patients may not require extensive surgical debridement as the disease is slowly progressive, allowing time for assessment of antifungal therapy.

EAR AND MASTOID INFECTIONS

Auricular Cellulitis and Perichondritis

In *auricular cellulitis*, the ear is usually red, edematous, hot, and mildly tender. The lobule is especially swollen and red. There may be a history of minor ear trauma from earrings, scratching, Q-tips, etc. Treatment is with warm compresses and antibiotics (e.g., nafcillin) directed against *S. aureus* and streptococci.

Perichondritis is an infection of the perichondrium of the ear that is often accompanied by infection of the cartilage of the pinna (chondritis). It may lead to ear deformity due to necrosis of the cartilage. Patients present with a swollen, hot, red, and exquisitely tender pinna; the lobule is usually spared. Usual causes include significant trauma to the ear (e.g., boxing) and burns. The most common pathogens are *Pseudomonas aeruginosa* and *S. aureus.* Intravenous antibiotics active against these organisms (e.g., ticarcillin-clavulanate or nafcillin plus ciprofloxacin) should be given for at least

4 weeks. This infection must be distinguished from relapsing polychondritis, a rheumatologic condition.

Otitis Externa

The external auditory canal is about 2.5 cm long. It is lined by a thin layer of skin, which covers cartilage in the lateral half of the canal and bone in the medial half. In the bony portion, the skin lacks a subcutaneous layer and is attached directly to the periosteum. This is an important feature in the pathogenesis of invasive otitis externa (see below). Glands secrete cerumen, which acidifies the canal and suppresses bacterial growth. Desquamated skin and retained moisture make the canal especially susceptible to *P. aeruginosa,* a hydrophilic organism.

Acute otitis externa, or swimmer's ear, occurs mostly in summer months and is often a result of exposure to water. It may be due to a decrease in canal acidity and the resulting bacterial overgrowth. The ear is pruritic and often extremely painful; the canal appears swollen and red. The usual pathogens are *P. aeruginosa, S. aureus,* and streptococci. Treatment consists of cleaning the ear (aural toilet) and topical antibiotic drops (e.g., ofloxacin 0.3 percent otic solution).

Herpes zoster oticus (Ramsay Hunt syndrome) is due to inflammation of the facial nerve by varicella-zoster virus. It is characterized by vesicles in the ear canal or concha, severe otalgia, loss of taste in the anterior two-thirds of the tongue, and ipsilateral facial nerve paralysis. Treatment is with an anti-herpes agent (acyclovir, valacyclovir, or famciclovir).

Invasive ("malignant") otitis externa (MOE) is a potentially life-threatening osteomyelitis of the temporal bone and skull base. First described in 1959, it occurs primarily in elderly diabetics and is nearly always caused by *P. aeruginosa.* The infection begins in the external canal, then invades the adjacent soft tissues, petrous apex of the temporal bone, and eventually the skull base. The typical patient is an older diabetic whose diabetes is in good control, who presents with unilateral hearing loss, ear pain, and drainage progressive over the previous weeks to months. The symptoms may have been misdiagnosed as chronic otitis media, a condition not characterized by otalgia. There is often a history of irrigation of the ear canal for wax removal a few days before the onset of ear pain. On examination, the ear canal is edematous, and there is granulation tissue in the inferior wall about halfway down the canal (the area overlying the bony-cartilaginous junction). Some patients also present with unilateral facial paralysis from involvement of cranial nerve VII; other cranial nerves (VI, IX, and X) may also be involved. Fever occurs in less than half of patients and the white blood cell count is usually normal. The sedimentation rate is almost always very elevated, however, typically in the 80 to 100 range. A CT and an MRI scan are essential for defining the extent of involvement. Bony involvement is best seen on CT, while soft-tissue changes are best seen on MRI. Cultures should be obtained of ear canal drainage or of superficial biopsies of canal granulation tissue; more extensive surgery is not usually indicated. Nearly all cases are due to *P. aeruginosa*, but cultures are important in determining antibiotic sensitivity and in excluding rare causes of invasive otitis (e.g., *S. aureus, Proteus, Aspergillus*). As soon as cultures are obtained, empiric treatment directed at *Pseudomonas* should be started. Usually two-drug therapy is given, such as intravenous ceftazidime plus ciprofloxacin (orally), and therapy is continued for at least 6 weeks. Aminoglycosides should be avoided due to the toxicities associated with prolonged therapy, especially in the elderly diabetics with hearing loss who typify the patient with MOE.

Acute Otitis Media

The middle ear is connected to the nasopharynx by the eustachian tube. Acute otitis media (AOM, Fig. 118-2), or infection of the middle ear, is thought to result from bacterial entry into the middle ear via the eustachian tube. It is often initiated by a viral upper respiratory infection, and is most common in fall through spring. The incidence of AOM decreases with age. More than two-thirds of children under age 3 have had at least one episode of otitis media, while the incidence in adults is only 0.25 percent. The most common symptoms are ear pain and decreased hearing. Children often have fever, but this is less common in adults. The tympanic membrane is usually red, opaque, and bulging. Spontaneous perforation of the tympanic membrane may occur, resulting in otorrhea and, frequently, decreased pain.

The bacteriology has been best defined in pediatric patients with AOM. The most common pathogens in nonneonates are *S. pneumoniae* (25 to 50 percent), *H. influenzae* (15 to 30 percent), and *M. catarrhalis* (3 to 20 percent). Most of the *H. influenzae* strains are nontypeable, but about 10 percent are type B and these cases may develop bacteremia or meningitis. Group B streptococci and enteric gram-negative bacilli are important in neonates. Viruses are recovered, sometimes along with bacteria, in 25 percent of pediatric cases. *H. influenzae* and *S. pneumoniae* are the most common isolates in adults.

Treatment of AOM is usually empiric and should be directed against *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis.* Approximately 50 percent of *H. influenzae* strains and 100 percent of *M. catarrhalis* strains produce β-lactamase, and approximately 30 percent of *S. pneumoniae* are not susceptible to penicillin (15 percent are highly resistant) due to altered penicillin-binding protein. Amoxicillin should not be effective for any of these resistant organisms, yet approximately 20 percent of children with *S. pneumoniae*, 50 percent with *H. influenzae*, and 75 percent with *M. catarrhalis* will clear their AOM despite no or ineffective antibiotic therapy. Therefore, recent practice guidelines by the American Academy of Pediatrics recommend amoxicillin as first-line therapy for most children with AOM at doses of 80 to 90 mg/kg/day. Amoxicillin-clavulanate is recommended for children who present with severe disease, defined as fever of 39°C or higher and/or severe otalgia, or for amoxicillin-treatment failures as determined at 48 to 72 hours. For most children with non–type I allergy to penicillin, cephalosporins (cefdinir, cefpodoxime, cefuroxime) are recommended, and azithromycin or clarithromycin is recommended for those

with type I allergy. Ceftriaxone is recommended for children with severe disease and who are either penicillin-allergic with a non-Type 1 penicillin allergy or who have failed initial antibiotic therapy with amoxicillin-clavulanate. Clindamycin is recommended in patients who have failed therapy and have a type I allergy to penicillin.

Otitis Media with Effusion

Otitis media with effusion (OME), also called serous otitis, refers to the persistence of middle-ear fluid without other signs of infection. This condition may occur spontaneously as a result of eustachian tube dysfunction, or may occur as a result of AOM. Approximately 50 percent of children will have OME in the first year of life, and 90 percent before school age. Diagnosis is made by otoscopy. Many episodes resolve spontaneously, but 30 to 40 percent have recurrent OME and 5 to 10 percent have OME episodes that last at least 1 year. The American Academy of Pediatrics published practice guidelines in 2004 that state that antihistamines and decongestants are ineffective, and that antibiotics and corticosteroids have no long-term efficacy and thus are not recommended routinely for treating OME. These guidelines recommend hearing tests for children with persistent OME at 3 months; decisions regarding the need for tympanostomy tube placement may be determined by these test results. Children with OME at special risk for developmental delays (e.g., who also have blindness, autism, Down's syndrome) should have earlier hearing, speech, and language assessments.

Chronic Suppurative Otitis Media

Chronic suppurative otitis media (CSOM) is an inflammatory disease of the middle ear and mastoid characterized by tympanic membrane perforation, hearing loss, and persistent or recurrent otorrhea. It is associated with irreversible pathological changes of the mucosa of the middle ear and mastoid. There are two major subtypes of CSOM: CSOM with cholesteatoma and CSOM without cholesteatoma.

In CSOM with cholesteatoma, there is a perforation of the tympanic membrane, usually at the margin, which leads into a sac within the middle ear lined by skin. This sac constitutes a cholesteatoma, which contains desquamated keratin and may be superinfected with bacteria. Bacterial overgrowth results in purulent drainage via the perforation. An important feature of a cholesteatoma is its ability to enlarge by erosion of surrounding bone, which can result in serious intratemporal and intracranial complications.

In CSOM without cholesteatoma, there is a chronic central perforation of the tympanic membrane. Bacterial infection of the middle ear or mastoid can occur and leads to purulent drainage through the perforation ("active" chronic otitis media). Such drainage may be constant or episodic. The latter may be incited by an upper respiratory infection or by exposure of the ear canal to water.

The classic symptoms of both types of CSOM are painless otorrhea and hearing loss. Diagnosis is made with otoscopy. The appearance of the tympanic membrane varies with the type of CSOM (Fig. 118-2). Audiological assessment

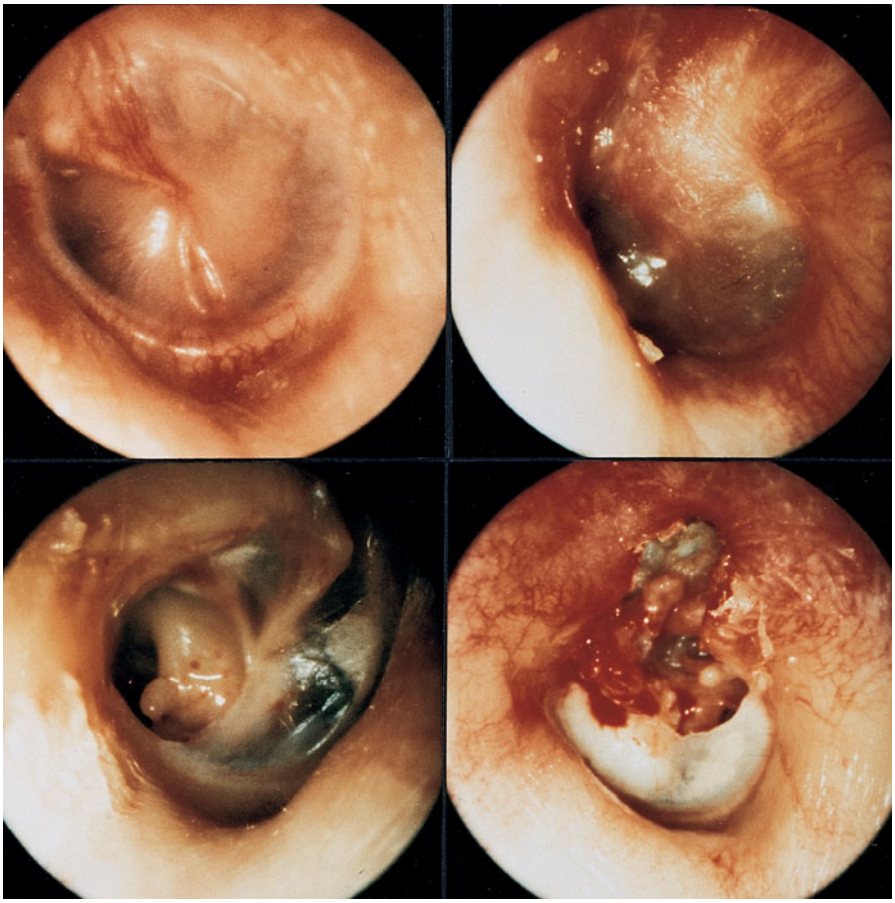

Figure 118-2 *Clockwise, from top left,* tympanic membranes: normal ear, resolving acute otitis media, chronic suppurative otitis media (CSOM) with cholesteatoma, CSOM without cholesteatoma. *(Courtesy of Steven D. Rauch, M.D.)*

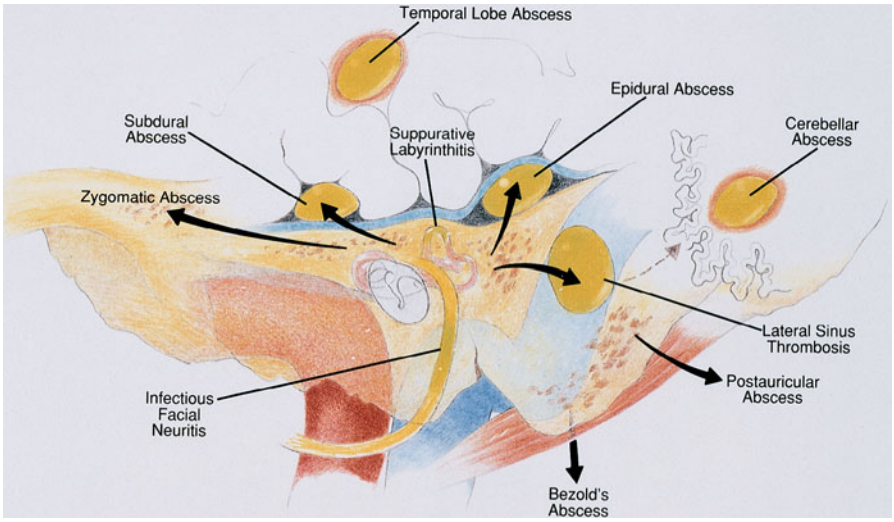

Figure 118-3 Complications of chronic otitis media. *(From Harris JP, Darrow DH: Surgery of the Ear and Temporal Bone. New York, Raven Press, 1993, with permission.)*

usually reveals a conductive type of hearing loss. Cultures of ears with CSOM in both adults and children often yield *S. aureus, Pseudomonas* and other gram-negative bacilli, and anaerobes. Most cases of CSOM with cholesteatoma require a mastoidectomy and tympanoplasty to remove the cholesteatoma and reconstruct the middle-ear sound transmission mechanism. Cases of "active" CSOM without cholesteatoma are treated with ear cleaning and topical antibiotic otic drops. Oral antibiotics are also sometimes used. The choice of antibiotics should be guided by culture results from the purulent middle-ear drainage, but most cases are treated empirically with a topical quinolone (e.g., ofloxacin 0.3 percent otic solution). Topical quinolones have proven to be nonototoxic and effective. Topical aminoglycoside therapy, commonly used in the past, is used infrequently now due to concern for ototoxicity. Surgery may be indicated in some cases of CSOM without cholesteatoma if medical therapy fails to control otorrhea or if surgery will improve hearing.

Acute Mastoiditis

The mastoid is the portion of the temporal bone posterior to the middle ear that contains a honeycomb of air cells lined by low, cuboidal epithelium. These air cells connect with the middle ear. Some degree of mastoid mucosal inflammation invariably accompanies episodes of AOM and is also present in many cases of CSOM. A CT scan of a patient with a middle-ear effusion or infection will often also show opacification of the mastoid air cells without destruction of the cells, and this usually represents a sterile effusion in the mastoid rather than acute mastoiditis. In contrast, acute mastoiditis is an acute bacterial infection of the mastoid. Untreated, this infection often results in breakdown of the bony partitions between the mastoid air cells and can extend beyond the mastoid compartment. Acute mastoiditis has become rare in the antibiotic era, and occurs primarily in children. It occurs with the first episode of AOM in 10 to 50 percent of children, but may also occur with an episode of recurrent AOM. Patients present with pain, tenderness, and swelling over the mastoid. The pinna is pushed out and forward when there is a subperiosteal abscess or cellulitis. A CT scan may demonstrate bony destruction or a mastoid abscess. Major pathogens include *Pseudomonas*, *S. pneumoniae*, group A streptococcus, and *H. influenzae*. *S. aureus* and enteric gram-negative bacilli are seen in a small percentage of cases. Treatment is with broad-spectrum intravenous antibiotics directed against these organisms; surgery is also necessary in many cases and may include myringotomy, drainage of subperiosteal abscess, and mastoidectomy.

Complications of Acute and Chronic Otitis Media

Otogenic complications are more likely to occur from chronic than from acute otitis media (Fig. 118-3). Extracranial complications include sensorineural hearing loss, labyrinthitis and the resulting vertigo, facial nerve palsy, and osteomyelitis of the petrous portion of the temporal bone. In mastoiditis, infection may track under the periosteum of the temporal bone and cause a subperiosteal abscess, or may break through the mastoid tip and cause an abscess in the neck deep to the sternocleidomastoid muscle (Bezold's abscess). Intracranial complications include epidural abscess, thrombophlebitis of the dural veins, meningitis, and temporal lobe abscess.

Acute Bronchitis and Community-Acquired Pneumonia

Th omas J. Marrie

ACUTE BRONCHITIS

Acute bronchitis is an inflammation of the tracheobronchial tree, usually in association with a generalized respiratory infection. It occurs most commonly during the winter months and is associated with respiratory viruses, including rhinovirus, coronavirus, influenza viruses, and adenovirus. *Mycoplasma pneumoniae, Chlamydia pneumoniae,* and *Bordetella pertussis* may also cause bronchitis. Secondary invasion with bacteria such as *Haemophilus influenzae* and *Streptococcus pneumoniae* may also play a role in acute bronchitis.

Cough is the most prominent manifestation of acute bronchitis. Initially, the cough is nonproductive, but later mucoid sputum is produced. Still later in the course of the illness, purulent sputum is present. Many patients with acute bronchitis also have tracheitis. Symptoms of tracheal involvement include burning substernal pain associated with respiration and a very painful substernal sensation with coughing. Rhonchi and coarse crackles may be heard on examination of the chest; however, there are no signs of consolidation and the chest radiograph shows no opacity.

Most cases of acute bronchitis require measures directed only at relieving cough. For patients with fever or a predominant tracheitis component and purulent sputum, the sputum should be gram stained and cultured. If there is a predominant microorganism seen in the presence of more than 25 polymorphonuclear neutrophils and fewer than 10 squamous epithelial cells per low-power field, antibiotic therapy directed against *S. pneumoniae* and *H. influenzae* should be instituted. Most patients, however, do not require antibiotic therapy for acute bronchitis; it is a self-limited disease.

PNEUMONIA

Definition

Pneumonia is defined as inflammation and consolidation of lung tissue due to an infectious agent. Pneumonia that develops outside the hospital is considered community-acquired pneumonia (CAP). Pneumonia developing 72 hours or more after admission to hospital is nosocomial, or hospital

acquired. There is still some debate as to whether nursing home–acquired pneumonia should be considered community acquired or nosocomial pneumonia. For this reason, it is perhaps best to divide pneumonia into community acquired and institution acquired. (The latter includes hospitals, nursing homes, extended care facilities, psychiatric institutions, and rehabilitation facilities.) This chapter focuses on community-acquired pneumonia.

Epidemiology

Pneumonia is a common disease. The overall attack rate is about 12 cases per 1000 persons per year. In adults, the rate of admission to hospital for treatment of pneumonia is low from age 17 to 55 years, at which point it begins to increase. The attack rates are highest at the extremes of age. Pneumonia is the sixth leading cause of death in the United States. In a study recently carried out in Seattle, investigators found that the overall rate for CAP among those aged 65 to 69 years was 18.2 cases per 1000 person years compared with 52.3 cases per 1000 person years for those who were greater than or equal to 85 years. Just over 59 percent of episodes among seniors were treated on an outpatient basis and they estimated that there were approximately 915,900 cases of CAP among seniors annually in the United States. Data from the National Hospital Discharge Survey in the United States indicate that from 1990 to 2002 there were 21.4 million hospitalizations among those 65 years of age and over and infectious diseases accounted for 48 percent of these hospitalizations. Forty-six percent of the infectious diseases hospitalizations were due to lower respiratory tract infections and 48 percent of the infectious diseases deaths were due to these infections. In another study that also used the National Hospital Discharge Survey to examine pneumonia among those 65 years of age and older over the 15-year period 1988 to 2002, the investigators noted a 20 percent increase in pneumonia as a first or any listed diagnosis. They also observed that the in-hospital mortality rate was 1.5 times higher for pneumonia as a first listed diagnosis compared with the other most common causes of hospitalization.

The epidemiology of pneumonia has changed in recent years. This is due in part to changes in the population at risk and in part to the discovery of new microbial agents that cause pneumonia and changes in antimicrobial susceptibility of old microbial agents, such as *S. pneumoniae, H. influenzae,* and *Staphylococcus aureus.* Population changes include continued increase in the number and proportion of patients who are 65 years of age or older.

There has been a steady increase in the number of organ transplant recipients in the general population and in the number of patients with HIV infection. This has created a subset of patients with community-acquired pneumonia who may be infected not only with the traditional pathogens that cause pneumonia but also with opportunistic pathogens; furthermore, these patients may have severe or atypical presentations of this infection. Newer pathogens recognized as causing pneumonia include Hantavirus, SARS Co-V, human metapneumovirus, and *S. aureus* isolates carrying the Panton Valentine leucocidin genes, some strains of which are also methicillin resistant. *Pneumocystis jirovecii,* previously a rare cause of pneumonia in intentionally immunocompromised patients, is a common cause of pneumonia in HIV-infected patients with CD_4 counts of less than 200/μl.

In a study carried out in a Swedish town in which all persons 60 years of age and older were studied, independent risk factors for community-acquired pneumonia were: alcoholism, relative risk (RR) 9; asthma, RR 4.2; immunosuppression, RR 1.9; age greater than 70 years vs. age 60 to 69 years, RR 1.5.

Risk factors for specific etiologies of pneumonia may differ from those for pneumonia as a whole. Thus, dementia, seizures, congestive heart failure, cerebrovascular disease, and chronic obstructive lung disease were risk factors for pneumococcal pneumonia in one study. In other studies, cigarette smoking and asthma have been found to be independent risk factors for invasive pneumococcal disease. Among HIV-infected patients, the rate of pneumococcal pneumonia is 41.8 times higher than those in the same age group who are not HIV infected. However, with the advent of highly active antiretroviral therapy, the incidence of pneumococcal bacteremia among HIV infected persons has dropped from 24.1 episodes per 1000 patient years to 8.2 per 1000 patient years. Up until a recent study from the Centers for Disease Control, the effect of chronic illness on the incidence of invasive pneumococcal disease in adults was underappreciated. In this study, the overall incidence rates of invasive pneumococcal disease was 8.8/100,000 adults. For those with diabetes it was 51.4; 62.9 for adults with chronic lung disease; 93.7 for those with chronic heart disease; and 100.4 among those who abused alcohol. The rate was highest in adults with solid cancer, 300.4, and HIV/AIDS, 422.9.

Risk factors for Legionnaires' disease include male gender, tobacco smoking, diabetes, hematologic malignancy, cancer, end stage renal disease, and HIV infection. Risk factors for severe respiratory syncytial virus infection in elderly persons include the presence of underlying chronic pulmonary disease (odds ratio [OR] 3.97), functional disability (OR 1.67), and low serum neutralizing antibody titer (OR 5.89). The usual risk factors for aspiration pneumonia are altered level of consciousness and various neurological diseases that interfere with the swallowing mechanism. Recently, there has been an association between the use of gastric acid suppressive drugs and aspiration pneumonia. The incidence rates of pneumonia in non–acid-suppressive drug users and those who used these agents was 0.6 and 2.45 per 100 person years, respectively. The risk seemed to be highest among those using proton-pump inhibitors.

There is seasonal variation in the rate of pneumonia. Both attack rates and mortality rates are highest in the winter months. This is likely due to many factors, including more time spent indoors (crowding) and hence more opportunity for person-to-person spread of infectious agents. In a study carried out in Tennessee, the weekly frequency of invasive pneumococcal disease correlated with the weekly frequency of isolation of respiratory syncytial virus and influenza virus.

Antimicrobial resistance of the common bacterial pathogens is also a key component of the epidemiology of CAP. Penicillin-resistant *Staphylococcal pneumoniae* (PRSP) is now a fact of life in most North American communities. Many of the PRSP isolates are resistant to three or more antibiotic classes (multidrug resistance). In one study, 14 percent of bacteremic *S. pneumoniae* isolates were resistant to penicillin, 12 percent to ceftazidime, and 24 percent to trimethoprim-sulfamethoxazole. In a recent study, the investigators examined 1817 *S. pneumoniae* isolates collected from patients with community-acquired respiratory tract infections at 44 U.S. medical centers during the winter of 2002 to 2003. The overall rates of resistance were as follows: penicillin 34.2 percent; ceftriaxone 6.9 percent; erythromycin 29.5 percent; clindamycin 9.4 percent; tetracycline 16.2 percent; and trimethoprim-sulfamethoxazole 31.9 percent. There was no resistance to the following agents: vancomycin, linezolid, and telithromycin. Multidrug resistance was present in 22.2 percent of the isolates and 2.3 percent of the isolates had ciprofloxacin MICs of greater than or equal to 4 μg/ml. These investigators also made the observation that since 1994 to 1995, rates of resistance to beta lactams, macrolides, tetracyclines, and trimethoprim sulfamethoxazole have plateaued or begun to decrease. In contrast, fluroquinolone resistance is increasing. Fortunately, it is possible to predict who is likely to have pneumonia due to PRSP. Previous use of beta lactam antibiotics, alcoholism, noninvasive disease, age of less than 5 or greater than 65 years, and immunosuppression are risk factors for PRSP pneumonia.

Clinical Manifestations

Symptoms that are suggestive of pneumonia include fever, chills, pleuritic chest pain, and cough. The cough may be nonproductive (dry) or productive of mucoid or purulent sputum. It may be rusty in color and frankly bloody; in patients with a lung abscess (anaerobic infection), it may have a foul odor. The latter is suggestive of anaerobic infection.

Elderly patients complain of fewer symptoms than do younger patients. Indeed, those greater than 75 years of age with pneumonia had 3.3 fewer total symptoms than did patients aged 18 through 44 years with pneumonia.

For some time it was held that typical pneumonia (due to pyogenic organisms such as pneumococcus, staphylococcus, or *H. influenzae*) could be distinguished from that due to *Mycoplasma pneumoniae*, *Legionella* spp., and *Chlamydia pneumoniae*—so-called atypical pneumonia—on the basis of a distinct clinical presentation. Atypical pneumonia is said to be characterized by a more indolent illness than that of typical pneumonia, with a cough that is nonproductive or productive of mucoid sputum only. Careful studies have shown that one cannot reliably distinguish between typical versus atypical pneumonia on clinical grounds. However, this is not to say that a careful history and physical examination are not helpful in suggesting a cause of the pneumonia. Table 119-1 gives a partial list of clues to the cause of pneumonia that may be obtained from the history and physical examination.

Nonrespiratory symptoms such as headache, nausea, vomiting, abdominal pain, diarrhea, myalgia, and arthralgia are also common symptoms in patients with pneumonia. It is wise to remember that the elderly complain of fewer symptoms with pneumonia than do younger patients.

In some instances extrapulmonary signs and symptoms may dominate the clinical picture. Thus, *M. pneumoniae* pneumonia may be complicated by a variety of neurological manifestations including encephalitis, meningitis, and cranial nerve palsies. In addition a maculopapular skin rash is not uncommon. Occasionally, Stevens-Johnson syndrome develops. Patients with *Legionella* pneumonia may have glomerulonephritis or cerebellar ataxia. One should also remember that pyogenic bacteria that cause pneumonia *(S. aureus, S. pneumoniae)* can cause metastatic infections such as endocarditis, brain abscess, and meningitis. Indeed, all patients with pneumonia and *S. aureus* bacteremia should have a careful evaluation for endocarditis.

Physical Examination

Fever is usually present, but some patients may be hypothermic (a poor prognostic sign), and some (20 percent) are afebrile at the time of presentation with pneumonia. Crackles are heard on auscultation over the affected area of lung, and physical findings of consolidation (dullness to percussion, increased tactile, vocal fremitus, whispering pectoriliquy, and bronchial breath sounds) are present in about 20 percent of patients with pneumonia. A pleural friction rub is heard in about 10 percent of cases.

Radiographic Diagnosis

A clinical suspicion of pneumonia usually prompts a chest radiograph. An opacity on the chest radiograph is considered the gold standard for the diagnosis of pneumonia. However, this opacity may be due to infection, infarction, hemorrhage, edema fluid, malignancy, or inflammation caused by a variety of processes, such as vasculitis or adverse drug reactions. Several studies have shown that radiologists cannot differentiate bacterial from nonbacterial pneumonia on the basis of the radiograph. Representative chest radiographs of patients with pneumonia are shown in Figs. 119-1 to 119-4. For patients with pneumonia treated on an ambulatory basis, there is considerable disagreement (in up to 50 percent of cases) between the radiologist's reading of the chest radiograph regarding the presence of pneumonia compared with that of the attending physician. In about 20 percent of patients with symptoms compatible with pneumonia and a chest radiograph read as normal or no pneumonia by the radiologist, computed tomography of the chest will be compatible with pneumonia. It is noteworthy that when patients who are admitted to hospital with a clinical diagnosis of pneumonia (radiologist says no pneumonia) are compared with those with radiologist-confirmed pneumonia, there is no difference in mortality between the two groups. While the percentage of patients with positive blood cultures does not differ between the groups, the microorganisms isolated do; about

Table 119-1

Clues to the Etiology of Pneumonia from the History and Physical Exam

Feature	Organism
Environmental	
Exposure to contaminated air-conditioning cooling towers, recent travel associated with a stay in a hotel, exposure to a grocery store mist machine, visit or recent stay in a hospital with contaminated (by *L. pneumophila*) potable water	*Legionella pneumophila*
Pneumonia after windstorm in an endemic area	*Coccidioides immitis*
Outbreak of pneumonia in shelters for homeless men, jails, military training camps	*Streptococcus pneumoniae; Mycobacterium tuberculosis*
Exposure to contaminated bat caves, excavation in endemic areas	*Histoplasma capsulatum*
Animal contact	
Exposure to infected parturient cats, dog, cattle, sheep, or goats	*Coxiella burnetii*
Exposure to turkeys, chickens, ducks, or psittacine birds	*C. psittaci*
Travel history	
Travel to Thailand or other countries in Southeast Asia	*Burkholderia (Pseudomonas) pseudomallei (melioidosis)*
Pneumonia in immigrants from Asia, India, Africa	*M. tuberculosis*
Occupational history	
Pneumonia in a health care worker who works in a large city hospital with patients infected with HIV	*M. tuberculosis*
Host factors	
Diabetic ketoacidosis	*S. pneumoniae* *Staphylococcus aureus*
Alcoholism	*S. pneumoniae* *Klebsiella pneumoniae* *S. aureus*
Chronic obstructive lung disease	*S. pneumoniae* *Haemophilus influenzae* *Moraxella catarrhalis* *Pseudomonas aeruginosa* (in the subset of patients with advanced COPD)
Solid organ transplant recipient (pneumonia occurring >3 months after transplant)	*S. pneumoniae* *H. influenzae* *Legionella* spp. *Pneumocystis jiroveci* *Cytomegalovirus* *Strongyloides stercoralis*
Sickle cell disease	*S. pneumoniae*
HIV infection with	*P. jiroveci*
CD4 cell count <200/μl	*S. pneumoniae* *H. influenzae* *Cryptococcus neoformans* *M. tuberculosis* *Rhodococcus equi*

Table 119-1

(Continued)

Physical findings	
Periodontal disease and foul-smelling sputum	Anaerobes, may be mixed aerobic-anaerobic infection
Bullous myringitis	*Mycoplasma pneumoniae*
Absent gag reflex, altered level of consciousness, or a recent seizure	Polymicrobial (oral aerobic and anaerobic bacteria) can be macro- or microaspiration
Encephalitis	*M. pneumoniae* *C. burnetii* *L. pneumophila*
Cerebellar ataxia	*M. pneumoniae* *L. pneumophila*
Erythema multiforme	*M. pneumoniae*
Erythema nodosum	*C. pneumoniae* *M. tuberculosis*
Ecthyma gangrenosum	*P. aeruginosa* *Serratia marcescens*
Cutaneous nodules (abscesses) and CNS findings	*Nocardia* spp.

60 percent of the isolates for those with definite pneumonia are *S. pneumoniae* compared with 31 percent for those with clinical pneumonia.

Etiologic Diagnosis

Pneumonia represents a difficult challenge for the clinician, since the etiology cannot be determined from the clinical presentation and data from microbiologic studies are not available for at least 48 hours. Even then, in the case of microorganisms isolated from the sputum, one cannot be sure that this is the organism causing the pneumonia, and not just a microorganism that had colonized the upper airway through which the sputum passed on its way to the specimen jar. For this reason, it is useful to categorize the etiology of pneumonia as definite or probable (Table 119-2).

The etiology of community-acquired pneumonia (CAP) as determined in prospective studies is given in Tables 119-3, 119-4, and 119-5. Table 119-4 shows data for patients with severe pneumonia requiring admission to intensive care units. Table 119-5 gives the etiologic data for bacterial pneumonia in patients with HIV infection. Early in the course of the HIV epidemic, *P. jiroveci* accounted for most cases of pneumonia. Now, with widespread use of prophylaxis to prevent *Pneumocystis* pneumonia, bacterial pneumonia is more common in HIV disease than previously seen (see Chapters 129 and 139). Indeed, the rates of pneumococcal pneumonia and *H. influenzae* pneumonia are 20 times higher among HIV-infected persons than in those of an age- and sex-matched population without HIV infection. In any young person with pneumococcal bacteremia, consider underlying HIV infection. However, one should not forget about *P. jiroveci* pneumonia, since many persons do not know they have HIV and this form of pneumonia is the presenting manifestation of HIV disease in these individuals. Likewise, one should never forget *Mycobacterium tuberculosis* as a cause of pneumonia, especially in the elderly.

Admission Decision

Once a diagnosis of pneumonia has been made, the next decision is whether or not to admit the patient to the hospital. Now, more than ever, there is considerable pressure to treat as many patients as possible at home. In order to do this, it is

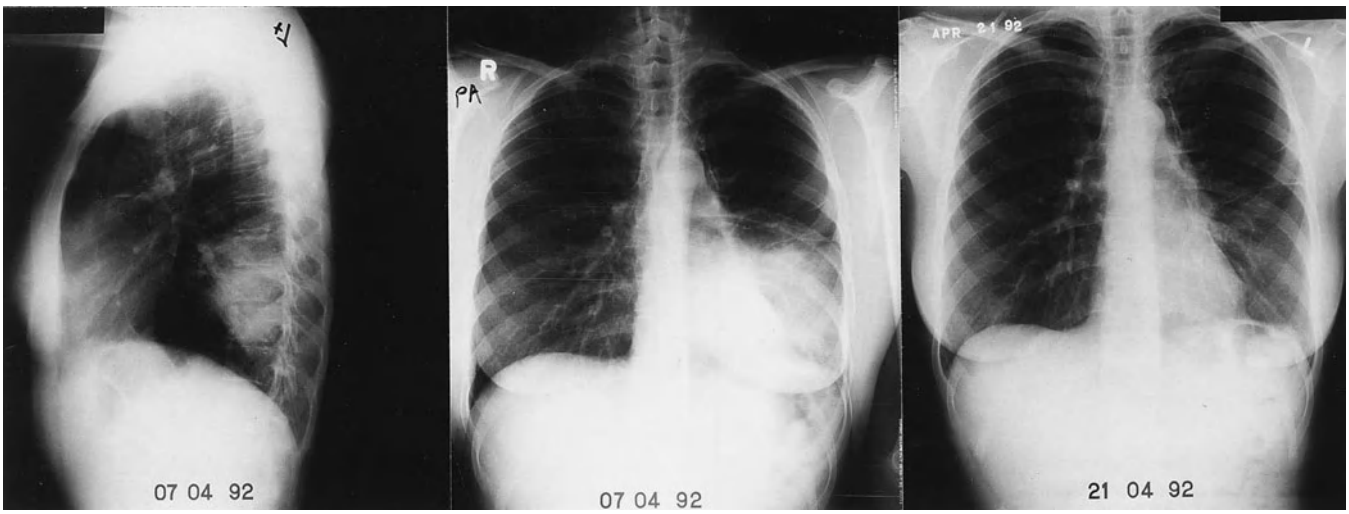

Figure 119-2 Serial chest radiographs of a 32-year-old nurse with *Chlamydia psittaci* pneumonia. She was severely ill with fever, chills, and headaches. She had severe fatigue for 8 months after this episode of pneumonia.

important to know the factors that are predictive of complicated course in pneumonia, some of which are given in Table 119-6. Several clinical rules that predict mortality have been developed that are often used to guide the admission decision. Two of these are the pneumonia severity index, often known as the PORT (patient outcomes research team) score (Tables 116–7 and 116–8) and the CURB-65 (confusion; urea; respiratory rate; blood pressure; age ≥65 years) rule (Table 116–9). The former, developed by Michael Fine and colleagues, assigns points to each of 20 different items that had been shown to be associated with mortality (see Table 119-7). This system allows categorization of patients with pneumonia into five strata, with increasing risk for mortality from risk class I to V. Mortality is less than 1 percent for patients in risk classes I to III, but increases to 9 percent in class IV and to 27 percent in class V (see Table 119-8). Patients in risk classes I and II can usually be treated at home; those in risk class III may require a period of observation in the emergency room before a decision is made about the optimal site of treatment. Patients with pneumonia generally prefer to be

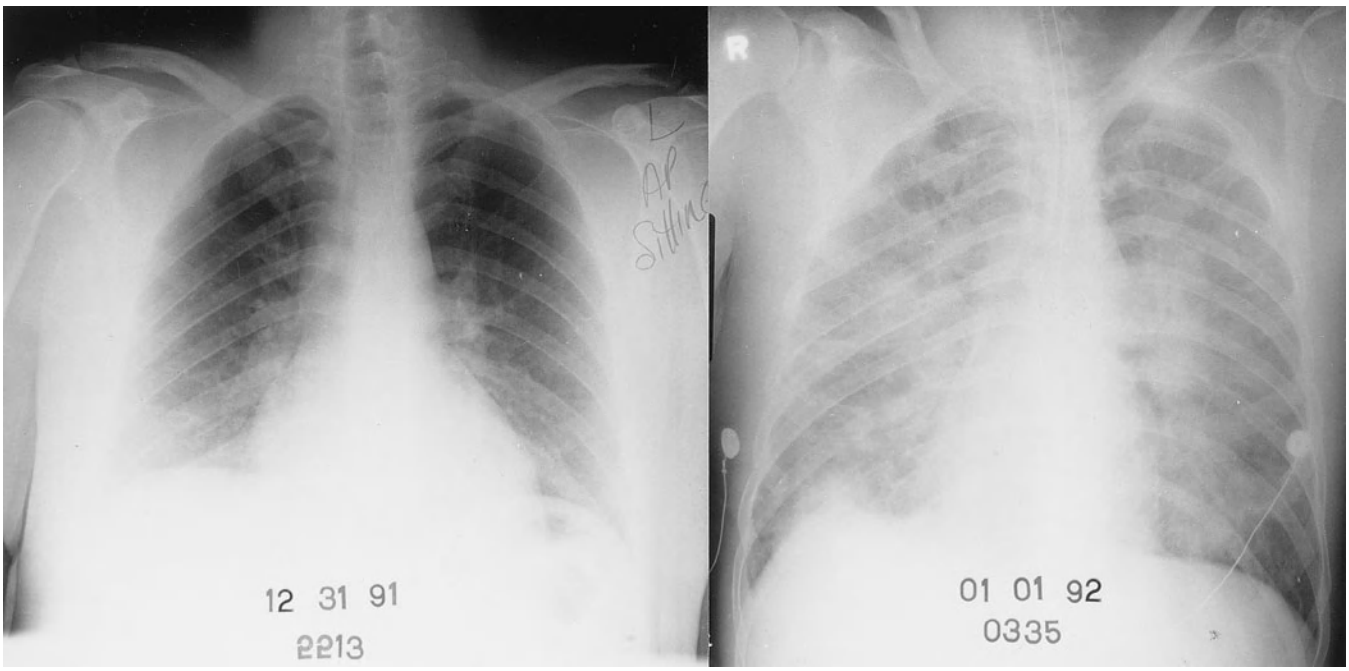

Figure 119-3 Chest radiographs showing rapidly progressive diffuse pulmonary opacities in a 22-year-old man with bacteremic *Streptococcus pneumoniae* pneumonia. This patient had had his spleen removed 6 years earlier. He rapidly developed septic shock and died about 8 hours after admission.

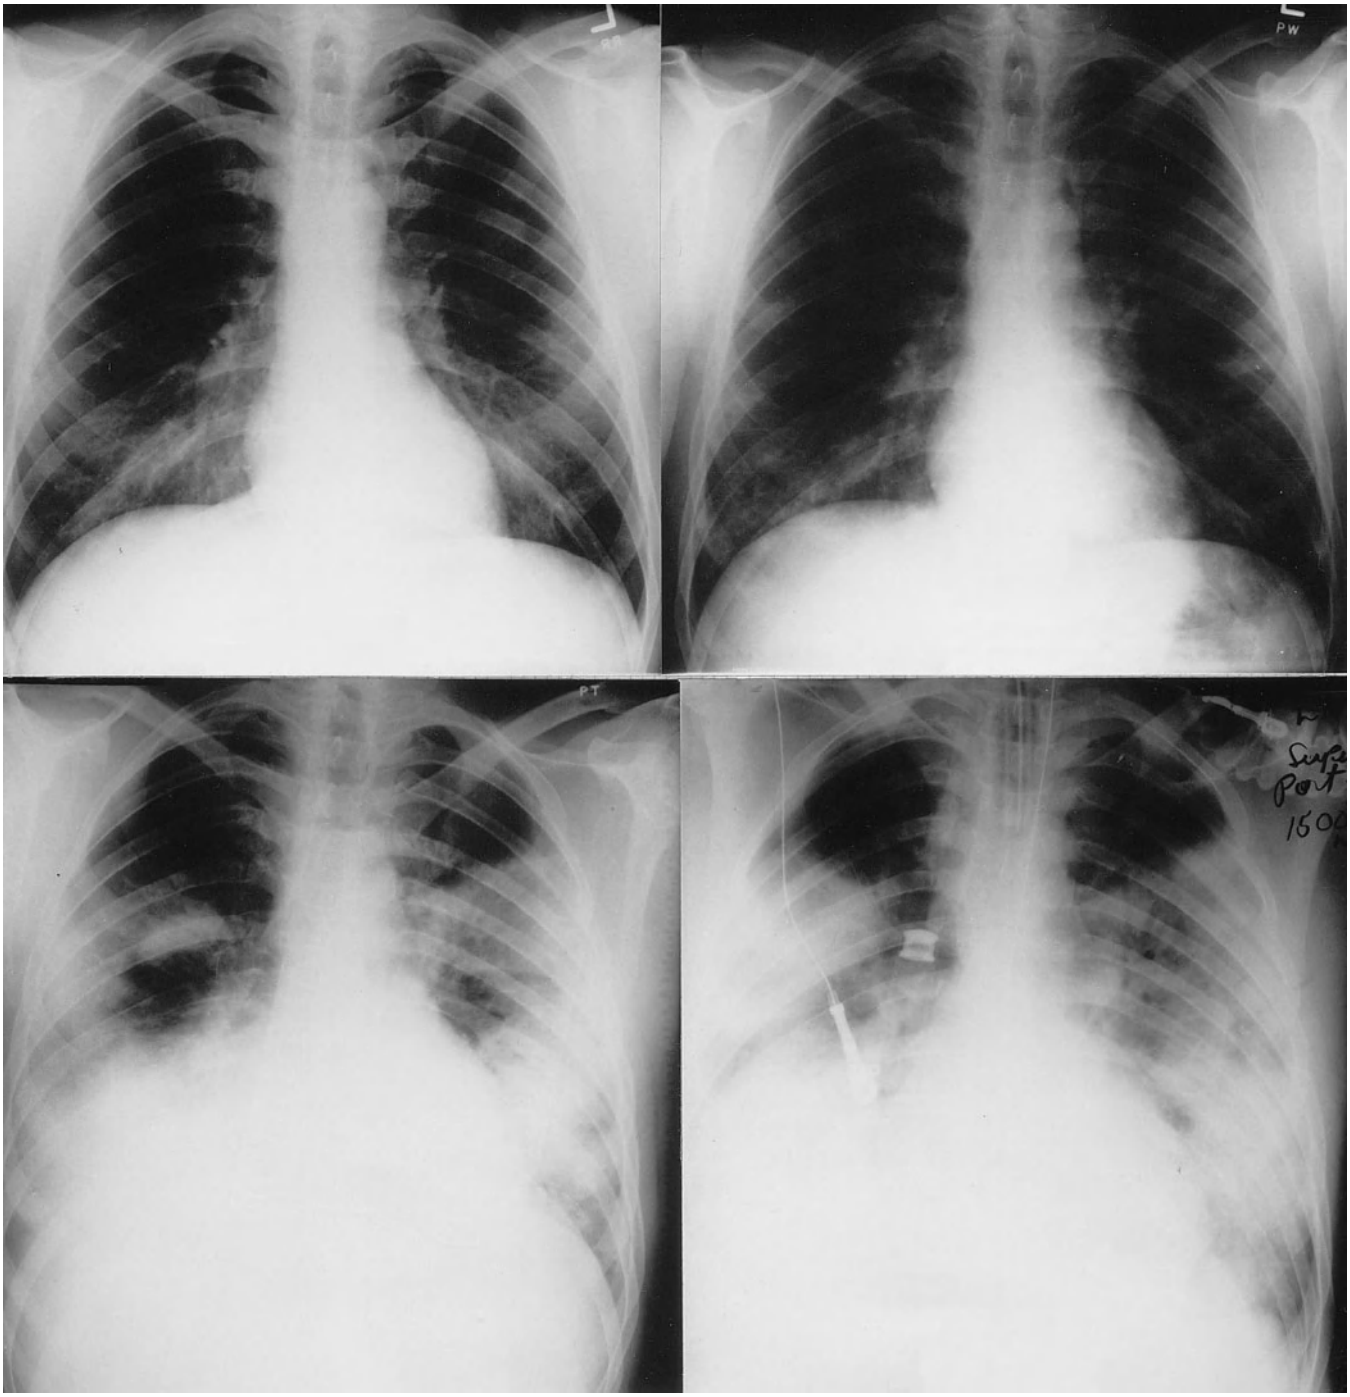

Figure 119-4 Serial chest radiographs of a 40-year-old man with pneumonia due to *Legionella pneumophila* serogroup 6.

treated at home if it can be done safely. As more experience has been gained with this predicition rule, not unexpectedly we have learned that the rule is only a guide. It does not factor social circumstances into the score and since the score is heavily age dependent, many young patients fall into the first three classes when it is readily apparent that they should be admitted.

In the CURB-65 rule the score can range from 0 (none of the elements present) to 5 (all of them present). For a score of 0 the mortality rate is 0.7 percent; 1 to 3.2 percent; 2 to 3 percent; 3 to 17 percent; 4 to 41.5 percent, and 5 to 57 percent (see Table 119-9).

However, the most important element in the admission decision is the physician's judgment. Prediction rules are no substitute for this. Functional status of your patient in the week prior to admission is also a powerful predictor of mortality. In one study, for those who were fully functional, the in-hospital mortality rate was 3.9 percent; for those

Table 119-2

Guidelines for Determining the Degree of Certainty of the Etiology of CAP

Definite
- Blood cultures positive for a pathogen
- Pleural fluid positive for a pathogen
- Presence of *Pneumocystis jiroveci* in induced sputum or in bronchoalveolar lavage luid
- A fourfold or greater rise in antibody titer to *Mycoplasma pneumoniae, Chlamydia pneumoniae, Coxiella burnetii*, or other pathogens for which serological testing is available.
- Isolation of *Legionella pneumophila* or a fourfold rise in antibody titer or positive urinary antigen test for *Legionella*
- Positive direct fluorescence antibody test for *Legionella* plus an antibody titer of ≥1:256 for *Legionella*
- Serum or urine positive for *Streptococcus pneumoniae* antigen
- Isolation of *Mycobacterium tuberculosis* from sputum
- Amplification of nucleic acid of *Legionella* species from a nasopharyngeal swab specimen

Probable
- Heavy or moderate growth of a predominant bacterial pathogen on sputum culture and a compatible Gram's stain
- Light growth of a pathogen in which sputum Gram's stain reveals a bacterium compatible with the culture results
- Amplification of nucleic acid of *Mycoplasma pneumoniae; C. pneumoniae;* influenza viruses A and B; parainfluenzae viruses 1,2,3; adenovirus, respiratory syncytial virus; human metapneumovirus from a nasopharyngeal swab specimen.
- Aspiration pneumonia as diagnosed on clinical grounds.

walking with assistance, it was 5.6 percent; for those who used a wheelchair, it was 20 percent; and for those who were bedridden, it was 25 percent.

Diagnostic Work-up

Patients who are well enough to be treated as outpatients need minimal diagnostic work-up. This should include a chest radiograph, complete white blood count, electrolytes, creatinine, and oxygen saturation by pulse oximetry. It is worth noting that there is controversy as to whether or not all patients who present in an office setting and are suspected of having pneumonia should have the described work-up. However, there is no doubt that those who present to a hospital emergency department and are suspected of having pneumonia should at the very least have the work-up outlined in the preceding. In addition, all individuals who have pleuritic chest pain and symptoms and signs suggestive of pneumonia should have a chest radiograph, and pulmonary thromboembolic disease should be considered. Pulmonary infarction can mimic pneumonia on occasion. Despite the opinion of some experts, a sputum specimen should be submitted for culture whenever possible. Blood cultures should be done on all ambulatory patients with fever (oral temperature greater than or equal to 38°C) and suspicion of pneumonia.

In patients who are ill enough to be admitted to the hospital, two sets of blood cultures should be performed. About 10 percent of patients with pneumonia have positive blood cultures. *Streptococcus pneumoniae* is the most common cause of bacteremic pneumonia, accounting for 60 percent of all cases. Despite the controversy about the utility of sputum gram's stain and culture, this is still a useful test. Take the time to obtain the specimen yourself. One of the chief reasons why this test has fallen into disrepute is that collecting the specimen is a task assigned to other members of a busy health care team. A sample collected hours after antimicrobial therapy has been initiated is useless.

All patients who present to the hospital with pneumonia should have their oxygenation status assessed. This can by done by pulse oximetry, and a blood gas analysis should be obtained if the oxygen saturation is less than or equal to 90 percent. Patients with chronic obstructive lung disease should have blood gases done because hypercarbia can not be detected by pulse oximetry.

Sputum Gram Stain and Culture

A sputum specimen should be cultured only if a smear of a representative portion shows more than 25 polymorphonuclear neutrophils and fewer than 10 squamous epithelial cells per low-power field. The gram stain on such a specimen is useful. If only one morphologic type of bacteria is seen in such a specimen, it is likely that this microorganism is causing the pneumonia. Indeed, in one study, when more than 10 gram-positive lancet-shaped diplococci were seen, the sputum was considered positive for pneumococci. This criterion was met in 62 percent of specimens that were culture positive for *S. pneumoniae*. The value of sputum culture in the diagnosis, management, and outcome of CAP remains a matter of controversy. The Infectious Diseases Society of America pneumonia guidelines recommend gram staining and culture of expectorated sputum for inpatients with CAP. The reasons for this recommendation are to permit optimal antibiotic selection directed to causative agent; limit injudicious antibiotic use in terms of cost, inducible resistance, and adverse drug reactions; allow for a rational basis for change from parenteral to oral therapy and any change in therapy necessitated by an adverse drug reaction; identify drug-resistant pathogens and monitor trends such as penicillin-resistant *Streptococcus pneumoniae*, beta lactamase–producing *Haemophilus influenzae*, or methicillin-resistant *Staphylococcus aureus*; and

prompt tracing of the contacts of those with *Neisseria meningitidis* pneumonia. On the other hand, the American Thoracic Society pneumonia guidelines recommend sputum culture only if a drug-resistant pathogen, or an organism not covered by usual empiric therapy, is suspected.

In patients with HIV infection, sputum production may be induced by inhalation of hypertonic saline, which irritates the tracheobronchial tree and produces bronchorrhea. This results in a specimen that is useful for examination for *P. jiroveci,* thereby obviating the need for bronchoscopy.

Patients who are ill enough to require admission to an intensive care unit for the treatment of their pneumonia should have an aggressive diagnostic work-up. This will usually include at least a bronchoscopy, with use of a protected brush to sample respiratory secretions and brochoalveolar lavage. If this is carried out before the initiation of antibiotic therapy, the diagnostic yield is up to 80 percent. When this procedure is performed after 72 hours or more of antibiotic therapy, however, the microbiologic yield is much lower, 18 percent.

Transthoracic needle aspiration can be used when the basal segment(s) of the lungs is (are) consolidated. A 20-gauge 3.5-inch needle is used to inject 2 to 3 ml of nonbacteriostatic saline into the lung. This is then aspirated and placed into a blood culture bottle. The diagnostic yield from this procedure ranges from 33 to 85 percent. This procedure is

contraindicated in those who are receiving mechanical ventilation. Occasionally, patients with CAP require an open lung biopsy. However, this is usually a last resort in a patient whose condition continues to deteriorate and there is no etiologic diagnosis despite the usual work-up, including bronchoscopy.

An acute-phase serum sample should be obtained from all patients who are admitted to hospital with CAP. If the patient responds promptly to antibiotic therapy, there is no need to obtain a convalescent sample. If the patient responds poorly to therapy, however, a convalescent sample should be obtained 3 to 6 weeks after the acute-phase sample. The diagnostic battery ordered depends on local epidemiologic conditions. In general, *M. pneumoniae, C. pneumoniae, Coxiella burnetti, Legionella pneumophila,* adenovirus, influenza A and B viruses, parainfluenza viruses 1, 2, and 3, and respiratory syncytial virus antibodies can be measured in most laboratories. Antibody titers to *S. pneumoniae* pneumolysin and detection of immune complexes to this antigen may be a tool for diagnosis of pneumococcal pneumonia in those who do not have sputum available for culture.

L. pneumophila serogroup 1 infection can be reliably diagnosed from detection of antigen in urine with a radioimmunoassay or an enzyme-linked immunosorbent assay. In the absence of an outbreak, *Legionella* spp. accounts for about 2 percent of cases of CAP. Thus, the dilemma is when to order this test. To some extent this depends on local epidemiology (in some hospitals the test is ordered for all patients sick enough to be admitted for treatment of CAP), but in general for patients with severe pneumonia this test probably should be done.

There is also a urinary antigen test for pneumococcal pneumonia. This test detects C polysaccharide, which is present in all serotypes of *S. pneumoniae.* It is reasonably sensitive and specific when bacteremic pneumococcal pneumonia is used as the gold standard. The question is, what is its usefulness in patients with negative blood cultures? There are false-positives in children with nasopharyngeal colonization with *S. pneumoniae.*

Multiplex polymerase chain reaction (PCR) is a tool that may be useful in the etiological diagnosis of CAP. Currently, from one specimen such as a nasopharyngeal swab or sputum, the following agents can be detected by multiplex PCR: *M. pneumoniae; C. pneumoniae; Legionella* spp.; influenza viruses A and B; parainfluenza 1,2,3 viruses; adenovirus; respiratory syncytial virus; human metapneumovirus; coronaviruses; and rhinoviruses. Using this technology, we have learned that viral pneumonia is more common in adults

Table 119-6

Risk Factors for a Complicated Course or Mortality in Patients with CAP

Age >65 years
Comorbid illnesses that are likely to be made worse by the pneumonia, especially chronic renal failure, ischemic heart disease, congestive heart failure, severe COPD, concurrent malignancy
Postsplenectomy state
Altered mental status
Alcoholism
Immunosuppressive therapy
Respiratory rate >30 breaths per minute
Diastolic blood pressure <60 mmHg; systolic blood pressure <90 mmHg
Hypothermia
Creatinine >150 mM/L or BUN >7 mM/L
Leukopenia <3000/μl or leucocytosis >30,000/μl
P_{O_2} < 60 mmHg or P_{O_2} >48 mmHg while breathing room air
Albumin <30 g/l
Hemoglobin <9 g/l
Pseudomonas aeruginosa or *Staphylococcus aureus* as the cause of the pneumonia
Bacteremic pneumonia
Multilobe involvement on chest radiograph
Rapid radiographic progression of the pneumonia defined as increase in the size of the pulmonary opacity of ≥50% within 36 h

patients with pneumonia. The inference is that patients with this level of procalcitonin have viral pneumonia.

TREATMENT

The initial therapeutic approach to pneumonia is empirical. Categorize the severity of the pneumonia as mild, moderate, or severe. It is then usually self-evident where the patient should be treated; at home, in the hospital, or in an intensive care unit. Table 119-10 outlines the guidelines for initial antimicrobial therapy for community-acquired pneumonia as proposed by the American Thoracic Society and the Infectious Diseases Society of America. A key concept in selecting empiric antibiotic therapy is to inquire about antibiotic therapy in the past 3 months and then select an agent that has not been used in that time period. If a macrolide has been used in this time period, then 35 percent of *S. pneumoniae* isolates are resistant to a macrolide compared with 7 percent if the patient did not have macrolide therapy in this time period. For penicillin or a cephalosporin, resistance increases from 5 to 9 percent in this setting. Thus, use a different class of antibiotic than the one the patient received in the past 3 months.

Since in everyday practice an etiologic diagnosis is frequently not made, antibiotic therapy has to be empirical. Osterheet et al. attempted to answer the question of whether combination therapy or monotherapy with a fluroquinolone (as recommended by the North American guidelines) is better than other therapy for the empiric treatment of CAP. They carried out a Medline search of studies published from January 1997 to April 2003. Only eight of the 135 articles fit their criteria for further analysis. In six of the eight studies, a significant reduction in all-cause mortality was found for patients treated with a combination of a beta lactam plus a macrolide or with monotherapy with a fluroquinolone. Three of these studies involved only patients with bacteremic pneumococcal pneumonia and in one study an effect was noted in one study year, 1993, but not in 1995 or 1997. Seven of the studies were retrospective and two involved administrative data bases. Clearly, a properly designed and conducted randomized clinical trial is necessary to answer this, the most fundamental question in the treatment of CAP.

Data from several retrospective studies suggest that combination therapy of bacteremic pneumococcal pneumonia with a macrolide and a beta lactam is better than single-agent therapy. Unfortunately, we do not have randomized control data to advise us. Recent data indicate that intravenous cefuroxime should not be used to treat bacteremic pneumococcal pneumonia, because the failure rate is higher than with other regimens.

In one study, treatment of patients hospitalized with CAP with moxifloxacin was associated with faster resolution of symptoms compared with patients who were treated with ceftriaxone plus erythromycin.

Table 119-10

Initial Empiric Antimicrobial Therapy for CAP

Outpatient
- Previously healthy
  - No recent antibiotic therapy: a macrolide, doxycycline telithromycin now known to cause hepatic necrosis.
  - Recent antibiotic therapy (within past 3 months). In general choose from a class of agents that the patient has not received within the past 3 months: a respiratory fluoroquinolone alone, an advanced macrolide (clarithromycin or azithromycin) plus high-dose amoxicillin, an advanced macrolide plus amoxicillin-clavulanate.
  - Co-morbidities such as congestive heart failure, chronic obstructive pulmonary disease, diabetes, or malignancy
  - No recent antibiotic therapy: an advanced macrolide or respiratory fluoroquinolone
  - Recent antibiotic therapy: Choose from a class of agents that the patient has not received within the past 3 months.
  - Suspected aspiration with infection: amoxicillin-calvulanate or clindamycin
  - Influenza with bacterial superinfection: a vancomycin or linezolid or respiratory fluoroquinolone

Inpatient
- Ward
  - No recent antibiotic therapy: a respiratory fluoroquinolone, or an advanced macrolide plus beta lactam, cefotaxime, ceftriaxone ampicillin ertapenem for selected patients.
  - Recent antibiotic therapy: An advanced macrolide plus a beta lactam, or respiratory fluoroquinolone alone. (The regimen selected depends on the nature of the recent antibiotic therapy. Choose from a class of agents that the patient has not received within the past 3 months.
- ICU
  - *Pseudomonas* infection is not an issue: a beta lactam plus an advanced macrolide or respiratory fluoroquinolone
  - *Pseudomonas* infection is not an issue but patient has a beta lactam allergy: a respiratory fluoroquinolone with or without clindamycin
  - *Pseudomonas* infection is an issue: an antipseudomonal agent plus ciprofloxacin or antispseudomonal agent plus aminoglycoside plus respiratory fluoroquinolone or macrolide
  - *Pseudomonas* infection is an issue and patient has a beta lactam allergy: aztreonam plus levofloxacin or aztreonam plus moxifloxacin or gatifloxacin with or without aminoglycoside
- Nursing home
  - Treatment in the nursing home: a respiratory fluoroquinolone or advanced macrolide plus amoxicillin-clavulanate
  - Hospitalized: same as ward or intensive care unit

Once an etiologic diagnosis has been made, treatment should be changed to the cheapest, narrowest-spectrum agent effective against that microorganism. For example, if penicillin susceptible *S. pneumoniae* is determined to be the cause of the pneumonia, penicillin therapy is still the most appropriate treatment.

The response of patients to treatment depends on the severity of the pneumonia and the presence of co-morbidities that may be made worse by the pneumonia. Outpatients with mild to moderate pneumonia do very well. Mortality is rare (less than 1 percent), and only about 4 percent of patients fail therapy and require hospitalization. The issue of the most appropriate treatment for patients with pneumonia due to PRSP is unclear. We do know that pneumonia due to this microorganism can be treated successfully with high-dose intravenous penicillin. We also know that treatment with penicillin is not successful if there is concomitant pneumococcal meningitis. In this setting, vancomycin and ceftriaxone are recommended. If beta lactam antibiotics are used, the concentration of the antibiotic must exceed the MIC of *S. pneumoniae* 40 percent of the time for cure of pneumococcal pneumonia. In one study, high-dose amoxicillin was the most effective oral beta lactam antibiotic for the treatment of PRSP. Macrolide-resistant *S. pneumoniae* is also an issue in many communities. Because most cases of ambulatory pneumoniae are of unknown etiology and since there is less than 1 percent mortality among patients with pneumonia treated on an ambulatory basis, a worse outcome for

macrolide treated patients vs. other antibiotics may not be detected unless large RCTs are performed. Currently, about 2 percent of penicillin-susceptible *S. pneumoniae* isolates are resistant to macrolides, 12 percent of isolates intermediately resistant to penicillin are resistant to macrolides, while 25 percent of isolates that are highly resistant to macrolides are resistant to penicillin. Macrolide susceptibility of *S. pneumoniae* is defined as an MIC of up to 0.5 mg/L. The mean MICs for strains resistant because of an efflux mechanism is 10 mg/L; this accounts for 55 percent of the macrolide resistance in *S. pneumoniae*. Modification of the target (ribosomal) site accounts for 45 percent of the resistance and results in MICs of 64 mg/L. Thus, strains with resistance due to efflux mechanism may very well respond to treatment with a macrolide, whereas those due to target alteration will not. Resistance due to the efflux mechanism is more common in North America, while the reverse is true in Europe, i.e., most resistance is due to target alteration. Telithromycin, a new oral antibiotic, may be valuable for the ambulatory treatment of CAP in communities in which macrolide resistance is high. Telithromycin, a semisynthetic derivative of erythromycin, is the first of a new class of antibiotics, the ketolides. The α L-cladinose at position three is replaced by a keto group that prevents telithromycin from inducing MLS B resistance and results in improved activity against certain macrolide resistant bacteria. It is noteworthy that constitutively resistant *S. pneumoniae* is highly susceptible to telithromycin, but *S. pyogenes* and *S. aureus* expressing constitutive MLS B resistance are also resistant to telithromycin. Telithromycin is not affected by macrolide efflux mechanisms in bacterial cells. The dose is 800 mg OD for 5 to 10 days. Diarrhea, nausea, and vomiting are the major side effects followed by headache and dizziness. It has also been associated with elevations in hepatic transaminases and prolongation of the QT interval. It is a strong inhibitor of cytochrome P450 3A4 isoenzyme. Therefore, it is important to monitor for potential drug interactions with medications that prolong the QT interval or are metabolized by the CYP system. There is no need for adjustment in dosage for renal or hepatic failure.

The overall mortality for those admitted to hospital for treatment of pneumonia is 8 to 10 percent. In patients with nursing home–acquired pneumonia, it may approach 40 percent. For many of these patients, pneumonia is the final common pathway for a variety of chronic debilitating illnesses.

A recent concept in therapy of pneumonia requiring hospitalization is early switch to oral antibiotics. Patients who are stable by hospital day 3 (as evidenced by temperature of 37.5°C or less for 16 hours, white blood cell count returning toward normal, normal hemodynamics, no requirement for auxiliary oxygen, no complications of pneumonia such as empyema, and ability to take antibiotics by mouth) can be switched to antibiotics and discharged shortly thereafter. About one-third of patients qualify for this therapy. Prompt administration of antimicrobial therapy following a diagnosis of pneumonia intuitively makes sense. One study showed a lower mortality rate for elderly patients who received the first dose of antibiotics within 8 hours of presentation to an emergency department. In another large administrative data base study of over 18,000 patients among the 24.4 percent who were receiving antibiotics prior to presentation, antibiotic therapy within 4 hours of presentation was associated with a reduction in length of stay but not in mortality. Among the 75.6 percent of patients who were not receiving antibiotics prior to admission, there was both a reduction in LOS and mortality for those who received their first dose of antibiotic within 4 hours of presentation.

In a study of 399 patients with CAP treated on an ambulatory basis, symptoms had resolved within 14 days in 67 percent. The mean time to return to work in this population was 6 days compared with a median of 22 days for those who required hospitalization.

Some patients see their condition fail to improve or indeed worsen during therapy. Table 119-11 gives the factors that should be considered in this setting. One should not forget methicillin-resistant *S. aureus* (MRSA) as a cause of failure of initial treatment in patients with CAP. Also, in those who are admitted from nursing homes, consider extended spectrum beta lactamase (ESBL) producing enterobacteriaceae. Radiographic evidence of resolution of pneumonia lags behind clinical resolution and correlates with age and the presence of chronic obstructive pulmonary disease (COPD). In general, those who are under 50 years of age and have no COPD show radiographic resolution of pneumonia within 4 weeks. In contrast, resolution requires 12 or more weeks for those with pneumonia who are older than 50 years and have coexistent COPD or alcoholism. In about 2 percent of patients, pneumonia is the presenting manifestation of carcinoma of the lung (postobstructive pneumonia). It is important to demonstrate that the pneumonia has resolved radiographically for those who are at risk for carcinoma of the lung. In general, all tobacco smokers and those who are 50 years of age or older and have pneumonia should have a chest radiograph to determine whether or not the pneumonia has completely resolved. Table 119-11 gives an approach to the patient whose pneumonia is not responding to therapy.

ADJUNCTIVE THERAPY

In the PROWESS trial, drotrecogin alfa activated resulted in a 28 percent relative reduction in mortality among patients with severe CAP. Currently, patients with CAP and an APACHE II score of greater than 25 qualify for this drug, although the data suggest a beneficial effect beginning at an APACHE II score of 20. Tissue factor pathway inhibitor may also have a beneficial effect in severe pneumonia, and currently trials of this compound are underway.

Low-dose corticosteroid therapy is beneficial to those who are relatively adrenal insufficient (less than 9 μg/ml response in cortisol level to a dose of adrenocorticotrophic hormone). Hyperglycemia has been shown to be associated with higher mortality rates in patients who require hospitalization for community-acquired pneumonia, so it is likely that

Table 119-11

Considerations When Pneumonia Fails to Resolve or Worsens During Therapy

Reconsider the pneumonia diagnosis: Could this be pulmonary infarction, malignancy, vasculitis, drug reaction, or eosinophilic pneumonia?
Reconsider the etiologic diagnosis: Are you treating the appropriate microorganism(s)?
Remember that 10% of cases of community-acquired pneumonia are polymicrobial. Tuberculosis can mimic pyogenic pneumonia. Also consider unusual organisms such as *Actinomyces* or *Nocardia* species.
Are you dealing with a resistant microorganism? *Streptococcus pneumoniae* resistant to penicillin, erythromycin, and tetracycline is common in several European countries and the United States.
Has your patient developed nosocomial pneumonia? Such an event is common, particularly in patients who require endotracheal intubation and assisted ventilation. Is your hospital's potable water supply contaminated by *Legionella* spp.? If so, consider nosocomial Legionnaires' disease. Nosocomial legionnaires' disease should be a consideration anytime a patient with CAP is improving and develops nosocomial pneumonia.
Could this be postobstructive pneumonia (i.e., is endobronchial obstruction present)?
Have you considered empyema? Pus in the pleural space will continue to cause fever until it is drained.
Has metastatic infection occurred? Occasionally, patients who are bacteremic as a result of their pneumonia develop endocarditis, meningitis, septic arthritis, or a deep abscess such as splenic or renal abscess.
Always consider drug fever.

control of hyperglycemia will be beneficial to patients with pneumonia and elevated blood sugar.

Treatment of Pneumonia in the Nursing Home

In one study, if more than two of the following factors were present—respiratory rate greater than 30 per minute, temperature greater than 100.5°F, pulse rate greater than 90 beats per minute, and feeding dependence and mechanically altered diet—the failure rate of therapy of pneumonia in the nursing home was high. It is important to take patients' wishes into consideration in the decision to treat in the nursing home or transfer to the hospital. Treatment with ampicillin for nursing home–acquired pneumonia was associated with a significantly higher failure rate than was treatment with ceftriaxone. It seems that, given their antimicrobial spectrum and almost complete absorption following an oral dose, treatment of nursing home–acquired pneumonia with one of the "respiratory fluoroquinolones" is appropriate, although data from RCTs are still lacking for this group of patients.

PREVENTION

Influenza vaccination of the elderly results in reduction in the rate of hospitalization for pneumonia and influenza by 48 to 57 percent. The role of pneumococcal vaccine has not been as clearly defined as that of influenza vaccine; however, the Advisory Committee on Immunization Practice recommends pneumococcal vaccine for persons older than 65 years of age. A somewhat unexpected benefit of the use of a protein-polysaccharide conjugated pneumococcal vaccine during childhood has been the reduction of invasive pneumococcal disease in 20 to 39 year olds and among those equal to or greater than 65 years of age. Indeed, in the United States, the incidence of invasive pneumococcal disease among adults 50 years and older declined from 40.8 cases/100,000 prior to the introduction of the vaccine to 29.4 only 4 years later. The rate of death following an episode of invasive pneumococcal disease among adults aged 50 years or older decreased from 6.9 to 5.7/100,000. The authors estimated 6250 fewer cases and 550 fewer deaths per year among those 50 years of age and older in the United States compared with the years prior to introduction of the conjugate vaccine.

Prevention of aspiration in those at risk (post-stroke, advanced Parkinson's, and advanced Alzheimer's disease) is difficult. Head positioning, stimulation techniques, exercises to enhance the swallowing reflex, and eating pureed foods can all help to reduce the risk of aspiration. In addition, intensive oral care (cleaning teeth after every meal with an applicator of povidone iodine, and frequent dental care to control plaque) reduced the rate of pneumonia from 19 percent in the control group to 11 percent in the treatment group.

Of course, all those who are asplenic should be vaccinated with pneumococcal vaccine, *Hemophilus influenzae* B vaccine, and meningococcal vaccine. If possible, this should be done prior to splenectomy.

Patients with hypogammaglobulinemia should have periodic infusions of gammaglobulin in a regimen designed to keep the levels high enough to prevent infection.

QUALITY OF CARE MEASURES: PNEUMONIA

The following have been adopted as quality of care measures for patients with CAP requiring admission to the hospital: blood cultures prior to administration of antibiotics; measurement of oxygenation status; administration of antibiotics within 4 hours of presentation to the emergency department; ascertainment of influenza; and pneumococcal vaccination status and administration of these vaccines as necessary. In addition, for those who smoke tobacco products, at the very least information about cessation, and preferentially counseling regarding cessation of smoking.

A number of studies have examined the effect of using guidelines on patient care, and while the designs have differed, there is a strong suggestion that following guidelines has a "halo effect" in improving patient care and results in decreased mortality and, in some instances, reduced length of stay.

End-of-Life Decision Making

As indicated, many patients with CAP are elderly and many of these enter the hospital with advance directives. For all of these patients it is important to discuss life-sustaining measures such as assisted ventilation and admission to an intensive care unit should the need arise.

Specific Pathogens

Streptococcus pneumoniae

Streptococcus pneumoniae is still a common cause of pneumonia. Patients with bacteremic pneumococcal pneumonia are more likely to have diabetes mellitus, COPD, or alcoholism than those who have other causes of CAP. Capsular polysaccharide types 14, 4, 1, 6A/6B, 3, 8, 7F, 23F, and 18C are the most frequent causes of pneumococcal disease. Currently, 10 to 15 percent of *S. pneumoniae* isolates in the United States are intermediately or highly resistant to penicillin. These isolates are usually also resistant to erythromycin, tetracycline, and trimethoprim-sulfamethoxazole. Types 19A, 6A, 23, 19, 11, 6, 16, 9, and 14 are most frequently associated with penicillin resistance. The minimal inhibitory concentration (MIC) of penicillin for susceptible strains is under 0.06 μg/ml; isolates with MICs of 0.1 to 1 μg/ml are of intermediate resistance, and those with MICs of at least 2 μg/ml are highly resistant. These levels were established for central nervous system infections, for which trough concentrations of penicillin at 10 times MIC are necessary for cure. Generally, with intravenous antibiotics, high concentrations can be achieved in pulmonary tissue; therefore, even resistant strains of *S. pneumoniae* usually respond to treatment with high doses of penicillin or third-generation cephalosporin. If there is concomitant meningitis, however, both a third-generation cephalosporin and vancomycin should be given. A number of observation studies have indicated that the combination of a macrolide and beta lactam results in lower mortality rates for patients with bacteremic pneumococcal pneumonia compared with monotherapy or therapy with other combinations. Indeed, there is a suggestion that the combination of a beta lactam agent and fluoroquinolone results in higher mortality.

Staphylococcus aureus

Pneumonia due to this agent is usually of sudden onset, affects persons with co-morbid illnesses (except during influenza outbreaks, when healthy young adults may be infected), and is frequently complicated by cavitation (20 percent), pneumothorax (10 percent), jaundice (8 percent), empyema (5 percent), acute renal failure (5 percent), and pericarditis (2 percent).

MRSA is a rare cause of CAP. It does occur, however, and once established in a region, it can be a major problem. Vancomycin is used to treat MRSA, whereas cloxacillin or nafcillin is used to treat methicillin-susceptible strains. Surgical drainage is necessary for treatment of empyema. If multiple rounded opacities are seen in a patient with *S. aureus* pneumonia, suspect right-sided endocarditis. Toxic shock syndrome may complicate *S. aureus* pneumonia. Strains of *S. aureus* with the gene for Panton-Valentine leukocidin (PVL) have been described recently. PVL is an extracellular product of *S. aureus*. It is associated with primary skin infections such as furunculosis, and severe necrotizing pneumonia. In a recent report of eight cases of severe CAP caused by *S. aureus* strains carrying the PVL gene, six were fatal. The patients were all immunocompetent children or young adults. All had a preceding influenza-like syndrome before developing pneumonia, and the six deaths occurred shortly after diagnosis. Necropsy showed diffuse necrotizing hemorrhagic pneumonia. In another study, PVL-positive infections were more often marked by temperature greater than 39°C ($p = 0.01$), heart rate above 140 beats per min ($p = 0.02$), hemoptysis ($p = 0.005$), onset of pleural effusion during hospital stay ($p = 0.004$), and leucopenia ($p = 0.001$). The survival rate 48 hours after admission was 63 percent for the PVL-positive patients and 94 percent for PVL-negative individuals ($p = 0.007$). Histopathological examination of lungs at necropsy from three cases of necrotizing pneumonia associated with PVL-positive *S. aureus* showed extensive necrotic ulcerations of the tracheal and bronchial mucosa and massive hemorrhagic necrosis of interalveolar septa. Both methicillin-sensitive and methicillin-resistant strains have been described.

Haemophilus influenzae

This cause of pneumonia is more common in older patients with COPD. Both type B and non-B strains can cause pneumonia. About 30 percent of all *H. influenzae* isolates now produce beta lactamase and hence are resistant to ampicillin and amoxicillin. Between 7 and 14 percent of *H. influenzae*

isolates are resistant to trimethoprim-sulfamethoxazole. More than 90 percent of *H. influenzae* isolates are resistant to erythromycin; and 1 to 2 percent are resistant to tetracycline. Amoxycillin-clavulinic acid and a second- or third-generation cephalosporin reliably treat *H. influenzae* pneumonia.

Streptococcus pyogenes (group A streptococcus)

This agent is uncommon as a cause of pneumonia. One of its presentations is pneumonia accompanied by explosive pleuritis. Cases of group A streptococcal pneumonia may be accompanied by "toxic strep syndrome." Clindamycin, 600 mg given intravenously every 8 hours is superior to penicillin for the treatment of serious group A streptococcal infections. Of 2079 cases of invasive group A streptococcal (GAS) infection, 222 (11 percent) had pneumonia. The median age was 56 years. Underlying illness was present in 61 percent of cases. Most cases were community acquired (81 percent). The case fatality rate was 38 percent for GAS pneumonia, compared with 12 percent for the entire cohort with invasive GAS infection. In 2002, the largest outbreak of 127 cases of GAS pneumonia in the United States occurred among military recruits in San Diego. The epidemic continued despite prophylaxis with penicillin and required additional prophylaxis to end it.

Mycoplasma pneumoniae

This agent accounts for up to 30 percent of pneumonias treated on an outpatient basis. The extrapulmonary manifestations of *M. pneumoniae* are many and include cold agglutinin–induced hemolytic anemia, thrombocytopenia, encephalitis, cerebellar ataxia, Guillain-Barré syndrome, Stevens-Johnson syndrome, and myocarditis. This is primarily a disease of younger patients, but it accounts for 5 percent of all cases of pneumonia in persons 65 years of age or older. Macrolides (erythromycin, clarithromycin, and azithromycin) or tetracyclines are the treatment of choice.

Legionellaceae

This family, which includes 29 species and more than 49 serogroups (there are 15 serogroups of *L. pneumophila)*, causes two clinical syndromes: Legionnaires' disease and a self-limited flu-like illness (Pontiac fever). *L. pneumophila* serogroup 1, the microorganism responsible for the 1976 outbreak in Philadelphia that gave this disease its name, accounts for 70 to 90 percent of the cases of Legionnaires' disease. Legionnaires' disease can be community or hospital acquired, and it can occur in sporadic, endemic, and epidemic forms. Exposure to contaminated water (showers, cooling towers, or even ingestion of such water and subsequent microaspiration) is the prime mode of acquisition of this illness. Older age, male gender, immunosuppression (especially with corticosteroids), nosocomial acquisition, end-stage renal disease, and infection with *L. pneumophila* serogroup 5 are risk factors for death from this infection. On a molecular level, a mutation leading to a stop codon at position 392 resulted in a dysfunctional toll like receptor 5 protein unable to recognize flagellin. This was a risk factor for *Legionella pneumophila* infection.

There is now considerable evidence that quinolone antibiotics are superior to macrolides for the treatment of Legionnaires' disease. Azithromycin appears to be the macrolide of choice if this class of antibiotics is used. The disease may continue to progress for up to 4 days despite optimal therapy. Other options are doxycycline, 100 mg given twice intravenously in 24 hours and then 100 mg OD intravenously. Mild to moderately severe LD can be treated for 7 to 10 days while severe cases or LD in immunocompromised hosts should be treated for at least 21 days.

Hantavirus

In May 1993, reports of deaths due to severe pulmonary disease were received by the New Mexico Department of Health. Many of the affected persons were residents of the Navajo reservation located near the Four Corners area of New Mexico, Arizona, Colorado, and Utah. Within a few months a new Hantavirus (sin nombre, "no name" virus) had been isolated and shown to be responsible for this outbreak, which affected 17 persons. Hantavirus pulmonary syndrome (HPS) is characterized by a flu-like prodromal illness, followed by rapidly progressive noncardiogenic pulmonary edema. Fever, myalgia, cough or dyspnea, nausea or vomiting, and diarrhea are the most common symptoms. Hypotension, tachypnea, and tachycardia are the usual findings on physical examination. Leukocytosis (often with a severe left shift), thrombocytopenia (median lowest platelet count 64,500/mm^3), prolonged prothrombin and partial thromboplastin times, and elevated serum lactate dehydrogenase concentration are the most common laboratory findings. The mortality was high (88 percent) in the Four Corners outbreak. The initial chest radiograph showed infiltrates in 65 percent and no abnormality in 24 percent of patients. Subsequently, 16 patients (94 percent) had rapidly evolving bilateral diffuse infiltrates. In the few months after identification of this new Hantavirus, two more new Hantaviruses were identified in the United States and cases of HPS continue to be reported. The deer mouse, *Peromyscus maniculatus,* is the primary rodent reservoir for this virus.

Chlamydophila pneumoniae

This intracellular pathogen of humans is spread by aerosols. It causes sinusitis, pharyngitis, bronchitis, otitis media, and pneumonia. The last can be as a result of primary infection or as reactivation of latent infection. Primary infection affects mainly young adults and may be followed by reactive airway disease. Two weeks of treatment with doxycycline is adequate. Clarithromycin is very active in vitro against *C. pneumoniae,* but whether it is superior to doxycycline is not known.

The reactivation type of infection occurs in older adults, often as part of a polymicrobial infection. The rate of *C. pneumoniae* in this setting is unknown.

Diagnosis is by isolation of the organism from respiratory secretions or by serology. A greater than fourfold rise in IgM or IgG by microimmunofluorescence test or a single IgM titer of at least 1:16 or an IgG titer of at least 1:512 is considered diagnostic.

Severe Acute Respiratory Syndrome Coronavirus

In November 2002 an outbreak of severe acute respiratory syndrome (SARS) started in Guangdong Province in southern China and spread worldwide, affecting more than 8000 persons. SARS was due to a novel coronavirus that jumped the species barrier from civet cats to humans. Patients with typical SARS usually present 2 to 10 days following exposure with nonspecific symptoms including fever, myalgia, headache, malaise, and chills. Three to five days later, a nonproductive cough and dyspnea develop. Twenty percent of patients subsequently develop worsening respiratory distress requiring admission to an intensive care unit. Approximately 10 percent of all patients die from progressive respiratory distress or complications of their hospital admission, typically around the third week of symptomatic illness.

Approximately 75 percent of patients have unilateral or bilateral infiltrates on chest radiograph at the time of presentation. The majority of those without visible infiltrates have ground-glass opacities detectable on high resolution computer tomography at the time of presentation or progress to develop radiographic infiltrates. Generally, radiographic opacities peak between 8 and 10 days after onset of illness and then improve, correlating with the worsening and improvement of respiratory symptoms, but progressive radiographic deterioration may occur associated with a more protracted clinical course. There is no effective antiviral therapy. The management of severe cases is that of the management of severe respiratory failure. Attention to infection control measures designed to prevent spread of SARS is most important.

Human Metapneumovirus

Human metapneumovirus is a newly described member of the *Paramyxoviridae* family. Since its initial description in 2001, when it was isolated from nasopharyngeal aspirates of young children in the Netherlands, it has been described worldwide. Despite almost universal infection in early childhood, repeat infections do occur in adulthood, and it appears to account for about 2 to 3 percent of cases of pneumonia in adults. Unfortunately, there are no clinical or routine laboratory features that allow one to distinguish this type of pneumonia from bacterial pneumonia.

Mimivirus

A giant virus that stains gram-positive with gram stain has been found in amoebae. This virus is an uncommon but definite cause of some cases of community-acquired pneumonia.

Acute Exacerbations of Chronic Obstructive Pulmonary Disease

Fernando J. Martinez • Jeffrey L. Curtis

DEFINITION

Although the topic remains controversial, a generally accepted definition of acute exacerbations of COPD (AE COPD) is "a sustained worsening of the patient's condition, from the stable state and beyond normal day-to-day variations, that is acute in onset and necessitates a change in regular medication in a patient with underlying COPD." It is important to exclude alternate causes of acute deterioration, including congestive heart failure, pneumothorax, and pulmonary emboli, among others. Two major approaches to defining an AE COPD have been advocated: symptom-based and event-based definitions. Symptom-based definitions are the most frequently used, with most modifying the criteria of Anthonisen et al. Although symptom-based definitions are the most relevant to patient care, some investigators have documented that a significant proportion of patients with an AE COPD may not report these symptoms to health care professionals. To circumvent difficulties with quantifying symptoms, event-based definitions have been utilized, particularly in clinical trials. This approach, which defines an AE COPD on the basis of health care utilization and therapy, may capture significantly fewer events. In fact, one group has compared symptom-based definition from daily diary cards to an event-based definition in a large, prospective study of an inhaled steroid/long-acting β-agonist; the correlation between the two definitions was quite weak. Accordingly, intensive investigation continues, seeking to develop optimal definitions both for clinical use and research studies.

The frequency and severity of exacerbations are quite variable among COPD patients. This variability may reflect the nature of data collection (prospective vs. retrospective), disease severity, medications administered, vaccinations, and smoking status. For example, investigators who identify AE COPDs through review of daily diary cards tend to identify more episodes per year. Studies that include patients with more severely impaired pulmonary function identify a greater number of yearly episodes.

IMPACT

Pulmonary Function

AE COPD episodes have been reported to result in measurable acute deteriorations in pulmonary function. Several groups have identified modest changes in pulmonary function, particularly in lung volumes, during the course of an AE COPD and its resolution. Importantly, persistent negative longitudinal effects of repeated AE COPDs have been reported by several groups; the additional decline in lung function averaged approximately 7 to 8 mL/year in FEV_1. As such, AE COPDs have measurable negative short- and long-term impacts on pulmonary function.

Health Care Utilization

AE COPDs are also major source of health care expenditure. Numerous groups have examined the economic impact of AE COPD on measures of health care utilization. In the United States in 1995, they were estimated to result in a total treatment cost of $1.2 billion in patients $\geq$ 65 years of age and $419 million in those < 65 years of age; these costs were predominantly for hospitalizations. A prospective Spanish study confirmed that patients who failed outpatient therapy, particularly those who required emergency department treatment and hospitalization, accounted for the majority of the total cost of care. Thus, patients with AE COPD, particularly those who require hospitalization, result in major health care expenditures.

Health Status

The negative effects of AE COPD are particularly evident on health-related quality of life (HRQoL). Cross-sectional studies have reported reduced HRQoL during AE COPD, while longitudinal studies have found that HRQoL improves from exacerbation to recovery. The greatest improvement in HRQoL after a single episode occurs during the first 4 weeks, although HRQL continues to improve over 26 weeks. A recurrence of AE COPD results in a markedly attenuated improvement.

ETIOLOGY

Viral Pathogens

Viral infections are increasingly recognized as causative in AE COPD. Rhinovirus infection of the bronchial epithelium induces the expression of numerous proinflammatory genes, including IL-8, Groα, and ENA-78. In fact, induction of NF-κB and other transcription factors has been clearly demonstrated with several viruses, including rhinovirus, respiratory syncytial virus (RSV), and influenza infection. In addition, rhinovirus and RSV infection of bronchial epithelial cell lines can be associated with the production of eotaxin, eotaxin-2, and CCL5. Experimental evidence has confirmed that rhinovirus infection can infect the lower airways. It is evident that viral infection could account for the inflammatory response previously described as typical of AE COPD.

Table 120-1

Viral Pathogens Implicated in Exacerbations of COPD

Rhinovirus

Clinical data implicating multiple viral pathogens in AE COPD are increasing (Table 120-1). Early studies, which relied on serologic studies or viral cultures of the upper airway, reported a relatively minor role for viral infection. More recent studies have utilized more sensitive techniques for virus identification, including polymerase chain reaction (PCR). Results have suggested that a much higher proportion of cases of AE COPD are related to viral infections (up to 60 percent in some series). As noted in Table 120-1, picornaviruses, respiratory syncytial virus (RSV), influenza and human metapneumoviruses have been identified most frequently. A prospective study of hospitalized patients with AE COPD found a viral pathogen in more than 48 percent of episodes (vs. 6.25 percent in the stable state), with a similar distribution of viral pathogens as previously noted; a clear relationship between viral infection and the inflammatory process was documented by this group (Fig. 120-1).

Bacterial Pathogens

The role of bacterial infection in individual AE COPD episodes remains controversial, in part due to the evolving diagnostic methods used to establish their etiologic role. These methods have included sputum culture, bronchoscopic sampling, molecular epidemiologic studies of bacterial pathogens, identification of an immune response, and recording a response to antimicrobial therapy.

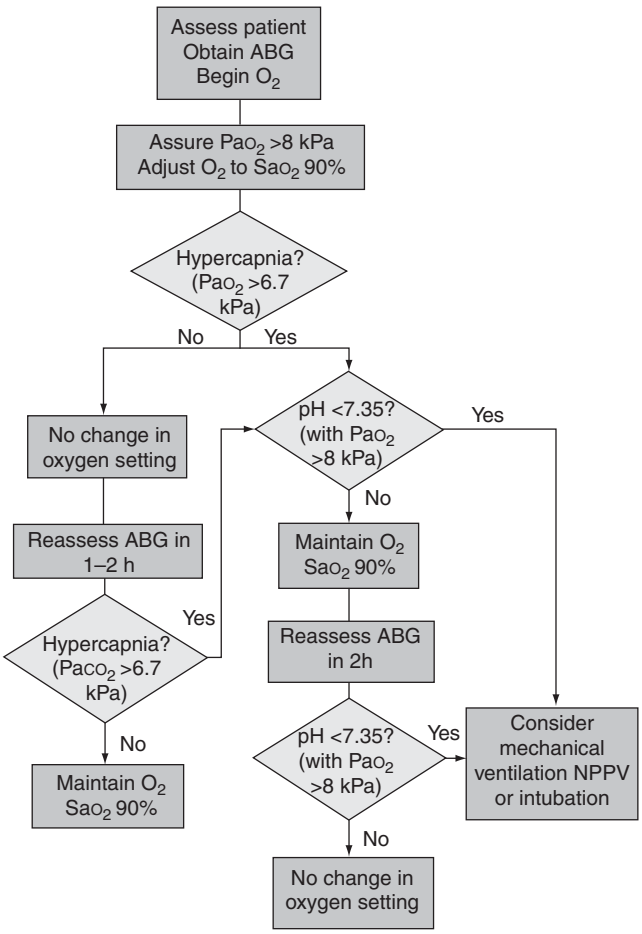

Figure 120-1 Proposed algorithm for the correction of hypoxemia in the acutely ill patient with AE COPD. ABG, arterial blood gas; NPPV, noninvasive positive pressure ventilation; O_2, oxygen; Pa_{O_2}, arterial oxygen tension; Pa_{CO_2}, arterial carbon dioxide tension; Sa_{O_2}, arterial oxygen saturation. *(From Celli BR, MacNee W, committee members: ATS/ERS Task Force. Standards for the diagnosis and treatment of patients with COPD: A summary of the ATS/ERS position paper.* Eur Respir J *23:932–946, 2004.)*

Sputum cultures have been the classic approach to identifying potentially pathogenic microorganisms (PPM) in AE COPD. Comprehensive reviews of comparative antimicrobial trials identified wide variable frequencies of PPM. The organisms most frequently isolated are non-typeable *Haemophilus influenzae* (NTHI), *Moraxella catarrhalis*, and *Streptococcus pneumoniae*. In general, greater airflow obstruction and prior use of antimicrobial agents identify COPD patients at higher risk for infection with *Pseudomonas* spp. or other enteric gram-negative rods.

Whether PPM are etiologic in AE COPD has been questioned, as early longitudinal studies showing that the frequency of bacterial isolation from sputum in a patient with AE COPD was no different from that of the stable state. Recent insights suggest that patients who have bacterial pathogens in the sputum during the stable phase have more frequent AE COPD and greater decline in lung function. These findings imply that the results of earlier studies were heavily influenced by case selection. Moreover, sputum cultures have important limitations, e.g., seriously underestimating colonization with NTHI in comparison to PCR-based detection. Although bronchoscopically collected samples have confirmed that PPM are found in many patients with COPD at a stable state, the burden of organisms increased during AE COPDs.

Recent longitudinal cohort studies that analyzed surface antigen diversity show that acquisition of a bacterial strain with which the patient had not been previously colonized more than doubled the risk of a clinical exacerbation. Interestingly, the identification of a new NTHI strain was not associated with a symptomatic exacerbation in the majority of patients. This finding is consistent with evidence that *H. influenzae* and *M. catarrhalis* strains associated with symptomatic exacerbations appear to differ inherently from strains not associated with such a clinical response, in that they are more likely to lead to neutrophil recruitment and IL-8 release. Further support for the importance of bacterial infection in the etiology of AE COPD comes from recent studies that confirmed a systemic immune response to homologous strains of *H. influenzae* and *M. catarrhalis* isolated simultaneously from sputum of patients during evaluation at time of stability and with symptomatic exacerbations. Demonstrating a systemic immune response has confirmed an interaction between bacterial and viral infections. It has been reported that almost half of exacerbations associated with a new NTHI strain are associated with evidence of acute viral infection. Overall, evidence of a viral infection was identified in 79 percent of patients with AE COPD. Taken together, these data strongly support a pathogenic role for bacterial pathogens in a large proportion of patients with AE COPD.

Which patients are more likely to experience AE COPD as a result of bacterial infection has been addressed by numerous investigators. Sputum purulence has been examined most critically in the clinical setting; patients with purulent sputum have been reported to be more likely to have polymorphonuclear cells and organisms in sputum. A multicenter study reported that increasing sputum purulence, as defined by a semiquantitative colorimetric scale, was associated with bacterial growth. Furthermore, deepening sputum color (yellowish to brownish) was associated with increased yield of gram-negatives and *P. aeruginosa/Enterobacteriaceae*. Importantly, the definition of color by patients and investigators was concordant in only 68 percent of cases without the aid of an objective color stick. A prospective study of 40 patients hospitalized for AE COPD provided sputum samples and underwent bronchoscopy with protected brush sampling (PSB). The concordance between sputum and PSB culture was high ($k = 0.85$, $p < 0.002$), while the presence of patient-reported sputum purulence was highly associated with positive PSB cultures (Fig. 120-2). The totality of these data suggests that new purulent sputum may identify a patient more likely to experience AE COPD related to bacterial infection.

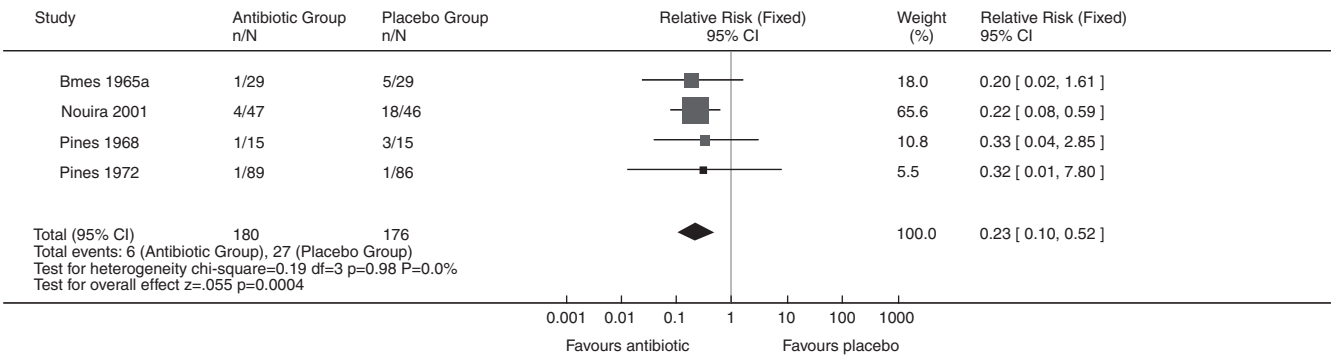

Figure 120-2 Comparison of effect of antibiotics versus placebo on short-term mortality during study intervention. *(From Ram FSF, Rodriguez-Roisin R, Granados-Navarrete A, et al: Antibiotics for exacerbations of chronic obstructive pulmonary disease (Review).* Cochrane Database Syst Rev *2006; Issue 3.)*

Environmental Exposures

Epidemiological studies and the inflammatory response provoked in patients with COPD by exposure to pollutants strongly support a role for environmental exposures in triggering AE COPD. Both particulate matter and nonparticulate gases have been implicated. For example, sulfur dioxide, ozone, black smoke, and nitrogen dioxide have been associated with an increased risk of admission to the hospital for COPD.

EVALUATION

Clinical

As noted, AE COPD is generally defined by a change in symptoms out of proportion to the usual daily variation, which may be considerable in a given patient. Given the central role of respiratory infection in AE COPD pathogenesis, in the absence of sputum purulence the diagnosis of AE COPD should be suspected and alternative diagnoses evaluated. Congestive heart failure, pneumothorax and pulmonary emboli are particularly important possibilities to exclude. In fact, pulmonary emboli have been identified in 25 percent of patients with COPD admitted with a severe exacerbation and no obvious evidence of infection. Previous thromboembolic disease and malignancy have been associated with pulmonary emboli in COPD patients. Similarly, the clinical history should be examined for risk factors for congestive heart failure.

Laboratory

Given this differential diagnosis, focused laboratory testing is of value in the assessment of a patient with a suspected AE COPD. Recent data have suggested a valuable role for the measurement of natriuretic peptides in differentiating congestive heart failure from non-cardiac disorders in patients with acute breathlessness, including patients with AE COPD. Numerous investigators have confirmed that this neurohormone is elevated in patients with left ventricular dysfunction and correlates with severity as well as prognosis in CHF.

Observational studies suggest that a chest radiograph (CXR) identifies abnormalities leading to changes in management in suspected AE COPD in 16 to 21 percent of cases. As such, an evidence-based review has suggested that CXR should be considered in AE COPD managed in the emergency room or hospital. Assessment of oxygenation, including arterial blood gas sampling in selected patients, adds valuable information in stratifying disease severity. Developing and validating cost-effective diagnostic algorithms is an important unmet research goal in AE COPD.

Table 120-2

Potential Therapeutic Options for an AE COPD Managed in the outpatient Setting

Patient education
Check inhalation technique and reinforce correct use
Consider use of spacer device
Bronchodilators
Short-acting β_2-agonists and/or ipratropium MDI with spacer or via handheld nebulizer as appropriate
Consider adding long acting bronchodilator
Corticosteroids
Prednisone 20–40 mg orally/day for 10–14 days
Consider use of an inhaled corticosteroid
Antibiotics
Can be considered in patients with altered sputum characteristics
Choice of agent should be based on local bacterial resistance pattern and host characteristics

SOURCE: *Adpted from Celli BR, MacNee W, and committee members: ATS/ERS Task Force. Standards for the diagnosis and treatment of patients with COPD: A summary of the ATS/ERS position paper.* Eur Respir J *23:932–946, 2004.*

Physiologic

Physiologic changes have been demonstrated during an AE COPD. A modest improvement in pulmonary function, particularly in lung volumes, has been reported over the first two weeks after therapy for an AE COPD started. On the other hand, several observational studies have concluded that spirometric assessment at the time of presentation is of limited value in the care of patients with AE COPD.

TREATMENT

Optimal therapy for AE COPD is multifactorial and depends, in part, on the site of therapy. Tables 120-2 and 120-3 enumerate suggested therapeutic options in patients with AE COPD treated as outpatients or in the hospital. The bases for these recommendations are discussed in individual sections.

Bronchodilators

Both inhaled β-agonists and anticholinergic agents have been documented to decrease airflow obstruction during AE COPD. Systematic reviews suggest that short-acting β-agonists and anticholinergic-inhaled bronchodilators have comparable effects on spirometry exceeding that of parenterally administered bronchodilators. Although the combination of an anticholinergic agent with a β-agonist has the potential for increased therapeutic benefit, studies combining agents from these classes have shown varied results, which, on average, do not seem to support the routine use of multiple agents for AE COPD. On the other hand, it is reasonable to add a second agent if a patient is experiencing suboptimal benefit on a single agent. The evidence for and against the utility of adding a methylxanthine to inhaled bronchodilators is also conflicting, although the high incidence of adverse reactions makes it difficult to recommend their routine use for AE COPD.

Steroids

The role for systemic corticosteroids in AE COPD is becoming better defined. A systematic review suggested that systemic steroid use results in physiologic improvement over the first 72 hours and reduced the odds of a treatment failure over the subsequent 30 days (OR 0.48, 95 percent CI 0.34 to 0.68), but with an increased risk of adverse drug reaction (OR 2.29, 95 percent CI 1.55 to 3.38). The largest study in hospitalized patients confirmed that parenteral steroid use

Table 120-3

Potential Therapeutic Options for an AE COPD Managed in the Inpatient Setting

Bronchodilators Short-acting β_2-agonists and/or ipratropium MDI with spacer or via handheld nebulizer as appropriate Consider adding long-acting bronchodilator
Supplemental oxygen
Corticosteroids Prednisone 20–40 mg orally/day for 10–14 days if tolerated If patient cannot tolerate oral steroids equivalent dose intravenously for 10–14 days Consider using inhaled corticosteroid
Antibiotics Can be considered in patients with altered sputum characteristics Choice of agent should be based on local bacterial resistance pattern and host characteristics

(methylprednisolone 125 mg/day for 3 days followed by either a 15-day or 8-week taper) was associated with a faster improvement in FEV_1, a lower number of treatment failures, and a shorter length of hospital stay, although with greater side effects (particularly hyperglycemia). Subsequently, others confirmed these findings while using lower doses for shorter periods, including patients being discharged from the emergency department. Non-controlled studies have suggested that prednisone therapy hastened AECB recovery (by 2.63 days) while prolonging time to the next event. Thus, the modest but proven efficacy of systemic steroids in severe AE COPD implies that modulating the host immune response may benefit some patients. It remains unclear how one can best identify which patient is most likely to benefit from parenteral steroids.

Antimicrobial Agents

Given compelling data that bacterial infection is likely causative in approximately 50 percent of patients with AE COPD, it is not surprising that antimicrobial therapy has been intensively studied in this disease. Numerous placebo-controlled trials of antibiotics in AE COPDs have been published over the past several decades. Systematic reviews of these trials have suggested a treatment effect, including a potential survival benefit (Fig. 120-3). There has been significant heterogeneity in the results of the individual studies, with none designed in an optimal fashion. The majority of recent international guidelines interpreted these data to suggest that antimicrobial agents provide additional benefit in selected patients. Most recommend the use of antimicrobials in patients with an AECOPD who are more likely to have bacterial infection (Table 120-4), i.e., those experiencing a change in sputum characteristics or multiple symptoms as defined by Anthonisen et al. Serum procalcitonin has been shown by one group to define patients with AECOPD who have a higher likelihood of bacterial infection; additional, prospective investigation is required to better define this evolving technique.

The choice of antimicrobial agent remains contentious, although increasingly guidelines have taken the approach of stratifying patients according to the risk of treatment failure. One such schema is illustrated in Table 120-5. These stratification schemes have generally suggested features for a

Table 120-4

International Guideline Recommendations for the Use of Antimicrobial Therapy in an AE COPD

Guideline, Year	Recommendation
Canadian Thoracic Society, 2003	"The Panel proposes that antibiotics should only be considered for use in patients with *purulent exacerbations*."
Gold, 2004	"Antibiotics are only effective when patients with worsening dyspnea and cough also have *increased* sputum volume and *purulence*."
American Thoracic Society/ European Respiratory Society, 2004	"[Antibiotics] May be initiated in patients with *altered sputum characteristics*."
National Institute for Clinical Excellence, 2004	"Antibiotics should be used to treat exacerbations of COPD associated with a history of *more purulent sputum*."
European Respiratory Society, 2005	"[Hospitalized patients with COPD exacerbations should receive antibiotics if] I. Patients with all three of the followings symptoms: *increased* dyspnea, sputum volume and *sputum purulence* (a type I Anthonisen exacerbation). II. Patients with only two of the above three symptoms (a type II Anthonisen exacerbation) when *increased purulence of sputum* is one of the two cardinal symptoms. III. Patients with a severe exacerbation that requires invasive or noninvasive mechanical ventilation. IV. Antibiotics are generally not recommended in Anthonisen type II without purulence and type III patients (one or less of the above symptoms).

Table 120-5

Potential Antimicrobial Options for an AE COPD Based on Host and Pathogen Factors

Category	Likely Pathogens	Antimicrobial Treatment
Uncomplicated AECOPD Age < 65 years FEV_1 > 50% predicted < 4 exacerbations/year No comorbid conditions	*H. influenzae* *S. pneumoniae* *M. catarrhalis* *H. parainfluenzae* Viral *M. pneumoniae* *C. pneumoniae*	Macrolide* Ketolides† Doxycycline 2nd or 3rd generation cephalosporin Respiratory quinolone†
Complicated AECOPD Age > 65 years FEV_1 < 50% predicted ≥ 4 exacerbations/year Comorbid conditions	*H. influenzae* *S. pneumoniae* *M. catarrhalis* *H. parainfluenzae* Viral *M. pneumoniae* *C. pneumoniae* Gram-negative enteric bacilli	Respiratory quinolone† Amoxicillin/clavulanate
Complicated AECOPD at risk for *Pseudomonas aeruginosa* infection FEV_1 < 35% predicted Recurrent courses of antibiotics or steroids Bronchiectasis	*H. influenzae* *S. pneumoniae* *M. catarrhalis* *H. parainfluenzae* Viral *M. pneumoniae* *C. pneumoniae* Gram-negative enteric bacilli *Pseudomonas aeruginosa*	Fluoroquinolone with antipseudomonal activity‡

* *In active smokers* H. influenzae *infection is more prevalent—azithromycin and clarithromycin demonstrate improved in vitro activity.*
† *Levofloxacin, moxifloxacin, gatifloxacin, gemifloxacin, and telithromycin have activity against penicillin-resistant* S. pneumoniae.
‡ *Ciprofloxacin and levofloxacin have enhanced antipseudomonal activity.*
SOURCE: *Martinez FJ, Han MLK, Flaherty K, et al: Role of infection and antimicrobial therapy in acute exacerbations of chronic obstructive pulmonary disease.* Expert Rev Anti Infect Ther *4:101–124, 2006.*

high likelihood of infection with organisms that are not covered with standard antibiotic regimens (e.g., *P. aeruginosa*, drug-resistant bacteria) or host factors that predict treatment failure. The latter include worse lung function, increased frequency of exacerbation/office visits, ischemic heart disease and other comorbid conditions. The clinical implication of increasing antimicrobial resistance among common respiratory pathogens in patients with AECOPD remains unclear. COPD patients are at higher risk for infection with resistant organisms. In data collected prospectively, patients with complicated AE COPD appear to experience an inferior clinical response rate compared with those with uncomplicated AE COPD. The impact of utilizing different antimicrobial regimens based on different patient strata remains unproved. Hence, tailoring the initial antimicrobial regimen selection in individuals at increased risk for treatment failure (Table 120-5) is an attractive concept that requires prospective validation.

Mucolytics

An analysis of five randomized controlled trials concluded that pharmacological mucus clearance strategies did not shorten the course of treatment, but they may improve

symptoms. The agents evaluated in these trials included domiodol, bromhexine, ambroxol, S-carboxymethylcysteine, and potassium chloride.

Oxygen Therapy

Oxygen therapy has been described as a cornerstone of hospital treatment for COPD exacerbations. The benefits include decreasing pulmonary vasoconstriction, decreasing the right heart strain and possible ischemia, improving cardiac output, and subsequent oxygen delivery to the central nervous system and other vital organs. The concern regarding oxygen use is the relationship to hypercarbia and subsequent respiratory failure. A systematic review found that supplemental oxygen therapy increased Pa_{CO_2} in most patients, but most patients did not require subsequent mechanical ventilation. Patients with combined baseline hypercarbia and more severe hypoxemia had the highest risk of requiring mechanical ventilation following the administration of supplemental oxygen.

Oxygen should be administered for patients with AE COPD with a goal oxygen saturation of 90 to 92 percent (Pa_{O_2} 60 to 65 mmHg) under tightly controlled circumstances. Figure 120-3 illustrates an algorithmic approach to administering oxygen supplementation in a patient suffering from an AE COPD.

Mechanical Ventilation

Noninvasive positive-pressure ventilation (NPPV) has the potential of resting fatigued muscles and thus preventing the need for endotracheal intubation and mechanical ventilation. Decreased need for invasive mechanical ventilation and a potential survival advantage have been seen in several studies. Expert opinion supports administration of NPPV in an ICU or other similar closely monitored setting for optimal results. Criteria suggested to identify patients likely to benefit are enumerated in Table 120-6. A clinical practice guideline to the application and titration of this modality in AE COPD patient has been published. Patients who are intolerant of or do not benefit from NPPV should be considered for invasive mechanical ventilation (Table 120-7).

Table 120-6

Indications and Contraindications to the Use of Nasal Positive Pressure Ventilation in a Severe AE COPD

Criteria for consideration
Moderate to severe dyspnea with use of accessory muscles and paradoxical abdominal motion
Respiratory acidosis (pH $\leq$ 7.35) and hypercapni (Pa_{CO_2} > 45 mmHg)
Respiratory frequency > 25 breath/minute
Contraindications (relative/absolute)
Cardiac or respiratory arrest
Cardiovascular instability
Failure of nonrespiratory organs
Severe encephalopathy
Severe hemorrhage of upper digestive system
Uncooperative patient
Recent facial or gastrointestinal surgery
Craniofacial trauma, fixed nasopharyngeal abnormalities
Obstruction of the upper airway
High aspiration risk
Inability to cooperate or protect the airway
Extreme obesity
Burns

Table 120-7

Indications and Contraindications to the Use of Invasive Mechanical Ventilation in a severe AE COPD

Absolute indications
Cardiac or respirtory arrest
Failure of noninvasive ventilation or contraindication to such
Persistent, life threatening hypoxemia (Pao_2 < 40 mmHg or Pao_2/FIo_2 < 200)
Worsening or severe respiratory acidosis (pH < 7.25 and hypercapnia—PaCO2 > 60 mm Hg)
Contraindications (relative/absolute)
Severe dyspnea with use of accessory muscles
Respiratory rate > 35 breaths/min
Somnolence, impaired mental status
Cardiovascular complications
Other complications (severe pneumonia, metabolic abnormalities, sepsis, pulmonary embolism, barotraumas, pleural effusion)

SOURCE: *Adapted from Global Intiative for Chronic Obstructive Lung Disease: Executive Summary: Global strategy for the diagnosis, management, and prevention of COPD.* http://www.goldcopd.org. *Accessed: July 24, 2006; Carrera M, Sala E, Cosio BG, et al: Hospital treatment of chronic obstructive pulmonary disease exacerbation: an evidence-based review.* Arch Bronchoneumol *41:220–229, 2005.*

Table 120-8

Indications for Hospitalization in Patients with an AE COPD

Presence of high-risk comorbid conditions
Indequate response of symptoms to outpatient or emergency department management
Marked increase in dyspnea
Inability to eat or sleep due to symptoms
Worsening hypoxemia
Worsening hypercapnia
Change in mental status
Inability of patient to care for herself or himself
Uncertain diagnosis
Inadequate home care

Pneumonia in Childhood

Mark S. Pasternack

Pneumonia and influenza are the seventh leading cause of childhood death in the United States. Although in this country the impact on overall childhood mortality is limited (0.4/100,000 children annually), the worldwide mortality due to acute respiratory tract infections in childhood may exceed 2 million deaths annually. In addition, the morbidity of lower-respiratory tract infections (LRTIs) is substantial. For example, the hospitalization rate for influenza among U.S. children under the age of 5 is comparable to that of adults over the age of 50.

LRTIs in children may be organized as a collection of distinct clinical syndromes based on the age of the child and the clinical setting. Pneumonia is a rather common problem for the practicing pediatrician, yet its management is frequently problematic because of a paucity of objective data. Historical information is often scant, especially when managing younger patients. The clinical and especially the radiologic features of pneumonia frequently are not closely correlated with particular etiologic agents, and it is often difficult or impossible to obtain sputum for microscopic analysis and culture. Rapid diagnostic methods detect only a fraction of the common viral causes of LRTI, and similarly blood cultures identify bacterial pneumonia in a small subset of children, and then only after significant delay. Occasionally, pneumonia in early childhood and syndromes of recurrent pneumonia may reflect a congenital or acquired anomaly or a genetic disorder associated with impaired host defense. Thus, the management of pneumonia in children often presents a greater challenge to the clinician than do similar illnesses in adults.

NEONATAL PNEUMONIA

Bacterial pneumonia in neonates generally follows acquisition of a pathogen during passage through the birth canal, and is a common focus of early onset neonatal sepsis. The incidence of neonatal bacterial infection is roughly 0.1 percent of all births, but is much greater in "high-risk" infants—infants delivered before the 36th week of gestation, after prolonged rupture of maternal membranes, maternal intrapartum fever, etc. At present group B streptococcus (*Streptococcus*

agalactiae, GBS), especially serogroup III, is the most common cause of neonatal sepsis, resulting in up to 60 percent of episodes; enteric gram-negative bacilli (predominantly *Escherichia coli*) are responsible for roughly 25 percent of episodes, greatly exceeding *Listeria monocytogenes*. The widespread adoption of universal third trimester maternal screening for GBS carriage and administration of intrapartum antibiotic therapy to GBS-positive mothers as well as to high-risk mothers at delivery has been successful in reducing significantly the incidence of all forms of invasive GBS disease over the past decade.

Early-onset GBS infection is commonly acquired intrapartum, with clinical evidence of sepsis appearing within the first few hours of life. In contrast, meconium aspiration is more common among term infants and is generally apparent in the delivery room. Respiratory distress, with grunting, flaring, and intercostal retractions, is the most commonly encountered sign of neonatal pneumonia. Thus, infants with GBS pneumonia cannot be readily distinguished clinically from those newborns with respiratory distress syndrome. The presence of fever or hypothermia, irritability, or hypotonia all point toward neonatal sepsis. The white blood cell count is frequently abnormal with either marked leukocytosis and an associated left shift with bands and earlier myeloid forms, or with leukopenia, but is not a reliable indicator of neonatal infection. Approximately half of the chest radiographs of infants with GBS pneumonia demonstrate symmetric ground-glass airspace infiltrates that are indistinguishable from the radiographic findings of hyaline membrane disease (Fig. 121-1). The remaining infants have asymmetric lobar or multilobar consolidations which are typical of bacterial pneumonia. The presence of a unilateral pleural effusion in a neonate with pulmonary infiltrates strongly suggests GBS pneumonia. Since the clinical features of GBS pneumonia overlap with those of respiratory distress syndrome, all infants with respiratory distress should undergo a "septic work-up" including blood, urine, and cerebrospinal fluid examination, followed by the empiric administration of ampicillin and gentamicin for 48 to 72 hours pending the results of the initial cultures. Infants requiring intubation and mechanical ventilation because of hypoxemia should also have endotracheally suctioned specimens sent for Gram's stain and culture. These infants must be monitored for the development of enlarging pleural effusions, which may require drainage to improve ventilatory function, and for the development of metastatic skeletal infections or meningitis. The duration of therapy is determined in part by the presence of bacteremia and metastatic infection, since meningitis will require 3 weeks of therapy, and skeletal infection will require even longer treatment.

Low-birth-weight infants with protracted stays in a neonatal intensive care unit (NICU) are at risk for the late development of nosocomial pneumonia, particularly those infants requiring prolonged intubation in the setting of severe prematurity and respiratory distress, or those with anatomic (e.g., tracheoesophageal fistula, duodenal atresia) or neurological defects resulting in aspiration. In such infants the spectrum of potential pathogens causing pneumonia is broad. In addition to the conventional neonatal pathogens, nosocomial flora may contain multiply resistant organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA), *Enterobacteriaceae (Klebsiella, Enterobacter, Serratia*), including extended spectrum β-lactamase producing organisms, or nonenteric gram-negative bacilli, such as *Pseudomonas aeruginosa* or *Acinetobacter*. Hence, potent broad-spectrum empiric antibiotic therapy such as vancomycin and gentamicin or amikacin, often with a broad-spectrum β-lactam agent such as cefepime or meropenem, should be given until a specific pathogen can be identified; antibiotic therapy can be modified at that time. The particular nosocomial

Figure 121-1 Early onset group B streptococcal pneumonia. There are hazy symmetric "ground-glass" infiltrates bilaterally obscuring the cardiac silhouette. Note the presence of a small right pleural effusion.

pathogens which pose the greatest risks to infants with nosocomial pneumonia reflect colonization patterns which may vary among different hospitals, and so the empiric antibiotic therapy used in this situation is frequently nursery-specific. Epidemics of nosocomial pneumonia often reflect breaches in standard precautions by physicians, nurses, or other direct care providers, and active surveillance for colonization of highly resistant pathogens as well as infections within NICUs, infant cohorting, and active hand disinfection programs are critical for controlling these outbreaks.

Congenital viral infections such as cytomegalovirus and rubella may occasionally be responsible for pneumonitis early in the neonatal period. Congenitally infected infants who have symptomatic tachypnea and/or hypoxemia in addition to the stigmata of congenital viral infection usually have extensive viral disease, with hepatosplenomegaly, microcephaly, and/or jaundice. Despite the radiologic findings of diffuse interstitial infiltrates, the clinical picture of systemic viral disease usually predominates, and frank respiratory failure is infrequent. In contrast, neonatal herpes simplex virus (HSV) infections are the consequence of intrapartum acquisition of virus through the birth canal of a (generally primarily) infected mother rather than a true congenital infection. Early onset herpetic infection can occur despite the absence of typical perinatal risk factors for bacterial sepsis. HSV pneumonitis in this setting is usually seen in early onset disseminated disease where the systemic features of fulminant herpetic infection with hepatitis, encephalitis, and myocarditis predominate. The prognosis in this setting is poor despite the availability of the nucleoside antiviral acyclovir. Rarely, hemorrhagic pneumonitis may be the sole manifestation of late-onset perinatal HSV infection. Similarly, early postnatal viral infections such as adenovirus may also result in fulminant respiratory failure in previously healthy full-term infants.

PNEUMONIA IN EARLY INFANCY

The bacterial pathogens responsible for neonatal pneumonia are rarely encountered after the first month of life, since most episodes of bacterial pneumonia accompany the early onset form of neonatal bacterial sepsis. By the second month of life, infants have an increasing risk of developing viral infection as well as chlamydial pneumonia (Fig. 121-2). Despite the broad range of potential pathogens, the lungs of young infants have a limited repertoire in response to illness. The combination of diminutive airways, compromised further by inflammatory mucosal edema and/or intraluminal secretions, results in characteristic airway obstruction. Infants may wheeze, and chest radiographs demonstrate hyperinflation and interstitial infiltrates, with or without atelectasis. Patchy asymmetric airspace disease may be present as well. Thus, the nonspecific chest radiographic findings are not helpful in narrowing the differential diagnosis, and clinical and epidemiological features guide management and therapy.

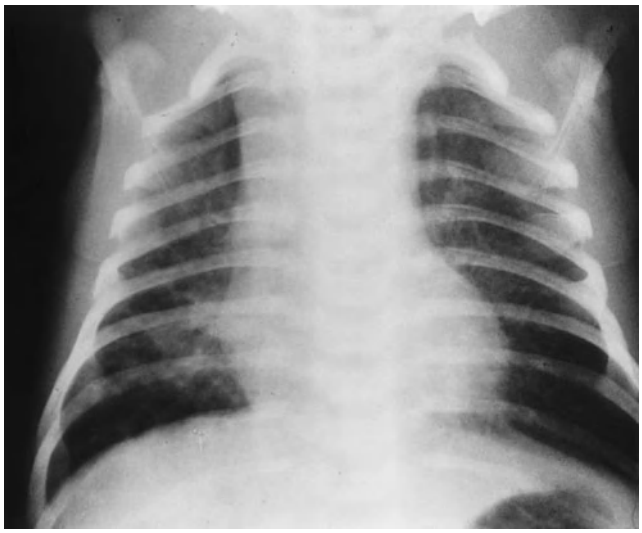

Figure 121-2 *Chlamydia trachomatis* pneumonitis. This 12-day-old infant had stereotypic findings of hyperinflation and asymmetric interstitial infiltrates.

Chlamydia trachomatis Pneumonia

Worldwide, *C. trachomatis* is the most common sexually transmitted pathogen. Vertically transmitted chlamydial pneumonia accounts for up to one-third of pneumonias in infants during the first 4 months of life. Infants generally acquire*C. trachomatis* during their passage through the birth canal from chronically (and usually asymptomatically) infected mothers, although horizontal infection in a nursery or at home due to inadequate handwashing is possible. The incidence of chlamydial infection is inversely proportional to the mother's age and directly proportional to the number of her sexual partners. *C. trachomatis* LRTI can develop despite ophthalmia prophylaxis with silver nitrate solution or tetracycline or erythromycin ointments. When infected secretions are aspirated intrapartum, symptomatic LRTI may develop during the first month of life. More commonly, the conjunctivae and/or upper-respiratory tract mucosa are infected initially, with subsequent spread of infection following aspiration of infected upper-respiratory secretions. The illness progresses insidiously, with the gradual development of cough and congestion over several days, with low-grade or no fever. Respiratory distress is generally only mild to moderate unless there is concomitant infection with a second pathogen (such as respiratory syncytial virus) or there is an underlying pulmonary process such as bronchopulmonary dysplasia. Chest auscultation generally reveals scattered rales, and the chest radiograph shows the nonspecific patchy pneumonitis and hyperinflation pattern described above. Infants often have mild leukocytosis, sometimes with modest eosinophilia. Hyperglobulinemia is common but nondiagnostic. Only half of infants with chlamydial pneumonitis have associated conjunctivitis. The laboratory diagnosis of chlamydial pneumonia may be confirmed by antigen detection in nasopharyngeal swab samples using monoclonal antibody or nucleic acid

detection methods, including polymerase chain reaction (PCR) technology. Systemic therapy with erythromycin (50 mg/kg/d divided q 6 h for 14 d) or azithromycin (20 mg/kg/d for 3 d) hastens resolution of symptoms. Infants with conjunctivitis should also receive topical therapy with erythromycin ophthalmic ointment or tetracycline solution.

Acute Viral Pneumonia

Most episodes of pneumonia in infants over 2 months of age present as acute febrile illnesses and are due to viral pathogens. Viral LRTIs may present primarily with clinical and radiologic features of bronchiolitis or with viral pneumonia and may be due to any of a variety of viral pathogens, requiring laboratory confirmation for definitive diagnosis. In addition to the traditionally recognized causes of viral pneumonia in infants and children (respiratory syncytial virus, parainfluenza viruses, influenza, and adenoviruses), which can be diagnosed by rapid antigen detection methods, molecular diagnostic approaches have identified important, newly recognized agents, such as human metapneumovirus and novel coronaviruses.

Respiratory syncytial virus and human metapneumovirus

Respiratory syncytial virus (RSV) is the most important cause of LRTI in infants, and is responsible for the majority of hospitalizations for bronchiolitis among young children. Interestingly this incidence has risen steadily over the past 25 years. Virtually all infections are symptomatic, although there is a clinical spectrum ranging from pure bronchiolitis, with wheezing, atelectasis, and hyperinflation as the dominant clinical features, to pneumonia, with true airspace disease. Most infants possess features of both processes. RSV circulates widely every winter, although in a given community the peak incidence may shift anywhere from early fall to early spring in a particular year. There are two major RSV serotypes, with considerable genotypic variation within these groups, and in a particular year, a single RSV serotype may predominate. However, the immune response following RSV infection in infants is not significantly protective against symptomatic lower-respiratory tract disease following exposures during subsequent winters regardless of the circulating serotype. The interplay between RSV and the adaptive immune response of infants and children is quite complex, and specific modulation by the RSV envelope G glycoprotein of CD8+ and CD4+ Th1 function may be responsible for the lack of protective immune responses and a propensity for prominent allergic symptoms (Th2 responses). RSV pneumonia is not common until the second month of life, and it is believed that among term infants, transplacentally acquired anti-RSV antibodies may be protective. As the titer of protective antibody wanes, infants are at risk for more severe illness.

RSV infection generally begins with a brief prodromal illness with low-grade fever and nasal congestion and/or rhinorrhea. Within a day or two, infants develop increased fever (101° to 103°F) and progressive respiratory distress, with tachypnea and intercostal retractions. Approximately 1 percent of infected infants develop respiratory distress requiring hospitalization.

Wheezing is prominent, and is believed to reflect mechanical obstruction of the airways due to inflammation, edema, and associated secretions, as well as true immunoglobulin E (IgE)-mediated allergic wheezing. The presence of rales reflects atelectasis and areas of pneumonitis. In very young infants, and in formerly premature infants, the initial presentation of RSV disease may be atypical, with little or no fever or wheezing, and with frequent but less specific episodes of apnea and bradycardia. High-risk infants (i.e., those with severe immunodeficiency states, primary congenital heart disease, particularly those with left to right shunts with pulmonary hypervascularity, pulmonary disease such as bronchopulmonary dysplasia, and low birth weight) are at particular risk for prolonged and life-threatening infection. In general, RSV infection in children infected with human immunodeficiency virus (HIV) is well-tolerated, although prolonged viral replication and shedding may persist, with attendant risks of nosocomial spread. The specific diagnosis of RSV infection can be confirmed in 85 to 90 percent of cases by rapid antigen detection techniques such as enzyme-linked immunosorbent assay (ELISA) or direct immunofluorescence of nasopharyngeal wash specimens. Specimens that are negative by rapid diagnostic methods can be cultured for RSV on Hep2 cells, with diagnostic syncytia appearing after 3 to 6 days. The treatment of RSV infection with the aerosolized nucleoside ribavirin is not often used at present due to concerns regarding efficacy, side effects, and potential teratogenicity risks for health care workers. Hospitalized infants with RSV pneumonia should be isolated (and cohorted if necessary) and placed under contact and respiratory precautions, since the virus can spread by large droplet, fomite, and aerosol. Long-term follow-up has suggested that recurrent wheezing and abnormalities in pulmonary function testing may be common in children after initial episodes of pneumonia and particularly after bronchiolitis, but whether this is a direct effect of RSV or other viral infection or whether subsequent chronic respiratory disease reflects an inherent underlying predisposition to asthma remains controversial. Passive immunoprophylaxis of high-risk infants against RSV infection has been shown to be safe and protective. The use of a high-titered polyclonal human RSV immune globulin (requiring IV administration) for the first two winters of life has been supplanted by palivizumab, a humanized murine monoclonal antibody to the F surface glycoprotein of RSV (administered intramuscularly); a second-generation monoclonal antibody with enhanced affinity and neutralization is under clinical development.

Human metapneumovirus (HMPV), a syncytium-forming negative-strand RNA virus, characterized in 2001, with significant genetic relatedness to RSV, is now established as the second human pathogen within the viral subfamily Pneumovirinae. It has clearly been associated with bronchiolitis and viral pneumonia in young children as well as in the elderly and immunocompromised. Like RSV, HMPV has two major genotypes, and generally causes significant

lower-respiratory tract disease in young children. It is estimated that HMPV is responsible for roughly 10 percent of LRTI infections requiring hospitalization in children, confirming that HMPV infections are an important public health issue. Dual RSV/HMPV infections may result in particularly severe illness, but data are limited. In contrast to RSV, rapid antigen-based diagnostic testing is not widely available for HMPV, and PCR-based methodologies are limited to research settings. Thus, most children with HMPV infection fall into the group of infants with typical bronchiolitis and/or viral pneumonia with negative studies. Potential therapeutic and immunoprophylactic strategies for HMPV are only beginning to be formulated.

Other Common Respiratory Viral Pathogens in Infancy

Parainfluenza viruses

The influenza viruses (of which there may be two type A strains and a type B strain circulating during a particular winter season) and the parainfluenza viruses (PIV, of which there are three major serotypes, 1, 2, and 3, and a less common serotype, PIV4), also are important causes of LRTIs in infants. Although PIV1 is commonly associated with croup (viral laryngotracheitis) among preschool-age children (especially in odd-numbered years), and PIV3 frequently mimics RSV and is more commonly associated with bronchiolitis and viral pneumonitis in the first year of life, all three serotypes may produce any syndrome of upper- and/or lower-respiratory tract infection. Thus, bronchiolitis and/or viral pneumonia in infants, mimicking RSV infection, may be caused by a parainfluenza virus or even influenza. Although parainfluenza viruses are ubiquitous and responsible for limited serious morbidity among most infants, fulminant disease leading to respiratory failure and death can rarely occur even in the absence of underlying immunodeficiency. Distinguishing among these distinct viral etiologies is of some use in the severely ill, since neuraminidase therapy may be considered for influenza. Aerosolized ribavirin has had only anecdotal usage in parainfluenza virus infection, and is probably even less active in these infections than in RSV disease; thus specific antiviral therapy for PIV is limited to the very rare infants with life-threatening infections. Children with primary or acquired immunodeficiency are at increased risk for developing progressive and ultimately fatal infections with these respiratory viral pathogens, and efforts to establish a prompt etiologic diagnosis by rapid diagnostic testing or viral culture is crucial in order to institute prompt antiviral therapy.

Influenza

Like RSV, influenza is a very important cause of lower-respiratory tract disease in infancy. The remarkable morbidity of influenza in children is demonstrated by the hospitalization rates (approximately 250/100,000) of young children with influenza, rates that are comparable to those of adults over the age of 50. Careful statistics of fatal influenza in children have been collected only recently, but in a single year (2003) at least 150 children in the United States died of influenza, and nearly half of these deaths occurred in previously healthy children. Universal immunization of children 6 to 59 months of age, as well as their family members and caregivers, is currently recommended to prevent influenza in children. Prompt diagnosis of influenza is critical if antiviral therapy is under consideration, since the efficacy of antivirals decreases when therapy is instituted after 48 hours of symptoms. When suspicion of influenza is high, the diagnosis may be confirmed by rapid antigen detection testing and the illness treated by the administration of amantadine (8 mg/kg/d divided q 12 h) or, for children over age 1 year, oseltamivir. Antiviral therapies have only moderate activity, shortening the duration of typical influenza illness by about 1 day; it is not clear if they are effective in treating high-risk patients or reducing the incidence of complications and/or severe disease. Unfortunately, there appears to be a significant secular trend toward amantadine resistance among influenza A isolates, so that oseltamivir is becoming the gold standard of anti-influenza therapy. Treatment decisions should incorporate the latest sensitivity data from the World Health Organization (WHO) and/or the Centers for Disease Control (CDC).

Concern has been increasing about H5N1 highly virulent avian influenza strains since the first recent human cases were reported in Hong Kong in 1997. Unlike conventional influenza A, the H5N1 isolates have been notable for remarkable lethality (mortality rate greater than 50 percent among more than 250 reported cases), with particular virulence among infected children. H5N1 disease has a more prolonged incubation period (2 to 8 days), and has been associated with prominent gastrointestinal prodromal symptoms, although multifocal pulmonary infiltrates and respiratory failure follow. Although human-to-human spread of H5N1 virus has been documented as the result of prolonged intimate contact between a mother and her sick child, to date there is little evidence of human adaptation of these strains. H5N1 isolates are resistant to M2 channel inhibitors, and have variable sensitivity to oseltamivir, but neuraminidase inhibitor therapy has been offered as the only therapeutic option.

Additional Respiratory Viral Pathogens

Adenoviruses are another important, but sporadic, cause of severe viral pneumonia in infants. The availability of rapid diagnostic tests is helpful from a diagnostic perspective, particularly since some infected children with prominent conjunctivitis and pharyngitis may be thought to have Kawasaki's disease, but no specific therapies are available. An important new strain of human coronavirus (HCoV NL-63, a type I coronavirus) was recently cloned from infants with bronchiolitis using molecular biologic approaches. Like HMPV, HCoV NL-63 is responsible for up to 10 percent of lower-respiratory tract illnesses (bronchiolitis and viral pneumonia) among hospitalized children whose conventional diagnostic studies are negative. The peak incidence of HCoV infection occurs among children under 2 years of age, similar to RSV

and HMPV. A nonspecific DNA primer amplification strategy has also identified a novel respiratory tract parvovirus, human bocavirus, which has been detected in respiratory specimens from children with acute respiratory tract infections. Bocavirus, like HMPV and HCoV NL-63, may be responsible for a significant fraction of LRTIs in hospitalized children.

Acquired cytomegalovirus pneumonia

Occasionally, infants in the first two months of life have an indolent syndrome of interstitial pneumonitis which mimics chlamydial pneumonia but actually represents cytomegalovirus (CMV) pneumonia. In contrast to infants with congenital CMV, in whom pulmonary disease is associated with severe congenital infection, otherwise healthy infants may develop mild-moderate respiratory distress as the result of peripartum or neonatal acquisition of CMV through breast milk or, in premature infants, through blood transfusion. A single culture for CMV obtained at the time of respiratory symptoms cannot readily distinguish between postnatal primary infection and asymptomatic shedding of congenitally acquired CMV. Otherwise uncomplicated postnatal CMV pneumonia does not serve as an indicator of significant underlying immunodeficiency. Extreme low-birth-weight infants with perinatally or postnatally acquired CMV may have more severe chronic lung disease than uninfected infants, but the role of ganciclovir therapy in this population has not been studied.

Additional Causes of Pneumonia in Infancy

Conventional clinical diagnostic techniques for chlamydial and viral pathogens fail to identify a pathogen in up to half of all cases of pneumonia in infants. As noted above, a significant fraction of these infections may be due to viral agents, such as HMPV and HCoV NL-63, for which routine testing is not available. Additional microbiological and serological analyses have suggested that occasional infants may have neonatal pneumonia due to *Pneumocystis carinii* and *Ureaplasma urealyticum* in addition to the conventional pathogens described above. Pneumonitis associated with these pathogens was not readily distinguished from infections due to *C. trachomatis*. The short-term prognosis of these infections is presumably favorable, since diagnostic techniques to identify such infections are not employed in most centers, and infants with indolent pneumonia generally do well with supportive care.

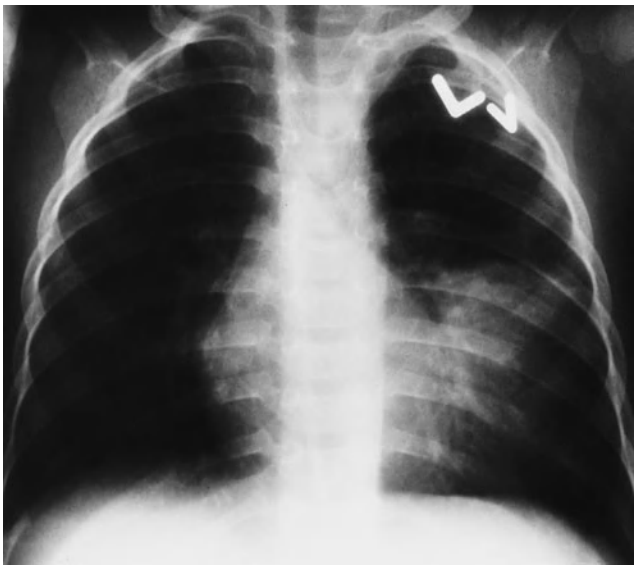
PNEUMONIA AFTER THE FIRST 6 MONTHS OF LIFE

After the first 4 to 6 months of life, *C. trachomatis* pneumonia is no longer observed. Longitudinal studies of LRTIs in infants and children using conventional microbiological and serological techniques to determine the specific etiologies of pneumonia in infancy fail to identify a specific pathogen in roughly half of all episodes. Combined antigen detection testing, newer serological tests, and pneumolysin PCR testing identified approximately 80 percent of responsible agents, and multiplex PCR testing identified viral etiologies, due to the same viral pathogens that are responsible for viral pneumonia in early infancy, in approximately 90 percent of all episodes of pneumonia. Such intensive techniques commonly identify dual viral or mixed viral-bacterial infections. As noted above, recurrent symptomatic RSV disease in the second and third years of life is very common, and often results in clinically significant episodes of bronchiolitis and/or RSV pneumonia. Since the related parainfluenza and influenza agents represent at least six immunologically distinct pathogens that circulate in epidemic fashion each year, it is not surprising that infants remain at risk to develop significant viral pneumonia. The diagnostic and therapeutic challenges of managing community-acquired pneumonia in children were recently summarized by McIntosh.

Bacterial Pneumonia

Although far less common than viral pneumonia, bacterial pneumonia may be difficult to distinguish prospectively on clinical grounds from episodes of viral pneumonia. Both forms of pneumonia are common during the first two years of life after the neonatal period. Since the pathogenesis of bacterial pneumonia generally represents aspiration of pharyngeal pathogens, often in the setting of inflammatory edema and increased secretions triggered by an upper-respiratory tract infection, both processes may have similar initial prodromal findings associated with a low-grade fever. As the lower-respiratory process evolves, infants and toddlers will have similar features of significant fever, tachypnea, and possible respiratory distress with acral cyanosis and intercostal retractions regardless of etiology. A few physical findings are helpful: diffuse wheezing, when present, usually reflects bronchiolitis, making RSV or other viral pathogens (especially HMPV, parainfluenza viruses, and to a lesser extent, influenza viruses) the likely cause of infection. Similarly, markedly asymmetric breath sounds, with unilateral percussive dullness or a unilateral pleural friction rub, strongly suggest bacterial infection with spread of disease to the pleural space. Laboratory findings are also often nonspecifically abnormal, since the presence of moderate leukocytosis (e.g., to 15,000) and band forms may be seen in either type of pneumonitis. Extreme leukocytosis, with abundant early forms, usually suggests a bacterial process, often with bacteremia and/or spread of infection to the pleural space. Blood cultures should routinely be obtained in children with high fever, leukocytosis, or moderate respiratory distress, since such cultures may represent the only ready approach to recovering a bacterial pathogen. Chest radiographs are sensitive but surprisingly nonspecific in attempting to assess the etiology of pneumonia in children. Although focal consolidation is usually caused by bacterial infection, viral pneumonia may present with a dense focal infiltrate (Fig. 121-3). Conversely, bacterial infection may be associated with patchy segmental infiltrates or even interstitial changes, particularly in younger children. Radiologic

A



B

Figure 121-3 Viral pneumonia. *A.* This infant's chest radiograph is notable for hyperinflation and asymmetric interstitial infiltrates, representing a combination of atelectasis and pneumonitis. *B.* The presence of focal consolidation does not reliably distinguish between bacterial and viral infection in young children. This child did not respond to intravenous antibiotic therapy, and adenovirus was recovered in anasopharyngeal specimen.

investigation is helpful in assessing the extent of disease and the presence of intrathoracic complications, but has a more limited role in determining the etiology of pneumonia. Thus, the pediatrician must often initiate antimicrobial therapy for possible bacterial pneumonia based on inconclusive clinical and laboratory findings. In patients sufficiently ill to require hospitalization who have difficulty clearing respiratory secretions, nasotracheal suctioning should be considered both for pulmonary toilet as well as for diagnostic testing (Gram's stain and culture).

Even when these parameters point toward a bacterial process, identification of a specific pathogen remains problematic. Only the most severely ill infants and children have bacteremia accompanying pneumonia. Unless a bacterial pathogen is recovered from the blood or from a site of a secondary infection (pleural fluid, joint fluid, cerebrospinal fluid), the specific etiology cannot be readily determined. It is not generally possible to obtain expectorated sputum, and invasive attempts at culture at the time of nasotracheal suctioning or bronchoscopy may be unrewarding because of the incidental recovery of pharyngeal flora, or because prior antibiotic therapy suppresses the recovery of the true pathogen in the lung. In general, rapid bacterial antigen detection techniques have not been helpful in determining the etiology of pneumonia in children because of limited sensitivity. Recovery of the pathogen from a sterile site facilitates antimicrobial susceptibility testing, but most episodes require empiric therapy.

The microbiology of community-acquired pneumonia in infancy and early childhood reflects pharyngeal carriage of respiratory pathogens, and the spectrum of causative agents resembles that seen with otitis media. The dissemination of antibiotic resistant strains of *Streptococcus pneumoniae* and *S. aureus* in recent years has complicated empiric antibiotic therapy for childhood pneumonia. Although amoxicillin is inexpensive and well-tolerated, one can predict that conventional dose amoxicillin therapy will be efficacious in less than 85 percent of cases. Since failure of initial oral therapy may lead to hospitalization and greatly enhanced morbidity and expense, one should consider high-dose amoxicillin (approximately 100 mg/kg/d) to cover possible penicillin-insensitive *S. pneumoniae* isolates, or with more severe disease, an initial broad-spectrum oral agent, such as a second- or third-generation cephalosporin, to decrease the risk of primary antibiotic failure; macrolide resistance is generally high among pneumococci with reduced β-lactam susceptibility. Among hospitalized infants, the use of ceftriaxone has become increasingly popular since it is effective against β-lactamase–producing strains of *Haemophilus influenzae* and *Moraxella* and all but a small fraction of penicillin-resistant pneumococci. Nevertheless, it has limited efficacy against conventional *S. aureus* pneumonia and no activity against MRSA. The β-lactam/β-lactamase inhibitor combination agents such as ampicillin-sulbactam are also popular although more costly, and are ineffective against fully penicillin-resistant pneumococci as well as MRSA.

Pneumococcal Pneumonia

Pneumococci are the cause of most episodes of bacterial pneumonia in infants and children. The importance of polysaccharide-based serotype-specific opsonizing antibody, and the inability of children to mount anti-polysaccharide antibody responses in the first two years of life presumably explain why these encapsulated pathogens cause pneumonia so frequently. Pneumococci colonize the upper-respiratory tract, and spread contiguously to cause otitis media and sinusitis as well as pneumonia, or invade the bloodstream primarily from the pharynx or secondarily from the initial sites of invasive infection. Children with sickle cell disease or other

hemolytic anemias associated with splenic dysfunction are at particular risk of life-threatening infection. The adoption of a heptavalent polysaccharide-carrier protein conjugated pneumococcal polysaccharide vaccine in 2000 into routine infant immunization practice has had a striking impact in reducing invasive pneumococcal infections due to these prevalent serotypes, but the decline in pneumonia episodes among immunized children was a more modest 17 percent overall (although the decline was 32 percent in infants under 1 year of age).

Haemophilus influenzae Pneumonia

The routine use of conjugate *H. influenzae* type *b* (*Hib*) vaccine, the first polysaccharide-carrier protein conjugate vaccine, led to a marked diminution in pharyngeal carriage of *Hib* and a virtual disappearance of invasive *Hib* disease. Nevertheless, upper-respiratory carriage of nontypeable *H. influenzae* persists, and these strains continue to cause otitis, sinusitis, and pneumonia. The risk of bacteremia and metastatic infection is very low following nontypeable *H. influenzae* pneumonia, in contrast to the significant frequency of metastatic infections associated with *Hib* pneumonia. A significant fraction of these strains produce β-lactamase, requiring therapy with a second- or third-generation cephalosporin or a β-lactam/β-lactamase inhibitor combination. If an infant has proven invasive *Hib* disease, family contacts (as well as the index case) should receive eradicative therapy with rifampin.

Staphylococcal Pneumonia

S. aureus pneumonia is associated with necrotizing infection in infants, just as in older patients. Nasal carriage may lead to the aspiration of staphylococci, particularly in the setting of an acute viral upper-respiratory tract infection. Severe systemic toxicity, respiratory distress, and clinical and/or radiologic evidence of necrotizing pneumonitis are common. Chest radiographs characteristically demonstrate focal airspace disease, often with lobar consolidation, associated with cavitation or the development of smaller subpleural pneumatoceles. Pleural space involvement is also common, and frequently patients with *S. aureus* pneumonia present with dyspnea due to a giant pleural effusion. Depending on the duration of illness before evaluation, the pleural effusion may be small or large, and free-flowing or loculated. Later diagnosis is associated with larger and more viscid or even loculated pleural effusions. Pneumothorax or pyopneumothorax may develop, depending on the extent of subpleural necrotizing infection. These extensive abnormalities are not unique for staphylococcal pneumonia, and are occasionally encountered in the course of other bacterial infections in children, particularly in aspiration pneumonitis and, rarely, in pneumococcal disease. Traditionally, initial empiric antibiotic coverage with a second-generation cephalosporin such as cefuroxime or with ampicillin/sulbactam was reasonable. If staphylococcal disease was confirmed, antibiotic therapy with high doses of a semisynthetic penicillin (nafcillin, 200 mg/kg/d), or a first-generation or second-generation cephalosporin (cefazolin, 100 mg/kg/d or cefuroxime, 150 mg/kg/d, respectively) were administered. In patients who have immediate hypersensitivity to β-lactam agents, parenteral clindamycin (40 mg/kg/d) is far easier to administer than vancomycin (30 to 40 mg/kg/d). However, the current epidemic of methicillin-resistant staphylococcal infections (MRSA) has complicated empiric management considerably. Widespread MRSA disease is primarily due to the sudden appearance and rapid dissemination of MRSA infection among individuals who lack epidemiological risk factors for the acquisition of nosocomially spread MRSA. These community-acquired strains (CA-MRSA) are readily distinguished from nosocomial strains by greater susceptibility to other anti-staphylococcal agents such as macrolides, clindamycin, and trimethoprim-sulfamethoxazole, as well as by the presence of the Panton-Valentine leukocidin (PVL), a potent virulence factor in CA-MRSA strains. In many communities, MRSA is now responsible for a majority of serious skin and soft-tissue *S. aureus* infections, and vancomycin is necessary when treating likely staphylococcal disease, especially necrotizing pneumonia.

The management of pleural space infection varies widely among institutions due to variations in local expertise as well as the paucity of controlled clinical trial data to establish best practices. Thoracentesis has the potential of confirming the microbiologic diagnosis and establishing antimicrobial susceptibilities, reducing respiratory distress by enhancing lung expansion, and preventing the evolution of a thick, loculated empyema which may be the source of continuing respiratory distress and ongoing infection. Thoracentesis under sedation or anesthesia, particularly when guided by ultrasound or computed tomography (CT) scan, is a generally safe procedure even in infants and young children. When the fluid is thin, free-flowing, and not grossly purulent, the initial drainage procedure aimed at evacuating the pleural space is generally sufficient. If the initial fluid is turbid or viscous, thoracostomy drainage (pigtail catheter vs. larger bore surgical thoracostomy tube) should be instituted. The clinical course following closed drainage procedures is usually one of gradual improvement; fever for a week or more is common. Although generally safe, the efficacy of thrombolytic therapy as part of the management of pediatric empyemas remains controversial. Unfortunately, many infants are referred to a tertiary care center after the development of established empyemas, and remain persistently febrile with an increasing erythrocyte sedimentation rate despite placement of an initial chest tube. Sometimes persistent loculated infection may be identified by ultrasound or chest CT scan and evacuated by additional drainage procedures, but often these infants will require video-assisted thoracoscopy (VATS) with evacuation of the loculated pleural space infection and placement of additional thoracostomy tubes or open thoracotomy and decortication. In some centers early utilization of VATS as the primary drainage procedure has reduced the length of in-hospital stay.

Streptococcal Pneumonia

Pneumonia due to group A streptococcal infection is, like staphylococcal disease, commonly associated with the development of pleural effusions. In contrast to staphylococcal pneumonia, where empyema is a relatively late complication of destructive subpleural infection, group A streptococcal pneumonia elicits a prompt and marked increase in lymphatic drainage. When the rate of inflammatory edema generation exceeds the fixed capacity of pulmonary lymphatic vessels to drain this fluid, the excess lymphatic drainage accumulates as a pleural effusion. These collections occur very frequently with group A streptococcal pneumonia, and may be considered a part of the process rather than a complication. The effusions are generally free-flowing and often sterile parapneumonic collections early in the course of infection. These collections may become infected as group A streptococci are carried to the pleural space, and may become exudative in character, resulting in frank empyemas requiring surgical debridement. Once again, early intervention by percutaneous drainage may obviate the need for more extensive surgical procedures late in the course of the infection. In addition to concerns regarding the local complications of group A streptococcal pneumonia, one must be vigilant for the possible systemic sequelae following group A streptococcal infection. The expression of pyrogenic exotoxin A, particularly in M serotypes 1 and 3, has been associated with the development of streptococcal toxic shock syndrome, with scarlatiniform rash, shock, and multiple-organ system dysfunction.

Atypical Bacterial Pathogens

The atypical bacterial pathogens *Mycoplasma pneumoniae, Chlamydia pneumoniae*, and *Legionella pneumophila* are often considered together as "atypical" pathogens because of their inability to grow on routine bacterial culture media, the prominence of nonproductive cough, and their responsiveness to macrolide therapy.

Mycoplasma pneumoniae

The frequency of pneumonia due to the encapsulated bacterial pathogens such as pneumococci and *H. influenzae* decreases with increasing age, as do all invasive infections associated with these pathogens. Traditionally, young children with mycoplasma infection were thought to have mild or nonlocalizing infections, while school-age children developed "atypical pneumonia." The syndrome of *M. pneumonia* in school-age children, which is probably responsible for greater than 50 percent of all episodes of pneumonia in this age group, closely resembles symptomatic infection in adults who manifest an indolent influenzal illness, with fever, pharyngitis, myalgias, headache, and a progressive hacking nonproductive cough, or (in older children) a cough productive of mucoid or mucopurulent sputum. Although symptomatic atypical pneumonias were considered to be rare in young children, based on culture and complement-fixing antibody studies, more recent studies of pneumonia in young children, using reverse transcriptase-polymerase chain reaction (RT-PCR) or more sensitive serological assays, have demonstrated that roughly half of mycoplasmal and chlamydial infections develop in children under age 5, perhaps reflecting spread within day care centers. A variety of extrapulmonary features may be present, such as rash (including urticaria, maculopapular eruptions, erythema multiforme, and Stevens-Johnson syndrome), hemolytic anemia, bullous myringitis or meningoencephalitis, or rarely, hepatitis, perimyocarditis or arthritis. On occasion these features overshadow any mild pulmonary symptoms that a child may have, or occur in the absence of any respiratory tract complaints. Immunocompromised children and children with sickle cell disease may have more complicated illness, and *Mycoplasma* is a well-recognized cause of the acute chest syndrome. Indolent intrafamilial secondary spread of infection occurs regularly, with sequential illnesses occurring among siblings separated by intervals of 1 to 2 weeks. Physical examination is notable for fever and tachypnea, but there is often a paucity of adventitial sounds on chest auscultation. The radiologic features of *M. pneumoniae* may range from patchy asymmetric bibasilar infiltrates with plate-like atelectasis to dense focal airspace disease suggestive of bacterial pneumonia. Pleural effusions and hilar adenopathy may occur but are infrequently seen. Laboratory diagnosis of *M. pneumoniae* infection currently relies generally upon nucleic acid detection technology such as RT-PCR; serological confirmation of mycoplasmal infection requires paired acute and convalescent specimens. The development of cold agglutinins, immunoglobulin M (IgM) antibodies reactive with autologous erythrocytes, occurs in a minority of patients and is not truly specific for mycoplasmal disease. Thus, the diagnosis of *M. pneumoniae* is a presumptive one in children, especially in outpatients, and the most likely cause of pneumonia in school-age children. The differential diagnosis of atypical pneumonia includes adenoviral infection and *C. pneumoniae* infection. Both mycoplasmal and chlamydial infections respond to macrolide therapy, as do many pneumococcal infections; consequently, macrolides are routinely administered for the treatment of pneumonia in school-age children. In children who are intolerant of erythromycin, the newer macrolide agents, clarithromycin or azithromycin, may be given. Alternatively, tetracycline administration may be considered in children over the age of 8 years of age.

Chlamydia pneumoniae pneumonia

A second rather common cause of atypical pneumonia is attributed to the chlamydial species *C. pneumoniae. C. pneumoniae* infections have a broad spectrum of illness and range from asymptomatic seroconversion and mild isolated upper-respiratory tract syndromes (pharyngitis and/or sinusitis) to bronchitis and clinically significant episodes of pneumonia; it is thought to be responsible for over 10 percent of cases of community-acquired pneumonia in children over the age of 5 as well as in adults. Co-infection with *Mycoplasma* or *S. pneumoniae* or common viral pathogens often occur.

Pneumonia due to *C. pneumoniae* in young children, once thought to be rare, is now recognized more readily by sensitive serological or nucleic acid techniques. Pharyngitis is more common with this agent than with *M. pneumoniae*, although in individual patients, distinction between these two illnesses using clinical criteria is difficult and not really necessary, since both agents respond to macrolide or tetracycline therapy.

Legionnaires' disease

Seroepidemiological surveys of pediatric inpatients with pneumonia have documented a widely variable incidence (less than 2 to 52 percent) of *L. pneumofila* among children of all ages, presumably reflecting variation in environmental exposures. Although most children with *Legionella* infection are chronically ill due to a variety of underlying diseases, including hematologic malignancy and/or immunosuppression, no discrete pattern of underlying immunodeficiency has been specifically associated with the development of legionellosis. The clinical features of pediatric legionellosis mimic other bacterial processes, with fever, cough, and tachypnea, and are associated with unilateral or bilateral infiltrates, and cavitation or pleural effusion in a significant fraction of patients. Environmental exposures, particularly to contaminated sources of warm water, remain the dominant risk factor for *Legionella* infection. Nosocomial infections, including nosocomial pneumonia in premature infants in neonatal intensive care units, are an important problem. Although macrolide therapy is beneficial, an extremely high index of suspicion is required to pursue this diagnosis among pediatric patients. Rapid diagnostic options include urinary antigen testing for *L. pneumophila* serogroup 1 and direct fluorescent antibody staining or PCR testing of secretions. Culture of secretions on selective media and serological diagnosis (documenting either a high-titered acute specimen or a conventional rise or fall in paired serum samples) are also available. The presence of legionellosis among adults within a community due to an endemic source or an acute epidemic of legionellosis should alert pediatricians to the risk of *L. pneumofila* among children within the community.

TUBERCULOSIS

The prompt diagnosis and therapy of tuberculosis in children is particularly important since the development of life-threatening complications such as tuberculous meningitis or miliary tuberculosis (Fig. 121-4) can develop soon after the clinical onset of primary tuberculous pneumonia in infants and young children. The development of tuberculosis in a child reflects the presence of a contagious individual within the patient's circle of family, neighbors, or day care or school personnel. The pathogenesis of tuberculosis in young children is the same as for adults (i.e., one or a few *M. tuberculosis* bacilli are inhaled as small droplet aerosols and deposited within an alveolus, typically in a lower lobe). Unlike adults with primary tuberculous infection, in children the local and regional lymphatic barriers to mycobacterial dissemination are often less

Figure 121-4 Miliary tuberculosis. The miliary pattern is quite prominent in this radiograph. Routine chest radiography may be normal in miliary tuberculosis.

effective, presumably because of subtle developmental deficiencies of T-lymphocyte activation and/or macrophage mycobactericidal activity. As a result, mycobacterial proliferation at the site of primary infection may result in local spread of organisms (producing primary tuberculous pneumonia (Fig. 121-5) as well as spread through the regional lymph nodes (with early bacillary dissemination to extrapulmonary foci of infection). Infants and children with primary tuberculous pneumonia are often only mildly ill, with persistent

Figure 121-5 Acute tuberculous pneumonia. This 15-year-old Haitian boy had slowly progressive fatigue, cough, and low-grade fever for 1 month prior to evaluation.

cough in the setting of little or no fever despite (often repeated courses of) conventional oral antibiotic therapy. Chest radiographs demonstrating paratracheal or hilar adenopathy ipsilateral to an area of airspace consolidation strongly suggest possible mycobacterial infection. At times, atelectasis or lobar emphysema may be seen due to extrinsic compression of a bronchus by enlarged lymph nodes, and this may be accompanied by localized wheezing. The presence of pleural effusions or pulmonary cavitation is rare in children with primary tuberculosis. A positive tuberculin reaction usually develops within 4 to 6 weeks of initial infection, so that many children have a positive Mantoux test at the time they are evaluated for persistent respiratory symptoms. The presence of a compatible clinical illness with a positive Mantoux test provides presumptive evidence for *M. tuberculosis* infection. Since young children lack a productive cough, confirmation of the diagnosis can be achieved in roughly half of cases through the culture of gastric aspirates obtained by nasogastric suction each morning on three successive days, or by bronchoscopy (usually reserved for children where the differential diagnosis may be broader or where airway compromise mandates bronchoscopy to exclude the presence of an obstructing foreign body). It is highly desirable to obtain an *M. tuberculosis* isolate for each child in order to confirm the diagnosis and determine antibiotic susceptibility, although this information generally can be extrapolated safely from a newly diagnosed index case.

The therapy of tuberculosis in children utilizes the same principles used to treat adult tuberculosis, but unique challenges arise due to the lack of pediatric formulations and limited outcomes data. Initial combination chemotherapeutic regimens should include isoniazid, rifampin, and pyrazinamide. In communities where there is significant concern regarding drug-resistant tuberculosis, such as among immigrants and in children residing with adults who have failed conventional therapy for tuberculosis (including patients with HIV infection), ethambutol should be included as a fourth initial agent until a child's isolate has been studied for drug resistance. After a 2-month course of intensive (3- or 4-drug) therapy, in the absence of proven drug resistance, pyrazinamide and ethambutol may be stopped to complete a 6-month course of therapy. The incidence of isoniazid hepatotoxicity in children is considerably lower than in adult patients, but monitoring for hepatotoxicity in the setting of multidrug regimens is prudent. Although the ocular toxicities associated with ethambutol use cannot be elicited by history or color vision screening in young children, the incidence of this side effect is very low, particularly when ethambutol dosage is reduced to 15 mg/kg/d following an initial 4- to 6-week period of 25 mg/kg/d.

PNEUMONIA COMPLICATING CHILDHOOD VIRAL EXANTHEMS

Both varicella and measles may be complicated by the development of primary viral pneumonia as well as life-threatening bacterial superinfection. Pneumonia is a common complication requiring hospitalization among children with varicella (mean age 4 to 6 years) and measles (mean age 2 years), and occurs among normal as well as immunocompromised children.

Varicella

Varicella pneumonia generally develops a few days after the onset of the typical bullous eruption, but can occur before the onset of the rash. Symptoms of dyspnea, cough, and tachypnea are associated with an interstitial and fine nodular infiltrate, and may be severe, requiring intubation and mechanical ventilation. The prognosis generally is favorable if the child can be supported adequately during the acute phase of the illness. Symptomatic pneumonitis in this setting should lead to the prompt institution of parenteral acyclovir therapy (30 mg/kg/d divided q 8 h). Bacterial superinfection occurs in a large fraction of children with varicella pneumonia. This complication is associated with the development of typical focal consolidation and can be accompanied by the development of a pleural effusion or frank empyema. The common bacterial pathogens—*S. pneumoniae, S. pyogenes, S. aureus, H. influenzae*—are the usual etiologic agents, and require appropriate antibiotic coverage in addition to primary therapy with acyclovir. Although the risk of varicella pneumonia is extremely high in children receiving chemotherapy for hematologic malignancy, the risk of serious visceral complications is actually rather low in children with HIV infection. Neonates with peripartum exposure to maternal varicella are also at high risk of developing primary varicella pneumonia, and should be given zoster immune globulin at birth and parenteral acyclovir if they develop varicella.

Measles

The epidemiology of measles pneumonia and its complications closely resemble the features of varicella pneumonia, although most cases of measles pneumonia are seen in younger children. In contrast to the low incidence of varicella pneumonia in children, radiologic evidence of pulmonary involvement is more frequently seen in measles (2.7 to 36 percent), although some children have few symptoms, and some children develop a croup syndrome rather than pneumonitis. Primary measles pneumonia is associated with a diffuse interstitial infiltrate, and may also be associated with the development of secondary bacterial pneumonia. Fulminant respiratory failure may develop in association with diffuse interstitial pneumonia, diffuse airspace consolidation consistent with the adult respiratory distress syndrome, bacterial pneumonia, and/or spontaneous pneumothorax prior to intubation and mechanical ventilation. As with varicella pneumonia, typical community-acquired bacterial pathogens are generally responsible for bacterial pneumonia, and may be associated with bacteremia. The acute mortality of measles pneumonia requiring intensive care support approaches 50 percent, and pulmonary fibrosis and/or bronchiolitis obliterans may develop during after the acute phase of illness.

ASPIRATION PNEUMONIA

Aspiration commonly is observed among children with strong clinical risk factors for this complication, so that the diagnosis of aspiration pneumonia is usually rather straightforward. Infants with neonatal asphyxia and other causes of profound neurological impairment frequently have feeding difficulties and may aspirate oral feeds or saliva. In these infants, fundoplication and placement of a feeding gastrostomy tube may reduce the risk of aspiration of gastric contents but not of oral contents. However, aspiration pneumonia may occur in otherwise normal infants (Fig. 121-6). Aspiration during or shortly after feeding is most commonly due to gastroesophageal reflux and is far less commonly due to tracheoesophageal fistulae or vascular ring anomalies. Thus, the occurrence of aspiration pneumonia in infants mandates an appropriate diagnostic evaluation in addition to antibiotic therapy. Similarly, infants with recurrent pneumonia may be aspirating despite the absence of apparent feeding difficulty, and should undergo a structural evaluation in addition to the screening studies for occult immunodeficiency. Aspiration pneumonia is also a common complication of status epilepticus and of posttraumatic neurological injury, and may be seen as a complication of general anesthesia, particularly after emergency procedures. Older children may develop aspiration pneumonia as the result of alcohol or drug use or from primary neuromuscular disorders such as muscular dystrophy or myasthenia gravis, or generalized metabolic disease including the mitochondrial disorders. The radiologic features of aspiration pneumonia usually demonstrate the expected airspace consolidation in the dependent portions of the lung, recognizing that infants and children may be supine at the time of aspiration. Cavitation or pleural disease is infrequently seen at the time of initial evaluation, since the interval between the aspirational event and presentation with pneumonia is usually brief. A radiopaque foreign body is occasionally seen on chest radiograph and mandates prompt bronchoscopy.

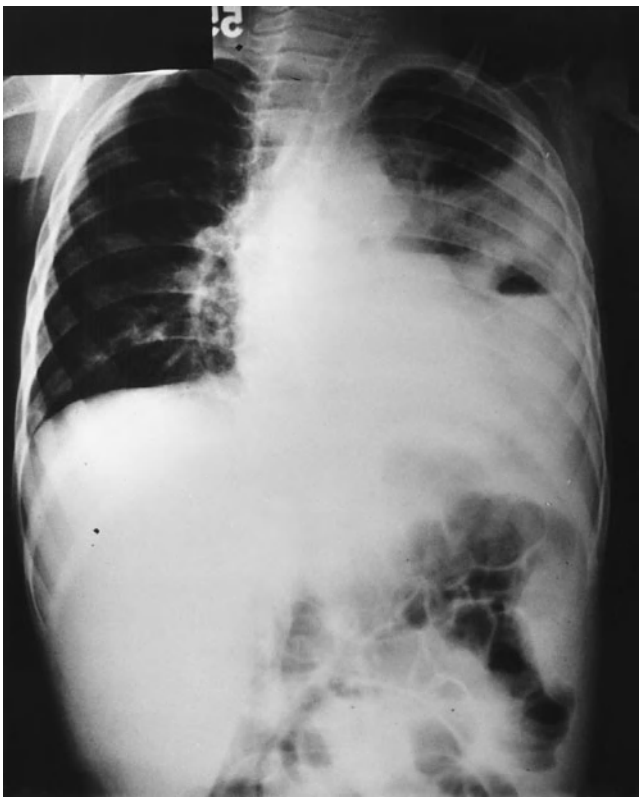


Figure 121-6 Aspiration pneumonia. This toddler presented with a loculated empyema (note multiple air-fluid levels) which grew mixed oropharyngeal flora in association with left lower-lobe pneumonitis.

The therapy of aspiration pneumonia depends on the child's age and overall clinical status. Neonates are usually given ampicillin and gentamicin to treat the conventional neonatal pathogens, since infants are not usually colonized by anaerobic bacteria until the eruption of primary dentition. Colonization of the normal oropharynx by ampicillin-resistant encapsulated pathogens such as *H. influenzae* or *Moraxella catarrhalis* or β-lactamase producing anaerobes offers a rationale for treating older infants and toddlers with a β-lactamase–resistant regimen such as ampicillin sulbactam or a combination of metronidazole together with ceftriaxone or cefuroxime. Chronically ill children have an increased risk of colonization by Enterobacteriaceae. In older children ampicillin-sulbactam or clindamycin (in β-lactam–allergic patients) may be considered for serious infections, and penicillin or ampicillin for milder episodes. A poor response to initial antibiotic therapy may be the result of inadequate antibiotic coverage or the presence of an obstructing endobronchial foreign body. Aspirated foreign bodies are particularly common in toddlers and preschool children who often place small objects in their mouths. Bronchoscopy is indicated in children who respond poorly to therapy or develop cavitation or empyema to exclude the presence of a foreign body as well as to obtain suitable endotracheal specimens for bacterial culture, and to improve bronchial drainage.

PNEUMOCYSTIS JIROVECI PNEUMONIA (PCP)

Symptomatic infections in children due to *P. jiroveci* generally occur in infants rendered immunodeficient by profound malnutrition, and in children of any age with significant compromise of cell-mediated immunity due to underlying disease or to immunosuppressive chemotherapy (Fig. 121-7). A more benign form of PCP in normal infants has also been reported. The infantile form of *P. jiroveci* is an indolent and generally afebrile process manifested by progressive tachypnea and poor feeding over a period of weeks. In contrast, older children typically present with an acute febrile illness with nonproductive cough and tachypnea disproportionate to the bland physical examination and often mild symmetric interstitial and fine alveolar infiltrate present on chest

Figure 121-7 *Pneumocystis jiroveci* pneumonia in a teenager with acute leukemia. Depending on the extent of disease at the time of presentation, there may be predominance of interstitial or airspace disease. The radiographic findings are nonspecific, and may mimic viral pneumonitis and noninfectious causes of interstitial and alveolar lung disease such as drug hypersensitivity reactions.

radiograph. The course of *P. jiroveci* infection in HIV-infected children may be quite variable, and resemble either the indolent progressive course seen in malnourished infants or the more rapidly progressive illness seen in older children. The diagnosis of PCP can be made noninvasively in older children by microscopic examination of induced sputum, but in infants and young children bronchoscopy or lung biopsy is required. Trimethoprim-sulfamethoxazole therapy remains the mainstay of treatment, usually given at a dosage of 20 mg/kg/d of the trimethoprim component divided q 6 h for 2 to 3 weeks. Children intolerant to sulfonamide therapy are usually given intravenous pentamidine 4 mg/kg/d for 2 weeks. Short-term administration of methylprednisolone (1 mg/kg q 6 h for 7 d, followed by 7-day tapering course) has been associated with improved survival in HIV-infected patients. Long-term prophylaxis (with trimethoprim-sulfamethoxazole or one of several alternate regimens) is essential to reduce the risk of relapse.

RECURRENT PNEUMONIA

The occurrence of more than one episode of focal consolidative pneumonia, especially within a 1-year interval, raises concerns that a child may be experiencing recurrent pneumonia due to local or systemic risk factors. The radiologic distribution of these infiltrates directs the subsequent evaluation: recurrent pneumonia in a single lobe or lung suggests local risk factors, and recurrent infections distributed throughout the lungs suggest systemic causes of heightened susceptibility to infection.

Recurrent Focal Pneumonia

Recurrent pneumonia in a single lobe may be due to a variety of intraluminal lesions, particularly the presence of a foreign body, or to extraluminal compression due to enlargement of perihilar or regional lymph nodes due to granulomatous infection or malignancy (Fig. 121-8). In addition, a variety of pulmonary or bronchial lesions may be responsible for recurrent infection. Bronchial stenosis and bronchiectasis (especially involving the right middle lobe bronchus) are the most common bronchial abnormalities responsible for recurrent focal pneumonia. Congenital lesions such bronchogenic cysts and pulmonary sequestra may present as recurrent or nonresolving pneumonia. Since these structures lack normal communications with functional bronchi, pneumonitis which develops in these regions as a result of contiguous spread of infection from normal lung is slow to resolve and frequently fails conventional medical therapy. Aspiration should be considered in the setting of recurrent basilar pneumonia. Evaluation of children with recurrent focal pneumonia should begin with chest CT scanning and bronchoscopy to identify obstructing intraluminal lesions, intrinsic bronchial abnormalities such as bronchiectasis, extrinsic bronchial compression, or

Figure 121-8 Recurrent pneumonia. This 5-year-old girl had three episodes of right lung consolidation, involving different lobes, shortly after immigrating to the United States from the Azores Islands. At bronchoscopy, cellophane tape was recovered from the right mainstem bronchus.

congenital malformations and serves as the primary modality for the removal of retained foreign material. When pulmonary sequestration is suspected, vascular imaging by conventional contrast or magnetic resonance angiography demonstrates the aberrant systemic vascular supply associated with these lesions.

Recurrent Pneumonia in Different Locations

Compromise of any of a variety of pulmonary or systemic host defense mechanisms may be associated with recurrent pneumonia, and in the setting of a such a generalized impairment, recurrent infections may occur anywhere in the lungs.

Defects in Pulmonary Defenses

Abnormalities in the bronchial mucociliary transport system are important considerations. Children with cystic fibrosis (CF) first may become symptomatic beyond the neonatal period with recurrent bronchopneumonia rather than with a picture of steatorrhea and failure to thrive, as is common in neonates. A large number of distinct CF genotypes have been identified, and some are associated with a later and milder onset of respiratory symptoms; in fact, on occasion the diagnosis of CF may not become apparent until adulthood. A family history of CF is often lacking among the families of children with CF. Initial episodes of pneumonia in these patients may be associated with conventional encapsulated bacterial pathogens or *S. aureus*; the development of chronic *P. aeruginosa* infection may be a relatively late event. The diagnosis should be explored with pilocarpine iontophoresis testing ("sweat test") at a center experienced in the diagnosis of CF, with genetic screening considered for borderline tests.

In contrast, congenital abnormalities of the ciliary system are very rare. Kartagener's syndrome of bronchiectasis, sinusitis, and dextrocardia is a subset of the group of immotile ciliary disorders. Such children often experience recurrent upper-respiratory tract infections such as sinusitis and suppurative otitis media in addition to recurrent pneumonia. Ciliary disease can be assessed by analysis of ciliary beat frequency from nasal mucosal specimens. The classic method of diagnosing immotile cilia based on ciliary morphology requires electron microscopic analysis of a bronchial biopsy. This procedure should be performed some weeks after recovery from an acute episode of pneumonia, since ultrastructural abnormalities may be seen after infection in the absence of a heritable ciliary defect. Tracheomalacia and tracheobronchomegaly (Mounier-Kuhn syndrome) also impair clearance of mucus and are associated with recurrent pneumonia.

Defects in Systemic Host Defenses

Humoral immunodeficiency

Humoral immunodeficiency states are the most common host defects associated with recurrent bacterial pneumonia. A variety of different antibody deficiency syndromes have been identified. Bruton's (X-linked) agammaglobulinemia is the most extreme example with a virtual absence of all circulating immunoglobulins. The hyper-IgM syndrome is due to the inability of T cells to activate B cell CD40 which is necessary to drive B-cell differentiation to produce normal quantities of IgG and IgA antibodies. In these children with profound hypogammaglobulinemia, recurrent pyogenic infections, including recurrent pneumonia, develop after transplacentally derived maternal antibody wanes following the first 6 months of life. Common variable hypogammaglobulinemia and transient hypogammaglobulinemia of infancy have moderate reductions in IgG and IgM levels, and may have little or no IgA. In contrast to these more dramatic conditions, IgG subclass deficiency states, particularly of IgG2 and IgG4, have been associated with recurrent respiratory tract infections. Rarely, patients with normal IgG subclass levels have an isolated inability to mount IgG responses to the conventional encapsulated bacterial pathogens; this can be assessed by obtaining pre- and post-immunization titers after administering a bacterial polysaccharide vaccine. Definitive therapy with intravenous immunoglobulin (IVIG) administration can be cumbersome, especially in young children where peripheral venous access is problematic, and where central venous catheters have a significant rate of catheter-associated bacteremia. It is reasonable to offer a trial of chronic oral suppressive antibiotic therapy with a β-lactamase–resistant agent in patients with mild or moderate disease, and to reserve IVIG therapy only to children who fail to improve on suppressive antibiotics. Complement deficiency states, particularly C3, C5, and properdin deficiencies are rare heritable causes of recurrent bacterial infections as well. These patients have an increased incidence of a variety of soft tissue and systemic infections in addition to recurrent pneumonia.

Granulocyte disorders

Quantitative and qualitative granulocyte abnormalities are rarely causes of recurrent pneumonia. Routine differential white cell counts will identify children with agranulocytosis; serial monitoring and bone marrow examinations will distinguish among cyclic neutropenia, immune neutropenia, and congenital agranulocytosis. In these children, pneumonia is often due to *S. aureus* or gram-negative bacilli, including *Pseudomonas*, or to fungal pathogens such as *Aspergillus*. If no response is seen to initial empiric therapy, bronchoscopy or lung biopsy may be necessary to guide further antibiotic therapy. A trial of granulocyte colony-stimulating factor (GCSF) is reasonable in this setting since the transient response in granulocyte number may hasten the resolution of the pneumonia. In contrast, children with chronic granulomatous disease (CGD) have a normal granulocyte number but impaired intracellular killing of bacteria. Like patients with complement deficiency, focal soft-tissue, skeletal, and lymph node infections may be seen in addition to recurrent pneumonia. The use of interferon-γ and long-term antibiotic suppressive therapy has greatly improved the long-term outlook for such patients. Defects in granulocyte function may result in invasive pneumonia due to fungi as well as bacterial pathogens. As

with neutropenic children, focal infiltrates which persist or progress (particularly with cavitation) despite reasonable initial empiric antibiotic therapy require vigorous investigation with chest CT scanning and biopsy.

Cell-mediated immunodeficiency

Defects in T-cell function are associated with primary immunodeficiency diseases such as severe combined immunodeficiency and DiGeorge syndrome, lymphoid malignancies such as acute lymphoblastic leukemia, therapy with immunosuppressive agents for the treatment of a variety of inflammatory diseases and organ transplantation, and HIV infection. The immunodeficient state triggered by acute systemic viral infection is transient and rarely associated with opportunistic pulmonary infection. Regardless of the initial mechanism of T-cell immunosuppression, these children are at risk of developing life-threatening pneumonia due particularly to common viral pathogens such as RSV, measles, and parainfluenza virus; fungal infections such as cryptococcosis or the endemic soil fungi; higher bacteria such as *Nocardia asteroides* and mycobacteria (both *M. tuberculosis* and atypical mycobacteria); and *P. jiroveci*. The radiologic features may point toward particular pathogens (e.g., focal infiltrates implicate fungal or bacterial pathogens, and diffuse infiltrates implicate viral pathogens or *P. jiroveci*) but the broad differential diagnosis, the possibility of polymicrobial infection and noninfectious processes such as drug hypersensitivity reactions, and the complexities of therapy mandate an invasive approach to diagnosis via bronchoscopy and/or open lung biopsy.

Human immunodeficiency virus

HIV infection in children results not only in a heightened susceptibility to infection by *P. jiroveci* and other pathogens classically associated with T-cell immunodeficiency states, but also in an increased susceptibility to bacterial infection, with an increased risk of bacterial pneumonia and bacteremia due to encapsulated pathogens such as *S. pneumoniae*. Tuberculosis is another important pathogen among HIV-infected children living in resource-limited environments. In addition, lymphoid interstitial pneumonia, an infiltrative process possibly associated with Epstein-Barr virus infection, may be responsible for pulmonary infiltrates and respiratory distress in these children. Unlike adult HIV-infected patients, the risk of *P. jiroveci* pneumonia in HIV-positive infants is not closely correlated with the CD4 count. Infants with vertically transmitted HIV have an increased risk of acquiring PCP regardless of CD4 count during the first year of life. All infants born of HIV-infected mothers should begin *P. jiroveci* prophylaxis at 4 weeks of life, and continue treatment until 1 year of life, or until follow-up PCR testing is negative for HIV transmission at 4 to 6 months of age. The need for continued prophylaxis thereafter among HIV-infected infants is based on the CD4 count. The syndrome of recurrent bacterial infections, including pneumonia, in these infants, has become less common since the widespread introduction of highly active antiretroviral therapy (HAART), and maintenance intravenous immunoglobulin (IVIG) therapy for HIV-infected infants is now rarely necessary. When HIV-infected children develop respiratory distress associated with diffuse interstitial and alveolar infiltrates, the broad differential diagnosis and the significant possibility of multiple concurrent processes warrants early consideration of an invasive biopsy process. Depending on the severity and tempo of illness, an empiric trial of therapy for PCP may be given, with lung biopsy reserved for those patients who fail to improve.

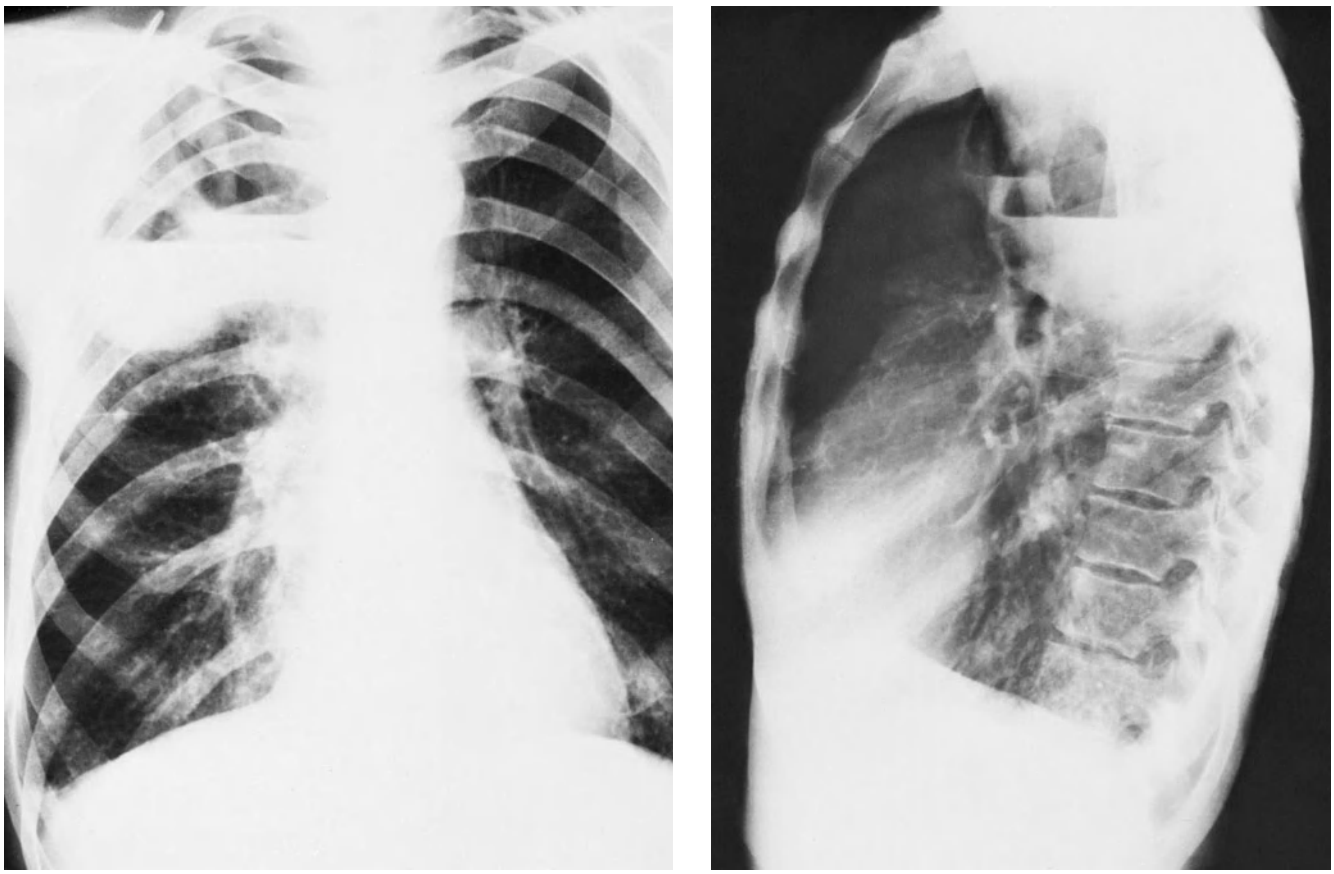
Aspiration, Empyema, Lung Abscesses, and Anaerobic Infections

Jay A. Fishman

Infection due to aspiration, lung abscesses, and empyema are important syndromes dominated, in part, by the unique role of anaerobic bacteria in the pathogenesis of each. *Aspiration pneumonia* refers to the pulmonary consequences that follow abnormal entry of fluid, particulate substances, or endogenous secretions from the upper airways or gastric contents into the lower airways. To develop aspiration pneumonia, there needs to be a compromise of the host defense mechanisms that normally protect the lower airways, including glottic closure, cough reflex, or other clearance mechanisms. The material aspirated must generate an inflammatory response or cause obstruction. The nature of the pneumonia that develops depends on the inoculum and the host response. Anaerobic bacteria are the most common pathogens in this setting, reflecting both pathogenic potential and importance in the normal flora of the upper airways. Risk factors for aspiration may be transient (anesthesia, intoxication) or persistent (e.g., neuromuscular disorders, achalasia) with the risk for recurrence depending on recognition and resolution of the inciting defect.

Empyema refers to a purulent collection in any body site, but is commonly used to indicate infection of the pleural space. Empyema is commonly associated with underlying pulmonary parenchymal infection, but may also be associated with blood-borne infection, thoracic surgery, trauma, abdominal infection, or neoplasm. *Lung abscesses* reflect infection with an unusual microbial burden (e.g., acute aspiration), a failure in microbial clearance mechanisms (e.g., bronchial obstruction), or both, with necrosis of pulmonary tissue and formation of cavities containing necrotic debris or fluid (Fig. 122-1). The formation of multiple smaller (less than 2 cm) abscesses in pulmonary tissue is occasionally referred to as *necrotizing pneumonia* or *lung gangrene*. Both lung abscess and necrotizing pneumonia are manifestations of the same pathologic processes, and the distinction is, therefore, arbitrary. Failure to recognize and treat either empyema or



A *B*

lung abscess is associated with a poor clinical outcome. In the pre-antibiotic era, lung abscess was associated with a mortality approaching 40 percent. However, controversy exists over the best approaches to both processes in terms of antimicrobial selection and physical drainage.

HISTORY

The clinical and bacteriologic features of anaerobic infections of the lung have been documented by extensive studies during two periods of investigation. The first was at the turn of the century, when anaerobic bacteria were initially reported as important causes of empyema. This early work continued through the late 1920s, when David Smith conducted classic studies on the pathogenesis of lung abscess. At that time, approximately one-third of patients with lung abscess died. Smith noted that the bacteria in the walls of the abscess at autopsy resembled the bacteria found in the gingival crevice, leading him to conclude that aspiration was the major mechanism in pathogenesis. He subsequently supported this hypothesis by inoculating the trachea of experimental animals with gingival crevice material to reproduce the sequence of events of pneumonitis, followed in 7 to 10 days by lung abscess formation. Bacteriologic studies of the inoculum showed that four bacterial species were critical, and all were anaerobic bacteria: a fusiform bacterium now recognized as *Fusobacterium nucleatum, Prevotella melaninogenica* (formerly *Bacteroides melaninogenicus*), Peptostreptococcus, and an anaerobic spirochete. This study is one of the first demonstrations of bacterial synergy; the demonstration of two or more bacterial species is required to produce a pathologic process that could not be reproduced by any single component of the inoculum.

In the first two or three decades of the antibiotic era, the role of anaerobic bacteria in this and other pathologic processes was largely ignored. Patients with lung abscesses often had putrid sputum and no identifiable pathogen; these infections were frequently referred to as *nonspecific lung abscess.* Although the microbial cause was unknown, it was well established that these patients almost invariably responded to penicillin treatment. The role of anaerobes in empyema was also largely ignored. Much of this neglect is ascribed to the paucity of laboratories capable of cultivating oxygen-sensitive bacteria. Studies of anaerobic bacteria were spawned by the ability to culture anaerobes in clinical laboratories with the introduction of GasPak jars, the description of the taxonomy

of these organisms, and the availability of new antimicrobial agents (clindamycin, metronidazole, cefoxitin) for therapy. The introduction and widespread use of transtracheal aspiration (TTA) in the late 1960s made it realistic to collect uncontaminated specimens from the lower airways that could be used for anaerobic cultures. TTAs are seldom performed at present, so anaerobic bacteria are rarely established as pulmonary pathogens. These organisms are often suspected on the basis of the etiologic route (oropharyngeal flora) of infection and their importance in patients with aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema.

MICROBIOLOGY OF ASPIRATION PNEUMONIA

The establishment of anaerobic bacteria in pulmonary infections requires specimens of respiratory secretions that are devoid of contamination from the upper airways. The usual procedures satisfying this criterion are TTA, transthoracic aspiration, open lung biopsy, thoracentesis, and most recently, bronchoscopy with quantitative cultures. In addition, there must be appropriate laboratory expertise for cultivation of anaerobic bacteria. The incidence of anaerobic lung infections reported in published studies from the antibiotic era that satisfy both requirements is summarized in Table 122-1.

Most published reports deal with the role of anaerobic bacteria in aspiration pneumonia or lung abscess, and these show recovery rates ranging from 62 to 100 percent. The usual specimens in these studies are TTA and transthoracic aspiration. One of the best studies is by Beerens and Tahon-Castel, who used transthoracic needle aspiration to characterize the flora in lung abscesses; this series showed recovery of anaerobic bacteria, usually in pure culture, in 22 of 26 cases (85 percent).

There have been few studies to identify the frequency of anaerobic bacteria in unselected cases of community-acquired pneumonia. One was by Ries and co-workers, who performed TTAs in patients hospitalized with a diagnosis of pneumonia and recovered anaerobic bacteria in 29 of 89 cases (33 percent). A more recent study by Pollock and colleagues, using fiberoptic bronchoscopy with a protected catheter and quantitative cultures, showed recovery of anaerobes in 16 of 74 patients (22 percent). These two reports suggest that anaerobic bacteria are actually relatively common pathogens among patients with community-acquired pneumonia and presumably account for a substantial proportion of cases that are now considered enigmatic. In nosocomial pneumonia, a study by Bartlett and colleagues utilized TTA in 159 consecutive patients and showed anaerobes in 56 (35 percent). Nevertheless, most of these patients also showed the concurrent presence of aerobic gram-negative bacilli or *Staphylococcus aureus,* with the clinical course determined largely by the aerobic pathogens.

MICROBIOLOGY OF EMPYEMA

In the pre-antibiotic era, up to 11 percent of cases of pneumococcal pneumonia were associated with empyema; 64 percent of all cases of empyema were associated with *Streptococcus pneumoniae.* β-Hemolytic streptococci (15 percent) and staphylococci (8 percent) were the other organisms most commonly isolated from empyema fluid. In the 1960s and 1970s, with new culture techniques, one study found *only* anaerobic bacteria in pleural empyema fluid in 35 percent of cases, and a *mixture* of aerobic and anaerobic bacteria in 41 percent in a series of 83 medical patients who had not received antibiotics or surgical intervention (Tables 122-2 and 122-3; Figs. 122-2, 122-3, and 122-4). With the introduction of the sulfa drugs and penicillins, the expansion of thoracic surgery, and the emergence of antibiotic resistance in the

staphylococci, the isolation of *S. pneumoniae* decreased and that of *S. aureus* and other nosocomial pathogens in empyema fluids increased. In more recent studies of empyema, the pneumococcus accounts for only 5 to 10 percent of cases, while anaerobes are found in 25 to 40 percent. The highest yield reported in recent years is a collaborative study at Cook County Hospital in Chicago and two VA hospitals in Los Angeles. Anaerobes were recovered in 63 of 83 cases (76 percent).

Anaerobic Bacteria in Empyema

The frequency of anaerobic infection of the lung and pleural space is a function of the colonization pattern of the individual patient, including the presence of hospital-acquired pathogens and the role of aspiration in many of these infections (Table 122-3). The most frequent isolates are the anaerobes *Prevotella, Fusobacterium nucleatum,* and *Peptostreptococcus* and the streptococci (Figs. 122-5 and 122-6). In early studies, the *Bacteroides fragilis* group was isolated from 15 to 20 percent of patients with anaerobic pleuropulmonary infections. However, later studies employing newer techniques and utilizing newer taxonomic criteria found *B. fragilis* group in only 6.8 percent of 46 patients with pleural empyema specimens. The *B. fragilis* group is important because of resistance to penicillin G (a property shared by a number of common anaerobes) and other antimicrobial agents. Subdiaphragmatic infection may extend to the lung or pleural space by way of lymphatics, directly through the diaphragm or defects in it, or by way of the bloodstream. Anaerobic pulmonary and pleural processes rarely extend to the chest wall unless associated with actinomycosis, tuberculosis, or tumor.

Non-anaerobic Infections

In immunologically normal adults, the aerobic organisms currently most often associated with empyema and lung abscesses are *S. aureus,* β-hemolytic streptococci, and various gram-negative aerobic or facultatively anaerobic bacilli, particularly *Pseudomonas aeruginosa, Escherichia coli, Klebsiella* species, and other nosocomial enteric gram-negative organisms—reflecting infections associated with pneumonia treated with antimicrobial agents to which the causative organism is resistant, with thoracic surgery or high-grade bacteremias. Mixed aerobic-anaerobic infections are often related to subdiaphragmatic processes. Increasingly, *Mycobacterium tuberculosis, Nocardia asteroides,* and fungi have been identified. In the immunocompromised host, the infecting organisms will more often be gram-negative bacteria (especially *Pseudomonas* and *Enterobacter*) or *Candida* or *Aspergillus* species, or will be due to reactivation of latent or subclinical infections due to *M. tuberculosis, Candida* species, or the less virulent streptococci. In all hosts, the colonization pattern of the individual will often predict the causative organisms, even if these are not easily isolated.

MICROBIOLOGY OF LUNG ABSCESS

In lung abscesses, anaerobes are recoverable from up to 89 percent of patients. In some patients, anaerobic organisms of presumably greater virulence (e.g., *Fusobacterium nucleatum* or *Peptostreptococcus* species) may be found as the sole infecting organism. In studies by Bartlett and coworkers, 46 percent of patients with lung abscesses had *only* anaerobes isolated in cultures, while an additional 43 percent had a *mixture* of anaerobes and aerobic bacteria. In addition to anaerobes, among the organisms often implicated in lung abscess formation or in necrotizing pneumonia are *S. aureus, Streptococcus pyogenes, Klebsiella pneumoniae,* and *P. aeruginosa.* Infrequently, other gram-negative bacilli, such as *E. coli* and *Haemophilus influenzae* type B, may cause pulmonary

necrosis. Uncommon but important causes of cavitating pneumonia are *N. asteroides, Paragonimus westermani, Legionella* species, *Burkholderia pseudomallei,* and *B. mallei* (glanders), and tuberculosis. Certain fungal infections may cause cavitation in diabetic and immunocompromised hosts (e.g., the *Mucoraceae, Aspergillus* species). *Entamoeba histolytica* is an important, but uncommon, cause of lung abscess, almost always in the basilar portion of the right lower lobe.

Pathophysiology of Aspiration, Empyema, and Lung Abscess

The bacteria implicated in anaerobic lung infections represent the normal flora of the oral cavity—primarily the gingival crevice, where anaerobic bacteria are found in concentrations that approach the geometric limits with which bacteria occupy space: 10/g. Compromised consciousness or dysphagia predisposes most frequently to clinically significant aspiration. Common conditions associated with clinically significant aspiration include alcoholism, general anesthesia, seizure disorder, drug abuse, esophageal lesions, and neurologic deficits.

Numerous studies indicate that virtually all healthy persons aspirate, but that this is usually inconsequential. In one study, in which contrast material was placed in the mouths of sleeping patients, chest radiographs the following day showed contrast material in the lung in most of them, but there was no evidence of a disease process. Similarly, dye markers placed in the stomach of postoperative patients can be aspirated from the tracheobronchial tree at the time of surgery, indicating aspiration of gastric contents during general anesthesia in 7 to 16 percent. Scintigraphic methods have also been used to demonstrate frequent aspiration in patients with intubation of the airways or gastrointestinal tract. None of these studies have demonstrated any clinical consequences from this type of occult aspiration. The conclusion is that aspiration is relatively common, but usually resolves spontaneously. The decisive factor for the development of lung complications depends on the frequency, volume, and character of the material in the inoculum. The conditions cited in the preceding as causing clinically significant disease are associated with more frequent aspiration or aspiration of large volumes—factors that define the populations at greatest risk.

C.* Pus showing microaerophilic streptococcus. *D.* Microscopic morphology of *Bacteroides fragilis.* Organism is an irregularly stained, gram-negative rod. Bipolar staining may be seen.

Additional conditions that appear to predispose to anaerobic infections include pulmonary infarction, obstruction due to carcinoma or a foreign body, and bronchiectasis. These conditions are associated with stasis or necrosis of tissue, which presumably accounts for the association with anaerobic infections.

A somewhat unique feature of anaerobic lung infections is the penchant for necrosis of tissue, resulting in abscess formation or a bronchopleural fistula associated with empyema. Virulence factors of anaerobic bacteria presumed to account for this association include the capsular polysaccharide of anaerobic gram-negative bacilli. The most extensively studied is the polysaccharide of *Bacteroides fragilis,* but the same observations appear to apply to *P. melaninogenica* and probably other anaerobic gram-negative bacilli as well. The capsule consists of a family of polysaccharides composed of oligosaccharide repeating units with sugars containing positively charged free amino groups and negatively charged carboxyl or phosphorite groups. These positive and negative charges mediate the capacity to induce abscess formation in experimental animals. Another virulence factor possessed by most anaerobic bacteria is the production of short-chain fatty acids that inhibit phagocytic killing at low pH levels. Short-chain volatile fatty acids are metabolic products of anaerobic bacteria that are used to classify these organisms taxonomically, and they appear to be responsible for the putrid odor that is often a characteristic feature of infections by these organisms.

Because the most important predisposing condition for lung abscess is *aspiration*, lung abscesses are most often located in the posterior segment of the right upper lobe, less often in the left upper lobe, and the apical segments of the lower lobes (Fig. 122-1). Periodontal disease is highly associated with lung abscess formation; in edentulous people, lung abscesses are uncommon and may suggest the presence of an obstructing lesion of the bronchus, pulmonary embolus,

septic embolus, or unsuspected pathogen. Nosocomial aspiration often involves gram-negative bacteria, particularly organisms with hospital-acquired antibiotic resistance patterns.

Lung abscesses generally develop after inflammation produces tissue necrosis with cavitation. In the presence of pre-existing cavitary disease (emphysema or old tuberculous lesions), infection may proceed without frank necrosis. The abscess cavity may become lined with regenerated epithelium. Local obstruction may produce bronchiectasis or emphysema in the surrounding lung.

The classification of lung abscesses is based on the duration and likely cause of the process. *Acute abscesses* are less than 4 to 6 weeks old, whereas *chronic abscesses* are of greater duration. *Primary abscesses* are infections due to aspiration or to pneumonia in the normal host; *secondary abscess* is due to preexisting conditions (obstruction, spread from an extrapulmonary site, bronchiectasis, immune compromise). Abscesses with foul odors associated with anaerobic organisms are often called *putrid abscesses.*

Clinical Features of Aspiration and Anaerobic Lung Infections

Aspiration Pneumonia

Common clinical features of anaerobic pulmonary infections are summarized in Table 122-4, which categorizes the patients with respect to pneumonitis, lung abscess, or empyema. Features of anaerobic infections that are nearly unique are the association with conditions that predispose to aspiration and infection in the gingival crevice, putrid discharge, and a high frequency of suppurative complications in late stage-disease. Anaerobic lung infections may be acute, subacute, or chronic.

The first stage in the infection is pneumonitis. One review of 46 patients with anaerobic bacterial pneumonitis showed clinical features that were similar to those of pneumococcal pneumonia. The diagnosis was established by TTA, and the results in this group were compared with those in a second group of patients in whom TTAs yielded *S. pneumoniae.* The two groups were similar in terms of age, changes on the chest radiograph, peak temperature, and peripheral leukocyte count. Significant differences in the group with anaerobic infections were the lack of rigors, a somewhat longer duration of symptoms before presentation, and a more frequent association with predisposing conditions for aspiration. An important point to emphasize is that patients seen in this early stage of infection rarely have the features that are commonly associated with anaerobic lung infections, such as putrid sputum, tissue necrosis with abscess formation, and a chronic course. These infections presumably account for some and possibly many of the cases of community-acquired pneumonia in which no etiologic diagnosis is established despite extensive study; such cases account for 40 to 50 percent of cases in most series.

The initial stage of pneumonitis is often more subtle or neglected, so that patients may not seek medical attention until the infection has been present for weeks or even months. These cases are more analogous to tuberculosis than to most bacterial infections of the lung. As noted, many of these infections progress to suppurative complications, with presentation as lung abscess or empyema. Generally, 7 to 14 days is required for cavity formation.

Nearly all patients with anaerobic lung infections have the usual constitutional findings for patients with infection (Table 122-4). A review of 193 bacteriologically confirmed cases showed that the mean peak temperature for hospitalized

Table 122-5

Classification of Aspiration Pneumonia

Inoculum	Pulmonary Sequelae	Clinical Features	Therapy
Acid breathing	Chemical pneumonitis	Acute dyspnea, tachypnea; tachycardia; cyanosis, bronchospasm, fever Sputum: pink, frothy Radiographic: infiltrates in one or both lower lobes Hypoxemia	Positive-pressure Intravenous fluids Tracheal suction
Oropharyngeal bacteria	Bacterial infection	Usually insidious onset Cough, fever, purulent sputum Radiographic: infiltrate in dependent pulmonary segment or lobe ± caviation	Antibiotics
Inert fluids positive-breathing with isoproterenol	Mechanical obstruction Reflex airway closure	Acute dyspnea, cyanosis ± apnea Pulmonary edema	Tracheal suction Intermittent pressure oxygen and matter
Particulate	Mechanical obstruction	Dependent on level of obstruction, ranging from acute apnea and rapid death to irritating chronic cough ± recurrent superimposed infections particulate matter	Extraction of matter Antibiotics for infection

patients was 39.1°C, and all but five patients were febrile. The average peripheral leukocyte count was 15,000/ml^3. Patients who presented with the suppurative complications had a longer duration of symptoms before presentation; this was commonly associated with other evidence of chronic disease, including weight loss and anemia. Another common feature of patients with suppurative complications was putrid sputum or empyema fluid, which was noted in 40 to 60 percent. It should be emphasized that the putrid discharge in these cases is considered diagnostic of anaerobic infection, since aerobic bacteria are not capable of producing this characteristic odor either in vitro or in vivo. Thus, anaerobic bacteria may cause a diverse range of pulmonary infections, which may be acute, subacute, or chronic. The anaerobic etiology is rarely established or even suspected in patients with acute pneumonitis unless the appellation *aspiration pneumonia* is applied; in this case, anaerobes are the presumed pathogens in most community-acquired cases, and they may be contributing factors in many nosocomial infections. By contrast, anaerobic bacteria are readily recognized as probable pathogens in patients who have the late suppurative complications, such as lung abscess or empyema.

Other Aspiration Syndromes

Aspiration Pneumonia

Aspiration pneumonia refers to distinctive syndromes that are distinguished on the basis of the character of the inoculum, which dictates the pathogenesis of pulmonary complications, clinical presentation, and management strategies (Table 122-5). Aspiration pneumonia includes at least three different syndromes: chemical pneumonitis, bacterial infection, and airway obstruction.

Chemical Pneumonitis

Chemical pneumonitis refers to the aspiration of an inoculum that is inherently toxic to the lungs. Examples include acid, animal fats such as milk and mineral oil, and volatile hydrocarbons. These substances are toxic to the lower airways, and they initiate an inflammatory reaction. The prototypic example based on extensive study is gastric acid pneumonitis as classically described by Mendelson and often referred to as Mendelson's syndrome. This is a severe pneumonitis with fever and hypoxia and respiratory alkalosis, that generally either rapidly clears in 4 to 7 days in healthy hosts or may progress (e.g., with lung injury and superinfection) to pneumonia, lung abscess, or ARDS. Factors that contribute to hypoxemia are pulmonary edema, reduced surfactant activity, reflex airway closure, hyaline membrane formation, and alveolar hemorrhage. These patients' pulmonary function tests show decreased compliance, abnormal ventilation-perfusion, and reduced diffusing capacity. The pathophysiology of gastric acid pneumonitis has been studied in experimental animals with intratracheal instillation of graded acid inocula. This work shows that the pH must be 2.5 or less for the

inflammatory process to be initiated. There must also be a relatively large inoculum, usually 1 to 4 ml/kg. It is possible that smaller volumes initiate a less dramatic presentation or may go undetected. Support for this hypothesis is the observation of frequent bouts of pneumonitis and otherwise unexplained pulmonary fibrosis in patients with gastric reflux or esophageal disease.

The pathologic changes in acid pneumonia occur rapidly. Atelectasis occurs within seconds and is extensive by 3 min. There is also peribronchial hemorrhage, pulmonary edema, and bronchial epithelial cell degeneration. The alveolar spaces are filled with neutrophils by 4 h and hyaline membranes are seen within 48 h. Resolution begins by the third day and may be complete or may result in residual scarring of the pulmonary parenchyma.

Long-term follow-up studies in patients who have gastric acid pneumonia show either complete recovery or radiographic evidence of pulmonary fibrosis with abnormal gas exchange.

The diagnosis of acid pneumonia is usually presumed on the basis of clinical observations such as the abrupt onset of dyspnea in a patient who is aspiration prone and has radiographic evidence of infiltrates, usually in the lower lobes. Other characteristic clinical features are the rapid clearing of the infiltrates and progression to ARDS. Bronchoscopy demonstrates erythema of the bronchi, suggesting a "chemical burn." Confirmation of the acid inoculum is not possible because of rapid neutralization by pulmonary edema fluid and bronchial secretions within minutes after aspiration.

The treatment of gastric acid aspiration includes tracheal suction to clear fluids and particulate matter that may be aspirated concurrently. Supportive care consists primarily of ventilatory support with positive pressure ventilation, and intravenous fluids due to decreased intravascular volume with hypotension. Corticosteroids have not be useful. Antimicrobial agents are reserved for superinfection.

Mechanical Obstruction

Aspiration pneumonia may involve fluid or particulate material. In this form of aspiration pneumonia, the inoculum is not toxic to the lung but may cause obstruction or reflux airway closure. In most cases there is only transient, self-limited hypoxemia due to rapid clearance. Some patients develop pulmonary edema, with hypoxemia and reduced compliance apparently due to an intrinsic pulmonary reflex closure. Other patients suffer sequelae due to failure to clear relatively large volumes of the aspirate, as with near drowning victims and patients with profound neurologic deficits or in coma. The obvious critical intervention is tracheal suction.

Aspiration with mechanical obstruction may also be associated with solid particles. Foreign-body aspiration is most frequent in children 1 to 3 years of age. The most common objects in the lower airways are vegetable particles, inorganic materials, and teeth. The severity of the obstruction depends on the relative size of the material aspirated and the caliber of the lower airways. Large objects may cause obstruction at the level of the larynx or trachea, leading to sudden respiratory distress, cyanosis, and in some cases, aphonia. This is referred to as *café coronary syndrome* because it often involves meat aspiration during restaurant dining and may simulate an acute myocardial infarction. Aspiration of smaller particles may result in complete obstruction of more distant components of the tracheobronchial tree or partial obstruction. Chest radiographs often show atelectasis or obstructive emphysema. An important clue in some cases is unilateral wheezing. Bacterial infection is not important in the early stages of obstruction, but is a common feature when obstruction has been present for more than 1 week. The most common pathogens are anaerobic bacteria from the upper airways. These patients may respond well to antibiotics, but often have recurrent infections in the same pulmonary segment. The most important therapeutic intervention is removal of the foreign body, usually with bronchoscopy.

Empyema and Lung Abscess

The pathogenesis and presentation of both pleural empyema and lung abscesses are often indistinguishable. Shared presentations of empyema and lung abscess include the indolent development of symptoms, most often fever, sweats, cough, dyspnea, weight loss, and pleurisy; an association with conditions predisposing to aspirational events (altered consciousness, dysphagia, and gingivitis); and foul odors of sputum or breath associated with anaerobic bacteriology. Lung abscesses and empyemas often coexist. Both are generally associated with primary pneumonias.

The clinical presentation of empyema is determined by the underlying cause of infection. Empyema associated with aspiration pneumonia may develop over 1 to 3 weeks, usually with associated symptoms of pneumonia. The patient may have high fever and leukocytosis. Physical examination reveals dullness to percussion and decreased breath sounds on auscultation. These changes may be quite localized in the setting of loculated fluid. The empyema fluid is generally purulent by the time of detection, but pleural infection may be noted only after treatment for pneumonitis has failed to resolve fever or pleurisy. Empyema associated with thoracic surgery may be radiologically "hidden" in areas of the chest not drained by chest tubes or behind relatively benign pleural effusions. The patient may appear minimally toxic or severely ill, depending on the extent of the infection and organisms present. The presentation is modified by routine prophylactic antibiotic use, sedation, intubation, and antipyretics. Acute empyema may be seen in staphylococcal and streptococcal infections and following rupture of hepatic abscesses, especially those due to *E. histolytica.*

Lung Abscess

The clinical presentation of lung abscess may be coincident with the initial presentation of pneumonia or other underlying condition, or may occur later in the clinical course. Suspicion may be heightened by the presence of conditions predisposing to aspiration or anaerobic pneumonia: alcoholism or other causes of altered consciousness, anaesthesia, dysphagia

Figure 122-7 Septic emboli due to *Pseudomonas aeruginosa* in a 33-year-old woman with sarcoidosis and pyelonephritis following spontaneous abortion. The patient presented with headache, fever, backache, and purulent sputum. *Pseudomonas* grew from the sputum culture. *A*. Chest radiograph before present illness. Bilateral hilar adenopathy of sarcoidosis. *B*. Posteroanterior view of chest shows bilateral cavitary lesions (arrows). *C*. Lateral view. The lesions are more dramatically seen.

or pharyngeal dysfunction, gingivitis or pyorrhea, blunt or penetrating chest trauma or lung surgery, obstruction due to neoplasm, bronchiectasis, or pulmonary embolism. Bad breath or putrid sputum may be noted. However, the absence of a foul odor does not exclude the possibility of anaerobic infection, since certain anaerobes do not generate the end products of metabolism responsible for this type of odor, and communication may be lacking between the lesion and tracheobronchial tree. A change in sputum production, either increased or decreased, may be noted in patients with chronic bronchitis or bronchiectasis.

The patient with *primary lung abscess* gradually develops fever, cough, pleurisy, chest heaviness, shoulder pain, and malaise. Pneumonia may be present or suspected from history for a period of 1 to 3 weeks before the recognition of the lung abscess. By contrast, *secondary lung abscesses*—due, for example, to septic pulmonary emboli with infarction—can evolve over 48 to 72 h (Fig. 122-7). Clinically, the distinction between primary and secondary abscesses may be inapparent at the time of presentation, but is important in the proper management of the patient. Thus, the patient with staphylococcal or streptococcal endocarditis may present with pneumonia,

lung abscess, and empyema. The main clue to the presence of underlying endocarditis may be the development of new lung abscesses during the course of therapy. The patient with lung abscesses complicating subdiaphragmatic infection (amebic abscess of the liver or pancreatic phlegmon) may have abdominal signs in addition to acute pulmonary disease. Seizures due to brain abscesses are occasionally the presenting clinical manifestation of bacteremia due to lung abscesses.

RADIOLOGY AND DIAGNOSIS OF ANAEROBIC PLEUROPULMONARY INFECTIONS

Radiologic Diagnosis

Chest radiographs in patients with anaerobic lung infections show infiltrates, with or without cavitation, that most frequently involve dependent pulmonary segments. The favored locations are the superior segment of the lower lobes or posterior segments of the upper lobes; these are dependent in the recumbent position. The basilar segments of the lower lobes are favored in patients who aspirate in the upright position. The right lung is more frequently affected, owing to the more direct takeoff of the right mainstem bronchus.

With empyema, chest radiographs generally reveal fluid, most often in the costophrenic angles; free-flowing effusions layer on lateral decubitus radiographs. Loculations and pleural disease are often best defined by computed tomography of the chest, which should include the neck and diaphragms to rule out extrathoracic sites of infection. Spinal disease is better detected with magnetic resonance imaging (MRI). Before invasive diagnostic procedures, a careful history and physical examination may suggest a reason for the accumulation of pleural fluid. Non-infectious causes include bland pulmonary embolus, malignant effusion, benign postsurgical changes, pericardiotomy syndrome, collagen-vascular diseases (systemic lupus, rheumatoid arthritis), congestive heart disease, sympathetic effusion related to subdiaphragmatic disease (pancreatitis), leakage of ascites or peritoneal dialysis fluids, and hemorrhage (from venous access catheters or aortic tears). Infectious causes include extension of all classes of pulmonary infections from the lungs (parapneumonic), esophageal rupture, parapharyngeal space drainage, drainage or sympathetic effusion due to hepatic or subdiaphragmatic abscesses, septic metastasis, and direct infection via thoracic defects or chest tubes used for pleural drainage. Pyopneumothorax, in the absence of bronchopleural fistula, prior surgery, or prior thoracentesis, suggests the possibility of gas formation by bacteria implicated in the infection. Although nonspecific, pyo- pneumothorax suggests a component of anaerobic infection.

The classic radiographic appearance of a lung abscess is an irregularly shaped cavity with an air-fluid level inside. Because the presentation is often indolent, numerous chest radiographs may be needed to follow the evolution of pneumonia into *necrotizing pneumonia* and then into a pulmonary cavity (Figs. 122-5 and 122-6). Anaerobic infection is suggested by rapid pulmonary cavitation within a dense segmental consolidation; there may be rapidly enlarging nodular lesions, with or without cavitation. Although anaerobic pulmonary infections may be acute and fulminating, almost two-thirds of them have a subacute or chronic presentation. Natural progression of virulent infection, delays in appropriate therapy, or tissue infarction may allow the underlying infection to progress into *pulmonary gangrene* (Fig. 122-4). Seeding of infection or rupture of a lung abscess into the pleural space may cause empyema (Fig. 122-7). Up to one-third of lung abscesses may be accompanied by empyema. Solitary cavities are generally observed with primary lung infections, whereas many smaller collections may be found in metastatic infection. Chest tomography will define the size and location of abscesses, and may distinguish between related processes (empyema, infarction) better than conventional radiographs. The common organisms and conditions associated with lung abscesses are listed in Table 122-6.

Laboratory Diagnosis

Aspiration pneumonitis is a clinical diagnosis. It is generally assumed that there is an anaerobic component to pneumonia in patients with altered consciousness or after surgical procedures.

It is important to emphasize the utility of the Gram's stain in making the diagnosis of anaerobic lung infection. Often culture data are not available to document the presence of such organisms. However, most anaerobic gram-negative bacteria have unique morphologic features that make them relatively easy to identify or suspect on direct Gram's stain. Peptostreptococci appear like their aerobic counterparts. These are usually mixed infections involving multiple bacteria, and about half of the cases demonstrate mixtures of aerobic and anaerobic bacteria. Thus, the detection of polymicrobial flora or bacteria with the unique morphology of anaerobes on any specimen that is devoid of contamination by normal flora represents an important clue to the probable presence of anaerobic infection.

Determination of the microbiology of anaerobic infections of the lower airways requires a specimen devoid of contamination by the flora of the upper airways or quantitative cultures that distinguish pathogens from normal flora. Uncontaminated specimens that are considered valid for anaerobic culture include pleural fluid, transtracheal aspirates, transthoracic aspirates, and specimens obtained at thoracotomy. Quantitative cultures of specimens obtained at fiberoptic bronchoscopy, either by BAL or with the protected brush, may be used for this purpose also. Anaerobic bacteriology should not be used for bronchoscopic aspirates. It should be noted that quantitative culture of lower-airway secretions improves diagnostic accuracy with virtually any specimen that is subject to contamination, including expectorated sputum and tracheostomy aspirates. Most studies employing these techniques use them for detection of aerobic bacteria, and there are relatively few studies in which anaerobic cultures

Table 122-6

Organisms and Conditions Associated with the Radiographic Appearance of Lung Abscess

Infectious	Noninfectious and Predisposing Conditions
Bacteria Anaerobes; *Staphylococcus aureus*, Enterobacteriaceae, *Pseudomonas aeruginosa*, streptococci, *Legionella* spp., *Nocardia asteroides, Burkholdaria pseudomallei*	Anatomic Fluid-filled cysts, bland infarction Bronchiectasis Vasculitis
Mycobacteria (often multifocal) *M. tuberculosis, M. avium* complex, *M. kansasii*, other mycobacteria	Goodpasture's syndrome, Wegener's granulomatosis, periarteritis Obstruction (neoplasm, foreign body)
Fungi *Aspergillus* spp., Mucoraceae, *Histoplasma capsulatum, Pneumocystis carinii, Coccidioides immitis, Blastocystis hominis*	Pulmonary sequestration Pulmonary constusion Carcinoma
Parasites *Entamoeba histolytica, Paragonimus westermani, Strongyloides stercoralis* (post-obstructive)	
Empyema (with air-fluid level) Septic embolism (endocarditis)	

have been performed. It is important to emphasize the importance of obtaining specimens before inception of antibiotic treatment. Such specimens are not often obtained in clinical practice until the patient has developed complications of persistent infection (i.e., empyema or abscess). *Thus, the anaerobic component of infection should be considered in management even if an aerobic organism is isolated.*

It is essential that material obtained for culture be placed under anaerobic conditions promptly before transport to the laboratory. A sealed syringe provides the best container, with delivery of the specimen to the laboratory within 20 to 30 min for immediate plating. It is imperative that air bubbles be eliminated from the syringe and needle. Special anaerobic transport tubes are also available for brush or liquid specimens. It is important to obtain additional pulmonary specimens for culture and antibiotic susceptibility measurements from patients failing to respond to initial therapy (Fig. 122-8). Such data may demonstrate the presence of unrecognized or antibiotic-resistant organisms. Most of these infections are polymicrobial, and many of the organisms grow slowly in vitro. Thus, it often takes several days to separate, identify, and report results of anaerobic cultures. There is great variation in the availability and quality of in vitro susceptibility tests. These factors illustrate the need for empiric decisions regarding antibiotic selection.

Diagnosis of Empyema

The diagnosis of empyema is based on the characteristics of thoracic fluid. The urgency to diagnosis is due to the development of pleural scar and of loculated effusions in the presence of undrained pus. Thus, diagnostic thoracentesis should be attempted unless the nature of the pleural fluid is clear or the clinical risk to the patient is too great. Pleural fluid should be prepared for Gram's stain and cultures (routine, anaerobic, mycobacterial, and fungal), parasitologic examination when appropriate, fluid cell count and differential, cytology, pH, lactic dehydrogenase, and glucose measurements. Purulent fluid requires drainage. Empyema (defined in the preceding) is diagnosed on the basis of the neutrophilic predominance in fluids with more than 25,000 white blood cells per milliliter. Parapneumonic effusions will generally have lower white blood counts, negative Gram's stains and cultures, a pH over 7.3, and glucose over 50 percent of serum glucose levels. Parapneumonic fluids may become infected over time. Blood cultures and sputum cultures should be obtained as adjunctive guides to therapy.

DIAGNOSIS OF LUNG ABSCESS

Microbiologic specimens from patients with lung abscesses should be obtained, if possible, without contamination by oral flora, especially after nosocomial colonization. Thus, invasive procedures are preferred to routine sputum samples. In particular, the diagnosis of anaerobic infection is complicated by the prevalence of large numbers of anaerobes as normal flora in the mouth and upper respiratory tract (Fig. 122-9). However, there may also be significant

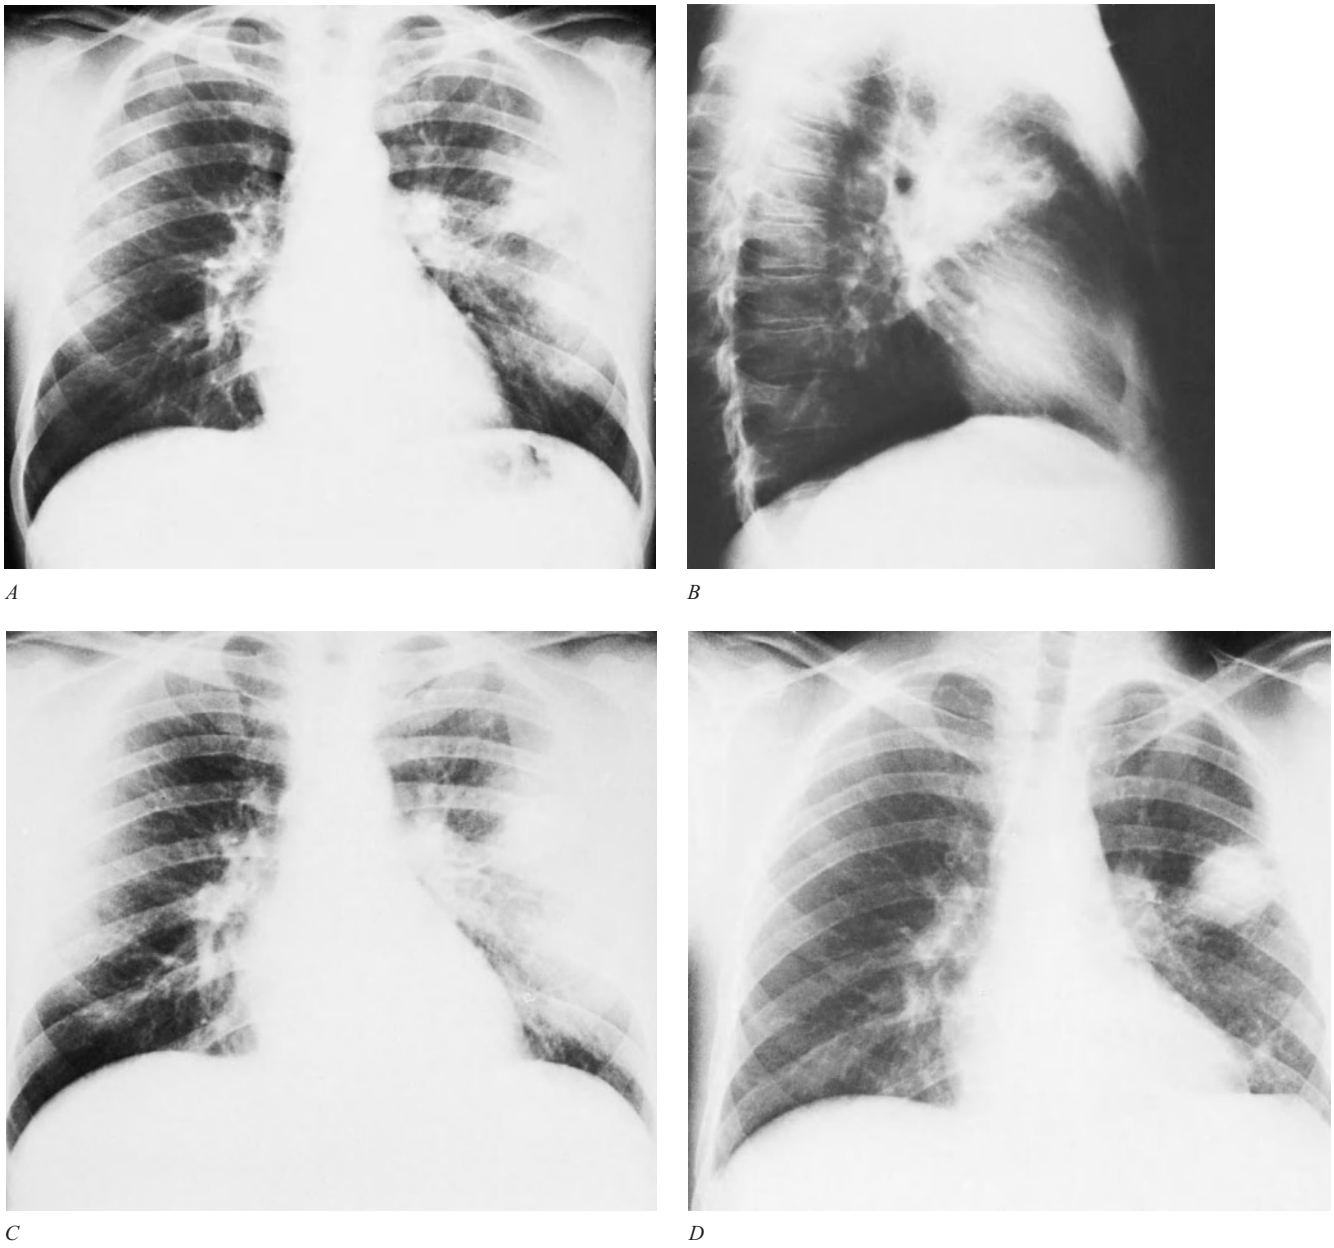

Figure 122-8 Failure of penicillin therapy for anaerobic lung abscess in a 29-year-old alcoholic man. *A*. Admission chest radiograph reveals a radiolucent area within a zone of consolidation in the left upper lung field. *B*. Lateral view demonstrates multiple cavities. The patient was treated for 5 days with penicillin (6 million units per day intravenously), followed by the same dosage orally for 10 days. *C*. Radiographic infiltrate persists but no cavity is visible. *D*. Six weeks after the cessation of penicillin therapy, the abscess has recurred in the same area. Marked pleural reaction is noted in the vicinity of the recurrent disease.

colonization with nosocomially acquired pathogens in hospitalized patients.

Blood cultures and sputum cultures should be obtained as adjunctive guides to therapy. When empyema or bacteremia complicates lung abscess, adequate specimens for microbiologic evaluation may be obtained from the blood or pleura. However, to obtain adequate specimens from the abscess, bronchoalveolar lavage, use of a protected double-lumen catheter, or percutaneous transthoracic aspiration under radiographic guidance is recommended. The specific procedure selected depends on the location of the infection and the expertise of the institution. Specimens collected through a fiberoptic bronchoscope, using bronchoalveolar lavage or a plugged double-lumen sampling catheter with a protected sampling brush, are preferred; these require the use of quantitative cultures. Growth at a dilution of 10 from a protected brush represents approximately 10 to 10 organisms per milliliter in the lower respiratory tract. Recovery of nonbacterial and anaerobic bacteria from these specimens has not been well standardized. Specimens obtained from blind, deep suctioning via an endotracheal tube may also be useful if cultured quantitatively and examined microscopically.

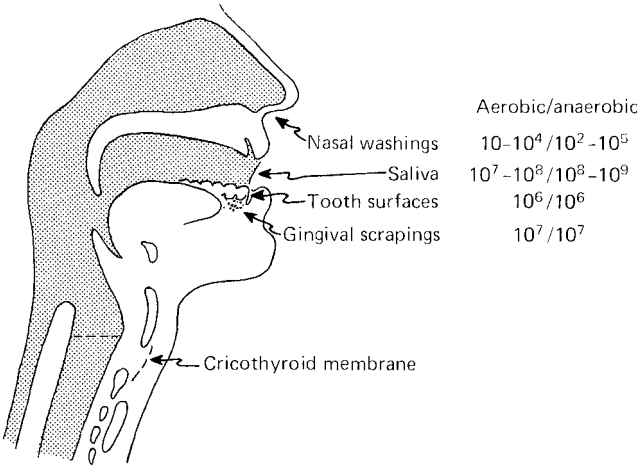

Figure 122-9 Sagittal section illustrating presence of large numbers of organisms, including anaerobes, as indigenous flora in upper respiratory tract. (Values given as number of aerobic/anaerobic organisms per milliliter.) *(Courtesy of P.D. Hoeprich.)*

Bacteriology

The bacteriologic findings in anaerobic lung infections from two large series are summarized in Table 122-7. Most of these infections involve multiple bacterial species, and approximately half of the patients have anaerobic bacteria combined with potentially pathogenic aerobic or facultative anaerobes. Analysis of community-acquired infections involving only anaerobes versus those that are mixtures of aerobic and anaerobic bacteria shows common clinical features with no difference in terms of the frequency of suspected aspiration, indolent presentation, or the frequency of putrid discharge. The implication is that a putrid lung abscess with *E. coli* in expectorated sputum or anaerobic bacteria plus *E. coli* in a TTA should usually be considered an anaerobic infection. Caution is advised in applying these conclusions to nosocomial pulmonary infections, since this is a setting in which the aerobic component of the infection is probably more important.

The major bacterial isolates in patients with anaerobic lung infections are Peptostreptococcus, *F. nucleatum,* and *P. melaninogenica.* Aerobic and microaerophilic streptococci are commonly present, and may be contributing factors in the pathogenic events. At least 15 to 25 percent of anaerobic bacteria responsible for lung infections are resistant to penicillin, generally because of penicillinase production. These susceptibility data are rarely available in individual cases unless specifically requested.

Table 122-7

Bacteriology of Anaerobic Lung Infections

	Bartlett	Marina et al.
Period reviewed	1968–1975	1976–1991
Patients	193	110
Total anaerobic isolates	461	404
Major isolates		
Gram-negative bacilli

**Numbers indicate the total number of isolates. Some of the differences are due to taxonomic changes.*
†Pigmented Prevotella refers to organisms previously classified as B. melaninogenicus.
‡Most peptococci have been reclassified as Peptostreptococcus.

TREATMENT OF ASPIRATION PNEUMONIA AND ANAEROBIC LUNG INFECTIONS

Prevention

Treatment is focused on optimal antimicrobial therapy and drainage of any abscess or empyema (see below). The reversibility of underlying conditions predisposing to aspiration must be considered. It has recently been recognized, for example, that aspiration in lung transplant recipients is a major predisposing factor to graft injury and obliterative bronchiolitis. In the general patient population, nasogastric-feeding tubes, sedation, laying flat in bed while sleeping, reflux, and frequent choking are associated with aspiration, and should suggest strategies for remediation. Gastric surgery for obesity has also been associated with a high incidence of aspiration disease.

Methods to prevent aspiration have been most extensively studied in hospitalized patients, especially those who are aspiration prone. Most important is use of the semirecumbent or upright position. Additional factors that have variable degrees of success are tracheostomies, reduction of the stomach volume with suction or metoclopramide, feeding via gastrostomy tube, and neutralization of gastric acid with H_2 blockers or antacids. Many of these procedures may alter colonization patterns and predispose to more significant infections. Neutralization of gastric acid may increase colonization of the oropharynx and increase the risk of bacterial infection following aspiration of gastric contents. Tracheostomy is useful

Table 122-8

Antibiotic Treatment of Anaerobic Lung Infections: Results of Two Randomized Trials

		Number of Patients with				
Source	**Treatment**	**# Pts**	**Failure**	**Relapse**	**Fever**	**Putrid Sputum**

	Clindamycin (2.4 g/d)	19	1 (5%)	0	6.4	3.9*

** Difference for treatment favoring clindamycin is statistically significant.*

in some patients with repeated aspiration, but inflation of the balloon may occlude the esophagus and promote aspiration of upper-airway contents. Patients who require nasogastric feedings are aspiration prone; percutaneous endoscopic gastroscopy is an attractive method to address this issue, but study results are quite variable. An alternative method sometimes favored is a feeding jejunostomy. The use of surgery with gastroesophageal reflux has given variable results.

Antimicrobial Therapy

It is essential, whenever possible, to obtain microbiologic samples from the lungs and blood in advance of antimicrobial therapy. As for all pneumonias, inappropriate initial therapy has an adverse impact on outcome. The initial choice of antimicrobial agents should be guided by the Gram's stain and the likely bacteriology of the infection, and then adjusted as culture data become available. The history and a review of old data may be useful in the selection of specific antibiotics. The standard drug historically for aspiration pneumonia and lung abscess involving anaerobic bacteria has been penicillin, usually given intravenously or with high-dose oral treatment. However, in the face of increasing penicillin resistance among *S. pneumoniae* and in 40 to 60 percent of strains of fusobacteria and *P. melaninogenica* as well as anaerobic gram-negative bacilli, alternatives should be considered for empiric therapy. In therapeutic trials in patients with lung abscess involving anaerobic bacteria (Table 122-8), clindamycin proved superior to penicillin in terms of response rates and time to defervescence. Alternative regimens that have been used successfully based on anecdotal experience include amoxicillin-clavulanate (Augmentin) and penicillin combined with metronidazole. Metronidazole should not be used as a single agent in patients with anaerobic lung infections, since there is a poor response in about 50 percent. The presumed explanation is the contributing role of aerobic and microaerophilic streptococci, which are resistant to this drug.

Many other antimicrobial agents are likely to be useful in anaerobic or mixed aerobic-anaerobic infections: combinations of a β-lactam with a β-lactamase inhibitor (ticarcillin-clavulanate, ampicillin-sulbactam, amoxicillin-clavulanate, piperacillin-tazobactam), chloramphenicol, imipenem or meropenem, and second-generation cephalosporins such as cefoxitin or cefotetan. Macrolides (erythromycin, clarithromycin, and azithromycin) offer good in vitro activity against most strains except fusobacteria. Tetracyclines show limited activity against many anaerobic bacteria in vitro; vancomycin is active only against gram-positive anaerobes. Oxacillin and nafcillin are much less active. Drugs that have virtually no activity against anaerobes include aminoglycosides, first-generation fluoroquinolones, aztreonam, and trimethoprim-sulfamethoxazole. Some of the newer fluoroquinolones (gatifloxacin, moxifloxacin) have broad coverage that includes anaerobes.

The appropriate duration of therapy is dependent on the clinical and radiographic response of the patient. Patients should be treated at least until fever, putrid sputum, and abscess fluid have resolved, and any fluid collection has resolved or stabilized over 2 to 3 weeks. A *minimum* of 2 to 3 weeks of antibiotics is recommended. Longer courses are often necessary. Relapse is common and may involve organisms resistant to initial antibiotic agents (Fig. 122-8).

Management of Empyema

The management of empyema includes antimicrobial treatment, identification and treatment of any anatomic processes, and drainage of the infected fluid. The approach to a specific patient is based on the clinical status of the patient as well as the microbiology of the infection. For example, patients with empyema following thoracic surgery and other hospitalized patients may have useful culture data available from chest tube drainage samples or sputum cultures to assist in the selection of antibiotics. The Gram's stain may indicate the predominant organism type. Mixed aerobic and anaerobic organisms may be the first suggestion of esophageal tear or parapharyngeal infection. Fastidious organisms (*S. pneumoniae*, anaerobes) may be seen on Gram's stain but not isolated in culture. Antibiotic susceptibility data should be used to guide therapy, especially in nosocomially acquired infection.

Local administration of antibiotics (e.g., inhaled, instilled) is unnecessary and may be irritating; intrapleural injection of antibiotics should be reserved for pleural ablation (pleurodesis), as may be achieved with erythromycin.

Drainage of empyema fluid is recommended but controversial. Ten to twenty percent of empyemas require external drainage or surgical intervention. Noninfected parapneumonic pleural fluids resolve with appropriate treatment of the underlying infections. *Drainage is required if infection or frank pus is present.* In the presence of pleural fluid and unexplained fever, leukocytosis, or bacteremia, or in the postoperative patient, thoracentesis should be performed routinely. Diagnostic thoracentesis may be performed with a needle adequate for removal of all but the most viscous material. Highly viscous or purulent fluids and fluids with acid pH require the insertion of a chest tube via thoracostomy or the thoracoscopic drainage of the fluid.

In the *early* or *exudative* phase of parapneumonic effusion, the fluid is thin and serous or serosanguineous. This may resolve during appropriate antibiotic therapy either without drainage or with multiple needle aspirations. If the pH is over 7.3, this method may be preferred. If the pH is less than 7.0, however, complete drainage should be performed, often requiring closed chest tube insertion. If the pH is between 7.0 and 7.3, failure to demonstrate improvement of infection or inflammation on multiple thoracenteses over 3 to 4 days should lead to consideration of formal drainage, especially if the primary process is adequately treated. Loculation of pleural fluid or failure to respond to antimicrobial therapy may require either multiple thoracenteses guided by ultrasound or chest tomographic evaluation (CT scans) or surgical intervention (see the following). Bloody fluid or persistent parapneumonic fluid should prompt cytologic evaluation and CT scans for lung masses or undrained mediastinal or retrocardiac collections.

Empyema diagnosed later in the course, persistently infected pleural fluid, viscous fluid, or fluids with acid pH may require large-bore tube drainage. This heavily proteinaceous fluid is characteristic of the *fibropurulent phase* of the evolving empyema. Indications for closed chest tube placement include bronchopleural fistula with empyema, loculated fluid unresponsive to thoracentesis and antibiotics, the presence of blood clots, and rapidly accumulating empyema not otherwise manageable. Under suction, and with removal of the gel-like material, pus, and clots, the lung expands and obliterates the empyema space. Failure to expand the underlying lung, persistence of drainage beyond 7 days, inability to achieve drainage assessed radiologically, fever without change in 2 to 3 days, or pus formation with persistent infection (as opposed to colonization of the chest tubes) necessitates a search for undrained foci of infection, failure to close a bronchopleural fistula or esophageal tear, undetected rupture of a lung abscess, or antibiotic failure. As the infection enters the *chronic phase,* open drainage with rib resection or pleurocutaneous fistula formation may be needed, with or without decortication, to achieve lung expansion and healing. Open drainage is obtained by making the pleura adherent to the chest wall during the insertion of chest tubes directly into the empyema cavities. Drainage achieved too late in the course of infection may result in the development of pleural scar and fibrous peel with restrictive pulmonary physiology. Decortication may be needed to achieve sterilization of the pleural space and restore lung expansion. Thoracoscopic drainage of empyema has been used with excellent results at a number of institutions, particularly in children. Often, thoracoscopic drainage of empyema is used as a temporizing maneuver (e.g., following acute rupture of a lung abscess into the pleural space). Patients achieving rapid re-expansion of the lungs may avoid open drainage procedures while achieving limited decortication and disruption of loculations. Alternatively, once a patient is stabilized and can better tolerate open drainage, or has demonstrated an inability to resolve the empyema without further drainage, surgical intervention may be needed. Early, aggressive treatment of empyema may reduce the duration of hospitalization and the risk of nosocomial superinfection.

TREATMENT OF LUNG ABSCESS

The treatment of lung abscess must be guided by the microbiology and knowledge of any underlying or associated conditions that may predispose to the development of severe pulmonary infection. A small abscess in an otherwise healthy person may respond to conservative management with antimicrobial therapy and chest physical therapy. A rapidly expanding pulmonary abscess in an immunocompromised host (e.g., due to one of the *Mucoraceae*) requires urgent lung resection in addition to antimicrobials. Intermediate to these approaches is the use of bronchoscopic or radiographically guided catheter drainage of any fluid and necrotic debris. In the absence of antibiotics, the mortality of lung abscess is approximately 33 percent. However, up to half of patients surviving a lung abscess acutely in the pre-antibiotic era had significant pulmonary complications, including recurrent infections and abscesses, pleural empyema and adhesions, chronic bronchitis, and bronchiectasis. The introduction of penicillin, orally or parenterally administered, resulted in resolution or collapse of the abscess in up to 90 percent of patients (although long courses of treatment were often needed). Therefore, these patients could avoid surgical resection.

The role of drainage or surgery is based on serial clinical assessments of the patient. Bronchoscopic drainage may be most useful in the relief of abscesses without air-fluid levels, which indicate the possibility of persistent connection with the bronchi. However, experience dictates *caution* with the bronchoscopic drainage of closed cavities; spillage of cavity contents into other lung segments may produce catastrophic pulmonary dysfunction. Further, there are few data to suggest that bronchoscopic drainage offers a significant advantage in terms of rapidity of recovery in the immunologically normal host. In patients with coexistent empyema and lung abscess, it is often useful to address drainage of the empyema first, stabilizing the patient, and then considering further procedures

for the lung abscess. In critically ill patients, or those with bronchial obstruction related to the abscess cavity, bronchoscopic drainage should be considered.

Bronchoscopy and chest CT have major roles in the evaluation of the patient failing therapy. Persistence of bacteremia or high-grade fevers after 72 h, or the absence of change in sputum production or character or in the radiographic images over 7 to 10 days suggests unappreciated anatomic or microbiologic problems. Obstruction or resistant organisms (including fungi, parasites, or mycobacteria) may be present. Multiple loculations may be present, or empyema, including drainage of the abscess into the pleural space, may develop. New sites of infection, including extrathoracic sites, may have developed in the bacteremic patient. Progression of pulmonary infiltrates may occur after the initiation of appropriate antibiotic therapy, reflecting the relatively poor activity of many antibiotics at the low pH levels of poorly ventilated and underperfused, infected lung tissues, as well as the delayed radiographic response to treatment.

Surgical resection of necrotic segments of lung is helpful if the response to antibiotics is poor, for large abscesses, or ventilation-perfusion scans suggest little residual lung function in a limited necrotic region. Infarcted lung or rapidly progressive infection may force surgical resection of the affected tissue. Surgery is also indicated if airway obstruction limits drainage. Such presentations are seen in the presence of tumor or a foreign body. In patients thought to be poor surgical risks, percutaneous drainage via catheters may be a useful temporizing measure. However, leakage of the abscess contents into the pleural space in such patients may be disastrous and must be avoided.

Mortality in patients with lung abscesses reflects the quality of the host's inflammatory response and overall condition. Patients with large abscesses (over 5–6 cm), progressive pulmonary necrosis, obstructing lesions, aerobic bacteria, immune compromise, old age, or systemic debility, and those with major delays in seeking medical attention have a significantly increased mortality.

Mediastinitis

Mark E. Rupp • Mary L. Ricardo-Dukelow

MEDIASTINITIS

Mediastinitis can be conveniently organized into acute or chronic forms with etiologies, clinical presentations, and treatments that are strikingly different. Acute mediastinitis is a life-threatening infection that is increasingly recognized as a postoperative complication of cardiovascular surgery. Other less common causes of mediastinitis include esophageal perforation and contiguous spread from oropharyngeal foci. Regardless of the route of infection, a high-index of suspicion must be maintained for this clinical entity so that aggressive, potentially life-saving, measures can be promptly initiated.

Chronic mediastinitis, also known as sclerosing mediastinitis, fibrosing mediastinitis, or granulomatous mediastinitis, is a rare disorder that is most often due to *Histoplasma capsulatum.*

Anatomical Considerations

Detailed descriptions of mediastinal anatomy are available; a thorough review of this material is beyond the scope of this chapter. However, a few fundamental points will be emphasized. The mediastinum is the region within the thorax between the pleural sacs (Fig. 123-1). It extends from the diaphragm inferiorly to the superior aperture of the thorax. The 12 thoracic vertebral bodies border the mediastinum posteriorly and the sternum and costal cartilages make up the anterior boundary. The mediastinum is arbitrarily divided into four subdivisions: superior, posterior, anterior, and middle. Structures within the mediastinum include the heart and great vessels, the esophagus, the distal portion of the trachea and mainstem bronchi, vagus and phrenic nerves, the thymic remnant, and the thoracic duct. These structures are surrounded by adipose tissue, loose connective tissue, and lymph nodes. The mediastinum communicates with the structures of the head and neck via several fascial planes and potential spaces (Figs. 123-2 and 123-3). The three major routes by which infection spreads from the head and neck to the mediastinum are (1) the pretracheal space, (2) the long fascial planes of the posterior neck, and (3) the viscerovascular or lateral pharyngeal space. The long fascial planes of the posterior neck extend from the base of the skull to the diaphragm and are made up of the retropharyngeal or retrovisceral space, the prevertebral space, and the danger space. Pearse attempted to delineate the relative importance of each route in the pathogenesis of mediastinitis and found the retropharyngeal space to be involved in 71 percent of cases followed in frequency by the lateral pharyngeal space (21 percent) and the pretracheal space (8 percent). Knowledge of these fascial planes and anatomic relationships helps one to understand the pathogenesis and potential complications of mediastinitis.

ACUTE MEDIASTINITIS

Epidemiology and Pathogenesis

Primary infection of the mediastinum is a rare event. Essentially all cases of mediastinitis are secondary to the spread of infection from other sites or direct inoculation due to trauma

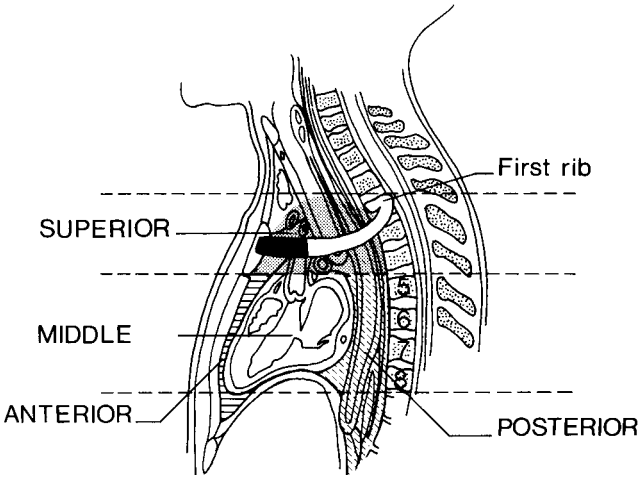

Figure 123-1 Anatomic boundaries and divisions of the mediastinum.

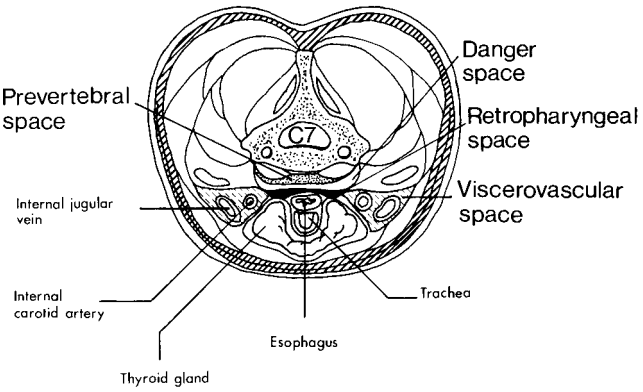

Figure 123-2 Cross-section of the neck at the level of the seventh cervical vertebrae demonstrating the potential spaces for spread of infection from the head and neck into the mediastinum.

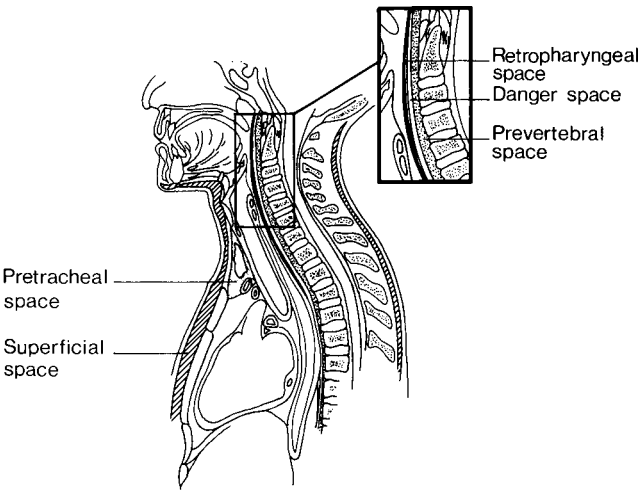

Figure 123-3 Sagittal section of the head and neck showing relationship of the fascial spaces to the mediastinum.

or surgery. The causes of mediastinitis are summarized in Table 123-1 and can be conveniently grouped into the following four categories: cardiothoracic surgery, esophageal perforation, head and neck infection, and infection originating at another site. The pathogenesis, clinical manifestations, and treatment vary with the underlying cause of mediastinitis. These aspects are summarized in Table 123-2.

Mediastinitis Secondary to Cardiothoracic Surgery

Cardiothoracic operations are among the most common surgical procedures performed in larger hospitals. Coronary artery bypass grafting and cardiac valve replacement accounted for 30 percent of the procedures reported between 1992 and 2004 to the Center for Disease Control's National Nosocomial Infection Surveillance System. Because of the large number of median sternotomies that are performed, mediastinitis has predominantly become a postsurgical infection. Numerous studies have documented the incidence of mediastinitis following cardiothoracic surgery and the risk factors for development of this serious complication. In 1984 Sarr et al reviewed the available literature and found the incidence of mediastinitis to range from 0.4 to 5 percent of patients undergoing median sternotomy. Since then studies documenting the experience in over 400,000 patients have been published, with incidence rates ranging from 0.66 to 2.4 percent. The largest study to date was derived from the Society of Thoracic Surgeons National Cardiac Database and involved analysis of over 330,000 coronary artery bypass graft cases performed during 2002 and 2003. Major infection occurred in 11,636 patients (3.51 percent), 25.1 percent of which was attributed to mediastinitis. The incidence of mediastinitis during outbreaks has been as high as 5 to 23.7 percent. Patients undergoing heart transplantation are at higher risk of developing mediastinitis, with frequencies of 2.5 to 7.5 percent. This risk of mediastinitis is further increased if a mechanical device, such as a left ventricular assist device or a total artificial heart, is used to support the patient awaiting a suitable donor heart. The frequency of mediastinitis in this circumstance ranges from 7.5 to 35.7 percent. Patients undergoing heart-lung transplantation appear to be at a roughly twofold greater risk of mediastinitis than those undergoing heart transplantation per se.

A number of factors have been identified as causes for an increase risk of mediastinitis. The studies examining these risk factors are primarily retrospective case-control studies; therefore, they are limited by the problems inherent in retrospective surveys. Risk factors can be divided into the following groups: preoperative, intraoperative, and postoperative (Table 123-3). Preoperative risk factors include diabetes mellitus, obesity, previous sternotomy, chronic obstructive pulmonary disease, cigarette smoking, low-cardiac output states, remote infection, history of endocarditis, method of hair removal, and prolonged preoperative hospitalization. Intraoperative and surgical risk factors include complexity of surgery, type of bone-saw used, type of sternal closure, use of internal mammary arteries in coronary artery bypass

Table 123-1

Causes of Acute Mediastinitis

Esophageal Perforation

Iatrogenic

Esophagogastroduodenoscopy, esophageal dilatation, esophageal variceal sclerotherapy, nasogastric tube, Sengstaken-Blakemore tube, endotracheal intubation, esophageal surgery, paraesophageal surgery

Swallowed Foreign Bodies

Bones, coins, can pull-tabs, drug-filled condoms, swords

Trauma

- Penetrating
  Gunshot wound, knife wound
- Blunt
  Steering wheel injury, seat-belt injury, cardiopulmonary resuscitation, whiplash injury, barotrauma

Spontaneous/Other

Emesis, cricoid pressure during anesthesia induction, heavy lifting, defecation, parturition, carcinoma

Head and Neck Infections

Odontogenic, Ludwig's angina, pharyngitis, tonsillitis, parotitis, epiglottitis

Infection Originating at Another Site

Pneumonia, pleural space infection/empyema, subphrenic abscess, pancreatitis, cellulitis/soft-tissue infection of the chest wall, osteomyelitis of sternum, clavicle, ribs, or vertebrae, hematogenous spread from distant foci

Cardio thoracic Surgery

Coronary artery bypass grafting, cardiac valve replacement, repair of congenital heart defect, heart transplantation, heart-lung transplantation, cardiac assist devices, other types of cardio thoracic surgery

grafting, use of bone wax, prolonged operative time, prolonged time on cardiopulmonary bypass, blood transfusions, indiscriminate use of electrocautery, and antibiotic prophylaxis. Postoperatively, patients at increased risk for mediastinitis require re-exploration to control bleeding, prolonged length of stay in the intensive care unit, mechanical ventilation for more than 24 to 48 hours, need for tracheostomy, use of cardiopulmonary resuscitation, and low cardiac-output states. However, agreement regarding these risk factors is not universal and their relative importance is undefined. For instance, even after three decades of surgical experience, it is unclear whether the use of internal mammary artery (IMA) grafts in coronary artery bypass surgery predisposes patients to mediastinitis. In 1972, based upon anatomical studies of sternal blood supply, Arnold suggested that the use of the IMA in coronary artery bypass procedures might lead to significant sternal ischemia and thus predispose patients to sternal osteomyelitis and mediastinitis. This suggestion has been supported by several laboratory and clinical studies. However, other investigators have not observed a significant increase in sternal wound infections in patients undergoing coronary artery bypass grafting when the IMA is used.

It is generally believed that the pathogenesis of postcardiac surgery mediastinitis is primarily due to the inoculation into the operative wound of organisms from the patient's endogenous bacterial flora or from the surgical field. Bacteria are able to propagate in the relatively protected avascular area of the surgical wound and cause infection. Therefore, a number of the putative risk factors are attractive intuitively, such as the duration of the surgery, the complexity of the surgery, and the need for re-exploration. In addition, outbreaks of mediastinitis have been linked epidemiologically to sources such as bacteria from a particular surgeon's hands or nares, lending support to the belief that intraoperative factors are important in the pathogenesis of mediastinitis. Following changes in the environment of the operating room, Ferrazzi et al observed a significant decrease in the incidence of gram-negative mediastinitis, without a significant change in the frequency of gram-positive infections. This observation supported the belief that many of these infections arise from gram-positive organisms resident on the patient's skin. Archer et al has demonstrated that patients are colonized by small numbers of antibiotic-resistant, coagulase-negative staphylococci which become the predominant species when subjected to the selective pressure of prophylactic antibiotics. In addition, various immunosuppressive effects of cardiopulmonary bypass have been elucidated that may contribute to the pathogenesis of mediastinitis after surgery.

The importance of postoperative factors has also been emphasized by outbreaks of mediastinitis which have been linked to environmental sources, including contaminated tap water and poor hand-washing technique in the postoperative care of cardiac surgery patients. However, Kaiser has warned persuasively against taking a "make-a-change-and-see-what-happens" approach to the analysis of risk factors related to the pathogenesis of postoperative infection. Controlled prospective studies are needed to improve the identification of factors that influence postcardiac surgery mediastinitis.

Table 123-2

Summary of Acute Mediastinitis

	Cardiovascular Surgery	Head and Neck Infection	Esophageal Perforation
Pathogenesis	Intraoperative wound contamination	Oral infection that extends to involve sublingual and submandibular spaces with spread through fascial planes of the neck into mediastinum	Inoculation of flora into mediastinum secondary to esophageal perforation
Clinical Presentation	Fever, chills, sternal instability, sternal wound drainage	Pain, fever, local signs and symptoms of infection	Pain, dysphagia, respiratory distress
Most Common Microbial Etiology	Gram-positive cocci: *saureus* (methicillin-sensitive or resistant), Coagulase-negative *Staphylococcus*, Streptococci, Gram-negative bacilli	Oral flora: Streptococcus *viridans*, peptococci, peptostreptococci, *Bacteroides sp, Fusobacterium*, Gram-negative bacilli	Similar to microbiology of head and neck infections
Risk Factors	Cardiac assist-device Low-cardiac output Prior heart surgery Length of surgery Co-morbid conditions Obesity Method of hair removal Prolonged preoperative hospitalization Poor hemostasis Hyperglycemia COPD Smoking	Conditions predisposing to dental infections or other head and neck infections: poor dentition, parotid stone, recurrent tonsillitis	Conditions predisposing to esophageal perforation: esophageal tumor, endoscopy, swallowed foreign body
Laboratory Testing and Findings	Leukocytosis Blood cultures (bacteremia observed in more than one-half of cases)	Leukocytosis Microbiologic cultures using anaerobic techniques	Leukocytosis Microbiologic cultures using anaerobic techniques
Radiologic Diagnosis	CT chest localized mediastinal fluid, pneumomediastinum	CT head and neck CT chest	Contrast esophagography, CT neck and chest
Surgical Treatment	Surgical debridement required Vacuum-assisted closure	Prompt surgical intervention when descending odontogenic or pharyngeal infection is observed	Prompt surgical intervention with drainage, debridement, and repair
Antibiotic Treatment	Initial broad-spectrum coverage, include vancomycin (or other anti-MRSA agent) if MRSA is likely; adjust antibiotics according to microbiologic data	Initial antibiotic coverage for oral flora including *Bacteroides sp*; pencillin G + metronidazole, clindamycin, or broad-spectrum β-lactam/β-lactamase inhibitor	Similar to antibiotic choice for head and neck infection

COPD, chronic obstructive pulmonary disease; CT, computed tomography; MRSA, methicillin-resistant S. aureus.

Table 123-3

Risk Factors for Mediastinitis

Preoperative	Preoperative New York Heart Association physiologic class ≥III Preoperative hyperglycemia Presence of one or more co-morbid conditions (pulmonary, hepatic, gastrointestinal, or malignant disease processes) Diabetes mellitus Obesity Previous sternotomy Chronic obstructive pulmonary disease (COPD) Cigarette smoking Remote infection History of endocarditis Method of hair removal Prolonged preoperative hospitalization
Intraoperative	Poor hemostasis at the time of closure Complexity of surgery Type of bone saw used Type of sternal closure Use of internal mammary arteries in coronary artery bypass grafting Use of bone wax Prolonged operative time Prolonged time on cardiopulmonary bypass Blood transfusion Indiscriminate use of electrocautery Inappropriate antibiotic prophylaxis Avoidance of staple use
Postoperative	Re-exploration to control bleeding Prolonged length of stay in the intensive care unit Mechanical ventilation >24–48 h Need for tracheostomy Use of cardiopulmonary resuscitation Low cardiac-output states Use of contaminated tap water to remove Betadine following cardiac surgery

Mediastinitis Secondary to Esophageal Perforation

Prior to the development of cardiac surgery, perforation of the esophagus was the leading cause of mediastinitis, followed by suppurative infections of the oropharynx. In 1724 Herman Boerhaave graphically described the first case of mediastinitis due to spontaneous rupture of the esophagus in a Dutch admiral who died 18.5 hours after self-induced emesis. Since then this entity has been known as Boerhaave's syndrome. Currently, esophageal perforation is most frequently due to iatrogenic etiologies. Flexible fiberoptic endoscopy of the upper-gastrointestinal tract is complicated by esophageal perforation in 0.074 to 0.4 percent of the procedures. The frequency of complication increases when sclerotherapy or dilatation procedures are performed. Swallowed foreign bodies, esophageal carcinoma, and nonsurgical trauma may also cause perforation of the esophagus and mediastinitis.

Depending on the site of the esophageal perforation, mediastinitis may result from migration into the mediastinum via the fascial planes of the neck or from direct spillage of esophageal contents into the posterior mediastinum. A necrotizing chemical mediastinitis ensues, followed by an aerobic and anaerobic bacterial mediastinitis. Often a synergistic necrotizing form of mediastinitis occurs. Spread of infection from the neck into the mediastinum is influenced by respiratory dynamics by which the negative intrathoracic pressure generated during respiration tends to force the infection into the mediastinum.

Mediastinitis Secondary to Head and Neck Infection or from Other Sites

Before antibiotics were widely available odontogenic and pharyngeal infections caused between 10 to 31 percent of cases of mediastinitis. Fortunately, these infections have currently become a rare cause of mediastinitis. The prototypic odontogenic infection leading to mediastinitis is Ludwig's angina which usually stems from an infection of the second or third mandibular molar to involve the sublingual and submandibular spaces. From these spaces, the infection can spread via the lateral pharyngeal space to involve the retropharyngeal space or carotid sheath and thus track into the mediastinum. During the antibiotic era approximately 3.5 percent of Ludwig's angina cases have been complicated by mediastinitis. Mediastinitis resulting from infections which involve the lateral pharyngeal space may originate from a number of sources including the teeth, parotid glands, tonsils, or, rarely, from otitis or mastoiditis. Infections of the retropharyngeal space generally arise from perforation of the esophagus or by extension from pharyngitis, epiglottitis, or tonsillitis. From the long fascial planes of the neck, these infections spread readily into the superior mediastinum, or, if the danger space is involved, the posterior mediastinum. The pretracheal space descends into the anterior mediastinum and most often is involved in mediastinitis, which complicates surgery of the thyroid or trachea. Rarely is mediastinitis due to spread from other sites. Instances have been described secondary to the following conditions: pneumonia, pleural space infection, osteomyelitis of the ribs, clavicle, sternum or vertebrae, subphrenic abscess, pancreatitis, cellulitis, and hematogenous seeding from distant foci.

Bacteriology

The bacteriology of mediastinitis complicating cardiovascular surgery is strikingly different from mediastinitis secondary to odontogenic or other head and neck infections (Table 123-4). Mediastinitis secondary to cardiothoracic

Table 123-4

Microbiology of Mediastinitis

Organisms Frequently Recovered in Mediastinitis Secondary to Infection of the Head and Neck or Esophageal Perforation

Anaerobic
- Gram-positive cocci
  - *Peptococcus* spp.
  - *Peptostreptococcus* spp.
- Gram-positive bacilli
  - *Actinomyces*
  - *Eubacterium*
  - *Lactobacillus*
- Gram-negative cocci
  - *Veillonella*
- Gram-negative bacilli
  - *Bacteroides* spp.
  - *Fusobacterium* spp.

Aerobic or Facultative
- Gram-positive cocci
  - *Streptococcal* spp.
  - *Staphylococci* spp.
- Gram-positive bacilli
  - *Corynebacterium*
- Gram-negative cocci
  - *Branhamella*
- Gram-negative bacilli
  - *Enterobacteriaceae*
  - *Pseudomonas* spp.
  - *E. corodans*
- Fungi
  - *C. albicans*

Organisms Frequently Recovered in Mediastinitis Secondary to Cardiothoracic Surgery

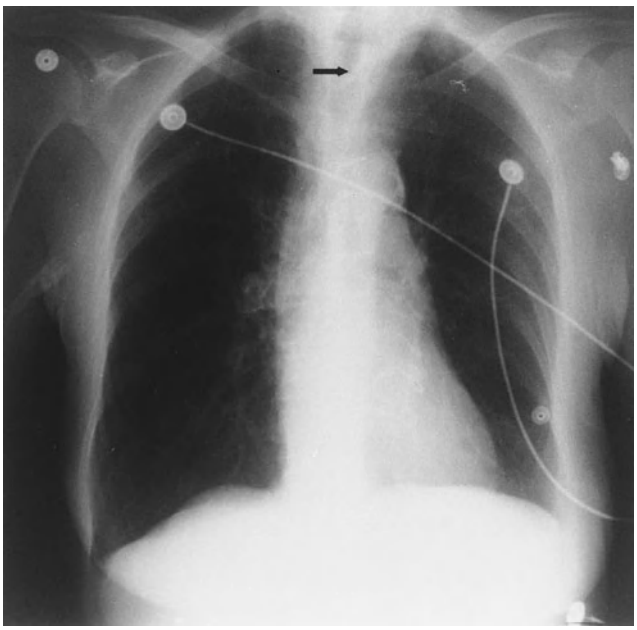
Organism	Range	Representative Rate
Gram-positive cocci		
S. aureus	7.1%–66.7%	25%
S. epidermidis	6%–45.5%	30%
Enterococcus spp.	8%–18.8%	10%
Streptococci spp.	0%–18.2%	2%
Gram-Negative Bacilli		
E. coli	0%–12.5%	5%
Enterobacter spp.	4%–21.4%	10%
Klebsiella spp.	0%–21.1%	3%
Proteus spp.	0%–7.1%	2%
Other		
Enterobacteriaceae	0%–20%	2%
Pseudomonas spp.	0%–54%	2%
Fungi		
C. albicans	0%–14.3%	<2%
Polymicrobial	0%–40%	10%
Other Occasionally Reported:		
Acinetobacter, Legionella spp. *B. fragilis, C. tropicalis, Nocardia* spp. *Kluyvera, M. fortuitum, M. chelonei, R. bronchialis*		

Other Unusual Causes of Mediastinitis:
Anthrax, brucellosis, actinomycoses, paragonimiasis

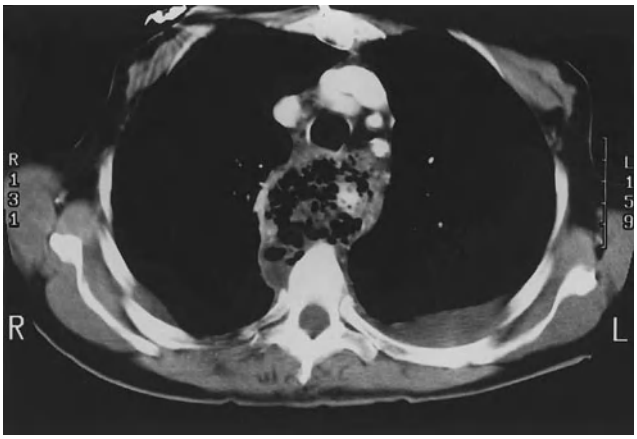
surgery is predominantly due to gram-positive cocci and less often by gram-negative bacilli. A recent review of 316 consecutive patients with mediastinitis that occurred in fewer than 30 days after sternotomy revealed the most common causative microorganisms to be methicillin-susceptible *Staphylococcus aureus* (45 percent), methicillin-resistant *S. aureus* (16 percent), gram-negative bacilli (17 percent), coagulase-negative staphylococci (13 percent), and streptococci (5 percent). A case-control study examined whether risk factors for specific pathogens could be identified. Multivariate analysis revealed that diabetes, female gender, and age greater than 70 years were associated with infection due to methicillin-resistant *S. aureus*, whereas obesity was the only independent risk factor associated with infection due to methicillin-susceptible *S. aureus*. The bacteriology of mediastinitis secondary to extension from head and neck sources is somewhat more complicated. The majority of these infections is polymicrobic. Often a synergistic infection made up of a number of oral anaerobes and gram-negative bacilli is evident. The most frequently isolated organisms include viridans streptococci, peptococci, peptostreptococci, *Bacteroides* spp., and *Fusobacterium*. The relative frequency with which these organisms are isolated is difficult to determine due to the difficulty of obtaining reliable anaerobic culture data.

Clinical Manifestations and Diagnosis

The clinical manifestations of mediastinitis also differ based on the underlying cause of disease. Patients who experience mediastinitis from extension of odontogenic or pharyngeal infections usually have obvious primary infections with significant pain, fever, and swelling of the affected site. Esophageal perforation may be clinically obvious or inapparent. Early in the course of mediastinitis, signs and symptoms may be subtle, but as the condition progresses, patients note increasing chest pain, respiratory distress, and dysphagia. Chest pain is often the most prominent symptom and may localize depending on the portion of the mediastinum involved. In anterior mediastinitis, pain is often located in the cervical or substernal region. Pain due to posterior mediastinitis may localize to the epigastric area with radiation to the interscapular region. Pleuritic chest pain may also be experienced due to pleural effusion, a relatively frequent complication. Retroperitoneal extension may be accompanied by acute abdominal signs and may prompt needless exploratory laparotomy. Examination may reveal fever, tachycardia, crepitus, and edema of the chest or neck. "Hamman's sign", a crunching rasping sound heard over the precordium synchronous with the cardiac rhythm, due to emphysema of the mediastinum, may be audible in up to 50 percent of patients with pneumomediastinum. The heart sounds may be distant and dull. In the later stages of mediastinitis, signs of bacteremia and sepsis may predominate. The early diagnosis of mediastinitis in the infant or neonate may be particularly challenging. A peculiar, interrupted, staccato type of inspiration has been described in a number of patients. The signs and symptoms of mediastinitis in older children are similar to those in adults.



A



B

Figure 123-4 *A*. Chest radiograph of elderly woman with esophageal perforation and mediastinitis. The patient had senile dementia and had unknowingly swallowed a portion of a broken glass jar resulting in esophageal perforation. The chest radiograph reveals a foreign body within the esophagus (arrow) and widening of the mediastinum. *B*. Computed tomography of the chest at the level of the sixth thoracic vertebrae demonstrating a large abscess within the posterior mediastinum and a left-sided pleural effusion. *(Radiographs courtesy of Dr. J. Gurney, University of Nebraska Medical Center.)*

Laboratory tests usually reveal a leukocytosis with a leftward shift evident on the differential blood count. Radiographically, plain films of the chest may reveal mediastinal widening, air-fluid levels, and subcutaneous or mediastinal emphysema. A lateral chest radiograph may be useful in demonstrating superior mediastinal gas not evident on upright films. In about 50 percent of instances of pneumomediastinum lateral views are required to establish the diagnosis. Examples of some of the radiographic manifestations of mediastinitis are shown in Figs. 123-4 and 123-5. Complications of mediastinitis, such as pleural effusion or

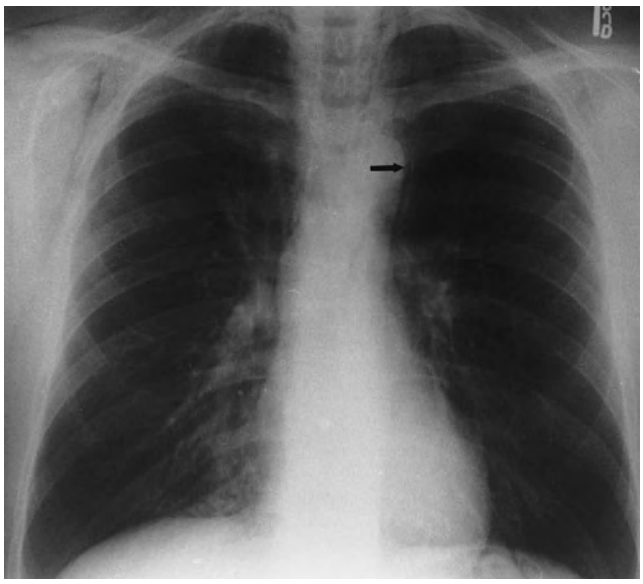


Figure 123-5 Chest radiograph demonstrating pneumomediastinum (arrow). *(Radiograph courtesy of Dr. J. Gurney, University of Nebraska Medical Center.)*

pneumoperitoneum, may also be evident on the chest radiograph. Esophageal perforation is best demonstrated by contrast esophagography which reveals extravasation of dye in 59 to 100 percent of cases. It is recommended that a water-soluble contrast agent be used initially to detect gross extravasation due to the inflammation and granuloma formation evoked by barium. If extravasation is not observed, barium should be used to detect subtle defects, since it provides better definition of the anatomy. Computed tomography (CT) is often helpful for patients in whom the diagnosis is not evident either clinically or on plain films. Technetium-labeled white blood cell scans are reported to be helpful in the diagnosis of mediastinitis in special circumstances when CT scan is not readily available. The role of magnetic resonance imaging (MRI) in the evaluation of mediastinitis is not well-established.

Postcardiothoracic surgery mediastinitis usually becomes evident clinically within the first 2 weeks following surgery. However, rare instances have been described that presented more than 1 year postoperatively. Infections due to gram-negative organisms generally present earlier. One study found that all cases of mediastinitis that presented more than 2 weeks postoperatively were due to gram-positive organisms.

The presentation of mediastinitis may be fulminant or subtle. Some patients may present with sepsis without localizing signs. Some patients may experience more than normal postoperative pain which may be pleuritic in nature. Dysphagia is a rare complaint. Fever and an abnormal appearance of the surgical wound, characterized by erythema, cellulitis, or purulent discharge, are the most frequent signs of mediastinitis. Sternal instability, dehiscence, or bubbles emanating from the sternal wound are less frequent. Occasionally emphysema of the chest wall occurs.

Post-sternotomy mediastinitis presenting as a deep neck abscess without abnormal findings on examinations of the chest has been reported. Laboratory tests usually show a

Figure 123-6 Chest radiograph of patient with mediastinitis following cardiac surgery. Dehiscence of median sternotomy is demonstrated by asymmetry of sternal wires. *(Radiograph courtesy of Dr. J. Gurney, University of Nebraska Medical Center.)*

moderate leukocytosis with a leftward shift of the white blood cell differential. Radiographically, mediastinal widening is a rare finding on plain chest films and routine radiographs are usually of very little use for the diagnosis of mediastinitis following cardiothoracic surgery (Fig. 123-6). CT scanning has proved to be helpful in many instances of postoperative mediastinitis, particularly in differentiating superficial wound infections from deeper retrosternal processes. However, normal postoperative collections of fluid and gas are at times difficult to differentiate from early signs of mediastinitis.

The diagnostic value of nuclear scans has been espoused by several investigators. Browdie et al evaluated the relative value of CT, indium-111 (^{111}In)–labeled leukocyte scanning, and epicardial pacer wire cultures in 24 patients undergoing evaluation for possible mediastinitis. They found that CT had a sensitivity of 67 percent and specificity of 71 percent, ^{111}In–labeled leukocyte scan was 83 percent sensitive and 100 percent specific; and epicardial pacer wire cultures were reported to be 100 percent sensitive and 92 percent specific. However, another investigator found that epicardial pacer wire cultures were associated with an unacceptably high false-positive rate. The role of MRI is not well-defined; it is contraindicated in instances in which ferromagnetic metals are used in sternal wires, artificial heart valves, cardiac pacemakers, or vascular clips. Several investigators have found that mediastinal needle aspiration is useful for the diagnosis of mediastinitis. This method, which has been reported to be positive in 65.8 percent of patients, appears to be particularly useful in diagnosing mediastinitis before it becomes more clinically obvious.

Treatment

Treatment that includes both medical and surgical techniques should be promptly initiated once the diagnosis of mediastinitis is made. In all cases aggressive supportive and nutritional therapy is required. Barrett is credited with documenting in 1946 the first successful treatment of mediastinitis due to esophageal perforation. Since then, most experts recommend aggressive surgical drainage, debridement, and repair in patients with mediastinitis secondary to esophageal perforation. However, based on experience with eight patients, Cameron et al identified a subset of patients that could be treated without surgical intervention. These patients will have a well-contained disruption of the esophagus, the abscess should drain back into the esophagus, minimal symptoms are present, and there should be minimal evidence of clinical toxicity. Shaffer et al expanded upon these recommendations based on the patients with esophageal perforation due to instrumentation detected before major mediastinal contamination. Santos et al have recommended transesophageal irrigation for patients in whom primary repair of the esophagus is not possible due to advanced local infection with extensive tissue necrosis.

As in patients with mediastinitis due to esophageal perforation, patients in whom the mediastinitis is secondary to descending odontogenic or pharyngeal infection require prompt surgical intervention. Because transcervical drainage is frequently inadequate, a transthoracic approach is generally necessary.

Although the importance of supportive therapy and surgical intervention cannot be overemphasized, administration of appropriate antibiotics is also an essential component of therapy. Empirical regimens are based upon the underlying etiology and should deal with the major pathogens listed in Table 123-4. Penicillin G has traditionally been the antibiotic of choice in the treatment of anaerobic infections that originate above the diaphragm and continues to exhibit excellent activity against most oral anaerobic bacteria. Unfortunately, oral *Bacteroides* spp. are increasingly resistant to penicillin G. Therefore, when infection with *Bacteroides* is suspected, treatment with metronidazole, clindamycin, or broad spectrum β-lactam/β-lactamase inhibitor antibiotics with activity against *Bacteroides* spp., as well as other oropharyngeal anaerobes, may be indicated. In addition, gram-negative enteric bacilli are often implicated in mediastinitis and should be taken into account in the initial empiric therapy. Antibiotic therapy should then be more specifically tailored to the infecting organisms when definitive culture results are available, but treatment directed against anaerobic oropharyngeal organisms should probably be continued due to the difficulty in obtaining reliable anaerobic cultures. Duration of therapy, which may range from weeks to months, is determined by the virulence of the bacteria, host factors, and the patient's response to therapy.

The treatment of postcardiac surgery mediastinitis generally requires aggressive surgical drainage and debridement. A small number of patients have been successfully treated via percutaneous catheter drainage. Two approaches have been used in the surgical management of postcardiac surgery mediastinitis—an open technique and a closed technique. The open technique involves debridement of infected tissue

and open packing of the wound with delayed closure. Disadvantages of this technique include respiratory insufficiency due to lack of mechanical support for the thorax, delayed healing and closure of the surgical wound, and hemorrhage from exposed vessels. The closed method involves debridement of affected tissues, closure of the sternum, and postoperative irrigation through drainage tubes within the mediastinum. Irrigants have included a variety of antimicrobial and antiseptic solutions, such as neomycin, gentamicin, bacitracin, polymyxin B, saline, and Dakin's solution. The use of irrigants has been associated with a variety of complications including emergence of resistant organisms, pericardial and tissue toxicity, and systemic absorption and toxicity. The most commonly employed irrigant is povidone-iodine. Use of povidone-iodine has been associated with iodine toxicity, renal failure, metabolic acidosis, and seizures. Therefore, this agent must be used with caution, and it has been recommended that serum iodide concentrations be measured to insure that toxic levels are not reached. Durandy et al reported a closed technique that successfully used Redon drainage devices in 11 patients who did not require postoperative irrigation. A number of investigators have reported the successful use of muscle flaps and omental grafts in many instances at the time of initial debridement to close mediastinal wounds, with or without postoperative irrigation. Fuchs et al suggest that vacuum-assisted closure (VAC) is a promising new method for the therapy of mediastinitis. A retrospective analysis of 68 cases that compared VAC to conventional therapy with open packing revealed earlier microbiologic cure, more rapid decline in C-reactive protein, shortened hospital stay, earlier rewiring, and higher survival in the VAC group.

The use of parenteral antibiotics has remained a cornerstone of therapy. Generally, empiric therapy should be directed at staphylococci and gram-negative aerobic bacilli until definitive culture results become available. As with mediastinitis secondary to infection of the head and neck, the duration of therapy is determined by multiple factors and may be quite prolonged.

Antibiotic Prophylaxis

Although cardiothoracic surgical procedures are categorized as clean procedures, and the risk of infection is low, the consequences of infection are devastating. Therefore, despite the lack of placebo-controlled studies documenting efficacy, antibiotic prophylaxis has become commonplace. Cefazolin has generally been regarded as the drug of choice for prophylaxis. The use of vancomycin or second-generation cephalosporins, such as cefamandole and cefuroxime, has also been considered. Studies regarding the relative efficacy of first- and second-generation cephalosporins are conflicting, and no agent has conclusively been shown to be superior to another. In a comparison between vancomycin, cefazolin, and cefamandole, Maki et al demonstrated a significant reduction in postoperative wound infection in patients receiving vancomycin prophylaxis. Vancomycin should be considered as a choice for prophylaxis in centers with a high frequency of infections due to methicillin-resistant staphylococci. The major disadvantages associated with the use of vancomycin are the long infusion time and the small number of patients who experience adverse events, such as hypotension and "red man syndrome". In addition, the emergence of vancomycin-resistant enterococci and staphylococci, due in part to the inappropriate overuse of vancomycin, must be considered as a long-term disadvantage to the use of vancomycin as a prophylactic agent.

Complications and Prognosis

Complications of mediastinitis include extension of the infection into a number of contiguous structures and spaces including the pericardial space, resulting in pericardial effusion and tamponade, the pleural space, and the peritoneum, resulting in peritonitis. A major complication of postcardiac surgery mediastinitis is sternal osteomyelitis. Prior to the development of modern surgery and antibiotics, mediastinitis, due primarily to esophageal perforation, was regarded as uniformly fatal. Unfortunately, since the time of Barrett's first successful surgical repair of the esophagus, morbidity and mortality have remained high, with many studies recording mortality rates of 30 to 50 percent. Survivors of mediastinitis usually have no permanent sequela. In examining the economic ramifications of mediastinitis, Loop et al found that the hospital charges for coronary artery bypass surgery patients who experience mediastinitis were 280 percent greater than patients with uncomplicated bypass surgery, and the median length of stay ranged from 38 to 51 days. The most important factor in determining outcome has been the length of time to diagnosis and initiation of definitive therapy. Other prognostic indicators have included blood urea nitrogen, white blood cell count, culture positivity, type of surgical repair, and cytomegalovirus shedding.

CHRONIC MEDIASTINITIS

Sclerosing, fibrosing, or *granulomatous mediastinitis* are terms for a chronic form of mediastinitis characterized by an invasive and compressive inflammatory infiltrate as summarized in Table 123-5. The first report of this entity, which may cause up to 10 percent of all primary mediastinal masses, reportedly dates to a description by Ulmont in 1855. Although the etiology of up to 83 percent of patients with sclerosing mediastinitis remains obscure, many experts believe that most instances are secondary to infection with *H. capsulatum.* With careful analysis, up to 73 percent of patients previously characterized as nonspecific granulomatous mediastinitis can be reclassified as secondary to *H. capsulatum* by re-staining the tissue with fungal stains and thorough review of the pathological sections. Other infectious etiologies that have been reported to cause this condition include tuberculosis, actinomycoses, nocardiosis, blastomycosis, coccidioidomycosis,

Table 123-5

Summary of Chronic Mediastinitis

Pathogenesis	Lungs provide portal of entry, indolent/progressive inflammatory infiltrate
Clinical Presentation	Usually asymptomatic Mediastinal mass Superior vena cava syndrome Pulmonary venous obstruction (cough, dyspnea, hemoptysis)
Most Common Microbial Etiology	*H. capsulatum*
Laboratory Diagnosis	Histopathology of tissue Granuloma, lymphohistiocytic aggregates, diffuse mononuclear infiltrates Fungal cultures, *Histoplasma* urinary antigen
Radiologic Diagnosis	Chest radiograph Mediastinal lymphadenopathy, bronchial narrowing, pulmonary artery narrowing, superior vena cava narrowing, infiltrate with or without calcification
Surgical Treatment	Early surgical intervention may prevent end-stage fibrosis, stent placement for pulmonary artery or venous compression, Palmaz stents for superior vena cava syndrome
Antimicrobial Treatment	Usually not indicated

aspergillosis, and infection with *Rhizopus* spp. Older literature often lists syphilis as a prominent cause of granulomatous mediastinitis. However, this was based upon seropositivity without other supporting evidence. Other conditions that closely mimic this entity include sarcoidosis, silicosis, lymphoma, mesothelioma, and mediastinal fibrosis associated with radiation therapy, idiopathic retroperitoneal fibrosis, Reidel's struma, or sclerosing cholangitis.

Approximately 40 percent of patients with sclerosing mediastinitis are asymptomatic and come to medical attention when a chest roentgenogram incidentally reveals a mediastinal mass. Symptomatic patients usually note symptoms related to invasion or obstruction of structures within or adjacent to the mediastinum. Sclerosing mediastinitis is the most common nonmalignant cause of superior vena cava syndrome and is responsible for up to 23 percent of cases. These patients generally present with plethora and edema of the face, neck and upper torso, neck vein distention, headache, and visual disturbances. Patients with obstruction of the pulmonary arteries often present with cough, dyspnea, and symptoms consistent with right-sided heart failure. Pulmonary infarction, although rare, has been reported to occur in patients with sclerosing mediastinitis. Pulmonary venous obstruction causes patients to experience cough, dyspnea, and hemoptysis. Patients with airway obstruction due to sclerosing mediastinitis usually present with wheezing, cough, hemoptysis, and recurrent episodes of bacterial bronchitis or pneumonia. Patients complaining of dysphagia may have esophageal obstruction due to posterior extension of the mediastinitis.

Sherrick et al reviewed the radiographic findings in 33 patients with sclerosing mediastinitis. The findings included bronchial narrowing (33 percent), pulmonary artery narrowing (18 percent), esophageal narrowing (9 percent), and superior vena cava narrowing (39 percent). Two distinctly different patterns of pulmonary infiltration were noted: localized with calcification (82 percent) and diffuse without calcification (18 percent). The authors believed that the localized pattern was most often secondary to histoplasmosis while the diffuse pattern was more likely to be due to a noninfectious etiology. Patients with sclerosing mediastinitis often have a mediastinal mass, most frequently located in the superior mediastinum at the level of the bifurcation of the trachea. CT frequently reveals calcification and delineates the extent of infiltration whereas MRI is superior for the assessment of vascular integrity. Ventilation-perfusion lung scans often reveal large perfusion defects due to obstruction of the pulmonary vessels.

The diagnosis of sclerosing mediastinitis requires pathological examination. The histological appearance is a

continuum which ranges from a predominantly granulomatous entity to an almost completely fibrosing process. The lesions include caseating granuloma, dense hyalinized collagenous tissue, and infiltrations of lymphocytes, plasma cells, and giant cells. Specific stains for fungi often reveal organisms consistent with *Histoplasma*, but cultures are usually negative.

The pathological features of this disease suggest a marked inflammatory reaction. Several different mechanisms have been proposed to explain the pathology of fibrosing mediastinitis. Some investigators believe that a caseous lymph node from primary infection with *Histoplasma* ruptures into the mediastinum evoking an intense inflammatory reaction. A second hypothesis invokes the development of a delayed hypersensitivity reaction due to the spread of soluble *Histoplasma* antigens into the mediastinum. Another explanation proposes that fibrosing mediastinitis represents an abnormality of collagen production and organization similar to idiopathic retroperitoneal fibrosis or Riedel's struma. Noguchi et al have implicated the eosinophil in the pathogenesis of fibrosing mediastinitis by demonstrating eosinophils or major basic protein in tissue specimens from five of seven patients with fibrosing mediastinitis.

No controlled trials of medical or surgical therapy have been conducted for the treatment of fibrosing mediastinitis. Although there is some anecdotal evidence of a beneficial effect of antifungal agents, most experts believe that there is little evidence of an active infection at the time of presentation and that antifungal agents are not indicated. Because the natural history of this disease is variable, with some patients progressing to compression of vital structures whereas others seem to have self-limited disease, it is difficult to make recommendations regarding the timing of surgical intervention. It has been suggested that early surgical intervention and removal of granulomatous tissue may prevent the development of subsequent end-stage fibrosis and involvement of vital structures. Clearly, patients experiencing obstruction or invasion of mediastinal structures require intervention, even though such surgery is often difficult and results are at times less than optimal. The superior vena cava syndrome, due to fibrosing mediastinitis, has been successfully alleviated through use of Palmaz stents. Therapy with corticosteroids does not appear to have a role in the treatment of fibrosing mediastinitis.

Microbiology and Infection in Cystic Fibrosis

Scott H. Donaldson • Richard C. Boucher

Cystic fibrosis (CF) was first described as a unique disease entity in 1938. Patients typically presented with intestinal obstruction or malnutrition and died from overwhelming pneumonia within the first year of life. Postmortem studies revealed that CF was a multisystem disease characterized by mucous obstruction of pancreatic ducts, airways, and the gut early in life. Over the last 40 years, the median survival with CF has increased dramatically from 6 years in 1955 to 36 years in 2005. The improvement in CF outcomes has paralleled advances in antibiotic therapies, nutritional approaches, and the collection of clinical expertise into specialized treatment centers. These have been summarized by Voynow elsewhere in this volume. As CF patients survive longer, lung disease characterized by polymicrobial infection and progressive antimicrobial resistance have become prominent in patient management. Further, a multitude of pulmonary and non-respiratory complications are encountered. The pathogenesis and treatment of these issues are reviewed here.

DIAGNOSIS

The diagnosis of CF requires either detection of two disease-causing mutations in the CFTR gene, or a combination of a compatible phenotype with evidence for CFTR dysfunction. CFTR genotyping is usually restricted to the most common mutations in a given population, and is reviewed elsewhere. To date, more than 1500 individual CFTR mutations have been identified and are grouped into one of five classes based upon the effect that the mutation has on the resulting CFTR protein (Fig. 124-1).

PATHOGENESIS OF INFECTION

CFTR and Epithelial Transport

The CFTR gene encodes a cAMP-regulated chloride channel that appears to regulate other ion channels as well, including

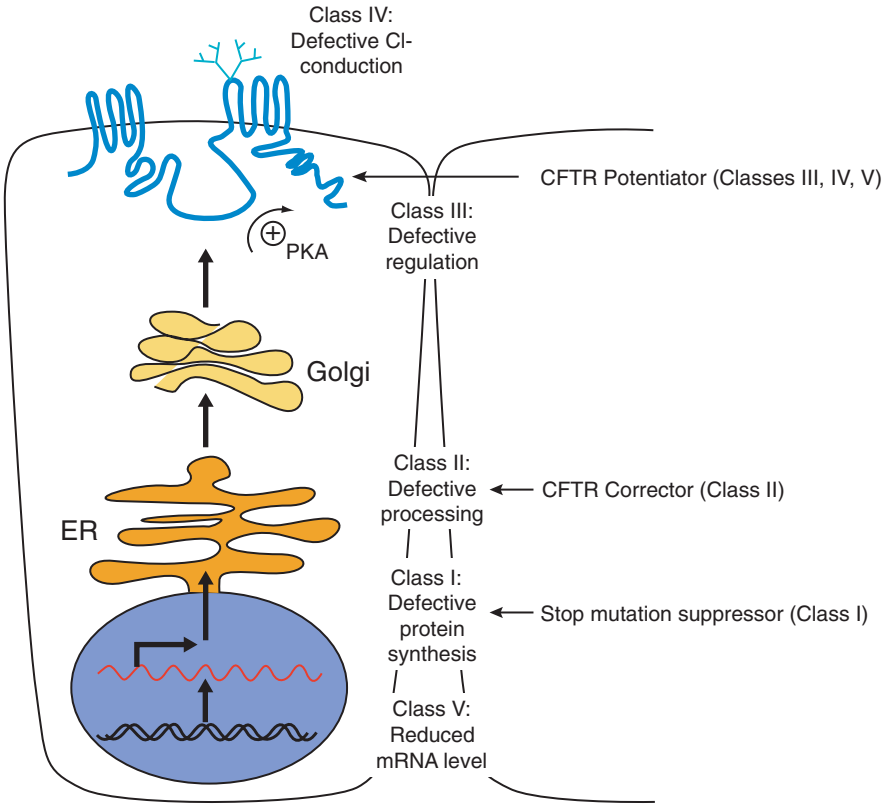

Figure 124-1 CFTR mutation classes. CFTR mutations are grouped into five classes, each characterized by a different problem in CFTR synthesis, maturation, regulation, or function as an ion channel. As shown, new therapies are being developed to target specific classes of CFTR mutations.

the epithelial sodium channel (ENaC) and calcium-activated chloride channel (CaCC). Therefore, CFTR plays a central role in the regulation of ion transport across airway epithelia. In CF, dysregulation of airway surface liquid (ASL) volume occurs as a consequence of ion transport dysfunction, which in turn impairs mucociliary clearance and, therefore, lung defense.

Airway Surface Liquid Regulation in Normal and CF Airways

Airway surfaces are coated with a thin layer of liquid, the ASL, which is composed of a periciliary layer (PCL) and a more viscous mucus layer. The mucus layer, which normally floats on top of the PCL, efficiently traps inhaled pathogens and particulates. The underlying PCL layer, in turn, provides a low viscosity environment in which cilia can beat freely and thereby propel the mucus layer toward the mouth. The PCL also acts as a lubricant layer that prevents adhesion of the mucus layer to cell surfaces. Therefore, proper regulation of ASL volume and the hydration of its component layers are critical to the maintenance of mucus clearance. Whereas an adequate PCL height is necessary to allow ciliary beating, adequate hydration of the mucus layer is a key determinant of its viscoelastic properties and transportability.

When considering the geometry and function of airways, it is clear that ASL volume must be regulated carefully. A gross excess of ASL volume would block small airway lumens, and thereby interfere with gas exchange, whereas even modest reductions in ASL volume may not be adequate to support mucus transport, as described. Therefore, the ability to add or subtract ASL volume is an important airway epithelial function that is carried out by active chloride secretion (in part via CFTR) and sodium absorption (via ENaC), respectively (Fig. 124-2 *A*). Normal airway epithelia blend these

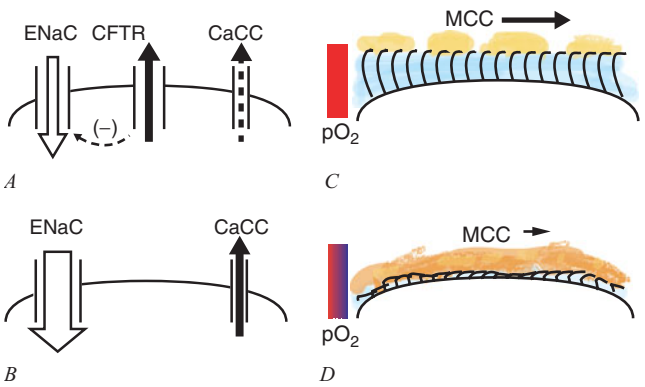

Figure 124-2 Relationship between ion transport and mucociliary clearance in normal and CF airways. *A*. In normal airway epithelia, CFTR and ENaC channels provide the pathways for coordinated chloride secretion and sodium absorption. The calcium-activated chloride channel (CaCC) is an important reserve pathway for additional chloride secretion. *B*. In CF, CFTR mediated chloride secretion is absent, as is the inhibitory effect this channel normally exerts over the ENaC. Preserved chloride secretion via CaCC partially compensates for the absence of CFTR. *C*. The normal airway epithelium maintains an adequate height of periciliary liquid, hydrates the overlying mucus layer, and thereby supports mucociliary clearance. *D*. In CF, the described ion transport abnormalities result in dehydration of the airway surface liquid components, impairs mucociliary clearance, and ultimately encourages the development of an anaerobic niche within airway-adherent mucus plaques.

activities in response to the local ASL environment, thereby maintaining an appropriate PCL height and adequate mucus hydration (Fig. 124-2*C*). In contrast, CF epithelia hyperabsorb liquid due to dysregulation of ENaC and have lost the capacity to secrete liquid via CFTR (Fig. 124-2*B*). As a result, the PCL layer becomes volume depleted and the mucus layer becomes concentrated and poorly transportable (Fig. 124-2*D*). These changes in the ASL compartment impair mucus clearance and predispose the patient to the development of chronic airway infections.

SECONDARY PATHOGENIC STEPS: MUCUS, PSEUDOMONAS, AND INFLAMMATION

As described, ASL dehydration produces progressive mucostasis and initiates a cascade of events that leads to clinically apparent CF lung disease. First, thickened mucus secretions eventually become adherent to airway surfaces with the loss of PCL volume, and begin to obstruct small airway lumens. Mucus plugs and plaques not only provide a protected environment in which bacteria can escape mechanical and immune-mediated clearance, but also create a unique environment that drastically alters bacterial gene expression. Paradoxically, the center of a mucus plug is in fact anaerobic (pO_2 less than 2 Torr) due to a combination of an increased diffusion distance for O_2 as well as increased oxygen consumption by CF epithelia (owing to heightened Na^+ transport). Within this environment, *P. aeruginosa* converts to an anaerobic mode of metabolism, increases alginate production, and ultimately establishes a biofilm structure. Organisms growing within the biofilm possess increased resistance to secondary host defense mechanisms (e.g., neutrophils and soluble antimicrobials), display vastly different antimicrobial sensitivity patterns, and are likely impossible to eradicate with antibiotic therapy. Ultimately, it is the persistent attempt but ongoing failure of neutrophils to clear this infection, accompanied by the release of proteases and other harmful substances, which destroys lung tissue and yields bronchiectasis.

Clinical Aspects

Optimal care for the diverse manifestations and complications of CF poses a significant clinical challenge (Fig. 124-3). This presentation focuses on management relevant to the risk for infection. An early, and perhaps primary, manifestation of CF lung disease is the development of airway obstruction with mucus driven by dehydration of airway surfaces, due to intrinsic ion transport abnormalities. With ASL volume depletion, mucus secretions become less transportable and ultimately adhere to airway surfaces, thus triggering further mucus accumulation and airway obstruction. Coupled with this accumulation is the development of a neutrophil-predominant inflammatory process with mucus hypersecretion in response to inflammatory mediators. The intensity of inflammation in relationship to the burden of

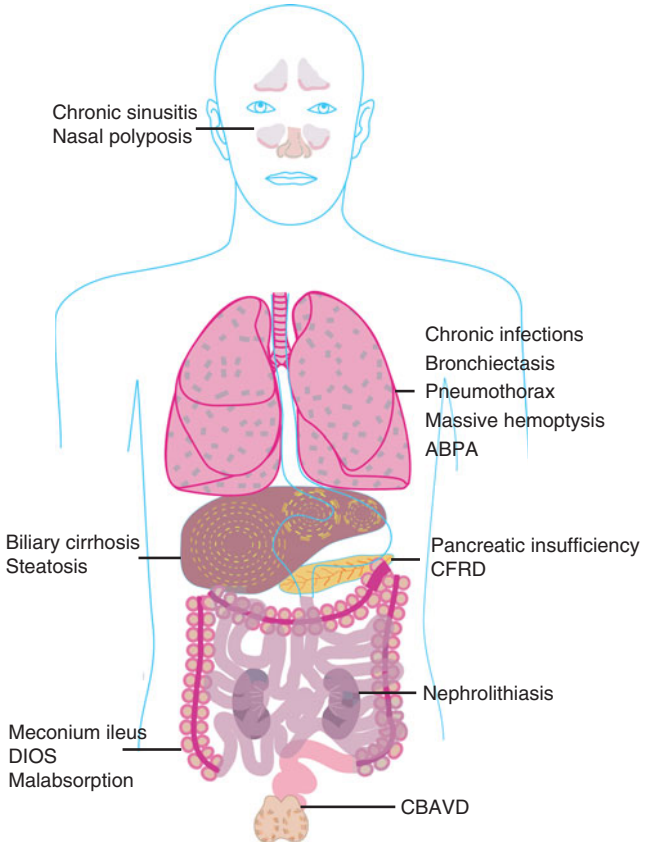

Figure 124-3 Multisystem manifestations of cystic fibrosis. Abnormal CFTR function in epithelial lined organs leads to a wide variety of manifestations in multiple organ systems.

identified pathogens is greater than in other childhood lung diseases and the tendency for the inflammatory process to persist after the apparent resolution of an acute infectious process is perhaps unique to CF. Interestingly, an animal model of CF lung disease, which exhibits ASL dehydration and mucus plugging, also develops chronic airway inflammation without readily identifiable bacterial infection. Current hypotheses to explain these findings include: (1) a low burden of typical bacteria avoids eradication in the dehydrated mucus environment of the CF lung and drives the inflammatory process in very early disease; (2) the presence of atypical, perhaps anaerobic, organisms are poorly identified with usual culture systems but dominate early disease and cause inflammation; and (3) intermittent events, including viral infections and/or gastric aspiration drive the inflammatory process early in life. Regardless, these observations point to the very early onset of lung disease, even in asymptomatic infants, and the need to develop and institute effective interventions in this population.

Over a relatively short period of time, the CF lung becomes chronically infected with typical pathogens. In childhood, *Haemophilus* influenzae and *Staphylococcus aureus* are often identified first, typically followed by the establishment of chronic *Pseudomonas aeruginosa* infection. *Pseudomonas* may take many morphologic forms, including rough, smooth, and small colony variants, but typically evolves to a mucoid

phenotype that signifies chronicity and the inability to eradicate this organism, even with aggressive antibiotic regimens. An increased emphasis on early detection and eradication has emerged, therefore, to delay the negative effects of chronic *Pseudomonas* infection. Other important pathogens that are encountered in CF include a variety of gram-negative bacteria, especially *Stenotrophomonas maltophilia, Achromobacter xylosoxidans,* and the *Burkholderia cepacia* complex (Bcc). The Bcc is currently subdivided into at least 9 genomovars, but genomovars II *(B. multivorans)* and III *(B. cenocepacia)* are most prevalent in CF. Bcc infection is associated with worse pulmonary outcomes, rapidly becomes antibiotic resistant, and certain strains carry the risk of rapid nosocomial spread to susceptible hosts (including other CF patients). Genomovar III is particularly problematic and is considered an absolute contraindication to lung transplantation at most centers because of the unacceptably high rate of early mortality due to sepsis. Mycobacterial pathogens are also encountered in CF, including *M. avium* complex and *M. abscessus.* MAC is the most prevalent mycobacterial pathogen in CF, but often does not cause discernible clinical disease, as opposed to the much more problematic infection with *M. abscessus.* Treatment of *M. abscessus* is often very prolonged (months), toxic, and often does not yield eradication. Viral infections, although probably not more frequent than in other populations, do appear to cause more morbidity and may be an important trigger of lung disease exacerbations. Fungi, particularly aspergillus species, are common colonizers but may cause allergic bronchopulmonary aspergillosis (ABPA).

Once the cycle of reduced mucus clearance, infection, and inflammation begins, progressive airway obstruction follows. This is manifested clinically by reductions in pulmonary function tests and radiographic changes. With spirometry, airflow rates reflecting the small airways (FEF_{25-75}) are affected first and most severely, followed thereafter by reductions in the FEV_1 and lesser changes in FVC. Routine spirometry, however, is often technically impossible in young children (less than 5 years) and is quite insensitive to the development of lung disease early in the course of disease. Chest radiographs may first show signs of hyperinflation followed by interstitial markings that reflect the development of bronchiectasis, but this technique is also a relatively insensitive tool for the detection of mild/early disease. More recently, thin-section CT scanning has been used to clinically characterize CF lung disease and has also been used as a clinical trial outcome measure. This technique, especially when combined with expiratory images to detect air trapping, often detects significant foci of disease prior to the ability to detect global airway obstruction with spirometry. Once CF lung disease becomes more advanced, all of these assessments of disease severity reflect the progressive development of bronchiectasis.

Exacerbations of CF lung disease are extremely important events in the life of a CF patient. These periodic illnesses often remove the patient from their usual work or school activities, are associated with significant reductions in quality of life, exact a large financial toll in terms of health care costs, and are associated with reduced survival. Exacerbations are typically acute to subacute events that are superimposed upon a previously stable clinical baseline. Patients usually report increased cough, sputum, fatigue, and weight loss during these episodes. Fever, leukocytosis, chest pain, and new infiltrates on chest radiographs are less consistent findings with exacerbations. The inciting events that trigger an exacerbation have not been clearly defined, although acute respiratory viral infection may be one important cause in addition to inadequate use of preventative therapies. Because significant disease progression can occur without many symptoms in patients with mild disease, lung function testing as a "screen" for exacerbations/progression are particularly important in this setting.

Other respiratory manifestations of CF lung disease, besides bronchiectasis, include massive hemoptysis and pneumothorax. In chronically inflamed, bronchiectatic CF airways the associated bronchial arteries often become massively dilated. In the setting of increased infection/inflammation, a dilated bronchial artery may erode through the overlying mucosa and bleed—under systemic arterial pressure—into the airway lumen. Minor to massive hemoptysis may ensue, at times requiring bronchial artery embolization in order to halt the bleeding. Massive hemoptysis is increasingly common in older patients, with an average annual incidence of 0.87 percent. Antibiotic therapy, correction of coagulation defects, and temporary cessation of unnecessary airway irritants (e.g., inhaled antibiotics) and chest physiotherapy are also mainstays of treatment for massive hemoptysis in CF.

Similarly, the incidence of pneumothorax also increases with the age of the patient. The annual incidence of this complication is 0.64 percent. In general, the management of pneumothorax in CF is not conceptually different than in other lung diseases. However, it should be recognized that, because of the inability of the lung to fully deflate in the setting of obstructive airways, even a small volume pneumothorax could in fact cause tension physiology. Also, because lung transplantation is often an eventual treatment consideration, persistent air leaks and recurrent pneumothoraces are preferentially dealt with via thoracoscopic approaches (bleb stapling and local pleurodesis) rather than with chemical or talc pleurodesis. These later approaches may significantly compromise the ability to excise the native lung at transplant.

ABPA complicates the clinical scenario of roughly 2 percent of CF patients. This syndrome, caused by allergic inflammation directed against colonizing fungi, may cause symptoms that mimic exacerbations of the underlying CF lung disease itself, and is therefore difficult to diagnose on clinical grounds. Laboratory tests, consequently, are quite useful. A total serum IgE level is often used as a screening test for the presence of ABPA and to track the level of disease activity. Classically, patients with active ABPA will have serum IgE levels greater than 1000 μg/L, although lesser elevations may also be observed in patients with active disease.

Immediate-type hypersensitivity reactions to an aspergillus skin test are sensitive but not specific for ABPA; therefore, a negative test can be used to rule out this entity. The demonstration of aspergillus-specific antibodies can be useful for the diagnosis of ABPA, as are the presence of sputum or blood eosinophilia. Of note, culture positivity for aspergillus may not always be demonstrated. Treatment is typically with systemic corticosteroids for fairly prolonged periods of time, although there is growing experience with the use of antifungal agents to limit the system exposure to corticosteroids.

Nasal and sinus disease are another troublesome respiratory manifestation of CF. Children in particular may experience recurrent nasal polyposis and require surgical removal of obstructing polyps. Sinus disease is nearly universal, either clinically or radiographically, and often requires chronic medical therapies (nasal steroids, antibiotics, nasal irrigation) as well as judicious use of surgery. It should be noted that the benefits of surgery for CF sinus disease are not well studied and often temporary. Overly aggressive surgical approaches may ultimately distort the underlying anatomy such that nasal/sinus mucus clearance mechanisms are disrupted and sinus symptoms recur and progress a short time after surgery.

Non-Respiratory Manifestations

Multiple epithelial lined organs outside of the lung are also affected by the absence of a functional CFTR protein (Fig. 124-3). Despite differences in the details of how CFTR normally functions in each of these organs, a general theme of altered luminal contents (e.g., altered ion composition, volume, or viscosity), causing reduced transit through the organ and obstruction, exists.

Pancreas, Gut, and Nutrition

The exocrine pancreas is affected in more than 90 percent of patients with CF. These issues are reviewed in detail elsewhere. Steatorrhea, malnutrition, and fat-soluble vitamin deficiencies (A, D, E, and K) are common and patients may also develop intestinal obstruction as the result of the bulky, poorly hydrated intestinal contents. This syndrome, termed distal intestinal obstruction syndrome (DIOS), occurs in roughly 20 percent of patients and increases in frequency with age. DIOS may present with abdominal pain, constipation, right lower quadrant mass, nausea, and vomiting. It is usually treated with relatively large volumes of iso-osmotic polyethylene glycol colonoscopy preparations by mouth or NG tube in the non-vomiting patient, or by enema treatments and bowel rest. A meglumine diatrizoate (Gastrografin) enema may be both diagnostic and therapeutic in severe cases. Meconium ileus, a similar syndrome that presents in the days after birth, is nearly diagnostic for the presence of CF and should prompt definitive diagnostic testing.

Endocrine functions of the pancreas, which do not rely on the presence of patent pancreatic ducts, are typically preserved much later into life than exocrine functions. Over time, however, progressive destruction of islet cells leads to insulin deficiency and the onset of CF-related diabetes (CFRD). The incidence of CFRD increases with age, with 15.6 percent of patients older than 13 years receiving insulin therapy. Given the insidious nature of CFRD and controversy over the need for insulin in patients without fasting hyperglycemia, this estimate of the problem is likely quite low. CFRD is a very important problem because it is associated with accelerated rate of lung function decline, worsened nutritional status, and poorer survival. For unclear reasons, females with CF appear to be particularly vulnerable to the adverse effects of CFRD, as its presence is associated with more pronounced effects on survival and lung function than in males. Therefore, screening for CFRD is recommended for all CF adults on an annual basis. Monitoring and treatment of hyperglycemia induced by acute illness (e.g., during exacerbations) is also recommended to avoid impairment of immune function and facilitate the return to normal nutritional status. Because CFRD represents an insulin-deficient state, insulin in the preferred therapy. Given the need to maintain an adequate nutritional status, calorie-restricted "diabetic diets" are not indicated. Rather, calorie-rich diets with adequate insulin coverage are prescribed. Interestingly, it appears that glycemic status can wax and wane in patients with CF over time, moving back and forth among normal glycemia, impaired glucose tolerance, and frank CFRD. Clearly, this CF manifestation warrants close, careful longitudinal assessments.

Hepatobiliary Disease

Steatosis and focal biliary cirrhosis are the most common pathological abnormalities of CF associated liver disease. Whereas severe malnutrition may contribute to fatty lesions in the liver, the absence of CFTR-mediated secretion by cells lining bile ducts is believed to cause the development of inspissated biliary secretions, which in turn leads to biliary cirrhosis. Portal hypertension and associated variceal bleeding occurs uncommonly, although roughly 2 percent of CF deaths are related to liver disease. Based on autopsy series, it appears that the prevalence of cirrhosis increases with age. Despite this observation, clinically apparent liver disease is usually diagnosed by the time patients reach adolescence and typically does not present de novo after age 20 years. Treatment of CF-associated liver disease with ursodeoxycholic acid can be considered. Although this treatment has the potential to prevent the development of cirrhotic lesions if started early in the course of disease, the unclear natural history and absence of factors that predict the development of clinically important disease makes this therapeutic decision somewhat difficult and controversial. Liver transplantation is an option for CF patients with end-stage liver disease and mild pulmonary dysfunction, and results are generally good. Liver failure may exceed pulmonary dysfunction requiring liver before lung transplantation.

Reproductive Tract and Other Manifestations

Males with cystic fibrosis have an approximately 99 percent chance of being infertile. Women with CF, in contrast,

have relatively intact intrinsic fertility. However, the presence of severe lung disease, CF-related diabetes, and significant malnutrition increase the risk of maternal morbidity and fetal intrauterine growth retardation. Other nonrespiratory manifestations include: (1) early and severe osteoporosis; (2) hypertrophic pulmonary osteoarthropathy; (3) cutaneous leukocytoclastic vasculitis; (4) calcium oxalate nephrolithiasis; (5) gallbladder abnormalities, including micro-gallbladder, stones and sludging; and (6) metabolic alkalosis and sweat loss syndromes in infants. A detailed review of these manifestations is beyond the scope of this chapter, but is presented elsewhere.

TREATMENT OF LUNG DISEASE

The strategies for treatment of CF lung disease are reviewed elsewhere. Available therapies include airway clearance maneuvers and exercise, inhaled mucoactive substances, bronchodilators, antibiotics, and anti-inflammatory agents. A cornerstone in the treatment of CF lung disease is the use of maneuvers and/or devices that facilitate the clearance of airway secretions. Because CF secretions are dehydrated and difficult to clear, additional efforts above and beyond cough must be applied on a regular basis to prevent their accumulation. Although indicated in almost all patients with CF, it remains controversial whether chest physiotherapy is appropriate for asymptomatic infants with normal lung function. Choices are often made based on an individual patient's perception of efficacy and preference for assisted vs. independent modalities. Chest percussion and vibration, with or without postural drainage, have long been the traditional airway clearance modalities, and are favored by many patients, especially when they are ill. Negative factors pertaining to this mode of therapy is the need for a caregiver to perform the treatment and the additional risk of inducing gastroesophageal reflux and aspiration when using head-down tilt positions in infants. Exercise is an additional treatment modality that may augment airway clearance, while providing other beneficial effects as well. Anecdotal experiences have long supported the usefulness of exercise in CF lung disease, but short-term studies only showed improved exercise tolerance rather than more substantial pulmonary benefits. One long-term, randomized controlled study of an in-home exercise program in CF, however, demonstrated that children with mild to moderate lung disease who were assigned to at least three times per week exercise sessions had slowed decline of lung function over a 3-year period; therefore, a program that combines exercise with other airway clearance maneuvers should be considered.

Medications that impact mucus clearance and benefit patients with CF include dornase alfa and hypertonic saline. Dornase alfa is an inhaled recombinant human DNAse enzyme that hydrolyzes free DNA molecules present in CF airway secretions. Because DNA is exceedingly viscous, the action of dornase alfa improves the cough-clearance of secretions and has been shown to improve lung function and reduce the frequency of exacerbations. The optimal time to initiate dornase alfa treatment is somewhat unclear. However, it has been shown that children (mean age 8.4 years) with mild lung disease (mean FEV_1 95 percent predicted) have sustained improvement in lung function and reduced disease exacerbations over 2 years of observation when treated with dornase alfa, and separately was shown to prevent an increase in markers of inflammation (IL-8, free elastase) as assessed by bronchoalveolar lavage at 18-month intervals.

Inhaled hypertonic saline draws water into the luminal compartment, thereby improving the hydration of the periciliary layer and of mucus secretions. Unlike dornase alfa, hypertonic saline has been shown to acutely stimulate mucociliary clearance, as measured via studies that use inhaled radiotracer particles, and to have sustained effects on mucus clearance rates (greater than 8 hours) in patients with CF as well. Unfortunately, there are no data that support the use of other mucolytics, including *N*-acetylcysteine, and their use cannot be recommended at this time. Bronchodilators, particularly beta-adrenergic agonists, are very commonly used in the setting of CF lung disease, although data supporting their efficacy are mixed.

ANTIBIOTICS

Antibiotics are a mainstay in the treatment of CF, and their use fulfills different purposes at different times. Oral azithromycin, although generally not active against the major colonizing organisms, has been shown to improve lung function and reduce exacerbations in CF patients with *Pseudomonas* infection when used chronically. The mechanism may be via anti-inflammatory actions. However, *Pseudomonas* growing under biofilm conditions has very different antimicrobial susceptibility patterns, and sensitivity to macrolides may actually occur under these conditions. Coexistent infection with mycobacteria is generally a contraindication to macrolide use and should be excluded prior to initiation of therapy.

Other oral antibiotics are also widely used in CF. Continuous use of anti-staphylococcal antibiotics was a common practice in the United States in patients who were infected with sensitive *S. aureus* species. This practice has fallen out of favor because of an absence of demonstrated benefit and an increased rate of *Pseudomonas* acquisition. Proponents of anti-staphylococcal treatment still exist, although this practice should be examined carefully, given the very real harm associated with an earlier acquisition of *Pseudomonas*.

Oral anti-pseudomonal agents are principally confined to the quinolone class of antibiotics. Quinolone use is associated with the rapid development of resistance and therefore should not be used chronically/prophylactically. Instead, inhaled antibiotics have become very important in the chronic management of CF. The inhaled route is attractive because

higher concentrations of drug reach the endobronchial site of infection via the inhaled route, so microbial resistance may be overcome. Also, inhaled tobramycin is associated with low blood levels and much less systemic toxicity than with the intravenous route. Six-month studies of inhaled tobramycin demonstrated improved lung function and fewer exacerbations when used in a cycling fashion (i.e., 1 month on, 1 month off). A small increase in *Pseudomonas* resistance was observed over these relatively short duration studies, but did not affect efficacy over this time period. However, it is unknown whether the same efficacy profile will be preserved with longer-term use of inhaled tobramycin, especially in the face of the progressive antimicrobial resistance that is likely to occur over time. Therefore, whether prophylactic use every other month is superior to less frequent dosing, or even intermittent use for minor changes in symptoms or lung function, is unknown.

Colistin has seen considerable use for CF, particularly in Europe. There are substantially fewer data to support the safety and efficacy of colistin use. Because this agent has excellent in vitro activity versus *Pseudomonas* and is infrequently used as an intravenous agent to treat exacerbations, use in maintenance therapy has theoretical advantages. There are also concerns over whether colistin is adequately converted to the active form in sputum by local hydrolases, difficulty with bronchospasm in some patients, and the need for somewhat complicated regimens to get the powdered drug into solution while avoiding problematic foaming during delivery.

A number of other antibiotics are either being formally developed for use via the inhaled route or have a history of being nebulized without adequate research into its delivery, safety, and efficacy. With adequate testing, additional inhaled antibiotic agents should prove to be useful in the treatment of CF.

ANTI-INFLAMMATORY AGENTS

Anti-inflammatory agents are an attractive option for the treatment of CF lung disease given the fact that persistent, neutrophil-predominant inflammation ultimately is the cause of airway destruction. Ibuprofen is currently the only available agent for chronic treatment with proven efficacy and safety in CF. In a long-term, prospective study ibuprofen slowed the rate of lung function decline, and the affect appeared to be greatest in younger patients with mild disease. Importantly, ibuprofen levels must be monitored during treatment, as therapy may be associated with gastrointestinal bleeding and renal dysfunction, whereas subtherapeutic levels are associated with a paradoxical increase in neutrophil migration, and super-therapeutic levels are more likely to yield toxicity (e.g., GI bleeding). Use of ibuprofen should be stopped during administration of other nephrotoxic agents, such as intravenous aminoglycosides. Inhaled steroids are of unproven benefit for the typical patient with CF.

ANTIMICROBIALS IN THE TREATMENT OF ACUTE EXACERBATIONS

The choice of antibiotics to treat an exacerbation should be made based upon the most recently available pretreatment sputum culture result. For mild exacerbations in a patient chronically colonized with *Pseudomonas,* an oral quinolone with antipseudomonal activity or inhaled tobramycin may be effective either as monotherapy or in combination. Combination therapy has the theoretical advantage of inducing less drug resistance, but this has not been well studied. For more severe exacerbations, selection of empiric intravenous antibiotics should be based on prior antimicrobial susceptibility data and, generally, two drugs from different classes should be selected. This may lessen emergence of bacterial resistance; true synergy for *Pseudomonas* has been documented only between aminoglycoside and β-lactam antimicrobial agents. It is unclear whether in vitro testing of *Pseudomonas* under log-phase growth conditions is clinically relevant given the role of biofilm in growth in vivo. In patients with CF, some drugs, particularly aminoglycosides, are renally cleared faster than normal individuals and levels should be followed to guide dosage adjustments. The treatment of other gram-negative infections (e.g., *B. cepacia* complex, *Stenotrophomonas maltophilia*, and *Achromobacter xylosoxidans*) is similarly based on susceptibility patterns. Coinfection with *S. aureus* or, increasingly, with non-tuberculous mycobacteria, may merit separate therapy.

CONCLUSIONS

A detailed understanding of the molecular events that underlie the pathogenesis CF lung disease is emerging. This knowledge is now guiding the development of new treatment strategies, using both existing and novel agents, to more effectively treat this disease. With the development of drugs that correct the earliest defects in CF, i.e., CFTR dysfunction and ASL dehydration, further increases in the already vastly improved survival with CF are predicted. It is likely, however, that improved survival will paradoxically increase the complexity of caring for adult patients with CF who continue to develop complications related to reaching older ages. Continued research, the identification of best available practices, and broader dissemination of expertise will certainly continue to drive improved outcomes in coming years.

Bronchiectasis

Alan F. Barker • Sheela Y. Ahmed

Bronchiectasis (*broncos,* airways; *ectasia,* dilatation) is a morphological term used to describe abnormal irreversibly dilated and often thick-walled bronchi. This is an anatomic definition and is thought to have evolved from Laennec's original description in 1819 of ectatic bronchi in pathological specimens. Bronchiectasis represents the end stage of a variety of pathologic processes that cause destruction of the bronchial wall and its surrounding supporting tissues. The clinical manifestations include chronic cough and copious mucopurulent expectoration, often lasting months to years. Bronchiectasis shares many features with chronic bronchitis, including inflamed and easily collapsible airways, airflow obstruction on spirometry, and frequent exacerbations. The distinction between the two processes is a matter of degree and extent of the abnormality. Patel et al. from St. Bartholomew's Hospital in London evaluated the presence and extent of bronchiectatic changes in stable patients with moderate to severe chronic obstructive pulmonary disease (COPD). They showed that 50 percent of these patients had evidence of radiologic bronchiectasis, with high-resolution computed tomography (HRCT) changes seen most frequently in the lower lobes.

PREVALENCE

Bronchiectasis was a common disabling and fatal condition in the pre-antibiotic era. It remains an important cause of suppurative lung disease in the developing world. More recently, the declining incidence of this disease in the developed world has led to repeated suggestions that it be considered an orphan disease. The decline has been variously attributed to the advent of improved living conditions, frequent and early use of antibiotics, improved sanitation and nutrition, and introduction of childhood immunization, particularly against measles and pertussis. In the United States, the prevalence has recently been estimated to be 52 per 100,000. A slight female preponderance has been suggested in two large series of patients. Bronchiectasis has been reported to act more

virulently in women, but whether this represents an altered inflammatory-immune response, or there are environmental, genetic, and anatomic differences leading to this predisposition is not clear.

PATHOPHYSIOLOGY

The abnormal bronchial dilatation in bronchiectasis principally affects the medium-sized bronchi, but often extends to the more distal bronchi and bronchioles. On gross examination of surgically resected or autopsied lungs, the affected bronchi and bronchioles are so prominent as to be visible all the way to the pleural surface. These dilated and ectatic bronchi are commonly filled with purulent secretions. The affected bronchi show transmural inflammation, mucosal edema, cratering, ulceration, and neovascularization. The bronchial epithelium may show a polypoidal appearance due to underlying granuloma formation and mucosal prominence, ridging due to bronchial smooth muscle hypertrophy, and pitting due to the dilated bronchial mucous glands. Severe cases may show denudation of epithelial lining, with destruction of underlying elastic laminae, smooth muscle, and cartilage with fibrotic changes replacing these structures. Dilated and tortuous bronchial arteries may be seen secondary to the development of extensive bronchial-pulmonary anastomoses.

Microscopically, bronchiectasis is associated with loss of cilia, cuboidal and squamous metaplasia, hypertrophy of bronchial glands, and lymphoid hyperplasia. Intense infiltration of the bronchial wall with neutrophils, lymphocytes, and monocytes is seen. It has long been recognized that these changes are associated with chronic bacterial infection. The concept of the "vicious cycle" proposed by Peter Cole and colleagues from the Brompton Hospital has largely been accepted over the last three decades. While acute inflammation is an important host defense against bacterial infection, if it fails to clear the infection, it can result in lung damage. This theory proposed that chronic bacterial endobronchial infection and inflammation damage or destroy mucociliary defenses, leading to secretion stasis, which in turn propagates furthers bacterial infection, and increases airway inflammation and bronchial dilatation. Bacterial colonization and/or infection of the airways alone is not sufficient to produce true bronchiectasis. It seems likely that focal disturbances resulting in airway obstruction or impairment of drainage and/or systemic conditions, resulting in uncoordinated airway clearance or impaired immune response are required in addition to airway colonization and/or infection. The appearance of *Pseudomonas aeruginosa* in the respiratory tract of bronchiectasis patients on a chronic or recurring basis has been associated with worsening ciliary function and deleterious effects on host defenses, resulting in impaired health-related quality of life and worsened lung function. This may be due to the ability of this organism to release virulent exotoxins, form surrounding biofilms on tissue surfaces, and easily develop hypermutable *P. aeruginosa* strains resistant to antibiotics, all factors perpetuating and propagating bronchial damage.

Angrill et al., in a study looking at parameters of bronchial inflammation and colonization in clinically stable bronchiectasis, demonstrated findings suggesting that airway inflammation may occur even in the absence of bacterial colonization. They found a higher percentage of airway neutrophils and higher concentrations of IL-8 and IL-6 in the BAL fluid of patients with bronchiectasis and negative microbial cultures, than in nonsmoking controls who had no evidence of respiratory disease.

CLINICAL FEATURES

The classic clinical manifestations of bronchiectasis are daily cough and mucopurulent sputum production. Cough is invariably present and often may be the only symptom for years. Purulent, tenacious sputum production, frequently worse in the morning (having accumulated during recumbency in sleep) is present in most patients. Sputum production may be intermittent, being affected by recurrent infections, bronchial plugging, and antibiotic therapy. "Dry bronchiectasis" presenting as cough, minimal sputum expectoration, and/or hemoptysis is occasionally described. Hemoptysis may be seen in 40 to 70 percent of patients and may vary from blood streaks to large clots. Increasing cough, dyspnea, and volume of sputum production, fever, hemoptysis, and chest pain are hallmarks of acute exacerbations. Often patients give a history of recurrent chest infections, although single episodes of severe pneumonia, tuberculosis, or pertussis with secondary pneumonia may also result in bronchiectasis.

Most patients have abnormalities on physical examination. Chest auscultation usually reveals findings of early and mid-inspiratory crackles as well as diffuse rhonchi and prolonged expiration. Bronchial breath sounds may be heard in severe cases or patients with a complicating pneumonia. Digital clubbing and hypertrophic pulmonary osteoarthropathy, although common in the pre-antibiotic era, are rarely seen now. In severe advanced cases, there may be evidence of respiratory insufficiency and cor pulmonale.

CLASSIFICATION USING RADIOLOGY

Bronchiectasis may be classified by predisposing factors, pathological features, and radiographic appearance. Reid in 1950 described a correlation between pathological and bronchographic findings in bronchiectasis; since then, this has been the most widely used classification. There is considerable overlap and coexistence among the various forms of bronchiectasis. In c*ylindrical* bronchiectasis, the bronchi are regularly outlined (tubular), dilated in diameter, with straight

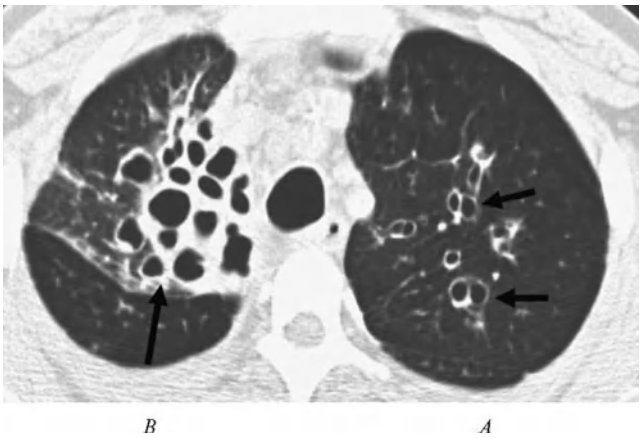

Figure 125-1 Chest computed tomography. *A.* (Left chest) *Cylindrical* bronchiectasis: Dilated and thickened airways. *B.* (Right chest) *Saccular* or cystic bronchiectasis: Very dilated airways clustered into saccules, cysts, or grapelike clusters.

walls, often coming to a straight abrupt end, instead of a tapering end, due to obstruction of the peripheral bronchial tree by secretions, casts, and inflammatory wall edema. *Varicose* bronchiectasis (illusion to varicose veins) is marked by the presence of irregular dilatations, outpouchings, and tortuosity of the airways. *Saccular* (cystic) bronchiectasis is characterized by the presence of cystic distortion of the distal airways that may be focal or more generalized, resulting in saccules that appear as a cluster of grapes (Figs. 125-1 and 125-2). Traction bronchiectasis, a term used to describe the dilated airways seen in diffuse pulmonary fibrosis secondary to fibrous tissue traction and elevated negative intrathoracic pressure, should be distinguished from usual bronchiectasis, because of the lack of intrinsic airway pathology and paucity of sputum expectoration. Congenital bronchial cysts (central and peripheral) are developmentally abnormal cystic bronchial structures, often filled with mucus and lined with respiratory epithelium. While usually lacking connection with the parent bronchus and distal alveoli, if infected they may communicate and mimic localized bronchiectasis. Intralobar bronchopulmonary sequestration too, may become infected and communicate with the bronchial tree, mimicking localized bronchiectasis.

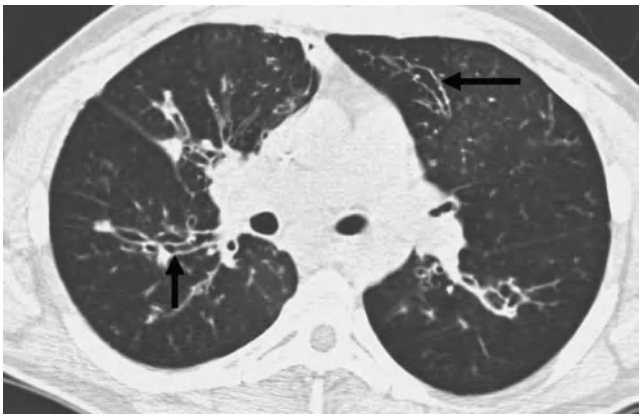

Figure 125-2 Chest computed tomography shows *varicose* bronchiectasis: dilated airways with irregular thickened mucosa.

PREDISPOSING OR ASSOCIATED FACTORS

Previously bronchial damage secondary to childhood respiratory tract infections such as pneumonia, pertussis, complicated measles, and tuberculosis were implicated as common causes of bronchiectasis. However, with the early use of antibiotics and childhood immunizations, the focus has shifted from postinfectious to intrinsic causes. Often regarded as a condition in which extensive investigation is unlikely to yield treatable causes, recent studies have shown results to the contrary. Thus, Pasteur et al. in a study of a northern European cohort of bronchiectasis patients with a low incidence of HIV and tuberculosis were able to identify a cause in 47 percent of cases. Postinfectious causes (29 percent) were still the largest group. Li et al. in a study of 136 patients were able to find an etiologic cause in 101 (74 percent) cases, and in 77 cases these diagnoses had implications for treatment and prognosis. The etiologic distribution in these studies is detailed in Table 125-1.

Infections

A number of pulmonary infections have been associated with the development of bronchiectasis. The association of

Table 125-1

Associated Factors or Etiology

Author, years studied	Li (1986–2002)	Pasteur (1995–1997)

Idiopathic	35	80
Ulcerative colitis	0	2

measles with bronchiectasis has been considered a complication secondary to the intense bronchial and peribronchial inflammation and epithelial proliferation. Complicating secondary infections with adenovirus, herpesvirus, and bacteria such as *Staphylococcus aureus, Klebsiella pneumoniae,* and *P. aeruginosa* possibly further contribute to the severity of a necrotizing bronchopneumonia.

Primary necrotizing bacterial pneumonias due to *S. aureus, K. pneumoniae*, and *P. aeruginosa* may result in bronchiectasis. *Streptococcus pneumoniae, H. influenzae,* and *Moraxella* infections typically do not cause bronchiectasis, but may be colonizers of bronchiectatic airways. Necrotizing anaerobic pneumonias secondary to aspiration or bronchial obstruction are often complicated by parenchymal destruction and bronchiectasis. Tuberculosis can result in bronchiectasis by several mechanisms. Bronchiectasis may be a consequence of tuberculous bronchitis, postobstructive bronchial damage secondary to post-tuberculous bronchial wall stenosis, and extraluminal bronchial obstruction by enlarged tuberculous lymph nodes.

The association of *Mycobacterium avium* complex (MAC) with bronchiectatic airways is well documented. While traditionally considered a secondary pathogen in an abnormal host or a colonizer in damaged lungs (bullous emphysema, cavitary lung disease) it is now recognized that MAC or other environmental mycobacteria infection can cause bronchiectasis in apparently normal hosts. CT scan of the chest in such cases is relatively specific, showing small irregular nodules in the middle lobe or lingula, but other parts of the lung may be affected. The phenotype for MAC-associated bronchiectasis seems to involve predominantly slender white women 50 to 70 years old without underlying lung disease or immune compromise. It is likely that a narrow angulated middle lobe bronchus and ineffectual coughing due to increased airway collapsibility explain this syndrome.

Bronchial Obstruction

Bronchial obstruction may result in the development of localized bronchiectasis. Various explanations have been advanced for this phenomenon. It has been suggested that following bronchial obstruction, airways proximal to the collapse are exposed to strong dilating forces caused by the difference in the atmospheric pressure in the bronchi and the negative pressure in the pleural space. Over time, these forces acting on weakened, inflamed airways may result in permanent and pathological airway dilatation. The presence of surrounding lung fibrosis, atelectasis, and loss of lung volume leading to regional increases in local retractile lung forces may also play a role. Animal experiments suggest that obstruction may facilitate the development of bronchiectasis by interfering with bronchial clearance and promoting bacterial infection, bronchial wall inflammation, and weakening.

Endobronchial adenomas, fibromas, chondromas, and lower respiratory tract papillomatosis causing partial airway obstruction and bronchiectasis have been described.

Localized bronchiectasis may also been seen in middle lobe syndrome, and is usually caused by intraluminal or extraluminal obstruction secondary to tumor, enlarged lymph nodes, or abnormalities of bronchial structure and branching.

Aspiration/Inhalation Airway Injury

Aspiration or inhalation of foreign matter, such as noxious fumes or particulates into the airways, may result in bronchiectasis. This may involve aspiration of oropharyngeal secretions containing microaerophilic and anaerobic bacteria, which may result in a necrotizing pneumonia. Refluxed material from the esophagus or stomach containing food particles, gastric, biliary, and pancreatic secretions, and gut microbes may enter and damage airways, especially if the aspiration events are large and repeated. Depressed sensorium (stroke, alcohol and drug use, seizure, postanesthetic), brain stem dysfunction (amyotrophic lateral sclerosis, multiple sclerosis, syringomyelia), defective laryngeal function (postsurgery, postirradiation), esophageal disorders (dysmotility, gastroesophageal reflux disease [GERD], achalasia, tracheoesophageal fistula), and gastric disorders (gastric outlet obstruction) influence the likelihood and frequency of aspiration. Bronchiectasis may present years after foreign body aspiration (aspiration is often unrecognized), though bronchiectasis has been seen to occur in animals as soon as 2 to 8 weeks after experimental foreign body introduction into the bronchial tree. GERD is the most common condition in this category contributing to the risk of bronchiectasis, and several studies are available documenting increased frequency of reflux in patients with bronchiectasis, asthma, and pulmonary fibrosis, all chronic pulmonary inflammatory conditions. The cause-effect conundrum of GERD in these conditions is still being debated. However, given the high rate of association of GERD with bronchiectasis and the fact that it is often treatable, GERD evaluation should be part of the bronchiectasis work-up.

Cystic Fibrosis

Cystic fibrosis (CF) and its variants are a common cause of bronchiectasis in the United States and other developed countries. This is a monogenic disorder that presents most commonly in childhood as a multisystem disease. However, 3 to 7 percent of patients with cystic fibrosis are diagnosed in adulthood, and due to improvements in therapy, 25 percent of childhood cases reach adulthood. This is an autosomal recessive condition resulting from a genetic defect located on chromosome 7 leading to a deficiency in the CF transmembrane regulator. However, more than 200 mutations in the CF gene have been identified and the specific manifestations, severity, and rapidity of progression of CF vary according to the genotype. Clues suggesting CF as a cause of bronchiectasis include upper lobe radiographic involvement and sputum cultures showing mucoid *P. aeruginosa*. Adults diagnosed with CF after the age of 20 are less likely than children to have homozygous cystic fibrosis transmembrane conductance regulator (CFTR)

mutation, pancreatic insufficiency (but not pancreatitis), and diabetes mellitus. The diagnosis of CF rests on a combination of clinical criteria accompanied by sweat chloride values above 60 mEq/L. However, normal sweat chloride values may be seen in patients with clinical manifestations of CF and genetically confirmed CF. Screening for other mutations in the CFTR gene may be necessary in these circumstances.

Young's Syndrome

Young's syndrome consists of a combination of obstructive azoospermia (with normal spermatogenesis) and chronic sinopulmonary infections (bronchiectasis and sinusitis). This syndrome is distinguished from ciliary dyskinesia by its lack of ultrastructural ciliary abnormalities. Young's syndrome is distinguished from CF by its lack of family history, absence of CF genetic mutations, the presence of normal sweat electrolytes, and normal pancreatic secretion. Typically, the pulmonary manifestations of Young's syndrome appear usually in childhood and become milder in adulthood, although severe progressive cases have also been reported. Diagnosis is usually made when affected individuals are evaluated for infertility.

Primary Ciliary Dyskinesia

Primary ciliary dyskinesia (PCD) is phenotypically and genetically a heterogeneous group of conditions. It has an autosomal-recessive inheritance pattern, although rarely other modes of inheritance, such as X-linked, are described. It is estimated to affect 1:20,000 to 1:60,000 people, with approximately 12,000 affected people in the United States. The disease phenotype is caused by defects of respiratory cilia, sperm tails, and cilia of the embryonic node.

Currently three genes (DNAI1, DNAH5, and DNAH11) that encode for dynein proteins (axonemal and cytoplasmic) have been linked to recessive PCD. It is hypothesized that given the small numbers of well-characterized affected families, the large size of the dynein genes, the different dynein proteins present in the axoneme, and the large number of regulatory and structural proteins necessary for ciliary function, dynein mutations may not be the only cause of primary ciliary dyskinesia. Since its initial description in 1933, Kartagener's syndrome (triad of situs inversus, bronchiectasis, and either nasal polyps or recurrent sinusitis) and the description by Afzelius in 1975 of the defects in the dynein arms underlying this condition, incomplete forms of this syndrome have increasingly been recognized. Thus, clinical findings may be varied in patients with PCD, including respiratory distress in neonates, recurrent respiratory tract infections, bronchiectasis, situs inversus, heterotaxia, infertility, and hydrocephalus, singly or in various combinations. In a study looking at 94 patients from 68 families, Noone et al. showed that cough was seen in 100 percent of patients, bronchiectasis (98 percent), sinusitis (47 percent), otitis media (92 percent), and situs inversus (46 percent).

Exhaled nitric oxide (NO) may be used as a screening test, with levels of NO being characteristically low. Ciliated epithelial cells obtained from the inferior or middle turbinate using a sterile cytology brush may be studied for ciliary beat pattern and frequency using digital high-speed video imaging, when the dyskinetic cilia are seen to lack the classical sideway recovery sweep. Abnormalities in ciliary beat have been correlated to ultrastructural defects, and normal ciliary motion essentially excludes PCD. Axonemal structure of respiratory cilia may be visualized by transmission electron microscopy and defects in dynein arms, peripheral and central tubules, radial spokes, and basal bodies may be seen. No structural abnormalities are found in 3 percent of cases of PCD, and diagnosis may be confirmed by establishing dysmotility. Several of these tests are only available in research centers.

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) is a hypersensitivity lung disease caused by the ubiquitous fungus *Aspergillus fumigatus* and usually occurs as a complication of persistent asthma or cystic fibrosis. The excessive mucus production and impaired mucociliary clearance in these conditions allow the inhaled conidia of *Aspergillus* to persist and germinate, releasing exoproteases and other fungal products that further compromise clearance, breach epithelium, and activate immune responses. ABPA is characterized by a marked local and systemic eosinophilia, an elevated level of *Aspergillus fumigatus*–specific IgG and IgE antibodies, as well as a nonspecific elevation of total IgE. Clinically, ABPA manifests as recurring episodes of asthma, pulmonary infiltrates, and central bronchiectasis that may progress to fibrosis. Criteria have been established for the diagnosis of ABPA in the non-CF (Patterson criteria) as well as the CF population.

Inflammatory Disorders

Inflammatory and fibrotic processes affecting large and small airways may be seen in several rheumatic diseases and idiopathic inflammatory states. Significantly higher frequencies of bronchiectasis (20 to 35 percent) have been found in *rheumatoid arthritis* (RA) patients undergoing HRCT, both in symptomatic (30 percent) and asymptomatic (8 percent) patients, and was independent of smoking status. Bronchiectasis may precede or follow the development of rheumatoid arthritis, and the coexistence of both conditions is considered to portend a reduced survival. *Sjögren's syndrome* may also be complicated by bronchiectasis presumed to be secondary to the effects of inspissated bronchial secretions causing atelectasis and bronchial wall destruction. *Relapsing polychondritis* may be complicated by bronchiectasis in regions of recurring pneumonia as well as regions free of infection. It is not clear whether the chondritis itself or the recurrent infections predispose to bronchiectasis. While pulmonary involvement in *systemic lupus erythematosus* is diverse, bronchiectasis by

HRCT findings is less frequent than in patients with RA. *Idiopathic ulcerative colitis* has been reported to be associated with bronchiectasis. The pathogenesis remains unknown, although autoimmune and immune complex deposition theories have been proposed. This variant of bronchiectasis does not respond to colectomy and has been known to appear and progress after colectomy. Response to steroids is said to be dramatic. Bronchiectasis seen in sarcoidosis is usually traction bronchiectasis secondary to parenchymal and peribronchial fibrosis. Endobronchial sarcoid may result in localized bronchiectasis secondary to obstruction, atelectasis, and bronchial wall destruction.

Hypogammaglobulinemia

Recurrent sinopulmonary infections and bronchiectasis are clearly associated with hypogammaglobulinemia. Several forms of antibody deficiency have been linked with the development of bronchiectasis, including X-linked agammaglobulinemia, common variable immunodeficiency, IgA deficiency, and IgG subclass deficiency (usually IgG-G2 and IgG-G4). The issue of subclass deficiency (in the presence of normal or near-normal levels of total IgG) as a cause of bronchiectasis is controversial due to the wide range of values in normal individuals and the difficulties involved in accurately measuring these levels. A challenge with common humoral bacterial antigens, such as capsular polysaccharides of *H. influenzae* and *S. pneumoniae* followed by measurement of antibody titers 6 weeks later, may help establish the presence of such a deficiency. Early diagnosis of these conditions and replacement with intravenous immunoglobulin significantly reduces infections and prevents bronchiectasis, although the efficacy of this treatment in patients with selective IgM, IgA, and IgG subclass deficiency remains controversial. Standard doses in adults of 300 mg/kg by intravenous infusion every 4 weeks have been proved to reduce rates and severity of respiratory infections, but higher doses of 600 mg/kg appear more efficacious in reducing respiratory exacerbations and preserving pulmonary function in some patients.

DIAGNOSIS OF BRONCHIECTASIS

The diagnosis of bronchiectasis is based on history, clinical features, and radiologic demonstration of bronchiectatic airways. The diagnostic evaluation in these patients is largely aimed at identifying potentially treatable underlying causes of bronchiectasis. Thus, esophageal pH monitoring and ciliary analysis may be evaluated depending on the age of presentation; family history; other organ system involvement and level of clinical suspicion; total white blood cell count and differential for eosinophilia; immunoglobulin G, A, M, and E levels; serum α_1-antitrypsin levels; sputum cultures for bacteria, mycobacteria, and fungi; sweat chloride levels; skin prick tests or precipitins to *Aspergillus* spp.

Chest Radiograph

The chest x-ray may be abnormal and show the presence of increased pulmonary markings, ringlike structures, atelectasis, dilated and thickened airways (tram lines), and mucus plugging (finger-in-glove) appearance; however, the chest radiograph may be normal even in the presence of bronchiectasis.

High-Resolution Computed Tomography

The HRCT has been proved to be a reliable and noninvasive method for assessment of bronchiectasis. HRCT can accurately (sensitivity of 97 percent) diagnose bronchiectasis, localize and describe areas of parenchymal abnormality, and identify bronchiolar abnormalities and mucus plugging to the level of fifth- and sixth-order bronchi. It also can identify focal areas of air trapping as an indicator of small airway disease. It is indicated in the evaluation of bronchiectasis when surgical resection is contemplated, bronchiectasis is strongly suspected clinically and routine chest radiographs are normal, and other parenchymal abnormalities have to be better defined.

Airway dilatation can be detected by finding tram lines or end-on-ring appearance. A luminal diameter more than 1.5 times the adjacent vessel is indicative of bronchiectasis (Fig. 125-1). Bronchial wall thickening may also be seen. Evidence of small airway plugging with debris (tree-in-bud) may also be seen (Fig. 125-3).

Reports are available suggesting that the distribution and pattern of bronchiectasis may be sufficient to implicate a specific cause. Cartier et al. found that bilateral predominantly upper lobe bronchiectasis is seen most commonly in CF and allergic bronchopulmonary aspergillosis, a unilateral upper lobe predominance in tuberculosis and a lower lobe predominance in childhood viral infections.

Pulmonary Function

Pulmonary function is usually abnormal. The degree of impairment depends not only on the nature and extent of the

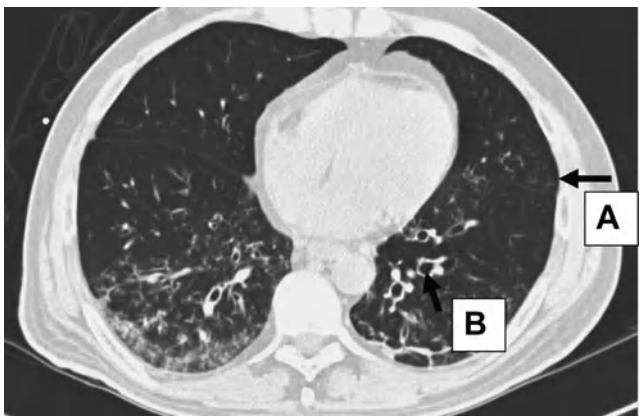

Figure 125-3 Chest computed tomography. *A.* Extensive peripheral branching opacities of tree-in-bud. *B.* Extensive peripheral branching dilated and thickened airways.

morphologic abnormalities of bronchiectasis, but also on the presence or absence of associated chronic bronchitis, emphysema, and so on. Thus, patients with mild localized bronchiectasis and no chronic bronchitis may have normal lung function tests. Patients with diffuse involvement may show on spirometry a pattern of airways obstruction, with normal or reduced forced vital capacity (FVC), reduced forced expiratory volume in 1 s (FEV_1), and reduced FEV_1/FVC ratio. In some patients with accompanying atelectasis, parenchymal and pleural scarring, restrictive or mixed/obstructive and restrictive physiology may be seen with reduced FVC and normal FEV_1/FVC ratios. Lung volumes may help identify restriction, as the total lung capacity (TLC), functional residual capacity, and residual volume (RV) are reduced. With mainly obstruction, air trapping is evident with increased residual volume and increased RV/TLC.

BACTERIOLOGY

Patients with bronchiectasis are frequently found to be colonized by potentially pathogenic microorganisms. Thus even in stable conditions 60 to 80 percent of patients with bronchiectasis are known to be colonized. The most frequent microorganisms isolated are *H. influenzae* and *P. aeruginosa* and are often implicated as the cause of periodic exacerbations. Colonization with *P. aeruginosa,* in particular, has been associated with more severe impairment of lung function, more intense inflammatory response, and more extensive lung disease. Shah et al. showed an association between the isolation of *S. aureus* and the presence of ABPA or CF. Instances of airway colonization with other potential pathogens that may require specific treatment include *Nocardia asteroides, Aspergillus fumigatus,* and environmental *Mycobacterium* spp. Microbiologic flora isolated in three studies are shown in Table 125-2.

TREATMENT

The treatment of bronchiectasis is aimed at controlling infection, reducing inflammation, and improving bronchial hygiene, with surgical resection of affected areas being useful in selected patients. With few clinical trials for guidance, treatment often has to be tailored to the specific needs, tolerances, and preferences of individual patients.

Control of Infection

Since infection plays a major role in the causation and perpetuation of bronchiectasis, reducing the microbial load and

associated inflammatory mediators remains a cornerstone of therapy. Antibiotics are indicated to treat an acute exacerbation. However, they have been used variably to prevent recurrent infections by suppression and/or elimination of attendant flora. Antibiotics are directed at commonly isolated pathogens such as *H. influenzae, S. pneumoniae*, and *P. aeruginosa*. Oral fluoroquinolones are often used as initial antibiotic choices for treatment durations of 10 to 14 days. In the face of failure to respond to treatment or the occurrence of frequent exacerbations over short periods of time, sputum cultures and sensitivity tests should be done to help define antibiotic selection and/or aid in alternate diagnoses, e.g., atypical mycobacteria or fungae. Severe exacerbations due to *P. aeruginosa* require the intravenous administration of two antipseudomonal antibiotics and potential hospitalization.

The role of prophylactic/suppressive antibiotics remains controversial. Several approaches to the prescription of suppressive antibiotics exist, including daily antibiotics, antibiotics given for 1 to 2 weeks each month, as well as more prolonged courses lasting weeks to months.

The use of daily, twice weekly, and thrice weekly azithromycin as a biological response modifier in CF and diffuse panbronchiolitis has generated considerable interest about a role in the treatment of bronchiectasis. A pilot trial reported decreased frequency of exacerbations, reductions in sputum volume, and improvements in quality of life and pulmonary function and reductions in levels of C-reactive proteins. Macrolides have been shown to have several biologic effects not related to antibacterial effect. These include effects on nuclear transcription factors with down-regulation of proinflammatory cytokines, suppression of iNOS, reduced adhesion molecule expression, reduced neutrophil chemotaxis and degranulation, cytoprotection against phospholipids, improvement in mucus rheology, reduction in bronchial hyperreactivity, effects on *Pseudomonas* biofilm production, and quorum sensing function.

Administration of antibiotic aerosols (chiefly tobramycin 300 mg nebulized twice daily against *Pseudomonas*) is effective in CF. Pilot studies of non-CF bronchiectasis have demonstrated a reduction in *Pseudomonas* density and even eradication of *Pseudomonas* in some patients, although side effects were also noticed, including increased cough, wheezing, dyspnea, tinnitus, voice alteration, and tobramycin resistance. The effects of other aerosolized antibiotics, such as aztreonam, colistin, and gentamicin alone or in rotation with tobramycin need to be assessed for efficacy and side effects.

MAC-associated bronchiectasis should be considered in patients not responding to antibacterial therapy. The diagnosis requires three or more independent sputum cultures (or two positive cultures and one positive smear) and radiologic evidence of progressive infiltrates, multiple nodules, and cavitation on chest imaging. In this setting MAC should be treated per American Thoracic Society guidelines with a macrolide, rifampicin, and ethambutol for at least 12 months after culture negativity. Streptomycin should also be considered for the initial 8 weeks in patients with a substantial MAC burden, e.g., patients with persistent strongly positive sputum cultures and cavitary disease on radiology.

ABPA responds to oral prednisone in doses of 0.5 to 1 mg/kg per day. The addition of antifungal azoles (itraconazole 400 mg/day for 2 months; then 200 mg/day) may confer additional benefits in terms of reducing fungal burden, steroid dose, and exacerbations. Early and appropriate therapy for ABPA may prevent or delay permanent airway destruction. Because of its relapsing course, monitoring of clinical, radiographic, and serologic responses (IgE) is necessary.

Bronchial Hygiene

Airway mucus clearance is a problem in bronchiectasis. Chest percussion and postural drainage have been the traditional method of facilitating mucus clearance. The onerous and labor intensive nature of physical therapy procedures such as chest wall percussion and postural drainage, and potential issues of hypoxemia and chest discomfort may result in poor patient compliance and the search for alternative therapies. Autogenic drainage, mechanical vibration with ultrasonic devices, positive expiratory pressure, and Flutter valve use without the assistance of another caregiver have been shown to achieve good chest clearance provided the patient has motivation, breath control, and the neuromuscular function to perform. An intrapulmonary percussive ventilation device and vibratory vest help provide mucus clearance in patients unable to perform the other techniques mentioned in the preceding. Studies document increased sputum expectoration using all these methods, with no method being demonstrably more effective or preferred. Thus it is recommended that patients should choose their modality based on ability, motivation, preference, needs, and resources.

Mucus Clearance

Mucus hypersecretion is a prominent feature of chronic inflammatory airways disease and little is known about the effects of current therapies for airways disease, because of the difficulties in quantifying mucus hypersecretion in clinical studies, both at baseline and in response to treatment. Maintenance of hydration with oral and/or intravenous fluids is considered useful in preventing inspissated sputum retention. Humidification of inhaled air or oxygen as an adjunct to chest physical therapy has been shown to significantly increase the wet weight of sputum produced. The use of nebulized normal or hypertonic saline and acetylcysteine may be considered as important adjuncts to chest physical therapy, although bronchospasm may be associated with the use of these agents. A randomized multicenter study evaluating the efficacy of aerosolized DNAse in non-CF bronchiectasis did not find it efficacious in this group of patients. Rather it was associated with increased pulmonary exacerbation

rates, hospitalizations, antibiotic use, and a fall in FEV_1 and FVC.

Bronchodilators

Bronchodilators such as beta agonists, anticholinergics, or theophyllines are frequently used in patients with bronchiectasis, since these patients show signs of airway obstruction and hyperreactivity. There are few reports documenting efficacy in bronchiectasis.

Anti-inflammatory Therapy

Persistent endobronchial inflammation isknown to play a significant role in the pathogenesis of bronchiectasis, and anti-inflammatory therapy may be beneficial. The role of inhaled steroids (fluticasone) in bronchiectasis was evaluated by Tsang et al., who found reduced sputum volume and purulence and reduced rates of exacerbations.

Surgery

Bronchiectasis generally is a diffuse disease and surgical extirpation of affected areas is often not feasible. However, in selected cases surgical resection of the most severely affected segments, bleeding segments, or areas harboring resistant tuberculosis or atypical mycobacteria may confer significant benefits in terms of symptom control, reduction of tenacious sputum production, elimination of large-volume bronchial bleeding, reduction of acute infective episodes, and improved quality of life. The surgical approach varies according to the centers offering this treatment, with some preferring a video-assisted thoracoscopy approach, while others recommend the lateral thoracotomy approach. The complications associated with surgery include spread of infection, bleeding, prolonged air leak, and poor lung expansion following surgery.

Lung transplantation is now considered a viable option in advanced cases, when earlier the risks of persistence of infection in the face of prolonged immunosuppression seemed prohibitive. The outcomes of patients receiving lung transplantation in non-CF bronchiectasis were recently reported by Beirne et al. Overall 1-year survival was 68 percent, and overall 5-year survival was 62 percent. Survival was higher in patients receiving two lungs, as was the FEV_1 and FVC.

Miscellaneous

While not evaluated specifically for bronchiectasis, vaccinations against *S. pneumoniae* and influenza should be considered in these patients. Smoking cessation should be emphasized as a matter of routine. Patients with advanced bronchiectasis with evidence of exercise and/or nocturnal desaturation should be considered for oxygen supplementation to delay the onset of pulmonary hypertension and cor pulmonale and improve exercise tolerance. Pulmonary rehabilitation and inspiratory muscle training may be considered, as these modalities have been documented to improve exercise tolerance.

CHAPTER

Pneumonia in Surgery and Trauma

Judith Hellman/Luca Bigatello

Pneumonia is the most common infectious complication in surgery and trauma patients, and importantly impacts on morbidity and mortality. Most postoperative and post-traumatic pneumonias and are acquired more than 48 hours after hospitalization and therefore are defined as nosocomial pneumonias. Nosocomial pneumonia is reviewed in detail in Chapter 130. Ventilator-associated pneumonia (VAP) is a subset of nosocomial pneumonia that occurs in critically ill surgery and trauma patients who are intubated and on mechanical ventilation. Although community-acquired pneumonia rarely occurs in surgery and trauma patients, the pathogens that are involved in pneumonia that occurs early after hospitalization may be the same as those that cause community-acquired pneumonia.

Several terms are currently used to describe various different nosocomial pneumonias. Hospital-acquired pneumonia (HAP) occurs 48 hours or more after admission to the hospital, and may or may not require treatment in the intensive care unit (ICU). Ventilator-associated pneumonia (VAP) occurs at least 48 to 72 hours after intubation. Health care–associated pneumonia (HCAP) occurs in patients who have had significant exposure to a health care facility, such as hospitalization within the 90 days prior to infection, residence in a nursing home or chronic care facility, recent treatment with intravenous antibiotics, or treatment in a hemodialysis unit.

Pneumonia is most often caused by gram-positive and -negative bacteria. Fungal and viral pneumonias are rare in surgery and trauma patients and generally occur in patients who are severely immunocompromised.

Numerous factors are involved in the development of pneumonia in surgery and trauma patients. Important host factors include age; pre-existing medical conditions; smoking; and pulmonary, nutritional, and immune status. Intubation

and mechanical ventilation increase the risk of pneumonia. Anesthesia increases the risk of developing pneumonia because there is the potential for aspiration during induction and intubation, particularly during emergency surgery and in patients with gastroesophageal reflux.

Making the diagnosis of pneumonia in surgery and trauma patients is fraught with difficulty because noninfectious pulmonary processes often have similar clinical and radiographic manifestations, and the respiratory tract may be colonized with bacteria that are not acting as pathogens. Generally, the combination of clinical findings (fever, cough, sputum production, and respiratory dysfunction) and laboratory and radiographic data are used to make the diagnosis of pneumonia. However, this strategy likely results in an overestimation of the rate of pneumonia.

Guidelines have been published for the management of nosocomial pneumonia. These guidelines are evidence based as much as possible and were generated based on extensive review of clinical studies, and on expert opinions in areas that have not yet been fully investigated. The guidelines are included in publications that provide exhaustive reviews of nosocomial pneumonia, including epidemiology, microbiology, diagnosis, and treatment.

Management of pneumonia in surgery and trauma patients falls into two basic categories: prevention and treatment. Preventive strategies are implemented to reduce the likelihood of developing pneumonia. Postinjury interventions are used to minimize the risk of aspiration, facilitate secretion clearance, decrease colonization of the respiratory tract, and facilitate opening of small airways and alveoli.

Treatment of established pneumonia includes antimicrobials and supportive therapies. Early appropriate treatment has been shown to be important in reducing mortality. Initial antimicrobial therapy is generally empiric and has broad coverage of gram-positive and -negative bacteria, and possibly anaerobes. Antifungal and antiviral therapies may be appropriate in some situations. Subsequently, the antimicrobial regimen should be tailored based on response to empiric therapy and culture results.

EPIDEMIOLOGY

Pneumonia is the most common cause of infection in surgery and trauma patients. The reported incidence and outcome of pneumonia following surgery and trauma depend on a variety of factors, including the diagnostic criteria for pneumonia, the surgical procedure or pattern and intensity of trauma, baseline host factors, and management strategies. Not surprisingly, critically ill patients with pneumonia have a particularly high mortality rate. However, for unclear reasons, nosocomial pneumonia has not been shown to be an independent risk factor for death.

The incidence of pneumonia following trauma has been reported to be as low as 4 percent, and as high as 87 percent. More recent studies suggest that the incidence in trauma patients is roughly 20 to 45 percent. The incidence of pneumonia is higher in patients cared for in the ICU. Head trauma patients are at highest risk of developing pneumonia. Several factors may contribute to the increased risk of pneumonia in head trauma patients. Intubation and mechanical ventilation, which are frequently required in patients with neurotrauma are known to increase the risk of pneumonia. In addition, altered levels of consciousness or impaired swallowing/airway reflexes due to localized neurological injuries may predispose patients to aspirate by impairing mechanisms involved in protecting the airway and clearing respiratory secretions. Trauma patients who develop pneumonia have a high mortality, although pneumonia is often not the direct cause of death. The mortality rate in trauma patients who develop pneumonia has been reported at approximately 44 percent versus 19 percent in trauma patients without pneumonia. The mortality rate is higher in patients who are infected with *Pseudomonas aeruginosa (P. aeruginosa)* or when there is associated bacteremia.

Pneumonia is currently the most commonly diagnosed postoperative infection, surpassing surgical wound, urinary tract, and bloodstream infections, which were more common than pneumonia in studies in the 1960s to 1980s. The postoperative nosocomial pneumonia rate has been reported in the approximately 1.5 to 20 percent. Pneumonia occurs more frequently in surgery patients with pre-existing lung disease and patients who undergo major upper abdominal or thoracic surgery. The mortality associated with postoperative pneumonia varies in different studies and has been reported at 20 to 50 percent. In one study, the mortality rate was reported at approximately 20 percent in surgery patients who develop pneumonia, and 2 percent in surgery patients without pneumonia.

RISK FACTORS

Numerous risk factors have been identified for the development of post-injury pneumonia (Table 126-1). Modifiable risk factors should be identified early so that preventive strategies can be implemented (Table 126-2). In some cases it may be appropriate to delay elective surgery to optimize the status of high-risk patients preoperatively.

Preinjury Risk Factors

Risk factors for development of postinjury pneumonia vary between surgery and trauma patients. Factors that have been shown to be associated with the development of pneumonia in trauma patients include: age greater than 55 years, low Glasgow coma score, head trauma, high injury severity score, blunt injury, shock, and emergency intubation. Pneumonia occurs most frequently in neurotrauma patients, perhaps due to aspiration resulting from a decreased ability to protect the airway, and increased need for emergency intubation.

Factors that have consistently been shown to increase the patient's risk of postoperative pneumonia include advanced age, pre-existing lung disease, a history of smoking,

Table 126-1

Factors that Increase the Risk for Nosocomial Pneumonia

Baseline Characteristics of Patient
- Age >55–60 years
- Preexisting lung disease
- History of smoking
- Obesity
- Poor nutritional status
- Immunocompromise
- High ASA* class

Operative Factors
- Emergency surgery
- Site/type of surgery: Highest with upper abdominal and thoracic surgery
- Anesthesia: General anesthesia

Trauma-Related Factors
- Aspiration during trauma
- Injuries to abdomen
- Injuries to chest
- Low Glasgow coma score

Post-Injury/Post-Operative Factors
- Prolonged intubation and mechanical ventilation
- Immobility
- Inadequate analgesia
- Enteral tubes and feeds
- Prior treatment with antibiotics
- Treatment with corticosteroids

*ASA = *American Society of Anesthesiologists.*

Table 126-2

Preventive Strategies

Preoperative and Intraoperative
- Optimize pulmonary status
  - Smoking cessation
  - Bronchodilators for COPD
  - Consider steroids for refractory wheezing in asthma patients
- Weight reduction
  - Decrease risk of aspiration during induction of anesthesia and intubation in patients with GE reflux, gastroparesis, full stomach
  - Metoclopramide to facilitate gastric emptying prior to induction
  - Consider rapid sequence induction of anesthesia and intubation with cricoid pressure throughout

Postoperative/Post-trauma
- Early ambulation
- Head of bed elevation
- Optimize analgesia
- Specialized beds: rotation and percussion
- Minimize antibiotics: limit duration of perioperative coverage if required
- Chest physiotherapy
- Oral antisepsis

obesity, poor baseline nutritional status, and immunocompromise. The baseline health status is clearly important. Additional factors that also have been reported to be associated with increased risk of postoperative pneumonia include weight loss over a 6-month period, long-term steroid use, recent significant alcohol use, and history of cerebrovascular accident or impaired sensorium. The American Society of Anesthesiologists physical status scale (ASA class) attempts to quantify patients' overall status preoperatively by assigning a score of 0 (no significant baseline medical problems) to 5 (moribund with little chance of survival). Studies suggest that the risk of postoperative complications is increased in patients with a higher ASA class.

Operative Risk Factors

The frequency of pneumonia is increased in patients undergoing emergency surgery. Various factors may contribute to pneumonia in patients undergoing emergency surgery. First, because time will not permit preoperative optimization, patients may be physiologically worse than patients who have been prepared for nonemergent surgery. Second, the nature of the process requiring emergency surgery is more likely to be associated with a worse overall physiological state. Third, patients undergoing emergency surgery often have a full stomach as they have not fasted preoperatively and may also have impaired gastrointestinal motility. This increases the risk of vomiting and aspiration during induction of anesthesia and endotracheal intubation.

The type of anesthetic may impact on postoperative pneumonia in patients who undergo nonemergent surgery. Studies suggest that the risk of pneumonia is higher in patients who undergo general anesthesia alone versus spinal or epidural anesthesia with or without general anesthesia. Patients undergoing upper abdominal, thoracic, neck, peripheral vascular, and neurosurgery have an increased likelihood of developing postoperative pneumonia. The risk of pneumonia is highest following upper abdominal and thoracic surgery. The risk of postoperative pneumonia is also increased in trauma patients who undergo craniotomy.

Trauma-Related Risk Factors

Pneumonia may result from aspiration at the time of or following trauma. Injuries to the chest or abdomen may predispose patients to respiratory infections because of inability to adequately clear secretions from the airways due to pain, and

inability to maintain adequate expansion of distal airways and alveoli, which is presumed to lead to atelectasis and collapse.

Postinjury Risk Factors

A variety of postoperative and post-traumatic causes may contribute to the development of pneumonia. Hospitalized patients have higher rates of colonization with gram-negative bacteria. The combination of increased oropharyngeal and gastric colonization, and decreased ability to clear secretions and fully expand small airways and alveoli probably contribute to the development of pneumonia. Normal host defenses that are designed to protect the airways from aspiration and facilitate clearance of microbes often are impaired. Factors that predispose include impaired immunity, the inability to protect the airway due to altered level of consciousness, inadequate cough and expansion of the lungs due to pain and splinting, and the presence of endotracheal tubes, which can provide a direct conduit for inoculation of microorganisms.

Immobility is an important factor in the development of pneumonia. Factors that contribute to immobility include inadequate pain control, weakness, alterations in level of consciousness, and the type of surgical procedure. Early ambulation and participation in efforts to mobilize secretions such as coughing or chest physiotherapy are important preventive measures. Adequate pain control to facilitate ambulation, coughing, and deep breathing decreases the likelihood of developing pneumonia in surgery and trauma patients. However, if narcotics are used in excess, they can depress the level of consciousness and impair the ability to protect the airway, and hence increase the risk of pneumonia.

The presence of devices such as endotracheal tubes and nasogastric tubes increase the risk for pneumonia. Intubation and mechanical ventilation has been reported to increase the risk three- to 21-fold, and the risk also increases with longer duration of intubation. The presence of nasogastric tubes and the use of enteral feeding also increase the risk. However, avoidance of enteral feeding is not encouraged since poor nutritional status and alternative options for nutrition (e.g., parenteral feeding) also increase the risk of infection. The supine position has also been shown to increase the risk of pneumonia in intubated and nonintubated patients perhaps due to increased tendency of gastric contents to regurgitate into the oropharynx. Many ICUs currently have protocols for routinely maintaining patients in a semirecumbent position, with the head elevated to 30 to 40 degrees, rather than in a fully supine position.

Gastric colonization with bacteria also may contribute to nosocomial pneumonia. In general, the stomach has an extremely low pH, which minimizes bacterial colonization of the stomach. The use of agents that alkalinize the stomach in order to prevent gastric stress ulcers increases gastric colonization with bacteria. Some reports suggest that ICU patients who are treated prophylactically for stress ulcer have a higher incidence of pneumonia. However, the populations under study may differ, and some studies suggest that trauma patients treated with H_2 receptor antagonists are not at an increased risk of developing pneumonia.

The in-hospital use of antimicrobial agents has been associated with an increased risk of nosocomial infections, including nosocomial pneumonia. Particularly in critically ill mechanically ventilated patients, the prolonged use of antimicrobial agents is thought to favor selection and subsequent colonization of the airways with multidrug-resistant pathogens. The use of broad-spectrum antibiotics has been shown to promote the occurrence of VAP from resistant strains of *P. aeruginosa*, *Acinetobacter* spp., and methicillin-resistant *staphylococcus aureus* (MRSA). A recent observational study of ICU patients identified the prolonged use of antibiotics and the use of quinolones as independent risk factors for the development of multidrug-resistant bacteria in tracheal aspirates, including MRSA, *P. aeruginosa*, *Acinetobacter* spp., and *Stenotrophomonas maltophilia*. In patients with acquired multidrug-resistant organisms, the infections were related to these organisms, longer duration of mechanical ventilation, and longer stay in the ICU are required.

Other factors that have been shown to be important include reintubation, tracheotomy, use of positive end-expiratory pressure, intense sedation, and the use of corticosteroids, muscle relaxants, barbiturates, and inotropic agents. However, many of these factors seem to reflect the poor overall status of the patient, and may not be directly responsible for causing pneumonia.

PATHOGENESIS

Environmental factors, the surgical procedure, the pattern and degree of traumatic injuries, and patient characteristics play a role in the development of pneumonia in trauma and surgery patients. Early pneumonia may result from gross aspiration at the time of the trauma, or during induction of general anesthesia. General factors that may contribute to the development of pneumonia include aspiration of colonized oropharyngeal secretions or inhalation of aerosolized matter, the inability of the patient to clear secretions, and impaired host immunity. Inadequate secretion mobilization may result from abnormal mucociliary function, inactivity, supine positioning, and inadequate cough due to weakness or splinting from pain.

Severe tissue injury causes generalized dysregulation of immunoinflammatory responses, which contributes to the development of infections in patients undergoing surgery or who have experienced trauma. It is currently believed that tissue injury activates a biphasic inflammatory response in which initial generalized hyperinflammation is followed by immunodepression. The generalized inflammation, or systemic inflammatory response syndrome (SIRS), leads to activation of the coagulation and complement cascades, and is believed to cause disturbances in microvascular blood flow, impaired use of oxygen, and to be responsible for the multiple organ dysfunction syndrome (MODS).

The anti-inflammatory response is characterized by increased levels of anti-inflammatory cytokines, decreased responsiveness of inflammatory cells to microbial toxins, and altered ratios of T-suppressor to T-helper cells. The immunodepression resulting from major trauma and surgery predisposes patients to the development of infectious complications, including pneumonia. Studies are currently underway to evaluate methods designed to restore proper balance to the immune system, so that there will be adequate defenses against infection without tipping the balance toward hyperinflammation (reviewed in Faist et al., 2004).

Numerous other factors also contribute to the development of pneumonia in particular situations. Prolonged intubation is known to increase the risk of VAP, probably through pooling and microaspiration of oropharyngeal secretions around the endotracheal tube cuff, and inoculation via devices such as suction catheters and bronchoscopes. Although there may be some advantage to the use of noninvasive ventilation in appropriately selected patients, studies do not support a strategy of noninvasive ventilation to avoid reintubation in patients who are failing extubation. In trauma patients with pulmonary contusions, lung lacerations, or pneumatoceles, the presence of blood or devitalized tissue provide conditions for bacterial growth leading to development of pulmonary infections.

MICROBIOLOGY

Pneumonia following surgery and trauma is most often caused by a mix of bacteria. Particular pathogens vary with the duration of hospitalization prior to the onset of infection, antecedent antibiotic treatment, and exposure to health care facilities. Early-onset pneumonia, which occurs within 4 days of hospitalization in patients who have not received antibiotics, is more likely to be caused by non–drug-resistant bacteria that had colonized the patient prior to admission. Pneumonia in the first week following trauma or surgery is most often caused by *Haemophilus influenzae*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*.

Late-onset pneumonia, which occurs 5 or more days after admission, is more likely to be caused by multidrug-resistant bacteria. Common gram-negative bacterial pathogens include *Escherichia coli*, *Enterobacter* spp., *P. aeruginosa*, *Acinetobacter* spp., *Klebsiella pneumoniae*, and *Citrobacter* spp. *S. aureus* is the most common gram-positive pathogen in burn and surgical ICU patients. Methicillin-resistant *S. aureus* (MRSA) has increasingly become a problem in ICU patients. Recent studies suggest that more than 50 percent of *S. aureus* infections in the ICU are caused by MRSA. MRSA is also a common pathogen in head trauma patients. Anaerobic bacteria also have been cultured from respiratory secretions of patients with pneumonia, and may be important in the development of lung abscesses.

Fungi such as *Candida* spp. and *Aspergillus fumigatus* may cause pneumonia in patients who undergo organ transplantation, are neutropenic, or are otherwise severely immunocompromised. Although *Candida* spp. often colonize the respiratory tract of hospitalized patients, true *Candida* pneumonia is rare in immunocompetent patients.

CLINICAL FEATURES AND DIAGNOSIS

As mentioned, pneumonia in trauma and surgery patients is most often nosocomial, which is reviewed in detail in Chapter 130. Ventilator-associated pneumonia (VAP) is defined as pneumonia that occurs more than 48 hours after tracheal intubation. Since most clinical studies of nosocomial pneumonia have focused on VAP, our discussion of the diagnosis of pneumonia in surgery and trauma patients will focus on the entity of VAP.

Unlike community-acquired pneumonia, the diagnosis of VAP is difficult, and is still the subject of much debate. Clinically, the diagnosis of VAP includes three main components: a new or worsening consolidation on the chest radiograph, local (bronchial secretions) and systemic signs of infection, and microbiological evidence of respiratory infection. However, in trauma and surgical patients, systemic signs of inflammation can be virtually indistinguishable from infection (fever, leukocytosis, tachycardia, etc.). At one time, a dispute existed between those who favored a clinical versus a bacteriological diagnosis; it is now clear that a purely clinical diagnosis is no longer acceptable because of its low specificity in hospitalized, mechanically ventilated patients. Radiographic findings are notoriously nonspecific in critically ill patients and in those that have sustained chest trauma. Noninfectious infiltrates may be present in patients with pulmonary contusions, atelectasis or lobar collapse, or during episodes of congestive heart failure. Therefore, the clinical findings must be associated with definite microbiological evidence of deep seeded respiratory infection.

The current diagnostic debate in the literature is concerned with the type of bacteriological methodology that should be added to the clinical findings suggestive of nosocomial pneumonia. Although lung biopsy could be considered the gold standard diagnostic test, it is risky and impractical in most situations. The main available alternatives include: (1) blind tracheal aspiration of tracheobronchial secretions; (2) specimens of the distal airways by biopsy obtained using either broncho-alveolar lavage (BAL) or protected specimen brush (PSB), and (3) blindly collected specimens of the distal airways, or mini-BAL (Table 126-3). The major recommendations by experts concerning the use of these techniques have been published recently and can be summarized as follows:

1. Whenever possible, a sample of the distal airways should be obtained before starting or changing antimicrobial therapy. In principle, bronchoscopic techniques seem to be more reliable than blind techniques because they can direct the collection of

Table 126-3

Techniques Available to Sample Tracheobronchial Secretions to Diagnose Ventilator-Associated Pneumonia

	Advantages	Diagnostic Power	Disadvantages
Blind tracheal aspirate	Easy, safe, does not need a physician, rapid qualitative reading	High sensitivity (>90%), but high contamination rate—very low specificity	May lead to overuse of antimicrobial therapy
Bronchoscopic PSB	Lowest contamination from higher airways	Moderate sensitivity (90%), best specificity (≥90%)	24–48 hr wait for growth, technically difficult, expensive
Bronchoscopic BAL	Samples a large alveolar area, rapid qualitative reading	High sensitivity (>90%), moderate specificity because not protected	Time consuming, not ideal in unstable patients
Mini-BAL	Deeper than tracheal, protected, does not need a physician	Equivalent to BAL (small number of studies)	Blind, potential for inadequate sampling

specimens to the areas of the lung that the radiographs indicate are probably affected. However, this premise has not fully been confirmed by controlled studies. Non-protected specimens, such as those collected by simple bronchoscopy and BAL, can be contaminated by upper airway nonpathogens. The PSB yields the most specific results, but may decrease sensitivity somewhat because the specimen is limited in size and does not yield a result for 24 to 48 hours. Moreover, the PSB technique is somewhat cumbersome and expensive. BAL samples a larger area of the lung (including alveolar epithelium), and can be plated immediately.

2. Nonbronchoscopic sampling techniques of the distal airways (mini-BAL) are becoming popular because they are less labor intensive and can be safely and effectively performed by nonphysicians. Commercially available mini-BAL catheters enable protected collection of samples. The obvious concern with the use of these catheters is that they cannot be directed visually into the specific areas of the lung. However, a recent study has indicated that BAL specimens obtained using blindly inserted mini-BAL catheters and using bronchoscopy are equivalent.
3. Blind tracheal aspiration has the obvious advantage of being simple to implement and inexpensive. It has a high sensitivity for pneumonia, but low specificity. Consequently, blind tracheal aspiration tends to favor overuse of antibiotics, a known risk for nosocomial infection, including VAP. One situation in which tracheal aspirates may be almost equivalent in their specificity to the bronchoscopic techniques is during ongoing antimicrobial therapy, which tends to decrease the bacterial load in the airways.
4. Quantitative or semiquantitative cultures are suggested, as opposed to simple qualitative sampling.
5. Use of tracheal aspirates to guide therapy during the evolution of the process is not universally recommended, because of the lack of specificity of the technique, which will lead to unnecessary prolongation of therapy.

The distinction between aspiration pneumonitis and actual aspiration pneumonia can be difficult and is important in determining whether or not to initiate the use of antibiotics. Infectious and noninfectious pulmonary complications may result from aspiration during induction and tracheal intubation as well as at other times in the perioperative period. Aspiration pneumonitis, or Mendelson's syndrome, is a noninfectious chemical pneumonitis that results from aspiration of sterile gastric contents (reviewed in Marik PE, 2001). Aspiration pneumonia is an infectious process that results from aspiration of oropharyngeal or gastric secretions that contain bacteria. For both aspiration pneumonia and aspiration pneumonitis the chest radiograph may show an infiltrate in dependent portions of the lung, most often in the right lower lobe. Antibiotics are often begun in patients who have been witnessed to aspirate and are deemed to be at high risk of developing aspiration pneumonia; such patients include those who are immunocompromised or otherwise severely debilitated, are taking H_2 blockers or antacids, and/or have preexisting pulmonary disease. Antibiotics are often withheld in patients who have been witnessed to aspirate, but that do not have significant risk factors for developing pneumonia. In such patients, antibiotics are initiated only if there is failure of the pneumonitis to improve after 48 hours of observation.

Complications of pneumonia include acute lung injury/acute respiratory distress syndrome (ALI/ARDS),

empyema, lung abscess, and very rarely necrotizing (gangrenous) pneumonia.

PREVENTION

Preoperative/Intraoperative

Preoperative interventions, such as optimizing the pulmonary status, smoking cessation, and bolstering nutritional status may be indicated prior to elective surgery. Postoperative pulmonary complications have been shown to be decreased in COPD patients treated with bronchodilators preoperatively, and there is evidence that there are also fewer pulmonary complications in adequately treated asthma patients. In asthma patients with refractory wheezing, it may be appropriate to initiate corticosteroids prior to surgery and continue the steroids through the early postoperative period. Although smoking cessation has been shown to decrease the incidence of postoperative pulmonary complications, studies suggest that this decrease does not occur until more than 8 weeks following cessation.

Gastroesophageal reflux, gastroparesis, obesity, pregnancy, and emergency surgery increase the risk of aspiration during induction of general anesthesia and intubation. Measures to prevent reflux and aspiration should be considered preoperatively such as treating the patient with the promotility agent metoclopramide to facilitate gastric emptying. In addition, a rapid sequence induction with application of cricoid pressure should be considered in patients who are at high risk of vomiting and aspirating. The rapid sequence induction is generally accomplished by simultaneously providing the induction agent and muscle relaxant. In order to avoid distention of the stomach, the patient is then intubated without attempting to ventilate via a mask. Pressure is applied to cricoid cartilage on the anterior neck starting immediately before administration of induction agents throughout the entire induction and intubation to occlude the esophagus so that gastric contents do not reflux into the pharynx. This method of induction can be risky and have catastrophic consequences in patients who cannot be intubated and cannot be ventilated by mask. Thus, modifications may be appropriate depending on the patient's airway and pulmonary function/reserve.

A variety of interventions can be implemented following surgery or trauma to decrease the likelihood of developing pneumonia. The basic goals of these interventions are to: (1) prevent aspiration of colonized oropharyngeal or gastric secretions; (2) facilitate clearance of respiratory secretions; and (3) maintain adequate tidal volumes so that small airways and alveoli remain open to avoid atelectasis and collapse, which presumably provides good conditions for bacterial growth. Although the general principles of prevention are similar, the strategies used to prevent pneumonia vary based on the clinical status of the patient. For instance, nonintubated patients actively participate in prevention, whereas intubated patients play a more passive role. Other strategies include minimizing the duration of intubation, using specialized beds for percussion and oscillation to facilitate clearance of secretions, and oral decontamination with antiseptic.

1. **Early mobilization, including ambulation.** Patients who are not intubated and who are physically able to do so should begin to mobilize as soon as feasible after surgery and/or trauma. The measures include sitting at the edge of the bed or in a chair, and if possible, ambulating.
2. **Head of bed elevation.** Studies suggest that the frequency of pneumonia is decreased in patients who are maintained in a semirecumbent position, with the head of bed elevated at least 45 degrees, than in patients who are fully supine.
3. **Analgesia.** Adequate analgesia is required after surgery and trauma to allow patients to clear secretions through coughing and mobilization, and facilitate ventilation and prevent or correct atelectasis and collapse. A properly titrated analgesic should alleviate pain without sedating the patient. Excessive oversedation may lead to aspiration due to inability to protect the airway. Epidural analgesia may be of benefit in both surgery and trauma patients; a properly functioning epidural catheter should provide excellent analgesia without significantly affecting the sensorium.
4. **Rotational beds and percussion.** Specialized beds often are used to limit pooling of secretions and facilitate the clearance of secretions. Options include turning the patient, changing posture, and percussion.
5. **Chest physiotherapy (performed in both intubated and non-intubated patients).** It is believed to assist with mobilization of respiratory secretions and to prevent or facilitate expansion of atelectatic and collapsed areas of the lung.
6. **Oral antisepsis.** Oropharyngeal colonization has been shown to be an independent risk factor for the development of gram-negative pneumonia in ICU patients. Although oral antisepsis using chlorhexidine has been reported to decrease the rates of nosocomial respiratory infections in patients undergoing cardiac surgery, until now studies in ICU patients have not confirmed a decrease in pneumonia.

TREATMENT OF PNEUMONIA IN TRAUMA AND SURGERY PATIENTS

This section provides a general overview of the principles of treatment of pneumonia in surgery and trauma patients. A more comprehensive review of specific treatment protocols is discussed in Chapter 130. Early treatment with appropriate antibiotics significantly impacts on outcome, underscoring the importance of selecting particular antibiotics. Often

initial treatment must be empiric, without definitive culture data to guide therapy. Most empiric treatment is broad, covering gram-positive and -negative bacteria, and possibly anaerobes. When culture and sensitivity data become available, there should be a de-escalation of antibiotics. The final regimen should target individuals pathogens based on sensitivities to individual antibiotics and the regimen should be least likely to facilitate colonization and/or infection with more resistant bacteria.

The empirical choice of antibiotics in trauma and surgery patients is influenced by a number of factors, including the duration of hospitalization or exposure to health care facilities before the pneumonia, previous antibiotic treatment, prior culture results, the likely mechanism of the pneumonia (aspiration versus hematogenous spread versus invasion via a wound), and the presence of severe immunosuppression. The severity of illness may also factor into decisions about the choice of antibiotics and may prompt earlier empirical initiation of antibiotics. Empirical choices of antibiotics also must take into account the local flora and antibiotic resistance patterns that can vary considerably between different hospitals and communities. Much of the literature concerning treatment has focused on VAP, from which diagnostic and treatment strategies have been extrapolated and applied to the larger population of patients with hospital-acquired pneumonia.

Postoperative and trauma patients with pneumonia fall into two broad categories, which have important treatment implications. One category includes patients who develop pneumonia early during their hospitalization and have not had recent exposure to health care facilities. These patients are unlikely to be infected with multidrug-resistant pathogens; consequently they are not treated with empirical regimens that target resistant bacteria. The other group includes patients who develop HAP and VAP later during their hospitalization, and who therefore are likely to be colonized/infected with drug-resistant pathogens. These patients should receive broad-spectrum empirical therapy that targets multidrug-resistant bacteria. Empirical treatment with two agents against resistant gram-negative bacteria should be considered in patients who are severely ill and/or are likely to be infected with multidrug-resistant bacteria. Empirical treatment of pneumonia in patients who have recently received antibiotic should include an agent from a different antibiotic class.

Comprehensive guidelines for management of HAP, VAP, and HCAP and a comprehensive review of ventilator-associated pneumonia were recently compiled by a committee of experts from the ATS and IDSA. Important aspects of the guidelines include: (1) the early initiation of appropriate antibiotics; (2) tailoring empiric therapy to the likelihood of being infected with multidrug-resistant pathogens; (3) considering the use of combination antibiotic therapy for empiric or directed treatment of resistant gram-negative bacteria and for *P. aeruginosa*; (4) de-escalating therapy promptly when indicated by cultures of lower respiratory tract secretions and clinical response to therapy; (5) limiting the duration of therapy for "uncomplicated" pneumonia to 7 to 8 days to reduce the development of multidrug-resistant pathogens; and (6) considering using linezolid in lieu of vancomycin for treating MRSA VAP.

CONCLUSIONS

Pneumonia, a common problem following surgery or trauma, is associated with increased morbidity and mortality. Most instances of pneumonia in surgery and trauma patients are nosocomial because they occur more than 48 hours after admission to the hospital. However, pneumonia occurring early after surgery or trauma may be caused by the same pathogens that usually cause community-acquired pneumonia. Early pneumonia in patients who have not recently had significant exposure to a health care facility may be caused by non–drug-resistant microorganisms. Pneumonia that occurs later during hospitalization or in patients who have had significant exposure to health care facilities is more likely to be caused by antibiotic-resistant bacteria. This distinction has important implications when resorting to empirical antimicrobial therapy.

The diagnosis of pneumonia in patients who have experienced trauma or surgery can be difficult because the manifestations are non-specific. At present, the approach to the diagnosis is based on a combination of clinical, laboratory, and radiographic data. Sputum and blood cultures should be obtained before starting antibiotics to maximize the chance of identifying the pathogen. Initial treatment of pneumonia is usually empirical and uses broad-spectrum antibiotics that cover gram-positive and -negative aerobic and anaerobic bacteria. Subsequent antimicrobial therapy should be tailored to the pathogens identified in cultures of respiratory secretions or blood. Treatment with antiviral and/or antifungal agents may be appropriate in severely immunocompromised patients. When choosing antibiotics for the empirical treatment of pneumonia, it is important to take into account the local bacterial flora and patterns of antibiotic resistance.

Pulmonary Infection in Immunocompromised Hosts

Jay A. Fishman

OVERVIEW

Prolonged survival of individuals with AIDS, after solid organ and bone marrow transplantation, with connective tissue diseases, primary immune deficiencies, and after intensive chemotherapeutic regimens for cancer, has greatly expanded the population of immunocompromised hosts. These patients are defined by their susceptibility to infection with organisms that have little native virulence for the normal host. The detection of underlying immune compromise has been facilitated by improvements in microbiologic techniques, particularly molecular assays, and advances in imaging. Survival has also been improved by the availability of new antimicrobial agents, including antifungal agents, macrolides, antivirals (ganciclovir, foscarnet, and oral agents),

hematopoietic growth factors, and highly active antiretroviral therapies (HAART) for HIV infection. The major challenges in these populations include systemic infections for which adequate therapies have not yet been developed (e.g., hepatitis C virus) and the progressive antimicrobial resistance of common pulmonary pathogens, including *Staphylococcus aureus*, Enterococcus, *Pseudomonas*, and *Stenotrophomonas* (formerly *Xanthomonas*) spp., and selection of novel strains of bacteria, including non-tuberculous mycobacteria and *Nocardia* spp. In addition, the incidence has increased of strains of streptococci (including pneumococci) resistant to antimicrobial agents used for routine prophylaxis (i.e., trimethoprim-sulfamethoxazole and quinolones). With the changing health care scene, medical care of immunocompromised individuals is increasingly managed outside of academic centers. Therefore, information about the clinical management of these patients has become increasingly important to the entire spectrum of medical practitioners.

GENERAL PRINCIPLES

Opportunistic Infection

Opportunistic infection is defined as an infection occurring in an individual as a result of a compromised immune function that would not be expected to occur or would cause disease of lesser intensity in the presence of normal immune function. Thus, immunocompromised individuals are subject to the common infections that are present in the community, but these infections are likely to be of greater frequency or severity than in the immunologically normal host. In addition, infection in these patients may be caused by organisms of low native virulence or that cause insignificant disease in the normal host, including such organisms as *Pneumocystis carinii (jiroveci)* or cytomegalovirus (CMV).

The risk of infection in any patient is determined by the interaction of two factors: the potential pathogens to which the individual is exposed (epidemiologic exposures), and a measure of the individual's susceptibility to infection, termed the "net state of immunosuppression" (Table 127-1). The occurrence of infection in an individual at a time when the immune status of the patient is thought to be nearly normal is evidence that either an excessive environmental exposure has occurred or that the immune status of the individual is depressed. Conversely, even minimal environmental exposures can cause invasive infection in an individual who is maximally immunosuppressed.

Epidemiologic Exposures

Epidemiologic exposures of importance to the immunocompromised patient can be divided into two general categories: those occurring within the community and those occurring within the hospital. Exposures within the community vary based on such factors as geography and socioeconomic status. Thus, opportunistic pathogens acquired in the community include the geographically restricted systemic mycoses (blastomycosis, coccidioidomycosis, and histoplasmosis), *Mycobacterium tuberculosis, Strongyloides stercoralis, Leishmania donovani, Pneumocystis carinii, Legionella* species, and community-acquired respiratory viral infections (e.g., influenza, respiratory syncytial virus, and parainfluenza). Common viral agents may include herpes simplex virus, cytomegalovirus, varicella zoster, and hepatitis B and C viruses. Due to the limited effectiveness of many vaccines in immunocompromised individuals, infections resulting from *Streptococcus pneumoniae* and *Haemophilus influenzae* are common.

Within the hospital, excessive environmental exposures can be divided into two general categories: domiciliary and non-domiciliary. Domiciliary exposures occur on the hospital unit where the patient is housed. When the air, food, equipment, or potable water supply is contaminated with pathogens such as *Aspergillus* species, *Legionella* species, or vancomycin-resistant enterococci, clustering of cases of infection in time and space are observed. As a result, an increased incidence of nosocomial pneumonia or catheter and wound infections may be seen. Non-domiciliary exposures occur when the patient is transported to contaminated operating rooms, radiology suites, or catheterization laboratories for procedures. Non-domiciliary outbreaks, although possibly more common, are more difficult to detect because of the lack of clustering on a particular hospital unit. The leading clue to the presence of a nosocomial hazard is the occurrence

Table 127-1

Factors in the Net State of Immune Suppression

Immunosuppressive therapy: dose, duration, temporal sequence
Underlying immune deficiency: autoimmune disease, functional immune deficits
Mucocutaneous barrier integrity: catheters, epithelial surfaces, devitalized tissue, fluid collections
Neutropenia, lymphopenia
Metabolic conditions Uremia Malnutrition Diabetes Alcoholism with cirrhosis
Viral infection: Cytomegalovirus Epstein-Barr Virus Hepatitis B and C Human immunodeficiency virus

of opportunistic infection in a patient whose net state of immunosuppression would not normally lead to such an event, or nosocomial infection with organisms not known to be present on the clinical unit on which the patient is housed.

Net State of Immunosuppression

The net state of immunosuppression (Table 127-1) is a concept that describes all of the host factors that determine infectious risk, including: the dose, duration, and temporal sequence in which immunosuppressive drugs are deployed; injuries to the primary mucocutaneous barrier to infection (e.g., indwelling catheters, gastrointestinal or bronchial anastomoses in organ transplant patients); neutropenia or lymphopenia; underlying immune deficiency; pulmonary aspiration injury; metabolic problems, including protein-calorie malnutrition, uremia, and, perhaps, hyperglycemia; the presence of devitalized tissues, and fluid collections (hematoma, effusions, ascites); and infection with immunomodulating viruses (cytomegalovirus or CMV, Epstein-Barr virus or EBV, hepatitis B or HBV, hepatitis C or HCV, and the human immunodeficiency viruses, HIV-1 and -2), which predispose to other opportunistic infections, and also to graft rejection and graft-vs-host disease. The sum of the congenital, metabolic, operative, and surgery-related factors is the patient's net state of immune suppression. Generally, more than one factor is present in each host; the identification of the relevant factors, and correction when possible, are central to the prevention and treatment of infection in these hosts.

For example, in the alcoholic patient with hepatitis C and cirrhosis who has undergone liver transplantation, the so-called net state of immune suppression includes immunosuppression needed to maintain graft function, immune deficits caused by cirrhosis and chronic illness; immunologic and inflammatory effects of infection by hepatitis C virus; exposure to, and colonization with, community-acquired and nosocomial organisms; and new infections (e.g., spontaneous peritonitis) that may occur during the prolonged waiting period for a compatible organ. When the organ for transplantation does become available, it may arrive contaminated by organisms acquired by the donor during hospitalization. This gravely ill patient is then subjected to a major surgical procedure. After surgery the lungs are apt to be compromised, recovery of function in the allograft is often slow, immunosuppressive drugs are initiated, biliary (T-tube), intravenous, and urinary catheters are placed, and major incisions need to heal. Drug toxicities at this stage are common, often resulting in neutropenia and hepatitis. Biliary function and anastomotic integrity are assessed by injecting contrast dye into ducts and tubes (e.g., T-tube cholangiogram) that are colonized by native and nosocomial organisms. The sum of the underlying, operative, and transplant-related factors is the *net state of immune suppression.* Thus, the spectrum of susceptibility to infection is a *continuum* from individual deficits (e.g., viral upper respiratory infection that paves the way for bacterial superinfection) to multiple simultaneous deficits (e.g., the transplant recipient).

Timetable of Infection

In the broad spectrum of immunocompromised hosts, the risks of infection may be *relatively stable* over time, as in the diabetic with vasculopathy and neuropathy who is prone to skin and soft tissue infections. The risks of infection may be *time limited,* as in the postsurgical patient without complications or in the autologous bone marrow transplantation recipient with effective engraftment. The risk of infection may be *cumulative and progressive,* as in the AIDS patient, in whom infection is a function of declining immunity (without therapy), falling CD4 lymphocyte counts, rising viral loads, and the effects of other persistent infections (CMV, *Cryptosporidium*) (Fig. 127-1). In these individuals the occurrence of new infections suggests the progression of immune compromise. The risks may also be *progressive but not cumulative.* Thus, the risks of infection in the recipient of allogeneic stem cell or solid organ *change predictably with time* as a function of the evolving condition of the patient. For example (Fig. 127-2), in the early phase after hematopoietic stem cell transplantation (HSCT), infection is often the result of nosocomial exposures during neutropenia. Subsequently, following marrow engraftment but in the absence of preformed cellular immunity, viral pneumonitis (CMV) and hepatic veno-occlusive disease may occur. Finally, during the development of, and treatment for, acute and chronic graft-vs-host disease, susceptibility to infection is a function of immune suppression and mucosal injuries (possibly from chemotherapy, radiation, or infections such as *C. difficile* colitis).

With standardized immunosuppressive and chemotherapeutic regimens, specific types of infections often occur in a predictable pattern (time line) as a reflection of the specific risk factors (surgery, immune suppression, acute and chronic rejection, re-emergence of underlying diseases, viral infections—see Figs. 127-1 and 127-2) present at each phase of the post-transplantation course. The patterns have been altered by the availability of a broader range of immunosuppressive and chemotherapeutic agents, the use of stem cells instead of marrow for transplantation, and antimicrobial prophylaxis. However, the general concepts and major determinants of infection remain the same—the exogenous immune suppression or chemotherapy and any additional immune suppression used to treat either graft rejection or graft-vs-host disease. Superimposed viral infections will enhance the risk of infection at any point along the time line.

Because each risk factor renders the patient susceptible to infection by new groups of pathogens, *infections occurring with the "wrong" pathogen or at the wrong time suggest an undiscovered immune deficit (fluid collection, neutropenia) or an unusual epidemiologic exposure.* the occurrence of specific infections can be prevented by the use of antimicrobial prophylaxis, vaccines, and behavioral modifications (e.g., no raw vegetables or digging in gardens without masks). This results in a shift to the right of the time line—infections generally observed later in the course of disease or therapy are observed at the appropriate time *in the absence of infections that tend to occur earlier* but have been prevented by a variety of preventive

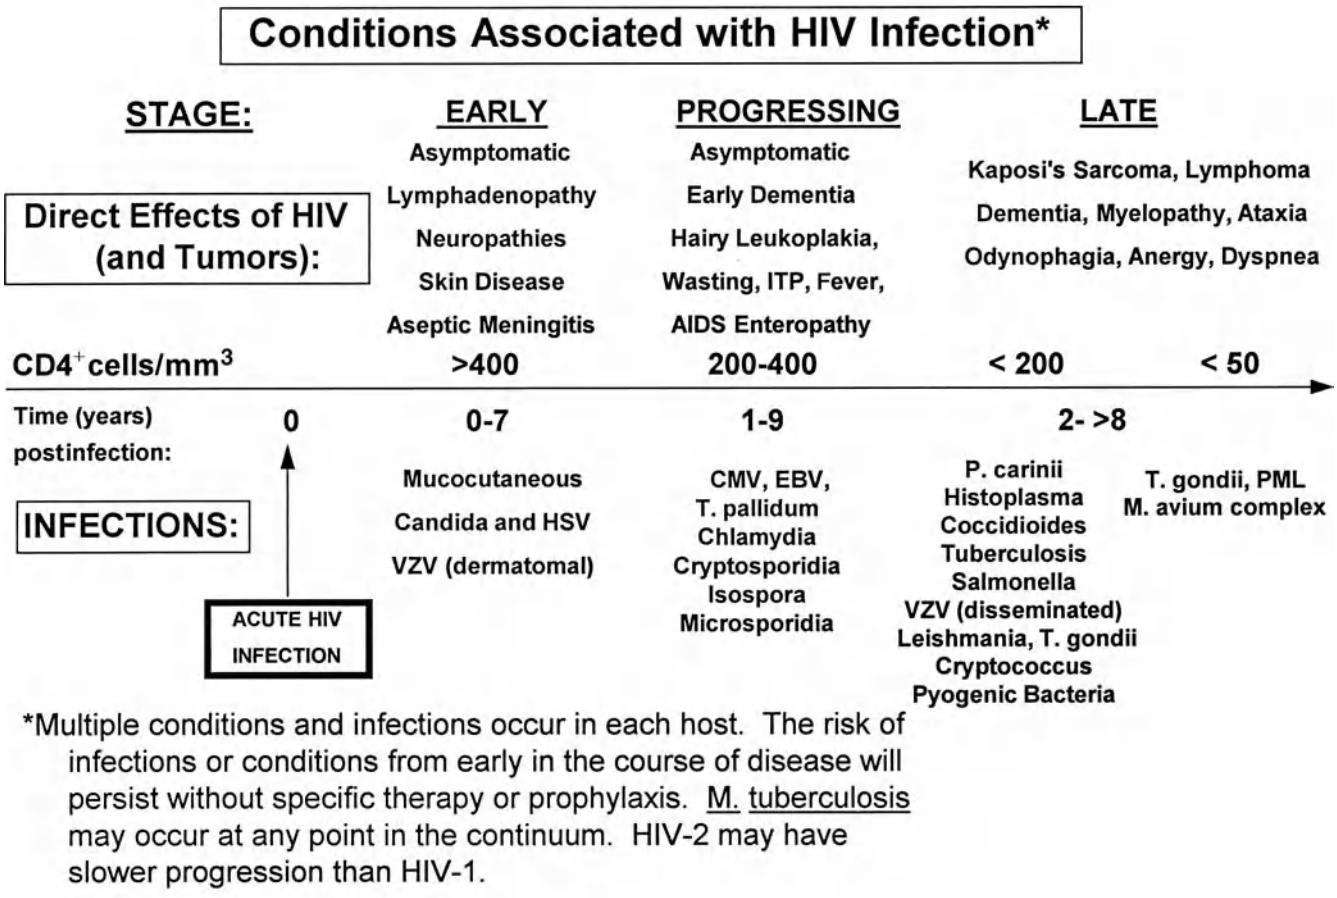

Figure 127-1 The progression of AIDS-associated conditions.

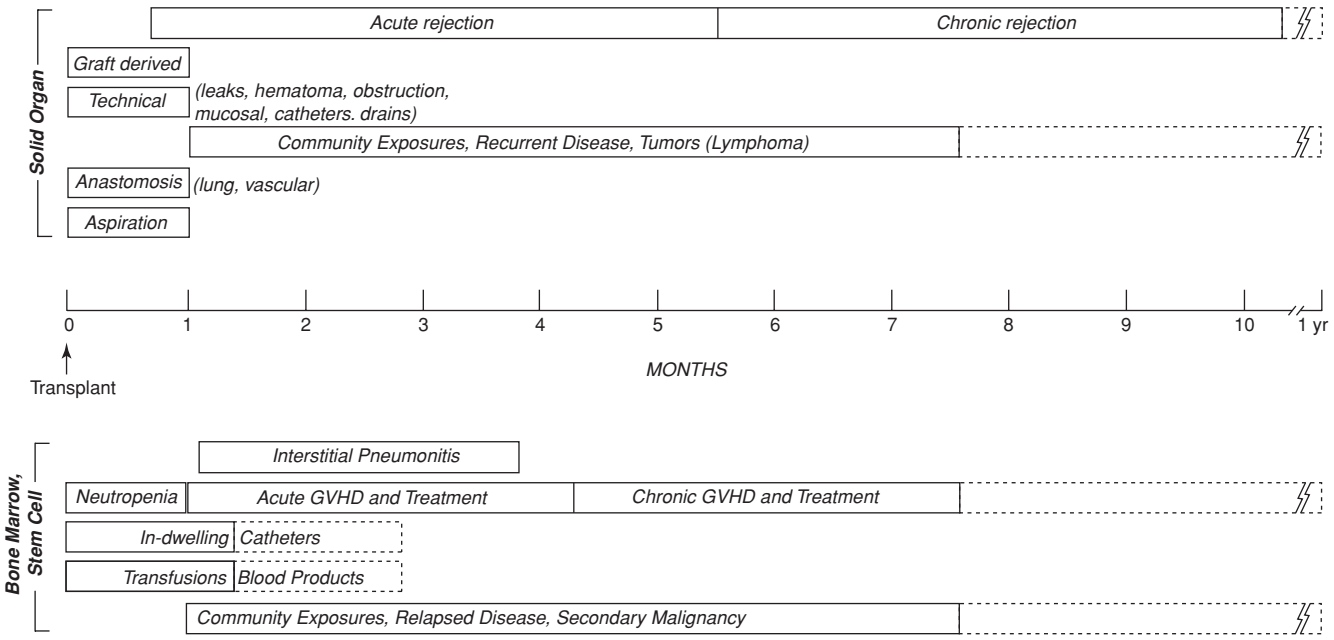

Figure 127-2 The timeline of conditions predisposing to infection in solid organ transplantation (above the timeline) and in bone marrow and stem cell transplantation (below the timeline). Patients will vary in individual susceptibility patterns.

measures. the timetables presented in Figs. 127-1 and 127-2 are useful in a number of regards:

1. Developing a differential diagnosis for infectious syndromes by time post-transplant: What type of infection is most likely at various times after transplantation.
2. Identification of excess epidemiologic hazards
   - Nosocomial: Aspergillus, MRSA, VRE: Clustered in time and space, by inpatient unit, procedures, or surgical suite
   - Community: Influenza, RSV, Legionella outbreaks
   - Individual: Unique exposures, travel, occupational hazards
3. Excessive immune suppression: Too many infections, too severe, or at the wrong time on time line suggests that a problem exists with immunosuppressive regimens used by a program.

MICROBIAL VIRULENCE AND INFECTION

The risk of infection in any individual patient depends not only on the sum of the immune deficits and the nature, duration, and intensity of the exposures to potential pathogens, but also on the *virulence* of the organism. Recent data suggest that the *specific host-pathogen interactions* are a critical factor in the development of infection. Such factors as the distribution of toll-like receptors, microbial production of biofilm, or antimicrobial resistance influence the pathogenesis of infection. Host cells may *enhance* the virulence of the invading organism by the *induction of genes in that organism* that contribute to bacterial persistence or invasion. Thus, resistance to phagocytosis is induced by target cells in *Yersinia* infections. Also, the survival of uropathogenic *E. coli* in urine and the growth of pili for attachment are induced by contact with the targeted uroepithelial cells. Another example of the host-pathogen interaction is the role of cytomegalovirus (CMV) in transplantation. CMV is the cause of common clinical syndromes that frequently occur in immunocompromised patients. Among these are pneumonitis, hepatitis, glomerulonephritis, gastritis, colitis, retinitis, and mononucleosis-like syndromes. CMV also induces an array of host responses (i.e., neutropenia, immune suppression, up-regulation of histocompatibility antigens and other cell surface antigens, TNFα secretion, graft rejection) that contribute to the host's susceptibility to infection (Table 127-2). Thus, the concept of immune status balanced against epidemiologic exposure may be incomplete: The immunoregulatory effects of some pathogens and the interaction of the organisms with the "correct" target cells of the host are best regarded as only part of the response to opportunistic infection.

Physical defects may also contribute to virulence. Foreign materials (vascular grafts, sutures, and eye or limb prostheses) may provide a nidus for infection by an organism that would not be capable of causing infection under normal conditions. Local immune defects coupled to physical factors may predispose to life-threatening infection. Thus, corticosteroid eye drops used for inflammation due to prosthetic lens implants may lead to eye infections with *Streptomyces, Bartonella, Sporothrix,* and *Fusarium* species. *Salmonella* infection in the organ transplant recipient "homes" to vascular anastomoses and may persist despite appropriate therapy, causing mycotic aneurysms.

Table 127-2

Effects of Viral Infection in the Immunocompromised Host

Direct causation of invasive viral infection
Immunomodulatory effects Systemic immune suppression—opportunistic infection Allograft injury Cellular effects—up-regulation of surface antigens and graft rejection
Oncogenesis and cellular proliferation Hepatitis B: hepatocellular carcinoma Epstein-Barr virus: B-cell lymphoproliferative disease (PTLD) Papillomavirus: squamous cell carcinoma, anogenital cancer HHV8 (KSHV): Kaposi's sarcoma, effusion lymphoma Cytomegalovirus: accelerated atherogenesis, bronchiolitis obliterans

PROTECTING THE PATIENT FROM INFECTION

Although the clinical care of the compromised host has improved, flaws in the armamentarium against infection have been highlighted by the emergence of bacteria and fungi that are resistant to common antimicrobial agents. For example, increasingly *Streptococcus pneumoniae* and *Neisseria gonorrhoeae* are detected that are resistant to penicillin, fluoroquinolones, and macrolides; enterococci are resistant to β-lactam antimicrobials, macrolides, vancomycin, teicoplanin, linezolid, quinupristin-dalfopristin, and aminoglycosides; *Pseudomonas* and enteric gram-negative bacteria are resistant to broad-spectrum β-lactam agents; and azole-resistant yeasts, all of which are routinely isolated both in the community and hospitalized patients. Moreover, decreases in the acquisition of infection by compromised hosts can only be accomplished by *complete* reverse precautions that entail the use of laminar airflow rooms and access to the patient only via glove-ports or the use of gowns, gloves, masks,

caps, and shoe covers. This practice reduces the incidence of hospital-acquired infection (as distinguished from spread of endogenous infection) by up to 50 percent, to the approximate rate of such infections in granulocytopenic patients.

However, the practice of *complete* reverse precautions is very costly and reduces patient contact by health care providers. Consequently, protection against both acquired and endogenous infections has fallen onto the broad use of prophylactic antimicrobials. Such oral agents as trimethoprim-sulfamethoxazole, quinolones, acyclovir (and related agents), and azole antifungal drugs now have widespread use in the management of both inpatients and outpatients. Oral decontamination regimens (i.e., nonabsorbable antimicrobials) have not been proved to prevent disease beyond limited periods of time, and are poorly tolerated because of taste, consistency, malabsorption of glucose and xylose bases, and cost. Moreover, the use of such prophylactic agents contributes to the emergence of antimicrobial-resistant organisms.

RECOGNITION OF NEW SYNDROMES

The identification of *new* infectious disease syndromes has often occurred in individuals with immune deficits. Thus, the cluster of cases of *Pneumocystis carinii* pneumonia in homosexual males was the first indicator of a new viral pathogen (HIV-1), and the role of *Cryptosporidium* as a common cause of diarrhea in both normal and compromised individuals was elucidated as a result of diarrheal disease in AIDS patients in the 1980s. Similarly, many uncommon bacteria (*Bartonella* species, *Rhodococcus equi*), viruses (Kaposi's-associated human herpesvirus 8, polyoma viruses), fungi *(Penicillium),* and parasites *(Microsporidia)* have been identified in immunocompromised patients. Thus, a continuing lookout for new pathogens or novel presentations of known pathogens is essential for the care of the immunocompromised patient. Often, infection in immunocompromised hosts presents without the expected signs and symptoms of infection. This lack of clinical manifestations may delay identification of the critically ill patient. In the outpatient setting, the practitioner must have a low threshold for performing tests (e.g., blood counts, cultures, radiographs) on patients with minimal complaints.

CONCOMITANT PROCESSES

Early and aggressive therapy of infection is required in the immunocompromised patient. Thus, most febrile or possibly infected patients are treated empirically while awaiting data that identify specific pathogens. The occurrence of multiple simultaneous infections or conditions often complicates and delays appropriate therapy (Fig. 127-3). For example, CMV infection may complicate the treatment of graft rejection or graft-vs-host disease and contribute to the pathogenesis of *Pneumocystis* or *Toxoplasma* pneumonia.

Figure 127-3 Chest radiograph of a 48-year-old heterosexual man with community-acquired pneumonia unresponsive to therapy. The patient was diagnosed as having AIDS on the basis of HIV seropositivity, CD4 lymphocyte count of 113 per milliliter, and *Pneumocystis carinii* and *Mycobacterium avium-intracellulare* complex pneumonia.

The radiologic appearance of pneumonia is altered by immune suppression (Fig. 127-4) (see also Chapter 114). Radiographic patterns may change during the care of the patient (e.g., cavitation of pulmonary nodules after the resolution of neutropenia). Noninfectious causes of pulmonary infiltrates may coexist with infection, and atypical patterns predominate. Drug toxicities (bleomycin, Cytoxan, sulfa drugs), leukoagglutinin reactions, radiation injury, pulmonary emboli, and lesions of metastatic cancer may coexist with opportunistic infection (Fig. 127-5). The typical evolution of pulmonary infection may be altered by the presence of underlying (e.g., interstitial) pulmonary disease as well as by diminished inflammatory responses. It is commonly necessary to repeat tests, to utilize computed tomography (CT), or invasive diagnostic modalities (biopsy) in the evaluation of the patient who is unresponsive to therapy. In the compromised host with fever and pneumonitis, chest radiographs may be difficult to interpret.

Complications of therapy may contribute to the development of new infections: Trimethoprim-sulfamethoxazole can cause pneumonitis, hepatitis, or Stevens-Johnson syndrome; ganciclovir can cause neutropenia; transfusion reactions can cause pulmonary infiltrates and hemolysis; cyclosporine can cause hemolytic-uremic syndrome; antimicrobials can contribute to thrush and *C. difficile* colitis.

Figure 127-4 Chest radiograph of an AIDS patient with atypical cryptococcal pneumonia. Diffuse interstitial infiltrates may be observed in fungemic patients with primary or secondary pulmonary infection.

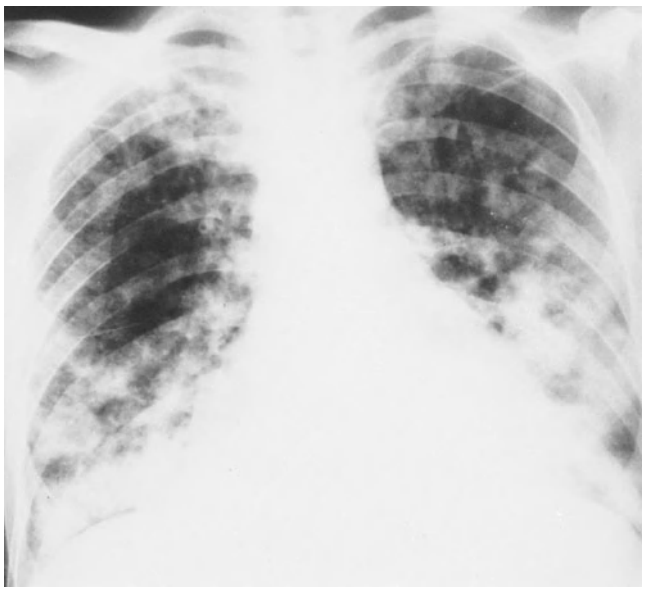

Figure 127-5 Chest radiograph of a 36-year-old homosexual man not known to be HIV-1 infected, with bilateral nodular infiltrates due to pulmonary Kaposi's sarcoma.

PATIENT MANAGEMENT

Antimicrobials alone may not suffice in the treatment of infection in the immunocompromised host. Improvement in host responses is often needed to clear ongoing infection. Infections may respond to a decrease in exogenous immune suppression, correction of neutropenia by growth factors, or treatment of simultaneous infections that predispose to superinfection (e.g., respiratory syncytial virus, CMV). Drainage of collections of infected fluid such as a hematoma or a lymphocele, or removal of drains or catheters enhances the treatment of infection. Identification of metastatic sites of infection (e.g., infections of the central nervous system due to *Nocardia* or *Cryptococcus* species) may facilitate management. Synergistic antimicrobial therapy must be used when available. Compromises often must be made. The loss of renal function due to antimicrobials used in the treatment of fungal infections significantly hinders patient management. However, progression of a fungal infection while on inadequate doses of amphotericin must be avoided.

Infection must be prevented in the susceptible host, since antimicrobials are often ineffective during acute infection. Whenever possible, vaccines should be given before immune suppression or splenectomy. During immune suppression, only killed or conjugate vaccines should be used. Repletion of immunoglobulin deficiencies (after BMT or solid organ transplantation) and the use of specific hyperimmune globulins (i.e., for exposure to varicella or for CMV) may help to prevent infection. Similarly, in patients susceptible to infection, the use of antimicrobials to prevent common infections is cost effective. The use of preemptive therapies based on tests that demonstrate the presence of infection (e.g., the administration of ganciclovir in patients with evidence of CMV infection by antigenemia assays or polymerase chain reaction studies) allows the interruption of infection before disease becomes manifest clinically. Similarly, routine surveillance cultures have been useful to detect specific pathogens in subgroups of patients (e.g., neutropenic patients with *Aspergillus* colonization) or in specific geographic regions.

The clinical *evaluation of the patient prior to immune suppression* may be very helpful in preventing disease. Patients with cystic fibrosis or chronic bacterial sinusitis may become colonized in the airways or sinuses with *Pseudomonas* or *Aspergillus*s pecies. These colonizing organisms may reactivate during immune suppression. Careful evaluation by radiography and invasive cultures may prevent major infection. Similarly, patients who are not immune to varicella zoster *may* benefit from vaccination. Patients seronegative for *Toxoplasma gondii* or CMV are at high risk of reactivation in the presence of an organ transplant from a seropositive donor. Similarly, seropositive patients with AIDS or before seronegative bone marrow transplantation are at high risk for reactivation disease due to *Leishmania,* CMV, or *Toxoplasma.* In endemic areas, transfusions and transplants may provide entry of *T. gondii, Trypanosoma cruzi* (Chagas' disease),

Leishmania species, *Acanthamoeba, Naegleria, Strongyloides stercoralis, Taenia* species, or *Echinococcus* species with exacerbation of infection by immune suppression. A careful clinical history and pretreatment of known infections or specific antimicrobial prophylaxis may prevent such complications of immune deficiency. Serologic tests are often useful in the stratification of risk for infection in the immunocompromised host.

GENERAL CONSIDERATIONS IN SPECIAL HOSTS

The spectrum of common infections varies with specific immune defects in each type of host (Table 127-3) and are considered subsequently.

HIV Infection and AIDS

The management of HIV infection has been dramatically altered for those individuals with access to antiretroviral therapies and is covered in detail by Fangman and Sax in Chapter 128. Anti-HIV therapy should be started before the immune system is irrevocably compromised. Most practitioners are treating all individuals with progressive HIV infection, and all HIV-infected individuals with CD4 counts below 200/mm^3. HAART has resulted in the recrudescence of immunity as manifested by rising CD4+ lymphocyte counts and diminished signs of opportunistic infection and cancer associated with severe T-cell deficits. Treatment of HIV infection with highly active antiretroviral therapy (HAART) with reversal of immune deficiency appears to eliminate the risk of *Pneumocystis* pneumonia (studied up to 2 years) in AIDS patients with and without prior *Pneumocystis* pneumonia. The risk of *Mycobacterium avium* complex, tuberculosis, and

Table 127-3

Infections Associated with Specific Immune Defects

Defect	Common Causes	Associated Infections
Granulocytopenia	Leukemia, cytotoxic chemotherapy, AIDS, drug toxicity, Felty syndrome	Enteric gnr, *Pseudomonas, S. aureus, S. epidermidis,* streptococci, *Aspergillus, Candida,* and other fungi, *S. aureus, Candida, streptococci*
Neutrophil Chemotaxis	Diabetes, alcoholism, uremia, Hodgkin's disease, trauma (burns) lazy leukocyte syndrome, CT disease	
Neutrophil killing	CGD, myeloperoxidase deficiency	*S. aureus, E. coli, Candida, Aspergllus, Torulopsis*
T-cell defects	AIDS, congenital lymphoma, sarcoidosis, viral infection, CT ds, organ transplants, steroids	Intracellular bacteria (*Legionella, Listeria,* mycobacteria), HSV, VZV, CMV, EBV, parasites (*Strongyloides, Toxoplasma*), fungi (*P. carinii, Candida, Cryptococcus*)
B-cell defects	Congenital/acquired agammaglobulinemia, burns, enteropathies, splenic dysfunction, myeloma, ALL surgery, sickle-cell anemia, cirrhosis	*S. pneumoniae, H. influenzae, Salmonella,* and *Campylobacter* spp., *Giardia lamblia*
Splenectomy		*S. pneumoniae, H. Influenzae, Salmonella* spp., *Capnocytophaga.*
Complement	Congenital/acquired defects	*S. aureus, Neisseria* spp., *H. influenzae, S. pneumoniae*
Anatomic	IV/Foley catheters, incisions, anastamotic leaks, mucosal ulceration, vascular insufficiency	Colonizing organisms, resistant nosocomial organisms

cytomegalovirus (CMV), has also decreased. Thus, prophylactic (both primary and secondary) and therapeutic regimens must be considered in light of the individual's immune status. Not all patients respond to HAART or maintain viral suppression during therapy. The specifics of antiviral therapy are not considered here.

One of the features of HAART is a syndrome of intensified inflammatory responses referred to as the immune reconstitution syndrome, which generally occurs within the first 3 months of starting effective antiretroviral therapy. This is thought to represent a hyperacute response to pathogens to which the HIV-infected individual has been exposed. It has been observed in *P. carinii* pneumonia, cytomegalovirus retinitis and vitreitis, disseminated *Mycobacterium avium* complex (MAC) as pneumonitis and lymphadenitis, cryptococcosis with meningitis and necrotizing lymphadenitis, and with acceleration of hepatitis C virus infection, including cryoglobulinemia and renal failure. Thus, effective antiviral therapy may result in more intense symptoms and unusual manifestations of some opportunistic infections while the overall incidence of new infections has declined.

HIV testing should be considered for all persons either in high-risk groups or with unusual infections. High-risk groups include intravenous drug users, sexually active homosexual or bisexual men, hemophiliacs or individuals requiring blood or clotting factors, persons with sexually transmitted diseases (especially syphilis), pregnant women, health care workers with exposure to body fluids or needle stick injury, and all patients with conditions commonly associated with AIDS (Table 127-4). Testing for HIV infection is generally divided into viral culture assays (uncommon now that molecular resistance tests are available), antibody tests, and specific, quantitative (molecular) viral tests, including molecular antiviral susceptibility testing. Most patients produce antibodies to HIV within 6 to 8 weeks, and almost 100 percent have detectable antibodies by 6 months after exposure. These tests are well standardized and easy to perform, but are troubled by false-positives (cross-reacting antibodies) and false-negatives (e.g., in the early period). Between 4 and 20 percent of Western blot tests are *indeterminate* because of seroconversion in progress, loss of antibody in advanced HIV disease, cross-reacting antibodies in pregnancy, blood transfusions, autoantibodies from collagen vascular disease, infection with HIV-2, recent influenza vaccination, or trial HIV vaccines. These subjects should be retested and inconclusive assays resolved with specific viral (molecular, p24 antigen, or culture) testing. *Specific viral tests* include the p24 antigen detection, molecular amplification by PCR, and culture-based assays. These are positive earlier than the antibody tests and therefore may be useful in primary infection before the development of antibody; they have high sensitivity (95–99 percent) and are often useful when the Western blot is indeterminate. Quantitative techniques are very useful in assessing the response to antiviral therapy and disease progression.

Measures of HIV viral RNA in plasma may not correlate with the CD4 lymphocyte count. The CD4 count provides a surrogate marker for the response to antiviral therapy and

Table 127-4

When to Suspect HIV Infection and AIDS

- History
  - High-risk behaviors or exposures
    - Unsafe or promiscuous sex
      - Sex with prostitutes
      - Sex with person at risk for HIV
    - Injection drug use
    - Blood or blood product transfusion between 1975 and 1985 (especially in high-prevalence areas)
    - Blood clotting concentrate transfusion before January 1985
  - Sexually transmitted disease
  - Tuberculosis, especially extrapulmonary
  - Racial and ethnic minority populations in high-prevalence areas of HIV disease
  - Homeless persons in high-prevalence areas of HIV disease
  - Individuals from high-prevalence areas for heterosexual transmission
- Symptoms and signs
  - Acute retroviral syndrome
  - Unexplained constitutional symptoms
    - Fatigue, malaise, fever, diarrhea, night sweats, anorexia, weight loss
  - Lymphatic
    - Persistent generalized lymphadenopathy
  - Dermatologic manifestations
    - Infectious
      - Severe herpes simplex (oral, anogenital), oral or genital candidiasis, staphylococcal skin infections, herpes zoster (especially recurrent), superficial dermatophytoses (tinea nail infection), molluscum contagiosum, warts, condyloma acuminata, oral hairy leukoplakia (EBV), necrotizing gingivitis or periodontitis
      - Kaposi's sarcoma, petechiae (ITP), seborrheic dermatitis, psoriasis (new or worsening), eosinophilic folliculitis, severe drug eruptions, aphthous ulcers, intraepithelial neoplasia
  - Neurologic conditions
    - Cranial neuropathy, Guilian-Barré syndrome, aspectic meningitis, peripheral neuropathy, myopathy, cognitive impairment
- Laboratory findings
  - Unexplained anemia, leukopenia, lymphocytopenia, atypical lymphocytosis, thrombocytopenia
  - CD4 lymphocytopenia
  - Polyclonal hyperglobulinemia
  - Elevated blood urea nitrogen or serum creatinine, proteinuria, hypoalbuminemia
  - Elevated lactate dehydrogenase
  - Hypocholesterolemia and hypertriglyceridemia

the risk of infection and death. At present, the best predictive value of testing is the combination of viral load with CD4 lymphocyte enumeration. Viral RNA levels in long-term nonprogressors are consistently under 10,000 copies per milliliter, whereas progression and immunologic deterioration are often associated with loads over 50,000 to 100,000 copies. Patients with viral loads of 10,000 to 50,000 are considered at intermediate risk. Viral load changes generally precede CD4 count changes. Immune alterations due to infection (e.g., cytomegalovirus) or immune modulation therapy (interferons) are not yet interpretable.

Immunization is a part of the routine management of AIDS. In general, HIV-infected persons are susceptible to the same community-acquired respiratory pathogens (with additions) as the normal host but with a greater severity of disease. Thus, patients should be vaccinated early in the course of disease when they are clinically stable. Live vaccines are generally contraindicated, but measles vaccine is generally well tolerated in children, and MMR is recommended for unvaccinated adults born after 1957 or vaccinated between 1963 and 1967. The efficacy of vaccination in this population is not clear; HIV viral loads may temporarily increase after vaccination. However, general practice suggests that pneumococcal, influenza (inactivated whole virus and split virus vaccines), *Haemophilus influenzae,* hepatitis B recombinant vaccine, and MMR be given as indicated.

Underlying lung disease is common in HIV-infected patients even before the development of opportunistic infection. Although FEV_1 and FVC are nearly normal, 11 to 13 percent of patients with CD4 lymphocyte counts below 200 per mm^3 or with a history of AIDS-associated extrapulmonary diseases (including thrush and varicella zoster infections) and weight loss have decreased D_{LCO} measurements. Intravenous drug users have a higher incidence of abnormal FVC, FEV_1, and D_{LCO} measurements (33.3 percent), consistent with patterns of cigarette smoking and racial distribution. Thus, susceptibility to pulmonary infection is further exacerbated in this population and the importance of vaccination increased.

Opportunistic Infections in AIDS

The problem of opportunistic infection in the *untreated or newly diagnosed AIDS patient* is unique because of the *progressive decline* in immune function when compared with the intermittent compromise seen after chemotherapy or the relatively stable immunosuppression used after solid organ transplantation. This progression appears to have been reversed by HAART, but such therapies are far from universally available. Specific opportunistic infections depend on the nature and duration of immune suppression as well as on the infectious exposures of the patient (Table 127-5). As a result of the progressive and cumulative risks, the incidence of opportunistic infections *increases* over time. A time line exists for the common infections and noninfectious manifestations seen in progressive AIDS, relating to the total CD4 lymphocyte count as a measure of susceptibility (Fig. 127-1). In an individual, the time line is also related to the patient's viral load, but an exact correlation does not exist. The specific pattern of opportunistic syndromes changes for individual patients, but it reflects the overall progressive immunological deterioration of untreated AIDS.

Many opportunistic pulmonary infections in AIDS patients were initially assumed to be reactivation of latent infection. However, some of these processes—including *P. carinii, T. gondii,* tuberculosis, and histoplasmosis—represent a mix of both new exposures and old disease. Similar observations have been made in terms of the drug susceptibility of mycobacterial isolates in recurrent disease (Fig. 127-6). The clinical manifestations of opportunistic infections in AIDS are

Figure 127-6 Chest radiographs of a 39-year-old man with AIDS on zidovudine, ritonavir, and trimethoprim-sulfamethoxazole prophylaxis, and with a CD4 lymphocyte count of 89/ml. The patient presented to the outpatient clinic with low-grade fever, fatigue, and mild cough. *A.* Physical examination and chest radiograph were unremarkable. The patient was anergic on both PPD and control skin testing. Induced sputum examination was negative for bacteria, for *P. carinii,* and by mycobacterial stains. Blood cultures for mycobacteria were obtained. *B.* Ten days after initial presentation, the patient was admitted to the hospital with minimal dyspnea and cough; chest radiograph was remarkable for bilateral pulmonary reticulonodular infiltrates. Bronchoalveolar lavage samples were positive for mycobacteria. The organisms were subsequently identified from cultures of both blood and sputum as *M. tuberculosis,* resistant to both isoniazid and ethambutol. Induced sputum sample cultures remained negative for mycobacteria.

altered by prophylactic and therapeutic regimens, adverse drug reactions, and drug interactions. Toxicities of both prophylactic and therapeutic drug regimens (particularly rash, marrow suppression, and hepatic toxicities) are much more frequent in HIV-infected patients and are exacerbated by the simultaneous need for antiviral therapies.

Continued primary prophylaxis in AIDS patients who maintain CD4 lymphocyte counts above 200/mm^3 for over 3 to 6 months and with low or undetectable viral loads appears to be unnecessary, at least for *P. carinii* and mycobacterial infections. For other infections and secondary prophylaxis, the data are less clear. Up to 15 to 20 percent of AIDS patients have more than one opportunistic infection at one time. The spectrum of clinical diagnoses in pulmonary disease in AIDS includes bacterial infection (45.5 percent), *P. carinii* pneumonia (27 percent), Kaposi's sarcoma (7 percent), bronchitis (5 percent), *M. tuberculosis* (4.3 percent), other mycobacteria (4 percent), lymphoma (2.1 percent), and a variety of other processes. Common community-acquired upper respiratory infections, manageable on an ambulatory basis, constitute more than 50 percent of respiratory illnesses in HIV-infected persons. The incidence of fungal infections varies by geographic region, whereas the rate of demonstration of viral pulmonary infection is closely related to the diagnostic testing techniques used at each center and seasonal variation.

Approaches to the Diagnosis of Opportunistic Pulmonary Infections in AIDS

With the wide array of potential pathogens causing disease in HIV-infected patients, the frequency of atypical and multiple infections, and the urgency to diagnosis of infection in the immunocompromised host, a systematic approach to lung disease in these hosts is imperative. A few general rules are useful.

1. *Prophylaxis is generally effective.* When failure of prophylaxis occurs, it is usually due to noncompliance, malabsorption of drugs, emerging antimicrobial resistance, or coinfection or tumor that alters the local environment. For example, it is often impossible to eradicate *Candida* esophagitis unless erosive

esophageal herpes simplex virus infection is also treated. *Pneumocystis* is difficult to treat in the presence of CMV infection or bronchial obstruction.

2. *Specific therapies for individual infections have a high incidence of adverse reactions in the HIV-infected patient.* Thus, presumptive or empiric therapy without microbiologic confirmation, although often appropriate, has a greater risk in this population than the normal host.
3. *The utilization of newer diagnostic tests has improved the care of AIDS patients.* The interpretation of some tests is unclear, and the availability of some tests (urinary *Histoplasma* antigen or immunoperoxidase stains for *T. gondii*) is not universal. The *induced sputum examination* has been very useful in the early, noninvasive diagnosis of *Pneumocystis* infection, and for mycobacterial disease in the absence of spontaneous sputum production. The sensitivity of sputum induction for *Pneumocystis* infection approaches 90 percent, but the negative predictive value of the test is only 50 percent. The cost and sensitivity of this procedure cannot be justified for the routine diagnosis of bacterial infections, particularly in persons capable of producing sputum samples. The use of *more invasive tests,* such as bronchoscopy, with the obvious limitations of cost and risk to the patient, has the advantage of providing subglottic specimens and the potential for diagnosis of a broader range of pathogens. The interpretation of positive cultures for CMV or MAC may be uncertain without tissue histopathology for confirmation. In patients with a rapidly deteriorating clinical condition or a failure to respond to initial therapy, bronchoscopy with biopsy or needle aspiration may be preferable to bronchoalveolar lavage or sputum induction as an initial procedure. In general, noninvasive, nuclear isotope–based radiologic tests are rarely useful in the diagnostic evaluation of pulmonary disease in AIDS patients.
4. *The rate of progression of infection is often a clue to the type of disease.* Thus, community-acquired pneumonia develops rapidly (2–5 days), whereas the initial episode of *P. carinii* pneumonia generally evolves more slowly (over 7–12 days) in AIDS (as compared with other compromised hosts). Fungal infection and mycobacterial infection are generally preceded by systemic complaints. Pyogenic pulmonary infection is generally associated with sputum production, whereas the "atypical" infections may have little or no sputum despite cough and dyspnea.
5. *The radiographic pattern is often suggestive of the diagnosis (Table 127-6).* All "typical" patterns are altered by progressive immune deficits and coexisting or prior lung disease. *Diffuse infiltrates* (alveolar or interstitial) may be seen with a homogeneous distribution, as in *P. carinii, T. gondii,* CMV, mycobacterial species, *Histoplasma,* or *Coccidioides.* Drug toxicity may also cause pulmonary infiltrates. Inhomogeneity with these pathogens reflects altered pulmonary parenchyma from previous disease,

Table 127-6

Roentgenographic Findings in Opportunistic Pulmonary Diseases in AIDS

Diffuse Infiltrates	Cavitary Lesions	Hilar Adenopathy	Focal Infiltrates	Nodular Lesions	Pleural Effusions
Pneumocystis carinii	Tuberculosis	Tuberculosis	*Legionella* sp.	*C. neoformans*	Tuberculosis
Tuberculosis	Pyogenic bacteria	Lymphoma	Tuberculosis	*H. capsulatum*	Fungal
Toxoplasma gondii	Aspergillosis	Kaposi's sarcoma	*P. carinii*	Tuberculosis	Pyogenic
Histoplasma capsulatum	*Cryptococcus neoformans*	*Cryptococcus neoformans*	*Streptococcus pneumoniae*	*P. carinii*	Lymphoma, Kaposi's sarcoma
P. carinii and other agents	*P. carinii Rhodococcus equi*	HIV acute	Kaposi's sarcoma	Lymphoma	sarcoma
Lymphocytic interstitial pneumonitis	Septic emboli (addicts)	EBV acute	*Nocardia asteroides C. neoformans*	Septic emboli	

obstruction (e.g., with tumor, *Strongyloides stercoralis*), or upper-zone disease or pneumothorax in *Pneumocystis* pneumonia. Tumors may appear with interstitial radiographic patterns in HIV disease. Lymphoid interstitial pneumonitis is an interstitial process of unknown origin that is seen in AIDS patients. Diffuse interstitial infiltrates are often due to *P. carinii,* but not in patients receiving TMP-SMX prophylaxis and rarely without hypoxemia. Thus, the presence of a sepsis-like picture with a diffuse interstitial infiltrate in a patient receiving anti-*Pneumocystis* prophylaxis might suggest mycobacterial disease, *Legionella* infection, or *C. neoformans. Focal airspace disease* is most often seen with bacterial infections (pyogenic, mycobacteria, *Legionella* species), *Mycoplasma pneumoniae* (viral influenza, adenovirus, CMV), and mixed infections (e.g., CMV and *P. carinii*). Occasionally, primary cryptococcal pneumonia, *Aspergillus* infection, or obstructive disease presents with focal infiltrates. Each of these processes may evolve to frank *cavitation,* particularly infections due to pyogenic bacteria (*Staphylococcus, Klebsiella, S. pneumoniae*) or *M. tuberculosis.* Small cavities are seen with *P. carinii,* mycobacteria, and metastatic tumors. Large cavities are uncommon: *M. tuberculosis* or aspergilloma is most often present. *Nodular lesions* can be seen with any of the metastatic tumors or hematogenous infections. Endocarditis, KS, toxoplasmosis, tuberculosis, MAC, and *Cryptococcus* may all progress from nodules to small cavities. In particular, unusual bacterial pathogens (*Bartonella, Rhodococcus, Candida,* and *Salmonella*) have been observed as pulmonary nodules associated with right-sided endocarditis in AIDS patients. *Intrathoracic adenopathy* is common in AIDS patients, most often with infections earlier in the course of disease (CD4 count greater than 400/ml) and with tumors late in disease. Fungal infections (*Cryptococcus*, *Histoplasma,* and *Coccidioides*), CMV, and mycobacterial infections may also cause adenopathy. Adenopathy should prompt invasive diagnosis in the absence of a clear etiology in AIDS. *Pleural effusions* are common with tuberculosis, other pyogenic bacterial infections, and tumors.

6. *The CD4 lymphocyte count is a good indicator of susceptibility to specific infections, while the viral load is most closely associated with overall disease prognosis.* Unresolving community-acquired pneumonia due to *S. pneumoniae, H. influenzae, Mycoplasma,* or *Legionella* species may be the sentinel infection of HIV disease. As host immunity declines, other opportunistic infections occur. *M. tuberculosis,* an organism of high virulence, causes infections at *any* CD4 lymphocyte count but occurs increasingly as the CD4 lymphocyte count falls below 500/ml (Fig. 127-6). In contrast, less virulent organisms cause disease only with greater degrees of immune compromise.
7. *Chronic or recurrent sinus infection may provide a source of Pseudomonas or Aspergillus for pulmonary infection.*
8. *The spectrum of pulmonary disease varies by geographic region and by HIV transmission category.*
9. *Physical findings are often useful in establishing a differential for pulmonary disease in contrast, often, with other types of immunocompromised hosts.*

Infection in Cancer Patients

Immune Defects Due to Tumors and Chemotherapy

The incidence of infection in cancer patients is determined in part by the nature of the underlying neoplasm. Studies of infection in cancer have focused on patients with leukemia and lymphoma, due to severe and predictable immune deficiencies. In a series by Bodey and colleagues, fatal infections in acute leukemics were caused by bacteria in 66 percent, fungi in 33 percent, viruses in 0.2 percent, and protozoa (including *P. carinii*, now considered a fungus) in 0.1 percent (Fig. 127-7). In contrast, fatal infection in lymphoma patients (86 percent) and solid-tumor patients (94 percent) were more often bacterial. In studies of cryptococcal infection in cancer patients, the rate of cryptococcal infection in chronic lymphocytic leukemia was more than double that in Hodgkin's disease (24.3 versus 10.9 per thousand), and the rate in breast cancer was only 0.159 per thousand. Other tumors are also associated with specific infections. For example, lung cancer is associated with tuberculosis at a rate of 92 per 1000,

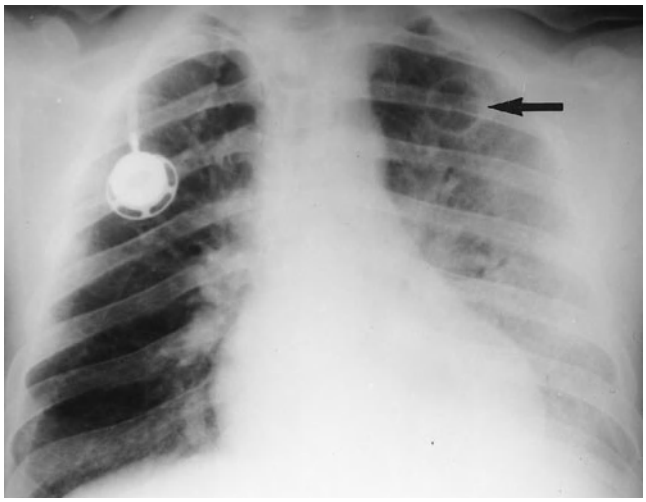

Figure 127-7 Lung abscess (arrow) in a febrile patient following intensive chemotherapy for relapsed acute myelogenous leukemia. Patient developed fever while granulocytopenic (less than 50 neutrophils/mm^3 for 8 days) without localizing symptoms and a clear chest radiograph. When the neutrophil count exceeded 200/mm^3, a lung abscess was detected in the left upper lobe. *Aspergillus fumigatus* was detected in fluid obtained from the abscess via CT-guided percutaneous needle aspiration. The infection responded well to amphotericin B treatment.

second only to the rate in patients with Hodgkin's disease (96 per 1000) due to cellular immune deficits. Without therapy, the degree of depression in cellular immunity (delayed-type hypersensitivity) is more prominent in lymphoma, whereas humoral immunity is impaired to a greater degree in diseases affecting B-lymphocyte function, such as multiple myeloma and chronic lymphocytic lymphoma. Thus, the lymphoma patient is particularly susceptible to intracellular organisms, including *Listeria monocytogenes*, *Mycobacterium tuberculosis*, viruses, and fungi, whereas the myeloma patient is more apt to develop pneumonia or bacteremia due to *Haemophilus influenzae*, *Streptococcus pneumoniae*, and a variety of other acute bacterial infections. Acute leukemia is associated with a depression in the number and function of circulating granulocytes and is associated with severe pyogenic bacterial infections. Patients with acute and relapsed leukemia have demonstrated impaired phagocytosis and killing of fungi and bacteria by these cells, which may appear morphologically normal. *These defects may persist well into periods of remission and may progress along with progression of the underlying disease.*

The impact of the various forms of chemotherapy on host defenses must be added to those caused by the underlying malignancy. Multiple immune functions are impaired by chemotherapy, including the phagocytosis and killing of bacteria by neutrophils (corticosteroids, carmustine, radiation); antibody production (methotrexate, cyclophosphamide, L-asparaginase, 6-mercaptopurine); uptake and processing of antigen by macrophages (corticosteroids, cyclophosphamide, dactinomycin); recognition of antigens by T and B lymphocytes (corticosteroids, cyclophosphamide); and antigen-driven lymphocyte proliferation (methotrexate, 5-fluorouracil, fludarabine, cytarabine, L-asparaginase, dactinomycin, 6-mercaptopurine, hydroxyurea). Predisposition to infection induced by chemotherapy may mask more subtle defects due to underlying disease; e.g., the effects of granulocytopenia due to intensive chemotherapy generally predominate over the effects of underlying lymphoma or myeloma.

Table 127-7

Causes of Neutropenia

Iatrogenic
Cancer chemotherapy
Drug toxities (TMP-SMX, chloramphenicol, gancicolovir, AZT)
Infection
Viral (cytomegalovirus, HIV, Epstein-Barr virus, hepatitis B)
Parasitic (*Leishmania*)
Bacteria (*Clostridium*)
Acute neutropenia of sepsis/endotoxemia (gram-negative sepsis)
Bone marrow failure of neonatal sepsis
Immune
Drug-induced autoimmunity (haptenic: penicillins, sulfa drugs)
Aplastic anemia (includes idiosyncratic reactions: phenothiazines, chloramohenicol)
Alloimmune neonatal neutropenia (maternal-fetal incompatibility)
Congenital autoimmune neutropenia
Primary autoimmune (systemic lupus erythematosus, Felty's syndrome, rheumatoid arthritis)
Transfusion induced
Antineutrophil antibody mediated
Cyclic neutropenia (CD57 lymphocyte expansion)
Hereditary
Infantile genetic agranulocytosis
Familial neutropenia
Cyclic neutropenia (autosomal dominant)
Old age

Neutropenia

The most common predisposing condition for infection in the cancer patient is granulocytopenia; it is often due to chemotherapy and occurs while awaiting engraftment of hematopoietic transplants. The *function* of inflammatory cells and other immune (e.g., mucosal) barriers is also of great importance and are much more difficult to assess. The risk of infection increases as granulocyte counts decrease. Thus, the risk of infection in the patient with neutropenia (under 1000 total granulocytes per mm^3) increases when granulocyte numbers fall further, to below $500/mm^3$; the risk is greatest when counts are lower than $100/mm^3$. The many causes of neutropenia differ qualitatively (Table 127-7). They include iatrogenic neutropenias (chemotherapy, drug toxicities), aplastic anemia and other immune neutropenias, the hereditary and acquired cyclic neutropenias, and malignancy-associated (especially acute leukemias) and infection-induced neutropenias. The rate of decline in white blood cell numbers and the duration of neutropenia influence the risk of infection. Thus, the patient with acute leukemia and rapidly falling neutrophil counts is at greater risk than the person in whom counts are falling slowly or are stable.

The Microbiology of Infection in Neutropenia and Cancer

Pulmonary infections in patients with functional or quantitative defects in neutrophils can reach the lungs via inhalation, microaspiration of colonizing organisms, and bacteremia after non-respiratory penetration and bacteremia (e.g., from vascular catheters or disrupted mucosal surfaces). Decisions about the management of these patients are often made empirically because of the urgency of therapy in

the immunocompromised host. Distinctions between pulmonary and extrapulmonary infections often become blurred in the attempt to treat most of the likely pathogens in a febrile neutropenic cancer patient. Often a specific, unsuspected pulmonary pathogen is detected on routine blood or urine culture or from a biopsy of an extrapulmonary infected site.

Common infections in the neutropenic host and cancer patient are most often the result of colonization with, and infection by, pyogenic bacteria, including *S. pneumoniae*, *Staphylococcus aureus*, the Enterobacteriaceae, *Pseudomonas aeruginosa*, *H. influenzae*, and *Stenotrophomonas* (formerly *Xanthomonas*) *maltophilia*. Common fungal pathogens include *Candida albicans*, *Aspergillus* species, *C. krusei*, *C. glabrata*, *Mucor*, *Absidia*, and *Rhizopus* species. The emergence of bacteria and fungi with antimicrobial resistance takes on special importance in the neutropenic host because therapy is generally empiric and is started before microbiologic data become available. The common "resistant" organisms include vancomycin-resistant *Enterococcus faecium* and *faecalis (now also resistant to linezolid, quinupristin-dalfopristin)*, methicillin-resistant *S. aureus*, inducible chromosomal and acquired plasmids encoding β-lactamase in gram-negative bacteria, and azole (i.e., fluconazole) resistance to *C. krusei* and *C. glabrata*. In individual patients, the spectrum of colonizing organisms also changes over time, especially with antimicrobial use (and abuse). Seeding from blood-borne infection (e.g., due to vascular access catheters or localized infection) occurs most often with the organisms described in the preceding; other organisms are *Candida* and *Aspergillus* and, occasionally, mycobacteria. Patients with solid lung tumors may develop obstructive pneumonia or pulmonary hemorrhage, followed by superinfection with the flora of the upper respiratory tract and oropharynx (Fig. 127-8).

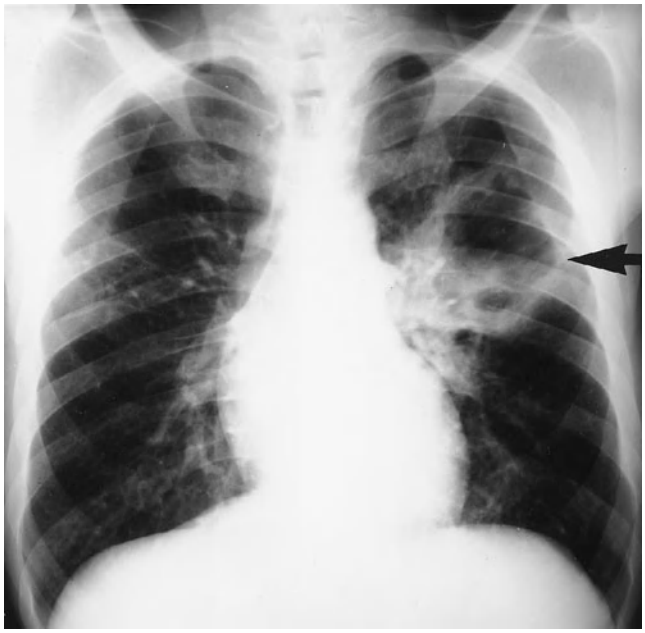

Figure 127-8 Postobstructive pneumonia and lung abscess (arrow) in a 45-year-old man with adenocarcinoma of the lung in the right hilum. The abscess was drained via a bronchoscopic approach. Cultures of the abscess fluid grew common oral bacterial flora, including *Prevotella melaninogenica* and *Bacteroides* species.

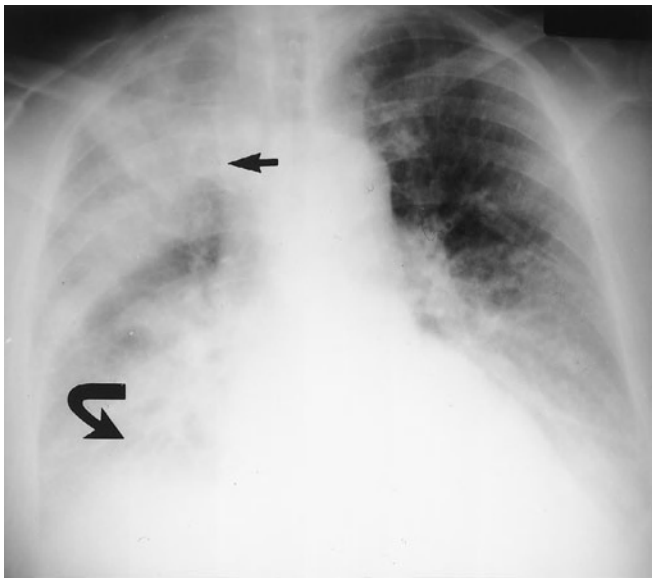
Fungi and Less Common Pathogens

Combined cellular and granulocytic deficiencies are often present after chemotherapy. As a result, in addition to the common pathogens described above, pathogens normally controlled by cellular immune mechanisms (especially intracellular pathogens) can be detected; among these are *M. tuberculosis*, *Brucella* species, the geographic fungi, *Cryptococcus neoformans*, *Strongyloides stercoralis*, *Salmonella*, and *Pneumocystis carinii*. Unusual pathogens have been identified in increasing numbers of cancer patients with neutropenia. The classic presentations of pneumonia, inflammation and perforation of the cecum (often with *Pseudomonas* and anaerobes), and "typhlitis" (often *Clostridium septicum*) may be the first signs of life-threatening infection in a neutropenic patient. Atypical presentations of infection may be from a portal of entry other than the gastrointestinal tract or the lungs. Thus, the first clinical signs of infection may be "spontaneous" or line-associated bacteremia (*Staphylococcus, enterococci*, gram-negative rods, *Bacillus*, *C. jeikeium*, *Candida* species, *Fusarium*), skin lesions (gram-negative sepsis, *Candida* species, *Nocardia asteroides*, *C. neoformans*, herpes simplex or varicella zoster), gingivitis (anaerobes), hepatic dysfunction (hepatosplenic candidiasis), or seizures (*Nocardia* or *Aspergillus* species in brain abscess associated with a slowly progressive pneumonia) (Fig. 127-9).

Because of the widespread use of antibacterial agents, mucosal injury, use of intravenous catheters and bone marrow transplantation, fungal infections have occurred with increasing frequency, most often in acute leukemia patients and following stem cell transplantation and graft-vs-host disease (Table 127-8). *C. glabrata* and *C. krusei* that may carry resistance to fluconazole may develop during antimicrobial treatment. Although Mucoraceae *(Rhizopus, Mucor, Absidia)*, like the *Aspergillus* species, may present with invasive disease of the sinuses and periorbital and frontal cortex in diabetics, they can also cause rapidly progressive hemorrhagic pneumonia with infarction and fungemia. Invasive disease of the sinuses and periorbital and frontal cortex is especially prevalent in neutropenic diabetics and in patients treated with deferoxamine, with prolonged corticosteroid therapy, or with broad-spectrum antimicrobials. The treatment of this invasive disease is *surgical débridement* in addition to antifungal therapy. In patients with neutropenia or acute leukemia, a group of "benign" dermatophytes—including *Trichosporon beigelii*, *Aureobasidium*, *Alternaria*, *Curvularia*, *Phialophora*, *Wangiella*, and *Cladosporium*—have been associated both with disease of the skin and with invasive infection of the lungs, the sinuses, and the central nervous system. Occasionally infections are caused by "atypical fungi" (e.g., *Saccharomyces cerevisiae*, *Pseudallescheria boydii*, *Cunninghamella bertholletiae*, *Drechslera*, *Fusarium* species, *Geotrichum candidum*, and *Penicillium* species). *Fusarium* causes infection of



A

B

Figure 127-9 Multiple simultaneous infections in a 46-year-old man with Wegener's granulomatosis treated with cyclophosphamide and prednisone. The patient developed progressive pneumonia and neutropenia. Sputum cultures were unrevealing. *A*. Bronchoalveolar lavage revealed *Nocardia asteroides* (curved arrow) there was no clinical response to trimethoprim-sulfamethoxazole therapy. Bronchoscopic biopsy of a small abscess in the upper lobe (small arrow) revealed *Fusarium* species. *B*. Magnetic resonance imaging (MRI) of the brain revealed numerous small abscesses (arrows) diffusely distributed throughout the brain. These were initially thought to be consistent with infection due to *Toxoplasma gondii*. Brain biopsy revealed *Nocardia asteroides*.

the bloodstream and lungs that is indistinguishable from that due to *Aspergillus*, but with greater tendency to cutaneous involvement. The cardinal sign of *Pneumocystis* pneumonia is the presence of arterial hypoxemia out of proportion to physical or radiologic signs.

Viral Infections

Viral infection has become increasingly prevalent in cancer patients. This is a reflection of prolonged T-cell defects, use of depleting antilymphocyte antibodies, and improved molecular diagnostic assays. Herpes simplex virus (HSV) and varicella zoster virus (VZV) are frequently reactivated during periods of neutropenia or as a sign of the presence of new malignancies. Patients who are undergoing chemotherapy for Hodgkin's disease or who have received bone marrow transplants are at greater risk than other immunocompromised hosts (35–50 percent in the first year). Specific antiviral prophylaxis is effective in reducing the incidence and severity of these relapses. Most often, these viruses cause painful, but relatively benign, skin or mucosal (especially esophageal, gastrointestinal, and perianal) lesions. These lesions may progress in neutropenic patients and the skin rash may become more diffuse, with hemorrhagic or nonhemorrhagic lesions extending beyond dermatomal limits. Systemic dissemination to visceral organs occurs in 10 percent of patients with disseminated skin disease commonly involving the liver, lungs, brain, or gastrointestinal tract. Nasal, oropharyngeal, or esophageal HSV or VZV infections may spread directly to the lungs with the development of vesicular lesions in the trachea, or may cause viral pneumonitis in the parenchyma as a result of viremia secondary to cutaneous reactivation. Primary varicella pneumonia may accompany chickenpox in adults and in the compromised host. Pulmonary invasion occurs within the first 7 days of illness, with mortality approaching 18 percent. Chest radiographs reveal nodular or interstitial infiltrates in up to 16 percent of adults with chickenpox, whereas only 10 to 25 of these have clinical symptoms. Pulmonary invasion by HSV and VZV in the neutropenic host should be considered a life-threatening emergency.

In hematopoietic stem cell and bone marrow transplantation (BMT) recipients, CMV pneumonitis occurs in the CMV-seropositive recipient of CMV-seronegative cells. Because much of the lung injury is due to immune responses to CMV antigens, the full pneumonitis develops not during lymphopenia but, rather, with the engraftment of the marrow and with the re-emergence of immune function. Viral replication is not needed for CMV pneumonitis to occur. In the granulocytopenic host, pulmonary CMV infection may be fatal.

Table 127-8

Factors in the Development of Fungal Infections in Cancer Patients

Age/performance status
Prior chemotherapy or radiotherapy: dose and duration Steroids Purine analogues
Prior infections (specific isolates)
Recent antimicrobial use (resistance) Broad-spectrum antimicrobials Prophylactic agents
Functional immune status (cell number, activity)
Hematopoietic transplantation–related Delayed engraftment or function of marrow Graft-vs-host disease and treatment Degree of donor-recipient histocompatibility mismatch Insufficient dose of stem cells (CD34) Total T-cell number
Integrity of mucosal barriers (catheters, gastrointestinal)
Neutropenia (severity, duration > 2 weeks)
Hospital environment
Home environment—hobbies, travel
Nonhematopoietic organ failure (e.g., dialysis)
Other simultaneous infections (e.g., cytomegalovirus)

Parasitic Infection

The predominant parasitic infection enhanced by immune compromise is that due to *S. stercoralis*, a nematode that infects more than 100 million people worldwide, producing lifelong infection. *Strongyloides* is distinguished by its *ability to complete the replicative cycle within the human host.* Malnutrition is a major cofactor; neutropenia and corticosteroids are common coinducers of parasite replication. In the normal pattern of infection, the filariform larvae penetrate the skin, follow the veins to the lungs, and are then swallowed, entering the small intestine. The hyperinfection syndrome is the result of activation in the gastrointestinal tract by immune suppression, which causes penetration or transudation of worms across the wall, carrying gastrointestinal organisms with them. Peritonitis, bacteremia, and gram-negative, eosinophilic meningitis may result. Pneumonia may result from bacteremia or obstruction of small airways and pneumonitis; the pulmonary infection fails to resolve without therapy directed at eliminating the nematode.

In endemic regions, activation of *Toxoplasma gondii*, Chagas' disease *(T. cruzi)*, pulmonary or disseminated microsporidiosis or cryptosporidiosis (rare), leishmaniasis, and acute infection with *Acanthamoeba* and *Naegleria* species (primary amebic meningoencephalitis) must be considered in the differential of systemic and pulmonary infections. Splenectomized hosts are at special risk for intense infection due to babesiosis, malaria, and ehrlichiosis.

Clinical Approaches to Infection in the Cancer Patient

Clinical Signs of Infection

Clinical recognition of infection is often delayed in the neutropenic or cancer patient because the inflammatory response is diminished (decreased numbers or mobilization of granulocytes) and the usual signs of infection are absent. Thus, in neutropenic patients, pneumonia may not be associated with sputum production and radiologic changes. In the febrile neutropenic patient with leukemia, the source of obscure infection is often the perineal and perirectal areas; less common are infections of the urinary tract, skin (including venous lines and wounds), and the lungs. In nonhematopoietic cancer patients, however, pulmonary infections predominate. A site of origin for a febrile episode is undetermined in 20 to 50 percent of patients. Many sites of infection are detected only at autopsy, notably in patients with disseminated fungal or combined fungal and bacterial infections. Mortality in the febrile neutropenic population is 30 to 50 percent. Noninfectious causes of fever are common; among them are pulmonary thromboembolism, tumor, radiation pneumonitis, atelectasis with pulmonary edema, drug allergy or toxicity, and pulmonary hemorrhage. Often, the resolution of fever in response to a trial of antimicrobials is the only evidence of infection.

Initial Management of the Cancer Patient with Fever: Stratification of Risk

Each patient presenting with signs of infection must be evaluated in terms of the perceived risks of infection and noninfectious causes of fever and for the presence of neutropenia or other immune dysfunctions. Attempts to manage patients with greater efficiency and to shorten hospital stays have led to the development of *critical pathways*, which include standard patterns of evaluation and treatment for many patients, including those with cancer. Such uniform approaches are useful in establishing a *minimal standard* of care, but they do not address concerns about the pitfalls of failing to individualize therapy.

The safe application of critical pathways for the outpatient management of neutropenic patients necessitates careful stratification of these compromised patients by experienced clinicians in terms of their risk for infectious complications. *Any sign of infection* requires at least a brief hospitalization

(1–3 days), with careful evaluation. However, many experienced oncologists now manage some febrile neutropenic patients as outpatients. Any febrile neutropenic patient—or patient in whom absolute neutrophil count (ANC) is expected to fall below 1000/mm^3—with localizing signs (headache, altered mental status, rash, dyspnea, chest pain, pain over an indwelling catheter site, pulmonary infiltrates) should be considered for emergency admission. In particular, patients with leukemia or lymphoma, uncontrolled metastatic cancer, recent need for antimicrobials, or ANC under 100 (or expected to fall below 100) are generally considered higher-risk patients and are best managed as inpatients until clinically stable. Patients with a history of frank rigors or hypotension merit admission. Any febrile cancer patient needs an assessment of vital signs, oxygen saturation, complete blood count with differential, electrolytes and blood urea nitrogen and creatinine (for obstruction by tumor or acute drug toxicity), blood cultures (at least one peripheral and one from any indwelling catheter), urine sediment examination and culture, sputum Gram's-stain examination and culture, and chest radiograph. After a careful physical examination, the threshold for lumbar puncture and determination of serum or spinal cryptococcal antigen should be low. The patient's history and medical record should be reviewed, with attention to current drugs, recent chemotherapy (especially corticosteroids), recent microbiologic data, and antimicrobial use, allergies, and exposures.

Empiric Use of Antimicrobials in Fever and Neutropenia

After appropriate smears and cultures have been obtained, empiric antimicrobial therapy in the febrile neutropenic patient is essential. The specific antimicrobials selected for routine use in the febrile neutropenic patient remain controversial. Ultimately, this is because many combinations appear to work equally well, and there are few studies of various combinations in identical patient populations using the same entry and end point criteria. The antimicrobials selected must cover previously documented infections or surveillance culture data, physical findings, known hospital flora, and potential community exposures.

Initial therapy should assume that the organisms causing infection are likely to be resistant to current prophylactic or therapeutic antimicrobials. Many infections are loculated and require drainage (sinusitis, postobstructive pneumonitis) (Fig. 127-8). Patients thought to be at *low risk* for infection or other complications (nonleukemic, underlying cancer not progressing, no serious coexisting illness, no recent infections or courses of antimicrobials, expected ANC to remain above 100) may be *considered* for home management after 24 h (to await blood culture data), based on the clinical assessment. In these patients, empiric antimicrobials might include ticarcillin (or ticarcillin-clavulanate, piperacillin with or without tazobactam, ceftriaxone) plus gentamicin (or tobramycin or amikacin). Monotherapy with cefepime, ceftazidime, or carbapenems has also been found to be effective in medical centers that do not have nosocomial flora resistant to these agents. Optimal antimicrobial therapy should include synergistic therapy for *Pseudomonas* infection in medical centers in which this organism is prevalent or if the patient is profoundly neutropenic. The routine use of quinolones or aztreonam for initial therapy in high-risk patients has not been well studied and is not recommended, especially for patients receiving these agents for prophylaxis.

A decision regarding the use of coverage for gram-positive organisms, including MRSA or VRE (e.g., vancomycin) is made based on the possibility of catheter-associated infection and clinical judgment. Such patients might include those with skin wounds, decubitus ulcers, or indwelling vascular access catheters. Gram-positive bacterial infections generally progress more slowly than do gram-negative infections. Therefore, the *routine use* of vancomycin in these patients does not appear to be justified, because of the increased risk of vancomycin-resistant enterococci. Routine surveillance for VRE may be of assistance in adjusting the regimen if fever persists.

If an abdominal or anaerobic bacterial source is suspected, clindamycin or metronidazole can be added. Anaerobic infections other than those due to *Bacteroides fragilis* are uncommon as a source of major morbidity in these patients. Restrictions on the use of clindamycin have been instituted at many centers because of outbreaks of *C. difficile* colitis. Topical oral antifungal therapy (clotrimazole, nystatin) is commonly administered with broad-spectrum parenteral antimicrobials. Antimicrobials may be adjusted on the basis of microbiologic data or if the patient is afebrile for 7 to 10 days with the ANC over 500 and increasing.

Fever and Pulmonary Infiltrates

Pulmonary disease in the cancer patient is clinically challenging, owing to the large array of processes that may cause radiologic infiltrates (Table 127-9). Non-infectious causes of pulmonary infiltrates and fever (edema, cancer, radiation injury, drug toxicity, leukoagglutinin transfusion reaction, pulmonary embolus, hemorrhage, alveolar proteinosis) are common (up to 25 percent) and may closely mimic infection (discussed also in Approach to the Patient with Pulmonary Infections). Conversely, the absence of inflammatory cells or mobilization may mask signs of significant infection. In the patient undergoing chemotherapy or in the neutropenic host, cough, sputum, radiologic infiltrates or cavitation, and fever may all be absent. Infection may spread to the chest from contiguous structures (e.g., perforation of the esophagus due to *Aspergillus*) or may complicate anatomic changes (e.g., bronchial obstruction in lung cancer).

Radiologic Clues to Diagnosis

A number of clues are available to assist in the differential diagnosis of pulmonary infiltrates in cancer patients. For example, the clinical and radiographic appearance and progression of disease may suggest a diagnosis based on the time course and nature of the infiltrate (Table 127-9 and Chapter 114). In general, acute processes include both bacterial infections and

Table 127-9

Common Causes of Pneumonia in Cancer Patients Based on Radiographic Abnormalities and Disease Progression

Abnormality on Chest Radiograph	Common Cause by Rate of Disease Progression*	
	Acute (<24 h)	**Subacute-Chronic**
Consolidation	Bacteria (include *Legionella*) pulmonary embolus, hemorrhage, pulmonary edema	Fungi, *Nocardia*, tuberculosis (drug, virus [RSV], *P. carinii*, radiation)
Interstitial infiltrate	Pulmonary edema (include drug) Leukoagglutinin reaction (bacterial)	Viral, *Pneumocystis*, radiation, drug (fungi, *Nocardia*, tuberculosis, tumor)
Nodular infiltrate	Bacteria, edema (CMV, VZV)	Tumor, fungal, *Nocardia*, TB *Pneumocystis* (CMV)

** Common causes (and less common in parentheses) in the absence of specific epidemiologic exposures or past history.*

noninfectious injuries, such as pulmonary embolus or edema. Subacute processes include *P. carinii*, viral, *Mycoplasma*, or *Nocardia* or *Aspergillus* infections. More chronic processes include drug-induced, radiation-induced, mycobacterial, nocardial, or malignant invasion of the lungs.

In particular, bronchial obstruction by tumor or enlarged lymph nodes may cause atelectasis or postobstructive pneumonia. The underlying process may be suggested by pneumonia that fails to respond to antimicrobial therapy or recurs in the same location after successful treatment. Tumor masses, especially those due to lymphoma, may cavitate, giving the appearance of a lung abscess. Finally, it is important to bear in mind that a chronic process may be superinfected by an acute bacterial, viral, or drug-induced lung injury.

The clinical assessment coupled with the radiologic pattern of lung disease is usually the basis for forming a differential diagnosis for the patient with fever and pneumonitis. Computed tomography (CT scans) has greatly improved differentiation of some processes. For example, in patients with simultaneous processes affecting the lung (e.g., aspiration and tumor), CT scans may disclose distinctive patterns of parenchymal involvement (consolidation and infiltrative lesions with associated adenopathy) better than do conventional chest radiographs. Subtle interstitial infiltrates *(P. carinii)* or nodules *(Cryptococcus)* are better detected by CT scans than by conventional radiographs.

Noninfectious Pneumonitis

After a dose of radiation greater than 2000 rads, radiation injury is common. The injury may become evident either acutely or more than 6 months after the initial exposure. The acute form of radiation pneumonitis may present as a bronchitis or esophagitis with dry cough, fever, fatigue, hypoxemia, and dyspnea that develop over 6 to 12 weeks. The histologic picture reveals vascular damage, mononuclear infiltrates, and edema. The severity of lung injury due to radiation appears to correlate with the rapidity of the withdrawal of steroid therapy, but it may also reflect the emergence of the underlying inflammatory response. Radiation fibrosis usually occurs in 6 to 9 months, and pulmonary function may take up to 2 years to plateau.

Acute, drug-induced lung disease may reflect hypersensitivity to chemotherapeutic agents or sulfonamide agents. Methotrexate, bleomycin, and procarbazine can cause a syndrome of nonproductive cough, fever, dyspnea, and pleurisy with skin rash and blood eosinophilia. Chest radiographs demonstrate diffuse reticular infiltrates. Cytoxan may cause a syndrome of subacute pulmonary disease with interstitial inflammation and pulmonary fibrosis, with fever, dyspnea, fatigue, and cough. Drug toxicity for agents such as bleomycin, BCNU, and CCNU may be related to the cumulative dose (for bleomycin, over 450 mg) and patient age. Synergistic toxicity for the lung occurs between radiation and a variety of chemotherapeutic agents (e.g., bleomycin, mitomycin, and busulfan) and supplemental oxygen use. A variety of non-infectious processes may mimic infection. Alveolar proteinosis may be associated with hematologic malignancies or accompany infection due to *Nocardia* or, less often, *Cryptococcus*, *Aspergillus*, *M. tuberculosis*, and *Histoplasma*. Pulmonary infarction may mimic infections by causing hemoptysis, leukocytosis, pleuritic chest pain, and segmental pleural-based infiltrates on the chest radiograph.

Approach to Antimicrobial Therapy in Patients on Empiric Therapy

Empiric therapy must be individualized. In a patient receiving empiric therapy who becomes afebrile on antimicrobials by 72 h and with a neutrophil count above 500 per mm^3, the antimicrobials may be stopped after 7 days and the patient re-evaluated if no localizing source is found or untreated

pathogens detected. Patients who are clinically well and who become afebrile with neutrophil counts of 100 to 500 per mm^3 should be afebrile for 5 to 7 days before antimicrobials are stopped in order to re-evaluate sources of infection. If the patient is not clinically well (e.g., has mucositis, fewer than 100 neutrophils per mm^3, or unstable vital signs), the antimicrobials should be continued until the patient is stable and afebrile for 48 to 72 h.

Unless a specific source of infection is located and the pathogen(s) identified, patients with persistent fever and neutropenia should have antimicrobials broadened 48 to 72 h after the start of therapy. The options include: (1) addition of vancomycin (or other gram-positive agent if colonized with resistant organisms such as VRE); (2) addition of antianaerobic therapy for oral mucositis or gingivitis, abdominal pain, or perirectal tenderness; (3) expansion of gram-negative bacterial coverage (generally adding a second agent from a different class of antimicrobials); (4) consideration of antiviral therapy in patients with esophagitis or a history of HSV or VZV or at risk for CMV infection; and (5) addition of antifungal therapy. The toxicities of antifungal agents must be considered carefully in these patients, notably those with decreased renal function or systemic fungal infection. The use of amphotericin B products (lipid-associated) or deoxycholate form must be in full dose and patient must be well hydrated with attention must be paid to magnesium and potassium maintenance. Slowly advancing doses of this drug have been advocated without supporting data and entail the disadvantage of delay in achieving adequate therapy. Voriconazole (and other azoles) have significant interactions via the hepatic P450 metabolic system and the incipient has been associated with cardiac arrhythmias in renal dysfunction. The echinocandins have fewer drug interactions but are rarely the drug of choice for initial therapy of filamentous fungal infection. The Mucoraceae lack susceptibility to both voriconazole and echinocandins. Cryptococcus lacks susceptibility to echinocandins.

Special attention must be paid to any symptoms of pulmonary disease, the presence of new pulmonary infiltrates on chest radiographs, or the presence of sinus or CNS symptoms in patients with persistent fevers. New infiltrates should prompt examinations of sputum and procurement of specimens (open biopsy, thoracoscopic biopsy, or bronchoscopy, preferably with biopsies, or needle aspirates under tomographic guidance) for histologic and microbiologic evaluation.

BONE MARROW AND STEM CELL TRANSPLANTATION

Temporal Sequence of Pulmonary Disease Syndromes

The patterns of infection in hematopoietic transplantation have shifted due to earlier engraftment with hematopoietic stem cell transplantation (HSCT) compared with bone marrow transplantation (BMT) and the use of non-myeloablative transplantation (Fig. 127-2). The impact is apparent in the shorter duration of neutropenia in the initial phase, earlier engraftment—but has not decreased the incidence of graft-vs-host disease (GVHD) or the infections associated with immunosuppressive treatment of GVHD (Table 127-10). Specific pulmonary complications can be grouped according to the status of the individual patient: pre-engraftment neutropenia (1–4 weeks), engraftment (fever and cytokine release, renal dysfunction), early and late post-engraftment (up to approximately 26 weeks and 1 year), and late infections (based on the status of host immunity and epidemiology). Although this division is clinically useful, overlap occurs in the timing of specific complications, and the categorization of pulmonary complications is often arbitrary, since the cause of many respiratory abnormalities is uncertain. Inadequate tools are available to accurately assess the individual's immune function. T-cell depleted grafts and patients treated with T-cell depleting antibodies have less GVHD but more viral and fungal infections. Treatments including B-cell depletion have more bacterial infections due to encapsulated organisms. Prophylaxis served only to delay infection and to select resistant organisms unless immune function is restored. Killed organism vaccination is appropriate by one year post-transplant with use of live vaccines reserved until immune function has normalized, generally by two years post-transplantation.

In the early phase, neutropenia predominates with mucositis (and aspiration) being common, herpes simplex (in seropositive recipients), idiopathic pneumonia (respiratory viruses, cytomegalovirus [CMV], pulmonary edema), Aspergillus infection, and line-associated infections (Candida,

gram-positive and -negative bacteria). Viral pathogens predominate after engraftment but before T-cell function normalizes—CMV, varicella zoster virus (VZV), adenovirus (and other respiratory viruses), but also *Pneumocystis carinii* (*jiroveci*, PCP), *Toxoplasma gondii* and moulds (Figs. 127-10 and 127-11). Routine prophylaxis (trimethoprim-sulfamethoxazole, antivirals) is generally effective in preventing such infections. Late and uncommon infections may occur at any time in the post-HSCT course notably in those with persistent immune deficits. Such individuals are at persistent risk for infections due to *Legionella, Nocardia, Mycoplasma*, Mycobacteria, *Strongyloides stercoralis*,

Routine chest radiograph reveals diffuse pneumonia while *B*. CT scan demonstrates bronchiolitis. The patient failed to respond to cidofovir therapy but cleared infection after infusion of autologous stem cells.

Cryptosporidium species, Epstein-Barr virus (EBV, post-transplant lymphoproliferative disorder or PTLD), and in those with hypogammaglobulinemia, encapsulated organisms including *Streptococcus pneumoniae, Neisseria meningitis, and Haemophilus influenzae.*

The most important characteristic that separates patients receiving allografts from those receiving syngeneic or autologous marrow or stem cells is the occurrence of GVHD in the former group. Syngeneic and autograft recipients share early risk factors such as neutropenia with patients receiving allogeneic transplants, and are at risk of early pulmonary complications, such as bacterial or fungal pneumonia and non-infectious treatment-related pulmonary injury. Transplant recipients who have delayed engraftment or subsequent marrow failure are at continued risk of bacterial or fungal infection. Allogeneic marrow recipients with GVHD have continued abnormalities in immune function that increase the risk of opportunistic infections. Among patients with chronic GVHD, infection and pneumonia due to encapsulated organisms (e.g., *Streptococcus pneumoniae, Haemophilus influenzae,* and *Staphylococcus aureus*) appear related to deficiencies in specific antibody production, use of anti-CD20 antibodies, resistance to common antimicrobials used for prophylaxis, and possibly continued defects in macrophage and NK cell functions.

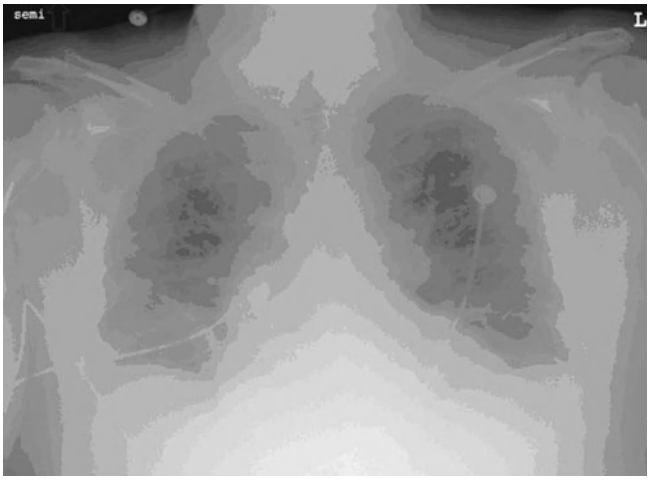
Common Clinical Presentations

Signs and symptoms of pulmonary disorders related to marrow and hematopoietic stem cell transplantation are often nonspecific (Fig. 127-12). Tachypnea is common, as are fever, cough, and rales. However, any or all of these may be absent at the time of presentation of pulmonary complications. Routine chest radiographs are obtained frequently during the first weeks of neutropenia and often provide the first indication of pulmonary impairment.

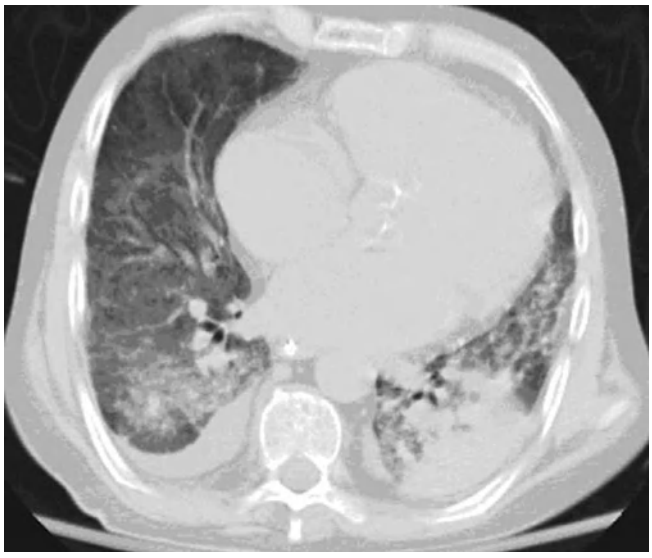
Diffuse Infiltrates

Diffuse infiltrates are common radiographic abnormalities noted in marrow recipients. However, these infiltrates are most often nonspecific. Infectious causes for diffuse infiltrates have been documented in fewer than 20 percent of marrow recipients undergoing open lung biopsy within 30 days after marrow transplantation. Within this early period, pulmonary edema syndromes predominate. The edema may be associated with cardiac decompensation or intravascular volume excess, or with acute respiratory distress syndrome (ARDS) and pulmonary capillary leak due to treatment-related toxicities or sepsis syndrome. Infections presenting with diffuse infiltrates within the first weeks after transplantation include respiratory viral causes, such as respiratory syncytial virus, while cytomegalovirus is uncommon (Fig. 127-11). Alveolar hemorrhage may contribute to the radiographic infiltrates in the presence of thrombocytopenia, regardless of the cause of the lung injury.

After marrow engraftment, infections are a major reason for diffuse radiographic abnormalities. Cytomegalovirus was common in the past, but it is now unusual in patients receiving appropriate prophylaxis. Diffuse pneumonia due to bacterial infections (occasionally disseminated nontuberculous mycobacterial disease, *Mycoplasma* or *Chlamydophila*) also is unusual; however, diffuse involvement with fungus may occur in as many as 20 percent of diffuse infiltrates and may be extremely difficult to detect.



A



B

CT scan revealed pattern most consistent with aspiration pneumonia. Bronchoalveolar lavage revealed *Pneumocystis* and antimicrobial-resistant *Klebsiella pneumoniae*. Treatment of both processes resulted in resolution of infection.

Focal Lesions

Focal parenchymal infiltrates are frequently due to infection regardless of the time of presentation after transplant. Focal consolidations or masses are related to local fungal infection in 80 percent of marrow transplant recipients receiving broad-spectrum antimicrobials. Other causes are *Legionella* species, *Nocardia,* relapse of lymphoma in patients transplanted for that disorder, bronchiolitis obliterans with organizing pneumonia (BOOP), and, rarely, infarct due to thromboembolic disease.

Aspiration

Desquamation of the oropharyngeal mucosa is a frequent complication after intensive chemotherapy, and the stomatitis is often referred to as mucositis. It develops within the first week after radiotherapy and reaches its greatest severity after 10 to 14 days, and impaired mucociliary clearance is common. Recurrent aspiration of oropharyngeal contents is common among transplant recipients with oral mucositis due to sedation, poor cough reflex, and dysphagia. These patients may present with basilar infiltrates or consolidation.

Pleural Effusions

Pleural effusions are common in the first weeks after marrow transplantation and are rarely related to an identifiable infectious source. Pleural effusions may be associated with fluid retention of any cause, especially with ascites secondary to hepatic veno-occlusive disease (HVOD). HVOD may occur in as many as 60 percent of patients after total-body irradiation or in association with GVHD. Characteristics include weight gain within the first weeks after transplantation and elevation of the serum bilirubin, which usually precede the development of pleural effusions. The effusions are frequently bilateral. Bilateral pleural effusions in the presence of weight gain can be approached conservatively without diagnostic thoracentesis. Cautious diuresis coupled with treatment of GVHD often produces satisfactory results. Small effusions are common and may be associated with treatment-related pleuropericarditis or thromboembolic events, but a specific cause is seldom determined. A large unilateral or rapidly accumulating effusion in the presence of fever or ipsilateral chest pain may represent hemorrhage or infection and should be evaluated promptly by thoracentesis.

Non-Infectious Etiology

Non-infectious causes of lung injury after marrow and hematopoietic stem cell transplantation include a spectrum of syndromes: idiopathic pneumonia, alveolar hemorrhage, pulmonary edema, obliterative bronchiolitis, or BOOP. Idiopathic pneumonia is characterized as a syndrome of hypoxemia and radiographic nonlobar infiltrates in the absence of congestive heart failure and without evidence of an infectious origin. It is included as a form of "interstitial" pneumonia. The term *interstitial pneumonia* in marrow transplant recipients refers to the syndrome of diffuse inflammatory pulmonary disease presenting with fever and tachypnea. This term includes noninfectious causes, as well as infectious pneumonia due to viruses (CMV) or protozoa. To avoid the ambiguity of the term *interstitial* in relation to inflammatory disorders of the lung, it is preferable to classify the clinical conditions as *diffuse* pneumonia on the basis of the radiographic presentation. Most non-infectious causes of lung injury are attributed to treatment-related toxicities. Alkylating chemotherapy agents and ionizing irradiation are likely contributors; however, ARDS secondary to sepsis syndrome also may occur. While pneumonia is associated with the presence of GVHD, whether GVHD causes a direct lung injury is unproved. The role of unrecognized infections remains a concern.

Idiopathic Pneumonia Syndrome

The largest studies of idiopathic pneumonia after allogeneic marrow transplantation estimate the incidence at 12 to 17 percent. The spectrum of idiopathic lung injury is referred to as a syndrome (idiopathic pneumonia syndrome, or IPS) in recognition of the multiple causes and varied clinical presentation of this process (Table 127-11). The diagnosis of IPS is defined by a bronchoalveolar lavage (BAL) that does not reveal an infection in the presence of nonlobar radiographic infiltrates and physiological changes consistent with pneumonia. A common series of laboratory evaluations is presented in Table 127-12. Many clinicians use IPS only to describe noninfectious lung injury occurring within the first 3 to 4 months after transplantation.

The causes of diffuse idiopathic pneumonia are often multiple, and include treatment-related toxicities due to radiation or chemotherapeutic agents. However, sepsis-related pulmonary toxicity may account for a proportion of cases of diffuse idiopathic pneumonia with histology consistent with ARDS. Although GVHD is associated with an increased incidence of idiopathic lung injury, it is unclear whether this is a cell-mediated immune response to the lung or related to an increased incidence of sepsis in these immunosuppressed patients. Also, administration of large volumes of blood products during the transplantation procedure may lead to pulmonary vascular injury through leukoagglutination reactions. Other unusual causes of non-infectious diffuse pneumonia after marrow transplantation are leukemic infiltration due to relapse of primary malignancy, injection of malignant cells with reinfused autologous marrow, and fat embolization due to marrow infusion. Several cases of fat embolization have been associated with pulmonary hemorrhage and steroid administration.

The clinical presentation of IPS is nonspecific. Most patients develop a syndrome of fever, nonproductive cough, and tachypnea. Hypoxemia with hyperventilation is common. The onset is most often rapid, occurring over a few days. Occasionally, insidious onset similar to that of idiopathic pulmonary fibrosis is seen. Median onset is within the first 3 weeks of transplantation, but it may occur up to months later. The chest radiograph shows diffuse intra-alveolar and/or interstitial infiltrates. The presentation is not sufficiently distinct to be readily differentiated from that of pulmonary edema syndromes or diffuse infectious pneumonia. Marked tachypnea in the absence of radiographic infiltrates should raise the suspicion of obstructive airway disease or pulmonary veno-occlusive disease rather than idiopathic pneumonia.

IPS after marrow transplantation represents a histologic spectrum ranging from a primarily interstitial reaction with diffuse or focal widening of the alveolar septa and interstitial spaces with mononuclear inflammatory cells and edema to diffuse alveolar damage (DAD) with alveolar epithelial necrosis, intra-alveolar hyaline membranes, edema and hemorrhage, and type 2-cell hyperplasia. The predominantly interstitial presentation has been referred to as *idiopathic interstitial pneumonia,* whereas the pathology of diffuse alveolar damage is identical to that of ARDS. Variable degrees of alveolar hemorrhage may be seen with either of these presentations. By definition, all microbiologic and histologic evaluations for infectious agents (viral, protozoal, fungal, and bacterial) are negative in idiopathic pneumonia. The importance of a thorough microbiologic examination lies in the fact that these histologic presentations are similar to those of infectious pneumonia, especially cytomegalovirus pneumonia.

Mortality from idiopathic lung injury after marrow transplantation remains over 70 percent. The diagnosis of idiopathic lung injury rests largely on the results of BAL. Lung biopsy (transbronchial or open) appears to add little to the diagnostic sensitivity of BAL for infection in the presence of diffuse parenchymal infiltrates. At present, histopathology does not help to direct therapy in idiopathic lung injury after hematopoietic stem cell transplantation. Lung biopsy should be considered in cases with patchy or multifocal infiltrates because of the higher incidence of infection and concern for false-negative results from BAL. There are no

randomized studies of treatment of idiopathic lung injury after marrow transplantation. High-dose corticosteroids (ranging from 1 to 16 mg/kg per day of methylprednisolone) and other forms of intensive immune suppression are commonly used.

Pulmonary Hemorrhage

Robbins and colleagues described a potentially specific form of idiopathic pneumonia: diffuse alveolar hemorrhage (DAH). The syndrome consisted of progressive dyspnea, hypoxemia, cough, and a progressively bloodier return from BAL in autologous marrow recipients, usually within 2 weeks of transplant. The incidence of DAH was 20.5 percent and was associated with age over 40 years, high fever, transplantation for a solid tumor, severe mucositis, white blood cell recovery, and renal insufficiency. Thrombocytopenia was a common finding, and patients with (DAH) received more platelet transfusions than patients without DAH. It is unclear whether this hemorrhagic pneumonia represents a unique syndrome or represents severe lung injury in the presence of a bleeding diathesis.

Pulmonary Edema Syndromes

Biventricular failure after transplantation is often iatrogenic and associated with excessive fluid administration and an increase in total body weight. Radiographic evidence of pulmonary edema after marrow transplantation has been reported in up to 50 percent of patients, most occurring in the second week. Close attention to the total amount of sodium and fluids administered can lead to dramatic reduction in the incidence of pulmonary edema. Also, pulmonary edema may be associated with left ventricular decompensation related to cardiotoxic cytoreductive regimens, including anthracyclines in excess of 500 mg/m^2 and high-dose cyclophosphamide. Posttransplantation cardiac and pericardial toxicity occur in 4 to 10 percent of cases, usually associated with total-body irradiation and cyclophosphamide, often in the setting of prior anthracycline administration. The utility of cardiac imaging studies before transplantation to predict heart failure is limited.

The most frequent noncardiac association with pulmonary edema states is HVOD. The syndrome is often associated with interstitial pulmonary edema, the formation of pleural effusions, and renal failure. Noncardiac pulmonary edema also develops in association with acute GVHD and may be due, in part, to DAD and capillary leak. The presentation of pulmonary edema is nonspecific and usually occurs within 30 days after marrow infusion. Marrow recipients are often febrile and tachypneic at this time in the transplant course, and recipients of allogeneic marrow may display evidence suggestive of acute GVHD. Thus, the distinction between pulmonary edema and idiopathic pneumonia often cannot be made with certainty without pulmonary artery catheterization. However, recent increase in total body weight appears to correlate well with total-body fluid accumulation and should prompt a trial of diuretic therapy and a search for other signs of GVHD (GI, liver, skin) before consideration of invasive diagnostic procedures. Noninvasive assessment of cardiac function with ultrasonographic or radionuclide techniques is often warranted to guide treatment.

New-Onset Airflow Obstruction and Obliterative Bronchiolitis

About 10 percent of allogeneic marrow recipients with chronic GVHD are likely to develop airflow obstruction consistent with obliterative bronchiolitis. However, the reported incidence of obliterative bronchiolitis varies, in part, with the method used to identify the presence of the disease. Possibly because of decreased airway diameter. The onset of progressive airflow disease is related to the development of GVHD. Factors associated with the increased risk of GVHD, such as increasing age and HLA-nonidentical marrow grafts, are not independent risk factors for the development of obliterative bronchiolitis. The cause of obliterative bronchiolitis after marrow transplantation is unknown.

The main manifestation of new-onset airflow obstruction is the insidious onset of tachypnea, dyspnea on exertion, and dry, nonproductive cough. Fever is uncommon. Although the chest radiograph is commonly interpreted as normal, high-resolution chest CT often reveals parenchymal hypoattenuation and segmental bronchial dilatation. Auscultation of the chest may reveal scattered expiratory wheezing and occasionally diffuse inspiratory crackles, but results are sometimes normal. Arterial blood-gas analysis reveals moderate hypoxemia and, in the later stages, hypercarbia. Systemic evidence of GVHD is usually present. The major differential diagnoses of the gradual onset of nonspecific respiratory symptoms in the presence of a normal chest radiograph include pulmonary veno-occlusive disease and pulmonary embolism. Obliterative bronchiolitis is characterized by reduction in expiratory airflow on spirometry and increases in residual lung volumes not found in the other two diseases. Obstruction may be recognized incidentally as a result of coinfection due to respiratory viruses or *Pneumocystis*.

Patients with early onset of airflow obstruction after marrow transplantation tend to have a rapid decline in pulmonary function and a fatal outcome. These patients may not survive long enough to develop manifestations of chronic GVHD but usually display acute GVHD after BMT or HSCT. It is possible that infection plays a role in the development of the airflow obstruction in some of these patients. Marrow and stem cell recipients with later onset of airflow obstruction tend to have a more gradual decline in lung function. Airflow may stabilize in 50 percent of these patients.

There are no prospective trials of treatment for new-onset airflow obstruction. At present, the accepted approach to these patients is to aggressively control with immunomodulating agents the chronic GVHD that most often accompanies the airflow obstruction. Treatment usually consists of increased immunosuppression. Reversal of the airflow obstruction is uncommon. The usual goal of management

is stabilization of the obstruction. For this reason, prompt recognition and treatment for this progressive process are critical. Supportive measures include prophylaxis against *Pneumocystis carinii* pneumonia and *S. pneumoniae* infection, inhaled bronchodilators, supplemental immunoglobulin administration to maintain normal serum levels, and prompt treatment of intercurrent infections.

Pulmonary Veno-Occlusive Disease

Pulmonary veno-occlusive disease (PVOD) is a rare complication of treatment with chemotherapeutic regimens, and as a solitary pulmonary complication, PVOD is an uncommon but potentially catastrophic complication after transplantation. The primary histologic lesion of PVOD—obstruction of the pulmonary veins and venules by loose intimal fibrosis proliferation—may be difficult to detect with hematoxylin and eosin stains alone, and specific stains for elastic tissues, such as Verhoff–van Gieson stain, are required to demonstrate the fibrotic reaction in the veins. The typical presentation of PVOD is that of insidious dyspnea on exertion and resting tachypnea within 3 to 4 months after transplantation. Significant hypoxemia may occur along with hyperventilation. The chest radiograph is often unrevealing. On cardiac exam, there is evidence of pulmonary hypertension. Auscultation of the lungs is often normal, although scattered inspiratory crackles may be heard. Noninvasive examinations, echocardiography, perfusion-ventilation nucleotide scans, and electrocardiograms are nondiagnostic. Pulmonary function testing may be consistent with mild restrictive defect, but airflow obstruction, suggesting obliterative bronchiolitis, is absent. BAL has failed to demonstrate pathogens or inflammatory cells. The diagnostic procedure of choice is a pulmonary angiogram. Right heart catheterization reveals elevated pulmonary artery pressure, with normal pulmonary artery wedge pressures. Angiography excludes the presence of thrombi as a cause of the pulmonary hypertension. In most cases presenting after treatment for malignancy, the disease follows an insidious course, with progressive hypoxemia and dyspnea on exertion due to pulmonary hypertension. Some patients recover with high-dose corticosteroid therapy or other immunosuppressive therapy.

Infectious Etiologies

Cytomegalovirus and Viral Pneumonias

The incidence of cytomegalovirus (CMV) pneumonia has declined significantly in recent years with routine prophylaxis and monitoring. Most CMV infection occurring in seropositive patients is due to reactivation of latent infection. In the seropositive recipient of a seronegative allograft, pneumonitis may be severe. The risk of infection in seronegative patients with seronegative marrow or stem cell donors is attributable to blood product exposure, and this risk can be virtually eliminated by use of screened seronegative or filtered blood products.

Clinical Presentation

The clinical presentation of CMV pneumonia is not distinct from that of other entities associated with diffuse pneumonia. Patients with CMV pneumonia may have nonproductive cough, dyspnea, hypoxemia, or fever, with a median onset of 60 days after marrow transplant. Onset within the first 2 weeks is unusual. The period of risk of CMV pneumonia generally ends by approximately the fourth or fifth month after transplant, although later cases occur among patients with chronic GVHD or after autologous transplant. The chest radiograph generally shows bilateral infiltrates; in later stages, diffuse consolidation occurs. Unilateral, focal, and even nodular infiltrates have been seen in the early stages.

Treatment of proved CMV pneumonia remains disappointing despite the availability of effective antiviral agents, including ganciclovir, cidofovir, and foscarnet and CMV-specific immunoglobulins. Early therapy (any effect takes at least 5 days) should allow survival of up to 80 percent, but poor outcomes are common, notably in patients with respiratory failure at time of initial treatment. CMV pneumonia can be prevented in most cases with the prophylactic administration of ganciclovir or oral valganciclovir to seropositive recipients. Most seropositive patients who are at the highest risk of developing CMV pneumonia can be prospectively identified by CMV antigenemia or molecular assays on blood or sputum. Prospective use of these techniques after allogeneic transplantation permits preemptive treatment with ganciclovir, which appears to eliminate the incidence of CMV pneumonia. The side effects of the antiviral agents (neutropenia, thrombocytopenia, renal toxicity, neurotoxicity, magnesium wasting) may be limiting.

Other Viral Infections: RSV, Parainfluenza, Adenovirus, HSV, HHV-6

The respiratory viruses, particularly respiratory syncytial virus (RSV), influenza, parainfluenza (PIV), adenovirus (AV), picornaviruses, and human metapnuemovirus (hMPV), are increasingly recognized as significant pathogens in these populations. Nosocomial transmission from infected health care workers has been documented. Respiratory syncytial virus (RSV) is the most common respiratory viral pathogen in transplant recipients, but little progress has been made in managing RSV infections. Influenza annually causes increased morbidity and mortality in transplant recipients. M2 and neuraminidase inhibitors, alone or in combination, result in shorter duration of viral replication, decreased progression to lower tract disease, and reduced mortality. Parainfluenza (PIV) continues to be recognized as a significant pathogen that is a risk factor for the development of acute and chronic rejection. Therapeutic options remain limited for PIV infections. Adenovirus has recently been shown to cause asymptomatic viremia in association with respiratory infection that resolves without therapy. Approximately 20 percent of marrow transplant patients with adenovirus infection develop pneumonia (Fig. 127-11). Cidofovir appears to be the drug of choice in managing disseminated or

life-threatening adenoviral infections, but not all strains are susceptible. Rhinoviruses have recently been recognized to cause significant lower tract disease and increased mortality. Human metapneumovirus (hMPV) and coronaviruses, including severe acute respiratory syndrome (SARS)-associated coronavirus, have been recently discovered and are increasingly recognized as significant pathogens in immunocompromised hosts. Therapeutic options for both viruses are not yet clearly defined.

Pneumonia due to herpes simplex virus (HSV) or varicella zoster virus (VZV) occurs uncommonly. HSV pneumonia is generally due to contiguous spread of virus to the trachea or aspiration from the oropharynx, although it may be due to generalized infection with viremia. Pneumonia due to VZV occurs among patients with disseminated infection and viremia. Both situations have become exceedingly uncommon with the advent of acyclovir treatment and, in the case of HSV, acyclovir prophylaxis. Human herpesvirus 6, the cause of childhood roseola (exanthema subitum), has been detected in the lungs of some patients with idiopathic pneumonia. It is unclear whether this virus is a cause of pneumonia or merely latently reactivated, since virtually all adults are seropositive for the virus.

Fungal Infections

Fungal infections are reviewed in detail elsewhere. Major risk factors for invasive fungal infections are the level and duration of neutropenia, age of the patient, the presence of GVHD, total number of other infections, and immunosuppressive administration after BMT or HSCT (Table 127-8). The frequency of *Aspergillus* infections is similar in recipients of allogeneic and autologous transplants, but they occur during periods of neutropenia before engraftment among autologous marrow recipients and after engraftment and during GVHD among allogeneic recipients.

Nonbacterial Infections

Pneumocystis carinii pneumonia occurs in as many as 10 to 15 percent of HSCT recipients without the use of trimethoprim-sulfamethoxazole prophylaxis, although regional and center-to-center variations exist. Except for patients being treated for chronic GVHD (who remain at risk and who should continue to receive prophylaxis), the risk period for *P. carinii* pneumonia ends approximately 120 days after transplantation. Because it is highly effective, trimethoprim-sulfamethoxazole is the prophylactic regimen of choice. Other regimens have been discussed elsewhere. Patients with allergies to sulfa may undergo desensitization so that prophylaxis with trimethoprim-sulfamethoxazole can be administered.

Most infections with *Toxoplasma gondii* infection have had only central nervous system disease diagnosed and treated during life, while involvement of heart and lungs may be documented at postmortem. Chest radiographs show diffuse, patchy involvement. These patients have also had concomitant bacterial or viral infections. Most infections have been fatal.

Pulmonary Function Testing in Hematopoietic Stem Cell Transplantation

Pulmonary function testing (PFT) is a standard part of the pretransplant evaluation at many centers. The results form baseline data for comparison with later testing, and have been used as an indication to exclude a candidate for transplantation. Abnormalities in the measures of airflow, lung volume, and diffusing capacity have been associated with increased risk of pulmonary complications after transplantation. After accounting for other clinical characteristics associated with death after transplantation (age, relapsed malignancy, HLA-mismatched graft), restrictive lung defect (decreased total lung capacity), hypoxemia, and reduced diffusing capacity are associated with statistically increased risk of death, especially within the first few months after transplant. The risks associated with these PFT results are applicable to autologous as well as allogeneic marrow recipients, suggesting that they predict mortality due to treatment-related toxicities. Hypoxemia and reduced diffusing capacity were independently associated with death, each carrying risk.

PFT performed after marrow transplantation has consistently revealed reductions in lung volumes and diffusing capacities associated with total-body irradiation and intensive chemotherapy. PFT abnormalities have been reported to include declines in lung volume, gas diffusion, and airflow. Losses of lung volume are more pronounced among patients who survive pneumonia after transplant. The declines in lung volume may be at least partly reversible within 2 years after transplantation, whereas the low diffusing capacity reportedly persists for several years. Development of airflow obstruction has been seen in approximately 10 percent of allogeneic marrow recipients in the presence of chronic GVHD and most often is related to obliterative bronchiolitis. Such PFT results strongly suggest that lung parenchymal and vascular injury are common features of marrow transplant, even in the absence of recognized infection or idiopathic pneumonia.

SOLID ORGAN TRANSPLANTATION

Timetable of Infection

As immunosuppressive regimens have become standardized in recent years, it has become apparent that *different infectious processes occur at different points in the posttransplant course.* That is, although pneumonia can occur at any point in the posttransplant course, the etiology of pneumonia varies depending on the amount of time that has passed since transplantation (Fig. 127-2).

Infections in the First Month after Transplantation

In the first month after transplant, two major causes of pulmonary infection apply to all forms of organ transplantation. The first is the recurrence of pneumonia that was present prior to transplantation (in the lung allograft donor or in the recipient), but was incompletely treated, and which may be

exacerbated after transplant due to superinfection with nosocomially acquired gram-negative bacilli and fungal species. This is most commonly seen in patients with end-stage liver or cardiac disease who require critical care support prior to transplant. Second, infection due to aspiration of nosocomial flora is often the result of postoperative vomiting (because of gastric distention or metabolic dysfunction) or due to a technical problem with the endotracheal tube in the perioperative period. The risk of antimicrobial-resistant pneumonia increases with the duration of the pretransplant hospitalization as well as with the duration of posttransplant intubation or ventilatory restriction (following the transplant operation).

Donor-derived infection has been recognized in many recipients of lung transplants (mycobacteria, Aspergillus, colonizing gram-negative bacteria), occasionally with rapid progression after transplantation. It is essential to distinguish early lung allograft dysfunction from diffuse infection due to donor-derived viruses (HSV, VZV, CMV, respiratory viruses) or other pathogens (e.g., Mycoplasma). Extensive pulmonary injury before transplant places the patient at high risk for postoperative pneumonia that is poorly responsive to therapy. In the special case of the lung transplant patient who may require prolonged intubation, bacterial pneumonia and infection that threatens the bronchial anastomosis, particularly with *Aspergillus*, are special concerns. These patients require exquisite attention to the technical aspects of the transplant procedure, to the management of the endotracheal tube, and the maintenance of pulmonary toilet (including, on occasion, repeated therapeutic bronchoscopy).

Notable by their absence in the first posttransplant month are the opportunistic infections, despite the fact that the highest daily doses of immunosuppression are administered during this first month. This emphasizes that it is the *sustained exposure to immunosuppressive therapy,* the area under the curve, that is the major determinant of the net state of immunosuppression.

Infections 1 to 6 Months after Transplantation

In the period 1 to 6 months after transplant, the nature of pulmonary infection changes markedly. During this time period the immunomodulating viruses, particularly CMV, are of importance in terms of direct effects (invasive disease) and immunological or indirect effects (rejection, opportunistic infections). CMV can directly cause pneumonia itself; CMV may contribute to the incidence of graft rejection necessitating increased exogenous immune suppression and increasing the risk of opportunistic infection; or CMV (and the other immunomodulating viruses) are globally immunosuppressive and can enhance the likelihood of pulmonary infections due to *Pneumocystis carinii, Aspergillus* species, and *Nocardia asteroides* in the *absence* of an unusual epidemiologic exposure. Unlike the bone marrow transplant recipient, the risk of active CMV *disease* (as compared with viral secretion) in the solid organ transplant recipient is greatest in the CMV-seronegative recipient of an organ from a seropositive donor. Thus, CMV prevention and the utilization of diagnostic techniques for CMV viremia (e.g., antigenemia assays, polymerase chain reaction testing, shell vial cultures with early antigen detection) are important parts of the therapeutic program.

During this period, *in the absence of specific prophylaxis,* significant nonviral pulmonary infections are also common including those due to *P. carinii, Aspergillus* species, endemic fungi *(Histoplasma, Coccidioides)* and *Nocardia asteroides* (Figs. 127-13 and 127-14). There is important regional variation in the occurrence of each of these pathogens. At centers with high endemicity of these infections, low dose trimethoprim-sulfamethoxazole prophylaxis (which effectively eliminates *Pneumocystis* and nocardial infection) and epidemiologic protection against *Aspergillus* (as with a HEPA filtered air supply within the hospital) are effective, particularly in the context of effective CMV prevention.

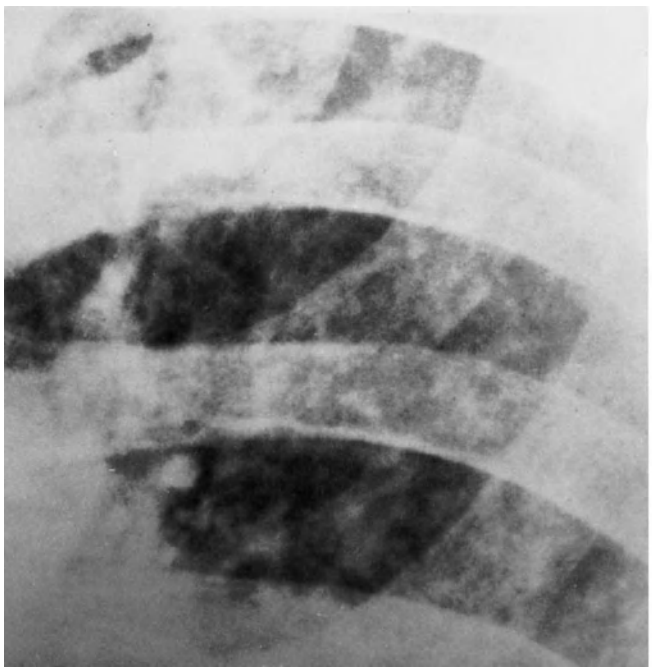
Infections beyond 6 Months after Transplantation

In the period more than 6 months after transplant, patients can be divided into two groups in terms of the forms of pulmonary infection that can develop. Most patients have a good result from their transplant and have good allograft function and receive relatively modest levels of maintenance immunosuppression. These patients are subject to community-acquired respiratory virus infection, particularly influenza and RSV, and pneumococcal pneumonia. The remaining patients have had a less positive outcome from their transplant; these individuals have less satisfactory graft function and require far more intensive acute and chronic immunosuppressive therapies to manage rejection. These patients, often termed "chronic ne'er do wells," are the subgroup of transplant patients at highest risk for pulmonary infection with such organisms as *Pneumocystis carinii, Cryptococcus neoformans, Nocardia asteroides,* and *Aspergillus* species (Fig. 127-15). For this subgroup of patients, prolonged trimethoprim-sulfamethoxazole prophylaxis, epidemiologic protection, and a consideration of fluconazole prophylaxis are indicated. Notable among the ne'er do well group is the liver transplant recipient with recurrent hepatitis C infection, the lung transplant with cystic fibrosis and resistant *Pseudomonas* or *Stenotrophomonas* infections, and the kidney transplant with chronic allograft dysfunction.

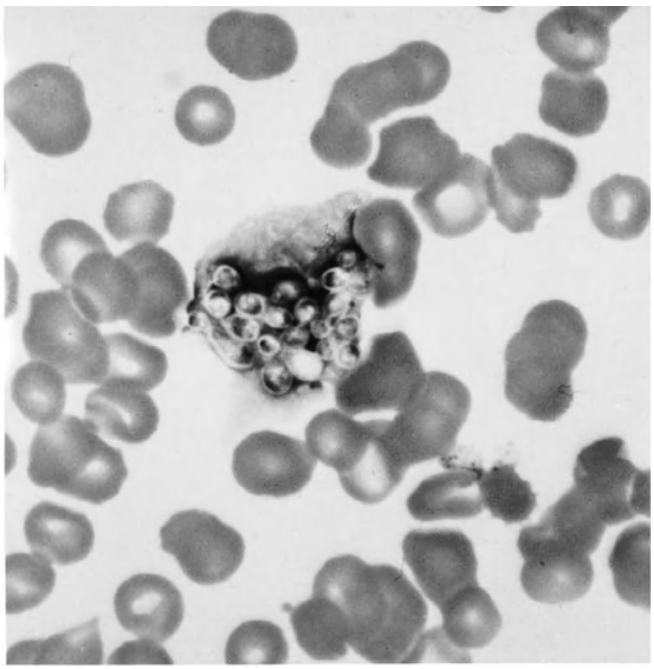
Radiologic Clues to the Diagnosis of Pneumonia in the Organ Transplant Patient

The presentation and evolution of the chest radiograph provide important clues to both the differential diagnosis of pulmonary infection in the transplant patient and the appropriate diagnostic workup that should be undertaken (Table 127-13). The following radiologic parameters are useful in developing clinical-radiologic-pathologic correlations:

1. Time of appearance, rate of progression, and time to resolution of pulmonary roentgenographic abnormalities in relation to clinical events.
2. Distribution of radiologic abnormalities. An abnormality confined to one anatomic area is considered



A



B

Figure 127-13 A 56-year-old man, lifelong resident of Kansas, presented 2½ years after a renal transplant with fever, nonproductive cough, and 3-month weight loss. The chest radiograph was diffusely abnormal. *A*. Close-up reveals extensive micronodular disease. *B*. Peripheral blood smear shows a macrophage laden with *Histoplasma capsulatum*. Treatment with liposomal amphotericin B resulted in clearing of the radiograph and cure of the infection.

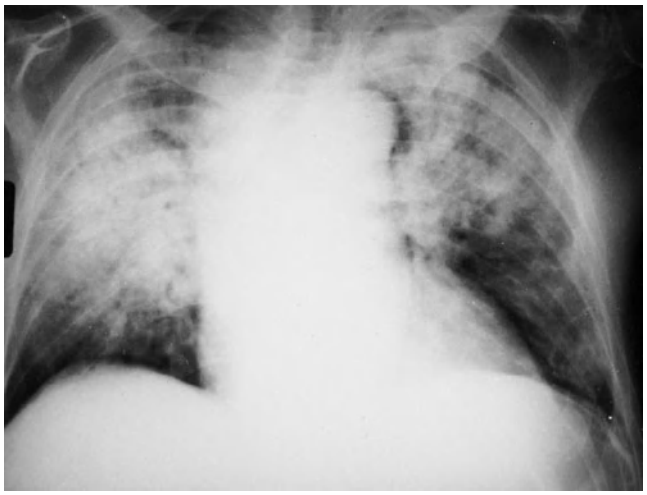


Figure 127-14 Invasive pulmonary aspergillosis after liver transplantation. A diffuse *Klebsiella* pneumonia was treated, with a good clinical response to therapy. After 2 days without fever, the patient became febrile with increasing shortness of breath although the chest radiograph remained unchanged. One day after this radiograph was taken, the patient died. Autopsy revealed two processes in the lungs: a diffuse gram-negative pneumonia and focal areas of invasive aspergillosis restricted to the right lower and middle lobes. This figure illustrates the difficulty in differentiating the focal areas of *Aspergillus* superinfection from the primary bacterial process.

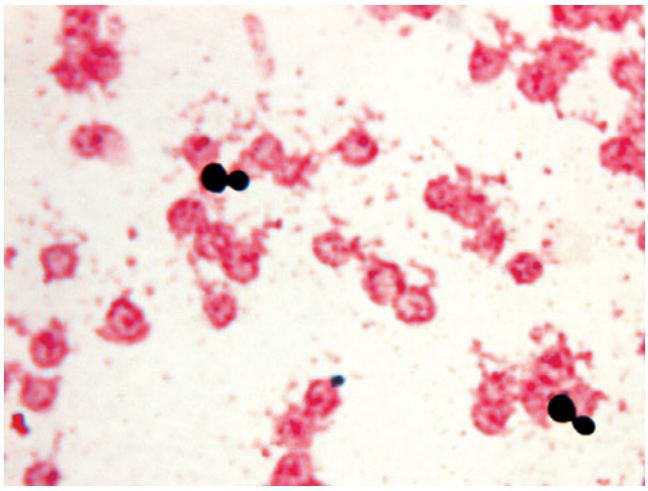
focal, whereas widespread lesions are considered *diffuse*. Abnormalities that are present in more than one area, but are countable, are termed *multifocal*. As visualized particularly on computed tomographic scanning (CT), abnormalities may be located *centrally* or *peripherally* or both.

3. Which of three types of pulmonary infiltrate is present? The first type is a *consolidation*, in which there is substantial replacement of alveolar air by material of tissue density, typically with air bronchograms and a peripheral location of the abnormality. The second type is *peribronchovascular* (or *interstitial*), in which the infiltrate is predominantly oriented along the peribronchial or perivascular bundles. Finally, *nodular* lesions are space-occupying, nonanatomic lesions with well-defined, more or less rounded edges surrounded by aerated lung.
4. Other characteristics. These include pleural fluid, atelectasis, cavitation, lymphadenopathy, and cardiac enlargement. Pleural fluid is a clue to congestive heart failure and fluid overload when bilateral, and to necrotizing or granulomatous infection, especially when associated with lymphadenopathy or cavitation, when unilateral.

By combining this classification with information concerning the rate of progression of the illness (Table 127-13), a useful differential diagnosis is then generated. Thus, focal or multifocal consolidation of acute onset quite likely is

A

B



C

Figure 127-15 *Cryptococcus neoformans* in an asymptomatic renal transplant patient. The patient presented with minimal complaint of nonproductive cough of a few weeks' duration. *A*. The chest radiograph was essentially clear other than a shadow in the right midlung field (arrow). *B*. Chest tomography revealed a nodular lesion in the right midlung field (arrow). Percutaneous needle aspiration of this lesion yielded *Cryptococcus neoformans* on fungal culture. *C*. India ink stain of cerebrospinal fluid from same patient reveals narrow-based budding yeast forms consistent with *Cryptococcus neoformans*.

caused by bacterial infection. Similar multifocal lesions with subacute to chronic progression are more likely secondary to fungal, tuberculous, or nocardial infections. Large nodules are usually a sign of fungal or nocardial infection in this patient population, particularly if they are subacute to chronic in onset. Subacute disease with diffuse abnormalities, either of the peribronchovascular type or miliary micronodules, is usually caused by viruses (especially CMV) or *Pneumocystis carinii* (or, in the lung transplant patient, rejection). Additional clues can be found by examining the pulmonary lesion for the development of cavitation, with cavitation suggesting such necrotizing infections as those caused by fungi, *Nocardia,* and certain gram-negative bacilli (most commonly with *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*). The depressed inflammatory response of the immunocompromised transplant patient may greatly modify or delay the appearance of a pulmonary lesion on radiograph, particularly if neutropenia is complicating the effects of the antirejection therapy. CT of the chest has revolutionized the evaluation of these immunocompromised patients, and CT is particularly useful when the chest radiograph is negative or when the radiologic findings are subtle or nonspecific (Fig. 127-15). An additional important application of CT in this patient population is defining the extent of the disease process. Particularly with opportunistic fungal and nocardial infection, precise knowledge of the extent of the infection at diagnosis, and the response of all sites to therapy, lead to the best therapeutic outcome, as therapy should be continued until all evidence of infection is eliminated, not just the primary site. CT findings are also quite useful in defining which invasive diagnostic procedure should be used to obtain diagnostic samples and in identifying the anatomic site at which sampling should be directed to optimize the diagnostic yield.

PRIMARY IMMUNE DEFECTS

Primary immune deficiencies are defined as alterations in the immune system that are congenital, as opposed to those

Table 127-13

Differential Diagnosis of Fever and Pulmonary Infiltrates in the Organ Transplant Recipient According to Roentgenographic Abnormality and the Rate of Progression of the Symptoms

Chest Radiographic Abnormality	Etiology According to the Rate of Progression of the Illness	
	Acute*	**Subacute-Chronic***
Consolidation	Bacterial (including Legionnaries' disease) Thromboembolic Hemorrhage (Pulmonary edema)	Fungal Nocardia Tuberculosis Viral (Drug-induced, radiation, *Pneumocystis* tumor)
Peribronchovascular	Pulmonary edema (Leukoagglutinin, reaction bacterial)	Viral *Pneumocystis* (Fungal, nocardial, tuberculous, tumor)
Nodular infiltrate†	(Bacterial, pulmonary edema)	Fungal Nocardial Tuberculous (*Pneumocystis*)

** An acute illness develops and requires medical attention in a matter of relatively few hours. A subacute-chronic process develops over several days to weeks. Note that unusual causes of a process are in parentheses.*

† A nodular infiltrate is defined as one or more large (> 1 cm^2 on chest radiography) focal defects with well-defined, more or less rounded edges, surrounded by aerated lung. Multiple tiny nodules of smaller size, as sometimes caused by such an agent as CMV or varicella-zoster virus, are not included here.

related to chemotherapy, autoimmune disease, organ transplant, or chronic systemic disease. Clinical problems that require evaluation of the immune system include chronic or recurrent bacterial or fungal infections of the skin, sinuses, and respiratory and digestive tracts and repeated infections with unusual viruses. Other suggestive signs and symptoms are persistent atypical rashes, chronic diarrhea, failure to thrive, paucity of lymphoid tissue, lymphadenopathy, chronic conjunctivitis, and unusual reactions to live virus vaccines. The evaluation of recurrent infections should analyze all compartments of the host defense system, including anatomic structures, mucociliary function, B- and T-cell activity, phagocytic cell function, and complement activity. Table 127-14 outlines both initial and confirmatory screening tests available to most clinicians.

Antibody (B-Cell) Deficiency

Antibody deficiency states are among the most common of the primary immunodeficiency diseases. Although the defect in immunoglobulin production can occur at any point in B-cell maturation/activation or secretion of antibody, or even in T- and B-cell interaction, the end result is a decrease in serum antibody levels or the inability to respond to antigens with specific antibody. Patients typically present with recurrent sinopulmonary infections caused by encapsulated bacteria such as *Streptococcus pneumoniae, Haemophilus influenzae* (both type b and non-typable), and *Staphylococcus aureus.* Diseases caused by mycoplasma, enteroviruses, and intestinal parasites also are seen occasionally. The incidence of autoimmune abnormalities and hematologic malignancies is also significant in patients with these defects. Treatment for most of these defects relies on the administration of gammaglobulin. Annual chest radiographs and pulmonary function tests are especially helpful, given that the lung disease in patients with hypogammaglobulinemia may be insidious in onset and progression.

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA or Bruton's agammaglobulinemia) is a relatively common inborn error of immunity, occurring in 1 per 50,000 live births. A block in the normal maturation of immunoglobulin-producing B cells (block in VHDJH recombination) results in the absence or severe reduction of serum immunoglobulin, absence of circulating mature B cells, and absence of plasma cells in all lymphoid tissue. T-cell number and function are intact. Inheritance is sex-linked recessive, although a clinically indistinguishable syndrome with autosomal recessive inheritance has been observed in some patients. Recent studies have localized the defect to a protein tyrosine kinase gene (Bruton's tyrosine kinase, *btk*) on the proximal region (q21.3–q22) of the X chromosome. After maternal antibody is consumed (usually after the first 4–6 months of life), patients develop sinopulmonary infections, bacteremia, and meningitis with encapsulated gram-positive and -negative bacteria, such as *H. influenzae, S. pneumoniae, S. aureus, Pseudomonas aeruginosa,* and

Table 127-14

Immunologic Workup of Primary Immune Deficiencies

Suspected Abnormality	Screening Tests	Confirmatory Tests
Antibody deficiency	Serum IgM, IgG, IgA levels IgG antibody response to protein (diphtheria, tetanus, influenza) and polysaccharide (pneumococcus, *Hemophilus influenzae*) antigens Isohemagglutinin titers for IgM antibody response Serum IgG subclass levels	B-cell enumeration (total B [CD20] surface IgM-, IgG-, IgA-, IgD-bea B cells) In vitro immunoglobulin synthesis
Cell-mediated immunodeficiency	Total lymphocyte count Delayed hypersensitivity skin tests (diphtheria, Tetanus, *Candida*, PPD, SK/SD for T-cell function) Tests for HIV antibodies	Enumerate total T cells and T-cell subsets (CD3, CD4, CD8) Measure T-cell function with mitogenic, antigenic, and allogenei (mixed lymphocyte reaction) respo lymphokine production, cytotoxic Assays for Th and Ts activity Enzyme assay (ADA, PNP) for ADA PNP deficiency
Complement deficiency	CH_{50} or CH_{100} for classical pathway activity APH_{50} for alternative pathway activity Serum C2, C3, C4, C5, and factor B levels	Other specific component levels C1 esterase inhibition levels C1 esterase functional component
Phagocyte defects	NBT test for respiratory burst activity (defect in CGD) Serum IgE levels for HIE	Leukocyte adhesive protein analysis: (CD11a/CD18, CD11b/CD18, and CD11c/CD18) Adherence and aggregation Chemotaxis and random motility Phagocytosis Assays for respiratory burst activity (chemiluminescence, oxygen radiography production) Bacterial killing test Enzyme assay (MPO, glucose-6-phosphate dehydrogenase) for phagocyte enzyme defects Cytochrome *b* or cytosolic protein measurement for CGD

Mycoplasma pneumoniae. Respiratory disease due to *Pneumocystis carinii* or gastrointestinal infection with *Giardia lamblia* is also commonly observed. Although viral infections are not typical, enterovirus (polio and echo) and hepatitis viruses may cause severe or fatal disease. Autoimmune diseases, such as rheumatoid arthritis, occur in up to 20 percent of patients, whereas lymphomas and other lymphoreticular malignancies occur in approximately 5 percent of cases. IgG levels are very low (less than 100 mg/dl), and IgA and IgM are often undetectable.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVI) is a common defect in general due to B-cell activation or differentiation defects, resulting in low serum levels of IgG and depressed levels of IgA or IgM. B cells may be normal, high, or low, and T-cell number and function, although usually normal at diagnosis, deteriorate with time. Although the disease is familial, it is not strictly X-linked or autosomally inherited. In some patients, the genomic defects of both CVI and isolated IgA deficiency appear to be localized to the major histocompatibility

B

Figure 127-16 *A*. PA chest radiograph of an adolescent boy with common variable immunodeficiency demonstrating marked bibasilar opacification, atelectasis, and infiltrative changes. Sputum culture grew only *H. influenzae* (non-typable). *B*. Pulmonary function tests from the same patient demonstrate significant restrictive, obstructive disease, supported by RV/TLC measurements. Marked improvement in radiographs and pulmonary function tests occurred with the use of continuous, rotating ciprofloxacin, Ceclor, and Biaxin, in conjunction with aggressive chest percussion via a percussor vest and inhaled DNAse.

complex region of chromosome 6.The disease is characterized by the development of recurrent sinopulmonary infections or chronic bronchiectasis in childhood or adulthood. Chest radiograph findings consistent with atelectasis, bronchiectasis, and/or interstitial markings, along with pulmonary function tests revealing mild to severe obstruction and restrictive disease, are seen in 60 to 80 percent of CVI patients (Fig. 127-16). A few patients with CVI present with infections with unusual organisms, such as *P. carinii*, mycobacteria, or fungi. Recurrent attacks of both herpes simplex and zoster are not uncommon.

Selective IgG Subclass Deficiencies

Patients with selective IgG subclass deficiencies have recurrent sinopulmonary infections associated with normal or decreased total concentrations of serum IgG, but with selective deficiencies of IgG subclass 1, 2, 3, or 4. Patients with IgG2 subclass deficiency can make antibody, but the spectrum of the response is decreased, resulting in recurrent infection. Recent studies suggest a critical role for IL-6 and IFN-γ in enhancing IgG subclass production. Titers to bacterial polysaccharide antigens are low even after immunization, since antibody responses to polysaccharides reside predominantly in the IgG2 subclass. Titers to protein antigens such as tetanus or diphtheria toxoids may be normal. IgG2 subclass deficiency may be associated with IgG4 subclass deficiency, IgA deficiency, Wiskott-Aldrich syndrome, and ataxia-telangiectasia. Persons with low or absent IgG2 or IgG4 appear to be particularly predisposed to recurrent or severe pneumonias and middle ear infections. Selective IgG3 deficiency is also associated with recurrent sinopulmonary infections, but the mechanism is not clear. These IgG3-deficient patients have normal responses to both common protein (Dt) and polysaccharide antigens; however, responses to influenza or rubella vaccine may be abnormal. Treatment is based on clinical findings of recurrent infections, rather than isolated laboratory abnormalities. It is important to document not only a low concentration of a subclass but also failure to make specific antibody when immunized, before immunoglobulin therapy is contemplated.

Selective IgA Deficiency

This most common of all the inborn defects of humoral immunity, occurring in 1 per 700 persons, accounts for more than 1 percent of recurrent infections in children. The defect is assumed to be a differentiation block affecting IgA-committed B cells. Typically, peripheral counts of patients with IgA deficiency show normal numbers of mature B lymphocytes, as well as normal numbers and proportions of CD4 and CD8 cells. Selective IgA deficiency has been defined as serum IgA less than 5 mg/dl in severe deficiency and greater than 5 mg/dl but less than 2 SD below the age normal mean in partial IgA deficiency. The diagnosis and treatment of IgA deficiency depend not only on the serum level of IgA but also on the history and results of related diagnostic studies, particularly the immune workup. In general, treatment relies on the administration of appropriate antimicrobials for acute infection or chronic suppressive therapy for chronic infection. When IgA deficiency is associated with IgG2 deficiency, IVIG depleted of IgA may be indicated.

Hyper-IgM Immunodeficiency

These patients have absent or markedly reduced IgA, IgE, and IgG levels, elevated levels of IgM, circulating mature B lymphocytes bearing IgM or IgD and plasma cells, as well as hyperplastic lymphoid tissue. Recurrent neutropenia, probably secondary to autoimmune phenomena, may coexist with the humoral defect. Because antibody protection for the

gastrointestinal and respiratory tracts is normally provided by IgA and IgG isotypes, patients with this syndrome are especially prone to respiratory and GI infections with pyogenic organisms. They are also predisposed to *P. carinii* pneumonia. As with other immunoglobulin deficiencies, patients with the hyper-IgM syndrome have very high rates of autoimmune (involving the formed elements of the blood) and lymphoproliferative disorders.

Complement Disorders

Disorders due to primary deficiencies of complement components are rare causes of pulmonary infections. Complement function can be assessed by determining the total hemolytic activity in serum (CH50), which measures the ability of serum to lyse antibody-coated sheep cells. A low to absent CH50 suggests a deficiency in a classic pathway complement component. Levels of specific complement components can then be determined.

Congenital absence of C3 or consumption of C3 due to deficiency of factor I (C3b inactivator) results in a clinical picture like that seen in deficiency of the critical antibody opsonins, including infections due to pyogenic bacteria including severe and recurrent pneumonias due to *S. pneumoniae, H. influenzae,* and Enterobacteriaceae.

The terminal complement components, C5–9, form the cytolytic membrane attack complex (MAC), and deficiency of any one of these will block MAC formation. C5–9 deficiencies predispose to disseminated infection with *N. meningococci* and *N. gonococci.*

C1 esterase inhibitor deficiency results in persistent consumption of C2 and C4 by the C1 esterases, resulting in release of vasoactive kinins and the development of nonpruritic angioedema. Although angioedema can occur in any tissue, including the GI tract, edema of the upper airway can be life threatening. Diagnosis is suggested by family history (autosomal dominant state), edema without pruritus, and chronically decreased C4 and C2 levels, especially during the 24 to 72 h of the episode. Patients with the familial form of the disease have low to absent C1 esterase inhibitor concentrations. Angioedema with later onset, without a familial pattern, may be due to the absence of the functional component of the inhibitor, which may be associated with malignancy. Treatment is with danazol or purified C1 inhibitor for acute attacks.

Cell-Mediated Immunity

Although the most characteristic infections in patients with cellular immune deficiency are those caused by opportunistic intracellular pathogens, including protozoa (*P. carinii* and *Toxoplasma gondii*), fungi (*Candida* and *Aspergillus* species), viruses (particularly those of the herpesvirus family), and some intracellular bacteria (including *Listeria* and *Mycobacteria* species), defects in humoral or phagocyte defense mechanisms can also be seen.

DIGEORGE'S SYNDROME

DiGeorge's syndrome (DGS) is a constellation of abnormalities resulting from dysmorphogenesis of the third and fourth pharyngeal pouches. Patients have hypoplasia or aplasia of the thymus and the parathyroid glands, complex cardiac malformations, esophageal atresia, bifid uvulas, cleft palate, short philtrums, mandibular hypoplasia, hypertelorism, and low-set notched ears. The severity of immunologic manifestations varies from severe forms with complete thymic aplasia, resembling severe combined immunodeficiency disease (SCID), to only latent hypoparathyroidism, which may also be seen in relatives of patients with DGS. Most patients have partial T-cell function, which may improve with age, presumably due to the adaptation of functional extrathymic sites for T-lymphocyte maturation. T-cell numbers are typically reduced, with reduced percentages of CD3 and CD4 cells, but CD8 cells may be normal or even elevated. Patients with more significant CD4 T-cell deficiency seem to have more frequent and severe infections requiring hospitalization. B-lymphocyte counts are usually normal; antibody production is also usually normal, but of poor biologic quality. Some patients may have low IgA or elevated serum IgE levels. Surviving infants often have the tendency to acquire parathyroid function, cell-mediated immunity, and functional T cells. Patients are prone to severe viral pneumonias, particularly those of the herpes and measles family. Pneumonias due to fungal and gram-negative bacilli and *P. carinii* also occur.

Severe Combined Immunodeficiency Disease

SCID is a syndrome of heterogeneous lymphocyte stem cell defects that affect both T- and B-cell function, resulting in profound hypogammaglobulinemia and absence of T-cell function. Laboratory analysis may reveal lymphopenia (10–20 percent) and normal or increased numbers of circulating B cells, but severely reduced IgG levels. In general, SCID syndrome patients present with a triad of mucocutaneous candidiasis, intractable diarrhea, and *P. carinii* pneumonia, evident shortly after birth or within 6 to 9 months of life and progressing to severe failure to thrive. Within a few days after birth, patients may also develop a morbilliform rash that is probably a manifestation of graft-vs-host disease (GVHD) from passively transferred maternal lymphocytes. Infections with a wide range of microbes occur in all forms of SCID, including viral pathogens, particularly herpesviruses (herpes, cytomegalovirus, and varicella), adenovirus, measles, influenza, and *Legionella.* Fatal giant-cell pneumonia has resulted from measles infection and live measles vaccination, and progressive vaccinia has occurred after smallpox vaccination.

Purine Nucleoside Phosphorylase

Absence of the enzyme purine nucleoside phosphorylase (PNP) is associated with marked cell-mediated immunodeficiency but intact humoral immunity. The gene encoding the enzyme is localized to chromosome 14q13.1. Patients are

prone to disseminated viral infections, *P. carinii* infection, mucocutaneous candidiasis, and chronic diarrhea. Neurologic disorders afflict more than 50 percent of patients, and more than a third of PNP patients develop autoimmune diseases.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is caused by a defect localized to the short arm of the X chromosome (Xp11.22–11.3), resulting in severely impaired production of antibodies to polysaccharide antigens, as well as variable reductions of T-cell numbers and impaired mitogen responses that tend to worsen with age. Both T-cell numbers and function progressively decrease, and profound lymphopenia becomes apparent at approximately 6 years of age. Most patients have abnormalities of serum immunoglobulin levels, with low IgM and isohemagglutinin concentrations, a tendency toward elevated IgA and IgE levels, and normal or slightly depressed IgG levels. Males afflicted with this syndrome suffer from a triad of recurrent infections, thrombocytopenia, and a skin disease indistinguishable from atopic dermatitis. Typical infections include pyoderma or cellulitis associated with eczematoid eruptions, chronic otitis media with persistent otorrhea and/or mastoiditis, and chronic pneumonitis. Encapsulated pyogenic bacteria, such as *S. pneumoniae, H. influenzae,* herpesvirus, and *P. carinii,* are the most frequently identified pathogens.

Ataxia-Telangiectasia

This syndrome (AT) is characterized by profound deficiencies of cellular immunity (including lymphopenia, defects in cutaneous anergy, decreases in Th:Ts ratios, decreases in cytotoxic T cells, and an increase in immature T cells with increased γ/Δ TCR expression), impaired humoral responses (thymic hypoplasia associated with IgA deficiency, IgE deficiency, and IgG2 and IgG4 subclass deficiency), and a constellation of progressive cerebellar ataxia with degeneration of Purkinje cells. The defective genes of the two most common AT variants map to chromosome 11q22.3, which may result in a recombination defect that interferes with the rearrangement of T- and B-cell genes, an inability to repair damaged DNA, and a failure of normal organ maturation. Telangiectasias, particularly ocular and cutaneous, and a high incidence of malignancies, particularly non-Hodgkin's lymphoma, and breast cancer (in heterozygous female carries of the AT allele) are seen. AT is also associated with insulin-resistant diabetes mellitus, gonadal agenesis, premature aging, elevated levels of serum α_1-fetoprotein and carcinoembryonic antigen, and hypersensitivity of fibroblasts and lymphocytes to ionizing radiation, reflecting an inability to repair damaged DNA. Patients suffer from an increased incidence of bacterial and viral sinopulmonary infections, and many eventually develop chronic bronchiectasis. The most frequent pulmonary pathogens are *S. aureus* and other encapsulated bacteria. Concurrent IgG2 (50 percent), IgG4, and IgA deficiencies (70 percent) may be associated with the tendency toward recurrent infections of the respiratory tract. Approximately 80 percent of patients have depressed IgE levels.

Phagocytic Defects

Disorders of Phagocyte Numbers

These disorders include cyclic neutropenia, Felty's syndrome, Kostmann's syndrome, Shwachman-Diamond syndrome, and autoimmune neutropenia. They are characterized by absolute PMN counts as low as 50 to 200/mm but typically lower than 1000/mm. Owing to the presence of a compensatory monocytosis, these disorders are associated with a low incidence of severe respiratory infections, although pneumonia is seen—as are furunculosis, subcutaneous abscess, and otitis media. Typical pathogens include *S. aureus, P. aeruginosa,* and enteric bacteria.

Defects of Phagocyte Function

Chronic Granulomatous Disease

CGD is caused by a defect in a membrane-associated nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in phagocytic cells, resulting in the failure of phagocytic cells to produce superoxide, hydrogen peroxide, and other reduction products of oxygen that are necessary for killing certain microbial species. Diagnosis is made by the inability of neutrophils to reduce nitroblue tetrazolium (NBT) from yellow to blue-black formazan and by the inability of neutrophils to kill staphylococci or other catalase-positive microorganisms. Additional laboratory findings suggestive of CGD include leukocytosis, elevation of erythrocyte sedimentation rate, abnormal chest radiographs, and hypergammaglobulinemia. Onset is typically in infancy, childhood or, less commonly, early adolescence, with a male-to-female ratio of 6:1. All forms of CGD are characterized by abscess formation at sites of bacterial tissue invasion and in lymph nodes, liver, and lung. Patients present with severe recurrent lymphadenitis and infections of the skin, sinopulmonary, and GI tracts. Severe and recurrent pulmonary infections occur in almost all patients with CGD, including bronchopneumonia, empyema, lung abscess, and hilar adenopathy syndromes. Most young adult patients demonstrate chronic bilateral infiltrates, pulmonary fibrosis, or pulmonary calcifications associated with restrictive/obstructive disease. Aggregates of granulomas, leading to mechanical obstruction, may form as a response of activated macrophages to microbial persistence and chronic antigenic stimulation. *S. aureus* represents by far the most common cause of infections in CGD. Other catalase-positive and non–H_2O_2-producing organisms include *Escherichia coli, Klebsiella,* and *Enterobacter* species, *Serratia marcescens, Salmonella,* and *Pseudomonas* species. Pneumonias in CGD patients may be caused by *Mycobacterium tuberculosis,* atypical mycobacteria, and *P. carinii.* In specific geographic locations, such as the southeastern United States, *Chromobacterium violaceum* has been recognized as the cause of infection in several CGD patients. *Nocardia* infection, particularly of the respiratory system, is also relatively

This radiograph reveals recurrent diffuse nocardial pneumonia. *B.* Pulmonary function tests from the same patient showing mild restrictive disease, probably secondary to right upper lobectomy and recurrent airspace disease.

common, as are fungal infections (Figs. 127-17 and 127-18). Antimicrobials and interferon-γ have been useful in therapy.

Glucose-6-Phosphate Dehydrogenase Deficiency

This is a variant of CGD, in which G6PD levels are less than 1 percent, and results in an inability to generate oxygen by products and a slightly milder form of disease than that in patients with CGD.

Chediak-Higashi Syndrome

CHS is a rare autosomal recessive defect characterized by abnormal fusion of azurophilic lysosomes of neutrophils and cytoplasmic granules of monocytes and lymphocytes. This defect results in impaired microbicidal activity of phagocytes due to the presence of giant lysosomal granules, which have abnormal post-phagocytic phagolysosome fusion and degranulation. In addition, neutrophil counts tend to be low, secondary to their rapid turnover. Chemotactic defects and impaired natural killer cell activity have also been noted. Patients present with recurrent skin and upper and lower respiratory tract infections, including recurrent or chronic otitis media, sinusitis, and pharyngitis, in addition to lower respiratory tract infections, including bronchopneumonia. Segmental or lobar lung involvement can account for up to 30 percent of documented infections. Most infections are due to *S. aureus, H. influenzae,* group A streptococcus, and gram-negative enteric organisms *(Klebsiella, Proteus, Shigella, Pseudomonas). Aspergillus* and *Candida* represent less common etiologic agents. Respiratory failure can occur with extensive histiocytic infiltration of the lungs during an accelerated lymphoma-like proliferative phase marked by widespread tissue infiltrates of lymphoid and histiocytic cells, usually without malignant histologic characteristics. Anemia, hypersplenism, and platelet dysfunction, associated with the accelerated phase, and albinism or hypopigmentation, due to abnormal fusion of melanocyte pigment organelles, are also seen.

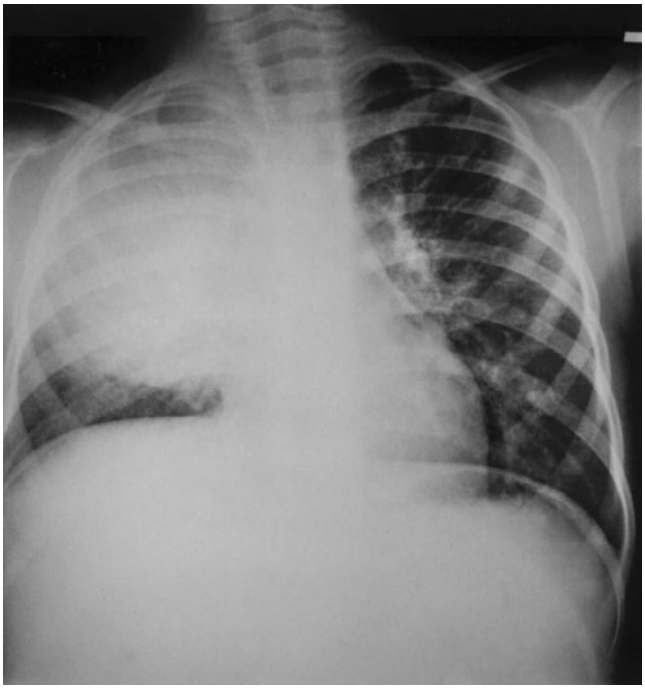

Figure 127-18 PA chest radiograph in a patient with CGD demonstrating nocardial abscess of right upper lobe, extending into the anterior chest wall.

Leukocyte Adhesion Deficiency

Patients with this autosomal recessive disease lack or have markedly reduced α_2 integrins, essential glycoprotein constituents of the CD11/CD18 receptor complex that mediates leukocyte adhesion. Recurrent necrotic and indolent infections of soft tissues, primarily in skin, mucous membranes, and the intestinal tract, are the clinical hallmarks of this disease. The recurrent infections reflect a profound impairment of leukocyte mobilization into extravascular inflammatory sites, despite peripheral blood granulocyte counts of 15,000 to 161,000/mm. A wide spectrum of gram-positive or -negative bacteria (*S. aureus* and gram-negative enteric bacteria) and

fungal microorganisms (*Candida* and *Aspergillus*) infect LAD patients, similar to those with neutropenia syndromes (Fig. 127-19).

Hyperimmunoglobulin E Syndrome

Also known as the hyper-IgE (HIE) recurrent infection or Job's syndrome, this unusual disorder, which appears to be autosomal dominant with incomplete penetrance, is lacking an exact immunologic defect. Serum levels of polyclonal IgE are markedly elevated (above 2000 IU/ml), but immunoglobulins other than IgE are normal. Complete blood counts and differentials are mildly abnormal, with occasional borderline neutropenia. Most patients have mild to moderate eosinophilia, despite lacking a significant history of classic allergic diseases. All patients have chronically elevated erythrocyte sedimentation rates. Diagnosis of HIE can be established in patients (usually during infancy) with a history of staphylococcal infections of the skin and sinopulmonary tract, and IgE levels at least 10 times normal. Coarse facies, chronic eczematoid eruptions, cold cutaneous or subcutaneous abscesses, eosinophilia, and mucocutaneous candidiasis are also seen, as are recurrent bone fractures and osteopenia.

"Cold abscesses" are not seen in all HIE patients, but are rare in other immunodeficiency states. They can present in any part of the body as fluctuant masses, with little evidence of inflammation and often without fever. Drainage of these abscesses usually reveals large volumes of purulent material, which almost always grow *S. aureus.* Otitis externa and chronic otitis media, occasionally complicated by mastoiditis, are common in HIE patients. Recurrent bronchitis represents the most common pulmonary manifestation of HIE. Patients often suffer several days a month of productive cough, rarely associated with fever. Less commonly, pneumonia, with or without associated complications—including

bronchiectasis, lung abscess, empyema, pneumatocele formation, and bronchopleural fistula formation—may represent serious and potentially devastating features in HIE patients. *S. aureus* and *H. influenzae* are the most frequent causes of pneumonias in HIE, but fungal infections may complicate management (Fig. 127-20). Management relies on the use of narrow-spectrum antistaphylococcal prophylaxis, such as cloxacillin or dicloxacillin. Trimethoprim-sulfamethoxazole may also be employed as a prophylactic agent.

ACKNOWLEDGEMENT

Human Immunodeficiency Virus and Pulmonary Infections

John J.W. Fangman • Paul E. Sax

Combination antiretroviral therapy has resulted in dramatic reductions in morbidity and mortality attributable to human immunodeficiency virus (HIV) infection. However, respiratory complications remain a common cause of adverse outcomes in HIV-infected individuals. Pulmonary complaints are often the sentinel event that leads to the diagnosis of HIV infection in persons who are unaware of their HIV status. The list of pulmonary complications seen in persons with HIV is long and includes both infectious and noninfectious entities (Table 128-1). A structured approach to respiratory complaints in HIV-infected patients can result in a timely and cost-effective evaluation. This chapter outlines such an approach by reviewing the pathophysiology, epidemiology, and management of HIV infection. It then outlines an approach to the evaluation of respiratory complaints in patients with HIV and discusses common infectious and non-infectious pulmonary complications of HIV infection. The chapter concludes with an algorithm for the management of HIV-positive individuals who present with respiratory complaints.

PATHOPHYSIOLOGY

HIV Pathophysiology

Although a comprehensive review of the virology and immunology of HIV infection is beyond the scope of this chapter, a basic understanding of the biology of HIV is critical to the care of patients with HIV infection. HIV is the most important member of the Retroviridae family of single-stranded RNA viruses. HIV belongs to the genus lentivirus that contains two specific species, HIV-1 and HIV-2. HIV-2 is found primarily

Table 128-1

Causes of Pulmonary Disease Associated with HIV Infection

Less common, but potentially clinically important in some settings	Bacterial *Pseudomonas aeruginosa* *Staphylococcus aureus (especially MRSA)* Enterobacteriaceae *Legionella* spp. *Nocardia* spp. *Rhodococcus equi* Mycobacterial *Mycobacterium kansasii* *Mycobacterium avium* complex Fungal *Cryptococcus neoformans* *Histoplasma capsulatum* *Coccidioides immitis* *Aspergillus* spp. *Blastomyces dermatitidis* *Pencillium marneffei* Viral Influenza Cytomegalovirus Herpes simplex virus Adenovirus Respiratory syncytial virus Parainfluenza virus Parasitic *Toxoplasma gondii* *Strongyloides stercoralis* *Microsporidia* spp. *Cryptosporidium parvum* Non-infectious Kaposi's sarcoma Non-Hodgkin's lymphoma Lung cancer Primary pulmonary hypertension Congestive heart failure Lymphocytic (or lymphoid) interstitial pneumonitis Emphysema Abacavir hypersensitivity

* *Frequency of* M. tuberculosis *infection is highly dependent on local rates of tuberculosis and the patient's exposure history.*
Processes are listed within categories in approximate order of frequency.

in patients who acquired their infection through contact with persons in West Africa and is far less common than HIV-1. Because the management of HIV-2 presents unique clinical challenges and is considerably less virulent than HIV-1 it is not covered in this chapter.

The HIV genome is composed of three structural genes *(gag, pol, env)* and a number of regulatory genes *(vif, vpr, tat, nef)*. The core of the HIV-1 virion is composed of two copies of single-stranded RNA that are packaged with the viral enzymes reverse transcriptase, protease, and integrase. This complex of RNA and viral proteins is encased in a conical nucleocapsid that is surrounded by a lipid bilayer envelope. The surface of the HIV-1 virion is studded with viral-derived gp41/gp120 glycoproteins as well as host-derived MHC class II molecules.

Although CD4-positive cells of macrophage lineage play an important role in HIV infection, the principal target of HIV-1 is the CD4-positive lymphocyte. Attachment of HIV-1 to target cells occurs when viral gp120 binds to the D1 domain of CD4 on the surface of lymphocytes. This interaction induces conformational changes in gp120 variable region that exposes a co-receptor binding domain in its V3 region. Based on the tropism of the infecting virus, this newly exposed binding site facilitates approximation of viral and targets cell membranes through interactions with either the CCR5 or CXCR4 co-receptor on the target cell. Further conformational changes in the gp120/gp41 complex lead to the insertion of gp41 into the target cell membrane, and that in turn brings the target cell and host lipid bilayers into close enough proximity that they fuse. After HIV-1 enters target cells, viral reverse transcriptase (RT) synthesizes a linear, double-stranded DNA copy (cDNA). The insertion of viral DNA into the chromosomal DNA of target cells is the hallmark of retroviral infection and is a prerequisite for transcription of the HIV-1 genome and translation of viral proteins. Using a variety of host and viral proteins, integrated proviral DNA is transcribed and mRNAs are subsequently translated into large polyproteins. Posttranslational modification of these polyproteins is catalyzed by HIV protease. Viral assembly occurs when *Gag* multimers complex with *Gag-Pol* polyproteins, viral RNA, *Vif, Vpr,* and several host proteins. These preassembled complexes are transported to specific lipid-rich regions of the host cell where budding occurs. Following budding, virions undergo protease-mediated structural modification, a process termed maturation.

Effective management of HIV infection depends on a working knowledge of several key features of this life cycle. Foremost among these is that fact that HIV replication requires incorporation of cDNA into the host's genetic material. Although nearly all infected CD4 cells are productively infected, a small minority (less than 1 percent) lie dormant after proviral DNA has been inserted into host DNA. Such latently infected CD4 cells are able to escape immune surveillance and are long lived. Because it is not currently possible to enhance the decay of the pool of latently infected CD4 cell, HIV infection can not be cured even with prolonged suppression of viral replication. Although cure of HIV infection remains an elusive goal, it is possible to control HIV replication.

Potent inhibitors of many steps in the life cycle of HIV have been developed, but their efficacy as monotherapy has been limited. The absolute requirement for combination antiretroviral therapy is due to two fundamental aspects of HIV replication: its rate of replication and the infidelity of HIV reverse transcriptase. Fundamental insights into the kinetics of HIV replication were derived through the application of PCR-based techniques to quantify viral replication in subjects receiving potent inhibitors of HIV protease. Using such techniques, investigators demonstrated that 1 to 10 billion viral particles were produced and cleared in the infected host each day. Further complicating management was the recognition that HIV's reverse transcriptase lacks a proofreading function and that on average an error occurs in every 1:1400 to 1:4000 base pairs transcribed. With limited exceptions, these insights led to a management strategy that uses multiple active agents with different mechanisms of action, often targeting different stages of the HIV replication cycle to control HIV infection.

PATHOPHYSIOLOGY OF HIV IN THE LUNG

When considering the impact of HIV infection on the lung, it is important to recognize that both systemic and lung-specific disturbances in immune function occur in HIV-infected individuals. The expression of altered pulmonary immunity is further affected by host-specific factors, viral determinants, and disease stage.

SYSTEMIC IMMUNODEFICIENCY

One of the hallmarks of HIV infection is the gradual decline in CD4-positive lymphocyte count that occurs during the course of the infection. Unlike other viral infections, HIV fails to produce a robust HIV-specific CD4 response. HIV preferentially infects activated CD4 cells, a fact that may blunt the expected clonal proliferation of HIV-specific CD4 expansion one expects with primary HIV infection. CD4-positive lymphocytes play a pivotal role in a variety of cell-mediated and humoral defenses, and the impact of HIV-induced CD4 dysfunction can be seen from early in the course of infection. Development of cytotoxic T-lymphocyte (CTL) response is also altered in HIV infection. The specificity and breadth of CTL response to HIV infection has been shown to inversely correlate with disease progression. Humoral immunity in HIV infection is limited as well. Although polyclonal elevations in immunoglobulin levels are quite common in HIV-infected individuals, the presence of neutralizing antibodies against HIV is very rare. This is due in part to the disproportionally high rate of mutations observed in regions of the gp41/gp120 surface proteins that are most accessible to immunologic recognition.

A variety of host factors have been identified that affect the infectivity and natural history of HIV infection. The identification of a 32-base pair deletion in the CCR5 gene (Δ32 mutation) in persons with repeated exposure to HIV-1 but no evidence of infection highlighted the importance of host-derived cofactors in HIV infection. Persons who are heterozygous for this mutation are able to be infected but have been shown to have a slower rate of progression to AIDS. HLA subtypes have also been shown to affect disease progression with HLA-B27 and HLA-B*5701 alleles generally correlating with slower rates of clinical progression. Virologic factors associated with alterations in the natural history of HIV infection are described as well. Since the 1980s, investigators have recognized that certain strains of HIV demonstrated trophism for macrophages, whereas others did not (so-called syncytia-inducing [SI] viruses). Isolation of SI viruses was less common, although the frequency increased in patients with advanced AIDS. The difference observed between these two strains in tissue culture was ultimately explained by a difference in tropism for chemokine receptors, which each type used to gain entry into target cells. Patients with SI viruses were shown to require the CXCR4 molecule to infect the target cell, and CXCR4 tropism was subsequently shown to be associated with more rapid progression to AIDS. Other examples of virologic factors that impact the natural history of HIV infection are less commonly observed. The most notable example of such uncommon viral variants is a cohort of patients with a common source exposure who experienced an exceptionally slow rate of progression to AIDS despite longstanding infection. Detailed analysis of their viral isolate revealed a deletion in the HIV regulatory gene *nef,* which is thought to explain the cause of their clinical stability despite longstanding HIV infection.

Neutrophil dysfunction is commonly seen in HIV-infected persons, especially in those with advanced immunosuppression. HIV infection itself can produce neutropenia, and is also commonly seen in association with medications used to treat HIV or an associated opportunistic infection such as AZT, trimethoprim/sulfamethoxazole or ganciclovir. Neutropenia has been associated with increased rates of serious bacterial infections and mortality in patients with focal infections such as pneumonia.

Although a variety of host and viral factors have been shown to alter the natural history of HIV infection, the immunologic defects associated with advanced AIDS are more stereotypical. Although HIV-specific CD4 response can be demonstrated in patients with advanced AIDS, the ability of such cells to undergo clonal expansion is limited. Advanced disease is correlated with loss of HIV-specific CTL, which in turn may be due to either impaired CD4 helper response or selection of escape mutants able to evade a previously generated CTL response. Alterations in coreceptor utilization is commonly seen in advanced HIV with a switch from CCR5-trophic virus to CXCR5 or mixed CCR5/CXCR4 strains.

LUNG-SPECIFIC IMMUNODEFICIENCY

Numerous studies support the principle that immune response to HIV infection may be different in tissue

compartments such as the gut or brain than that observed in the blood. A detailed understanding of the alterations in pulmonary immunity in HIV-infected persons allows a tailored approach to prophylaxis and treatment of pulmonary opportunistic infections. A comprehensive review of pulmonary immunology can be found elsewhere in this volume, but several features of lung immune function in patients with HIV deserve discussion. To date, most studies of the pathophysiology of HIV in the lung have focused on patients with advanced disease who were being evaluated for suspected pulmonary opportunistic infections. Investigators have tended to focus on alveolar macrophage function and other cell types that were accessible via bronchoalveolar lavage. Available data suggest that alveolar macrophages are an important reservoir for HIV in the lung. Studies have shown that alveolar macrophages obtained from uninfected donors can be infected by HIV-1 in vitro. The amount of HIV that can be obtained from alveolar macrophages is greater in patients with AIDS compared with those with less severe immunosuppression. Whether infection of pulmonary macrophages occurs predominantly in the lung or precursor cells in the bone marrow or peripheral blood is unknown. Arguing for differences in the biology of HIV infection in the lung are case reports demonstrating significant genotypic variation between isolates obtained from BAL and those obtained in peripheral blood mononuclear cells (PBMCs). Studies examining the impact of HIV infection on alveolar macrophage function show enhanced phagocytic activity against pathogens such as *Staphylococcus aureus* and *Cryptococcus neoformans,* but reduced activity against *Pneumocystis jiroveci.* Data on submucosal immune function in HIV infection are limited, as are studies looking at pulmonary immunology in those with less severe immunosuppression. Alveolar lymphocytes are increased in both early and advanced HIV infection. The impact of HIV infection on T-cell activity is less certain. Most investigators report normal to increased numbers of CD4+ lymphocytes in persons undergoing bronchoscopy for suspected opportunistic infection. CD4/CD8 ratios have been noted to be lower in such patients, a fact that may be explained by an influx of CD8 cells more than depletion of CD4-positive cells. Normal to increased numbers of CD8 cells do not necessarily confer enhanced cytotoxic T-cell response, however. Studies of CD8-positive lymphocytes obtained from patients with HIV have shown decreased cytotoxic activity compared with uninfected controls.

Humoral immunity is especially important in control of common bacterial pathogens. Although data on mucosal immunity are limited, studies of BAL fluid from patients with AIDS and respiratory complaints show increased levels of IgG, IgM, and IgA as well as increased numbers of B cells capable of secreting immunoglobulin. However, studies of asymptomatic patients with HIV infection demonstrated decreased levels of immunoglobulin compared with health controls, suggesting that impaired B-cell function may play a role in predisposition to opportunistic infection.

OVERVIEW OF HIV MANAGEMENT

HIV Natural History

Primary HIV infection is characterized by the presence of fever, lymphadenopathy, sore throat, mucocutaneous lesions, myalgia/arthralgia, diarrhea, headache, and weight loss. Symptoms typically last 1 to 2 weeks and can be quite severe. Primary infection is characterized by high levels of HIV viremia (usually greater than 300,000 copies/ml) and transient declines in CD4 count. Respiratory symptoms are uncommon during primary HIV infection, although case reports of typical opportunistic infections such as PCP have been described during this time. Following resolution of the acute illness, infected persons feel well. The average time between the acquisition of HIV and the development of AIDS is 7 to 10 years, although it may be as rapid as 2 to 3 years. Risk factors for more rapid progression include high viral load, rapid decline in CD4 count, advanced age, and injection drug use. Untreated, a variety of infectious, neurologic, and neoplastic complications may develop. Median survival is 3.7 years once a patient's CD4 count drops below 200 cell/mm^3, and 1.3 years after diagnosis of an AIDS-defining complication. Late-stage AIDS is characterized by profound CD4 cytopenia, high-level viremia, and often multiple concurrent opportunistic infections.

Combination Antiretroviral Therapy

The introduction of combination antiretroviral therapy in 1996 transformed the care of patients with HIV. Comprehensive guidelines are available on both antiretroviral therapy and the prevention and management of opportunistic infections. These guidelines are regularly updated: The most recent version can be found at http://www.aidsinfo.nih.gov. Optimal management of HIV infection requires early diagnosis. In the United States, about 25 percent of infected patients are unaware of their HIV status and 40 percent of newly diagnosed patients experience an AIDS-defining event in the following year. Risk associated with late diagnosis of HIV infection persists after treatment has been initiated. Even when asymptomatic at diagnosis, patients who present with advanced immunosuppression are more likely to develop complications related to their infection and therefore deserve particularly close monitoring. Patients with advanced age, active intravenous drug use, and marked CD4 depletion are less likely to regain a normal CD4 count, thus increasing their cumulative risk of opportunistic infection.

The decision to initiate antiretroviral therapy is based on clinical, immunologic, and virologic parameters as well as an assessment of an individual's readiness to adhere to antiretroviral therapy. The choice of a regimen depends on an assessment of co-morbid conditions such as liver disease, renal function, and cardiovascular risk factors and a review of the susceptibility of the dominant strain of virus the patient harbors (done through genotypic or phenotypic testing).

Treatment guidelines stress the importance of choosing a regimen that contains least three agents with preserved activity against HIV. A successful antiretroviral regimen is one that is well tolerated, convenient, and has a low incidence of short- and long-term complication while maintaining potent and durable suppression of HIV replication. With continuing advances in HIV drug development, the goal of antiretroviral therapy for all patients is to achieve an undetectable viral load in the blood using an ultrasensitive assay. Effective antiretroviral therapy should also result in restoration of at least partial cell-mediated immunity with successful treatment resulting in a rise of CD4-positive cells of 50 to 100 cells/mm^3 at the end of 1 year.

EPIDEMIOLOGY OF PULMONARY DISEASE IN HIV

HIV Epidemiology

According to 2005 data from the World Health Organization (WHO), 33.4 to 46 million people were estimated to be infected with HIV worldwide. In that year, approximately 4.1 million persons were newly infected with HIV and 2.8 million died, including an estimated 380,000 HIV-infected children. The HIV pandemic is global, but the vast majority of persons living with HIV infection reside in resource-limited settings. Although significant strides have been made in providing access to antiretroviral therapy to persons with HIV, most patients with HIV do not have access to comprehensive diagnostic, preventive, or treatment services. Lack of access to even basic preventive measures, such as immunizations and antimicrobial prophylaxis, has produced marked discrepancies is the epidemiology of HIV infection. Clinicians in the United States must also contend with disparities in access. Although men who have sex with men and injection drug users still make up the largest groups of people living with HIV in the United States, rates of heterosexual transmission are rising. New infections are increasingly occurring in women and ethnic minorities.

Epidemiology of Pulmonary Diseases in HIV

The spectrum of pulmonary disease seen in HIV-infected persons has changed since the identification of the first patients with HIV in 1981. Although *Pneumocystis jiroveci* remains a common pathogen, the introduction of prophylaxis and then combination antiretroviral therapy has dramatically reduced its frequency in patients receiving appropriate and timely care. Data from the era before combination antiretroviral therapy deserve review as they can inform the approach to patients who are entering care with newly diagnosed HIV infection, or in those who are poorly adherent to their prescribed antiretroviral therapy. The pulmonary complications of HIV infection study cohort followed 1100 HIV-infected patients from 1988 to 1994. The study also included 167 HIV-negative controls. Although the study preceded the availability of protease inhibitors and the widespread use of combination antiretroviral therapy, it provided the most accurate data regarding the incidence of specific pulmonary infections among HIV-infected individuals. Importantly, the study included the era, after which prophylaxis against *Pneumocystis jiroveci* pneumonia (PCP) became the standard of care. During the 5 years of follow-up in the study, acute bronchitis was the most common lower airway infection, occurring twice as commonly among those of HIV infection than in controls. By far the two most common AIDS-defining complications were bacterial pneumonia and PCP. These occurred with approximately equal frequency, with sequential follow-up showing higher rates of pneumonia with declining CD4 cell counts. Other specific causes of opportunistic infections occurred relatively infrequently, and included cases of cytomegalovirus, aspergillus, cryptococcus, and herpes simplex. The use of combination antiretroviral therapy has dramatically diminished the incidence of all of these complications, with some evidence of a greater decline in PCP than in bacterial pneumonia. For the former, this decline occurred independent of the frequency of use of PCP prophylaxis. Chronic administration of anti-*Pneumocystis* prophylaxis with trimethoprim sulfamethoxazole in particular, and *Mycobacterium avium* complex prophylaxis with macrolide antibiotics likely reduces the incidence of bacterial pneumonia. However, it has been shown that treatment with trimethoprim sulfamethoxazole increases the rate of colonization with resistant bacteria, especially pneumococci.

BASIC EVALUATION OF THE HIV-POSITIVE PATIENT WITH RESPIRATORY COMPLAINTS

The differential diagnosis of respiratory symptoms in a person with HIV is exceedingly broad and includes both infectious and noninfectious etiologies (Table 128-1). As noted, about 25 percent of infected patients in the Unites States are unaware of their HIV status, so the first step in managing such complaints is to consider the possibility of HIV infection in patients presenting with undiagnosed respiratory complaints. The diagnosis of HIV infection is made through identification of antibodies to HIV by enzyme-linked immunosorbent assay (ELISA) followed by confirmatory western blot of HIV-associated proteins. Whenever possible, such testing should use assays with rapid turnaround times (hours not days) so that preliminary results can be relayed to the patient during the initial encounter. Use of virologic assays such HIV viral load should be reserved for those with suspected acute HIV infection as the assay is subject to false-positive results and is not approved for the diagnosis of chronic HIV infection.

In patients with recognized HIV infection, optimal management of respiratory complaints starts with a careful review of presenting complaints, past medical history (including history of opportunistic infections), and current

medications. Rates of tuberculosis (TB) are higher in individuals with HIV infection. Because of the potential public health and infection control issues associated with HIV-TB co-infection, a decision on respiratory isolation should be made early in the course of the evaluation of most patients with HIV and respiratory complaints. The physical exam should ascertain the severity of the presenting complaints and should focus on identification of HIV-associated mucocutaneous, gastrointestinal, neurologic, and pulmonary diseases. Basic laboratory evaluation includes a CD4 cell count and percentage as well as complete blood count and comprehensive metabolic panel (including tests of renal and hepatic function). Quantification of peripheral viremia (viral load testing) can be helpful in discussions of prognosis and treatment in HIV infection, but is less useful in the evaluation of respiratory complaints. Coupled with a review of a patient's travel and exposure history, results of this basic evaluation helps structure microbiologic, imaging, and pathologic studies required to establish a definitive diagnosis.

Presenting Complaints

Although considerable overlap occurs in presenting complaints, the description offered by HIV-infected individuals often provides valuable clues to the origin of their respiratory complaints. Patients with bacterial pneumonia typically present much in the same way as those without HIV infection—with a relatively acute illness (measured in days) characterized by fever, chills, productive cough, and occasionally pleuritic chest pain. *Pneumocystis pneumonia,* by contrast, typically presents as a subacute to chronic illness of several weeks' duration, with the most prominent symptoms being fever and shortness of breath. Other helpful clues to PCP include chest tightness (specifically a sense that it is difficult to take a full breath) and a report that a typical day's activities (climbing stairs, conversing on the telephone) are now associated with dyspnea. The presence of constitutional symptoms, such as fever, night sweats, and weight loss, together with respiratory complaints suggest a systemic infectious process such as mycobacterial disease, fungal infection, or non-infectious conditions such as non-Hodgkin's lymphoma.

Past Medical History

One of the most fruitful approaches in the evaluation of pulmonary complaints in persons with HIV is to review their history of previous cardiopulmonary disease. It goes without saying that patients with a previous opportunistic infection such as PCP pneumonia are at higher risk of recurrence, especially if appropriate secondary prophylaxis and antiretroviral therapy are not taken. Although the pathophysiologic basis remains somewhat obscure, some patients with HIV appear to have more prominent B-cell dysfunction, and hence are at a much greater risk for the development of encapsulated bacterial infections, in particular those due to *Streptococcus pneumoniae* and *Haemophilus influenzae.* Such individuals frequently have a history of multiple prior visits or hospitalizations for bacterial pneumonia, as well as episodes of otitis media, bronchitis, and other bacterial respiratory infections. HIV-infected persons with active injection drug usage are more likely to develop invasive bacterial infections, including pneumonia, compared with HIV-positive individuals who acquired HIV from other routes. Even when CD4 cell counts are relatively high (greater than 500 cells/mm^3), HIV-infected patients are at substantially higher risk of bacterial pneumonia than non–HIV-infected controls. This relative risk increases as the CD4 cell declines.

Medication History

Faithful adherence to antiretroviral therapy is the most important intervention that alters the risk of opportunistic pulmonary complications in HIV infection. As discussed in the following, it is vital to review the specific medications used to treat HIV, as certain antiretrovirals may have direct effects on the lung and may alter the metabolism of coadministered agents. The differential diagnosis of respiratory complaints in HIV-positive patients is strongly influenced by the use of both primary and secondary prophylaxis has common opportunistic infections. Patients receiving trimethoprim sulfamethoxazole for *Pneumocystis* prophylaxis rarely suffer breakthroughs of PCP if they are compliant with therapy. By contrast, second-line prophylaxis such as atovaquone, dapsone, and aerosolized pentamidine are all associated with small but significant rates of treatment failure. Trimethoprim sulfamethoxazole has the added benefit of reducing the risk of all bacterial infections, including community pneumonia as well as less common HIV-associated opportunistic infections such as nocardia and toxoplasmosis. The effectiveness of prophylaxis has limitations and high rates of pneumococcal resistance to trimethoprim sulfamethoxazole and macrolides must be taken into consideration when selecting empiric therapy for patients with suspected bacterial pneumonia.

Physical Examination

A review of vital signs should identify patients with marked impairment of gas exchange or hemodynamic compromise. Pulse oximetry provides a non-invasive means of assessing gas exchange, although resting oxygenation saturation is not a sensitive test for mild hypoxemia. Signs of systemic inflammatory response syndrome (SIRS) are most commonly seen in patients with fulminant bacterial infections or rarely also with disseminated histoplasmosis, cryptococcosis, or other disseminated fungal infections. Alterations in mental status can be seen with overwhelming infections but should also prompt consideration of infections such as cryptococcus that produce both meningitis and respiratory complaints. Auscultation of the lung fields is commonly normal in diseases such as PCP but evidence of focal consolidation can be a clue to bacterial pneumonia. A careful cardiac examination may reveal the presence of both left- and right-sided heart failure.

Physical findings outside the chest can provide valuable clues to the etiology of pulmonary symptoms in patients

with HIV infection. Common opportunistic infections with prominent dermatologic findings include disseminated fungal infections (cryptococcus and blastomycosis in particular) and Kaposi's sarcoma. Funduscopic examination may suggest the presence of viral, fungal, or mycobacterial infection. The presence of hepatosplenomegaly or peripheral lymphadenopathy may be seen in disseminated mycobacterial disease, fungal disease, and non-Hodgkin's lymphoma.

Infection Control Issues

Because of the increased rates of tuberculosis in patients with HIV infection (see the following), it is essential that clinicians consider the possibility of TB when evaluating respiratory complaints in persons with HIV. As no clinical or radiographic presentation can entirely exclude TB, practitioners must have a high degree of suspicion and a low threshold to admit such cases to negative airflow rooms until TB has been ruled out or an alternative diagnosis has clearly been established. We admit patients with HIV and respiratory disease to negative airflow rooms if any of the following conditions is present: (1) any clinical presentation highly consistent with TB (cavitary lung disease, subacute course, weight loss); (2) prior residence in a highly TB endemic area; (3) other risk factors for TB exposure, such as contact with an active case, homelessness, or incarceration; (4) history of a positive tuberculin skin test without preventive therapy; (5) history of prior tuberculosis without documentation that appropriate treatment has been completed. Using these criteria minimizes, but does not eliminate, the chance that an HIV-infected person will be a potential source of a nosocomial exposure to tuberculosis. This topic is further reviewed elsewhere in this volume.

Basic Laboratory Evaluation

The laboratory approach to HIV-infected patients with respiratory complaints begins with several simple, commonly available non-invasive studies that are followed by increasingly intensive studies should these prove unrevealing (Table 128-2). These include a complete blood count with

Table 128-2

Diagnostic Tests Used in Patients with HIV Infection and Pulmonary Disease

Test	Comment
Indicated in all patients	
CBC with differential	If neutropenia is present, empiric therapy covering *Pseudomonas aeruginosa* is indicated
LDH	Elevated in most patients with PCP; non-specific
Blood cultures	Helpful for diagnosis of bacterial pneumonia, in particular that due to *Streptococcus pneumoniae*
Expectorated sputum	Often not available; gram stain and culture with low sensitivity and specificity, especially after antibiotics have been started
Induced sputum for PCP stain, AFB stain, and culture	Initial test of choice in most centers for *diagnosis* of *Pneumocystis jiroveci*, although sensitivity varies widely
Indicated for patients not responding to initial empiric therapy	
Fiberoptic bronchoscopy with broncheoalveolar lavage,+/− transbronchial biopsy	BAL highly sensitive for diagnosis of PCP; Kaposi's sarcoma often diagnosed by visualizing characteristic purple plaques, with no biopsy done due to risk of bleeding; biopsy often necessary to establish alternative diagnosis such as CMV, aspergillus, or lymphocytic interstitial pneumonitis
Video-assisted thoracoscopic biopsy	Useful in diagnosis of peripheral nodules, masses not reachable by bronchoscopic biopsy
Serum cryptococcal antigen	Nearly 100% sensitive for diagnosis of disseminated disease in patients with HIV; if positive, CSF examination is mandatory to exclude meningitis
Urinary histoplasmosis antigen	Indicated in patients residing in or from histoplasmosis-endemic areas, in particular if imaging demonstrates hilar adenopathy
High-resolution CT scan	May help identify abnormalities not evident on CXR; a normal test makes PCP highly unlikely
Gallium scan	Negative study rules out PCP; however, positive tests are non-specific, and other tests (high-resolution CT scan, sputum induction) provide more useful information with greater rapidity

differential (CBC), lactate dehydrogenase, two sets of blood cultures, and a sputum Gram stain and culture. Comprehensive metabolic profile should be obtained on most HIV-positive patients with respiratory complaints to rule out electrolytes disturbances as well as renal or liver disease. The CBC can provide important clues to the diagnosis of respiratory complaints in persons with HIV infection. Although anemia and thrombocytopenia are more common hematologic manifestations of HIV infection, neutropenia is not rare, particularly in patients with advanced AIDS. Neutropenia has been associated with increased risk of both bacterial pathogens (including *Pseudomonas*) and invasive fungi such as *aspergillus*. Pancytopenia is suggestive of disseminated infection, malignancy, or medication toxicity. Lactate dehydrogenase levels are generally elevated in patients with PCP, especially when the disease is severe enough to require hospitalization. A normal level suggests an alternative diagnosis, and conversely the level of elevation correlates with the severity of the disease. Since many conditions cause an increase in LDH, the test has a low specificity for PCP but is a helpful adjunctive diagnostic clue pending more definitive testing.

Clinical or Laboratory Stage of Immunosuppression

The vast majority of cases of *Pneumocystis jiroveci* pneumonia occur in individuals with CD4 cell counts less than 200 cells/mm^3. In cases in which the CD4 cell count is not immediately available, useful clinical correlates for advanced immunosuppression include the presence oral candidiasis or other clinical markers of advanced HIV disease such as weight loss. It should be emphasized that progressive immunosuppression increases the risk of all pulmonary infectious processes, including those that may occur with relatively preserved CD4 cell counts, such as bacterial pneumonia and tuberculosis.

Epidemiology

As noted, the most important epidemiologic consideration when evaluating HIV-positive persons with pulmonary complaints is to establish risk for tuberculosis. The incidence of tuberculosis as a complication of HIV infection varies markedly depending on local rates of TB and the patient's prior exposure history. In the United States, a high proportion of tuberculosis cases occur in persons who have emigrated from areas in which tuberculosis highly endemic; many of these areas (such as sub-Saharan Africa and parts of the Caribbean) also have high background rates of HIV infection. In addition, homelessness and incarceration both increase the risk of tuberculosis exposure and subsequent disease. A person's past residence or travel history may elicit potential exposure not only to tuberculosis, but also to endemic fungi such as histoplasmosis, coccidioidomycosis, and blastomycosis. A careful epidemiologic history can provide clues to a variety of HIV-associated pulmonary infections such as *Rhodococcus equi, Toxoplasma gondii, Strongyloides stercoralis, Cryptosporidium,* and *Microsporidia.*

Imaging

Chest Radiograph

All HIV-infected patients who present with respiratory complaints should receive posteroanterior and lateral radiographs of the chest. Although no x-ray findings are pathognomonic for a specific microbiologic diagnosis, certain radiographic patterns are observed more commonly with specific diagnoses (Table 128-3). Patients with bacterial pneumonia more likely have a focal infiltrate on chest radiograph compared with those with PCP, in whom diffuse interstitial infiltrates are much more common. Importantly, there are many exceptions to these generalizations, including the presence of a normal chest radiograph in up 10 percent of those with PCP or tuberculosis, and the occasional occurrence of diffuse interstitial infiltrates in persons with bacterial pneumonia (in particular secondary to *Haemophilus influenzae*). In fact, given the wide range of radiographic findings potentially due to PCP—including cavities, pneumatoceles, pleural effusions, nodules, and pneumothoraces—no radiographic appearance can entirely rule out the diagnosis of PCP in an otherwise susceptible HIV-infected host. Chest x-ray may also reveal mediastinal, pleural, and extrathoracic abnormalities, which should be aggressively pursued to obtain a definitive diagnosis.

Computed Tomography

Computed tomography (CT) has become an important tool in the evaluation of respiratory complaints in patients with HIV infection. The additive benefit of chest CT over plain films is discussed in detail elsewhere in this volume. Chest CT is more sensitive that plain film in detecting subtle interstitial changes and can provide more precise characterization of nodular lesions. Chest CT has a particular role to play in evaluating HIV-positive persons with respiratory complaints whose chest x-rays are normal. A normal chest CT has a high negative predictive value for opportunistic infections and HIV-associated malignancy. CT scan of the chest has also proved useful in directing invasive diagnostic studies such as bronchoscopy or transthoracic lung biopsy.

Nuclear Imaging

Radionucleotide imaging played a historically important role in the evaluation of HIV positive patients with respiratory complaints and a normal CXR. Although highly sensitive for PCP, radionucleotide studies (using gallium citrate, technetium, or thallium), are not specific for a particular pathogen, and this modality has been largely replaced by chest CT. The specificity of positron emission tomography (PET) imaging is likewise limited in diagnosing opportunistic

Table 128-3

Radiographic Appearance of Pulmonary Diseases in HIV Infection

Diffuse interstitial infiltrates
- *Pneumocystis jiroveci*
- *Mycobacterium tuberculosis,* (especially with CD4 < 200)
- *Histoplasma capsulatum*
- *Coccidioides imitis*
- *Cryptococcus neoformans*
- *Toxoplasma gondii*
- Cytomegalovirus
- Influenza
- Lymphocytic interstitial pneumonitis
- Abacavir hypersensitivity

Focal consolidation
- Pyogenic bacterial pnumonia due:
  - *Streptococcus pneumoniae*
  - *Haemophilus influenzae*
- *Mycobacterium tuberculosis*
- *Legionella* spp.
- *Rhodococcus equi*

Hilar adenopathy
- *Mycobacterium tuberculosis*
- *Histoplasma capsulatum*
- *Coccidiodes immitis*
- Non-Hodgkin's or Hodgkin's lymphoma
- *Mycobacterium avium* complex

Cavitary disease
- Pyogenic bacterial pneumonia:
  - *Pseudomonas aeruginosa*
  - *Staphylococcus aureus*
  - Enterobacteriaceae
- *Mycobacterium tuberculosis*
- *Cryptococcus neoformans*
- *Rhodococcus equi*
- *Histoplasma capsulatum*
- *Aspergillus* spp.
- *Nocardia* spp.
- *Mycobacterium avium* complex
- *Pneumocystis jiroveci*

Nodules or masses
- *Mycobacterium tuberculosis*
- *Cryptococcus neoformans*
- *Aspergillus* spp.
- *Histoplasma capsulatum*
- *Nocardia* spp.
- Non-Hodgkin's lymphoma
- Kaposi's sarcoma
- Lung cancer

Normal radiograph
- *Pneumocystis jiroveci*
- *Mycobacterium tuberculosis*

pulmonary infections in HIV-positive patients with respiratory complaints. As in patients without HIV infection, PET imaging has a role to play in staging patients with known or suspected thoracic malignancies.

Physiologic Testing

Arterial Blood Gas Analysis

Resting pulse oximetry is a useful, non-invasive tool for assessing gas exchange in HIV-positive individuals with respiratory complaints. The sensitivity of pulse oximetry for detecting milder disease can be improved if patients are monitored for desaturation below 90 percent while breathing room air during moderate exercise, a maneuver that has been used to screen for PCP in HIV-positive patients seen in outpatient settings. Measurement of arterial blood gases provides a more detailed picture of gas exchange. Although not commonly done, failure to demonstrate the normal decrease in alveolar-to-arterial oxygen gradient between rest and exercise is highly sensitive to PCP. Practically speaking, arterial blood gas analysis is performed most commonly in patients who present with severe respiratory distress or with a low oxygen saturation level on oximetry. Determining whether the Pa_{O_2} less than 70 mm Hg or A-a gradient greater than 35 mm Hg (see the following) has important therapeutic implications for potential use of adjunctive corticosteroids.

Pulmonary Function Testing

Pulmonary function testing (PFTs) can be useful in the evaluation HIV positive patients with idiopathic dyspnea and preserved CD4 counts, although their role in the evaluation of patients with AIDS is less clear. Measurement of the diffusing capacity for carbon monoxide (D_{LCO}) in HIV-positive patients with advanced disease is generally reserved for patients with normal CXR and undiagnosed respiratory complaints. Like radionucleotide imaging, an impaired D_{LCO} is common finding in patients with early or mild interstitial lung disease and may be the first objective sign that an opportunistic infection is present. Although typically not helpful in establishing a specific diagnosis, a D_{LCO} significantly below predicted levels should prompt further diagnostic testing.

Microbiologic Testing

Respiratory Secretions

Gram stain and culture of expectorated sputum is an important first step in the evaluation of HIV-positive patients with respiratory complaints. Empiric treatment decisions may be strongly influenced by the identification of a potential pathogen on Gram stain or AFB smear. The microbiologic evaluation of PCP and TB as well as the other less common opportunistic pathogens are reviewed in the following. If a definitive diagnosis has not been made with sputum Gram stain and culture, the decision to proceed with additional diagnostic tests, both non-invasive and invasive, depends on the patient's response to initial therapy. In practice, a prompt clinical response to empiric antibiotic therapy directed at the most common pathogens in HIV-related pneumonia (*Streptococcus pneumoniae* and *Haemophilus influenzae*) serves as indirect evidence that alternative processes have not been overlooked. For patients who have not improved clinically, and when the diagnosis is still unknown, expedited referral for fiberoptic bronchoscopy with bronchioalveolar lavage is indicated.

Peripheral Blood Cultures

The purpose of the blood cultures is to facilitate diagnosis of bacterial pneumonia, most notably due to *Streptococcus pneumoniae*, where rates of bacteremia in patients with HIV can approach 60 percent of cases. Given the low specificity of sputum gram stain, as well as the low sensitivity of sputum culture, a positive blood culture for a likely organism is often the only method of making a specific etiologic diagnosis in a patient with bacterial pneumonia. Fungal and mycobacterial cultures are occasionally useful in the diagnosis of disseminated histoplasmosis and MAC, as discussed in more detail in the following.

Tissue Diagnosis

For patients who have not improved clinically and in whom a diagnosis remains uncertain, tissue may be required to establish a definitive cause for respiratory complaints in the HIV-infected patient. Since BAL alone is highly sensitive for the diagnosis of PCP, and biopsy carries a risk of pneumothorax and pulmonary hemorrhage, many bronchoscopists prefer to perform a BAL alone initially, reserving biopsy for a repeat procedure if this is still indicated. The main indication to proceed with transbronchial biopsy is a high likelihood of an alternative diagnosis to PCP; this situation arises when a patient is taking trimethoprim sulfamethoxazole for PCP prophylaxis, has a relatively high CD4 cell count or atypical appearing CXR, or when a diagnosis requiring biopsy for identification is highly suspected. Examples of such conditions include CMV, aspergillus, lymphocytic interstitial pneumonitis, and malignancies other than Kaposi's sarcoma. Transbronchial needle aspiration should be reserved for the evaluation of mediastinal adenopathy, although the yield is variable. CT-guided biopsy is particularly useful when evaluation peripheral nodular lesions that are not amenable to transbronchial approach. Data on the diagnostic yield of CT-guided biopsy are limited but one study of patients with focal chest or mediastinal abnormalities on CT scan demonstrated a diagnosis in 84 percent using CT-guided biopsy. Open lung biopsy is the most invasive approach to obtaining a tissue diagnosis of respiratory complaints in HIV-positive patients and is generally reserved for patients with in whom transbronchial or CT-guided biopsy has failed to yield a diagnosis, although some clinicians favor this approach for HIV-positive individual with diffuse interstitial disease who have failed to respond to empiric therapy. Thoracotomy or, more commonly, video-assisted thoracic surgery (VATS) should be considered in such cases as it can yield valuable information in HIV-positive individuals with pulmonary complications. A study of open lung biopsy in HIV-positive patients with a non-diagnostic bronchoscopy, reported a definitive diagnosis in 13 of 18 patients (72 percent) who underwent open lung biopsy and similar study reported that open lung biopsy led to a change in therapy in 15 of 25 patients, eight of whom improved clinically and were discharged from the hospital. The authors outlined the following indications for open lung biopsy in HIV patients: (1) non-diagnostic bronchoscopy; (2) failed medical therapy after a diagnostic bronchoscopy; (3) failed empiric medical therapy after a nondiagnostic bronchoscopy; and (4) any of the preceding, in combination with a worsening chest radiograph. Even though no formal comparison of VATS and open lung biopsy has been made in HIV-infected patients, both procedures appear to be equivalent for obtaining diagnostic lung tissue. There may be less morbidity associated with VATS, as these patients generally require fewer days in hospital and less time with chest tube drainage. If the patient cannot tolerate single lung ventilation, which is necessary during VATS, or if the lesion can not be reached through a thoracoscope, then an open thoracotomy should be performed. In general, the choice of procedure is typically left to the surgeon.

Specific Pathogens

Bacterial Pneumonia

Bacterial respiratory infections are one of the most common causes of respiratory complaints in HIV-positive patients. In 1993, the classification system for HIV infection was revised to include recurrent pneumonia (with or without established microbiologic confirmation) as an AIDS-defining condition. Although HIV affects cell-mediated immunity most profoundly, abnormalities in antibody production and, in advanced AIDS, neutrophil function all contribute to the increased risk of bacterial pneumonia. The epidemiology of bacterial pneumonia is influenced by both epidemiologic and immunologic factors. Overall, the rate of bacterial pneumonia among patients with HIV is as much as 80-fold higher than in HIV-negative controls. Although this increased risk is seen throughout the course of HIV infection compared with HIV-negative controls, the relative risk increases as the CD4 count drops. In the era before combination antiretroviral therapy, studies documented 2.3, 6.8, and 10.8 episodes

of bacterial pneumonia per 100 patient years in patients with CD4 counts of greater than 500, 200 to 500, and less than 200 cells/mm^3, respectively. Bacterial pneumonia is more common in smokers with HIV than in nonsmokers. Injection drug use more than doubles the risk of bacterial lower respiratory track infections compared with those who acquired HIV through sexual exposure. HIV-infected injection drug users have much higher rates of *Staphylococcal* pneumonia, including necrotizing pneumonia complicating endocarditis. Interestingly, a previous diagnosis of PCP pneumonia appears to be an independent risk factor for bacterial respiratory infections. As with other opportunistic infections, use of potent combination therapy has resulted in decreased incidence of bacteria pneumonia (from 22.7 to 9.1 episodes/100 patient years in one study). Diagnosis of bacterial pneumonia is associated with increased risk of death in patients compared with HIV-positive patients who are matched for CD4 count. Mortality due to bacterial pneumonia is higher in HIV patients who have a CD4 cell count less than 100 cells/mm^3, radiographic progression of disease on therapy, and shock.

The microbiology of bacterial lower respiratory track infection is influenced by HIV disease stage as well. Since encapsulated bacteria (in particular *Streptococcus. pneumoniae*) are more intrinsically virulent than the opportunistic infections of advanced HIV disease, these infections may occur at any stage of HIV disease and hence be the sentinel opportunistic process in a person otherwise unaware that he or she has HIV infection. Neither the concomitant use of trimethoprim-sulfamethoxazole for PCP prophylaxis nor a history of having received immunization against *Streptococcus pneumoniae* are sufficiently protective against bacterial pneumonia to warrant a change in empiric therapy when considering this diagnosis. The most common identified pathogen in HIV-related bacterial pneumonia is *Streptococcus pneumoniae*, generally followed by *Haemophilus influenzae*. The presentation of these typical community acquired pathogens is similar to that observed in HIV-negative patients with pneumonia. Fever, productive cough, dyspnea, and chest pain are common. Although both typically present with a relatively acute illness and focal consolidation on CXR, *H. influenzae* may rarely cause a more subacute illness with diffuse interstitial infiltrates, suggestive of *Pneumocystis jiroveci* pneumonia.

Gram-negative bacilli and *Staphylococcus* aureus assume increasing importance as immunosuppression worsens, presumably due both to neutrophil dysfunction and selective pressure of other antimicrobials. *Pseudomonas aeruginosa* has been associated with neutropenia, prior treatment with cephalosporins, and CD4 cell counts less than 50 cells/mm^3. Like individuals with structural lung disease, pseudomonal respiratory infections in HIV-infected patients have a tendency to relapse and chronic colonization typically ensues, with relapse rates after therapy between 25 and 86 percent. Methicillin-resistant *Staphylococcus aureus* (MRSA) is increasingly common in may be acquired in health care setting or in the community. Although the epidemiologic picture is rapidly evolving, the impact of HIV infection on risk for

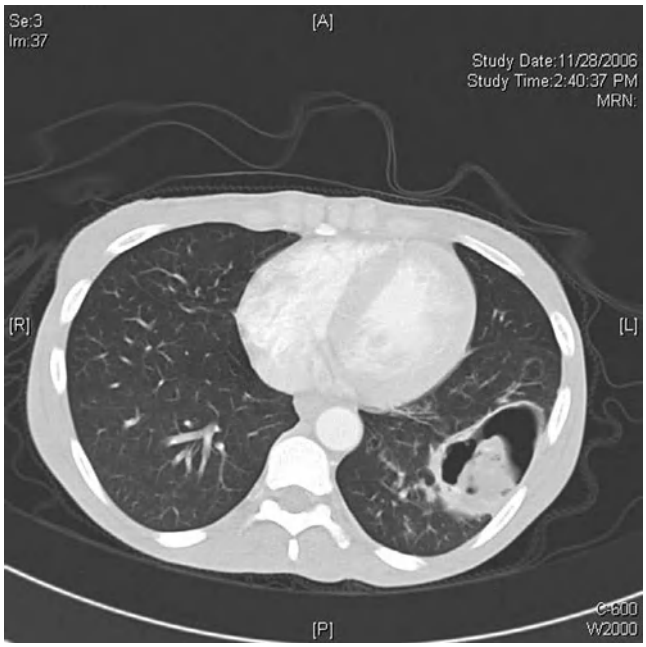

Figure 128-1 Cavitary pneumonia due to community-acquired methicillin-resistant *Staphylococcus aureus* in a 46-year-old man with AIDS, CD4+ cell count of 120. The patient was found to be bacteremic.

colonization and invasive disease with MRSA remains to be defined. Colonization with community-associated MRSA is more common in men who have sex with men (MSM) and injection drug users so the index of suspicion for MRSA infection should be high in HIV positive patients with these risk factors. MRSA pneumonia can be quite severe and commonly leads to cavitation (Fig. 128-1).

Compared with HIV-negative controls, atypical pathogens are a relatively uncommon cause of pneumonia in HIV-infected hosts, although important exceptions to this generalization exist. *Nocardia* species are an important cause of pulmonary disease in immunocompromised hosts, including those with HIV infection. The relative rarity of nocardiosis compared with other opportunistic processes may relate to the frequent use of trimethoprim-sulfamethoxazole for PCP prophylaxis, although this does not completely prevent nocardia infection from occurring. The disease is usually subacute to chronic, and limited to the lung, where cavitation may occur; therefore, it may present similarly to tuberculosis (Fig. 128-2). Dissemination with positive blood cultures is also possible, in particular in patients with advanced immunosuppression. *Rhodococcus equi* can cause both localized pulmonary and disseminated disease in HIV-infected hosts, who appear to be particularly susceptible to this pathogen. A gram-positive coccobacillus, *R equi* can be mistaken for routine oral flora on sputum smears. A potential clinical clue is that the organism appears weakly acid fast on sputum stains looking for tuberculosis. The typical presentation is one of a chronic pneumonia—with cough, sputum production, and sometime hemoptysis—with radiographs showing cavitary disease and often with associated pleural effusion; however,

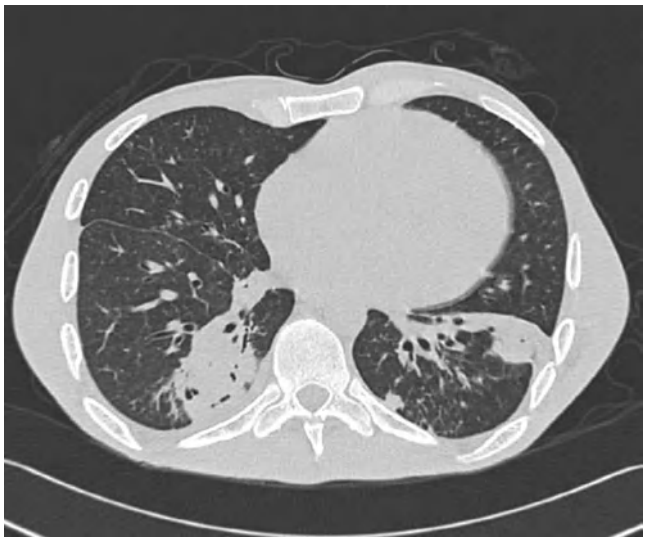

Figure 128-2 Pneumonia due to *Nocardia asteroids* in a 36-year-old man with AIDS, CD4+ cell count 30/mm^3. Infection resolved with prolonged therapy with imipenem.

diverse radiographic findings have been reported. Bacteremia commonly accompanies *Rhodococcus* pneumonia, and may be the most reliable way to make the diagnosis. As treatment requires prolonged therapy with multiple agents, persistence or recurrence of symptomatic infection is common unless the immune status can be improved with antiretroviral therapy. The frequency of *Legionella* pneumonia in HIV-positive patients who present with respiratory complaints has been difficult to define. Although early series seemed to suggest that these infections were relatively common, later studies have not supported the association. The epidemiology of *Legionella* infections shows significant variation and infections may be nosocomially acquired, facts that may alter the prevalence of such infections in both HIV-positive and -negative patients with respiratory complaints. TMP/SMX has activity against *Legionella* and hence TMP/SMX may partially protect HIV-positive patients if used for PCP prophylaxis.

The diagnosis of bacterial pneumonia in patients with HIV infection is similar to that of HIV-negative patients. Sputum should be collected for Gram stain and culture, preferably before administration of antibiotics. Susceptibility testing should be done on most clinical isolates giving rising rates of drug-resistant *Pneumococcus*, *Pseudomonas*, and MRSA. As bacteremia occurs in up to 60 percent of HIV-positive patients with pneumococcal pneumonia, two sets of blood cultures should also be collected. In patients with significant pleural effusions, consideration should be given to thoracentesis to rule out empyema. In patients in whom the diagnosis is unclear, supplemental testing such as a modified acid-fast stain (for *Nocardia* and *Rhodococcus*) or a urinary legionella antigen is appropriate.

Management of bacterial pneumonia is similar in both HIV-positive and -negative patients. Published guidelines for the treatment of community-acquired pneumonia are revised regularly and clinicians are encouraged to seek updated recommendations. Decisions on empiric therapy are based on the severity of the illness, presence of co-morbid disease and knowledge of local microbiology and resistance patterns. For patients with moderately severe disease, a third-generation cephalosporin along with either azithromycin or a respiratory fluoroquinolone such as levofloxacin or moxifloxacin is recommended. In HIV-positive patients with advanced disease, neutropenia or history of prior infection or colonization with *Pseudomonas* should receive an anti-pseudomonal cephalosporin such as cefepime or ceftazidime. Given the high rates of resistance in *Pseudomonas* infections, some experts advocate the addition of an aminoglycoside when this organism is isolated. Vancomycin or linezolid should be considered for HIV-positive patients who present with nosocomial pneumonia, rapidly progressive respiratory tract infection, or those with compatible clinical or Gram stain findings. Duration of therapy depends on the organism and response to treatment, but is generally similar to that of HIV-negative patients, typically 7 to 14 days.

Prevention of bacterial pneumonia should focus on restoration of immune function, observance of primary and secondary prophylaxis, and lifestyle modifications. Combination antiretroviral therapy should be considered for all patients with recurrent bacterial lower respiratory tract infections. In patients with severe neutropenia (less than 500 cells/mm^3), granulocyte colony stimulating factor (g-CSF) may reduce the risk of recurrent infection, whereas aggressive efforts are undertaken to identify and correct the cause(s) for neutropenia. Although not typically recommended for HIV-infected patients with recurrent bacterial respiratory track infections, TMP/SMX prophylaxis for PCP can reduce the rates of many bacterial pathogens as well. Pneumococcal vaccine is recommended for all HIV patients who have a CD4 cell count greater than 200 cells/mm^3, and the influenza vaccine should be given annually to all patients, regardless of CD4 cell count. Since most *Haemophilus influenza* infections in HIV patients are from non-typable strains, this vaccination is not recommended. Finally, given the strong links between bacterial respiratory infections and both tobacco abuse and intravenous drug use, HIV-infected patients with lower respiratory tract infections should be offered the full array of services to overcome these addictions.

Mycobacterial Infections

Detailed discussions of Mycobacterium tuberculosis and non-tuberculous mycobacteria can be found elsewhere in this volume, so we will limit our discussion to the distinct features of these infections in persons with HIV infection.

Mycobacterium Tuberculosis

Co-infection with HIV and TB accelerates the course of both infections. HIV viremia is higher in persons with active tuberculosis than those with similar CD4 counts as is HIV-related mortality. Whereas the lifetime risk of reactivation of latent tuberculosis infection (LTBI) is 5 to 10 percent in HIV-negative persons, it jumps to 7 to 10 percent annually in

HIV-positive persons. The likelihood that respiratory complaints in an HIV positive individual are due to tuberculosis is strongly influenced by environmental exposures, including current or past residence in TB endemic areas, and/or the presence of other known risk factors, such as homelessness or incarceration. Specifically, rates are high in immigrants from highly TB-endemic regions, such as sub-Saharan Africa, Latin America, Asia, and much of the Caribbean. The risk of co-infection with TB in patients with HIV in the United States is highest in the New York metropolitan area (including the cities of northern New Jersey), Florida, California, Chicago, the District of Columbia, Georgia, and Texas. Tuberculosis is seen at any stage of HIV infection. The frequency and clinical presentation of tuberculosis in HIV-infected patients depends on the degree of immunosuppression. In patients with relatively preserved higher CD4 cell counts (greater than 350 cells/mm^3), co-infection with TB tends to look like that seen in those without HIV (upper lobe predominance, cavitary disease and a low risk of extrapulmonary presentations). The presence of constitutional symptoms is variable in patients with higher CD4 counts but most HIV-positive patients with preserved CD4 count have fever, sweats, and weight loss. At more advanced stages of immunosuppression, HIV-positive patients with TB are more likely to have extrapulmonary disease accompanied by prominent constitutional symptoms (Fig. 128-3). In one series of 97 patients with HIV-TB co-infection, extrapulmonary disease was seen 30 of 43 patients with CD4 counts less than 100 cells/mm^3 versus 5 of 19 with a CD4 count greater than 300 cell/mm^3. Sites commonly involved with extrapulmonary TB in HIV-positive patients include the bloodstream, extrathoracic lymph nodes, bone marrow, genitourinary track, liver, and the central nervous system.

Figure 128-3 Disseminated tuberculosis with multiple small pulmonary nodules in a 40-year-old man with AIDS.

Non-Tuberculous Mycobacteria

Pulmonary symptoms due to non-tuberculous mycobacteria (NTB) are less common in HIV-positive than -negative patients. In the era before combination antiretroviral therapy, *Mycobacterium avium* complex (MAC) infection was a common opportunistic infection in persons with advanced AIDS (CD4 less than 50 cell/mm^3) and it still remains the most common NTB infection seen in patients with HIV. Clinical features of disseminated MAC include fever, anorexia, weight loss, hepatosplenomegaly, and anemia. Although the respiratory tract may serve as the portal of entry for MAC, it is rarely the primary cause of respiratory symptoms in patients with HIV. Recovery of MAC from respiratory secretions does not warrant treatment without compatible clinical and radiographic findings, although its presence may be a harbinger of disseminated disease. A discussion of the management of NTB mycobacterial infections can be found in Chapter 142 as well as the ATS guidelines for the diagnosis and treatment of non-tuberculous mycobacteria. Rates of disseminated MAC can be reduced by administering azithromycin 1200 mg by mouth once weekly to persons with CD4 counts less than 50 cells/mm^3; administration of effective antiretroviral therapy with improvement in the CD4 cell count virtually eliminates the risk of developing disseminated MAC.

Fungal Pathogens

Pneumocystis jiroveci

The initial case report of HIV infection in the June 5, 1981 issue of MMWR described five individuals without previously identified risk factors who were diagnosed with *Pneumocystis carinii* pneumonia (PCP). Pneumocystis infection is discussed in detail elsewhere in this volume. PCP in patients with HIV infection usually presents subacutely with progressive dyspnea, non-productive cough, and fever. Pleuritic chest pain or acute worsening of symptoms is an unusual manifestation of PCP in patients with HIV unless complicated by the development of a pneumothorax. Findings on physical exam are limited and nonspecific, and the lungs are generally clear on auscultation. Organism burden tends to be greater and neutrophil response diminished in HIV-associated PCP versus that seen in other immunocompromised groups, such as transplant recipients. Induced sputum is often the first diagnostic procedure, although a meta-analysis of studies in HIV-positive patients demonstrated a sensitivity of approximately 55 percent compared to the 95 percent sensitivity of BAL. Identification of cysts on appropriate stains is diagnostic of PCP, as there does not appear to be an asymptomatic carrier state. Persistence of organisms through and even after therapy is common, and does not reflect failure of therapy. Newer diagnostic techniques under investigation include polymerase chain reaction of saliva or sputum, as well as blood tests measuring levels of an S-adenosylmethionine, a metabolite used exclusively by *Pneumocystis jiroveci* and hence lowered in patients with active disease. Beta glucan, a component of the cyst wall of PCP, is also frequently elevated in patients with PCP, although the sensitivity and specificity of this test in various

Figure 128-4 Bilateral interstitial pulmonary infiltrates in a 38-year-old woman (CD4+ cell count 60/mm^3) with *Pneumocystis jiroveci*. This was the initial AIDS-defining illness.

at-risk populations has not yet been defined. Chest imaging may be normal but more typically demonstrates bilateral diffuse interstitial abnormalities (Fig. 128-4). The treatment of PCP is discussed in detail elsewhere in this volume. Patients with PCP typically worsen after 2 to 3 days of therapy. In patients without known contraindications, treatment with trimethoprim-sulfamethoxazole (TMP-SMX) is the drug of choice for both intravenous and oral therapy. Because TMP-SMX has good bioavailability, patients can be treated with oral preparation unless concomitant gastrointestinal disease or the severity of the respiratory symptoms makes administration of oral medications difficult.

Cryptococcus neoformans

Cryptococcus neoformans is an encapsulated budding yeast that is found in soil throughout the world, typically in areas in which bird feces or decaying vegetable matter are found. Symptomatic cryptococcosis is most often seen in patients with HIV infection. Although exposure typically occurs through inhalation, the most common presentation of cryptococcosis in HIV-infected persons is meningitis, not pneumonia. Cryptococcal pneumonia typically presents with subacute and nonspecific symptoms such as fever, malaise, and cough; other associated pulmonary symptoms may include dyspnea, chest pain, and hemoptysis. Extrapulmonary symptoms depend on whether dissemination has occurred, most commonly to the central nervous system, in which basilar meningitis can lead to headache, cranial neuropathies, and in more severe cases, depressed consciousness. On occasion, physical exam reveals white papular lesions on the skin mimicking molluscum contagiosum. HIV-related cryptococcosis tends to occur in patients with CD4 counts of less than 100 cells/mm^3, although periodically symptomatic disease is diagnosed at slightly higher CD4 counts. Diagnosis of invasive *Cryptococcus neoformans* infection is patients with HIV is generally by cryptococcal antigen (CRAG) test, an assay that can be done on blood, cerebrospinal fluid (CSF), and respiratory samples (BAL specimen, pleural fluid). Treatment of HIV-positive patients with cryptococcal pneumonia depends on the severity of disease and the presence or absence of CNS disease. Patients with hypoxemia or other signs of extensive pulmonary disease or those with signs of CNS involvement should received induction therapy with amphotericin B and 5-flurocytosine until clear clinical improvement (at least 2 weeks in persons with CNS disease) followed by 8 weeks of fluconazole 400 mg daily. Although fluconazole or itraconazole could in theory be used to prevent cryptococcal disease in patients with AIDS, studies of primary prophylaxis have failed to demonstrate a survival benefit. HIV-positive persons with a history of cryptococcosis should be maintained on fluconazole 200 mg daily for secondary prophylaxis until their CD4 count rises to over 200 cells/mm^3 for at least 6 months.

Endemic Fungi

Histoplasmosis, coccidioidomycosis, blastomycosis, and penicilliosis are dimorphic fungi that are endemic to distinct regions but that may reactivate years after travel or residence in the area where exposure occurred. The endemic fungi rarely causes disease in patients with HIV until the patient is significantly immunosuppressed (CD4 less than 250 cells/mm^3). The use of combination antiretroviral therapy has reduced the incidence of all of these infections. Although the extent to which they produce respiratory symptoms in persons with HIV is variable, they all enter the host through the lungs before dissemination occurs to other sites. We will limit our discussions to the four most common endemic dimorphic fungi in the United States. Infection with Paracoccidioides brasiliensis should be considered in patients who present with the typical pulmonary and systemic complaints seen with the other HIV-related opportunistic endemic fugal infections in a person from Central or South America, although it is less common outside those regions in part due to the activity of TMP-SMX against this pathogen.

Histoplasma capsulatum

In patients with HIV infection, histoplasmosis most commonly presents with disseminated disease in an individual with a CD4 cell count less than 150 cells/mm^3. Signs of disseminated histoplasmosis include with fever, weight loss, adenopathy, diarrhea, and mucosal lesions. *Histoplasma*

capsulatum occasionally occurs in person with HIV and preserved CD4 counts (greater than 350 cells/mm^3) with clinical features similar to those of normal hosts (fever, headache, non-productive cough, chills, and chest pain). Cough and dyspnea are the most common pulmonary symptoms seen in patients with histoplasmosis and HIV infection. *Histoplasma capsulatum* can produce a sepsis syndrome as well with fever, hypotension, and multiorgan system failure. Disseminated histoplasmosis in a patient with AIDS may have normal chest radiographs, especially if he or she does not have respiratory complaints. Typical radiographic findings in those with pulmonary complaints include diffuse interstitial or reticulonodular infiltrates. The presence of hilar or mediastinal adenopathy may help distinguish histoplasmosis from *Pneumocystis jiroveci*, as the clinical presentation in susceptible hosts overlap significantly, although these are uncommon findings for *Pneumocystis*. The test of choice for diagnosing histoplasmosis is detection of polysaccharide antigen in urine or blood, where urine testing has been shown to be positive in up to 95 percent of patients with disseminated disease and AIDS. This test has supplanted antibody and skin testing, which are rarely indicated. Amphotericin is currently considered the drug of choice for severe or disseminated histoplasmosis in HIV-positive patients and should be continued for 3 to 10 days until clear clinical improvement has occurred before patients are switched to itraconazole to complete a total of 3 months of therapy. Published guidelines suggest that patients with HIV infection be maintained on suppressive doses of itraconazole indefinitely. Discontinuation of secondary prophylaxis has not been studied sufficiently to comment on CD4 level at which it is safe to stop itraconazole in patients who have responded to antiretrovirals. The treatment of pulmonary histoplasmosis is persons with preserved CD4 counts (greater than 500 cell/mm^3) is controversial, as this is often a self-limited process. Antifungal therapy is not recommended for primary prophylaxis of patients with HIV infection and depressed CD4 counts, although such individuals should be advised to minimize exposure to soil.

Coccidioides immitis

Coccidioides immitis is endemic to the southwestern United States, Northern Mexico, and parts of South and Central America, where it is found in soil. Sporadic cases seen in areas outside of these regions are thought to represent reactivation of latent infection in persons who acquired *Coccidioides immitis* while traveling in endemic regions. Coccidiomycosis often presents with pulmonary complaints that may look like PCP. Symptomatic disease typically occurs in individuals with advanced immunosuppression (CD4 cell counts less than 250 cells/mm^3). Coccidiomycosis in patients with preserved CD4 counts is often confused with typical community-acquired pneumonia. As with histoplasmosis, pulmonary findings are often accompanied by clinical evidence of dissemination, including involvement of the skin, lymph nodes, bone, liver, and meninges. Radiographic abnormalities on chest radiograph are diverse, and may include reticulonodular disease, alveolar infiltrates, nodules, adenopathy, cavities, and pleural effusions. The presence of hilar adenopathy, eosinophilia, or lack of response to conventional antibiotics should prompt consideration of pulmonary coccidiomycosis in patients from endemic areas. Isolation of the organism in respiratory secretions—usually through bronchoscopy—is generally required to make the diagnosis. Culture of respiratory secretions in patients with active pulmonary disease is quite sensitive and often yields results in 3 to 5 days. A positive isolator blood culture confirms the presence of disseminated disease. Although serologic testing should be pursued, the sensitivity of these tests is probably lower in patients with HIV (about 70 percent sensitive). *Coccidioides immitis* serology has a more established role to play in monitoring response to therapy. Skin testing with coccidial antigen has no useful role diagnostically. Treatment guidelines list amphotericin B as the drug of choice for patients with isolated pulmonary disease or disseminated coccidiomycosis without meningeal involvement in patients with HIV infection. Treatment should be continued until clear clinical improvement has been demonstrated, at which time patients may be switched over to itraconazole or fluconazole. HIV-positive persons with meningeal involvement should be treated with high-dose fluconazole, which has demonstrated success rates of approximately 80 percent and, as with HIV-negative patients, therapy should be continued indefinitely. Coccidiomycosis has high rates of recurrence in patients with HIV, so suppressive therapy with either fluconazole or itraconazole should be administered. There are inadequate data to guide decisions on discontinuation of secondary prophylaxis in patients who have experienced CD4 recovery in the setting of effective antiretroviral therapy but, as noted, meningeal disease should be treated with lifelong therapy. There are no formal guidelines for primary prevention of *Coccidioides immitis* infection in patients with HIV. Preliminary studies suggest that preemptive therapy with itraconazole or fluconazole may be considered in patients with positive serology, although the potential benefits of this approach have not been established.

Blastomyces dermatitidis: Like *Histoplasma capsulatum*, *Blastomyces dermatitidis* is dimorphic fungi endemic to the Mississippi, Ohio, and St. Lawrence River valleys, although they are less common outside of the United States. Of the endemic fungi, *Blastomyces dermatitidis* is the least likely to act as an opportunistic pathogen in patients with HIV. In normal hosts, blastomycosis most commonly involves the lung and skin, although nearly every organ of the body may be involved including the CNS. HIV-associated blastomycosis tends to occur in patients with CD4 counts less than 200 cells/mm^3 and is more likely to be disseminated. Unlike some of the other endemic fungi, most HIV-positive patients with blastomycosis have pulmonary complaints, even if their infection is disseminated. A case series of blastomycosis in 15 HIV patients, 12 had evidence of pulmonary involvement and 5 also had disseminated disease at the time of diagnosis. The predominant symptoms at presentation were

fever, weight loss, and cough. Diagnosis of blastomycosis is most definitively made by fungal culture of respiratory secretions or tissue samples. A variety of serologic tests are available for *Blastomyces dermatitidis* but the utility of these assays have not been validated in HIV-positive patients. Antigen assays hold promise for diagnosing blastomycosis with reported sensitivities in normal hosts of 80 percent for disseminated disease and over 95 percent for patients with isolated pulmonary disease. Amphotericin is the drug of choice for severe or disseminated histoplasmosis, although there are no specific guidelines for the treatment of *Blastomyces dermatitidis* in HIV-positive patients. Treatment guidelines for HIV-negative patients suggest treating with amphotericin until the patient has received a total of 1.5 to 2.5 g. CNS or bone involvement may require longer courses. At the completion of this induction phase, patients should be switched over to itraconazole chronically. Discontinuation of secondary prophylaxis has not been studied and there are no data on primary prophylaxis in patients with AIDS. Importantly, such recommendations for use of prolonged courses of amphotericin and lifelong suppressive therapy precede the widespread use of azoles and the remarkable recovery of the immune system that occurs with antiretroviral therapy. As such, there are certain clinical cases where shorter courses of amphotericin and discontinuation of chronic suppressive therapy may be appropriate.

Penicillium marneffei

Penicillium marneffei is a dimorphic fungus that is endemic to Southeast Asia. It is isolated most commonly in the soil, especially in areas in which bamboo rats are found. Although direct inoculation through skin can occur, it is thought that inhalation is the main route of exposure. *Penicillium marneffei* has emerged as one of the leading opportunistic infections in persons with HIV in Southeast Asia, ranking behind only cryptococcosis and tuberculosis in some studies. *Penicillium marneffei* is generally seen in patients with advanced AIDS (CD4 less than 50 cell/mm^3), where it commonly presents with extrapulmonary symptoms (fevers, weight loss, sweats, hepatosplenomegaly, and hematologic abnormalities). It also commonly produces cutaneous findings, particularly umbilical papules that may be confused with either cryptococcosis or molluscum contagiosum. Respiratory symptoms are common though they are much more commonly associated with systemic disease, then isolated pneumonia. Chest radiographs most demonstrate interstitial changes though nodules, cavitation and pleural disease have all been reported previously. Serologic testing is of limited utility in penicilliosis and microbiologic diagnosis requires isolation of the organism from blood, skin, bone marrow, or lymph nodes. Treatment of *Penicillium marneffei* in patients with HIV infection depends on the severity of infection. In patients with disseminated infection, amphotericin B should be used to control the infection. Patients who have demonstrated clear clinical improvement can be switched to twice-daily itraconazole to complete a 3-month treatment course. Relapse is common in HIV-positive patients with *Penicillium marneffei*, so secondary prophylaxis with daily itraconazole should be maintained until patients have achieved a CD4 count of greater than 200 cells/mm^3 for at least 6 months. Fluconazole does not have activity against *Penicillium marneffei*. Primary prophylaxis with itraconazole for *Penicillium marneffei* has been shown to reduce the incidence of *Penicillium marneffei,* although it did not confer a survival advantage. HIV-positive persons traveling to endemic areas should be told to avoid concentrated exposure to dusts and soil while traveling.

Aspergillosis

Invasive pulmonary aspergillosis in patients with HIV infection occurs almost exclusively in those with advanced immunosuppression (CD4 cell count less than 50 cells/mm^3). Aspergillus species are found worldwide in soil, especially around decaying vegetable matter. Patients with AIDS who are diagnosed with invasive disease often have other risk factors for aspergillosis, such as receipt of corticosteroids or neutropenia. Although a number of species of *Aspergillus* have been reported in HIV infection, *Aspergillus fumigatus*, and to a lesser extent *Aspergillus niger* are the most common causes of invasive aspergillosis. Respiratory tract disease is the most common manifestation of aspergillosis and both tracheitis and invasive pneumonitis may develop. In the former, fever, cough, dyspnea, and wheezing are common symptoms: The diagnosis is established when endoscopic examination reveals an exudative pseudomembrane adherent to the tracheal wall. In invasive pneumonitis, fever and cough may be accompanied by pleuritic pain and hemoptysis. Radiographic abnormalities in both of these forms overlap, and can show diffuse infiltrates, cavities, and focal wedge-shaped abnormalities reflecting pulmonary infarction. Despite the predilection for the organism to invade blood vessel walls and disseminate, focal CNS disease due to aspergillus in AIDS patients appears to arise more commonly from contiguous spread from the sinuses, orbits, and ears. A definitive diagnosis of invasive aspergillosis requires identification of the fungus on a biopsy specimen in a patient with the appropriate clinical syndrome. Not uncommonly, a presumptive diagnosis of pulmonary disease is made when *Aspergillus* spp. are cultured from respiratory secretions in a patient fever, cough, infiltrates, and severe immunosuppression. The diagnosis is especially likely when concomitant risk factors (e.g., corticosteroid exposure or neutropenia) are present. It is important to note, however, that aspergillus is a common colonizer of diseased airways, so definitive diagnosis requires documentation of tissue invasion. Outside of isolated case reports, the utility of noninvasive tests such as the serum galactomannan or PCR-based techniques have not been studied in patients with HIV. Data on the management of invasive aspergillosis in HIV-positive patients are limited. Published guidelines list voriconazole as the agent of choice for invasive aspergillosis, although potential drug-drug interactions in patients receiving antiretroviral medications should be closely monitored. Amphotericin products and echinocandins remain potential

alternatives. There are no formal recommendations for length of treatment or prophylaxis (secondary or primary), although every effort should be made to provide effective antiretroviral therapy, to correct neutropenia by discontinuing offending agents or by using stimulatory cytokines, and to eliminate exogenous immunosuppression by discontinuing corticosteroids.

Viral Pneumonia

Although patients with HIV infection are at risk for viral pneumonia, the magnitude of risk is hard to estimate. As with immunocompetent patients, a definitive viral etiology for respiratory complaints is less commonly established than with other respiratory pathogens. Although many respiratory viruses produce disease in patients with HIV, only cytomegalovirus is an AIDS-defining opportunistic infection. Furthermore, not all viruses identified in respiratory secretions produce lower respiratory infections. For example, identification of herpes simplex virus from cultures of BAL fluid generally reflects disease in the upper airway or oropharynx, not the lungs. For this reason, HIV-positive patients with HIV infection and respiratory complaints may require an aggressive evaluation, including histopathology, to definitively establish a viral pathogen as the sole cause of a lower respiratory tract infection.

Cytomegalovirus

Cytomegalovirus (CMV) is a complex DNA virus belonging to the β-group of the family Herpesviridae. Like other herpes virus infections, CMV establishes latency in a variety of cell types, including polymorphonuclear cells, T lymphocytes, and salivary gland cells. Serologic evidence of CMV infection is common in patients with HIV infection, with rates of seropositivity over 95 percent reported in HIV-positive men who have sex with men. Asymptomatic persons with CMV infection excrete the virus in saliva, respiratory secretions, urine, and semen. Clinically significant HIV-related CMV infection is associated with severe immunosuppression (CD4 less than 50 cells/mm^3). CMV-associated syndromes most commonly seen in patients with AIDS are retinitis and enteritis (colitis or esophagitis). A variety of CMV-related neurologic complications have been described, including polyradiculitis, ventriculitis, and mononeuritis multiplex. As noted, the exact frequency of lower respiratory tract infection with CMV is difficult to establish. As is the case with herpes simplex virus, isolation of CMV from BAL specimens is relatively common. In most studies, patients with positive BAL cultures for CMV have evidence of a more likely alternative diagnosis (especially PCP or bacterial pneumonia), and may improve without specific therapy directed at CMV. Nonetheless, in a patient with advanced HIV disease (CD4 cell count less than 50 cells/mm^3), interstitial infiltrates on chest radiograph, and no alternative organism isolated, CMV pneumonitis may be the sole responsible pathogen. Because symptomatic reactivation of CMV in advanced AIDS often occurs in more than one location, patients being considered for treatment for CMV pneumonitis should be screened for GI symptoms and undergo a dilated retinal exam to rule out co-incident retinitis. When disease is limited to the chest, definitive diagnosis requires demonstration of cytopathic change on histopathology (usually obtained via transbronchial biopsy or VATS). In such cases, cultures are confirmatory rather than diagnostic. In the rare case of primary CMV infection, detection IgM antibody may be helpful, especially when IgG antibodies are negative. Unfortunately, CMV antigenemia assays or amplification-based techniques are neither specific nor sensitive enough to diagnose or exclude end-organ disease due to CMV, as viral replication occurs in asymptomatic persons as well. The agents of choice for the treatment of established CMV pneumonitis is oral valganciclovir, with the IV formulation a suitable alternative in those who cannot take oral therapy. For refractory disease, foscarnet would be an appropriate alternative, although its use is associated with high rates of renal dysfunction and other metabolic abnormalities. The duration of therapy for CMV pneumonitis is unknown, but is typically 2 to 3 weeks. For those who have started with intravenous therapy and improve, patients can be switched to oral valganciclovir. Unlike CMV retinitis, there is no standard secondary prophylaxis for CMV pneumonitis. However, as with other opportunistic infections, the antiretroviral therapy with restoration of the CD4 cell count plays a critical role in preventing recurrences. A study evaluating a strategy of preemptive valganciclovir in patient with AIDS and asymptomatic evidence of reactivation of CMV by PCR assay did not find benefit to this approach. Patients with HIV infection who are CMV IgG negative and require blood product support should followed standard guidelines for minimizing the risk of transfusion-related CMV infection.

Other Respiratory Viruses

Available data on the frequency and natural history of other respiratory viral infections are limited. Because of the availability of both rapid and reliable diagnostic techniques and antiviral agents with documented efficacy, influenza is the most important viral pathogen to consider when evaluating an HIV-positive patient with respiratory track symptoms. During influenza season, HIV-infected patients who present with a compatible clinic picture (an acute febrile illness associated with cough, myalgias, sore throat, and rigors), should be tested for influenza via either antigen or PCR-based techniques. Although data are limited, it appears that patients with HIV are at no greater risk for severe infection or secondary complications than HIV-negative controls. Chest radiographs are typically unrevealing, suggesting that, as with HIV-negative patients, primary influenza pneumonia is unusual. Data on the potential benefits of neuraminidase inhibitors in patients with HIV are limited, although it is reasonable to consider administering either oseltamivir or zanamivir to patients with documented influenza, especially when the onset of the symptoms are acute, immunosuppression is severe, or presentation is severe. Influenza is a preventable infection and all patients with HIV infection should be encouraged

to get annual vaccination. Although declines in CD4 count and rises in HIV viral load may be seen after influenza vaccination, these adverse laboratory events are generally transient and have not been shown to be associated with adverse clinical events. HIV-positive patients with significant exposure to persons with HIV may benefit from prophylaxis as well.

As with other immunosuppressed populations, pneumonitis in HIV patients has been reported due to herpes simplex virus, as well as adenovirus, respiratory syncytial virus, and parainfluenza virus type 3. These are rare causes of pneumonia in HIV-infected patients, but should be considered when clinicians cannot identify an alternative diagnosis. As discussed, identification of herpes simplex virus in respiratory secretions usually indicates evidence of reactivation in the aerodigestive tract rather than primary pneumonitis, although pulmonary or tracheal infection may rarely occur, especially in the context of endotracheal or nasogastric intubation.

Parasitic Pneumonia

Parasitic diseases do not commonly cause of respiratory tract symptoms in patients with HIV. Of the parasitic diseases seen with increased frequency in patient with HIV infection, *Toxoplasma gondii*, *Strongyloides stercoralis*, cryptosporidium, and microsporidia, all may produce pulmonary symptoms. Although parasitic diseases typically produce more prominent extrapulmonary symptoms, each of these pathogens may produce respiratory complaints, sometimes even overshadowing symptoms associated with the primary target of the infection. Of the parasitic disease that can produce respiratory complaints, *Toxoplasma gondii* is probably the most common pathogen to do so. Pulmonary toxoplasmosis is a cause of pneumonia in patients with HIV, and is most commonly seen in patients with markedly depressed immune function (CD4 less than 50 cells/mm^3). The clinical presentation of pulmonary toxoplasmosis is similar to that of PCP, but unlike PCP it may be accompanied by a sepsis-like syndrome with hypotension. Radiographic abnormalities are diverse, consisting most commonly of interstitial infiltrates, but also potentially nodules, effusions, or mass lesions. As with PCP, an elevated LDH is a commonly reported laboratory finding. Diagnosis may be established by identification of toxoplasma tachyzoites on Giemsa stain of BAL fluid or tissue obtained on biopsy. Treatment of pulmonary toxoplasmosis in patients with HIV infection is similar to that recommended for patients with CNS disease. Pyrimethamine plus sulfadiazine is the first-line treatment, although clindamycin may be substituted if the patient cannot tolerate sulfadiazine. The course of therapy is generally 6 weeks, and patients should receive secondary prophylaxis until their CD4 count is greater than 200 cell/mm^3 for over 6 months. Prophylaxis with double strength TMP/SMX once daily in HIV-positive patients with CD4 counts less than 100 cell/mm^3 has been shown to reduce the risk of CNS toxoplasmosis, and likely also prevents pulmonary disease. Patients who are IgG negative for *Toxoplasma gondii* should be counseled to avoid undercooked meat (in particular lamb, pork, and beef), and wash hands thoroughly after contact with cat litter. Despite its association with defects in cell-mediated immunity, disseminated infection to the lung of *Strongyloides stercoralis* is surprisingly rare in HIV-infected individuals, even in areas highly endemic for both HIV and strongyloides. Indeed, many patients with HIV who experience strongyloides superinfection syndrome have other classic risk factors, including receipt of corticosteroids, severe wasting, or HTLV-I co-infection. Despite its rarity, clinicians should consider the diagnosis of strongyloidiasis in an HIV-infected patient who presents with pneumonitis, or gram-negative sepsis with associated meningitis. Identification of strongyloides larvae on a centrifuged BAL specimen is diagnostic; eosinophilia is variably present, and its absence does not exclude the diagnosis. When strongyloides is identified in the lung, disseminated disease has occurred by definition; treatment should be with extended courses of ivermectin plus albendazole. Although predominantly involving the gastrointestinal tract, both cryptosporidiosis and microsporidiosis can rarely be found in the lung and lead to pulmonary disease. Diagnosis is through direct visualization of the organism on respiratory secretions or histopathology, using appropriate stains—modified acid-fast for cryptosporidiosis—and the modified trichrome stain for microsporidiosis. As antimicrobial treatment for these conditions is suboptimal, improving immune function with antiretroviral therapy is the preferred strategy.

Noninfectious Pulmonary Complications of HIV

Although opportunistic infections must be excluded when a patient with HIV infection presents with respiratory complaints, the differential diagnosis includes a number of noninfectious pulmonary complications as well. HIV-related malignancies such as Kaposi's sarcoma (KS) and non-Hodgkin's lymphoma (NHL) may involve the lung, and patients with HIV appear to have both increased rates of lung cancer and more aggressive disease compared with uninfected controls. In addition to these malignancies, HIV infection is associated with increased risk of pulmonary hypertension. Although interstitial lung disease is most often due to opportunistic infection, lymphocytic interstitial pneumonitis (LIP) may cause these findings, especially in children. Pulmonary diseases such as chronic obstructive pulmonary disease (COPD) and thromboembolic disease are reported with increased frequency in HIV-positive persons as well.

Kaposi's Sarcoma

Like PCP, KS was one of initial complications noted in the first descriptions of HIV infection. KS is associated with human herpes virus type 8 (HHV8) infection. Endothelial cells latently infected with HHV8 are activated by HIV, which in turn drive the angiogenesis characteristic of this vascular malignancy. KS may develop in patients with preserved CD4 counts, although the pulmonary involvement is most commonly seen in advanced disease (CD4 less than

100 cells/mm^3). In the United States, KS is most commonly seen in men who have sex with men. Rates are also high in some areas of sub-Saharan Africa, where HHV8 is endemic. The prevalence of KS has dropped dramatically since the introduction of combination antiretroviral therapy. Patients with pulmonary KS usually have evidence of cutaneous and/or mucosal disease. In one series, only 16 percent had disease limited to the lungs. Pulmonary KS may be asymptomatic even in patients with extensive abnormalities on chest radiograph. Radiographic finding of pulmonary KS are variable and can include nodular infiltrates with or without pulmonary effusions. Lesions tend to show peribronchovascular distribution. Diagnosis is generally made through direct visualization of characteristic purplish plaques on bronchoscopy. As these lesions are highly vascular and quite typical, biopsy is often deferred to avoid the risk of hemorrhage. Chemotherapy is indicated for symptomatic pulmonary disease. However, as with cutaneous KS, potent antiretroviral therapy can induce significant improvement in pulmonary KS, as well as sustained remissions. In some cases, antiretroviral therapy can even obviate the need for chemotherapy. As discussed in the following, antiretroviral therapy also has been rarely associated with inflammatory worsening of KS as a form of the immune reconstitution syndrome.

Non-Hodgkin's Lymphoma

The risk of developing non-Hodgkin's lymphoma (NHL) is 200 to 600 times greater in persons with HIV compared with those who are uninfected. Non-Hodgkin's lymphoma tends to be more aggressive in patients with HIV, and such patients tend to present more commonly with stage IV and extranodal disease. HIV-associated NHL can occur at any stage of the infection, but rates rise dramatically when the CD4 count falls below 100 cells/mm^3. The prevalence of NHL in HIV-infected persons has dropped significantly since the introduction of combination antiretroviral therapy. Most HIV-related NHL demonstrates high-grade histologic features (diffuse large cell or Burkitt-like) and many of these are Epstein Barr virus (EBV)–related. Primary effusion lymphoma (also called body cavity lymphoma) is a distinct type of HIV-associated NHL that presents with unexplained effusions of the pleura, pericardium, or peritoneum without associated mass lesion. Although evidence of EBV infection is often found in such lymphomas, HHV-8 infection appears to be the most important cofactor in the pathogenesis of HIV-associated NHL. The chest-specific radiographic findings of HIV-associated are diverse, and may consist of nodules, masses, and pleural effusions. Non-specific findings that suggest lymphoma are elevations in LDH and a positive gallium scan corresponding to the area of abnormality on chest imaging. Although the diagnosis can sometimes be established through BAL with cytology, transbronchial biopsy, or thoracentesis, these procedures have a low yield and VATS is often required. Management of HIV-related NHL depends on the specific histological features and organ involvement. In the era before combination antiretroviral therapy, prognosis for patients with HIV and NHL was generally poor, especially with low baseline CD4 cell counts. More recent data suggest that restoration of immune function with antiretroviral therapy along with chemotherapy improves survival.

Lung Cancer

Although the role of HIV infection in the pathogenesis of other malignancies is unproved, evidence is accumulating that HIV-positive patients are at increased risk of developing lung cancer. Furthermore, although rates of KS and NHL have declined, rates of lung cancer in HIV-positive persons are rising. Lung cancer is the most frequently diagnosed non-AIDS–related malignancy, with reported rates of three- to eightfold higher than those without identified infection. HIV-associated lung cancers appear to be more common in blacks than whites. Although the proportion of small cell and non–small cell lung cancers appear to be comparable with that seen in the general population in some studies, others report increased rates of adenocarcinomas in patients with HIV. The prognosis for persons with HIV-related lung cancer is worse, as these malignancies tend to present at a younger age and with more advanced disease. HIV-related immunologic decline does not appear to be a major factor in the higher death rate from lung cancer seen in patients with HIV. While CD4 count at the time of diagnosis of lung cancer may be depressed, it is more commonly preserved. Data from ALIVE cohort at Johns Hopkins demonstrated increased lung cancer death rates in HIV-positive injection drug users (IDVs) compared to HIV negative IDUs. The diagnostic approach to patients with suspected lung cancer is the same regardless of HIV status. In a subset of the John Hopkins cohort who received their HIV care in the system prior to diagnosis of lung cancer, 60 percent had had a chest radiograph in the year preceding diagnosis and several of these had either normal or non-specific findings that were attributed to an undiagnosed infectious complication. Whether more aggressive screening for lung cancer will prove effective in improving outcomes is yet to be determined, but it is important to maintain a high index of suspicion for lung cancer when evaluating HIV-positive patients with preserved CD4 counts and unexplained respiratory symptoms or radiographic abnormalities.

Pulmonary Hypertension

HIV infection is a risk factor for the development of pulmonary hypertension. Attempts to identify HIV in endothelium from the pulmonary vasculature have been unsuccessful. The most common hypothesis for the association of HIV and pulmonary HTN is an alteration in pulmonary cytokine profile that increases expression of vasoactive substances such as endothelin-1. HIV-related pulmonary hypertension (HRPH) is a diagnosis of exclusion and can only be made after other secondary causes of pulmonary hypertension have been excluded. HRPH can occur at all stages of HIV disease, with variable CD4 cell counts and HIV RNA levels at the time of presentation. In some series, women represent a disproportionate number of the cases. Like all patients with pulmonary

hypertension, the most common symptom of HRPH is exertional dyspnea, although cough, fatigue, and chest pain may also be present. The key to the diagnosis is recognizing that the symptoms are not related to a primary pulmonary infectious process. Physical exam signs consistent with right ventricular hypertrophy or failure are helpful, but often not present initially. An echocardiogram will show evidence of right atrial hypertrophy and elevated pulmonary pressures; this is then confirmed with right heart catheterization. Management of pulmonary hypertension is as for HIV-negative hosts, with prostaglandin agonists (epoprostenol), diuretics, and anticoagulation. Sildenafil may also have a role, but it is associated with potential drug-drug interactions in patients receiving with protease inhibitors. Unfortunately, reports have not shown a consistent beneficial response of this condition to antiretroviral therapy.

Lymphocytic Interstitial Pneumonitis

Although lymphocytic interstitial pneumonitis (LIP) is seen more commonly in HIV-infected children, adults may rarely develop this complication as well. LIP is characterized by polyclonal inflammatory lymphoid proliferation of bronchus-associated lymphoid tissue (BALT). In children, LIP has been associated with EBV infection and some experts suggest that LIP in adults is a lung-specific immune response to HIV itself. HIV-positive patients with LIP tend to present with gradual onset of cough, shortness of breath, and constitutional symptoms. Diffuse reticulonodular or interstitial infiltrates are seen on chest imaging, making differentiation from PCP difficult (Fig. 128-5). LIP in patients with can be confused with other HIV non-infectious causes of interstitial lung disease. Diffuse infiltrative lymphocytosis syndrome (DILS) is a multisystem disorder characterized by oligoclonal expansion of CD8+ T lymphocytes that can produce interstitial infiltrates similar to that seen in LIP. In addition to the pulmonary symptoms, DILS can involve produce parotitis, hepatitis, neuropathies, and myositis. However, compared with patients who develop HIV-related opportunistic infections, those with LIP usually have a relatively preserved or even normal CD4 cell count. Whereas the diagnosis of LIP in children may be made on clinical grounds after extensive evaluation for infectious complications of HIV, diagnosis of LIP in adults almost always requires transbronchial or video-assisted thorascopic biopsy to definitively establish the diagnosis. Several case reports have demonstrated that antiretroviral therapy may lead to substantial improvement in LIP. For unresponsive cases, corticosteroids may be effective.

Chronic Obstructive Pulmonary Disease

There is evidence that patients with HIV are at greater risk for the development of emphysema than HIV-negative subjects. Investigators have postulated that the higher proportion of CD8+ T lymphocytes seen in BAL fluid from patients with HIV compared with uninfected controls may help explain this difference. It is unknown whether effective antiretroviral therapy offsets the increased susceptibility to this condition. As cigarette smoking is highly prevalent in many clinical centers among HIV patients, this is an area of prevention often overlooked among providers.

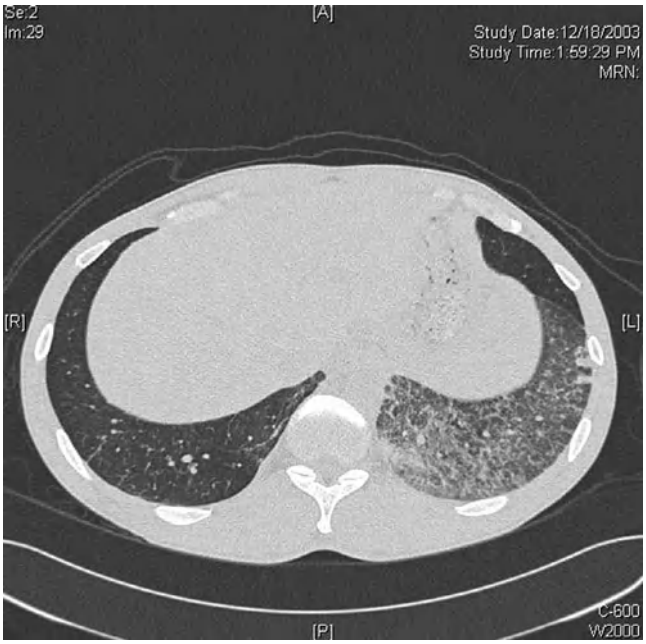

Figure 128-5 A 39-year-old man with HIV infection, CD4+ cell count 260/mm^3, presented with fever and cough. Ground-glass opacities were identified in the left lower lobe. Bronchoalveolar lavage was negative for all pathogens, but transbronchial biopsy demonstrated findings consistent with lymphocytic interstitial pneumonia. Antiretroviral therapy produced significant clinical improvement.

Thromboembolic Disease

Patients with HIV infection are at two- to tenfold increased risk of thromboembolic disease compared with healthy controls. The increased risk attributable to HIV (vs. the complications with which HIV is associated) is uncertain, although alterations in cytokine profiles in patients with untreated HIV infection have been proposed as a mechanism to explain such increased risk. Until large, well-controlled studies establishing the relative risk for thromboembolic complications have been completed, recommendations on the prevention and treatment of DVT and PE must follow those for patients who HIV status is unknown.

Special Considerations

Practitioners should be aware of several important clinical scenarios that require special consideration when managing HIV-positive patients with respiratory complaints. Despite the unquestionable benefits of antiretroviral therapy, combination antiretroviral therapy may rarely be associated with significant and even life-threatening toxicities. The nucleoside reverse transcriptase inhibitor (NRTI) abacavir may produce systemic reaction that can be fatal if not promptly recognized. In addition to toxicity produced by the medications directly, antiretroviral agents have may alter the pharmacokinetics of compounds with which they are co-administered.

Successful control of HIV replication (as evidenced by complete suppression of HIV in peripheral blood and rise in CD4 count) is not without the potential for respiratory complications, as restoration of immune function may itself produce a paradoxical worsening of symptoms, a syndrome called immune reconstitution inflammatory syndrome (IRIS). Finally, all practitioners should be aware of CDC guidelines for the management of occupational exposure to HIV infection to minimize nosocomial spread of this uncurable infection.

Abacavir-Hypersensitivity Syndrome

Abacavir is a nucleoside reverse transcriptase inhibitor that causes a systemic hypersensitivity reaction (HSR) in approximately 5 percent of individuals receiving the drug. Abacavir HSR is more common in whites, and is most strongly associated with HLA-B*5701 haplotype. Symptoms of the abacavir HSR usually appear in the first 6 weeks of treatment and include fever, rash, malaise, GI upset, myalgia, and arthralgias. Cough and dyspnea also may occur and may mimic bronchitis or pneumonia. It is critical that clinicians evaluating patients who have recently been started on abacavir who present with fever and respiratory symptoms consider abacavir hypersensitivity in the differential diagnosis, as continued abacavir treatment in the face of this reaction can be fatal. Symptoms generally resolve slowly after cessation of the drug. Abacavir should never be resumed in such circumstances, as re-challenge can lead to an immediate and life-threatening recurrence of the hypersensitivity reaction. As abacavir hypersensitivity can mimic other processes, in particular influenza, helpful clinical clues that make hypersensitivity more likely are worsening of symptoms after each dose, the presence of GI symptoms, and rash. Management of abacavir HSR requires prompt discontinuation of the drug and supportive care. Screening for the HLA-B*5701 haplotype has been introduced in some clinical centers, and markedly reduces the risk of this complication.

HIV Pharmacology

Protease inhibitors and non-nucleoside reverse transcriptase inhibitors are both substrates for and interact with the cytochrome P450 enzymes. In general, the protease inhibitors are potent inhibitors of CYP3A4, whereas the NNRTIs efavirenz and nevirapine are inducers. The inhibitory property of the PIs is used therapeutically when the ritonavir is administered at low doses to boost the levels of other agents. A detailed review of potential drug-drug interactions is beyond the scope of this chapter, but it is critical that physicians recognize the potential for drug-drug interactions when prescribing new agents to patients receiving combination antiretroviral therapy.

Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (IRIS) arises when patients develop paradoxical worsening after initiating combination antiretroviral therapy due to the development of an inflammatory response to a pathogen that may or may not have been evident before treatment for HIV infection was initiated. Patients with IRIS generally have initiated antiretroviral therapy when severely immunosuppressed (CD4 count typically less than 50 cell/mm^3), and demonstrate a particularly robust CD4 cell count recovery compared with those who do not develop IRIS. However, cases may occur even with relatively high baseline CD4 cell counts or, similarly before a substantial increase in the absolute CD4 cell count occurs. IRIS typically develops in the first several months after starting antiretroviral therapy, although it occasionally develops later than this. Symptoms of IRIS depend on the organ system involved. The most commonly described form involves inflammatory lymphadenitis, occurring in any of the visceral, thoracic, or peripheral lymphatic chains. IRIS was first described in response to unrecognized *Mycobacterium avium* infection, although the list of potential pulmonary pathogens that have produced IRIS includes tuberculosis, cryptococcus, PCP, histoplasmosis, aspergillus, CMV, Kaposi's sarcoma, and strongyloides. IRIS is a diagnosis of exclusion and coincident opportunistic infections, malignancies, and drug toxicities must all be ruled out. Management of IRIS should include anti-infective or anti-neoplastic therapy directed at the primary etiology; given the advanced state of immunosuppression typically encountered in patients with IRIS, every effort should be made to continue the antiretroviral therapy. Palliation of severe inflammatory symptoms (such as high fevers or expanding mass lesions) often can be achieved with corticosteroids. The dose and duration of such therapy are not well established, but may involve pharmacologic doses of prednisone for weeks or even months.

Occupational Exposure to HIV

It is estimated to approximately 400,000 occupational exposures to the HIV virus occur every year in the United States. Risk of transmission depends on the route of exposure and inoculum (HIV viral load). Risk of transmission from percutaneous exposure is estimated at 0.3 percent and that via mucous membrane exposure of 0.006 percent. After thoroughly rinsing the exposure area(s), health care workers with potential exposure to HIV should report immediately to their employee health department or the site designated by their facility for a formal evaluation. Animal studies of postexposure prophylaxis (PEP) have demonstrated efficacy of postexposure prophylaxis if administered within 24 hours of exposure and continued for 28 days. Retrospective analysis suggests that HIV PEP may reduce the risk of acquiring HIV by 79 percent. Decisions about the specific antiretroviral regimen that should be offered to health care workers depend on what is known of the exposure, likelihood of HIV infection in the source patient, and medical co-morbidities of the exposed health care worker. Whenever possible, the source patient should undergo rapid testing for HIV and other blood-borne infections to help guide PEP decisions. In addition to providing PEP for potential HIV exposure, exposed health care workers should be considered for post-exposure prophylaxis

against hepatitis B (if not immune) and should be educated about the signs and symptoms of acute hepatitis C so that this infection may be rapidly treated if they did develop.

EMPIRIC THERAPY AND THE HIV-POSITIVE PATIENT WITH PULMONARY COMPLAINTS

HIV-positive patients who present with respiratory complaints often require empiric therapy pending definitive diagnosis. We have outlined an approach to such decisions in Figs. 128-6 and 128-7. Patients presenting acutely with fever, productive cough, and focal infiltrates should be treated presumptively for community acquired bacterial pathogens pending further testing. Those presenting with subacute complaints and focal infiltrates should be placed in negative pressure isolation while being evaluated for TB, fungal pneumonia, and non-infectious causes. HIV-positive persons with a CD4 count of less than or equal to 200 cells/mm^3 who present with fever, progressive dyspnea, and diffuse interstitial infiltrates on CXR are likely suffering from PCP. When such individuals are at low risk for TB, have not been taking PCP prophylaxis, and are not suffering from severe impairment of gas exchange, it is reasonable to begin treatment for PCP while waiting for the results of induced sputum testing. Because of the high pre-test probability of PCP, HIV-infected persons with a depressed CD4 count and normal CXR should be treated empirically if they demonstrate impaired gas exchange. In patients at lower risk for PCP (CD4 count greater than 200 cells/mm, undetectable HIV viral load, or adherence to PCP prophylaxis) or those with more severe illness, empiric therapy for PCP may also be considered, but further testing should be aggressively pursued so that alternative etiologies for a patient's respiratory complaints can be evaluated. The extent of additional evaluation depends on the patient's degree of immunosuppression and the tempo of their illness. Patients with a CD4 count of less than or equal to 50 cells/mm^3 who present with progressive hypoxemia despite appropriate empiric treatment for PCP would likely benefit from early bronchoscopy with bronchoalveolar lavage. By contrast, individuals with preserved CD4 counts and chronic respiratory complaints may benefit first from pulmonary function testing or echocardiography to evaluate non-infectious causes of respiratory difficulties. In patients who remain undiagnosed, bronchoscopy with transbronchial biopsy, video-assisted thoracoscopic surgery (VATS), and/or open lung biopsy are often needed to make a definitive diagnosis.

129
CHAPTER

Pneumonia Caused by Gram-Positive Bacteria

Th omas A. Cumbo • Timothy F. Murphy

STREPTOCOCCUS PNEUMONIAE

Microbiology

Streptococcus pneumoniae is a gram-positive, catalase- and cytochrome-negative, facultative anaerobic organism that measures 0.5 to 1.25 μm in diameter. Alpha-hemolytic circular colonies are observed when the organism is incubated aerobically on blood agar. Both unencapsulated and encapsulated strains exist in vivo; virulent strains are usually encapsulated. Ninety serotypes of encapsulated strains have been identified to date. In adults, approximately 90 percent of bacteremic infections are caused by 23 of the capsular serotypes.

Pathogenesis

The organism periodically colonizes the human nasopharynx in most persons. Disruption of normal respiratory tract epithelial cells such as by antecedent viral infection predisposes to infection. In pneumococcal pneumonia, bacteria gain access to the lower respiratory tract by microaspiration. The organism is usually cleared from the

healthy respiratory tract by a combination of mechanical means and phagocytosis. In the early stages of infection phagocytosis is dependent on complement to stimulate cytokines and attract polymorphonuclear leukocytes. Capsule, however, inhibits opsonin-mediated phagocytosis by polymorphonuclear leukocytes. Without anticapsular antibodies, phagocytic cells have a limited ability to ingest and kill the organism. In addition, glycopeptide components of the pneumococcal cell wall provoke an intense inflammatory reaction. Damaged and congested alveoli provide a serous fluid-filled environment suitable for bacterial proliferation. Once the infection is established, alveoli become congested with white cells, erythrocytes, and debris but remain intact in this typically non-necrotizing infection. If host defense mechanisms cannot contain the infection, the organism may migrate through the lymphatic channels to the systemic circulation. Infection may occur in the pleural or pericardial space by direct extension. Metastatic infection can occur in the joints, bones, peritoneum, heart valves, and meninges through hematogenous dissemination.

Recovery from established infection is dependent on type-specific capsular antibodies that normally appear after 5 to 10 days of infection. Subsequent infection with the same serotype is rare in the absence of immunoglobulin dysfunction.

Epidemiology

Streptococcus pneumoniae is an obligate parasite of humans. The pneumococcus may cause up to one-half of all cases of community-acquired pneumonia in western countries. Pneumococcal pneumonia is not a reportable disease in the United States, so exact precise data concerning frequency are unavailable. However, data from the Active Bacterial Core Surveillance program estimate an overall incidence of pneumococcal bacteremia of 14 cases per 100,000 and an incidence of 42 per 100,000 population over age 65 (http://www.cdc.goc/ncidod/dbmd/abcs/survreports/ spneu03.pdf). Because bacteremia occurs in considerably less than one-half of the patients with pneumococcal pneumonia, these numbers represent an underestimate of the true incidence of pneumococcal pneumonia in the United States.

Certain ethic groups and co-morbid conditions are associated with higher rates of infection. For example, for unknown reasons, native Americans, native Alaskans, and African Americans are more susceptible to infection than is the white population. Although the following is not exhaustive, other risk factors include diseases associated with altered immunity (agammaglobulinemia, dysgammaglobulinemia, common variable immunodeficiency, complement deficiencies, acquired or anatomic asplenia, HIV/AIDS, glucocorticoid use, renal insufficiency, cirrhosis, diabetes mellitus, chronic lymphocytic leukemia), decrease in mechanical defense mechanisms (as caused by cigarette smoking, viral upper respiratory tract infection including influenza, chronic obstructive pulmonary disease, congestive heart failure with pulmonary edema), close interpersonal contact (prisons, day care, military, homeless shelters, refugee camps), generalized deconditioning, and others. The incidence of pneumococcal pneumonia in patients co-infected with HIV is higher than in healthy control subjects.

The incidence of invasive pneumococcal disease has decreased since the introduction of the heptavalent pneumococcal conjugate vaccine. Widespread use of the vaccine in children has been associated with a decrease in invasive disease in the elderly, perhaps by reducing the circulating pool of selected pneumococcal serotypes in the general population.

Clinical Manifestations

Pneumococcal pneumonia is often preceded by a viral respiratory tract infection manifested by coryza, nonproductive cough, and low-grade fever. Classically, bacterial infection is heralded by sudden onset with shaking chills, fever, cough productive of rusty sputum, and pleuritic chest pain. Nausea, vomiting, and diarrhea may be present and the patient often appears to be anxious. Herpes labialis may be present. Consolidation occurs during the next 24 to 48 hours and is suggested by increased vocal fremitus and tubular breath sounds over the affected area. Inspiratory crackles may be heard if the patient is able to move sufficient air through the affected airways. In untreated disease, fever typically lasts for 5 to 10 days. This period is then followed by a "crisis" marked by defervescence and the formation of anticapsule antibodies. However, elderly individuals may present with a more insidious course associated with confusion, low-grade fever, fatigue, and/or hypoxemia. Elderly, asplenic, and otherwise immunocompromised individuals may progress rapidly to septic shock without classic antecedent signs and symptoms. In the majority of patients, institution of appropriate antimicrobial therapy in a timely manner results in measurable clinical improvement and defervescence over several days.

Involvement of the pleural space may follow pulmonary infection. Empyema is suggested by splinting of the affected side, dullness to percussion at the lung base, absent vocal fremitus, and persistent fever despite appropriate antimicrobial therapy. Obtundation or neck stiffness suggests meningitis.

While *S. pneumoniae* is the most common bacterial cause of community-acquired pneumonia, the differential diagnosis of this infection is broad and includes both infectious and noninfectious etiologies. Infectious causes include "atypical" pneumonias caused by *Legionella pneumophila, Mycoplasma pneumoniae*, and*Chlamydia pneumoniae* as well as other bacteria including, *Haemophilus influenzae, Moraxella catarrhalis,* and *Staphylococcus aureus.* Anaerobic bacterial infection is associated with aspiration and poor dental hygiene. Viral and fungal etiologies of pneumonia may be suspected when there is an appropriate geographic and exposure history along with characteristic clinical manifestations. Mycobacterial infections that can present with consolidation and a similar clinical course include *Mycobacterium tuberculosis* and *Mycobacterium kansasii.* Noninfectious causes of

disease that can occasionally mimic pneumococcal pneumonia include lung cancer, foreign body aspiration or granuloma formation, pulmonary infarction, vasculitis, graft-vs-host disease, atelectasis, and congestive heart failure.

Diagnosis

Blood cultures are positive in approximately one-fourth of patients with pneumococcal pneumonia. A positive blood culture for *S. pneumoniae* in a patient with clinical and radiological evidence of pneumonia establishes the etiology. In most patients, etiological diagnosis of bacterial pneumonia is dependent on culture and gram stain of sputum. The positive predictive value of a sputum gram stain demonstrating a preponderance of polymorphonuclear cells, a paucity of squamous epithelial cells, and numerous gram-positive diplococci is quite good for the diagnosis of *S. pneumoniae* pneumonia (Fig. 129-1). For maximum yield, sputum culture must be obtained prior to antibiotic therapy and must be plated promptly after collection. Fewer organisms are recovered after a delay of only hours when compared to immediate plating of sputum at the bedside. Centralization of microbiology facilities as a cost-containment strategy requires transport and delay of clinical specimens and may affect recovery rates of fastidious bacteria. When incubated aerobically on blood agar, *S. pneumoniae* appears as alpha-hemolytic colonies. A zone of inhibition around an ethylhydrocupreine hydrochloride (Optochin) disk differentiates approximately 98 percent of *S. pneumoniae* from other viridans streptococci (Fig. 129-1). Identification of bacteria in sputum by molecular methods, such as PCR, is under investigation.

The pneumococcal urinary antigen test is useful in supplementing blood culture and gram stain and culture of sputum in adults. The assay is an immunochromatographic membrane test that detects pneumococcal cell wall polysaccharide which is common to all serotypes. Nasopharyngeal colonization in children gives a false-positive result so that the assay is more useful in adults, with a sensitivity of approximately 50 to 70 percent and a specificity of approximately 90 percent in comparison to standard methods. Advantages of the assay are the rapid results, use of a readily obtainable sample (urine), and its relatively high specificity in adults.

Antibiotic Resistance

A major consideration in the treatment of pneumococcal pneumonia is the increasing worldwide incidence of resistance to antibiotics. *S. pneumoniae* remained sensitive to penicillin for decades after the introduction of the drug, but resistance was detected in the late 1960s. β-lactam resistance is caused by altered penicillin binding proteins that possess lower affinity for β-lactam antibiotics. Genes that encode these altered proteins are often mosaics of native pneumococcal DNA and DNA acquired from viridans streptococci. Approximately 15 percent of strains in the United States are intermediately resistant to penicillin (minimum inhibitory concentration 0.1 to 1.0 μg/ml) while an additional 18 percent are fully resistant (minimum inhibitory concentration greater than 2.0 μg/ml). These concentration limits may not reflect accurate breakpoints for amoxicillin in pulmonary tissue (where much higher levels can be achieved), but instead

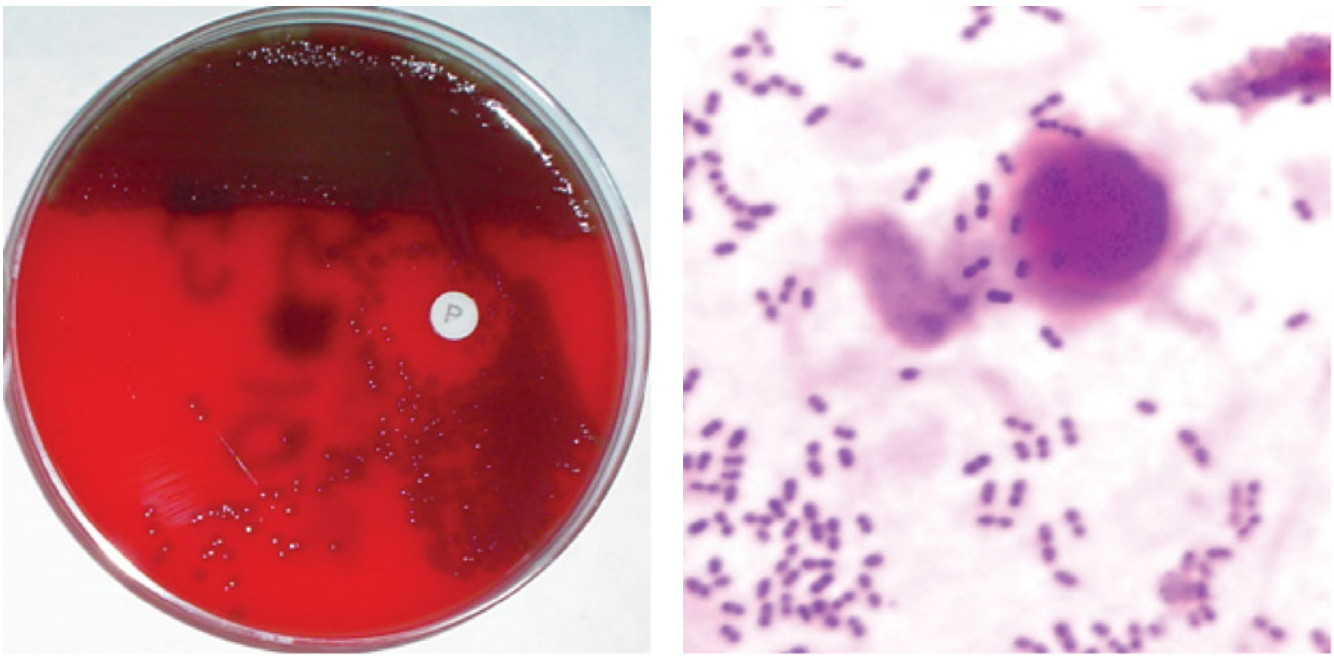

Figure 129-1 *Left*. Sputum cultured on blood agar and incubated overnight (5 percent CO_2, 37°C). *Streptococcus pneumoniae* growth is inhibited by Optochin (white disc). Therefore, its presence can be distinguished from the other Optochin-resistant alpha-hemolytic colonies also present in this sample. *Right*. Gram stain of the sputum sample demonstrating numerous gram-positive diplococci.

indicate appropriate cutoff levels for blood and meningeal infection. Approximately one-fourth of strains in the United States are resistant to the macrolide antibiotics including erythromycin, azithromycin, and clarithromycin. The majority of resistant strains seen in the United States possess macrolide efflux capacities encoded by the *mef*A gene. In Europe and South Africa, resistance is more often due to altered ribosomal targets encoded in the *erm*B gene. Strains that possess the latter mechanism usually possess high level resistance and often lack sensitivity to the lincosamides (clindamycin) and streptogramin (quinupristin). A disconcerting epidemiologic study of more than 31,000 strains of *S. pneumoniae* revealed an increasing number of organisms that possess both *mef* and*erm* encoded resistance mechanisms. Resistance to tetracycline and sulfa drugs occurs in approximately 16 and 32 percent of strains, respectively.

The organism is more predictably sensitive to other classes of antimicrobials. In most areas, resistance to the respiratory fluoroquinolones (e.g., levofloxacin, moxifloxacin, gatifloxacin) is low. However, higher rates of resistance occur in regions where usage is heavy. Vancomycin, linezolid, and telithromycin offer reliable activity. Rare tolerance to vancomycin has been reported. The glycyclines (tigecycline), a new class of antimicrobials related to minocycline, appear to be effective against resistant strains of pneumococci. Daptomycin should be avoided in pulmonary infections due to inability to achieve sufficient drug levels in the pulmonary parenchyma.

Treatment

Successful treatment necessitates appropriate antimicrobial therapy as well as the rapid institution of required supportive measures including oxygen, mechanical ventilation, and drainage of significant effusions. The overall mortality for bacteremic pneumococcal infection is 15 to 20 percent with a higher rate in the elderly (http://www.cdc.goc/ncidod/dbmd/abcs/survreports/spneu03.pdf).

Antibiotic therapy is generally started empirically when the patient is initially seen. Whenever possible, gram stain and culture of sputum, as well as blood culture, should be obtained prior to the initiation of antimicrobial therapy. Choice of empirical therapy may be influenced by local patterns of resistance of the organisms. It is important to inquire about recent antibiotic use and recent hospital admissions. Recent use of penicillin, trimethoprim-sulfamethoxazole, or a macrolide is associated with increased risk of resistance to all three agents. Although still rare in the United States, fluoroquinolone resistance is associated with previous use of a fluoroquinolone, current residence in a nursing home and nosocomial acquisition of the pneumonia. Commonly employed regimens for initial therapy include a third-generation cephalosporin/macrolide combination or monotherapy with a respiratory fluoroquinolone. Vancomycin should be considered as an alternative or as an additional agent in persons with severe illness or in those potentially infected with a multidrug resistant strain. Combination therapy with two effective agents may decrease mortality in severely ill patients with bacteremic disease.

After results of culture and antimicrobial susceptibility testing become available, antimicrobial therapy can often be specifically tailored. Therapy should be continued at least 5 days after defervescence and longer if bacteremia is proved or suspected. Persistent fever or deteriorating clinical status should prompt investigation for empyema or metastatic infection. Significant pleural effusion should be drained. Repeat chest imaging should be considered several weeks after resolution of disease to search for malignancy or anatomic obstructions in the pulmonary tree.

Prevention

Smoking cessation, influenza vaccination, and correction of reversible underlying immunosuppressive conditions are paramount preventive measures. Additional preventive measures should include immunization with the 23-valent polysaccharide vaccine in adults. Introduced in the year 2000, children are now routinely immunized with the heptavalent protein-conjugated vaccine that is effective against 82 percent of the most common bacteremic strains in the United States. Widespread use of the conjugate vaccine in children appears to have an indirect benefit in older adults, perhaps by reducing the circulating pool of selected pneumococcal serotypes in the general population.

The original polysaccharide vaccine was developed in the 1940s but was soon discontinued after penicillin use became widespread and effective. The 23-valent capsular polysaccharide vaccine was reintroduced in the 1970s and has been the subject of much investigation. Overall, analysis of multiple randomized controlled trials and objective studies suggest a modest benefit in preventing pneumococcal disease in adults. The vaccine is now recommended for certain populations by the Immunization Practices Advisory Committee, including all persons 65 years of age and older. Persons younger than 65 years of age with alcoholism, functional or anatomic asplenia, diabetes mellitus, chronic renal insufficiency, hepatic cirrhosis, chronic pulmonary disease, and a cerebrospinal fluid leak should be immunized. Immunosuppressed persons including those with multiple myeloma, lymphoma, HIV infection, an organ transplant or an indication for chronic glucocorticoid therapy should also be immunized. Persons 65 years of age and older who were immunized before 65 years of age should be offered a second dose if at least 5 years have passed since the original immunization. Persons undergoing elective splenectomy should be immunized several weeks in advance of surgery if possible.

STAPHYLOCOCCUS AUREUS

Microbiology

Of the many species within the *Staphylococcus* genus, *Staphylococcus aureus* is an especially virulent pathogen for humans.

It causes a wide range of infections ranging from relatively mild folliculitis and furunculosis to life-threatening cellulitis, pneumonia, bacteremia, and infective endocarditis. *S. aureus* is an aerobic, non-motile gram-positive coccus that is most often visualized as a small cluster of organisms on gram stain. The bacterium grows readily on a variety of laboratory media. Colonies are circular, smooth, and honey colored when cultured on blood agar and are often surrounded by a zone of β-hemolysis on blood agar. The organism elaborates multiple virulence factors. Coagulase, one such virulence enzyme, is the basis for laboratory differentiation from other "coagulase-negative" species of staphylococci such as *S. epidermidis.*

Epidemiology

The incidence of *S. aureus* infection has been increasing at a rapid rate. *S. aureus* transiently colonizes approximately 60 percent of the general population, persistently colonizes about 20 percent, and never colonizes 20 percent. The anterior nares are the most common site of colonization. Other sites of colonization include damaged skin, vagina, axillae, perineum, and pharynx. Higher rates are observed in patients with insulin-dependent diabetes mellitus, HIV infection, renal disease requiring hemodialysis, and those who use drugs administered by injection. These sites of colonization are often the source of invasive infections.

Risk factors for developing *S. aureus* pneumonia include nasal colonization, antecedent influenza infection, endotracheal intubation, tricuspid-valve infective endocarditis with septic emboli, structural diseases of the lung, certain immune defects, such as chronic granulomatous disease, and recent thoracic surgery. *S. aureus* is an uncommon cause of community-acquired pneumonia but causes 15 to 35 percent of nosocomial pneumonia. The incidence in any given population or facility depends on patient demographics and diagnostic methods. *S. aureus* is a common cause of severe ventilator-associated pneumonia. In addition, a recent increase in the incidence of community-acquired *S. aureus* infection, including pneumonia, has been observed in children and adults.

Pathogenesis

Lower respiratory tract infections with *S. aureus* most commonly originate from either aspiration of colonizing bacteria or hematogenous dissemination from an endovascular focus of infection. Local edema, hemorrhage, and necrosis are common sequelae of pulmonary infection. Pneumatoceles, or thin air-filled cavities, may occur in children. Thick-walled abscesses may be noted in adults.

Virulence factors, including serine proteases, hyaluronidases, thermonucleases, and lipases, facilitate the infection. The Panton-Valentine leukocidin (PVL) toxin, a virulence factor that is present in some strains of methicillin-resistant *S. aureus* (MRSA), is cytolytic to polymorphonuclear cells, macrophages, and monocytes and is associated with pulmonary infection by MRSA, including severe community-acquired disease.

Clinical Manifestations

Recognition of *S. aureus* pneumonia requires a high index of suspicion because the disease may resemble pneumonia caused by other bacterial pathogens. Once believed to be solely a severe and lethal infection, recent studies demonstrate a broad range of disease, including subtle manifestations. This recognition of the range of clinical manifestations of *S. aureus* pneumonia parallels a shift in patient demographics as well as a better understanding of the pathogenesis of the disease. Increasing numbers of patients requiring mechanical ventilation as well as an increasing population of nursing home residents have probably contributed to this appreciation of the range of clinical manifestations of *S. aureus* pneumonia. In children less than 1 year old, infection is commonly related to an antecedent influenza or measles infection. Fever, tachypnea, grunting, and productive cough are frequently observed. Diminished breath sounds and localized rales are heard over the involved area. Pleural effusion, empyema, pneumothorax, and pneumatocele formation may occur.

S. aureus remains an uncommon cause of community acquired pneumonia in adults who are otherwise healthy. When this does occur, it is usually preceded by influenza infection or tricuspid-valve infective endocarditis. More often, *S. aureus* pneumonia is hospital acquired and frequently associated with mechanical ventilation. Progression of the disease is highly dependent on both host susceptibility as well as bacterial virulence. Complications include purulent pericarditis, pulmonary necrosis with abscess formation, bronchopleural fistula with empyema formation, and endovascular infection from secondary bacteremia.

Diagnosis

In the proper clinical setting, pneumonia caused by *S. aureus* is strongly suggested by a gram stain of sputum demonstrating a large number of inflammatory cells and gram-positive cocci in clusters and a positive sputum culture. Antibiotic susceptibility testing is an essential diagnostic test. MRSA accounts for over one-half of hospital-acquired isolates of *S. aureus* in many hospitals and has more recently been recognized as a cause of community acquired disease. Because of the high frequency of upper airway consolidation in the general population, a positive sputum culture, however, does not establish an etiological diagnosis of *S. aureus* pneumonia. Clinical acumen is essential. Isolation of the organism from a source that is normally sterile, such as blood or pleural fluid, establishes the diagnosis. Approximately 20 percent of *S. aureus* pneumonia is associated with concurrent bacteremia. Bloodstream infection should prompt consideration of primary endovascular infection even in the presence of pneumonia since pulmonary disease may be hematogenously acquired. False negative sputum cultures are unusual given the hearty nature of the organism. Therefore, the absence of the *S. aureus* in a sputum

sample in a patient who is not receiving antibiotics argues against the diagnosis of *S. aureus* pneumonia.

Fever, cough productive of purulent and blood-tinged sputum, and hypoxemia are common. Imaging studies may reveal single or multiple patchy areas of bronchopneumonia with or without pleural effusion. Lobar consolidation is rare. Abscesses and/or pneumatoceles may be observed in advanced disease.

Antibiotic Resistance

Most isolates of *S. aureus* express β-lactamase, which mediates resistance to penicillin. Antistaphylococcal penicillin derivatives including methicillin, nafcillin, and oxacillin are active against β-lactamase–producing *S. aureus* isolates. An increasing proportion of isolates have acquired resistance to these agents. These methicillin-resistant *S. aureus* (MRSA) possess the *mec*A gene that encodes penicillin binding protein 2a, which has decreased affinity for all currently available β-lactam antibiotics, thereby causing MRSA to be resistant. MRSA comprise over half of *S. aureus* isolates in many hospitals in the United States. Hospital isolates of MRSA are often resistant to multiple antibiotics, including fluoroquinolones, trimethoprim-sulfamethoxazole, erythromycin, and clindamycin. Vancomycin is active against most isolates of MRSA. More recently, intermediate-resistant and resistant strains to vancomycin have been identified. Although strains with reduced susceptibility to vancomycin are rare, isolates of *S. aureus* should be monitored carefully for the development of resistance. The newer agents linezolid, dalfopristin/quinupristin, daptomycin, and tigecycline have activity against MRSA.

More recently, an increasing proportion of community-acquired *S. aureus* isolates have proved to be MRSA, including those causing pneumonia. These isolates were originally thought to be hospital strains that had spread to the community. However, in contrast to hospital-acquired MRSA that are clonal and resistant to multiple antibiotics, community-acquired MRSA are more polyclonal, susceptible to multiple antibiotics other than methicillin and are associated with severe pneumonia in otherwise healthy people. Community acquired MRSA are often susceptible to fluoroquinolones, trimethoprim/sulfamethoxazole, and clindamycin.

Treatment

The antistaphylococcal penicillin derivatives oxacillin and nafcillin are bactericidal against methicillin-sensitive *S. aureus* and are the treatment of choice when the organism is sensitive to these agents. If initial empirical therapy is started with vancomycin and the organism is eventually identified as MRSA, treatment should be changed to an antistaphylococcal penicillin derivative because superior efficacy is achieved compared to therapy with vancomycin.

When *S. aureus* is suspected as a cause of nosocomial pneumonia, therapy should be initiated with vancomycin until the results of susceptibility testing becomes available. The choice of empirical antimicrobial therapy for suspected community-acquired *S. aureus* pneumonia is more difficult. Risk factors that increase the likelihood of MRSA include nasal colonization by MRSA, recent hospital admission, and local epidemiological considerations. If such risk factors are present, then consideration should be given to empiric administration of vancomycin as initial therapy. In both hospital and outpatient settings, the results of antimicrobial susceptibility should be used to tailor treatment.

Recent retrospective data suggest that the efficacy of linezolid may be superior to that of vancomycin for the treatment of ventilator-associated pneumonia caused by MRSA. It is hypothesized that high and predicable levels of the agent in the pulmonary parenchyma may facilitate cure. Definitive recommendations will require prospective trials. If vancomycin is the chosen therapy, monitoring serum levels of vancomycin is important, especially in the setting of fluctuating renal function or fluid homeostasis.

Other agents with activity against *S. aureus* that may be considered in particular clinical settings include trimethoprim-sulfamethoxazole, doxycycline, clindamycin, quinupristin-dalfopristin, and tigecycline. Rifampin and an aminoglycoside may be considered as adjunctive therapy in some instances. Two to four weeks is often an appropriate length of therapy for *S. aureus* pneumonia in the absence of endovascular infection, metastatic infection or other complicating factors, which may require longer therapy. A careful evaluation for the presence of endocarditis should be undertaken in all patients who are bacteremic.

RHODOCOCCUS EQUI

Rhodococcus equi, formerly *Corynebacterium equi,* is a pleomorphic gram-positive coccobacillus that is isolated from a variety of land and water animals and is present in soil worldwide. The first reported case of *R. equi* human infection was in 1967. The incidence and recognition of *R. equi* infection in humans subsequently increased coincident with the emergence of HIV infection and advances in organ transplantation and cancer treatment. However, overall, *R. equi* is an unusual infection in humans.

The primary manifestation of *R. equi* infection is pneumonia. Two-thirds of reported cases of *R. equi* pneumonia are in patients with advanced HIV infection. Most patients have CD4 counts less than 100 cells/mm^3. *R. equi* pneumonia is also seen in other immunocompromised hosts, particularly in the setting of defective cell-mediated immunity. Case reports have documented the occurrence of *R. equi* infection in immunocompetent hosts but this is rare.

Patients with *R. equi* pneumonia typically present with a subacute onset of symptoms including fever, cough, and fatigue. Pleuritic chest pain is also common. Chest radiography reveals nodules, cavities, or infiltrates; cavitary lesions are the most common pattern in HIV infection. The differential diagnosis of cavitary lesions in the setting of advanced HIV infection should include tuberculosis, *Nocardia,* and *R. equi.*

A diagnosis is established by isolating the organism from blood, sputum, or samples obtained by bronchoscopy.

Blood cultures are positive in approximately half of HIV-infected people and one-third of organ transplant recipients. *R. equi* grows well on routine laboratory media but may be overlooked or discarded as commensal diphtheroids, so laboratory personnel should be alerted if *R. equi* is suspected.

R. equi pneumonia is associated with considerable mortality and infections have a propensity for recurrence. Standard treatment regimens have not yet been developed. Most isolates of *R. equi* are susceptible in vitro to vancomycin, erythromycin, fluoroquinolones, rifampin, imipenem, and linezolid. The organism is often resistant to penicillins, which are not recommended for therapy. A rational approach to therapy in immunocompromised hosts and those with serious infections includes intravenous treatment with two or three drugs, for 2 to 3 weeks, followed by at least two oral agents for 2 to 6 months. Patients with HIV infection may benefit from continued oral suppressive therapy until immune reconstitution occurs.

STREPTOCOCCUS PYOGENES (GROUP A STREPTOCOCCUS)

Overall, group A streptococcus is an uncommon cause of pneumonia in adults. However, in surveillance studies, pneumonia is recognized as the source in 10 to 20 percent of cases of invasive group A streptococcal infections. The organism is transmitted in households and in healthcare institutions and has a predilection for causing pneumonia in clusters and in people residing in crowded living conditions, such as a large recent outbreak in a military training facility. The very young and the elderly and those with underlying medical conditions are at increased risk.

Group A streptococcus causes a severe pneumonia, which typically has an abrupt onset with fever, chills, and productive cough. Pleural effusion and empyema occur in up to one-third of cases. A patchy bronchopneumonia picture is seen on the chest radiograph. Bacteremia occurs in 15 to 20 percent of patients. Treatment consists of a penicillin and drainage of empyema when present. While the mortality is low in the absence of significant underlying disease, substantial mortality is seen in elderly patients and those with co-morbid conditions. In view of the increased risk of serious infection in contacts, consideration should be given to prophylaxis of those in close contact with patients with group A streptococcal pneumonia.

Other streptococci, including Lancefield groups B, F, and G, are rare causes of pneumonia in adults. Most such patients have underlying conditions, most notably diabetes mellitus, alcoholism, or neurological disorders.

OTHER GRAM-POSITIVE PATHOGENS

Corynebacterium pseudodiphtheriticum is a rare cause of pneumonia in patients with advanced HIV infection and other immunocompromised hosts. *C. diphtheriticum* is part of the normal flora so diagnosis of this infection requires blood or tissue culture documentation.

Bacillus species, particularly *B. cereus,* are rare causes of pneumonia. These infections occur almost exclusively in profoundly immunocompromised patients and in this setting are associated with substantial mortality. Because *Bacillus* species colonize the normal upper respiratory tract, the diagnosis of these rare infections must be established by cultures of blood or pulmonary tissue.

Inhalation anthrax is caused by inhalation of spores of *B. anthracis.* While spores enter through the respiratory tract, inhalation anthrax does not cause pneumonia per se. The organisms are phagocytosed by alveolar macrophages and are transported to mediastinal lymph nodes where multiplication and systemic dissemination occur.

Nosocomial Pneumonia

Jay A. Fishman

Nosocomial pneumonia has been defined as an infection of the lung parenchyma that was neither present nor incubating at the time of hospital admission. Health care–associated and nosocomial pneumonias are the second leading cause of hospital-acquired infections and are increasing in proportion to the use of assisted ventilation and with prolonged care of critically ill patients. It has been estimated that there are up to 200,000 nosocomial respiratory tract infections per year in the United States or between 5 and 15 cases per 1000 hospital admissions depending on the case definition and study population. Nosocomial pneumonia results in an average of 5.9 extra hospital days at a cost of $5683 in 1992 dollars. Patients with ventilator-associated pneumonia are subject to prolonged intensive care unit (ICU) stays by over ~6 days and hospital costs increases of over $10,000 per episode. The incidence of ventilator-associated pneumonia (VAP) is 6- to 20-fold greater than in nonventilated patients. Overall, nosocomial pneumonia results in an estimated 7087 deaths and contributes to 22,983 deaths per year in the United States. Of note, while the microbiology of these infections has not changed substantially, increasing resistance to multiple antimicrobial agents is now a common feature of these infections that has substantially altered therapy. In the absence of new classes of antimicrobial agents, preventative strategies must be considered including noninvasive ventilation, drainage of subglottic secretions, and gastrostomy. Initial empiric antimicrobial therapy of nosocomial pneumonia should be based on knowledge of the individual's colonization history and local antimicrobial resistance patterns. Newer guidelines developed by a joint committee of the American Thoracic Society (ATS) and the Infectious Diseases Society of America (IDSA), emphasize microbiologic data and de-escalation of broad spectrum antimicrobial agents when possible with reduced duration of antimicrobial therapy (7 to 8 days). Clinicians need to adapt the treatment recommendations and preventive strategies to their own institutions, as the routes of infection and agents causing pneumonia vary considerably among health care facilities.

Included in this discussion are hospital acquired (HAP), ventilator-associated (VAP), and "health care–associated" pneumonias (HCAP), as a great proportion of patients in the acute care setting may be admitted from other chronic care facilities or with recent hospitalizations. The important distinction that must be made is the level of risk for multi-drug resistant (MDR) pathogens, which determines the need for initial, empiric, therapy with broad-spectrum antimicrobial agents. In general, HCAP is included in the spectrum of HAP and VAP, and patients with HCAP need therapy

for MDR pathogens. Antimicrobial agents quickly affect the ability to culture susceptible organisms from pulmonary secretions. Thus, a lower respiratory tract specimen for gram stain and culture needs to be collected from all patients before antibiotic therapy, but collection of cultures should not delay the initiation of therapy in critically ill patients. This practice assists the clinician in avoiding inadequately treated HAP, VAP, or HCAP; failure to initiate appropriate and adequate therapy promptly is associated with increased mortality. In general, the approach to nosocomial pneumonia should include:

- Suspicion that the patient is at risk for nosocomial pneumonia
- Early chest radiography and sputum gram stain and cultures
- Empiric therapy in the patient with pneumonia, initially with antimicrobial coverage broad enough for the likely pathogens given the individual patient's risk factors for colonization with antimicrobial resistant pathogens
- Use host to define the urgency and duration of empiric therapy
- Adjustment of therapy based on microbiologic data (days 3 to 5)
- Switch to oral therapy or discontinue antibiotics with clinical improvement or absence of documented infection
- *If no response, reassess, consider invasive diagnosis*

PATHOGENESIS

The pathogenesis of nosocomial pneumonia has been extensively reviewed. Bacteria may invade the lower respiratory tract by three major routes: aspiration of oropharyngeal flora, inhalation of infected aerosols, and less frequently, hematogenous spread from a remote focus of infection (Fig. 130-1).

The major cause of nosocomial pneumonia is believed to be colonization of the oropharynx and gastrointestinal tract by pathogenic microorganisms, followed by aspiration of these pathogens, and the development of pneumonia in the setting of impaired host defenses. Aspiration of oropharyngeal secretions has been noted in approximately 45 percent of normal subjects during sleep. In normal subjects, however, the volumes of aspirate are small and the aspirated flora are generally nonpathogenic. Several factors that are common in hospitalized patients are associated with an increased frequency or volume of aspiration: altered consciousness, abnormal swallowing, depressed gag reflexes, delayed gastric emptying, and decreased gastrointestinal motility. Oropharyngeal colonization with aerobic gram-negative bacilli is favored by coma, hypotension, acidosis, azotemia, alcoholism, diabetes mellitus, leukocytosis, leukopenia, pulmonary disease, use of nasogastric or endotracheal tubes, and antibiotic use. Thus, hospitalized patients, especially those in intensive care units, have an increased frequency of oropharyngeal colonization by more pathogenic aerobic gram-negative bacilli and are often at increased risk for aspirating this more pathogenic flora.

The importance of oropharyngeal colonization in nosocomial pneumonia was elegantly demonstrated by Johanson and colleagues, who showed that pneumonia occurred in 23 percent of patients colonized with aerobic gram-negative bacilli but only 3 percent of noncolonized patients. More recently, the stomach has been postulated as an important reservoir of organisms capable of causing nosocomial pneumonia. Normally, the stomach is rendered sterile by hydrochloric acid; however, elevations of gastric pH from normal levels to levels at or above 4 allow microorganisms to multiply to high concentrations. Elevated gastric pH may occur in patients with advanced age, achlorhydria, ileus, or upper gastrointestinal disease, and in patients receiving enteral feeding, antacids, or histamine$_2$ (H_2) antagonists.

Intubation for respiratory support is the most important risk factor for subsequent nosocomial pneumonia. Nasotracheal or orotracheal intubation predisposes patients to bacterial colonization and nosocomial pneumonia by a variety of pathophysiological alterations: (1) sinusitis and trauma to the nasopharynx (nasotracheal tube); (2) impaired swallowing of secretion; (3) acting as a reservoir for bacterial proliferation; (4) increased bacterial adherence and colonization of airways; (5) ischemia secondary to cuff pressure; (6) impaired ciliary clearance and cough; (7) leakage of secretions around the cuff; and (8) suctioning often required to remove secretions. Contaminated respiratory care equipment may lead to nosocomial pneumonia by two routes. First, respiratory care equipment may serve as a reservoir for microorganisms, especially gram-negative bacilli. Fluid-containing devices such as nebulizers and humidifiers may become heavily contaminated by bacteria capable of multiplying in water. Pathogens may then be spread to the patient by hospital personnel or aerosolization into room air. Second, contaminated equipment may lead to direct airway inoculation of microorganisms if it is directly linked to the ventilatory system or if contaminated medications are instilled by aerosolization. The role of contaminated respiratory equipment as a source or reservoir for nosocomial pneumonia has recently been reviewed.

Hospital personnel and the hospital environment also play an important role in nosocomial pneumonia. Cross-transmission between patients may occur when the hands of medical personnel become transiently colonized with pathogenic organisms. Such pathogens may be acquired from direct patient care or from contact with contaminated equipment or hospital surfaces. For this reason, it is crucial that health care providers carefully wash their hands before and after each patient contact. Patients may acquire respiratory infections—including influenza, respiratory syncytial virus, pertussis, group A streptococcus, diphtheria, and *M. tuberculosis*—transmitted by the droplet or airborne routes from infected health care personnel, other patients, or visitors.

The hospital environment may also serve as a reservoir for *Aspergillus, Zygomycetes,* and *Legionella.* Nosocomial

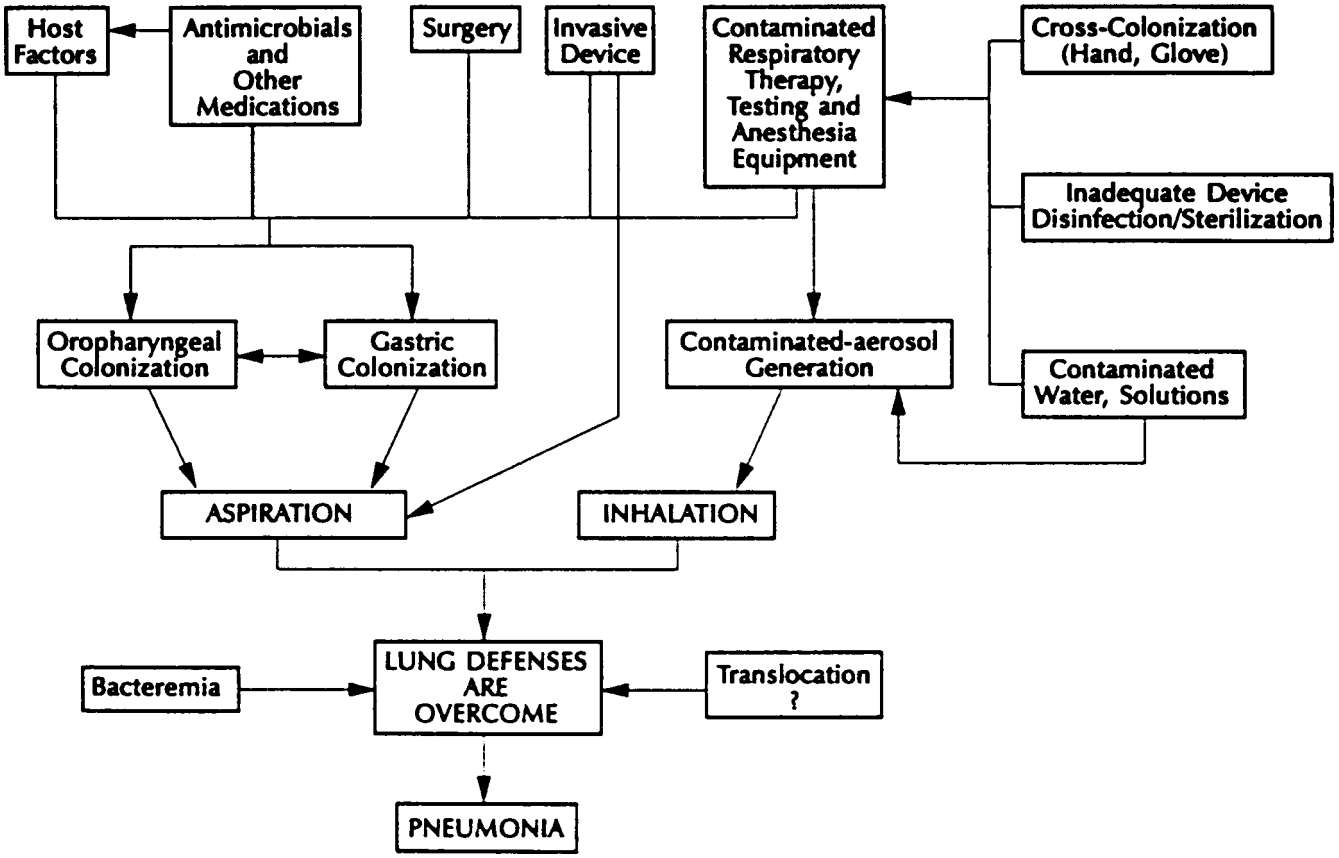

Figure 130-1 Pathogenesis of nosocomial bacterial pneumonia. *(Based on data from Tablan OC, Anderson LJ, Arden NH, et al, and the Hospital Infection Control Practices Advisory Committee: Guideline for prevention of nosocomial pneumonia.* Infect Control Hosp Epidemiol *15:587–627, 1994.)*

pneumonia may result when these pathogens are inhaled, especially if the patient is immunocompromised. The recovery of *Aspergillus* or *Zygomycetes* within hospitals has been variable, but commonly at least small numbers can be isolated from the air, accumulated dust, and environmental surfaces. More than 25 outbreaks of nosocomial fungal pneumonia have been reported. Sources of airborne fungi in hospitals have been reported to include: (1) dust associated with hospital renovations; (2) outside construction, with an inadequate or malfunctioning hospital ventilation system; (3) contaminated cellulose fireproofing material; (4) contamination of the hospital air supply by pigeon droppings, helicopter flights from a roof helipad, or contaminated air filters and air-conditioning coils; and (5) an inadequate filtration system, coupled with location of the outside air intake vent near a refuse container.

Nosocomial acquisition of *Legionella pneumophila* and *L. bozemanii* have been linked to contamination of hospital water supplies, and the association has been strengthened by use of molecular epidemiologic typing methods (e.g., DNA fingerprinting by pulsed field gel electrophoresis) and clinical and environmental strains. *Legionella* can be isolated from more than 50 percent of the potable water supplies and more than 10 percent of the distilled water supplies in hospitals. The subjects of *Legionella* in hospitals and disinfection of water distribution systems for *Legionella* have been reviewed.

INCIDENCE

The incidence of nosocomial pneumonia varies among hospitals for a variety of reasons, including the sensitivity and specificity of the surveillance definition, the vigor with which the diagnosis is sought, and the frequency of intrinsic (e.g., patient age) and hospitalization-specific (e.g., intubation) factors among patients that alter their risk for nosocomial pneumonia. The most representative data regarding the incidence of nosocomial pneumonia have been provided by the National Nosocomial Infections Surveillance (NNIS) system, a Centers for Disease Control and Prevention (CDC) surveillance system of more than 150 hospitals. In 1984, the overall incidence of nosocomial pneumonia was 6.0 per 1000 discharged patients. The incidence varied by hospital type, being 4.2 in nonteaching hospitals, 5.4 in small teaching hospitals, and 7.7 in large teaching hospitals.

The incidence of ventilator-associated pneumonia has ranged from 11 to 54 cases per 100 patients, depending on the population studied (Table 130-1). Intubation and mechanical

** Ratio: Number of cases per 100 patients.*

† Rate: Number of cases per 1000 ventilator days.

Note: Abbreviation: BICU = burn intensive care unit; CCU = coronary care unit; CTICU = cardiothoracic intensive care unit; EF = emergency floor; MICU = medical intnsive care unit; MSICU = medical/surgical intensive care unit; MV = mechanical ventilation; NSICU = neurosurgical intensive care unit; PICU = pediatric intensive care unit; PSB = protected specimen brush; RICU = respiratory intensive care unit; SICU = surgical intensive care unit; TI = tracheal intubation; TICU = trauma intensive care unit.

ventilation represent the most important risk factor for nosocomial pneumonia, with a 6- to 21-fold increased risk. For this reason, the CDC and other investigators now report the incidence of nosocomial pneumonia as cases per 1000 days of mechanical ventilation. This serves to adjust the rates to take into account the presence and duration of mechanical ventilation. Ventilator-associated pneumonia rates (cases per 1000 ventilator days) reported by the NNIS system vary by hospital, type of ICU, and for neonatal intensive care units, patient birth weight. Rates among ICUs ranged from 6.0 in the pediatric ICU to 22.2 in the burn ICU. Rates reported from individual hospitals exhibit considerable variation; for medical-surgical ICUs, the lowest 10 percent of reporting hospitals had a rate of 3.8, while the upper 10 percent had a rate of 20.0.

Several investigators have described the actuarial risk of pneumonia as a function of the duration of mechanical ventilation. Langer and associates showed that the rate of pneumonia was constant through the first 8 to 10 days of respiratory assistance and then decreased. While the rate of nosocomial pneumonia per day decreases, the cumulative incidence increases, so by day 30 of mechanical ventilation, an episode of nosocomial pneumonia will have developed in more than 60 percent of patients. Fagon and co-workers reported the actuarial risk of pneumonia during mechanical ventilation as 6.5 percent at 10 days, 19 percent at 20 days, and 28 percent at 30 days. Ruiz-Santana and colleagues reported actuarial risks for pneumonia as 8.5 percent at day 3, 21.1 percent at day 7, 32.4 percent at day 14, and 45.6 percent for ventilation after 14 days. In a systematic review of 38 prospective cohort and nonrandomized studies including approx 48 000 mechanically ventilated patients, the incidence of ventilator-associated pneumonia varied from 10 to 20 percent with twice the mortality of similar patients without VAP.

RISK FACTORS FOR NOSOCOMIAL PNEUMONIA

Many risk factors have been demonstrated to be associated with nosocomial pneumonia (Table 130-2). In general, these factors can be divided into several broad categories: (1) intrinsic host factors such as age, underlying medical disorders such as pulmonary disease, and nutritional status; (2) hospital factors such as abdominal or thoracic operations, antibiotic use, immunosuppression, and treatment in an ICU; (3) equipment and device use, especially intubation with mechanical ventilation; and (4) factors that increase the risk of aspiration such as depressed consciousness.

Intrinsic Factors

The incidence of nosocomial pneumonia is increased at the extremes of life. However, a case control study by Hanson and colleagues, using regression analysis, demonstrated that age was not an independent risk factor for nosocomial pneumonia. Rather, the increased incidence of pneumonia in the elderly was a function of an increased frequency of both intrinsic and hospital risk factors, such as poor nutrition, neuromuscular disease, and endotracheal intubation.

Intrinsic risk factors reported in the literature have included chronic lung disease, poor nutrition, thoracic surgery patients, and immunosuppression. Ventilator-associated pneumonia is common in patients with chronic obstructive pulmonary disease (COPD), reflecting poor pulmonary mechanics and clearance and increased colonization with antimicrobial-resistant pathogens after multiple courses of antibiotics for tracheobronchitis. In this population, *P. aeruginosa* is common (up to one-third) and initial antimicrobial therapy is often inadequate. After major noncardiac thoracic surgery, nosocomial infection is common and carries a high mortality. Pneumonia often masks empyema at the surgical site and CT scans may be needed to diagnose this complication. Lung resection is a special risk group, often with underlying lung disease, obstruction or malignancy, often with pre-existing bronchial colonization. *Haemophilus influenzae* and *Streptococcus pneumoniae* are commonly isolated (suggesting aspiration).

Nosocomial pneumonia outside the ICU or mechanical ventilation population has not been well studied, but often reflects severe community-acquired infection (*Streptococcus pneumoniae* and *Legionella* species) co-existing with nosocomial pathogens.

Hospital Factors

Management in an ICU has been reported as an important risk factor for the development of nosocomial pneumonia. The incidence (number per 100 patients) in various intensive care patients is as follows: ICUs, all patients, 0.5 to 31.5 (median 9.5); intensive care patients, no ventilation, 0.4 to 6.9; adult medical and surgical intensive care patients, mechanical ventilation, 8 to 54 (median 24); and pediatric intensive care patients, mechanical ventilation, 1.5 to 8.

Other important hospital factors reported in the literature are intracranial pressure monitor, chest and abdominal surgery, large-volume gastric aspiration, reintubation, tracheostomy, prior antibiotic use, organ failure, and use of H_2-blocker therapy.

Many studies have documented that the administration of antacids and H_2 blockers—used to prevent stress bleeding in critically ill, intensive care patients—has been associated with gastric bacterial overgrowth. Several studies and three meta-analyses have demonstrated a lower rate of pneumonia in patients treated with sucralfate, a cytoprotective agent, than in those treated with antacids or H_2 blockers. In their review, Craven and Steger note that most current data using a clinical diagnosis of ventilator-associated pneumonia suggest that sucralfate provides similar protection against stress bleeding but poses a lower risk of nosocomial

Table 130-2

Risk Factors for Nosocomial Pneumonia

- Ventilator-associated pneumonia
  - Independent risk factors
    - Age >60 years
    - COPD/PEEP/pulmonary disease
    - Coma/impaired consciousness
    - Therapeutic interventions
    - Intracranial pressure monitoring
    - Organ failure
    - Large volume gastric aspiration
    - Prior antibiotics
    - H_2 blocker +/− antacids
    - Gastric colonization and pH
    - Season: fall, winter
    - Ventilator circuit changes 24 vs. 48 h
    - Reintubation
    - Mechanical ventilation ≥2 days
    - Tracheostomy
    - Supine head position
- Ventilated and Nonventilated patients
  - Independent risk factors
    - Age >60 years
    - APACHE II >16
    - Trauma/head injury
    - Impaired airway reflexes
    - Coma
    - Bronchoscopy
    - Nasogastric tube
    - Endotracheal intubation
    - Upper abdominal/thoracic surgery
    - Low serum albumin
    - Neuromuscular disease
- Ventilator and nonventilated patients
  - Univariate risk factors for pneumonia
    - Age >60 years
    - Male sex
    - Smoking
    - Underling disease, rapidly fatal vs nonfatal/ultimately fatal
    - Simplified acute physiological score >9
    - ASA class IV
    - Inspired O_2 >0.50
    - Prior care facility
    - Alcohol intake
    - Renal failure/dialysis
    - Intra-aortic balloon pump
    - Chronic obstructive pulmonary disease
    - Chemical paralysis
    - Airway instrumentation
    - Aspiration before intubation
    - Mechanical ventilation >2 days
    - No prior surgery
    - H_2 blockers or antacids vs. sucralfate
    - Coma
    - Head trauma
    - Cascade humidifier vs. heat moisture exchanger
    - Tracheostomy
    - Continuous enteral feeding
    - Prior antibiotics
    - Nosocomial maxillary sinusitis
    - Type of intensive care unit
    - Repeat intensive care unit admission
    - APACHE II score
    - Emergency surgery
    - Nasotracheal tube
    - Nasogastric tube
    - Subglottic secretions

Interventions were markers of severe underlying disease and included dopamine, dobutamine ≥5 μg/min, barbiturate therapy for increased intracranial pressur and continuous intravenous antiarrhythmic or artihypertensive therapy.
Note: Abbreviation: APACHE = acute physiological score and chronic health evaluation; ASA = American Society of Anesthesiology; COPD = chronic obstructive pulmonary disease; PEEP = positive end-expiratory pressure.

pneumonia. For this reason, they recommend that if stress bleeding prophylaxis is prescribed and there is no contraindication, the risk–benefit ratio for reducing ventilator-associated pneumonia appears to favor the use of sucralfate over antacid or H_2 blockers for patients who require a gastric tube.

The use of a nasogastric tube is increasingly recognized as a risk factor for nosocomial pneumonia. Nasogastric tubes may increase the risk of nosocomial sinusitis, oropharyngeal colonization, reflux, and bacterial migration.

RISKS ASSOCIATED WITH RESPIRATORY DEVICES

Intubation with mechanical ventilation is the single most important risk factor for the development of nosocomial pneumonia. For this reason, intubation should be used only when medically necessary, and strict adherence to equipment maintenance is critical. Infected biofilm in the endotracheal tube, with subsequent embolization to distal airways, may be

important in the pathogenesis of VAP. Aspiration of oropharyngeal pathogens, or leakage of secretions containing bacteria around the endotracheal tube cuff, are major routes of bacterial entry into the lower respiratory tract and also suggest the advantage of subglottic suctioning for prevention.

Fluid-containing respiratory devices are the major environment-associated reservoirs for nosocomial pneumonia. However, most or all phases of respiratory support have been linked to nosocomial respiratory infections or suggested as potential environmental reservoirs. These include mechanical ventilation bags, ventilators, aerosolized medications, bronchoscopy, suction catheters, and respiratory support personnel. Evidence suggests that alterations in infection control practices during the 1960s decreased the number of cases of nosocomial pneumonia from environmental sources.

Flexible bronchoscopy has proved to be an invaluable diagnostic and therapeutic procedure. In general, the incidence of postprocedure fever or pneumonia has been reported to be less than 1 percent. However, the use of contaminated bronchoscopes has led to both pseudoepidemics and clinical infection. Pseudoepidemics with clusters of positive cultures of bronchoscopic washings have been linked to the use of contaminated bronchoscopes, contaminated tubing or suction devices, cocaine for topical use, and green dye added to the topical anesthetic. Microorganisms isolated in these cases included *Trichosporon cutaneum* and *Penicillium* species, *Pseudomonas aeruginosa, P. fluorescens-putida, Bacillus* species, *Mycobacterium* species, and *Rhodotorula rubra.* Cross-transmission of respiratory pathogens has led to clinical infections with *M. tuberculosis, P. aeruginosa,* and *Serratia marcescens.* Factors leading to the use of contaminated bronchoscopes have included post-disinfection rinsing in tap water and disinfection with an iodophor, cetrimide-chlorhexidine, and 70 percent alcohol. Failure to sterilize damaged bronchoscopes or bronchoscope suction valves contaminated by *Mycobacteria* has been noted with both ethylene oxide and immersion in 2 percent glutaraldehyde for 30 minutes. Prevention of nosocomial infection related to contaminated bronchoscopes requires adherence to guidelines that delineate proper techniques of cleaning and disinfection of bronchoscopes.

MORTALITY

Nosocomial pneumonia is an important cause of mortality in hospitalized patients. Nosocomial pneumonia has been reported to contribute to 60 percent of all infection-related hospital deaths. Daschner and colleagues reviewed 1000 autopsy reports and noted that pneumonia was associated with 7.5 percent of deaths and was the most common nosocomial infection contributing to death. Intensive care patients with nosocomial pneumonia have a two- to tenfold increased risk of mortality compared to patients without pneumonia. Independent risk factors for mortality in nonventilated patients include infection with *P. aeruginosa,* bilateral infiltrates on chest radiography, and respiratory failure.

Table 130-3

Risk Factors for Mortality in Patients with Nosocomial Pneumonia

Aerobic gram-negative bacilli as pathogen(s), especially *P. aeruginosa*
Severity of underlying illness
Inappropriate antibiotic therapy
Advanced age
Shock

The crude mortality for ventilator-associated nosocomial pneumonia has ranged from 13 to 70 percent, but most investigators have reported rates in the range of 20 to 40 percent. Many risk factors have been associated with mortality in ventilated patients (Table 130-3). Several studies using a matched cohort design have evaluated the attributable mortality from nosocomial pneumonia. In these studies, in which patients were matched by demographic factors and comorbidity, the attributable mortality was reported to be 13.7, 33.3, 27.1, and 35.8 percent, respectively.

ETIOLOGIC AGENTS

The common etiologic agents of nosocomial pneumonia reported from the NNIS hospitals from 1990 to 1992 were *Staphylococcus aureus* (20 percent), *P. aeruginosa* (16 percent), *Enterobacter* species (11 percent), *Klebsiella pneumoniae* (7 percent), *Candida albicans* (5 percent), *Haemophilus influenzae* (4 percent), *Escherichia coli* (5 percent), *Acinetobacter* species (4 percent), and *S. marcescens* (3 percent) (Table 130-4). Only *Acinetobacter* spp. were found to significantly increase over the period of study, from 4 to 7 percent. As a group, aerobic enteric gram-negative bacilli accounted

Table 130-4

Common Pathogens Currently Associated with Nosocomial Pneumonia

Pathogen	Frequency (%)	Source of Organism
Early-onset bacterial pneumonia		
S. pneumoniae	5–20	Endogenous; other patients
H. influenzae	<5–15	Respiratory droplet
Late-onset bacterial pneumonia	≥20–60	
Aerobic gram-negative bacilli		Endogenous; other patients, environment, enteral feeding; health-care workers; equipment, devices
P. aeruginosa		
Enterobacter spp.		
Acinetobacter spp.		
K. pneumoniae		
S. marcescens		
E. coli		
Gram-positive cocci		
S. aureus	20–40	Endogenous; health-care workers; environment
Early- and late-onset pneumonia		
Anaerobic bacteria	0–35	Endogenous
Legionella spp.	0–10	Potable water; showers, faucets; cooling towers
M. tuberculosis	<1	Endogenous; other patients, staff
Viruses		
Influenza A and B	<1	Other patients, staff
Respiratory syncytial virus	<1	Other patients, staff; fomites
Fungi/protozoa		
Aspergillus spp.	<1	Air; construction
Candida spp.	<1	Endogenous; other patients, staff
P. carinii	<1	Endogenous; other patients (?)

Crude rates of pneumonia may vary by hospital, patient population, and method of diagnosis.
Source: Adapted from Craven DE, Steger KA: Epidemiology of nosocomial pneumonia: New perspectives on an old disease. Chest *108(Suppl): 1S–16S, 1995.*

for approximately one-third of all pathogens responsible for pneumonia. In ventilated patients, gram-negative bacilli have accounted for 58 to 83 percent of infections, gram-positive cocci for 14 to 38 percent, and anaerobes for only 1 to 3 percent. Polymicrobial infections were common, being noted in 26 to 53 percent of cases (median 40 percent). The importance of viral diseases such as cytomegalovirus, influenza, and respiratory syncytial virus is unknown, but they have clearly been under-ascertained and underreported.

The relevance of the NNIS data is called into question by reports that document the inability of clinical criteria to accurately identify cases of nosocomial pneumonia and the failure of expectorated sputum or tracheal aspirates to reliably identify pathogens in the distal areas of the lung (Table 130-5). Combining reports in which the diagnosis of pneumonia was made by an invasive procedure and more specific microbiologic criteria were used, the etiologic agents of pneumonia were *P. aeruginosa* (16 percent), *S. aureus* (20 percent), *Acinetobacter* species (14 percent), *H. influenzae* (10 percent), *S. pneumoniae* (4 percent), and other streptococci (4 percent). Enteric gram-negative bacilli (*E. coli, Enterobacter, Proteus, Serratia, Klebsiella,* and *Citrobacter*) accounted for only 13 percent of isolates. Thus, generalizing from the NNIS data would overestimate the importance of enteric gram-negative bacilli and underestimate the importance of *Acinetobacter* species as causes of pneumonia in ventilated patients. One must stress that the specific etiologic agents isolated in an individual institution may vary from these summary statistics depending on many factors, including patient demographics, patterns of antimicrobial use, environmental reservoirs for pathogens such as *Legionella* and *Aspergillus,* and the mix of host defects in the patient population.

In the United States, while the list of common pathogens has not much changed, there has been a significant increase in cephalosporin-resistance, production of extended spectrum beta-lactamase (ESBL), and multidrug-resistance

in *Pseudomonas, Xanthomonas, Klebsiella* and *Acinetobacter* species. Of note, the role of methicillin-resistant *Staphylococcus aureus* (MRSA) has increased both in nosocomial and community-acquired infections, with a major impact on the related mortality. Nosocomial bacteremic *Staphylococcus aureus* pneumonia (NBSAP) occurs late in the hospital stay, generally in patients with prolonged mechanical ventilation and after previous antimicrobial therapy. When recognized and treated appropriately, the mortality and length of stay were not different between individuals with MSSA and MRSA-pneumonia. Mortality of nosocomial staphylococcal pneumonia is closely related to APACHE II score and early, appropriate therapy. The role of common organisms (*Streptococcus pneumoniae, Mycoplasma pneumoniae, Chlamydia pneumoniae*) in ventilator-associated pneumonia is difficult to assess given the high sensitivity of molecular diagnostic tools and the frequency of these organisms in the general population. *Candida* species are commonly isolated in respiratory specimens but are rarely, if ever, associated with invasive infection in the absence of underlying lung pathology (endocarditis with embolization, infarction, or surgery).

Enterobacteriaceae

Microbiology and Epidemiology

Enteric gram-negative bacilli are an important cause of nosocomial pneumonia. In certain patients, such as those in chronic care facilities, immunocompromised patients, or those with underlying lung disease, they are also an important cause of community-acquired pneumonia. Of the enteric pathogens, the most common agents in pneumonia are *Klebsiella, E. coli, Enterobacter, Acinetobacter, Proteus,* and *Serratia.* All these pathogens grow readily on blood or MacConkey's agar. These bacteria are normal flora of the gastrointestinal tract. As previously noted, hospitalization and other host factors (e.g., alcoholism) favor colonization of the oral cavity.

Clinical Features and Diagnosis

The enteric bacteria are opportunistic pathogens that cause pneumonia in the setting of impaired host defenses. All may produce a destructive pneumonia. Characteristically, patients with pneumonia due to enteric pathogens have fever, chills, cough with production of sputum, shortness of breath, and pleuritic pain. The clinical features are not specific enough to distinguish among the many enteric bacteria capable of causing pneumonia. In some patients—including immunosuppressed persons, the elderly, and patients with hematogenously spread pneumonia—the signs and symptoms of pneumonia may be reduced or absent. Blood cultures have been reported to be positive in 10 to 50 percent of patients, depending on the etiologic agent and the patient population. The radiographic findings do not allow microbiologic diagnosis, although they may be suggestive. As previously noted, the presence of a bulging fissure suggests pneumonia with *K. pneumoniae.* Gram-negative pneumonia is suggested by early necrosis and abscess formation, although it may also be seen with *S. pneumoniae, S. aureus,* and *Legionella.*

Treatment and Prevention

The most active agents against gram-negative enteric pathogens are the third- and fourth-generation cephalospo- rins (cefotaxime, ceftriaxone, ceftazidime, cefepime), a penicillin combined with a β-lactamase inhibitor (piperacillin-tazobactam), carbapenems (imipenem, meropenem), monobactams (aztreonam), and fluoroquinolones. Aminoglycosides are active but are rarely used as primary therapy as penetration into infected lung tissue is often inadequate. Some strains of *Klebsiella, Enterobacter, Acinetobacter,* and *Serratia* may be resistant to multiple antibiotics. Definitive therapy should be guided by in vitro susceptibility results and clinical response. Special hosts (cystic fibrosis, immunocompromised) may have invasive infection due to organisms of lesser virulence or dual infection (non-tuberculous mycobacteria or viral with gram-negative infection).

Pseudomonas Aeruginosa

Microbiology and Epidemiology

The family Pseudomonadineae contains more than 150 species. However, the most important member of this family is *P. aeruginosa. P. aeruginosa* is an obligate, motile, rod-shaped (0.5 to 0.8 by 1.5 to 3.0 μm) gram-negative bacillus with a single flagellum. It may produce a variety of pigments, including pyocyanin (a pigment produced by approximately 50 percent of clinical strains), which causes colonies to appear blue or green. *P. aeruginosa* is capable of utilizing more than 30 organic compounds for growth. It grows optimally at 37°C.

P. aeruginosa can be isolated from soil, water, plants, and animals. Its minimal nutritional requirements allow it to reproduce in many ecologic niches in the hospital. Reservoirs discovered during outbreaks have included many moist devices and surfaces found in hospitals, including endoscopes, endoscope washers, disinfectants, food mixers, and enteral foods. *P. aeruginosa* may also be part of the normal flora of humans. *P. aeruginosa* is primarily a nosocomial pathogen and is the most common gram-negative bacillus causing hospital-acquired pneumonia. Within the hospital, *P. aeruginosa* acts as opportunistic pathogen. Particularly vulnerable are patients with skin or mucous membrane disruption, intravenous catheters, urinary tract catheters, neutropenia, immunosuppressive medication, cystic fibrosis, and diabetes mellitus.

The pathogenesis of *P. aeruginosa* infections is very complex and includes many virulence factors. Key factors include the pili or fimbriae, which mediate adherence to respiratory epithelial cells; the mucoid capsule, which aids in anchoring the organism to its environment; cell-associated factors, which protect the organism from host phagocytes and complement; and extracellular enzymes and toxins, which promote penetration and impair host defenses.

Clinical Features and Diagnosis

P. aeruginosa causes respiratory infection almost exclusively in patients with impaired respiratory host defenses. Only

occasionally does *P. aeruginosa* cause community-acquired pneumonia, and then usually in patients cared for in extended care facilities or with chronic lung disease or other serious underlying illness. *P. aeruginosa* and *S. aureus* are the most important pathogens in patients with cystic fibrosis. Pneumonia due to *P. aeruginosa* is usually a fulminant infection and is characterized by fever, rigors, severe dyspnea, cough productive of sputum, cyanosis, and systemic shock. The chest radiograph commonly reveals diffuse bilateral bronchopulmonary pneumonia with distinctive nodular infiltrates and small areas of radiolucency. Although pleural effusions are common, empyema is rare.

Bacteremic pneumonia may occur in severely neutropenic patients. Patients with bacteremic pneumonia characteristically have ill-defined hemorrhagic, nodular areas that are frequently subpleural. Central necrosis of these areas may occur.

Treatment and Prevention

P. aeruginosa is typically treated with an aminoglycoside plus an antipseudomonal penicillin (piperacillin), cephalosporin (ceftazidime, cefepime), carbapenem (imipenem, meropenem), or monobactam (aztreonam). The fluoroquinolones are also active, but synergy with aminoglycosides has not been demonstrated. Despite therapy, the mortality from hospital-acquired pseudomonal pneumonia is approximately 70 percent. Unfortunately, there are no specific measures to prevent nosocomial pseudomonal infections available at the present time.

DIAGNOSIS

It is difficult to accurately diagnose nosocomial pneumonia. Clinicians have traditionally relied on the presence of clinical findings (i.e., fever, cough, the development of purulent sputum, and evidence of consolidation on physical examination), radiographic evidence of new or progressing pulmonary infiltrate, and laboratory findings (gram's stain of sputum and cultures of sputum, blood, tracheal aspirate, and pleural fluid). Many studies have demonstrated that clinical criteria with appropriate cultures of tracheal specimens may be sensitive for bacterial pathogens but are highly nonspecific, especially in intubated patients on mechanical ventilation. Blood cultures have been reported to yield the etiologic pathogen in approximately 10 to 20 percent of patients with nosocomial pneumonia. Among patients with severe nosocomial pneumonia, however, an additional source of infection has been present in up to 50 percent of those with positive blood cultures.

Several techniques are available for diagnosing nosocomial pneumonia or providing specimens for culture, including quantitative cultures of bronchoalveolar lavage (BAL) and quantitative culture of protected specimen brushing (PSB) or from plugged telescoping catheters (PTC). The reported sensitivity and specificity of these methods have ranged from 70 to 100 percent and 60 to 100 percent, respectively. In the absence of a "gold standard," however, the sensitivity and specificity of these measures cannot be definitely determined. False-positive results using PSB have been attributed to prior antibiotic therapy or bacterial colonization of the lower airway. False-negative results may also occur in significant numbers. Invasive procedures used to diagnose pneumonia may lead to clinical complications, including hypoxemia, bleeding, and arrhythmia. The clinician must also be cautious regarding interpretation of quantitative culture data. Cutoffs for "positive cultures" are somewhat arbitrary and cannot take into account patient-specific factors. Thus, bronchoscopy with quantitative cultures *may miss early forms of nosocomial pneumonia* based on exclusion criteria for the concentration of organisms/ml: i.e., Protected Specimen Brush (PSB) = 10^3; Bronchoalveolar Lavage (BAL) = 10^4; Endotracheal Aspirates (EA) = 10^5. Thus, in multiple series, when PSB contain a concentration of organisms between $10^2$and 10^3 (i.e., below the cutoff), repeat cultures (BAL) revealed over 10^4 within 72 hours in up to one-third.

Diagnostic strategies recommended in the literature for the diagnosis of nosocomial pneumonia range from a clinical approach to routine use of invasive techniques to obtain lower respiratory cultures. Controversy exists as to which invasive approach is most effective. For this reason, a definitive algorithm cannot be provided for the diagnosis of nosocomial pneumonia. However, the following approach to nosocomial pneumonia is suggested (Table 130-6). Patients with suspected nosocomial pneumonia should undergo a careful history and physical examination to define the severity of pneumonia. An arterial blood gas or pulse oximetry should be performed both to aid in defining the severity of infection and determine the need for supplemental oxygen. Mechanical ventilation should be considered for patients with hypoxia not correctable by supplemental oxygenation, hypercapnia, or inability to protect their airway. If the patient is suspected to have a communicable disease transmitted by the droplet or airborne route (e.g., respiratory syncytial virus, tuberculosis, influenza), appropriate respiratory precautions (droplet precautions or airborne precautions; see below) should be instituted. All patients should undergo chest radiography and two sets of blood cultures. The chest radiograph will aid in identifying the presence of pneumonia, the extent and location of infiltrates, and the presence of a pleural effusion. The radiographic appearance may provide clues to the cause of the respiratory failure. Other laboratory studies (complete blood count, electrolytes, liver function tests, tests of renal function, etc.) may be useful in patient management.

When a pleural effusion is present, consideration should be given to obtaining a diagnostic thoracentesis, especially if the patient is toxic or a large effusion (greater than 10 mm on a lateral decubitus film) is present. The pleural fluid should be sent for complete blood cell count and differential, protein, glucose, LDH, pH, gram's stain, and aerobic and anaerobic bacterial cultures. Consideration should also be given to fungal and mycobacterial stains and appropriate fungal and mycobacterial cultures.

Table 130-6

Evaluation of Patients with Suspected Nosocomial Pneumonia

Routine evaluation
- History
  - Recent exposure to possible pulmonary infectious agents (e.g., influenza, tuberculosis)
  - Travel
  - Occupational exposures
  - Animal exposure
  - Immunocompromising conditions (e.g., steroids, risk factors for HIV)
- Physical evaluation
- Chest radiograph
- Measure of oxygen saturation (arterial blood gas or pulse oximetry)
- Obtain expectorated sputum in nonventilated patients and a tracheal aspirate in patients who have been intubated or have a tracheostomy. Send the specimen for gram stain and bacterial cultures.
- Consider additional diagnostic tests, depending on the clinical findings and epidemiologic circumstances: viral culture, direct antigen testing for respiratory syncytial virus, *Legionella* DFA and culture, smear and culture for *Mycobacteria*, smear and culture for fungi, stain for *P. carinii*

Evaluation to exclude extrapulmonary sources of infections
- Routine evaluation
  - Blood cultures from two different sites
  - Urine analysis and culture
  - Examination of wounds, if present
- Additional tests directed by history, physical examination, and laboratory findings
- Consider removal of central and arterial vascular catheters, with semiquantitative culture of the subcutaneous portion and tip of the catheter in patients with positive blood cultures and/or evidence of sepsis
- Consider lumbar puncture following head CT or MRI in patients at high risk (e.g., after neurosurgery) or with unexplained change in mental status
- Consider radiographic imaging of the abdomen (CT or MRI) in patients with rigid abdomen, ileus, or localized or diffuse tenderness or at high risk for abdominal sepsis (i.e., after abdominal surgery, with pancreatitis, gastrointestinal bleeding, or carcinoma, or receiving high-dose corticosteroids)
- Consider abdominal ultrasound in patients with right quadrant tenderness or abnormal liver function tests, or who are too unstable for transfer to CT
- Obtain stools for *C. difficile* toxin assay in patients with more than two watery stools per day. If fever persists with a discernible cause, consider CT scan of sinuses to exclude sinusitiss, with aspiration of the maxillary sinus in patients with air-fluid levels or opacification, and/or consider nucleotide scan (gallium 67 scintigraphy,tagged white cell scan)

Additional pulmonary evaluation
- If pleural effusion is suspected, obtain decubitus films, ultrasound, or CT. If pleural effusion is present, consider diagnostic thorocentesis
- Consider need to exclude thromboembolic disease: impedance plethysmography or Doppler ultrasound evaluation of the lower extremities; ventilation-perfusion scan of the lung; pulmonary arteriogram
- Consider need for invasive diagnosis in patients with rapidly progressive pneumonia, severe pneumonia in intubated patients on mechanical ventilation, immunocompromised patients, and patients who have failed to respond to empiric therapy or have progressed on empiric therapy: bronchoscopy with protected specimen brush and bronchoalveolar lavage or protected bronchoalveolar lavage

Evaluation to rule out atelectasis
- Inhalation of bronchodilators every 2 h for 4 treatments, then every 4 h
- Percussion or vibration over the area of the chest with new densities on chest radiography
- Repeat chest radiograph in 48 h
- Consider Other Sources of Fever
  - Incorrect antibiotic administration: incorrect dose, route, frequency
  - Drug fever
  - Noninfectious source of fever and pulmonary infiltrate (e.g., aspiration, hemorrhage)
  - Foreign body
  - Superinfection
  - Overgrowth
  - Development of drug-resistant pathogen

Source: Adapted from Meduri GU: Diagnosis and differential diagnosis of ventilator-associated pneumonia. Clin Chest Med *16:61–91, 1995.*

In nonintubated patients, expectorated sputum should be obtained for gram's stain and bacterial culture. Epidemiologic or clinical findings should be reviewed, and consideration should be given to obtaining appropriate stains and cultures for viruses, fungi, mycobacteria, *Legionella,* and *P. carinii.* It is important, however, to remember that expectorated sputum is neither sensitive nor specific for the diagnosis of nosocomial pneumonia. Its major value is to identify the antibiotic susceptibilities of the organisms present and thereby aid in the proper choice of therapy.

In intubated patients, a tracheal aspirate should be obtained. The gram's stain may reveal a predominant pathogen. The culture has been shown to have both poor sensitivity and specificity in identifying the etiologic agents of nosocomial pneumonia. Cultures obtained by tracheal aspiration may be of most use in excluding certain potential pathogens (e.g., methicillin-resistant *S. aureus*) and providing information about the antimicrobial susceptibility spectrum of isolated pathogens. Studies of postintubation tracheal aspiration show this to be a reliable alternative to other techniques with the advantage of low cost and speed (recalling that specimens must be obtained prior to antimicrobial therapy whenever possible).

Consideration should be given to performing an invasive procedure to better assess the diagnosis of pneumonia and potential pathogens in the following circumstances: an immunocompromised patient with a broad range of potential pathogens (e.g., heart or lung transplant patient), a critically ill patient with severe hospital-acquired pneumonia (see below), and a patient whose condition does not improve with empiric antimicrobial therapy.

Clinicians should always consider other potential causes of fever and pulmonary infiltrate in the hospitalized patient—including atelectasis, acute radiation pneumonitis, large-volume gastric aspiration, pulmonary embolus with infarction, lung contusion (in trauma patients), pulmonary hemorrhage, and acute respiratory distress syndrome with diffuse alveolar damage.

THERAPY

General Considerations

Despite the development of broad-spectrum antibiotic agents, nosocomial pneumonia continues to carry an unacceptably high mortality. The ATS/IDSA recommendations should be considered general guidelines, for the following reasons: (1) new antibiotics continue to be approved for the treatment of nosocomial pneumonia (e.g., cefepime, linezolid); (2) the spectrum of pathogens causing nosocomial pneumonia varies among hospitals (e.g., frequency of *Legionella*, *Acinetobacter* spp.); (3) the antimicrobial susceptibility spectrum of nosocomial pathogens varies among hospitals (e.g., frequency of MRSA); and (4) the role of invasive techniques to diagnose nosocomial pneumonia remains incompletely defined.

Initial empiric therapy of presumed nosocomial pneumonia may be guided by an assessment of disease severity, the presence of risk factors for specific organisms, and time of onset of nosocomial pneumonia (Fig. 130-2; Tables 130-7, 130-8, and 130-9). An empiric therapy regimen should include agents that are from a different antibiotic class than the

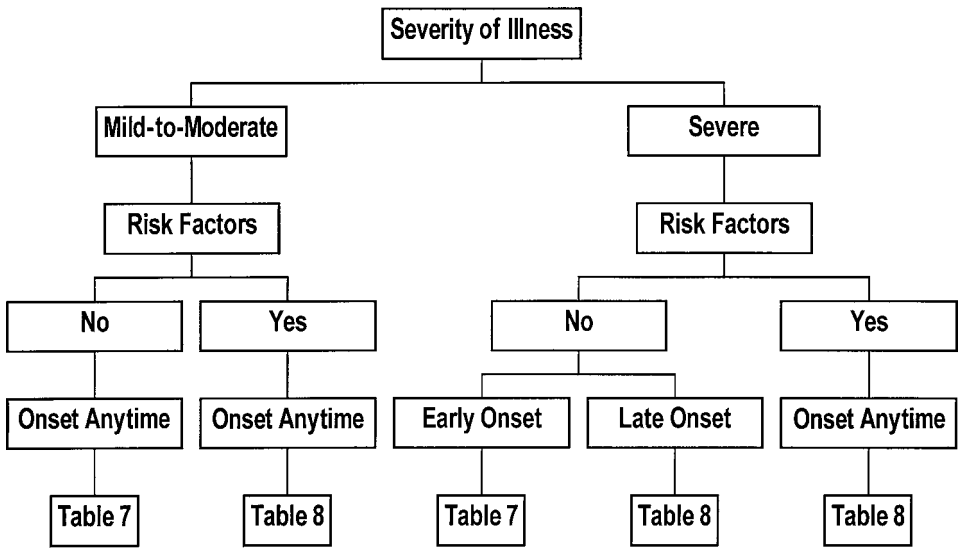

Figure 130-2 Algorithm for classifying patients with nosocomial pneumonia. Specific drugs and doses, recommended in Tables 130-7, 130-8, and 130-9, are adapted from the American Thoracic Society Consensus Statement and represent the views of the authors. Doses provided are for an adult of average weight and normal renal and hepatic function. Doses may need to be adjusted depending on the patient's weight, age, renal function, hepatic function, use of interacting agents, and other factors. Physicians should be thoroughly familiar with the guidelines in individual drug manufacturers' inserts regarding dosing, drug interaction, contraindications, precautions, and administration.

patient has recently received. Antimicrobial therapy should always be prescribed with adequate doses (e.g., loading doses where appropriate) to optimize efficacy. The choice of a specific agent will depend on several factors. The first is the spectrum of antimicrobial susceptibility of respiratory pathogens causing nosocomial pneumonia at one's health care facility. It is important for all health care facilities to periodically review the pathogens causing nosocomial pneumonia and their susceptibility patterns and disseminate this information to clinicians. Second, a history of allergic reactions to antimicrobials should be obtained from all patients. Because of the possibility of cross reactivity between β-lactam antibiotics, the use of a cephalosporin in a penicillin-allergic patient should be considered only if the benefit exceeds the risk. Third, antimicrobial therapy should be chosen to minimize drug interactions. Fourth, in patients with renal or hepatic dysfunction, specific drugs may be chosen to minimize the need for dose adjustment. Fifth, potential drug toxicities may provide relative contraindications to use in specific patients (e.g., avoidance of aminoglycosides in patients with neuromuscular disorders or avoidance of aminoglycosides in patients predisposed to renal dysfunction). Sixth, intrinsic patient factors—including age, pregnancy, and breast-feeding—may limit the choice of antibiotics. Finally, if several equally efficacious and safe choices exist, the least costly regimen should be instituted.

The mechanism of bacterial action may be relevant in antibiotic selection and dosing. In general, bactericidal rather than bacteristatic antibiotics are preferred. β-Lactam antibiotics (penicillins, cephalosporins, carbapenems, and monobactams) and vancomycin are bactericidal in a time-dependent fashion. Quinolones and aminoglycosides, which are bactericidal in a concentration-dependent fashion, exhibit killing more rapidly at high concentrations. In general, bactericidal antibiotics exhibit a prolonged postantibiotic

Table 130-9

Patients with Severe Nosocomial Pneumonia with Risk Factors, Onset, or Patients with Severe Nosocomial Pneumonia, Late Onset*†

effect in which bacterial replication is suppressed for a period after antibiotic levels have fallen below inhibitory concentrations. These pharmacologic features may lead to specific dosing recommendations such as the use of single daily dosing of aminoglycosides.

A controversial area in the treatment of respiratory infections is the importance of antibiotic penetration into lung tissue. It remains unclear whether concentrations in bronchial secretions or in epithelial lining fluid are relevant for predicting efficacy in patients with pneumonia. Also controversial is the role, if any, of inhaled antibiotics in seriously ill patients with nosocomial pneumonia.

Lower respiratory tract cultures are the key to knowing whether, in an immunologically normal host, antimicrobial therapy can be modified or stopped. De-escalation of antibiotics should be considered once microbiologic data are available and based on the patient's clinical response. Negative results can be used to stop antibiotic therapy in a patient who had cultures obtained in the absence of an antibiotic change since cultures were obtained and for at least 72 hours.

Specific Regimens

Initial empiric therapy for nosocomial pneumonia may be guided by severity, presence or absence of risk factors for specific pathogens, and length of hospital stay before the development of nosocomial pneumonia (Tables 130-7, 130-8, and 130-9). Guidelines have been developed for the management of antimicrobial agents; however the concepts remain the same. In the absence of specific risk factors for colonization with multi-drug resistant pathogens, the most common pathogens of early-onset nosocomial pneumonia are *S. pneumoniae, H. influenzae,* enteric gram-negative bacilli (*E. coli, Enterobacter* species, *Klebsiella* species, *Proteus* species, *S. marcescens*), and *S. aureus.* For these patients, a non-pseudomonal third-generation cephalosporin or β-lactam–β-lactamase inhibitor combination are generally used. Inducible β-lactamase may cause resistance to cephalosporins to emerge during therapy. Increasing resistance to fluoroquinolones (e.g., in MRSA or *Pseudomonas*) has made this class less useful as sole agents for this indication although recommended by ATS guidelines. The initial use of vancomycin must be considered in patents with gram-positive organisms on gram-stained sputum smear given the risk for MRSA and for penicillin-resistant pneumococcus. This should be modified according to local hospital epidemiology. Linezolid is an alternative to vancomycin, but advantages for VAP due to methicillin-resistant *S. aureus* need to be confirmed in trials larger than those currently available.

In the presence of certain risk factors and in later-onset infections, broader coverage may be warranted. Anaerobic bacteria are frequently isolated from the respiratory tract of patients with witnessed gastric aspiration, recent thoracoabdominal surgery, or the presence of an obstructing foreign body in the airway. The significance of these anaerobes is unclear, however, since the aerobic bacteria are generally more pathogenic. Nevertheless, patients with witnessed gastric aspiration should be treated with a broad-spectrum agent with anaerobic coverage (e.g., piperacillin-tazobactam, imipenem, meropenem) or have a specific anaerobic agent added (e.g., clindamycin).

Prolonged hospitalization, prior antibiotic therapy, and mechanical ventilation in an ICU increase the likelihood of infection with more resistant bacteria, including methicillin-resistant *S. aureus, P. aeruginosa, Enterobacter* species, and *Acinetobacter* species. In such patients, initial empiric therapy should be broad. Although few studies have evaluated severe nosocomial pneumonia, it is reasonable to initiate very broad empiric antibiotic coverage (i.e., including vancomycin, an anti–gram-negative agent, and macrolide) in such patients to treat methicillin-resistant *S. aureus* and *Legionella* species. In such patients, double or combination treatment for

gram-negative bacteria other than *P. aeruginosa* has not been proved to be superior to monotherapy. True synergy has been demonstrated only for the combination of β-lactam antimicrobials and aminoglycosides. Other combinations for gram-negative infection should be used only as part of initial empiric therapy until microbial susceptibility data are available.

Immunocompromised Patients

The preceding guidelines were not designed to provide recommendations for the treatment of patients with immunocompromising conditions such as HIV infection, organ transplantation, neutropenia, hematologic malignancies, or high-dose steroid use. The presentation and etiology of respiratory infection in immunocompromised patients depend on several factors: (1) the nature of specific host defense abnormalities; (2) the duration of immunosuppressing conditions; (3) the presence or absence of latent infections (e.g., cytomegalovirus); and (4) epidemiologic exposures. The patient's overall susceptibility to infection will reflect the net sum of all factors that alter host defenses, including underlying medical conditions, immunosuppressive therapy, and hospital-related interventions (e.g., indwelling lines). This subject is reviewed elsewhere.

PREVENTION

General Preventive Interventions

Prevention of nosocomial pneumonia begins with strict adherence to standard infection control guidelines (Table 130-10). Among the most important infection control guidelines are proper hand cleaning, isolation precautions, and proper disinfection, and sterilization of equipment. Patients with potentially communicable diseases should be rapidly evaluated and placed on appropriate isolation precautions. "Standard precautions" synthesize the major features of universal precautions (blood and body fluid precautions) and body substance isolation and apply them to all patients receiving care in hospitals, regardless of their diagnosis or presumed infection status. Standard precautions apply to blood; all body fluids, secretions, and excretions except sweat, regardless of whether or not they contain visible blood; non-intact skin; and mucous membranes. Standard precautions are designed to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection in hospitals. Standard precautions include handwashing before and after patient contact, whether or not gloves are worn; wearing gloves when touching blood, body fluids, secretions or excretions, and contaminated items; wearing a mask and eye protection or a face shield during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions (e.g., bronchoscopy, arterial line placement); and wearing a gown during procedures and patient-care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.

Airborne precautions are used for patients with a communicable disease transmitted by the airborne route, such as tuberculosis, varicella-zoster virus infections (with the exception of dermatomal zoster in the non-immunocompromised host), and measles. Patients with these diseases should be placed in rooms with the following air-handling characteristics: private room, room at negative pressure with respect to the corridor, air directly exhausted to the outside or

Table 130-10

General Methods to Reduce the Frequency of Nosocomial Pneumonia in Mechanically Ventilated Patients

General methods
Aggressive treatment of patient's underlying disease
Review need and avoid antacids + histamine2 blockers for stress ulcer prophylaxis
Keep patient elevated at ≥30°
Review nutrition regimen and tube feeding procedures
Extubate and remove nasogastric tube as clinically indicated
Controlled use of antibiotics
Respiratory care equipment
Discriminate between equipment with nebulizers and humidifiers
≥48-h circuit changes (tubing and humidifier) for mechanical ventilators with humidifiers; no changes for circuits with heat-moisture exchangers
Proper removal of tubing condensatte and education of staff to prevent washing contaminated condensate into the patient's trachea
No transfer of equipment or devices between patients
Review use and care of in-line medication nebulizers
Infection control
Surrveillance in the ICU
Education and awareness programs on nosocomial infection
Handwashingg and/or barrier precautions
Review technique for suctioning patients; type of catheter used
Review method of condensate hisposal
Use effective methods of disinfection of devices and equipment
Consider selective decontamination of the digestive tract with oral nonabsorbable antibiotics to prevent nosocomial infections

Source: Adapted from Craven DE, Steger KA: Nosocomial pneumonia in the intubated patient: New copncepts on pathogenesis and prevention. Infect Dis Clin North Am *3:843–866, 1989.*

monitored high-efficiency filtration before the air is circulated to other areas of the hospital, and 6 to 12 air exchanges per hour. Personnel caring for patients with known or suspected tuberculosis should don an N-95 respirator before entering into the room. Droplet precautions are used for patients with diseases transmitted by the droplet route, such as pertussis, meningococcal pneumonia, pharyngeal diphtheria, rubella, measles, *H. influenzae* epiglottitis, mycoplasmal pneumonia, and group A streptococcal infections (in infants and young children). Droplet precautions consist of private room and limiting patient transport. Personnel should don a surgical mask when working within 3 feet of the patient. Contact precautions are used for patients infected or colonized by direct contact, transient colonization of the hands of caregivers, or contamination of an inanimate object such as a medical instrument. Diseases requiring contact precautions include varicella-zoster infection, *C. difficile* infection, rotavirus, shigellosis, herpes simplex, methicillin-resistant *S. aureus,* and infection by multi-drug–resistant pathogens.

Many reports attest to the ability of contaminated bronchoscopes to transmit pathogens leading to outbreaks or pseudo-outbreaks. For this reason, all endoscopic equipment should be rigorously cleaned immediately after use and then appropriately disinfected or sterilized.

Selective Decontamination with Antibiotics

In recent years, many studies have tried to determine whether selective decontamination of the digestive tract (SDD) is associated with a decreased incidence of nosocomial pneumonia. The SDD regimens have usually included a combination of nonabsorbable local antibiotics (e.g., an aminoglycoside, polymyxin B, and amphotericin) and intravenously administered drugs (e.g., cefotaxime, trimethoprim, or a quinolone). The local antibiotics have been applied as a paste in the oropharynx, and often also provided orally or through the nasogastric tube.

Craven and Steger summarized all trials employing SDD to prevent lower respiratory tract infection. They noted that despite several favorable reports, two large double-blind, placebo-controlled trials were unable to demonstrate that SDD was beneficial. Concerns have been expressed that the use of SDD may lead to the emergence of antibiotic-resistant pathogens and the lack of effect on the duration of mechanical ventilation or hospital stay and cost-effectiveness. For these reasons, many experts and the CDC do not support the routine use of SDD for all medical and surgical intensive care patients. Additional data will be needed regarding the benefits of SDD in special patient populations, such as those with trauma.

Gram-Negative Pneumonia

Gram-negative pneumonias may be divided into several groups: community-acquired pathogens *(H. influenzae, Klebsiella, Bordetella pertussis),* hospital-acquired pathogens (enteric gram-negative rods, especially *E. coli, Enterobacter, Proteus,* and *Serratia*), and zoonotic pathogens (*Francisella tularensis, Yersinia pestis,* and *P. multocida*). The separation of gram-negative pathogens into community- and hospital-acquired groups is only relative, as any of these pathogens may cause pneumonia in either setting. The community-acquired pneumonias are discussed elsewhere in this text.

Aspergillus, Candida, and Other Opportunistic Mold Infections of the Lung

Georgios Chamilos • Dimitrios P. Kontoyiannis

PULMONARY ASPERGILLOSIS

Aspergillus is a ubiquitous saprophytic mold with worldwide distribution that plays an essential role in recycling carbon and nitrogen. This fungus has a simple biological cycle characterized by a high sporulating capacity, which results in the release of conidia at high concentrations (1 to 100 conidia/m^3) into the atmosphere. *Aspergillus* conidia have a diameter small enough (2 to 3 μm) to reach the lung alveoli. However, despite the fact that humans constantly inhale *Aspergillus* conidia, such conidia are effectively eliminated in immunocompetent individuals.

Epidemiology

Infections by *Aspergillus* species cause a wide spectrum of illnesses in humans depending on the immune status of the host. Hence, in normal hosts, isolation of *Aspergillus* spp. in respiratory secretions generally reflects colonization, not infection. In atopic individuals, the fungus triggers immune phenomena, including allergic rhinitis, asthma, hypersensitivity pneumonitis, and allergic bronchopulmonary aspergillosis (ABPA). In patients with preexisting cavitary pulmonary lesions, saprophytic growth of *Aspergillus* spp. leads to aspergillomas. Finally, in immunocompromised individuals, some *Aspergillus* conidia germinate into the lung to form hyphae, the invasive form of the fungus, which causes a severe, frequently fatal angioinvasive infection called invasive pulmonary aspergillosis (IPA). The degree of fungal invasion, response to antifungal therapy, and outcome of invasive aspergillosis (IA) depend on the type and severity of immunosuppression. In fact, there is a continuum between the colonization seen with aspergilloma and tissue invasion with *Aspergillus*. Thus, in patients with subtle or no immune defects, chronic forms of *Aspergillus* infections in the lung, which are characterized by a benign clinical course over the years with the development of progressive

Table 131-1

Spectrum of Pulmonary Aspergillosis

Clinical Manifestation	Immune Status	Underlying Lung Architecture	Degree of Tissue Invasion
Simple colonization	Normal	Chronic obstructive airway disease	None

§(↓) *Supressed immune response.*

May have features of invasive disease surrounding the cavity. It occurs in two settings with distinct histopathologies and immunopathogenesis: angioinvasive IPA in profoundly neutropenic patients and nonangioinavasive IPA in immunocompromised nonneutropenic individuals, including those receiving corticosteroid-based treatment, recipients of HSCTs with severe graft-versus-host disease (GVHD), patients with AIDS, recipients of solid organ transplants, and patients with chronic granulomatous disease (CGD). Mixed forms and significant overlap exist.

¶ ↓↓↓ *Severely depressed immune response, neutropenia.*

cavitary lesions, systemic symptoms, and minimal or no evidence of parenchymal invasion, have occasionally been described. A less acute form of IA, frequently called subacute IPA, has been described in patients with acquired immunodeficiency syndrome (AIDS) and chronic granulomatous disease (CGD), whereas rapidly progressive IPA has been encountered in severely immunocompromised hosts. The spectrum of pulmonary aspergillosis is described in Table 131-1.

There is no doubt that since it was first described in the 1940s, IA has emerged as the major problem of modern mycology. Currently, IA is a leading cause of death in severely immunocompromised individuals, with mortality rates approaching 70 to 90 percent in patients with leukemia and recipients of hematopoietic stem cell transplants (HSCTs). At the same time, over the past decade, we have witnessed a significant expansion in the antifungal armamentarium with the introduction of agents with anti-*Aspergillus* activity. In addition, new promising nonculture-based diagnostic methods are being developed, and considerable progress has been made in understanding the epidemiology and immunopathogenesis of IA. As a result, a significant portion of this chapter is devoted to IPA, which currently accounts for more than 90 percent of invasive *Aspergillus* infections.

Mycology and Host Defenses

Of the nearly 200 *Aspergillus* spp., around 20 have been encountered as pathogenic in humans. *Aspergillus fumigatus* is the most frequently identified of these species; however, other species, such as *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus nidulans*, have recently emerged as important pathogens in immunocompromised individuals. Notably, *A. fumigatus* is virtually always the cause of allergic pulmonary disease. *Aspergillus* spp. are rapidly growing, hardy molds identified by the appearance of the colony and microscopic examination of the spore-bearing structures. Microscopically, *Aspergillus* spp. are characterized by the production of uniform 4- to 6 μm–wide hyphae with

parallel walls and distinct septa. Dichotomous branching of hyphae occurs at 45-degree angles. A wide range of microscopic appearances may be observed in clinical specimens. Other filamentous fungi, such as *Fusarium* spp. and *Pseudallescheria boydii*, share the same histopathological features with *Aspergillus* spp.

Sputum specimens obtained from patients and examined by direct mounting or KOH and ink may reveal the typical 45-degree branching hyphal fragments of aspergilli, which are often associated with eosinophils and Charcot-Leyden crystals in patients with ABPA. Stained tissue sections reveal regular hyaline septate hyphae that are best observed with the use of periodic acid-Schiff (PAS) and Gomori's methenamine silver (GMS) stain. Fungus ball specimens obtained from cavities connected to open bronchi have hyphae that often appear to be lifeless and stain poorly. Also, although seldom seen, the fruiting heads and conidia may appear to be well formed.

Host Immune Responses

Despite significant improvements, the immunologic mechanisms of host resistance to *Aspergillus* spp. are not completely understood. Protection of the normal host against *Aspergillus* infection is mediated by a highly coordinated response that involves both innate and adaptive immunity.

Innate immunity consists of three main effector cells: (1) regional dendritic cells that orchestrate innate and adaptive immune responses and antigen presentation; (2) pulmonary alveolar macrophages that ingest and kill the inhaled conidia, primarily by nonoxidative mechanisms; and (3) circulating polymorphonuclear and mononuclear cells that mediate hyphal damage, mainly by oxidative killing. Not surprisingly, quantitative and qualitative defects in phagocytic cell function associated with prolonged and profound neutropenia and corticosteroid-induced dysfunction of macrophages and monocytes have long been recognized as the major risk factors for IA.

Humoral factors also participate in the initial events of host response to *Aspergillus* infection. Resting conidia, germinating conidia, and hyphae are all potent activators of both the alternative and classical components of the complement cascade, promoting opsonization and chemotaxis. In addition, C-type lectins, including mannose-binding lectins, surfactant protein A (SP-A), and surfactant protein D (SP-D), which are present in alveolar fluid, enhance chemotaxis, binding, phagocytosis, and oxidative killing of conidia. C-type lectins also appear to be able to agglutinate, immobilize, and inactivate conidia. Importantly, alteration of SP-D and certain polymorphisms in mannose-binding lectins were recently shown to be associated with an increased risk of chronic pulmonary aspergillosis (CPA).

Aspergillus antigens induce activation and maturation of dendritic cells, which play an instrumental role in linking innate and adaptive immune responses against fungi. Following exposure to *Aspergillus*, dendritic cells migrate to the spleen and drain lymph nodes and induce local and peripheral T-helper (Th) cell reactivity to the fungus. Ingestion of *Aspergillus* conidia and hyphae proceeds through distinct phagocytic mechanisms, and elicited immune responses differ depending on the morphotype encountered.

The development of specific Th responses is an essential determinant of the host's susceptibility or resistance to *Aspergillus* infection. Th CD4+ cells are the major effector cells responsible for cell-mediated immune responses against pathogens. Upon stimulation by exogenous antigens, Th cells differentiate into Th1 or Th2 cells, which are morphologically indistinguishable but differ in the pattern of cytokines they produce. Th1 cytokines induce a predominantly cell-mediated inflammatory response, whereas Th2 cytokines facilitate antibody production.

Th1 cytokines include tumor necrosis factor-alpha (TNF-α), interferon-γ, interleukin (IL)-12, and IL-15 and have been shown to confer protection against *Aspergillus* infection in animal models. These cytokines augment superoxide production and enhance the antifungal activity of polymorphonuclear and mononuclear phagocytes against *Aspergillus* spp. In a murine model of IPA, exposure of immunocompetent animals to a sublethal inoculum of *Aspergillus* conidia has been shown to lead to the development of resistance to subsequent systemic infection. The protective Th1 response was characterized by the presence of antigen-specific CD4+ T cells that produced interferon-γ and IL-2. Notably, adoptive transfer of *Aspergillus*-specific CD4+ splenic T cells from these animals conferred protection in naïve animals challenged with the *Aspergillus* conidia. Similarly, dendritic cells pulsed with *Aspergillus* conidia or transfected with conidial RNA can induce Th1-cell priming. Upon adoptive transfer, such cells were protective against IA in mice that underwent allogeneic hematopoietic stem cell transplantation. Thus, dendritic cells may be employed as one of the vaccine strategies against IA.

In comparison, Th2 responses, which are characterized by IL-4 and IL-10 production, have been associated with disease progression, and neutralization of them has been associated with resistance to infection in animal models. Th2 cytokines impair fungicidal activity and hyphal damage mediated by mononuclear cells, resulting in increased susceptibility to acute *Aspergillus* challenge. However, later in the course of *Aspergillus* infection, high-level production of IL-10 may be beneficial by contributing to resolution of the inflammatory response. Recent evidence suggests that IL-10 produced by cells of the innate immune system is responsible for preventing activation of the protective innate effector phagocytic cells, which accounts for fungal latency and persistence.

Cell surface and secreted pattern recognition receptors mediate the development of Th responses. Specifically, signal transduction mediated by toll-like receptors (TLRs) has been shown to play a key role in immunity against aspergillosis. Of the 10 human TLRs identified thus far, TLR2 and TLR4 are involved in the regulation of cytokines that are important to the

pathogenesis of *A. fumigatus*. In a previous study, *Aspergillus* conidia stimulated both TLR2 and TLR4 to induce a Th1 cytokine response, whereas germination of hyphae led to the loss of TLR4-mediated signals; however, TLR2-dependent mechanisms remained intact, induced IL-10 secretion, and ultimately led to a predominant Th2 response. Thus, switching from a proinflammatory to an anti-inflammatory cytokine profile during germination of *Aspergillus* hyphae may represent an escape mechanism by which the fungus evades the host defense.

Another recently identified secreted pattern recognition receptor, the pentraxin PTX3, has been shown to bind to a range of microbial products, including *Aspergillus* conidia, and to confer resistance to the fungus. In addition, PTX3-deficient mice were susceptible to IPA because of impaired recognition of aspergilli by alveolar macrophages and dendritic cells and inappropriate induction of a Th2 response.

Aspergillus Virulence Factors

Uncertainty remains regarding the attributes that mediate *Aspergillus* pathogenicity. Several putative virulence factors in *A. fumigatus* have been identified, including various proteolytic enzymes (elastases, collagenases, trypsin), phospholipases, ribotoxin, hemolysin, gliotoxin, and many other enzymes and toxins. The mycotoxin gliotoxin in particular has received significant attention and been studied extensively. Gliotoxin exhibits immunomodulatory properties, as it has been shown to inhibit the phagocytosis of macrophages, promote apoptosis of macrophages, and block B- and T-cell activation. In addition, some have postulated that the production of catalases, superoxide dismutases, and mannitol by *Aspergillus* may protect the fungus from oxidative damage induced by phagocytic cells. Moreover, the melanin pigment and rigid protein coat layer composed of rodlet fascicles on the *Aspergillus* conidial surface may also confer resistance to phagocytosis. However, molecular studies have yet to identify a single target that meets the Koch's postulates for virulence in IA. On the other hand, recent evidence from comparative genomic analysis across filamentous fungi suggests that *A. fumigatus* virulence results from the immunosuppression or possibly genetic susceptibility of the host rather than from specific, unique fungal determinants. Hence, *A. fumigatus* appears to be a saprotrophic fungus that only becomes pathogenic for very simple biological reasons: It is present in high concentrations in the atmosphere, it grows faster than any other airborne fungi at 40°C, and it can overcome the defense of the host not because of specific virulence mechanisms, but because of the failure of host immune responses. Taken together, these data suggest that approaches targeted at augmenting cellular immunity, such as neutralization of Th2 cytokines, enhancement of Th1 responses, and dendritic cell vaccine–based vaccination, warrant future investigation as therapeutic modalities for invasive *Aspergillus* infections.

Clinical Manifestations

Hypersensitive Reactions

Hypersensitivity lung diseases that result from exposure to *A. fumigatus* allergens include allergic asthma, ABPA, and hypersensitivity pneumonitis. In atopic individuals, inhalation of *Aspergillus* spores triggers an IgE-mediated allergic inflammatory response in the bronchial mucosa, leading to excessive mucus production, bronchial obstruction, and asthma. Similarly, ABPA develops following sensitization to *A. fumigatus* allergens in a unique subset of atopic individuals and patients with cystic fibrosis (CF), who are genetically susceptible for ABPA. The immune response to *Aspergillus* antigens in both patients with allergic asthma and those with ABPA is characterized by a robust Th2 CD4+ response.

In nonatopic individuals, persistent airway colonization and, more rarely, a type of hypersensitivity pneumonitis called *extrinsic allergic alveolitis* can occur as a result of massive or repeated inhalation of *Aspergillus* conidia. Hypersensitivity pneumonitis in these patients manifests with dyspnea because of pulmonary constriction and an influenza-like syndrome with fever, malaise, and fatigue. However, in contrast with other allergic diseases caused by *A. fumigatus*, hypersensitive pneumonitis is characterized by extensive infiltration of neutrophils in the acute phase as a result of a Th1 CD4+ response. Early recognition of these syndromes is important for early initiation of appropriate treatment to prevent progression to permanent lung damage. Table 131-2 summarizes the hypersensitivity syndromes that result from exposure to *Aspergillus*.

Simple Colonization

Although there is no uniform definition of colonization, it should be considered in cases of isolation of *Aspergillus* spp. from cultures of the respiratory tract in patients without concomitant evidence of invasive or allergic disease. Patients with structural lung diseases such as chronic obstructive pulmonary disease (COPD) are at increased risk for persistent *Aspergillus* colonization. Tissue invasion by aspergilli is not a feature of saprophytic colonization, although pulmonary aspergillosis with subsequent dysfunction of host defenses may develop. In fact, *Aspergillus* colonization has been shown to be a marker for the development of IA in immunocompromised individuals, particularly lung and bone marrow transplant recipients, and may precede invasion for up to 3 mo. Quantitative real-time polymerase chain reaction (PCR) holds promise as a tool for distinguishing *Aspergillus* colonization from invasive infection.

Allergic Bronchial Asthma

Asthmatic patients may become sensitized to *Aspergillus* conidia as a consequence of thick bronchial secretions that trap fungal spores. These spores seldom germinate in the bronchial airways. Allergic bronchial asthma develops in patients who are atopic and is perpetuated by inhalation of *Aspergillus*

Table 131-2

Hypersensitive Reactions to *Aspergillus*

	Asthma	ABPA	Extrinsic Allergic Alveolitis
Pathology	Hypertrophied mucus glands	Colonization of airways, viscid mucoid impaction, tissue eosinophilia	Lymphocytic infiltration of interstitium, noncaseating granuloma
Radiographic features			
Early	Normal, hyperinflation	Migratory peripheral infiltrates, atelectasis, bronchiectasis	Diffuse alveolar-interstitial infiltrates
Late	Normal, hyperinflation	Fibrosis	Reticulonodular interstitial opacities
Skin test reactions to *Aspergillus* antigens			
Immediate	Positive	Positive	Positive
Delayed	Negative	Positive	Positive
Peripheral eosinophilia	Negative*	Positive	Negative
IgG *Aspergillus* precipitins	Positive (up to 25%)	Positive	Positive
Serum IgE levels	Normal or mildly elevated	Marked elevation	Normal

** Occasionally positive.*

antigens, which typically cause acute bronchospasm. The presence of transient infiltrates has been described during the immediate reaction but is not frequent. As is typical in asthma of other etiologies, eosinophils and serum IgE antibody are increased. Immediate skin reactions to *Aspergillus* antigens are positive, but specific precipitating antibodies (IgG) are usually negative. Avoidance of exposure to *Aspergillus* spores can diminish the frequency and severity of bronchospasm in this group of patients.

ABPA

Immunopathogenesis-Risk Factors

It has been recently proposed that ABPA develops in genetically susceptible patients with asthma or CF because of increased activity of *A. fumigatus*–specific Th2 CD4+ cells. Hence, in addition to a history of atopy, predisposing factors for ABPA include immunogenetic human leukocyte antigen (HLA)–distinct phenotypes (e.g., HLA-DR 2– and HLA-DR 5–specific alleles), mutations in the CF transmembrane conductance regulator (CFTR) gene, polymorphisms of the collagen region of the surfactant protein A2, and/or other collectins (e.g., mannose-binding lectins). In addition, particular physicochemical characteristics of respiratory secretions and a history of environmental exposure may play a role in ABPA pathogenesis.

In patients with ABPA, inhaled *A. fumigatus* conidia are able to colonize, persist, and germinate, leading to growth of hyphae in mucus plugs, which are often seen in expectorated sputum. During this process, *A. fumigatus* releases a panel of proteases and other toxins that are capable of further compromising mucociliary clearance, breaching the airway epithelial barrier, and activating the immune system in the lung.

IgE molecules on the surface of mast cells initially recognize *A. fumigatus* antigens. Binding of these antigens with IgE causes mast cell degranulation, releasing mediators that cause vasodilatation and vascular leakage so that serum components, including anti-*Aspergillus* IgG, enter the bronchi and combine with *Aspergillus* antigens to form IgG-containing immune complexes. These complexes activate the complement cascade leading to inflammation and pulmonary damage. Importantly, investigators have identified specific *Aspergillus* antigens capable of inducing IgE and IgG responses in patients with ABPA but not in control patients who did not have ABPA, implying that an aberrant host response occurs in patients with ABPA.

The key element in the immunopathogenesis of ABPA appears to be an abnormal T-lymphocyte cellular immune

response to *A. fumigatus* conidia. Hence, *A. fumigatus* allergens released by mycelia are processed by antigen-presenting cells bearing HLA-DR 2 or HLA-DR 5 and presented to T cells within the bronchoalveolar lymphoid tissue. The T-cell response to *Aspergillus* allergens is then shifted toward a Th2 CD4+ cell response with synthesis and secretion of the cytokines IL-4, IL-5, and IL-13. In addition, production of chemotactic cytokines (chemokines) by inflammatory cells, including monocyte chemoattractant protein-1 (MCP-1/CCL2), eotaxin (CCL11), IL-8, and macrophage inflammatory protein-1α (MIP-1α/CCL3) appears to promote the Th2 cell response. In addition, T cells, B cells, natural killer cells, and eosinophils may be hyper-responsive to IL-4. This leads to a positive-feedback amplification loop of Th2 CD4+ cells, synthesis of IL-4, and polyclonal activation of CD23+ CD86+ B cells.

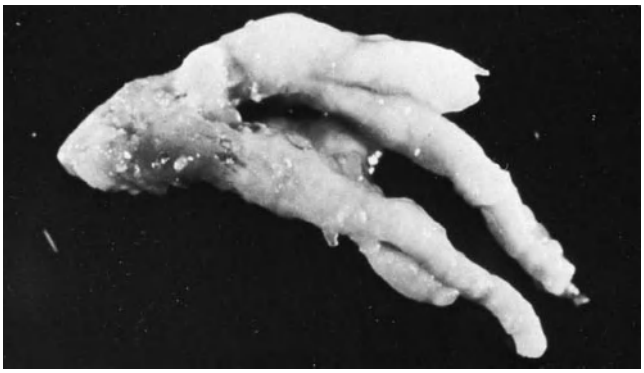

Figure 131-1 Mucus plug expectorated by a patient with ABPA. Of note is the tapering, cylindrical shape with branching characteristic of the parent bronchi. *(Courtesy of Frederic Askin, Chapel Hfl l, NC.)*

Clinical Features

ABPA is a hypersensitivity disease of the lung that is virtually almost always related to *A. fumigatus* (discussed in detail in Chapter 49). Some key points are highlighted here. Seven to 14 percent of patients with poorly controlled asthma and 7 to 9 percent of those with CF meet the diagnostic criteria for ABPA. In fact, nearly all patients with ABPA have a history of chronic asthma. Patients rarely present without symptoms or physical findings despite having radiographically detected abnormalities. Clinically, ABPA manifests with episodic wheezing, malaise, low-grade fever, cough, sputum containing brown flecks and plugs, chest pain, pulmonary infiltrates, and sputum and blood eosinophilia. Patients may have a history of recurrent pneumonia and frequent use of antibiotic therapy. Mucus plugs form in the proximal bronchi and can progress to mucoid impaction, resulting in atelectasis with transient pulmonary infiltrates. Mucus plugs often yield aspergilli in culture (Figs. 131-1 and 131-2). As ABPA progresses, central bronchiectasis becomes a dominant feature of the disease and may result in chronic bronchorrhea and occasionally hemoptysis, development of clubbing, and fixed, characteristic radiographic abnormalities. In patients with CF in particular, ABPA often manifests with hemoptysis and may be complicated by pneumothorax.

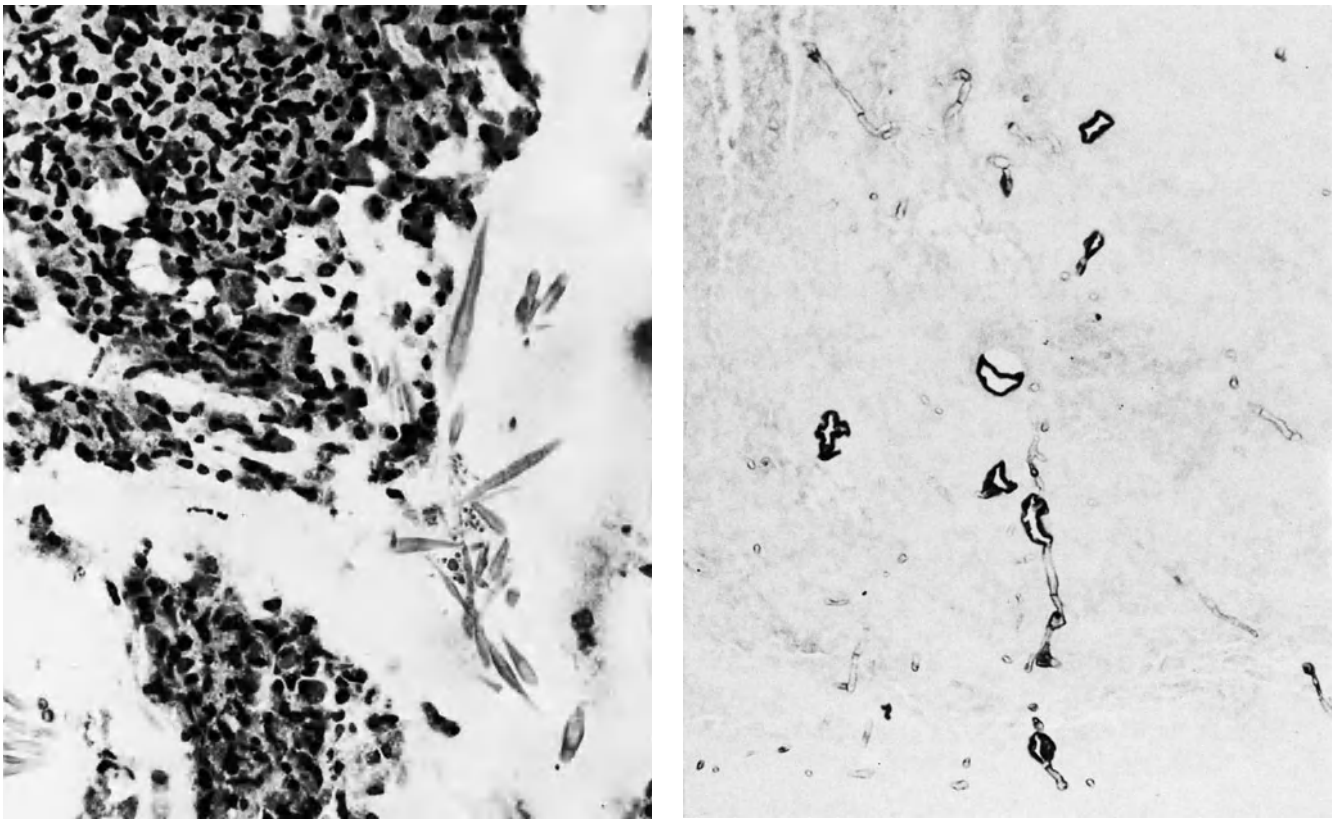
Radiographic Findings

The radiographic features of ABPA have an essential role in diagnosis, as they may distinguish ABPA from simple chronic asthma. Pulmonary infiltrates in patients with ABPA are initially transient, but they ultimately progress to permanent radiographic changes. In many instances, the ring sign indicative of bronchial wall thickening, "parallel" shadows or "tram lines" suggestive of bronchiectasis, and branching "finger-in-glove" opacification of the dilated bronchi because of mucoid impaction are seen on regular chest radiographs of patients with ABPA (Fig. 131-3). Such ABPA lesions are either focal or bilateral and tend to occur more frequently in the upper lobes. Late radiographic findings in patients with ABPA include cavitation, local emphysema, contracted upper lobes, and honeycomb fibrosis. However, the presence of proximal bronchiectasis (Figs. 131-3 and 131-4), which is characterized by normal filling of bronchi distal to the saccular bronchial lesion, is considered a hallmark for diagnosis of ABPA.

Chest computed tomography (CT) has been a significant aid in diagnosing ABPA because it is more sensitive than regular chest radiography; however, there are no pathognomonic CT findings for this entity. Besides central bronchiectasis, CT findings highly suggestive of ABPA include the presence of varicose or cystic bronchiectasis of segmental and subsegmental bronchi (90 percent in ABPA versus 30 percent in simple asthma), mucoid impaction of the segmental and subsegmental airway (67 percent in ABPA versus 4 percent in simple asthma), and small airway abnormalities such as centrilobular nodules and tree-in-bud opacities (93 percent in ABPA versus 28 percent in simple asthma). In patients with CF especially, CT diagnosis of ABPA is particularly challenging, as there is a significant overlap in the radiographic features of both entities. In fact, the presence of high-attenuation mucus plugs because of dystrophic calcification is the only CT finding that favors the diagnosis of ABPA in patients with CF.

Diagnosis

The "classic" patient with ABPA fulfills the criteria listed in Table 131-3. It has been suggested that the minimal essential criteria for diagnosis of ABPA include the presence of: (1) asthma; (2) immediate cutaneous reactivity to *Aspergillus* antigens; (3) elevated total serum IgE levels (greater than 1000 U/ml); (4) elevated serum IgE and IgG levels to *A. fumigatus;* and (5) central bronchiectasis. However, asymptomatic pulmonary involvement occurs in patients with ABPA and may lead to diagnostic uncertainty, delayed diagnosis, and irrevocable structural lung damage. Furthermore, corticosteroid-based therapy for asthma may mask the signs of ABPA, allowing a progressive decline in pulmonary function. Because the above criteria may not apply in such cases, some have proposed that serologic evidence (all three



A *B*

Talbot.)*

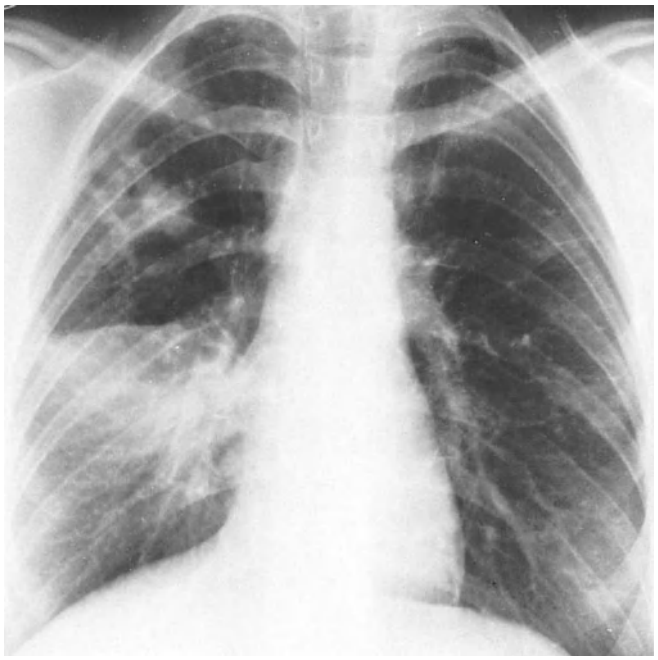
serologic tests listed in Table 131-3 and immediate skin reactivity test to *Aspergillus* antigens need to be positive) without the presence of bronchiectasis may be sufficient to support early diagnosis of ABPA. In addition, the diagnostic criteria for ABPA in patients with CF were recently modified, because there are overlapping features between these entities. The new criteria consist of: (1) clinical and/or pulmonary function deterioration from baseline status; (2) positive immediate cutaneous reaction to *A. fumigatus* antigens or elevated serum IgE *A. fumigatus* antibody level; (3) elevated total IgE level greater than 1000 U/ml; (4) elevated serum IgG *A. fumigatus* antibody level or positive *A. fumigatus* precipitins; and (5) abnormal chest imaging findings or a change in baseline abnormalities.

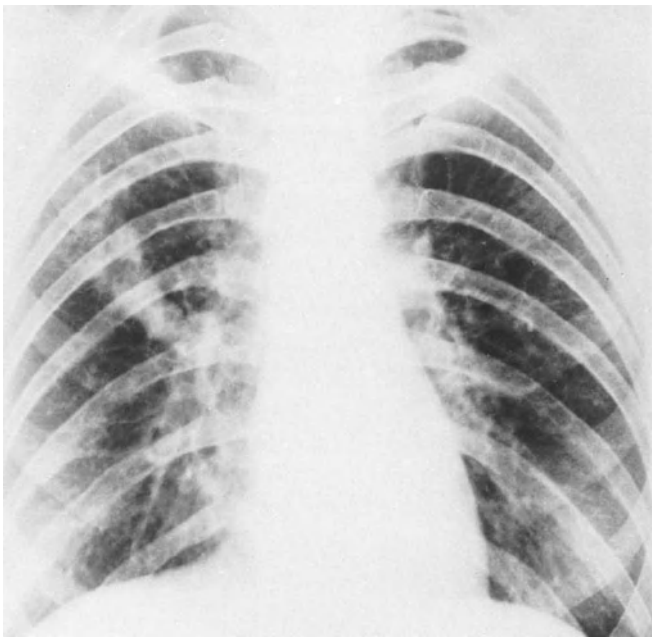
Important clinical clues that should alert clinicians to the possibility of ABPA include refractory asthma or asthma with any of the following features: bronchiectasis, radiographic infiltrates, prominent eosinophilia, and expectorated brown plugs that may contain eosinophils or hyphae in 50 percent of cases (see Fig. 131-2). In addition, in patients with CF, prominent wheezing is considered to be suggestive of ABPA. Rarely, ABPA may be caused by non-*fumigatus* aspergilli or other fungi; in such cases, the serologic tests will be negative.

Because no single clinical or immunologic feature is diagnostic for ABPA, this disease remains underdiagnosed. Until recently, serologic diagnosis of ABPA was based on *Aspergillus* crude extracts, which are cumbersome, lack reproducibility, and frequently crossreact with other antigens. However, recent studies indicate that standardized recombinant *A. fumigatus* allergens have the potential to substantially increase the specificity and sensitivity of diagnosis of *A. fumigatus*–related diseases, including ABPA. Several recombinant *A. fumigatus* allergens, including Aspf1, Aspf2, Aspf3, Aspf4, Aspf6, and Aspf16, show high specificity for the detection of sensitization to *A. fumigatus* and for diagnosis of ABPA and appear to be superior to crude *Aspergillus* allergen extracts. However, because the sensitivity of each recombinant *A. fumigatus* allergen is suboptimal, use of a panel of recombinant allergens is required to increase the sensitivity of diagnosis of ABPA. Further standardization and development of commercially available immunoassays containing a combination of these allergens holds promise for improving the diagnosis of ABPA.

Because patients with CF are at high risk for ABPA, initiation of annual screening at high school age for ABPA with monitoring of serum total IgE levels has been recommended in patients with IgE levels greater than 500 U/ml. Likewise,



A



B

C

Figure 131-3 A 23-year-old woman with documented ABPA. *A*. Chest radiograph showing mucoid impaction in the right upper lobe and alveolar consolidation in the right middle lobe. *B*. Eight months later, the alveolar consolidation has resolved, and the appearance of the mucoid impaction in the right upper lobe has changed. *C*. Talbot.)*

because treatment with corticosteroids has a significant impact on disease progression, screening CT has been advocated for asthmatics with a skin-prick hypersensitivity test positive for *A. fumigatus* to identify ABPA at an early stage.

Histopathology

Because the diagnosis of ABPA is based on clinical and laboratory criteria, use of lung biopsy to confirm the diagnosis is usually not required. The presentations of the hypersensitivity syndrome associated with fungi are discussed in detail in Chapter 49. Some of the histopathological presentations associated with ABPA overlap those of invasive *Aspergillus* infection. Thus, eosinophilic infiltrates may be present in patients with invasive *Aspergillus* infection as well as in those with other allergic lung entities, such as Loeffler's syndrome, tropical eosinophilic pneumonia, and chronic eosinophilic pneumonia (see Chapter 72). Mucoid impaction associated with ABPA or other fungi may predispose patients to superinfection (see Figs. 131-1 and 131-2). Necrotizing granulomata in association with the presence of *Aspergillus* spp. in asthmatic patients may be observed and is considered part of the ABPA syndrome. The histopathological distinction between

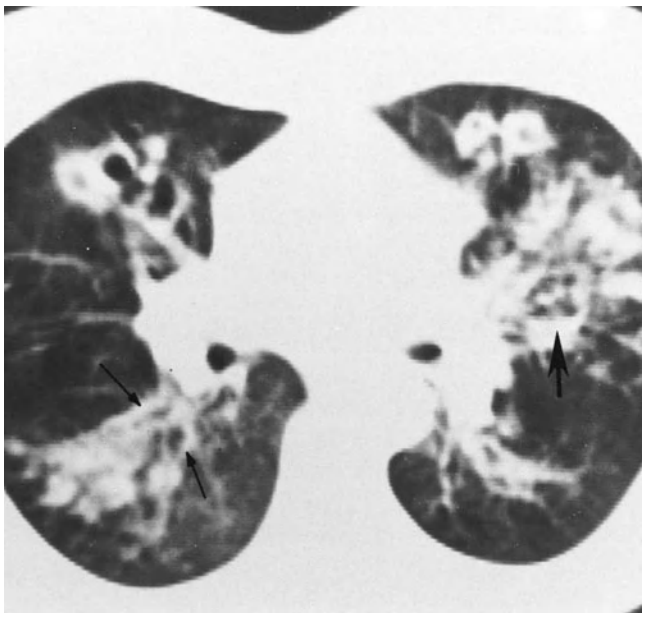


Figure 131-4 Proximal saccular bronchiectasis characteristic of ABPA. The CT scan reveals multiple rounded, dilated bronchi (small arrows). Note the air-fluid level (large arrow). *(Courtesy of S. Albelda and G. H. Talbot.)*

ABPA, with fungal elements restricted to the airways, and semi-invasive or fully IA may be obscured by tissue necrosis or poor granuloma formation. These presentations are discussed further below and in Chapter 49.

Table 131-3

Criteria for the Diagnosis of ABPA

Primary
Episodic bronchial obstruction (asthma)
Peripheral blood eosinophilia (>1000/mm^3)
Immediate type skin reactivity to *Aspergillus* antigens*
Precipitating serum antibodies (precipitins) against Aspergillus antigens*
Elevated serum IgE concentrations (>1000 ng/ml)*
Elevated serum IgE and/or IgG antibodies specific to *A. fumigatus**
History of pulmonary infiltrates (transient or fixed) on chest radiographs or CT scans
Central bronchiectasis on chest CT scans
Secondary
A. fumigatus in sputum (by repeated culture or microscopic examination)
History of expectoration of brown plugs or flecks
Arthus reactivity (late skin reactivityy) to *Aspergillus* antigen

** Test must be positive for serologic diagnosis in asymptomatic patients.*

Treatment

ABPA may progress through five stages based on clinical, serologic, and radiographic findings, which are summarized in Table 131-4. It is important to note that the first four stages are potentially reversible without long-term sequelae; only the last stage, which is characterized by fibrosis and bronchiectasis, is irreversible. The goals of therapy for ABPA are to treat acute exacerbations of disease and prevent the development of fibrosis and bronchiectasis. Therefore, early diagnosis of ABPA before permanent lung damage occurs is critical. Therapeutic modalities for ABPA include oral corticosteroids, metered-dose inhaler medications, and antifungal agents.

Use of oral corticosteroids remains the cornerstone of treatment of ABPA. These agents suppress the inflammatory response provoked by *Aspergillus* infection rather than eradicate the fungus. Recommended corticosteroid doses for acute exacerbations of ABPA are 0.5 to 1.0 mg/kg of prednisone equivalent daily for 1 to 2 weeks followed by 0.5 mg/kg every other day for 6 to 12 weeks. The physician should then attempt to taper the patient's corticosteroid dosage. However, some patients cannot be successfully weaned of corticosteroids and require a daily maintenance dose of at least 7.5 mg.

Increasing, use of itraconazole, an azole antifungal with activity against *Aspergillus* spp., has been employed as adjunctive fungal antigen-reducing therapy for ABPA, especially in patients with frequent relapses or corticosteroid dependence. A recent randomized controlled study reported that oral administration of itraconazole (200 mg twice daily) was beneficial in terms of significant improvement of symptoms, pulmonary function, chest radiographic findings, and serum IgE levels in asthmatic patients with ABPA; uncontrolled studies suggested a similar benefit in patients with CF and ABPA. However, use of itraconazole requires determination of drug levels to ensure adequate absorption and poses significant issues with long-term tolerability and drug-drug interactions. Voriconazole is a newer triazole that has shown improved fungicidal activity against *Aspergillus* spp. and better bioavailability when compared with itraconazole. However, there are no data available on the role of voriconazole in the treatment of ABPA. In addition, voriconazole is also associated with significant drug-drug interactions.

Use of inhaled corticosteroids may help control the symptoms of asthma but does not prevent episodes of eosinophilic infiltration and mucus impaction and is generally thought to have no influence on progressive lung damage. Inhaled bronchodilators such as β agonists, anticholinergics, and leukotriene antagonists may be used to treat asthma-related symptoms. Inhaled antifungal agents such as nystatin and amphotericin B deoxycholate (AMB-D) may offer temporary suppression of colonization, but their penetration into plugged bronchi is limited, and recolonization rapidly occurs once therapy ends. Meticulous bronchial toilet is important for clearance of *A. fumigatus* from the airway. Also, physical therapy with postural drainage is an important adjunctive

Table 131-4

Staging System for ABPA

Stage	Symptoms	Radiographic Features	Laboratory Features	Management
I. Acute	Fever, productive cough, wheezing	Pulmonary infiltrates, mucoid impaction	Blood eosinophilia, elevated serum IgE level, positive skin test	Corticosteroids to achieve remission
II. Remission	Asymptomatic	Normal	Decrease in IgE and blood eosinophilia	Careful follow-up
III. Exacerbation	All or some of acute-stage symptoms	All or some of acute-stage findings	At least a doubling of IgE in asymptomatic patients and an increase in IgE in symptomatic patients	Retreat with steroids to induce remission
IV. Corticosteroid dependent	Syymptomatic steroid-requiring asthma	Variabble	Usually continued elevation of IgE	Long-term steroids to control asthmatic symptoms and keep IgE levels at baseline
V. Fibrotic	Severe dyspnea, fibrotic lung disease, as well as bronchospasm	Pulmonary fibrosis	Restrictive plus reversible and irreversible obstructive function tests; may have continued increased IgE	Long-term corticosteroid use

Chest *87:334–339, 1985; and Patterson R, Greenberger PA, Radin RD, et al: Allergic bronchopulmonary aspergillosis: Staging as an aid to management.* Ann Intern Med *96:286–291, 1982.*

treatment. Increased hydration, use of expectorants, and in selected patients, bronchial lavage may aid in viscid mucus clearance. Avoidance of environmental reservoirs of *Aspergillus* spp. such as compost heaps, grain silos, and decayed organic matter may help prevent exacerbation of ABPA. In patients with CF ABPA differentiating between a bacterial exacerbation of CF and an ABPA flare is important, because initiation of corticosteroids may have detrimental effects in patients with bacterial infection; a serologic assessment is essential as part of this evaluation.

Immunotherapy with injection of conventional allergens has not been shown to be of value for ABPA. However, newer immunomodulatory approaches, including immune modulation toward a Th1 response by using *A. fumigatus* synthetic peptides, DNA-based vaccines, and immunostimulatory molecules such as cytosine polyguanine oligonucleotides, are being explored in animal models with promising results.

Monitoring of treatment efficacy and toxicity is imperative. Long-term follow-up of patients with ABPA has shown that increasing serum levels of IgE are often a harbinger of a clinical flare of the disease and that the levels decline with a clinical response to corticosteroids. Thus, a prudent course of action is to determine baseline serum IgE levels when ABPA has been controlled by corticosteroid-based therapy and then monitor serum IgE levels regularly (every 1 to 2 months). Total serum IgE levels usually should decrease by at least one-third within 6 weeks from the initiation of corticosteroid-based treatment; infiltrates should be resolved after 1 to 2 months, and the results of pulmonary function tests should improve. Although serum IgE levels seldom return to normal, reinstitution of corticosteroids should be considered even in asymptomatic patients if the serum IgE level is double that of the baseline value. In patients with symptomatic ABPA, chest radiographs should be obtained every 3 months during the first year of follow-up and yearly thereafter; pulmonary function tests also should also be performed yearly. However, no one has identified certain prognostic indicators for progression or regression of ABPA, and whether treatment of asymptomatic flares alters the natural history of the disease remains controversial.

Bronchocentric Granulomatosis

Bronchocentric granulomatosis is a rare hypersensitivity syndrome that is characterized histologically by replacement of

bronchial mucosa with necrotizing granulomatous tissue. Also, eosinophilic infiltration of bronchioles and fibrosis are prominent, whereas there is no evidence of *Aspergillus* invasion. *Aspergillus* hyphae have been demonstrated within the lesions in approximately one-half of the cases of bronchocentric granulomatosis. This syndrome is associated with asthma in one-half of the patients described and likely represents a severe manifestation of ABPA revealed as a localized pathological reaction rather than the more generalized pulmonary pathology evident in patients with ABPA. Patients typically present with chronic symptoms, such as malaise, cough, low-grade fever, dyspnea, dull chest pain, and hemoptysis associated with a focal lesion on chest radiographs, often in an upper lobe. Occasionally, radiographic findings of multiple nodular masses simulate metastatic carcinoma. Diagnosis of bronchocentric granulomatosis is made based on biopsy or often retrospectively after removal of the lesion, which is curative. Some patients may need corticosteroid-based therapy for ABPA, especially those with multifocal lesions.

Extrinsic Allergic Alveolitis

Heavy or repeated exposure to *Aspergillus* conidia and mycelia may result in a hypersensitivity reaction affecting the alveoli in nonatopic individuals known as *extrinsic allergic alveolitis.* Malt workers, distillers, brewers, and others exposed to moldy straw or grain have suffered attacks consisting of cough, dyspnea, fever, chills, myalgia, and malaise 4 to 8 h after exposure to *Aspergillus* antigens. Repeated exposure may lead to malt worker's lung or farmer's lung or to the development of granulomatous disease or interstitial fibrosis. The immunopathogenesis of extrinsic allergic alveolitis involves cell-mediated immunity (type IV response) and immune complex deposition (type III response) and likely involves an intricate interaction between these immune mechanisms.

Radiographic changes in the acute syndrome include diffuse alveolar-interstitial infiltrates that may resolve with removal of the inciting antigen. Patients with chronic extrinsic allergic alveolitis may have a fine reticulonodular interstitial infiltrate that may progress to pulmonary fibrosis with honeycombing. Serum IgG antibodies (precipitins) against *Aspergillus* antigens are present in patients with extrinsic allergic alveolitis; however, the serum IgE level is typically normal. Skin tests usually demonstrate an Arthus reaction at 4 to 8 h and occasionally may be preceded by an immediate wheal and flare reaction and followed by a delayed reaction (36 to 48 h afterward). Removal or avoidance of the source of antigen exposure is crucial in the management of extrinsic allergic alveolitis, as spontaneous recovery often ensues once exposure has ended. Administration of corticosteroids is helpful in aiding the resolution of acute symptoms and reduces the likelihood of structural damage. However, corticosteroids are not helpful once fibrosis has developed.

Aspergilloma

Saprophytic colonization of a parenchymal lung cavity by *Aspergillus* is referred to as *aspergilloma*,*mycetoma*, or a *fungus ball.* A fungus ball consists of both dead and living mycelial elements, fibrin, mucus, amorphous debris, inflammatory cells, and degenerating blood and epithelial elements. The mycelial mass may lie free within the cavity or be attached to the cavity wall by granulation tissue. Spontaneous shrinkage or disappearance of aspergilloma has been reported in 7 to 10 percent of cases and is often associated with bacterial superinfection of the cavity. Aspergillomas only rarely increase in size. Most aspergillomas are caused by *A. fumigatus*, but some, especially in patients with diabetes mellitus, are caused by *A. niger*, in which case oxalic acid crystals may be seen in the sputum.

Pathophysiology

The pathogenesis of aspergilloma usually involves colonization and proliferation of the fungus in a preexisting pulmonary cavity (secondary aspergilloma). The cause of a preexisting cavity is most commonly prior cavitary tuberculosis; aspergilloma has been reported in 11 to 17 percent of patients with post-tuberculosis cavities. However, an aspergilloma may complicate a wide spectrum of cavitating pulmonary diseases, such as sarcoidosis, histoplasmosis, blastomycosis, AIDS pneumonia (especially in cases of atypical *Pneumocystis jiroveci* pneumonia), and/or lung abscess, pulmonary or bronchial cysts, bronchiectasis, pulmonary fibrosis, asbestosis, adenocarcinoma, ankylosing spondylitis, rheumatoid nodules, cyanotic heart disease, and pulmonary infarction.

Primary aspergilloma, which arises within the bronchial tree with proliferation of *Aspergillus* leading to a pulmonary cavity, is far less common. The clinical conditions leading to the initiation of a cavitary process and formation of a fungus ball include IPA, chronic necrotizing pulmonary aspergillosis (CNPA), and ABPA. IPA may lead to primary aspergilloma during bone marrow recovery, as the host is able to mount an inflammatory response and ward off the fungus. Pneumothorax may be a severe complication of pulmonary mycetoma that is reported as a rare occurrence in patients with hematological malignancies. ABPA may cause bronchiectasis in the chronic phase of the disease and result in aspergilloma secondary to growth of a fungus distal to a plugged bronchus. In fact, aspergillomas have been found in 7 percent of patients with ABPA in one study. Thus, aspergilloma may provide a stimulus for the perpetuation of ABPA.

Clinical Features and Diagnosis

Hemoptysis is the typical manifestation of aspergilloma, as it is seen in 50 to 90 percent of patients. Hemoptysis is typically infrequent and mild but is occasionally massive or even fatal. The presence of any other symptoms, including dyspnea, fever, malaise, and weight loss, in patients with aspergilloma should be attributed to the underlying cavitary pulmonary disease or bacterial superinfection or suggest the presence of an overlapping IPA syndrome such as CNPA. The diagnosis is usually made based on clinical and chest radiographic features

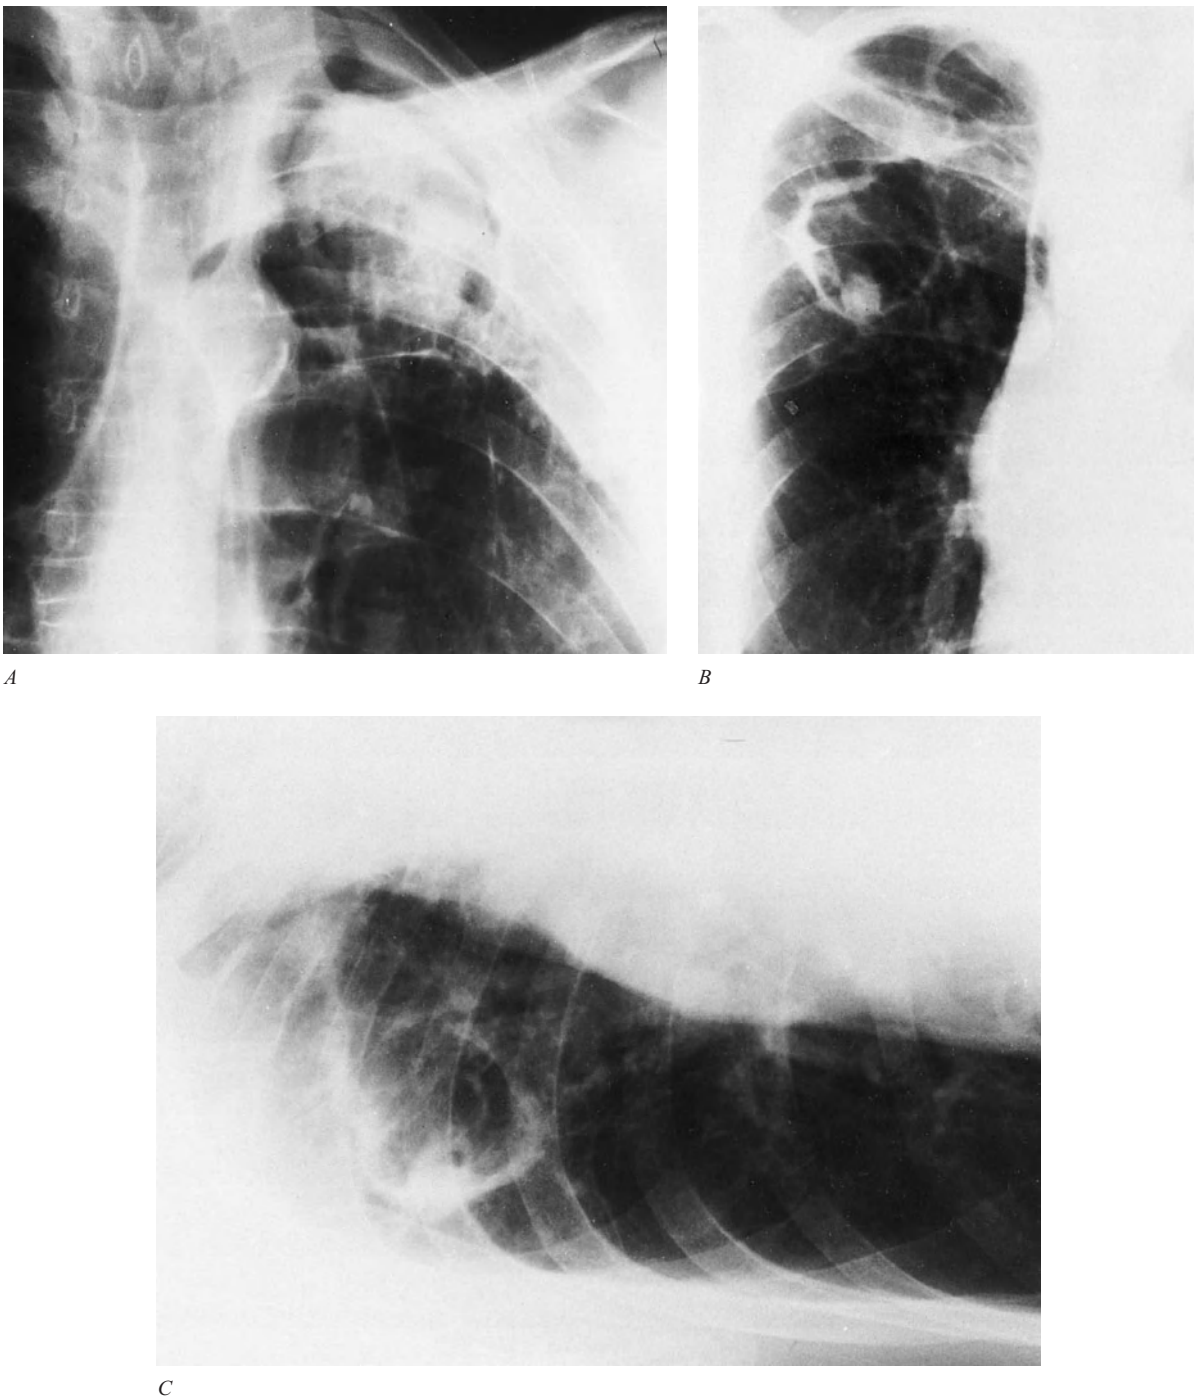

Figure 131-5 Radiographic appearances of pulmonary aspergillomas. *A*. A 51-year-old man with a history of tuberculosis showing the classic crescent-shaped patch of air (Monod's sign) as well as marked pleural thickening. *B*. A 49-year-old man with ankylosing spondylitis in whom an aspergilloma developed inside a thin-walled cavity. *C*. Decubitus film of the patient in (*B*) showing a fungus ball that moved when the patient changed position. *(Courtesy of S. Albelda and G. H. Talbot.)*

coupled with serologic evidence of precipitating antibodies to *Aspergillus* spp.

Chest radiographs reveal a solid round mass within a cavity (3 to 5 cm in diameter) partially surrounded by a radiolucent crescent (Monod's sign; Fig. 131-5). Movement of the fungus ball within the cavity may be appreciated when comparing upright and decubitus images. A solitary lesion in the upper lung fields is the most common radiographic feature of aspergilloma, as preexisting tuberculosis cavities are the most common predisposing condition. However, aspergillomas can be bilateral and multiple. In many cases, chest CT may be helpful in further delineating the radiographic

features of an aspergilloma that are not apparent on chest radiographs. On CT scans, globules of gas are often seen within the interstices of the hyphal mass. CT angiography may also provide useful information for patients with hemoptysis by identifying hypertrophic bronchial arteries that often supply the cystic wall of aspergillomas.

Although sputum cultures are positive for *Aspergillus* in more than one-half of all patients with aspergilloma, it is not a sensitive and specific diagnostic marker. Precipitating antibodies to *Aspergillus* antigens are present in the sera of more than 95 percent of patients with aspergilloma; however, some patients receiving corticosteroids may be seronegative. Eosinophilia, IgE, and skin-test reactivity may be seen in individuals who are allergic to the fungus, but these are not consistent findings. The main challenge for the clinician is to differentiate aspergilloma from other lung conditions, including lung cancer, cavitating Wegener's granulomatosis, a blood clot in a preexisting cavity, a disintegrating hydatid cyst, and a pulmonary abscess, all of which often share radiographic features with aspergilloma. Therefore, a positive precipitin reaction for *Aspergillus* is particularly helpful in establishing the diagnosis of aspergilloma. Clinical judgment and a low threshold for performing a lung biopsy in atypical cases are required.

Predictors of poor prognosis for aspergilloma include a progressive increase in the size and/or number of aspergillomas, severe underlying lung disease with a poor underlying lung reserve, immunosuppressive therapy, AIDS, sarcoidosis, a rising *Aspergillus*-specific IgG titer, and repetitive episodes of severe hemoptysis.

Treatment

There is no consensus on the treatment of aspergilloma because of a lack of controlled studies. Because life-threatening hemoptysis occurs only in a minority of patients, subjecting all patients with aspergilloma to surgical therapy, which is often associated with significant morbidity and mortality, seems to be inappropriate. Management options for aspergilloma currently include systemic or local administration of antifungal agents, surgical resection, and conservative management with careful follow-up without specific medical or surgical intervention. Often, the best course of action for asymptomatic patients with aspergilloma is carefully repeated clinical evaluation with periodic chest radiographs without surgical intervention. Therapeutic considerations must include the individual patient's health status with attention to the potential risks of each treatment.

The definitive treatment of aspergilloma is surgical resection. However, in many patients, surgery is contraindicated because of severe underlying pulmonary dysfunction, whereas the operation per se is associated with significant mortality and serious postoperative complications such as hemorrhage, bronchopleural fistula, bacterial superinfection, and empyema. Therefore, it has been suggested that surgical resection of aspergilloma should be restricted to patients with severe, life-threatening hemoptysis and preserved pulmonary function. Surgical resection should also be considered for patients with poor prognostic features (e.g., chronic immunosuppression, sarcoidosis, and increasing *Aspergillus*-specific IgG titers). Extrapleural resection has been reported to improve outcome. For patients who are unfit for surgical resection, an alternative approach is cavernostomy, which is performed under local anesthesia; however, cavernostomy is also associated with mortality and mediocre results. This procedure should be considered as a last resort.

Intracavitary instillation of an antifungal agent is a promising alternative treatment in patients with severe pulmonary dysfunction who are poor candidates for surgery. CT-guided percutaneous instillation of AMB-D has been shown to be effective for aspergilloma in several cases of massive hemoptysis, with resolution of hemoptysis within 5 d. The response to percutaneous injection of AMB-D is sustained with no recurrences for several months, improvement or even resolution of radiographic abnormalities, and reduction of serum *Aspergillus* antibody titers. Endobronchial instillation of ketoconazole via fiberoptic bronchoscopy has also been successful. Overall, topical therapy with antifungal agents is ideal for patients with a solitary aspergilloma who have severe hemoptysis and contraindications to surgical resection.

Bronchial arterial embolization (BAE) has been extensively used in the management of hemoptysis in patients with aspergilloma. However, this approach has proved to be only temporarily effective, and recurrence of hemoptysis usually occurs because of the presence of collateral vessels in the involved area. Hence, BAE seems to be appropriate only as a "bridge" procedure in patients with massive hemoptysis until surgical resection of the aspergilloma can be performed. Also, radiation therapy has been shown to be effective for aspergilloma, even in patients with massive hemoptysis. This modality has been recommended for cases of recurrence of life-threatening hemoptysis after BAE.

Itraconazole is an orally administered antifungal agent with activity against *A. fumigatus* and high tissue penetration into the lung. The use of itraconazole for aspergilloma has been reported in several noncontrolled studies. Data from these studies showed that the use of itraconazole at doses ranging from 200 to 400 mg/d for 6 to 18 mo resulted in radiographic and symptomatic improvement in almost two-thirds of the patients and may have a place for the treatment of aspergilloma. Serum itraconazole levels were not measured in most of these studies, but a recent study of treatment of pulmonary aspergilloma with itraconazole (100 to 200 mg/d) demonstrated sufficient itraconazole levels within the aspergilloma cavities. The major limitation of itraconazole is that it works slowly; thus, use of it would not be prudent in cases of life-threatening hemoptysis. In addition, recurrence of aspergilloma often follows discontinuation of itraconazole treatment, whereas acquisition of secondary resistance of *A. fumigatus* isolates to itraconazole has been described in patients with aspergilloma following prolonged treatment.

Invasive Bronchial Aspergillosis

The term invasive bronchial aspergillosis (IBA) refers to infection involving the large airways. Further subclassification of IBA based on the bronchoscopic appearance has been proposed, including tracheobronchitis, pseudomembranous tracheobronchitis, and ulcerative tracheobronchitis. In fact, these entities represent a continuous spectrum of this infection.

Aspergillus tracheobronchitis is the least invasive form of IBA and is characterized by the presence of a superficial tracheobronchial inflammation, intact mucosa with no evidence of ulcers, and pseudomembranes or other abnormalities; *Aspergillus* spp. are identified in mucus exudates. In contrast, pseudomembranous tracheobronchitis is characterized by significant necrosis of bronchial epithelium and formation of pseudomembranous plaques, which are white, gray, or black in color. These lesions may progress and result in extensive invasion of the large airways; however, in the majority of patients, the depth of invasion does not extend beyond the bronchial cartilage. Finally, ulcerative tracheobronchitis is the most aggressive form of IBA and manifests with endobronchial plaques, nodules, or areas of ulceration and necrosis; additionally, the infection may extend to the adjacent pulmonary parenchyma and pulmonary vasculature. Late sequelae of ulcerative tracheobronchitis include the formation of excessive granulomatous tissue with resulting bronchial stenosis.

The pseudomembranous form of IBA is typically seen in lung transplant recipients. In fact, IBA is the most common infection within 3 months following lung transplantation, whereas IPA tends to occur much later in this patient population. Occasionally, pseudomembranous tracheobronchitis is found in various clinical settings, including HSCT, hematological malignancies, metastatic renal cell carcinoma, postinfluenza, COPD, AIDS, and even in immunocompetent individuals. Patients may be initially asymptomatic or have symptoms attributed to the underlying illness with negative chest radiographs. However, as the infection progresses, symptoms become more pronounced, including characteristic stridor, resulting in respiratory failure and, ultimately, death.

The ulcerative form of IBA occurs almost exclusively at the site of bronchial anastomosis in lung transplant recipients. Bronchoscopically, the appearance is that of severe tracheobronchitis with multiple ulcers at the site of anastomosis. The symptoms are similar to those of pseudomembranous IBA. Complications include acute IPA, severe bronchial stenosis, anastomotic dehiscence, and bronchial necrosis with bronchoarterial anastomotic fistula. Rarely, ulcerative IBA develops in patients with AIDS or solid tumors. Diagnosis of all forms of IBA requires a high index of suspicion and is established only by bronchoscopic examination.

Bronchial stump aspergillosis is an unusual complication of lung resection. The period from pneumonectomy to the onset of infection usually ranges from 6 to 12 months, although one case was noted after 3 years. Patients may present with a productive cough and hemoptysis, sputum that may be putrid, and occasionally, expectoration of fungal material or suture thread. Chest radiographs are usually unchanged when compared with those taken at baseline. The cause is secondary *Aspergillus* infection of silk suture material used to close the bronchus after pulmonary resection. Local inflammation, compromised tissue viability, and the high capillarity of silk thread favor the establishment of *Aspergillus* infection. Substitution of nylon monofilament for silk sutures at surgery has virtually eliminated this infectious complication.

All of the forms of IBA, including bronchial stump anastomosis, require prompt treatment with systemic antifungals for IA (discussed in detail below). Data from controlled studies of the treatment of IBA are lacking, however. A common although unproven practice is to combine systemic antifungal therapy, such as intravenous AMB-D or voriconazole, with aerosolized AMB-D. Notably, most reported failures occurred during interruption of the treatment. Finally, surgical resection and stent placement may be necessary in conjunction with antifungal therapy if dehiscence of the anastomosis occurs because of tracheobronchial aspergillosis.

CPA

Chronic forms of *Aspergillus* infection of the lung have long been recognized. CPA occurs in patients with chronic cavitary lung disease and is characterized by an indolent clinical course over months to years, constitutional symptoms, serum precipitins to *A. fumigatus*, elevated acute phase markers of inflammation, and an immune status that ranges from normal to mild immunosuppression. Locally invasive (semi-invasive) *Aspergillus* infection may be evident histopathologically. However, both angioinvasion and dissemination are absent. A variety of terms have been used for CPA, including pulmonary aspergillosis with cavitation, complex aspergilloma, chronic granulomatous aspergillosis, semi-invasive pulmonary aspergillosis, and CNPA.

In an attempt to better define CPA, a subclassification of this entity based on clinical and radiographic findings was recently proposed, introducing the terms CNPA, chronic cavitary pulmonary aspergillosis (CCPA), and chronic fibrotic pulmonary aspergillosis (CFPA). CNPA comprises a syndrome of slowly progressive cavitary lung disease, chronic respiratory symptoms, and the presence of precipitating antibodies to *Aspergillus*. Some cases of CNPA have invasion of the lung parenchyma by *Aspergillus* spp. However, in most of the described cases, there is no tissue invasion despite the presence of extensive and progressive tissue damage. CCPA refers to cases in which there is formation and expansion of multiple cavities over time, whereas CFPA refers to cases in which cavity formation is followed by a pronounced fibrotic reaction. In addition, it has been recommended that any case with proven hyphal invasion of tissue should be classified as CNPA.

Defects in mucociliary clearance associated with structural lung disease appear to be a critical factor in the pathogenesis of CPA. Prior mycobacterial lung infection, emphysema, bullae, asthma, sarcoidosis, pneumoconiosis, lung cancer, thoracic surgery, upper lobe fibrosis complicating ankylosing spondylitis, and a history of *Legionella* infection have been described as predisposing conditions for CPA. In addition, subtle but essential defects in innate immunity may play a role in the pathogenesis of CPA. Hence, defects in mannose-binding lectins, alterations in surfactant protein D, certain polymorphisms in transforming growth factor-β, and systemic illnesses associated with a degree of immunosuppression, such as corticosteroid-based therapy, diabetes mellitus, AIDS, and alcohol abuse, have all been associated with CPA. However, the precise pathophysiological mechanism of new cavity formation remains uncertain.

CPA tends to affect middle-aged individuals who are not relatively immunocompetent and more male than female individuals. It has an indolent progressive course that lasts for years. Chronic productive cough and weight loss with mild hemoptysis, dyspnea, and fatigue are the usual presenting symptoms. Pleural fibrosis and *Aspergillus* empyema appear to complicate some cases of CPA.

Although the diagnosis of CPA may be suspected with a single chest radiograph, sequential chest radiographs are typically required to confirm the progressive nature of CPA lesions. CT is particularly useful in defining the precise pattern and extent of the disease. Typical radiographic findings include the presence of one or more cavities, which may or may not contain fungus balls, often located in the upper lobes. New cavity formation and expansion of preexisting cavities are also characteristic of CPA. Pericavitary infiltrates and adjacent pleural thickening are frequently observed and appear to correlate with the overall disease activity. With appropriate treatment, these radiographic abnormalities may regress, leaving residual thin-walled empty cavities.

The combination of characteristic clinical and radiological findings and either the presence of *Aspergillus*-positive precipitins or the isolation of *Aspergillus* spp. from respiratory samples is highly indicative of CPA. Although the demonstration of precipitating antibodies to *Aspergillus* is the cornerstone and a prerequisite for the diagnosis of CPA, these antibodies may be negative, especially in case of infection with non-*fumigatus Aspergillus* spp. Histopathology demonstrates chronic inflammation and fibrosis, sometimes with granulomatous features with or without hyphae. The absence of hyphae does not exclude the diagnosis of CPA because of the paucity of high fungal burden in patients with CPA.

Differentiating CPA from other serious lung conditions that require specific therapy, such as cancer and chronic cavitary mycobacterial and endemic fungal infections, as well as other inflammatory lung conditions is a major challenge. In fact, there is a strong association between CPA and atypical mycobacterial infections. In these cases, imaging is not helpful, so biopsy and comprehensive microbiological studies must be used to exclude the co-existence of CPA with such entities. In addition, CPA differs from simple aspergilloma because of the presence of constitutional symptoms, the development of persistent pericystic lung nodules or pleural thickening, consolidations or ground-glass opacities, and the development and/or progression of cavities. Finally, one should always consider the possibility of a pyogenic infection in a cavity that may require drainage and appropriate antibacterial treatment.

CPA requires prolonged treatment with systemic antifungal agents. In the literature, most patients with CPA have received treatment with oral itraconazole, whereas AMB-D has been successfully used in refractory cases. In a recent series of 18 patients, use of itraconazole resulted in improvement or stabilization of disease in 71 percent of the cases. Use of voriconazole has been associated with favorable responses in anecdotal reports and should be considered as another treatment option. Although the reported response to AMB-D (81 percent) appears to be slightly better than that to itraconazole, administration of it requires long hospitalization periods and is associated with considerable toxicity. Anecdotal reports of improved outcome as a result of adjunctive immunomodulating treatment with interferon-γ have also been reported.

Surgery plays a limited role in the treatment of CPA because of the poor overall lung function in many patients. Major postoperative complications, such as respiratory failure, bronchopleural fistulae, pleural extension of aspergillosis, and even dissemination of *Aspergillus* can occur. Thus, surgery should be reserved for selected patients with reasonable respiratory reserves for whom there are no other treatment options. For example, surgery may be appropriate for patients with severe hemoptysis if embolization fails.

Although systemic antifungal therapy for CPA seems to be beneficial, assessment of response to it is difficult to gauge because the activity of the disease may fluctuate over time. Weight gain and improved energy levels are the earliest and most reliable indicators of response. Inflammatory markers also improve albeit more slowly, and they usually remain elevated even during long-term therapy. Relapse months or years after discontinuation of treatment is frequently reported.

IPA

Epidemiology

Aspergillus has emerged as one of the most common causes of infectious death in severely immunocompromised patients, with mortality rates approaching 70 to 90 percent in patients with leukemia and recipients of HSCTs. Recent surveillance studies demonstrated a three- to fourfold increase in the frequency of *Aspergillus* infections at major cancer centers over the past two decades. In fact, IA has actually surpassed invasive candidiasis as the most common fungal infection found upon autopsy at several institutions, and approximately 15 to 20 percent of patients with leukemia die of fungal pneumonia caused by *Aspergillus* spp. Similarly, in allogeneic HSCT recipients, 15 to 30 percent of deaths are caused by refractory

fungal infections, mainly caused by *Aspergillus* spp., and most of these infections occur late in the postengraftment period in the setting of graft-versus-host disease (GVHD).

The reasons for the dramatic increase in *Aspergillus* infections are not completely understood, but they probably reflect improvements in the prevention or pre-emptive treatment of bacterial infections and other opportunistic pathogens, especially *Candida* and cytomegalovirus (CMV), broadening of the spectrum and intensity of immunosuppressive agents with profound and prolonged effects on T-cell function (e.g., purine nucleoside analogues, anti–T-cell immunoglobulin, monoclonal antibodies), and the growing number of allogeneic HSCT recipients who are at increased risk for GVHD.

In particular, changes in HSCT practices over the past decade have greatly impacted the epidemiology of IA. Autologous HSCT is associated with a low risk of IA because of shortened periods of pre-engraftment neutropenia and a lack of GVHD. On the other hand, IA has a bimodal distribution in allogeneic HSCTs, with patients at risk before and after bone marrow engraftment. The increasing use of peripheral blood stem cells, growth factors, and nonmyeloablative conditioning regimens (minitransplants) in allogeneic HSCT has shortened the duration of pre-engraftment neutropenia (0 to 30 days after engraftment) and the incidence of IA. In contrast, late (40 to 80 days after engraftment) and very late (80+ days after engraftment) IA has increased. This trend is associated with increased use of matched unrelated-donor allogeneic transplants and with interrelated risk factors, such as lymphopenia, chronic GVHD, corticosteroid-based therapy, and/or CMV infection. In fact, among HSCT recipients, IA now predominantly occurs in nonneutropenic patients late after engraftment, in whom GVHD and its management with increasingly intense immunosuppression have emerged as major risk factors.

In addition to the "classic" groups of patients at risk for IA, such as those with prolonged, profound neutropenia because of a hematological malignancy (5 to 25 percent risk) or aplastic anemia; recipients of allogeneic HSCTs (5 to 30 percent risk), or lung transplants (17 to 26 percent risk); those with AIDS, severe combined immunodeficiency, or CGD (25 to 40 percent lifetime risk); burn patients; and patients receiving chronic corticosteroids, IA has been increasingly described in new groups of patients. Hence, patients with systemic lupus erythematosus, patients with multiple myeloma who receive high-dose steroids, and premature neonates are prone to the development of severe IA. Furthermore, several cases of IA have been reported lately in patients with Crohn's disease or rheumatoid arthritis who received treatment with antitumor necrosis factor inhibitors (e.g., infliximab). Even the use of high-potency inhaled steroids may predispose some apparently normal hosts to IPA in rare instances.

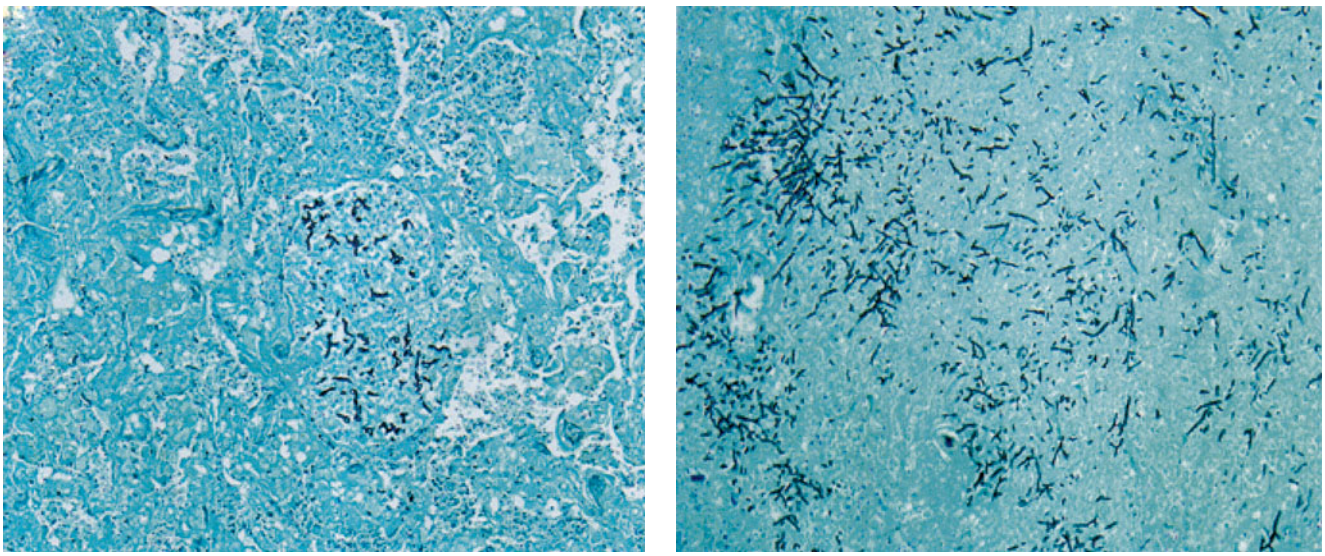
An alarming trend in the epidemiology of IA is the increasing frequency of infections caused by those less susceptible to antifungal such as *Aspergillus* spp. other than *Aspergillus fumigatus*, such as *A. terreus and A. flavus*. This phenomenon may be at least partially a reflection of antifungal selection pressure determined by extensive empirical and prophylactic use of antifungal agents in high-risk patients. Alternatively, because non*fumigatus* aspergilli cause nosocomial infections more frequently than *A. fumigatus* does, an epidemiological niche for these species may also account for their predominance in some institutions. These data are worrisome given that these species are inherently resistant to AMB.

A substantial number of nosocomial clusters of IA have been reported over the past three decades. There have been a large number of clusters associated with hospital construction and defects in air-handling equipment. Air and environmental surfaces have been the focus of most investigations. Recently, water has been implicated as an additional source of nosocomial transmission of *Aspergillus* spp., although this has not been confirmed in other studies.

Pathogenetic Mechanisms

Because *Aspergillus* is a saprophytic mold that colonizes in the respiratory tract of immunocompromised patients, the pathogenesis of infection depends on the host's underlying immunosuppression. In the immunocompromised host, IPA typically occurs following inhalation of *Aspergillus* conidia, although hematogenous dissemination from a cutaneous or gastrointestinal source is seen occasionally. Damage to respiratory epithelium because of radiation therapy, chemotherapy, GVHD, or infection may facilitate attachment of *Aspergillus* conidia to the respiratory epithelial surface. In the normal host, germinating conidia that escape phagocytosis by macrophages and hyphal forms are destroyed by recruited polymorphonuclear neutrophils (PMNs) and monocytes. However, these successive lines of cellular defense are most commonly impaired by corticosteroids (pulmonary macrophages) and cytotoxic chemotherapy (neutropenia), placing the host at risk for invasive infection by *Aspergillus* spp.

Once *Aspergillus* has invaded the respiratory tract, control of the infection is highly dependent on successful selection and clonal expansion of Th lymphocytes to direct professional effector cells with activity against *Aspergillus* hyphae. Lymphopenia and local/global dysregulation of the host adaptive Th1/Th2 polarization has been shown to play a key role in the subacute progression of IA in cases in which neutropenia is not an underlying risk factor. Hence, in the late postengraftment period, allogeneic HSCT recipients have a low interferon-γ/IL-10 ratio, which is suggestive of a Th2 response that potentially accounts for their susceptibility to IA. In comparison, healthy individuals mount a predominantly Th1-type cellular response to *Aspergillus* infection. In humans, iatrogenic suppression of protective Th1 responses is common, particularly in the setting of chronic GVHD (an excessive Th1 response of allograft T lymphocytes) treated with high-dose corticosteroids and/or other immunosuppressive regimens. Importantly, *Aspergillus*-mediated suppression of host Th1 responses by production of gliotoxin is also plausible. Similarly, recent preclinical data indicate that herpes virus reactivation and bacterial co-infection in the lungs



A *B*

Figure 131-6 The characteristic pattern of *Aspergillus* invasion in tissue obtained from (*A*) an HSCT recipient with IPA and severe GVHD, and (*B*) a patient with acute leukemia and severe neutropenia in whom IPA developed. Extensive inflammation, less *Aspergillus* burden and absence of angioinvasion was observed in the patient with GVHD. In comparison, the histopathology of IPA in the patient with severe neutropenia was characteristic for scant infiltration by phagocytic cells, extensive coagulative tissue necrosis caused by angioinvasion, and a high fungal burden. Gomori's methenamine silver stain, ×100. *(Courtesy of M. Luna.)*

induce profound dysregulation of immune responses, facilitating the development of IPA. For example, CMV infection can result in dysfunction of dendritic cells and phagocytes, which may predispose patients to IA.

Once germination of conidia occurs, *Aspergillus* hyphae rapidly invade pulmonary arterioles and lung parenchyma, leading to ischemic necrosis. Hematogenous dissemination with thrombosis, hemorrhagic infarction, and invasion of distant organs may result from invasion of arterioles by *Aspergillus* hyphae and is found in approximately one-third of patients with IPA at autopsy. Thus, IA can present with a clinical picture similar to that of other thrombotic and embolic diseases, such as pulmonary embolism, cerebral vascular accidents, Budd-Chiari syndrome, and renal papillary necrosis. In addition, IA can spread to contiguous structures, across the diaphragm to the stomach, or from the lung to the heart or superior vena cava.

Importantly, it has been recently demonstrated that IPA has different pathophysiological mechanisms depending on the type of immunosuppression. Thus, a low *Aspergillus* tissue burden, extensive inflammatory injury, absence of angioinvasion, and localized infection have been observed in corticosteroid-immunosuppressed mice, whereas minimal inflammation, extensive angioinvasive *Aspergillus* growth, and disseminated infection are characteristic of IPA in cyclophosphamide-treated neutropenic mice. In corticosteroid-treated mice, host immune effector cells appear to have limited activity against *Aspergillus* hyphae but cause extensive alveolar damage and exudative bronchiolitis, which appears to be more important than the *Aspergillus*-induced injury itself. This non-angioinvasive form of IPA has been increasingly recognized in a wide range of non-neutropenic hosts, including those who received corticosteroids, recipients of solid organ transplants and allogeneic HSCTs with GVHD, patients with AIDS, and patients with CGD (Fig. 131-6). Similar to the animal models of IPA, histopathology in those nonneutropenic patients is characterized by extensive pyogranulomatous inflammatory reactions, inflammatory necrosis, and extensive cavitation.

Clinical Features

Symptoms of IPA begin with fever (unless the patient is receiving corticosteroids), which may be followed by a mild nonproductive cough suggestive of bronchitis. Pleuritic chest pain and progression to pneumonia occur within 1 to 2 days. Cavitation tends to occur in patients if immunosuppression is decreased, such as in leukemic patients during recovery of bone marrow function or when steroid-based therapy is reduced significantly, and on occasion gives rise to massive hemoptysis (Figs. 131-7 and 131-8). Pleuritic pain and slight hemoptysis may suggest pulmonary infarction. Patients also may expectorate necrotic tissue filled with hyphae. Cough, sputum production, and pleural effusion are either absent or minimal. IA must be strongly considered when dealing with susceptible patients in whom treatment with broad-spectrum antibiotics fails.

Extrapulmonary sites may be involved, including the highly vascular organs such as the kidneys, liver, spleen, and central nervous system. Invasive disease of the nose and paranasal sinuses occurs in immunocompromised patients, and contiguous invasive spread into the orbit or into the

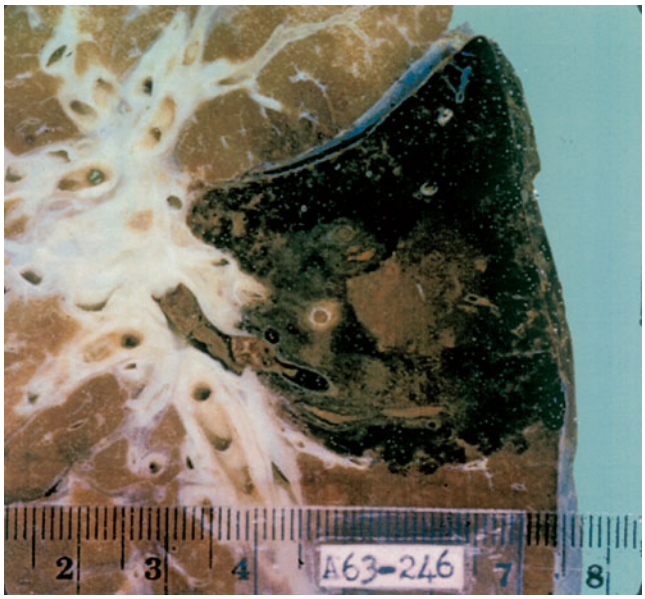


Figure 131-7 A 62-year-old man with acute leukemia in whom IPA developed. The gross appearance of the fungal lesion shows a central necrotic area surrounded by a lining of hemorrhagic infarction. *(Courtesy of G. P. Bodey.)*

cranial vault can result in a syndrome similar to rhinocerebral mucormycosis.

Diagnosis

Substantial delay in establishing an early diagnosis remains a major impediment to the successful treatment of IPA. Chest radiographs are not sensitive in detecting early forms of bronchopulmonary IPA, and up to 10 percent of patients with proven IPA have "normal" chest radiographs within a week of death. High-resolution CT scans of the chest may reveal small wedge-shaped subpleural lesions or nodules typically surrounded by intermediate attenuation. This halo sign correlates with hemorrhage and edema surrounding an infarct caused by thrombosis and is highly suggestive of acute IPA, especially in neutropenic patients with leukemia. However, the halo sign has been documented in 33 to 60 percent of patients and is transient. In fact, to be useful for the diagnosis of IA, CT must be performed within 5 days of the onset of infection, because more than 75 percent of initial halo signs disappear within a week. With neutrophil recovery, these lesions coalesce and cavitate, forming the "air crescent" sign, a classic sign of late filamentous invasive infection. However, the air crescent sign does not appear until the third week of the infection, and its appearance may be too delayed to be helpful in the diagnosis of IA. Importantly, even with effective antifungal therapy, lesions frequently increase in size until neutrophil recovery.

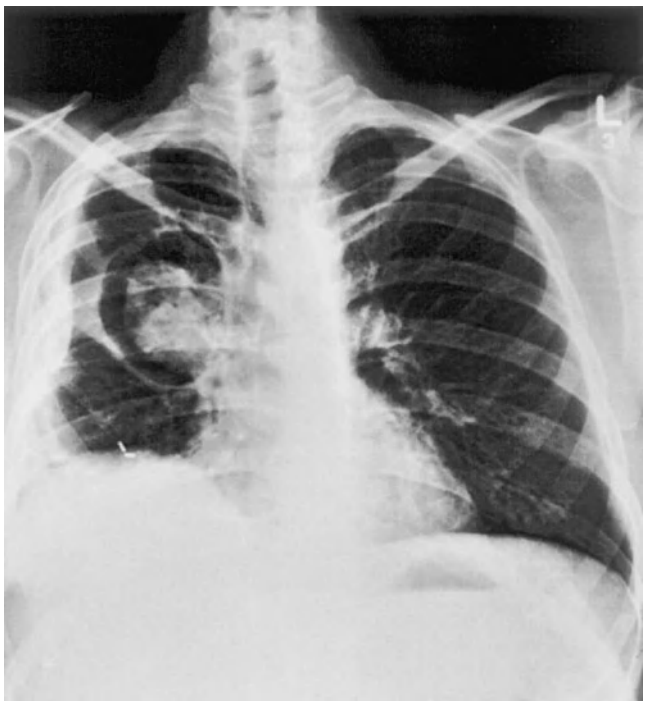

Figure 131-8 The characteristic radiographic features of IPA following neutrophil recovery illustrated in a patient with acute leukemia. A lesion has cavitated, creating the air crescent sign. *(Courtesy of G. P. Bodey.)*

Persistently febrile neutropenic patients with leukemia would benefit from the use of early high-resolution chest CT to identify early signs of IPA. In a recent study of febrile neutropenic patients, early and routine CT scanning coupled with early intensive antifungal-based treatment and surgery resulted in increased survival rates when compared with therapy initiated at the first sign of a pulmonary fungal infection. CT also plays a critical role in determining the feasibility of various diagnostic procedures (bronchoalveolar lavage [BAL], percutaneous needle biopsy, and open lung biopsy) in patients with IPA.

Respiratory cultures of *Aspergillus* from expectorated sputum, bronchial washings, or BAL specimens have low sensitivity (less than 30 percent) for diagnosing IA but a high positive predictive value (greater than 60 percent) in heavily immunocompromised patients. Blood cultures have little diagnostic value for IA but may reflect true disease cases of *A. terreus* infection. Ultimately, open lung biopsy may be required for a definitive diagnosis of IPA and may not be feasible until late in the course of infection or recovery of pancytopenia.

In recent years, efforts have been directed toward identifying nonculture-based markers for rapid, reliable diagnosis of IA. Those based on the detection of anti–*Aspergillus* antibodies have very poor sensitivity for IA, especially in patients receiving immunosuppressive agents. Instead, tests based on identifying circulating fungal antigens or metabolites are promising. To date, the two approaches that have demonstrated the greatest promise in early clinical studies are detection of antigens and measurement of *Aspergillus* nucleic acids by using PCR.

Galactomannan is a polysaccharide cell wall component of *Aspergillus* spp. that is released into the circulation during fungal growth in tissues and can be detected in the serum of patients with IA. A sandwich enzyme-linked immunosorbent assay (ELISA) capable of detecting galactomannan at concentrations as low as 0.5 ng/ml has been

developed recently. Studies evaluating the role of galactomannan assay in the diagnosis of IA have been predominantly conducted with profoundly neutropenic patients undergoing chemotherapy for cancer or recipients of HSCTs. These studies have documented sensitivity rates ranging from 67 to 100 percent and specificity rates ranging from 86 to 99 percent in these patients. When serially monitored, the galactomannan assay preceded the diagnosis of IA by an average of 6 to 14 days. However, in a recent study that evaluated the value of the galactomannan assay in the detection of early IA, the appearance of major lesions (halo sign, air crescent sign, and cavitation) on high-resolution CT scans almost coincided or even preceded the detection of the galactomannan antigen in serum. Furthermore, uncertainties remain regarding the performance of this assay in other settings, such as breakthrough IA to mold-active antifungal prophylaxis, pediatric populations, and solid organ transplant recipients. Other factors, such as the pretest probability of infection, the patient's immune status (neutropenia versus GVHD), antifungal therapy, antibacterials, and diet may affect both the performance and interpretation of the galactomannan assay. Hence, sensitivity rates as low as 30 percent have been reported in non-neutropenic HSCT recipients receiving mold-active antifungal prophylaxis and lung transplant recipients. In addition, false-positive results have been described in patients receiving β-lactam antibiotics, particularly piperacillin-tazobactam, as well as in those ingesting certain cereals, pastas, nutritional supplements, and soy sauce produced with fermentation products of *Aspergillus oryzae*, a fungus commonly used in food production. Finally, although the detection of galactomannan in other fluids, particularly BAL, appears to be highly sensitive, specificity might be an issue.

A colorimetric assay for the detection of 1,3-β-D-glucan, an integral cell-wall component in a number of pathogenic yeasts and filamentous fungi, recently became commercially available. The sensitivity and specificity rates for this test in limited studies thus far have ranged from 67 to 100 percent and from 84 to 100 percent, respectively. False-positive test results have been reported in patients with cirrhosis, those undergoing hemodialysis, receiving chemotherapy with particular agents, and patients following abdominal surgery. Furthermore, the 1,3-β-D-glucan assay has been reported to be less sensitive and reproducible and become positive later in the course of IA when compared with galactomannan antigen assay.

PCR detection of *Aspergillus* nucleic acids is a promising method for early detection of IA. The sensitivity of PCR is excellent, but its specificity for invasive infections can be problematic, and false-positive results are common. Multiple unresolved issues accompany the use of PCR for diagnosis of IA, including the sample type (serum, BAL fluid), amplification strategy (nested versus conventional PCR), protocol (real-time quantitative versus conventional PCR), and primer selection (*Aspergillus*-specific or pan-mold, pan-fungal primers). There have been no good studies examining how PCR performs in comparison with galactomannan detection for the early diagnosis of IA. However, it has been shown that PCR is inferior to serum galactomannan assay in animal models and in some but not all human studies. Like galactomannan antigen testing, PCR is likely to become an adjunct diagnostic method with standard microbiological, histological, and radiographic methods of diagnosing IA.

Treatment of IPA

Although the arsenal of agents with anti-*Aspergillus* activity has expanded over the past decade, the mortality rate in patients with IPA remains unacceptably high. Several strategies have been applied in an attempt to improve the outcome of IA. These include the use of investigational antifungals, increasing the dose intensity of antifungals, use of new delivery systems to improve the therapeutic index of currently available antifungals, combination antifungal therapy, surgical excision of sequestered large necrotic lesions, and use of immunomodulating agents. There has not been a systemic evaluation of the merit of each of these strategies in the treatment of refractory IA, however. This is not surprising in view of the complexity of IA and the paucity of organized, prospective controlled clinical studies of this opportunistic mycosis. Furthermore, difficulties with the early diagnosis of IA and methodological problems related to a lack of uniform criteria for treatment response complicate the evaluation of these strategies.

The principles of management of IPA are listed in Tables 131-5 and 131-6. Until recently, AMB-D was the only drug available for the treatment of aspergillosis, and no prospective evaluations of this drug had been attempted. A major obstacle to evaluating the merit of antifungal therapy for IPA was the difficulty in establishing the diagnosis; hence, most patients received empirical treatment. The recent introduction of uniform diagnostic criteria for proven, probable, and possible IA by the European Organization for Research and Treatment of Cancer (EORTC)/Mycoses Study Group (MSG) consortium has been a major advance. These criteria are practical, validated, standardized, and reproducible and consist of host-risk, microbiological, clinical/radiological, PCR, and/or galactomannan antigen criteria. However, the clinical applicability of the EORTC/MSG criteria was questioned in a recent study in which more than 60 percent of autopsy-proven cases of IA in patients with hematological malignancies were not identified antemortem according to the EORTC/MSG criteria.

Recently, the broad-spectrum triazole voriconazole was introduced for therapy for aspergillosis. It is available in both intravenous and oral preparations and is much better tolerated than AMB-D. In a large prospective randomized trial comparing voriconazole with AMB-D in patients with definite or probable aspergillosis, the response rate was 53 and 32 percent, respectively, and the survival rate at 12 weeks was 71 and 58 percent, respectively. Improved response was seen irrespective of the underlying condition, site of infection, and presence or absence of neutropenia. Patients in whom initial therapy failed received other medications; this occurred more

Table 131-5

Therapeutic Options for Invasive Fungal Infections

Regimen	Advantages	Disadvantages
AMB-D	Broad-spectrum activity, lack of frequent resistance, fungicidal activity, lower cost	Acute chronic toxic effects, minimally effective in patients with neutropenia and with chronic disseminated candidiasis, intravenous preparations only
Lipid formulations of AMB	Broad-spectrum activity, reduced nephrotoxicity, increased doses can be administered	Only prospective randomized trial, showed no advantage in efficacyy over AMB-D despite higher doses, more expensive, intravenous preparations only
Fluconazole	Oral and intravenous preparation, as effective as AMB in randomized trials of non-neutropenic individuals, minimal toxicity, more effective for chronic disseminated candidiasis, little experience in neutropenic patients but appears to be as effective as AMB	Variable activity against *C. glabrata* and *Candida dubliniensis*, inactive against *C. krusei*, some drug-drug interactions, inactive against molds
Itraconazole	Broad spectrum of activity, lower cost, oral and intravenous preparations	Drug-drug interactions and poor absorption (capsules) are common causes of clinical resistance, marked interpatient variability in serum levels
Voriconazole	Oral and intravenous preparations; broad-spectrum activity, including fluconazole-resistant species (e.g., *C. kursei)*; fungicidal against *Aspergillus*	Drug-drug interactions, more expensive than fluconazole, inactive against *Zygomycetes*, cross-resistance with fluconazole?
Echinocandins (caspofungin, micafungin)	Fungicidal activity against most *Candida* spp., minimal toxicity, lack of cross-resistace with azoles, as active as AMB and fluconazole in randomized trials	No oral preparation, poor central nervous system penetration, narrow spectrum of activity *(Candida, Aspergillus)*, limited experience in neutropenic patients
Flucytosine	Synergistic with AMB and fluconazole, combination of flucytosine and AMB may be superior to AMB alone for chronic disseminated candidiasis and *C. tropicalis* infection	No preparation, causes myelosuppression, often requires monitoring of serum concentrations, emergence of resistance if used alone

frequently among the AMB-D population primarily because of the drug's toxicity. The improved survival observed in this comparative study makes voriconazole the preferred drug for first-line therapy for IA. However, in view of the extensive and prolonged use of voriconazole, either prophylactically, empirically, or therapeutically for IA, it is unclear whether resistance would occur, thereby devitalizing this drug.

Use of lipid formulations of AMB is an attractive alternative to AMB-D because of reduced nephrotoxicity. Because many patients with aspergillosis have to undergo prolonged therapy, nephrotoxicity is a very frequent side effect of AMB-D that requires dosage modification. Many physicians believe that responses are more likely to occur with maximum tolerated doses and recommend initiating therapy with daily doses of AMB-D of 1.25 to 1.50 mg/kg, which inevitably lead to nephrotoxic effects. The standard daily dose of lipid formulations of AMB-D is 5 mg/kg, although the most appropriate dose has yet to be determined. Uncontrolled studies have shown efficacy rates for lipid formulations of AMB ranging from 40 to 60 percent in patients with aspergillosis whose

Table 131-6

Drug Dosages for Serious Invasive Fungal Infections of the Lung

Drug	Loading Dose	Daily Dose	Route
AMB-D	—	1.0–1.5 mg/kg	IV only
Lipid AMB	—	3–5 mg/kg	IV only
Fluconazole	800 mg	400–800 mg	IV, PO
IV itraconazole	200 mg bid × 2 d	200 mg	IV
Itraconazole sol	200 mg bid × 2 d	200 mg	PO
Itraconazole caps	200 mg bid × 3 d	200 mg bid	PO
IV voriconazole	6mg/kg q 12 h	4 g/kg q 12 h	IV
Voriconazole tab	—	200 mg q 12 h (($\geq$40/kg) 100 mg q 12 h ($<$40/kg)	PO
Caspofungin	70 mg	50–70 mg	IV

bid = twice a day; caps = capsule; p = day; h = hours; IV = intravenous; PO = oral; q = every; sol = solution; tab = tablet; tid = three times a day.

disease was refractory to AMB-D or could not tolerate it. Although no comparative trials between the lipid formulations of AMB have been conducted thus far, they appear to be equally efficacious, although both their toxic effects and costs differ. Whether the efficacy of AMB in the treatment of IA is improved by these formulations remains debatable. Moreover, the substantially higher acquisition costs of the lipid formulations of AMB has forced many hospitals to restrict first-line use of these agents to patients who are at highest risk for clinically significant nephrotoxic effects. An even more controversial issue is whether there are clinically meaningful differences between the various lipid formulations of AMB. Most of the available data have been derived from indirect comparisons and suggest that all lipid formulations of AMB, when given at the standard dosage of 5 mg/kg, appear to have comparable efficacy. However, the lipid formulations of AMB clearly differ with respect to the rate and extent of drug delivery to the respiratory tract. Specifically, use of lipid complex AMB results in substantially higher concentrations of the drug in lung tissue when compared with liposomal AMB and thus might theoretically achieve more rapid and complete *Aspergillus* killing. Liposomal AMB, which is the most expensive agent, also seems to be the least toxic, even though some of the toxic reactions that occur with the other formulations may be insignificant or preventable. Hence, the overall cost-effectiveness of these formulations remains undefined.

Itraconazole was the first azole introduced for the treatment of aspergillosis. All of the reported studies with this drug have been open trials. In a review of 269 cases reported in the literature, the complete and partial response rate was 63 percent, but it varied from 39 to 80 percent in the different series. Partial responses generally referred to cases in which the infections were controlled but residual lesions persisted. The role of neutrophil recovery in the response of neutropenic patients is unclear in these presentations. Initially, only an oral capsule preparation was available, and it was not consistently well absorbed from the gastrointestinal tract. Recently, an intravenous preparation and a well-absorbed oral solution of itraconazole have become available. Unfortunately, the oral solution is not well tolerated by some patients. A small multicentered trial of the intravenous preparation demonstrated that adequate serum concentrations of itraconazole were achieved, the drug was well tolerated, and about one-half of the patients had a response.

Caspofungin is one of a new class of antifungal agents (echinocandins) that inhibit the synthesis of 1,3-β-D-glucan an essential component of the cell wall of many fungi. It is available only in an intravenous preparation. In a noncomparative trial of 90 patients with definite or probable aspergillosis in whom other therapies had failed, a complete or partial response occurred in 45 percent of the patients. Responses were observed in 50 percent of the patients with pulmonary infection but in only 26 percent of patients with neutropenia. Finally, terbinafine, a squalene epoxidase inhibitor, has been shown to be efficacious against *Aspergillus* spp., and its use in combination with azoles has been shown to result in synergy in vitro.

Combination Treatment

The lack of an effective treatment modality for aspergillosis has made the concept of combination therapy theoretically appealing. To date, no clinical studies have convincingly determined whether antifungal combinations are more beneficial than monotherapy for aspergillosis. For instance, the sequence of administration of itraconazole in combination with AMB has produced a spectrum of responses ranging from synergy to antagonism. With the recent introduction of echinocandins, which have a different mechanism of action than other antifungals, determining whether use of new combinations (e.g., azoles plus echinocandins, AMB plus echinocandins, terbinafine plus azoles, AMB plus azoles, and echinocandins) given either concomitantly or sequentially would result in additive or synergistic effects is important. Recently, separate retrospective studies suggested that a combination of caspofungin and a lipid formulation of AMB may be more effective as primary therapy than the single agents alone. However, when this combination is used in salvage therapy for IA, less benefit is seen. A retrospective analysis of 47 AMB-refractory IA cases in HSCT recipients showed that salvage therapy with the combination of voriconazole and caspofungin was associated with better survival rates compared with voriconazole alone. Performance of well-conducted randomized clinical trials comparing voriconazole, the preferred drug for the treatment of IA, with a combination of voriconazole and an echinocandin (either as a primary or salvage therapeutic strategy) is an important direction in this complex area.

Surgery

The role of adjunctive surgery in the management of IPA also has not been demonstrated conclusively. Pulmonary infarcts and tissue sequestration are common causes of antifungal therapy failure and fatal hemorrhage in patients with IPA. Resection of infected pulmonary tissue is beneficial for some patients. Residual cavitary lesions, especially when containing fungus balls, after successful antifungal therapy may cause late exsanguinating hemorrhage or reactivation of infection during subsequent myelosuppressive chemotherapy. Removal of these lesions, if surgically feasible, should be considered and may provide survival benefit. Surgical intervention may be a life-saving procedure for patients with IPA who experience acute pulmonary hemorrhage, when preformed early in the disease process. It is less evident whether early removal of well-circumscribed lesions close to pulmonary arteries is beneficial. Likewise, the value of late debulking of a pulmonary mass if the patient has multiple fungal lesions that cannot be completely resected is uncertain. Recent uncontrolled data suggest that resection of the lobe most adversely affected by IA is beneficial in treating pulmonary lesions that worsen despite the use of intense antifungal therapy.

Immune Augmentation Treatment

Because host immunodeficiency is the critical determinant of the outcome of IA, a large number of studies, mostly preclinical ones, over the past two decades have focused on measures designed to augment cellular immune defenses against invasive mold infections. The available preclinical data suggest that quantitative and qualitative deficiencies in host cellular immune responses can be corrected with adjunctive cytokine therapy, such as the use of myeloid growth factors (e.g., granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]), interferon-γ, or a combination of these cytokines plus infusion of host effector cells [e.g., interferon-γ plus granulocyte transfusions]). Granulocyte transfusion therapy has become more feasible since the introduction of G-CSF/corticosteroid mobilization into the donor leukocyte collection process. Currently, there are no data from randomized clinical trials examining the efficacy of granulocyte transfusions for IA or other serious infections during neutropenia. Future studies in this area will likely examine the use of vaccinations and/or cellular transfer with or without adjunctive cytokines to boost adaptive Th1 immunity in immunosuppressed hosts. Clearly, this is a challenging area of investigation. Carefully designed clinical trials will be required to verify promising results in animal models and other preclinical observations.

Prophylaxis in High-Risk Patients

Specialized air-handling systems such as high-efficiency particulate air (HEPA) filtration with or without laminar airflow ventilation have proved to be effective at excluding *Aspergillus* spores. However, HEPA filters have not been shown to prevent *Aspergillus* infections during building renovation and may not prevent outbreaks of these infections related to building demolition or renovation. More recently, hospital water systems have been implicated as potential sources of high-level spore bursts of pathogenic fungi. During bathroom activities such as showering and toilet flushing, patients may create aerosolized mists of fungal spores that increase the risk of IA. In addition, researchers recently reported an association between molds (*Aspergillus* and *Fusarium* spp.) cultured on hospital sinks and water sources and invasive mold infections in patients with leukemia. As a result, some have recommended cleaning of patient showers and bathroom areas with a phenolic cleaning solution prior to use by severely immunocompromised patients. Although these preliminary data are intriguing, establishing a causal link between nosocomial exposure to *Aspergillus* spores and subsequent development of IA remains difficult and requires the demonstration of genetic relatedness of environmental *Aspergillus* strains and clinical isolates. In fact, one of the largest molecular epidemiological studies of IA suggested that any *Aspergillus* strain could be pathogenic in the appropriate host background and that isolates causing invasive disease are not necessarily nosocomially derived.

Fluconazole is inactive against *Aspergillus* spp. In addition, prophylactic trials of itraconazole have had controversial results. These differences may relate to the poor oral bioavailability of itraconazole. A recent meta-analysis suggested that intravenous and oral solutions but not oral capsules

of itraconazole were effective in preventing yeast and mold infections in neutropenic patients. Intravenous AMB-D is not appropriate for prophylaxis because of its nephrotoxicity. Also, low doses of liposomal AMB have failed to demonstrate any prophylactic efficacy in HSCT recipients. Inhalation of AMB-D is poorly tolerated (causing cough, bronchospasm, and nausea), and the overall benefit of it is not obvious; however, aerosolized lipid complex AMB is tolerated much better and results in higher tissue concentrations when compared with aerosolized AMB-D.

The new oral, extended-spectrum triazoles such as voriconazole and posaconazole have a satisfactory pharmacokinetic profile and documented efficacy in the treatment of infections, which may make them suitable for prophylaxis in HSCT recipients and neutropenic patients. Recently, antifungal prophylaxis with the echinocandin micafungin in HSCT recipients was shown to reduce the incidence of IA; however, the fact that echinocandins are parenteral drugs limits their ability for use as extended antifungal prophylaxis during the postengraftment period, when IA is most likely to occur.

Secondary Prophylaxis

Patients with a history of IA are at high risk of reactivation of the infection if they undergo further intensive chemotherapy or HSCT. Patients receiving prophylaxis have fewer relapses than those who do not. To date, no optimal drug or dose can be recommended for secondary prophylaxis in the absence of comparative clinical trials; voriconazole, itraconazole, and lipid formulations of AMB seem to be the most appropriate agents.

PULMONARY CANDIDIASIS

Candida, a commensal fungus of mucosal surfaces, is the predominant fungal pathogen in humans. The spectrum of *Candida*-induced illnesses is broad, ranging from mild, chronic mucocutaneous infections to life-threatening acute invasive infections involving potentially any organ. Pulmonary candidiasis is an infrequent form of invasive *Candida* infection that occurs in cases of aspiration pneumonia in immunocompromised patients who have heavy colonization of *Candida* spp. in the oral cavity (primary *Candida* pneumonia) or as part of disseminated candidiasis.

Candida pneumonia is a challenging infection because of a lack of established, reliable clinical criteria for making the diagnosis. Hence, *Candida* is frequently an asymptomatic colonizer, particularly among debilitated individuals who are receiving antibacterials. Thus, cultures of sputum and/or BAL that are positive for *Candida* in a patient with a pulmonary infiltrate do not establish the diagnosis of *Candida* pneumonia. A recent autopsy study of patients with cancer demonstrated that whereas many patients with pneumonia had *Candida* spp. cultured from sputum and BAL specimens, the specificity (57 to 60 percent) and positive predictive value (29 to 42 percent) of cultures of both types of specimens were low. Similarly, quantitative cultures of transbronchial lung biopsy samples in critically ill, mechanically ventilated patients have been of no predictive value for *Candida* pneumonia. Therefore, only histopathological demonstration of yeast cells or pseudohyphae in lung tissue is confirmatory of *Candida* pneumonia, which is often impossible in many patients.

Epidemiology

The true incidence of *Candida* pneumonia is unknown, and most of the data on this infection are extrapolated from autopsy series. The fact that only 55 patients with unequivocal evidence of primary *Candida* pneumonia had been reported in the literature up to 1993 emphasizes the rarity of this infection. Two of the larger autopsy surveys in patients with cancer reported a prevalence of primary *Candida* pneumonia ranging from 0.2 to 0.4 percent. In another autopsy study that included a general population of patients, primary *Candida* pneumonia comprised 17 percent of all *Candida* infections, with an overall prevalence of 0.3 percent. On the other hand, primary *Candida* pneumonia has been a relatively frequent finding in autopsy studies of high-risk patients, such as premature neonates (1 percent) and critically ill, mechanically ventilated patients (8 percent).

In contrast with primary *Candida* pneumonia, secondary lung involvement by *Candida* spp. is a common finding at autopsy, occurring in 42 to 81 percent of cases of disseminated candidiasis. However, the clinical significance of *Candida* pneumonia identified at autopsy, especially in cases of hematogenous dissemination, has been questioned. For example, a recent study demonstrated that almost one-half of such *Candida* infections were incidental autopsy findings without clinical significance.

Although large surveillance studies to capture the prevalence of *Candida* pneumonia are lacking, *Candida* was the third most common fungal pathogen after *Aspergillus* and *Cryptococcus* in a series of 140 patients with biopsy-proven invasive fungal pneumonia. Interestingly, an increasing number of patients with primary *Candida* pneumonia were reported during the last years of the study. However, whether these latter cases represented a true increase in the incidence of *Candida* pneumonia or simply reflected a bias because of improved diagnosis is not certain.

Mycology

Similar to the other forms of invasive candidiasis, *Candida albicans* is the predominant species in patients with primary *Candida* pneumonia, accounting for 40 to 70 percent of all reported cases. Until the early 1990s, *Candida tropicalis* and *Candida parapsilosis* were the most common non-*albicans Candida* spp. in patients with primary *Candida* pneumonia. However, the widespread use of broad-spectrum azole antifungals over the past decade has led to the emergence of less susceptible, non-*albicans Candida* spp., such as *Candida glabrata* and *Candida krusei*, as important causes of

Candida pneumonia. Hence, *C. glabrata* is currently considered the second most common *Candida* spp. in cases of primary *Candida* pneumonia in immunocompromised individuals. In cases of secondary *Candida* pneumonia caused by hematogenous dissemination, the distribution of the species appears to follow that in bloodstream candidiasis, with *C. albicans* being the predominant species followed by *C. glabrata*, *C. tropicalis*, *C. krusei*, and *C. parapsilosis*.

Pathogenesis

Most of the data on the pathogenesis of *Candida* pneumonia have been gained from analysis of histopathological findings at autopsy and studies of animal models of aspiration-induced pneumonia. *Candida* pneumonia develops only rarely in normal hosts, and most of the reported cases of this infection occurred in heavily colonized immunocompromised individuals. A constellation of factors suggests that primary *Candida* pneumonia has a distinct pathophysiology when compared with other forms of invasive candidiasis and develops under a particular clinical scenario. Specifically, the very high percentage of intrabronchial and intra-alveolar fungal involvement without significant vascular invasion, the frequent finding of aspirated material at autopsy, and the concomitant presence of candidal esophagitis at autopsy in most of the patients with primary *Candida* pneumonia demonstrate that the mechanism of entry of *Candida* is aspiration of oropharyngeal contents. In addition, several studies indicated that the typical risk factors for invasive candidiasis, such as chemotherapy-induced neutropenia, prolonged corticosteroid use, immunosuppressive agent use, prior antibiotic use, hyperalimentation, diabetes mellitus, and the presence of vascular devices were not significantly associated with the development of *Candida* pneumonia. In contrast, alteration of mental status (with or without subsequent aspiration) was the most important contributing factor in the majority of these patients. Thus, individuals prone to aspiration who experience heavy colonization of *Candida* spp., such as those with head and neck cancer receiving chemoradiation, premature neonates, and critically ill, mechanically ventilated patients, comprise the population at highest risk for primary *Candida* pneumonia.

However, a distinct type of overwhelming secondary *Candida* pneumonia caused by hematogenous dissemination has been described occasionally in profoundly neutropenic patients with cancer. The histopathological characteristics of *Candida* lesions mandate pulmonary seeding from systemic bloodstream infections. Specifically, autopsy examination of these patients found evidence of pneumonia with scant inflammation and pools of *Candida* yeast cells and pseudohyphae present in large portions of the involved lung sections in a pattern that closely resembled *Candida* growth in culture medium. Furthermore, in contrast with primary *Candida* pneumonia, destruction of lung parenchyma is subtle, whereas hemorrhage and angioinvasion by pseudohyphae are prominent. Although speculating that typical risk factors for disseminated candidiasis may apply in cases of secondary *Candida* pneumonia is reasonable, the majority of cases of clinically significant infection have been described in profoundly neutropenic patients with leukemia.

Innate immunity is the dominant protective mechanism against all forms of invasive candidiasis, including primary *Candida* pneumonia. Notably, studies in murine models of aspiration-induced *Candida* pneumonia revealed that immunocompetent animals were remarkably resistant to intrathecal inoculation of *Candida*, whereas they succumbed to infection after intravenous injection of a much lower inoculum. These studies revealed that resident pulmonary macrophages largely account for resistance against *Candida* infection, with a remarkable ability to engulf and kill yeast cells. In addition, neutrophils are recruited to the lung within a few hours after initial challenge and have a predominant role in clearing *Candida* infection from the lungs within hours after inoculation. Neutropenic mice are highly susceptible to *Candida* pneumonia. In contrast, although use of corticosteroids somewhat delays the clearance of *Candida* cells by phagocytic cells, it does not significantly increase the susceptibility of mice to infection. On the other hand, genetically engineered mice deficient in myeloperoxidase and/or other components of respiratory burst are extremely susceptible to *Candida* pneumonia, indicating the importance of mechanisms of oxidative killing of phagocytic cells. Although the role of humoral immunity has not been explored extensively, production of IgA and IgG1 has been shown to be important for protection against *Candid*a pneumonia in mice. In contrast with cases of disseminated candidiasis, in which a Th1 cellular response appears to be critical for outcome, a combination of Th1 and Th2 anti-*Candida* responses associated with synthesis of IL-4 and IL-5 is required for optimal immunity in cases of *Candida* pneumonia. Intriguingly, in patients with CF, colonization of respiratory epithelia with *Pseudomonas* species appears to play a protective role against the development of *Candida* pneumonia through production of toxins with potent anti-*Candida* activity.

Clinical Manifestations

The clinical manifestations of primary *Candida* pneumonia are nonspecific and mainly include persistent fever and tachypnea. Chest pain, cough, and sputum production occur occasionally. Also, physical examination and routine laboratory studies are nonspecific. Chest radiographs may demonstrate a local or diffuse infiltrate involving one or both lungs, which is most often associated with infection acquired by the endobronchial route. A miliary-nodular pattern is most often associated with hematogenous seeding of the lung in cases of disseminated candidiasis and often appears late in the clinical course of the disease (Fig. 131-9).

Extrapulmonary manifestations such as skin lesions, myositis, and endophthalmitis may be the first signs of *Candida* fungemia. Multiple organ involvement prior to or concurrent with pulmonary findings, particularly kidney and myocardial failure, may indicate hematogenous seeding that warrants investigation.

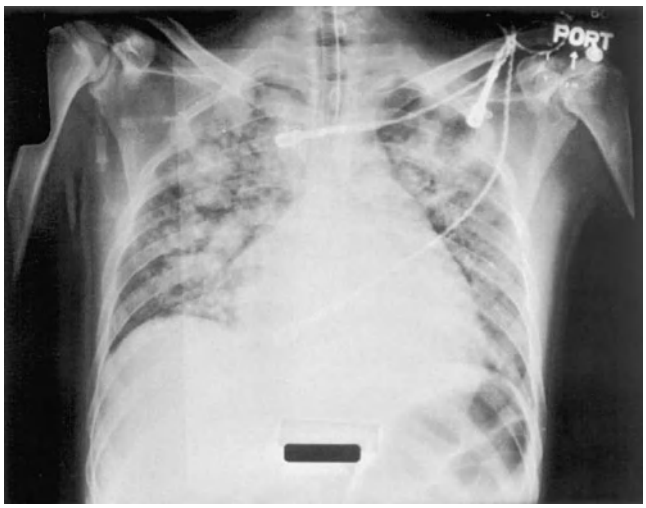

Figure 131-9 The radiographic features of *Candida* pneumonia in a patient with acute leukemia and severe neutropenia in whom disseminated candidiasis developed. Diffuse bilateral infiltrates along with the characteristic macronodular lesions are shown. *(Courtesy of G. P. Bodey.)*

Lung transplant recipients are prone to early (within 2 weeks after transplantation) and fulminant *Candida* pneumonia. This association is probably caused by occult aspiration of *Candida* colonizing the donor lung followed by invasive pulmonary *Candida* infection after transplantation, when immunosuppression is most intense.

Asthma related to an IgE-mediated allergy to *C. albicans* or allergic bronchopulmonary candidiasis develops occasionally. Allergic bronchopulmonary candidiasis should be considered in patients with ABPA with serologic and skin tests negative for *Aspergillus.* In addition, cases of chronic eosinophilic pneumonia with peripheral eosinophilia and selective sensitization to *C. albicans* occur rarely in the absence of asthma. Early diagnosis and corticosteroid-based therapy may prevent late fibrosis in those patients.

Diagnosis

Diagnosis of pulmonary candidiasis is challenging and depends on evidence of tissue invasion. Isolation of yeast from sputum does not prove invasive yeast infection of the respiratory tract because of contamination by commensals from the oropharynx. *Candida* is present in the oropharynx of approximately 20 to 40 percent of all patients, especially those with chronic lung disease and those receiving chronic antibacterial treatment.

Bronchial washings and BAL specimens provide a more representative picture of the respiratory pathology compared with sputum. However, they can still be contaminated with mouth flora. At least in a selected group of patients with acute leukemia and severe neutropenia, if other organisms are absent and abundant *Candida* yeast cells and pseudohyphae are detected in the cytologic examination of BAL specimens, clinical suspicion of *Candida* pneumonia should be high. On the other hand, cultures from lung specimens negative for *Candida* spp. have a high negative predictive value and virtually exclude *Candida* pneumonia.

Histopathological demonstration of tissue invasion by *Candida* spp. in open lung biopsy or fine-needle aspiration is definitive, although such biopsies are difficult to perform in pancytopenic patients with pneumonia. Transbronchial biopsy revealing tissue invasion by *Candida* spp. is also diagnostic.

Isolation of *Candida* from the blood may be helpful in diagnosis of disseminated candidiasis; however, the organism may not be isolated even from multiple blood culture specimens in up to 40 percent of patients with widespread infection demonstrated at autopsy. The use of lysis centrifugation, the BacT-Alert system that monitors CO_2 production, and the high-volume BACTEC system with infrared detection has improved the yield of *Candida*-positive blood cultures. A variety of methodologies have been developed to detect circulating *Candida* antigens and metabolites, including PCR, but none of them have been entirely satisfactory for routine adaptation to the clinical microbiology laboratory.

In cases of disseminated candidiasis, characteristic eye lesions suggestive of *Candida* infection may develop; hence, a careful ophthalmological examination should be performed when this infection is suspected. In addition, typical skin lesions, generalized or localized to the extremities, have been described in up to 10 percent of patients with hematogenous candidiasis. Some of these patients also have associated myositis, particularly in cases of *C. tropicalis* infection. *Candida* spp. can be identified in the dermis and cultured from about one-half of all biopsy samples. Finally, CT scans of the abdomen may suggest invasive hepatosplenic candidiasis in compromised hosts with an unrevealing microbiological evaluation.

Treatment

An unknown number of patients with primary *Candida* pneumonia may have had a response to empirical antifungal therapy but have gone unrecognized because of the difficulty in establishing the diagnosis of this infection. Primary *Candida* pneumonia is considered a life-threatening infection, with mortality rates approaching 70 percent in severely immunocompromised patients. Therefore, rapid clinical diagnosis and prompt initiation of systemic antifungal therapy are important upon suspicion of the infection in the appropriate setting.

Given the rarity of primary *Candida* pneumonia, there are no controlled studies of the treatment of it. Most patients with primary *Candida* pneumonia have received AMB-D (0.7 to 1.0 mg/kg per day) for a minimum of 2 weeks after all signs and symptoms of infection disappeared and until bone marrow recovery in those with neutropenia. In cases of secondary *Candida* pneumonia associated with hematogenously disseminated infection, therapy directed at disseminated candidiasis rather than at *Candida* pneumonia is indicated. However, over the past decade, several new antifungal agents, including fluconazole and the newer triazoles, lipid

formulations of AMB, and the echinocandins, have become available for treatment of invasive candidiasis, showing comparable efficacy and significantly less toxicity when compared with AMB-D in several prospective randomized trials. Nevertheless, most of the new antifungal agents have been studied in non-neutropenic patients with candidemia, and uncertainty remains as to how these drugs apply in immunocompromised neutropenic patients with *Candida* pneumonia.

With all of the limitations of the aforementioned studies, and given the fact that fluconazole has been used extensively for prophylaxis in many institutions, initiation of therapy for *Candida* pneumonia with AMB-D plus fluconazole with subsequent discontinuation of AMB-D use may be a reasonable approach in such cases. Also, using higher doses of fluconazole (800 mg/day), at least initially, may be appropriate in neutropenic patients.

Voriconazole has been recently found to be equally effective and significantly less toxic when compared with AMB-D and exhibits significant activity against fluconazole-resistant non-*albicans Candida* spp. However, there are concerns about cross-resistance with fluconazole, particularly against *C. glabrata* species.

Although lipid formulations of AMB are less nephrotoxic, there is no convincing evidence that they are more effective than AMB-D. Because most patients with candidiasis do not require prolonged therapy, use of these more expensive preparations is usually not justified.

The breakthrough in the treatment of invasive candidiasis has been the introduction of the echinocandins. Caspofungin, the first discovered agent in this class, has shown broad-spectrum fungicidal activity against *Candida* spp., including azole-resistant non–*albicans Candida* spp. In fact, because of its potency and minimal toxicity, caspofungin is displacing AMB-D as the drug of choice for candidemia in seriously ill and unstable patients. Recent studies demonstrated that the activity of caspofungin is superior to that of AMB-D and fluconazole in cases of candidemia. The accumulating experience with the treatment of other invasive pulmonary mycoses with caspofungin holds promise for the use of this agent in the treatment of *Candida* pneumonia.

PULMONARY ZYGOMYCOSIS (MUCORMYCOSIS)

Zygomycosis, or mucormycosis, is a life-threatening angioinvasive infection caused by fungi of the class *Zygomycetes*, order *Mucorales*. Fungi in the other order of Zygomycetes class, the *Entomophthorales*, rarely cause chronic subcutaneous infections, which predominantly afflict immunocompetent hosts in subtropical countries. *Zygomycetes* species have emerged as important opportunistic pathogens over the past decade, particularly in patients with hematological malignancies and recipients of HSCTs. Unlike *Aspergillus* and other opportunistic fungi, *Zygomycetes* spp. tend to cause infections in a wide range of hosts with qualitative and/or quantitative defects in phagocytic cells and occasionally in immunocompetent individuals.

Fungi of the order *Mucorales* are distributed into six families, all of which can cause serious invasive infections (Table 131-7). Species of the family *Mucoraceae* are isolated more frequently from patients with zygomycosis than are species of any other family. Among the *Mucoraceae*, *Rhizopus oryzae (Rhizopus arrhizus)* causes the vast majority (greater than 70 percent) of *Zygomycetes* infections. Other less frequently encountered species of the *Mucoraceae* family include

* *Based on the classification outlined by Ribes et al.*
† *These species are the more common etiological agents associated with zygomycosis in humans.*

Rhizopus microsporus, *Absidia corymbifera*, *Apophysomyces elegans*, *Mucor* spp., and *Rhizomucor pusillus*. *Cunninghamella berthollethiae* is an increasingly reported cause of zygomycosis and appears to be the most virulent *Zygomycetes* species in humans. All of these organisms are indistinguishable by histopathology. Various terms have been used in the past to indicate infections caused by *Zygomycetes*, such as mucormycosis, phycomycosis, and simply mucor. However, the more accurate term zygomycosis is used throughout this chapter to indicate opportunistic mold infections in humans caused by *Zygomycetes*, because this is the taxonomically correct description.

Epidemiology/Risk Factors

The *Zygomycetes* are saprophytic fungi ubiquitous in soil and decaying organic material. *Mucorales* species that are pathogenic in humans grow rapidly on any carbohydrate substrate and produce abundant sporangiospores. Spores produced by the fungi become airborne, and inhalation of *Zygomycetes* conidia into the respiratory tract occurs daily. Even though these fungi grow in many ecological niches, the rarity of zygomycosis reflects the low virulence potential of *Zygomycetes* in immunocompetent hosts.

The overall estimated incidence of zygomycosis is 1.7 cases per 1 million people annually. However, over the past decade, zygomycosis has emerged as the second most common opportunistic mycosis after IA in severely immunocompromised patients; this increase in the incidence of zygomycosis has been largely attributed to changes in HSCT practices, leading to increasing rates of chronic GVHD requiring steroid therapy and the broad use of relatively narrower spectrum, mold-active antifungals, including voriconazole and caspofungin, as prophylaxis or preemptive therapy in this patient population. In autopsy series, the prevalence of zygomycosis has ranged from 2 to 8 percent in patients with leukemia and recipients of allogeneic HSCT. For reasons that remain unclear, the incidence of *Zygomycetes* infections, particularly of *Cunninghamella, Absidia,* and *Apophysomyces* spp., is higher in male (65 percent) than female patients. A seasonal variation in *Zygomycetes* infections was implied in some studies, with the majority of infections occurring from August to November.

Zygomycetes cause acute angioinvasive infections in patients with a variety of immunosuppressive conditions, including poorly controlled diabetes mellitus (especially with diabetic ketoacidosis), neutropenia, malignancies, burns, chronic renal failure, and iron overload; recipients of transplants; and patients receiving chronic immunosuppressive therapies or deferoxamine-based therapy.

Disease Manifestations

The most common manifestation of zygomycosis is sinusitis, including rhinocerebral infection (39 percent), pneumonia (24 percent), disseminated infection (23 percent), soft tissue infection (19 percent), and gastrointestinal infection (7 percent). Of note, the different forms of zygomycosis tend to occur in patients with specific host immune defects. For example, patients with diabetic ketoacidosis are prone to the development of the rhinocerebral form of zygomycosis, but much more rarely suffer from pulmonary or disseminated infection. In contrast, patients with hematological malignancies and/or recipients of allogeneic HSCTs more commonly have pulmonary zygomycosis. The predominance of pulmonary infection in patients with malignancies may be a result of chemotherapy-related defects in innate pulmonary host defenses associated with neutropenia and/or chemotherapy-induced mucociliary dysfunction. Profound neutropenia, prolonged treatment with high doses of corticosteroids, GVHD, diabetes mellitus, malnutrition, and CMV reactivation are the main risk factors for zygomycosis in these patients. Administration of antithymocyte globulin or tumor necrosis factor inhibitors for the treatment of acute GVHD may pose additional risk for zygomycosis. Importantly, antifungal prophylaxis with agents that have anti–*Aspergillus* activity, such as voriconazole and caspofungin, was recently independently associated with the development of zygomycosis in severely immunocompromised patients.

Patients with renal failure receiving the iron (and aluminum)–chelating agent deferoxamine have an increased risk of pulmonary and disseminated zygomycosis. Although rare, there have been a number of reports of pulmonary zygomycosis in patients with AIDS. It is important to emphasize that dissemination may occur from one of the primary sites of *Zygomycetes* infection, mainly in patients with profound immunosuppression. In addition, nosocomial transmission of zygomycosis has been reported as a result of the use of iatrogenic interventions such as intravenous catheters, bandages, and even tongue depressors.

Mycology

Zygomycetes are molds characterized by growth of hyphae in the environment and in tissue. They grow rapidly—within 2 to 5 days on most culture media—as fluffy gray or brownish colonies, with many of the species demonstrating aggressive vertical growth toward the lid of the Petri dish; these species are referred to as "lid lifters." As the *Zygomycetes* colony matures, the mycelium may darken and exhibit a black pepperlike effect as large numbers of sporangia are formed. Cycloheximide inhibits the growth of these fungi, and media that contain this compound, such as Mycosel and mycobiotic agar, should not be used. All pathologic species grow well at 37°C.

Microscopic examination for the presence and location of rhizoids and apophyses and to determine the morphology of the columellae differentiates the genera. Isolating and speciating the organism is important for selection of treatment. However, morphological identification of *Zygomycetes* species is often imprecise.

Pathogenesis

Host factors influence each particular zygomycosis syndrome. The pathogenesis of pulmonary zygomycosis begins with

the inhalation of spores into the respiratory tract; however, hematogenous or lymphatic spread from other sites to the lungs occasionally occurs. Infection may remain localized in the lung or disseminate hematogenously.

Both mononuclear and polymorphonuclear phagocytes of the normal host kill *Zygomycetes* spores by generating oxidative metabolites and the cationic peptides defensins. Polymorphonuclear phagocytes are the major immune effector cells responsible for inhibiting hyphal growth of *Zygomycetes*, and neutropenic patients as well as patients with qualitative defects in immune effector cell function are at increased risk of zygomycosis. In addition, both hyperglycemia and acidosis are known to impair chemotaxis and the killing activity of phagocytic cells against *Zygomycetes* by impairing oxidative and nonoxidative mechanisms. Likewise, corticosteroid-based treatment impairs the ability of macrophages to prevent germination of the spores in vitro and in vivo. However, the exact mechanisms by which ketoacidosis, diabetes, and steroids impair the function of phagocytes remain unknown. Also, little is known about the interaction of *Zygomycetes* spp. with specific receptors of phagocytic and/or endothelial cells (e.g., TLR receptors).

Besides immunocompromised individuals, patients with iron overload states, including those undergoing chelation therapy with deferoxamine are uniquely at increased risk for zygomycosis. Deferoxamine abolishes the fungistatic effect of serum and increases in vitro fungal growth by acting as a siderophore for *Zygomycetes* spp. Similarly, there is evidence suggesting that the increased susceptibility to zygomycosis of patients with acidosis, including diabetic acidosis, is likely caused by increased availability of serum iron.

A hallmark of zygomycosis is extensive angioinvasion with resultant vessel thrombosis and tissue necrosis (Fig. 131-10). Interaction of *Zygomycetes* spores with endothelial cells appears to play a critical role in angioinvasion. Importantly, researchers recently showed that heat-killed germinating *Zygomycetes* spores are still able to induce endothelial cell damage in vitro and to kill mice in vivo; the molecular mechanisms of these interactions have not been elucidated yet.

Clinical Manifestations

The clinical manifestations of pulmonary zygomycosis are similar to those of IPA. In fact, these two entities are almost indistinguishable clinically. Timely diagnosis of pulmonary zygomycosis is challenging because symptoms are subtle and nonspecific even at the late stages of infection. Patients with pulmonary zygomycosis present with fever refractory to broad-spectrum antibiotics, cough that is typically nonproductive, severe or subtle pleuritic chest pain, and rapidly progressive dyspnea. Also, pleural friction may be heard upon auscultation. Angioinvasion results in necrosis of tissue parenchyma, which may ultimately lead to cavitation and/or hemoptysis. Fatal hemoptysis as a result of fungal invasion of a major blood vessel has been reported occasionally.

Figure 131-10 Pulmonary mucormycosis in a 63-year-old diabetic kidney transplant recipient with a rapidly expanding pulmonary mass. *(Courtesy of Jay A. Fishman, Massachusetts General Hospital.)*

In patients with a hematological malignancy, clues essential to distinguishing pulmonary zygomycosis from IPA are the presence of concomitant sinusitis and a history of antifungal prophylaxis with *Aspergillus*-active agents such as voriconazole and echinocandins.

A multitude of patterns may be present in a regular chest radiograph for a patient with pulmonary zygomycosis, including in descending order of frequency: lobar consolidation or nonspecific infiltrates, cavities, masses, and nodules. Wedge-shaped infarcts of the lung may also be seen, particularly following thrombosis of the pulmonary vessels caused by fungal angioinvasion. Previous studies found that pulmonary lesions in patients with zygomycosis have a predilection for the upper pulmonary lobes in 55 to 84 percent of all reported cases.

As with IPA, high-resolution chest CT is the best method of determining the extent of pulmonary zygomycosis and may demonstrate evidence of infection before it is seen on chest radiographs. The halo and air-crescent signs are encountered in zygomycosis at the same low frequency as in IPA. Importantly, the presence of the air-crescent sign has been

associated with an increased risk of massive hemoptysis. We recently found that the presence of multiple nodules and, to a lesser degree, pleural effusions on CT scans favors a diagnosis of pulmonary zygomycosis over pulmonary aspergillosis in high-risk patients with cancer.

Hematogenous dissemination to the contralateral lung and other organs occurs frequently when pulmonary zygomycosis is not treated promptly. Patients with untreated pulmonary zygomycosis usually die from of disseminated disease before respiratory failure occurs. The notable exception is the rare patient with massive hemoptysis. The overall mortality rate for pulmonary zygomycosis ranges from 50 to 70 percent but is greater than 95 percent when it is part of a disseminated infection.

Some atypical presentations of pulmonary zygomycosis include chronic infection with constitutional symptoms that last for several months in relatively immunocompetent hosts, multiple mycotic pulmonary artery aneurysms and pseudoaneurysms, bronchial obstruction, asymptomatic solitary nodules, or even normal chest radiographs. Of interest, patients with diabetes mellitus have an apparent predilection for the development of endobronchial lesions, accounting for more than 80 percent of reported cases in the literature. Furthermore, pulmonary zygomycosis tends to present with a less fulminant, subacute (greater than 4 weeks) clinical course in these patients. However, endobronchial lesions occasionally lead to obstruction of major airways or erosion of major pulmonary blood vessels and fatal hemoptysis.

Similar to *Aspergillus* spp., *Zygomycetes* spp. rarely produces an asymptomatic mycetoma within a preexisting lung cavity. Allergic *Rhizomucor* sinusitis has been also reported in immunocompetent individuals. In addition, hypersensitivity pneumonitis caused by *Rhizopus* has been described in farm workers as well as in Scandinavian sawmill workers (so-called wood trimmer's disease).

Diagnosis

Little improvement has been made over the past few decades in the diagnosis of zygomycosis, which relies on conventional culture methods. Timely diagnosis of zygomycosis requires a high index of suspicion and largely depends on histopathological demonstration of tissue invasion by the characteristic hyphae or by isolation of *Zygomycetes* spp. in cultures of sterile tissue.

To provide histopathological evidence of invasive zygomycosis, bronchoscopy with transbronchial biopsy, percutaneous needle biopsy of the lung, or open lung biopsy must be employed. Touch slides prepared from the biopsy specimen with potassium hydroxide may reveal fungal hyphae. Hematoxylin and eosin (H&E)–stained tissue sections will show the typical hyphae in infected tissue. These fungi stain poorly with the periodic acid-Schiff (PAS) and gram stains but stain very well with the Grocott-Gomori methenamine-silver and calcofluor white stains. The use of lectin-binding stains on histological preparations has been reported for the confirmation of the diagnosis of zygomycosis, but these stains are not widely available.

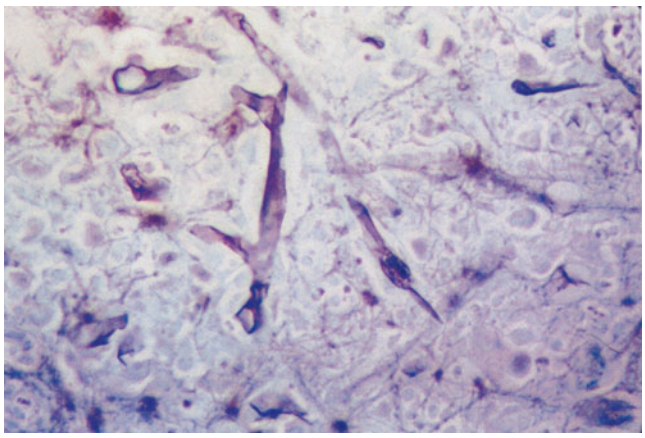

Figure 131-11 Histopathological features of *Zygomycetes* hyphae in a profoundly neutropenic patient with leukemia in whom pulmonary zygomycosis developed. Of note are the characteristic broad nonseptate or rarely septate hyphae with branches at right angles. H&E stain, ×400. *(Courtesy of G. P. Bodey.)*

In tissue specimens *Zygomycetes* appear as broad (10 to 20 μm in diameter) nonseptate hyphae with branches occurring at right angles. Rarely, occasional septae can be visualized. During the handling of infected tissues, hyphae may collapse and fold, giving the characteristic ribbon appearance (Fig. 131-11). Grinding of tissue for culturing is not recommended. Differentiation of *Aspergillus*,*Fusarium*, and *Pseudallescheria* subspecies from *Zygomycetes* hyphae in tissue involves visualizing thinner, more regularly shaped fungal elements with more frequent acute angle branching and the presence of septae in the former group. Tissue histology of *Zygomycetes* infection has revealed a neutrophil infiltrate (in non-neutropenic hosts), necrosis, and invasion of blood vessels with thrombosis in more than 94 percent of the cases. Inflammatory vasculitis involving arteries and veins, and in chronic cases mononuclear cell infiltration with occasional giant cells is observed in chronic cases.

However, in the majority of patients with pulmonary zygomycosis, establishment of a definite diagnosis with biopsy is hampered by the presence of comorbidities, such as thrombocytopenia. Furthermore, routine laboratory cultures, even if performed from specimens with abundant *Zygomycetes* hyphal growth, have a yield of less than 50 percent, and many specimens, including blood, sputum, gastric fluid, and nose swabs, are difficult to culture and often have no diagnostic value. Sputum cultures are not reliable indicators of infection, because some *Zygomycetes* spp. often colonize the respiratory tract. In addition, nonculture-based diagnostic methods such as fungal antigen detection and molecular diagnosis with the use of PCR remains investigational, and no assays with sufficient sensitivity or specificity have been identified. The fact that more than one-half of zygomycosis cases are diagnosed at autopsy indicates the importance of maintaining a high index of clinical suspicion and a low threshold for performing

diagnostic biopsy and repetitive imaging studies in high-risk patients.

Treatment

General Principles

Successful treatment of zygomycosis largely depends on timely diagnosis, reversal of the underlying predisposing factors (when possible), and early and ideally broad surgical débridement of infected tissue in conjunction with systemic antifungal therapy. Early diagnosis is critical to the outcome of patients with zygomycosis because small focal lesions can often be surgically excised before the infection progresses to involve critical structures or disseminates to other organs. Time is of the essence in the treatment of zygomycosis given the fact that the infection has the ability to rapidly spread and disseminate even in relatively asymptomatic patients. For example, studies have shown that making therapeutic decisions based on examination of frozen tissue sections instead of waiting for fixed and stained histopathology is correlated with better outcome in patients with zygomycosis. In addition, rapid correction of underlying conditions such as appropriate control of hyperglycemia and/or correction of diabetic ketoacidosis, tapering of corticosteroids and immunosuppressive drugs, and discontinuation of deferoxamine treatment is critical to outcome. Notably, there have been rare cases in which a patient with cavitary pulmonary zygomycosis recovered from the infection without undergoing antifungal treatment after correction of diabetic ketoacidosis.

Antifungal Treatment

There have been no prospective studies for the primary treatment of pulmonary zygomycosis. Most evidence of the activity of existing antifungal agents comes from small case series, anecdotal case reports, and in vivo studies in animal models of zygomycosis. Therefore, the optimal therapy is uncertain. Currently, the recommended antifungal therapy for zygomycosis includes AMB-D at the highest tolerated dosage, usually 1.0 to 1.5 mg/kg per day. The nephrotoxic effects and acute infusional toxic effects of high-dose conventional AMB frequently preclude long-term high-dose therapy. As a result, the liposomal preparations of AMB present an attractive alternative for treating zygomycosis. Lipid formulations have been used to treat zygomycosis, although no comparative studies have been performed thus far. Outcomes with the use of the lipid formulations of AMB appear to be similar to those historically reported for conventional AMB-based therapy, albeit with fewer adverse effects. In the largest reported case series of zygomycosis, 64 patients received a lipid complex of AMB for refractory disease or intolerance of conventional AMB. The overall response rate (improvement in or cure of infection) was 50 percent, and there were no significant toxic effects, even in patients with preexisting renal disease. Numerous case reports of liposomal AMB used for zygomycosis also indicate favorable responses, including those to the use of particularly high doses of liposomal AMB (10 to 15 mg/kg per day) or prolonged therapy to achieve a cure in some cases. Drainage and AMB instillation into refractory abscesses and cavities was also reported to be successful in a limited number of patients. Successful treatment of pulmonary zygomycosis with an aerosolized lipid complex of AMB (50 mg/day via a Respirgard II nebulizer) and combination antifungal treatment with terbinafine or rifampicin and AMB has been described in single case reports.

Most azoles, including fluconazole and voriconazole, have no meaningful activity against *Zygomycetes* spp. However, posaconazole (200 mg given four times a day), an orally available broad-spectrum investigational triazole, appears to possess potent activity against fungi of this class. In a recently reported open-label salvage trial, the overall success rate of posaconazole (800 mg) was 70 percent in 24 patients. The drug was well tolerated with only minimal gastrointestinal side effects. Similarly, a recent retrospective review of posaconazole-based salvage therapy in 91 patients who had refractory zygomycosis indicated an overall success rate of 61 percent, including a success rate of 65 percent in the group of patients with pulmonary zygomycosis. Furthermore, an additional 21 percent of subjects had stable disease after 12 weeks of treatment. These encouraging preliminary data suggest that use of posaconazole represents an unmet need in the treatment of zygomycosis. For patients requiring further immunosuppression following treatment of zygomycosis, secondary chemoprophylaxis is often desired. Posaconazole seems to be a favorable option for patients who need continuous long-term antifungal therapy because they remain at high risk for relapse of infection. Determining whether posaconazole alone or in combination with a lipid formulation of AMB is preferable will require further studies.

Caspofungin lacks significant activity against *Zygomycetes* in vitro, and clinical experience with caspofungin in the treatment of zygomycosis is extremely limited. Nevertheless, in case reports and a study with a model of disseminated zygomycosis in diabetic mice, echinocandins appear to have some role, especially in combination with a polyene, in serious cases of zygomycosis. Given the fact that several cases of breakthrough zygomycosis to echinocandins have been reported, further studies on the role of echinocandins in treatment of zygomycosis are needed.

Surgical Treatment

Because zygomycosis is a highly angioinvasive infection with resulting extensive thrombosis and tissue necrosis, antifungal agents often display poor penetration at the site of infection. Therefore, even if the causative *Zygomycetes* strain is susceptible to the antifungal agent in vitro, the agent may be ineffective in vivo. Surgical débridement of infected tissue should be performed on an urgent basis. In patients with pulmonary zygomycosis, surgical treatment in conjunction with antifungal therapy has been shown to significantly improve survival when compared with antifungal therapy alone. Hence, a comprehensive review of cases of pulmonary zygomycosis showed that the mortality rate in patients who received antifungal

agents alone was 55 percent versus 27 percent in patients who received antifungal agents and surgery. Removal of as much of the infected or devitalized tissue as possible while the infection is localized has the greatest benefit. Lobectomy is often required, and pneumonectomy may be necessary for proximal or extensive involvement. Also, repeated procedures may be needed. The benefit of pulmonary resection diminishes as dissemination occurs.

Other Adjunctive Therapies

A recent review of 28 cases of zygomycosis suggested that treatment with hyperbaric oxygen (HBO) may be a beneficial adjunct to the standard surgical and medical antifungal therapy for zygomycosis, particularly in patients with diabetes mellitus who have rhinocerebral disease. The increased oxygen pressure achieved with treatment with HBO appears to improve the ability of neutrophils to kill organisms. Furthermore, by correcting lactic acidosis, treatment with HBO promotes the oxidative action of AMB. Additionally, high oxygen pressure inhibits fungal growth in vitro and improves the rate of wound healing by elevating tissue oxygen levels and releasing growth factors. However, data on treatment with HBO of pulmonary zygomycosis are scarce, and its role in this setting remains uncertain.

The role of adjunctive cytokine therapy for zygomycosis has not been studied in detail. Cytokines that activate phagocytic activity, such as interferon-γ and GM-CSF, increase the killing efficacy of phagocytic cells against *Zygomycetes* spp. in vitro. Case reports have indicated a favorable outcome in patients with rhinocerebral zygomycosis following the addition of interferon-γ and GM-CSF to the treatment regimen. Further studies of cytokines that activate host phagocyte function are warranted for this infection.

The central role of iron metabolism in the pathogenesis of zygomycosis supports the hypothesis of using effective iron chelators as adjunctive antifungal therapy. In contrast with deferoxamine, other iron chelators do not allow the organism to take up iron, thereby inhibiting its growth in vitro in the presence of iron. Furthermore, whereas administration of deferoxamine in a previous study significantly worsened disseminated *R. oryzae* infection in an animal model of zygomycosis, treatment with an iron chelator significantly increased the median survival rate in the animals.

OTHER EMERGING OPPORTUNISTIC MOLDS

Over the past decade, and with the ever-expanding spectrum of immunocompromised patients, we have witnessed the emergence of less common but medically important opportunistic fungal pathogens, including septate filamentous fungi such as hyalohyphomycetes (e.g., *Fusarium*, *Scedosporium*, and *Trichoderma* spp.), dematiaceous fungi (e.g., *Phaeohyphomycetes*), endemic dimorphic pathogens (e.g., *Penicillium marneffei*), and rare pathogenic yeasts (e.g., *Trichosporon* spp.). The diagnosis of invasive fungal pneumonia caused by septate filamentous fungi is particularly challenging because of the similarity of the manifestations and histopathological features of these mycoses with those of IA. Given the fact that most of these infections have a poor outcome because of broad-spectrum resistance to conventional antifungal agents, timely diagnosis is critical for outcome. Therefore, pulmonary infections caused by hyalohyphomycetes, including *Fusarium* and *Scedosporium* spp., are discussed below.

Pulmonary Fusariosis

Fusarium spp. are ubiquitous filamentous fungi found in soil, water, and decaying material. Although *Fusarium* is a well-known plant pathogen, only a few of the 50 different species have been reported to be pathogenic in humans, including *Fusarium solani*, *Fusarium oxysporum*, *Fusarium moniliforme*, *Fusarium verticilloides*, *Fusarium dimerum*, and *Fusarium proliferatum*. Of these species, *F. solani* is the most virulent, causing one-half of all cases of invasive fusariosis reported in humans. Since the description of the first case of disseminated fusariosis in a child with acute leukemia in 1973, invasive fusariosis has emerged in several tertiary care cancer centers as the second most common invasive mold infection in profoundly immunocompromised patients after IA.

There seems to be a distinct seasonal peak and geographic distribution of invasive fusariosis. Hence, the vast majority of the cases have been reported in the United States during the rainy summer season, when the dispersion of fusarial conidia in the air is most pronounced. More than 90 percent of human invasive fusariosis cases occur in neutropenic patients with hematological malignancies, especially those with acute leukemia. Another risk factor for invasive fusariosis is GVHD treated with high doses of corticosteroids during the postengraftment period in HSCT recipients.

The skin and respiratory tract are the primary portals of entry for *Fusarium* infection. Inhalation of *Fusarium* conidia through the lung and paranasal sinuses by a severely immunocompromised host may lead to sinopulmonary infection characterized by angioinvasion, extensive tissue necrosis, and secondary dissemination. In addition, disruption of skin integrity because of local trauma or placement of a central venous catheter or in the setting of onychomycosis with associated cellulitis appears to be a relatively common portal of entry for disseminated *Fusarium* infection that involves the lung in immunocompromised hosts. The ability of *Fusarium* spp. to undergo adventitious sporulation with formation of microconidia in vivo facilitates dissemination and may account for the high rates of positive blood cultures and associated skin lesions in cases of fusariosis. Neutrophils probably play the most critical role in the control of human *Fusarium* infections. Several studies have demonstrated that the prognosis for patients with fusariosis is clearly associated with prompt recovery of neutrophil counts. In fact,

the mortality rate in patients with fusariosis in the setting of profound, prolonged neutropenia is essentially 100 percent, even with aggressive antifungal treatment, compared with a rate of approximately 30 percent in the setting of neutrophil recovery.

Fusariosis in immunocompromised patients manifests in four major patterns: refractory fever of unknown origin, sinopulmonary infection or pneumonia, disseminated infection, and a variety of focal single-organ infections. Pneumonia occurs in more than 80 percent of patients with invasive fusariosis. Sinopulmonary fusariosis is most often clinically and radiographically indistinguishable from the much more common IA and other invasive mold infections. Sinus involvement is also frequent, as it has been observed in up to 80 percent of cases in some reports. One of the diagnostic challenges in immunocompromised patients with fungal pneumonia is differentiating among IA, invasive fusariosis, and zygomycosis. Hence, recovery of *Fusarium* spp. from cultures of appropriate specimens is essential for a definite diagnosis.

The histopathological picture of *Fusarium* is identical to that of *Aspergillus* and other hyalohyphomycetes (e.g., *Scedosporium* spp.) and may lead to misidentification. Even so, there are subtle differences in the histopathological features of *Aspergillus* and *Fusarium* spp. that can facilitate differentiation between the two species based on the histopathology itself, including the presence of *Fusarium* chlamydospores in tissue (Table 131-8).

Because hyalohyphomycetes (*Aspergillus* versus *Fusarium* versus *Scedosporium* spp.) have different levels of susceptibility to antifungals, the ability to differentiate among these molds before culture results are available by using molecular identification methods could have significant implications on therapeutic decision making. In situ hybridization directed against ribosomal 18S RNA sequences was recently shown to rapidly and accurately distinguish *Fusarium*, *Aspergillus*, and *Scedosporium* spp. from histopathological specimens. However, further standardization of these promising molecular methods is needed. Thus, tissue cultures remain the gold standard for differentiation among these fungi.

Despite the clinical similarities between pulmonary fusariosis and IPA, there are some characteristics that favor the diagnosis of invasive fusariosis (see Table 131-8). First, *Fusarium* spp. are usually recovered from blood specimens in the setting of disseminated disease. The reported rate of positive blood cultures in patients with disseminated fusariosis ranges from 50 to 70 percent, and fungemia may be the only manifestation of infection. In fact, *Fusarium* spp. are the most common molds associated with true fungemia in HSCT recipients. This feature contrasts with disseminated IA and zygomycosis cases, in which these molds are rarely (less than 5 percent) isolated from blood specimens, with the notable exception of *A. terreus*.

Another distinctive feature of invasive fusariosis is the high incidence (50 to 70 percent) of skin lesions in patients with disseminated disease. This contrasts with the low incidence of skin lesions in patients with disseminated aspergillosis (less than 10 percent). In fact, skin lesions are frequently the sole diagnostic material for invasive fusariosis. Several patterns of skin lesions can be seen: subcutaneous nodules, purpura, red or gray macules and/or papules with or without progressive central necrosis, flaccid pustules, vesicles, and hemorrhagic bullae. The most characteristic skin lesions encountered in cases of disseminated fusariosis are "ecthyma gangrenosum-like" lesions, which are red or gray macules with central ulceration or black eschar. *Fusarium* skin lesions are often tender, especially subcutaneous nodules, and can involve any skin site, although they appear predominantly in the extremities. Most patients have lesions at different stages of evolution. Accompanying myalgia is also common, reflecting concomitant muscle involvement.

Fusarium is one of the fungi most resistant to the arsenal of modern antifungal agents, and breakthrough infections to AMB or triazoles are common. In particular, *F. solani* is the most resistant species within the genus. The mainstay in the treatment of fusariosis has traditionally been AMB-D. However, the in vitro susceptibility of *Fusarium* spp. to AMB-D is mediocre at best. Whether the in vitro susceptibility of *Fusarium* spp. alone can predict outcome is unclear, because other factors (e.g., neutrophil recovery) are probably the most critical determinants of the prognosis for fusariosis. There have been reports of improved outcome of fusariosis with the use of high-dose lipid formulations of AMB. Hence, the mortality rate in patients who received high doses of a lipid complex of AMB (greater than 5 mg/kg per day) was significantly lower (less than 30 percent) than that observed in patients who received conventional AMB-D doses (greater than 75 percent) in a previous study.

Among the antifungal triazoles, fluconazole and itraconazole are not active against *Fusarium* spp. However, the newer broad-spectrum triazoles voriconazole and posaconazole have variable in vitro activity against *Fusarium* spp. and show promise in the management of fusariosis. In a recent study, administration of voriconazole resulted in a favorable response in five (45 percent) of 11 patients with fusariosis refractory to or intolerant of standard therapy. Posaconazole, an investigational broad-spectrum triazole, is also active against *Fusarium* spp. both in vitro and in animal models. In a recent case series including patients with fusariosis refractory to or intolerant of standard treatment modalities, salvage treatment with posaconazole had a response rate of 50 percent. Given that AMB and the newer triazoles voriconazole and posaconazole are the most active agents against *Fusarium* spp., a strategy combining a lipid formulation of AMB with one of these triazoles is reasonable and should be explored further.

Because the neutrophil count seems to be the most crucial prognostic determinant in fusariosis cases, a potentially beneficial adjuvant therapeutic strategy is to transfuse granulocytes obtained from G-CSF– and GM-CSF–stimulated donors. Granulocyte transfusion has been suggested to result in more favorable response rates (33 to 50 percent) in profoundly neutropenic patients by shortening the duration of neutropenia.

Table 131-8

Differentiating Features among the Major Opportunistic Mold Infections of the Lung

Incidence	*Aspergillus* causes the vast majority of cases of fungal pneumonia, followed by *Zygomycetes*
Predisposing factors	*Zygomycetes* spp. are associated with the presence of diabetes mellitus, malnutrition, iron overload states, and voriconazole prophylaxis
Clinical features	Skin lesions are more common in disseminated fusariosis (50%–70%) than in disseminated IA (<10%) and disseminated zygomycosis (<10%)
	Skin lesions in fusariosis are different from those in IA and zygomycosis (*Aspergillus* and *Zygomycetes* skin lesions are fewer, less widespread, have a larger diameter, and present with a black eschar with a thinner erythematous halo)
	Fungemia is more common in fusariosis (60%–70%) than in IA (<5%) and zygomycosis (virtually absent)
	Fungemia also often occurs earlier in fusariosis than in IA (shortly before death or after death)
	The *Zygomycetes* and *Fusarium* spp. are highly resistant to antifungal agents and develop as breakthrough infections to antifungals with anti-*Aspergillus* activity
Histopathological features	Broad-based nonseptate or pauciseptate ribbon-like hyphae are pathognomonic for *Zygomycetes*
	The presence of chlamydosporia in histopathology is pathognomonic for *Fusarium* spp.
CT features	On CT scans, multiple nodules, and pleural effusions favor the diagnosis of pulmonary zygomycosis versus IPA
	Pulmonary zygomycosis has a predilection for the upper lung lobes
Serology	Positive galactomannan antigen is virtually diagnostic for IPA

Pulmonary Scedosporiosis

The genus *Scedosporium* comprises a group of filamentous fungi found ubiquitously in the environment. The two major human pathogenic species are *Scedosporium apiospermum*—the asexual state of *Pseudallescheria boydii*—and *Scedosporium prolificans*. Both of these species histologically resemble *Aspergillus* spp., with hyphae that are septate and branching at acute angles. Although *Scedosporium* infections can occasionally occur in immunocompetent individuals, the overall incidence has increased over the past decade because of improved diagnostic modalities and the expanding population of immunocompromised individuals. These fungi can cause fatal angioinvasive infections in immunocompromised hosts that manifest with sinopulmonary, central nervous system, osteoarticular, ocular, endovascular, and lymphocutaneous involvement. Disseminated infection is associated with high (greater than 75 percent) mortality rates. *Scedosporium* spp. are known to be remarkably resistant to most conventional antifungals, such as AMB; however, treatment with newer triazoles, such as voriconazole, appears to be more efficacious.

Spores of *Scedosporium* spp. enter the respiratory tract by inhalation and the skin by direct inoculation to areas of trauma. Germination of conidia results in hyphal invasion in tissue with the potential to disseminate hematogenously to distant anatomic sites. Similar to *Fusarium* spp., dissemination may be facilitated by the ability of *Scedosporium* spp. to undergo adventitious sporulation in vivo. In general, strains of *S. prolificans* are more virulent than strains

of *S. apiospermum*. *S. prolificans* produces melanin, which may be an important virulence factor contributing to in vivo protection against host defense mechanisms.

Patients with AIDS, congenital or acquired immunodeficiency, or hematological malignancies as well as recipients of stem cell and solid organ transplants and those receiving antineoplastic or immunosuppressive medications are especially susceptible to these filamentous molds. In these immunocompromised individuals, sinopulmonary disease with lymphatic and/or hematogenous dissemination to various organs most often occurs.

The spectrum of pulmonary scedosporiosis largely mimics aspergillosis, ranging from respiratory tract colonization to allergic bronchopulmonary hypersensitivity to saprophytic fungus ball formation in preexisting pulmonary cavities and finally to invasive pulmonary or disseminated scedosporiosis. Invasive disease without preexisting lung tissue damage caused by *S. apiospermum* can occur only in immunocompromised hosts during or immediately after periods of prolonged neutropenia, and fever is the most common clinical presentation. Onset of infection may also be manifested by pulmonary symptoms, maculopapular skin lesions that later may become necrotic, myalgia, and central nervous system and other organ involvement. On rare occasions, pulmonary infections that spread to involve the central nervous system are reported in immunocompetent individuals after massive inoculation with *S. apiospermum* by aspiration of polluted water. Fungemia is diagnosed in more than two-thirds of patients with disseminated *S. prolificans* and *S. apiospermum* infection. The radiographic appearance of pulmonary infections caused by *S. apiospermum* and *S. prolificans* is essentially indistinguishable from that of IPA. Because no radiographic findings are truly pathognomonic for *Scedosporium* infections, diagnosis relies on prompt histopathological and microbiological evaluation.

Histopathological features of *Scedosporium* spp. in tissue sections can be confused with those of other fungi that have acute-angle–branching septate hyphae. The melanin-specific Fontana-Masson stain may be used to confirm the presence of dematiaceous hyphae of *S. prolificans* in tissue. Nevertheless, definitive diagnosis requires fungal culture and is crucial for antifungal susceptibility testing.

In general, *S. prolificans* is resistant to all clinically available antifungal agents, whereas *S. apiospermum* is susceptible to miconazole, voriconazole, and posaconazole. Both species are inherently resistant to the polyenes, including AMB. Data from clinical studies are limited. In a multicenter study of voriconazole administered as salvage therapy for scedosporiosis, the overall response rate of voriconazole for scedosporiosis outcomes of voriconazole therapy for *S. apiospermum* (33 percent) was better than that for *S. prolificans* (25 percent).

Severe *S. prolificans* infections have been successfully treated with a combination of voriconazole and terbinafine. In combination with azoles, terbinafine, an allylamine that blocks squalene epoxidase in the ergosterol synthesis pathway, has demonstrated synergistic interactions in vitro against clinical isolates of *S. prolificans*. Limited experience in patients with disseminated *S. prolificans* suggests that the combination of voriconazole and terbinafine is a legitimate treatment option.

Surgical débridement in cases of pulmonary scedosporiosis should be considered, especially for abscess drainage as well as for localized infections. In general, neutrophil recovery has been associated with an improved prognosis. Interferon-γ and GM-CSF have been shown to enhance neutrophil oxidative mechanisms of killing against *S. prolificans* hyphae. Although clinical data are scarce, in view of the dismal prognosis for patients with *Scedosporium* infections, immunomodulating therapy, including G-CSF, GM-CSF, interferon-γ, and primed white blood cell transfusions, should be considered as an adjunct treatment modality for these infections.

Cryptococcosis and the Endemic Mycoses

L. Joseph Wheat • Mitchell Goldman • Kenneth Knox

Histoplasmosis and blastomycosis mostly afflict those living in the Mississippi and Ohio river valleys while coccidioidomycosis occurs primarily in the southwestern US desert (Fig. 132-1). Histoplasmosis and coccidioidomycosis also are endemic in parts of Mexico and Central and South America. Infection with *Cryptococcus neoformans* var. *gatti* is endemic to parts of British Columbia and Australia while *C. neoformans* var. *neoformans* exhibits no geographical predilection.

These organisms are found in the soil, and infection occurs following inhalation of the infectious forms of these fungi when sites containing the organism are disturbed. In some endemic areas over one-half of residents have acquired these mycoses early in life. In healthy individuals the infections are usually asymptomatic or clinically self-limited. In others, especially if the patient is immunosuppressed, the course is progressive and fatal without treatment. While these mycoses are less often seen in patients with acquired immunodeficiency syndrome (AIDS) who have access to effective antiretroviral therapy, they are occurring more frequently in those with other immunosuppressive conditions, and continue to be pathogenic for individuals without underlying disease.

In a study evaluating hospitalized patients with histoplasmosis, blastomycosis, or coccidioidomycosis in 2002, mortality was 5 percent in children and 7 percent in adults; only 13 percent were immunosuppressed; and the hospital costs exceeded $250 million, providing an estimate of the impact of the endemic mycoses in the United States. Advances in diagnosis and treatment provide opportunities to improve the outcome of these mycoses.

CRYPTOCOCCAL INFECTIONS

Cryptococcosis is caused by infection with the encapsulated fungus *Cryptococcus neoformans,* an organism with a worldwide distribution. Inhalation of *C. neoformans* initiates the infection in the lung with hematogenous dissemination most often involving the meninges. Although pulmonary infection

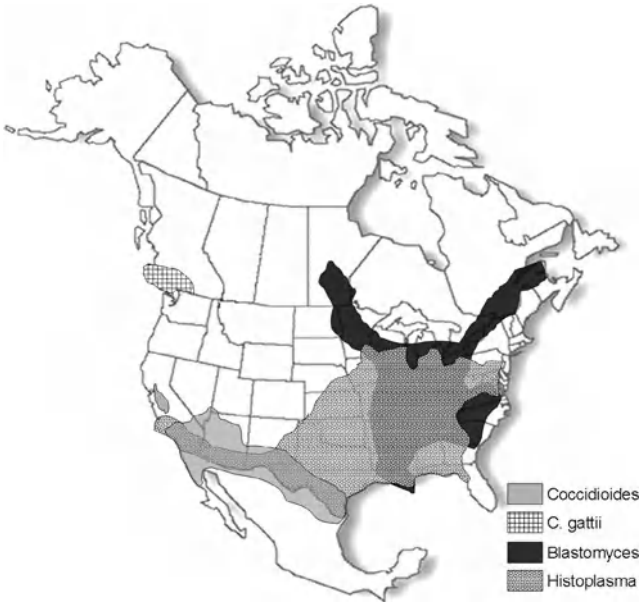

Figure 132-1 Geographical distribution of endemic mycoses in the Americas. The area of histoplasmin skin test reactivity in the southwestern US represents cross-reactivity caused by coccidioidomycosis, not endemic histoplasmosis.

may be discovered in the presence or absence of disseminated infection, meningoencephalitis remains the most commonly diagnosed form of cryptococcal infection. The spectrum of disease ranges from asymptomatic pulmonary infection in the immunocompetent host to diffuse pulmonary disease associated with respiratory failure and widespread disseminated disease in the immunocompromised host. The incidence of cryptococcosis in patients with AIDS in the United States has declined since the introduction of potent antiretroviral therapy; most cases now occur in those with limited access to care.

Mycology

C. neoformans is a yeast that is characterized by its thick polysaccharide capsule. The yeast measures 4 to 6 μm in diameter but the capsule thickness varies from 1 to more than 30 μm. Organisms are smaller and less well encapsulated in the environment, explaining their ability to reach the terminal airways following inhalation. *C. neoformans* grows readily in fungal media, allowing isolation in less than 48 hours and identification by biochemical tests or DNA probes. Four serotypes of *C. neoformans* have been described—A, B, C, and D.

Epidemiology

Serotypes A and D predominate in North America and Europe and grow best in composted bird droppings or rotted vegetation. Serotypes B and C are classified as *C. neoformans* var. *gatti* and are more common in tropical and subtropical regions in association with eucalyptus trees rather than avian excreta. Recently outbreaks of infection caused by *C. neoformans* var. *gatti* have been reported in British Columbia (Fig. 132-1). Otherwise outbreaks or clusters of cases are rare in cryptococcosis, and in most cases a history of exposure to birds or dust is lacking. Person-to-person transmission does not occur if cryptococcosis has been transmitted through organ transplantation; cutaneous infection has occurred after direct inoculation.

Patient populations at increased risk for progressive cryptococcosis include those with T-cell–mediated immune defects caused by AIDS, lymphoreticular malignancy (particularly Hodgkin's disease), or immunosuppressive medications, including tumor necrosis factor (TNF) inhibitors. The disease also appears to be more frequent in diabetics. *C. neoformans* var. *gatti* infection occurs mostly in immunocompetent hosts.

Pathogenesis

Cryptococcosis is acquired by inhaling aerosols containing the yeast but rarely by direct inoculation. Progressive disease often follows exposure in patients with impaired cellular immunity. In tissue, a mixed macrophage, lymphocyte, and plasma-cell response is seen, but inflammation may be minimal in immunodeficient subjects. Granulomas are uncommonly found in the nervous system and may be seen in other tissues.

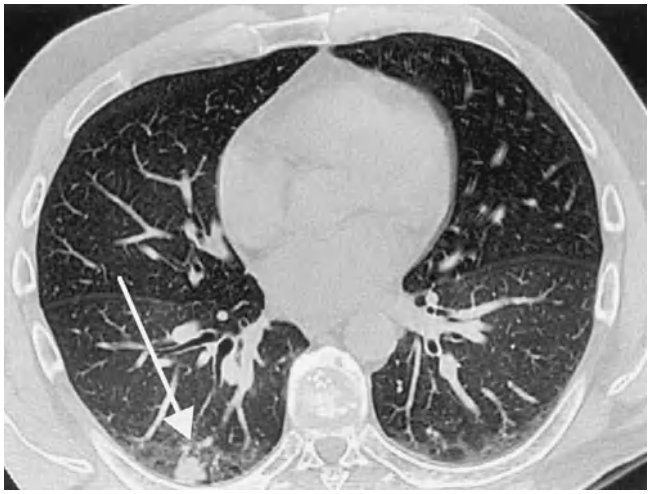
Macrophages, natural killer cells, and T lymphocytes play the key roles in cellular defense against *C. neoformans*. Inflammatory cytokines (interleukin [IL]-2, IL-12, interferon-γ) and macrophage colony-stimulating factor enhance the antifungal activity of these cellular mechanisms. Humoral immunity complements cellular mechanisms in defense against *C. neoformans*.

Clinical Findings

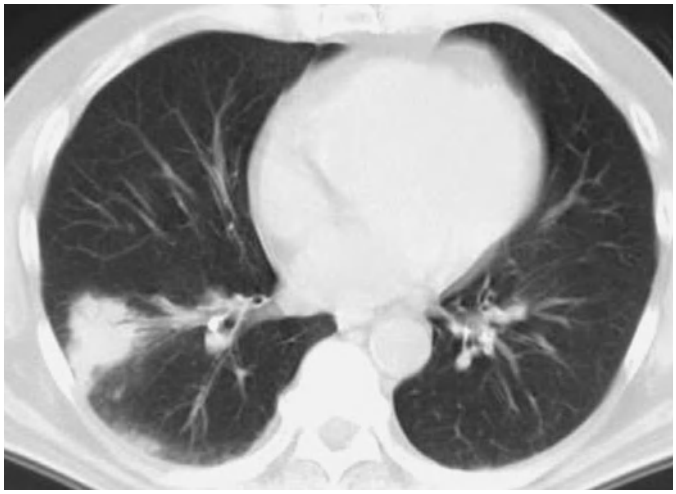
Cryptococcal infection results in asymptomatic or self-limited pulmonary disease in most healthy individuals. While symptomatic isolated pulmonary cryptococcosis may be diagnosed, meningoencephalitis is the most commonly recognized manifestation of cryptococcosis and the most common cause of death. Hematogenous dissemination to almost any tissue occurs in fewer than 25 percent of cases.

Pulmonary

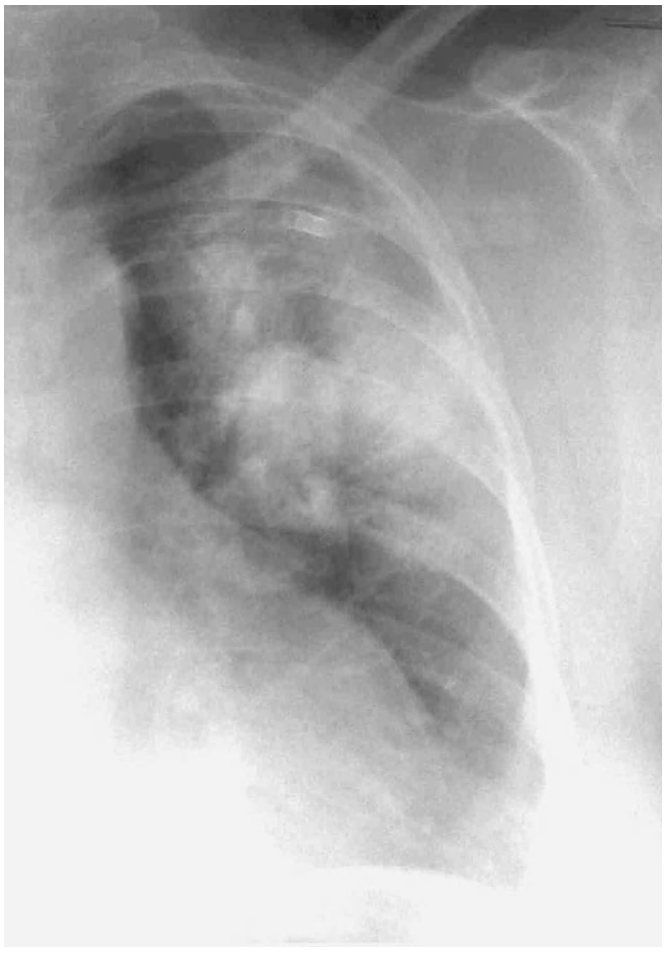
Isolated pulmonary infection is not uncommon, and saprophytic colonization has been observed. Pulmonary cryptococcosis often is asymptomatic, discovered when chest radiographs are done for other reasons. Concurrent disseminated disease occurs in about 15 percent of cases. In symptomatic cases, common complaints include dry cough, dull chest discomfort, and low-grade fever. Less commonly night sweats, fatigue, weight loss, or hemoptysis may occur. Nodular infiltrates are typical of pulmonary cryptococcosis in the normal host (Fig. 132-2). Pulmonary cryptococcosis in



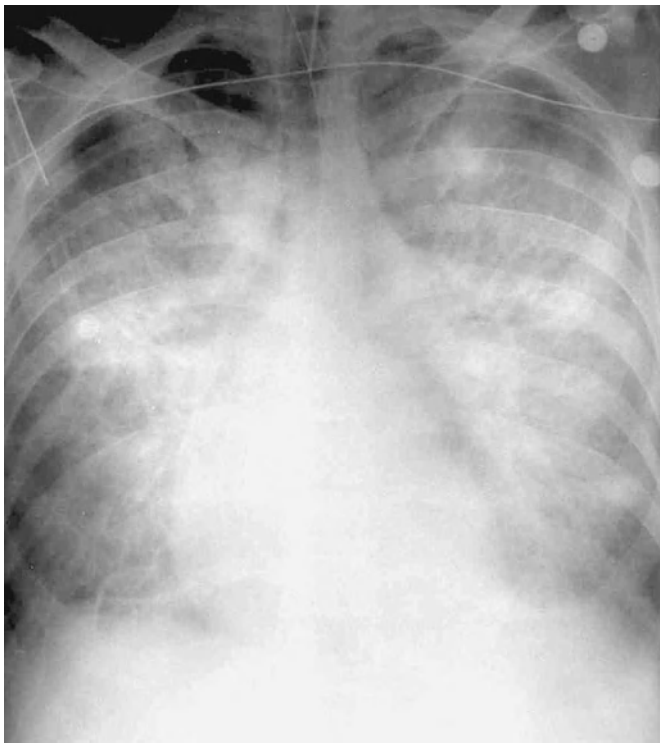
A



C



B



D

Figure 132-2 Chest radiograph findings of cryptococcosis. *A*. Peripheral nodule. *B*. Masslike lesion. *C*. Computed tomography of mass lesion. *D*. Chest radiograph showing diffuse infiltrate.

nonimmunosuppressed patients usually resolve without therapy. Occasionally pulmonary cryptococcosis progresses slowly or may be accompanied by meningoencephalitis or dissemination to other organs after improvement of the pulmonary process.

In contrast to nonimmunocompromised patients, most immunocompromised patients exhibit fever and cough. Diffuse interstitial infiltrates or widespread alveolar consolidation causing respiratory failure is common in severely immunodeficient hosts. Radiographs in patients with less profound cell-mediated immune defects usually show nodular or patchy alveolar infiltrates (Fig. 132-2). Mortality is high in immunosuppressed patients with diffuse pulmonary involvement. Mass lesions are not uncommon and may

resemble malignancy. Cavitation is uncommon and mediastinal adenopathy, pleural effusion, and calcification are rare. A halo sign, usually attributed to aspergillosis, may be observed in cryptococcosis. Empyema, pleural disease suggesting a Pancoast's tumor, and pneumothorax have been reported. As immunosuppressed patients with pulmonary cryptococcosis often have meningoencephalitis, a lumbar puncture is recommended in these patients even in the absence of signs or symptoms of central nervous system (CNS) infection.

Meningoencephalitis

Meningoencephalitis is the most common manifestation of cryptococcosis. A gradual onset is typical, but a more rapid presentation may be seen in patients with severe immunodeficiency. Symptoms include fever, headache, nausea, and vomiting, while less than one-third of patients exhibit meningismus, altered mentation, or focal neurological abnormalities. Elevated intracranial pressure is common and may cause brain-stem herniation. Focal brain lesions occur in about 10 percent of cases, alone or in combination with meningoencephalitis.

Other Sites of Dissemination

Extraneural involvement may be seen in patients with meningoencephalitis or pulmonary cryptococcosis. Hepatosplenomegaly and bone marrow suppression are seen most commonly while lesions involving the skin, eyes, bones, or joints occur in about 5 percent. Other sites of dissemination include the heart, pericardium, muscle, gastrointestinal tract, peritoneum, thyroid, larynx, breast, placenta, urinary tract, prostate, and organ of Corti.

Immune Reconstitution Syndrome

Up to 30 percent of patients with AIDS and a recently diagnosed cryptococcal infection may exhibit an immune reconstitution inflammatory syndrome (IRIS) following initiation of highly active antiretroviral therapy (HAART). Similar findings have been reported following organ transplantation. Clinical findings have included worsening of meningitis with development of intracranial hypertension, hypercalcemia, intrathoracic lymphadenopathy, cavitation of pulmonary lesions, and soft-tissue abscess. These findings represent sterile inflammation resulting from an enhanced inflammatory response made possible by immune reconstitution, and while such changes may resolve spontaneously at times, the inflammatory changes within the CNS have led to death. This has resulted in the suggestion of some researchers that HAART should be withheld for individuals recently diagnosed with cryptococcal meningitis, at least until control of the infection is assured.

Diagnosis

Pneumonia

The diagnosis is usually made by cytology of histopathology of respiratory secretions or lung tissue, and confirmed by culture (Table 132-1). Once a diagnosis of pulmonary cryptococcosis is made, an evaluation for extrapulmonary dissemination should be initiated. A serum cryptococcal antigen test should be performed along with fungal blood culture. Cerebrospinal fluid (CSF) examination is recommended if the patient has any symptoms of meningitis or brain involvement, or is immunosuppressed. The Infectious Diseases Society of America (IDSA) guidelines indicate that a lumbar puncture should be performed in all patients with pulmonary

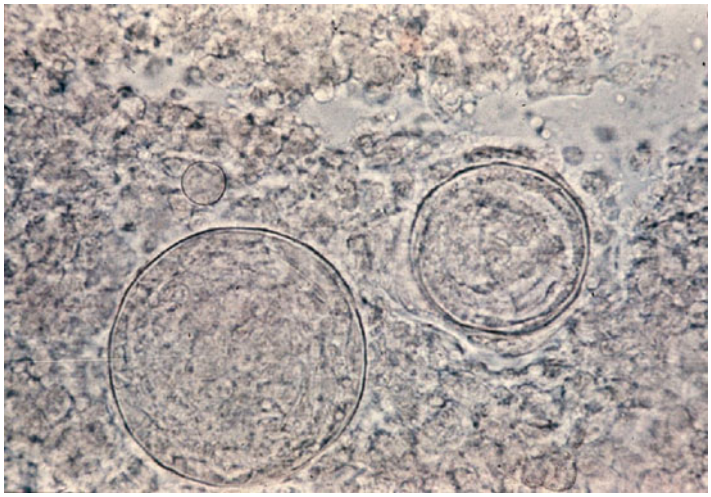
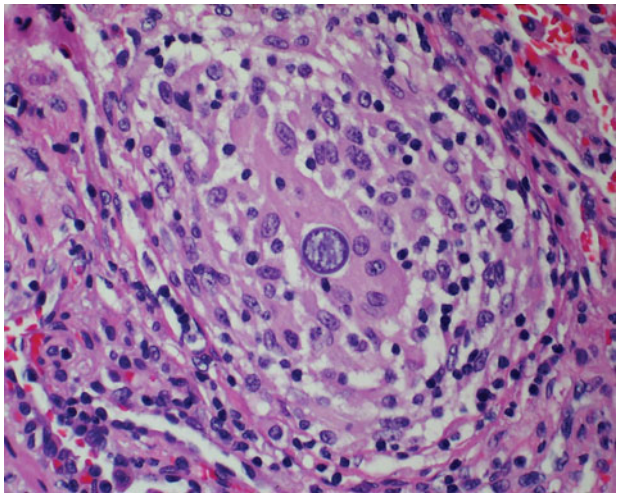
disease without exception, including those who are asymptomatic. However, data supporting such an approach are lacking, and not all experts agree that lumbar puncture is needed in those without clinical findings suggesting the presence of CNS involvement.

Histopathology and Cytology

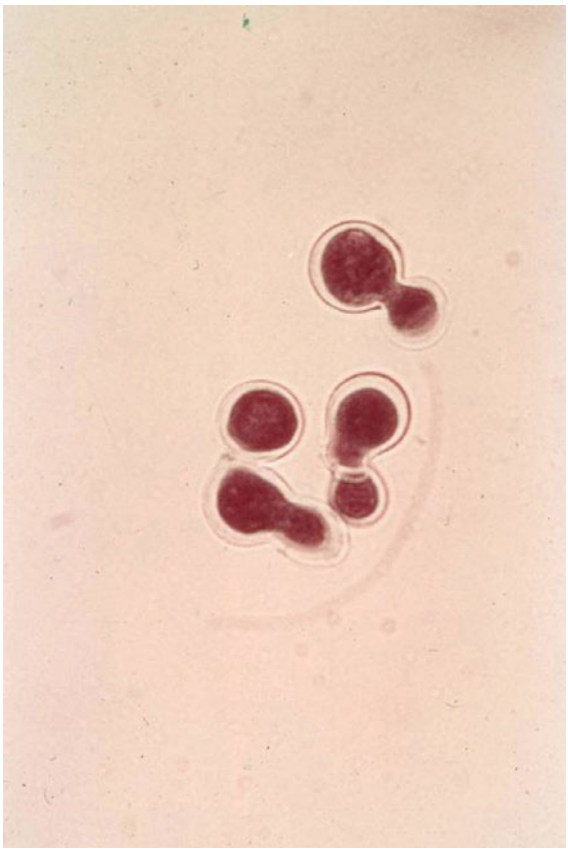
C. neoformans can be recognized in tissue as a globose or oval to lemon–shaped yeast with a polysaccharide capsule (Fig. 132-3). Cryptococci are readily identified by the Gomori methenamine silver (GMS) and periodic acid–Schiff (PAS) stains. More specific stains for *C. neoformans* include the Mayer's mucicarmine stain, which stains the fungal capsule and the Masson-Fontana melanin stain, which may detect capsule-deficient cryptococci. Direct microscopic examination of bronchoalveolar lavage (BAL) fluid sediment stained with India ink can identify the organism. The sensitivity of histopathology in patients with AIDS is about 67 percent.



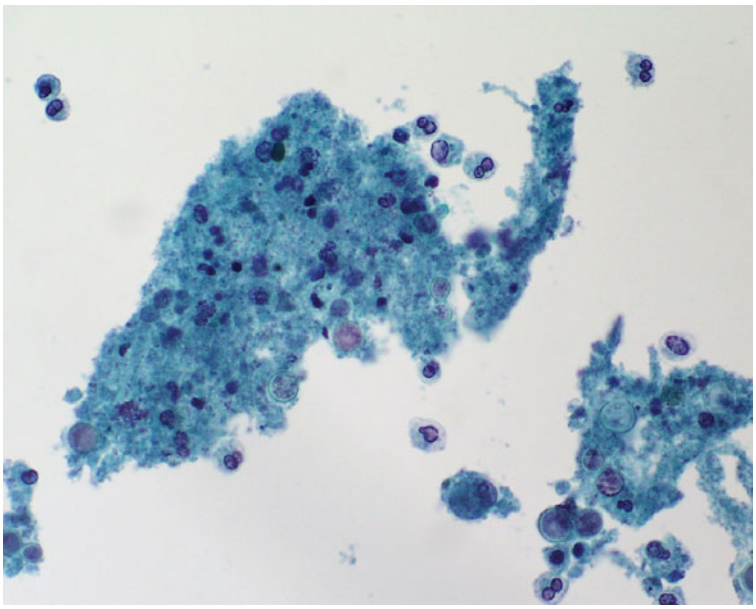
E



F



G



H

Figure 132-3 (*continued*)

In the nonimmunocompromised host, fungal stains of respiratory specimens are rarely positive (approximately 5 percent) despite isolation of the fungus in over two-thirds of cases.

Antigen Detection

In patients with cryptococcal pneumonia, the serum cryptococcal antigen is usually not detected unless extrapulmonary dissemination has occurred, the pneumonia is extensive, or the patient is immunosuppressed. A negative serum cryptococcal test should not be used to exclude the diagnosis of cryptococcal pneumonia. In patients with AIDS with pulmonary cryptococcosis the serum cryptococcal antigen is positive in most cases. Cryptococcal antigen also may be detected in BAL and pleural fluid.

Culture

C. neoformans often can be isolated from sputum in patients with cryptococcal pneumonia. However, isolation from sputum may represent mere colonization. In patients unable to

produce sputum, bronchoscopy may be useful. Cultures of BAL or lung tissue yield the organism in 50 to 90 percent of cases while fungal stains are positive less often. Needle aspiration of focal lesions also may be useful. Thoracentesis may yield the organism in patients with pleural involvement. Blood cultures may be positive in immunocompromised hosts.

Meningoencephalitis

The diagnosis of meningitis can be made initially by India ink stain or detection of antigen in CSF and confirmed by isolation of the organism from fungal cultures. Antigen also can be detected in serum, providing a clue to the diagnosis before lumbar puncture is performed. Cultures also may be positive from extrapulmonary sites in up to two-thirds of patients.

Treatment

Treatment is indicated in patients with symptomatic pulmonary infections, especially if they are immunocompromised and in all patients with meningoencephalitis or disseminated infection (Table 132-2). The rationale and supporting evidence for these recommendations are discussed in an IDSA guideline document. Patients with a diagnosis of cryptococcosis at any site should be provided close follow-up for at least 1 year as the majority of relapses occur during this time period.

Table 132-2

Treatment Recommendations for Cryptococcosis

Pulmonary disease only	
Mild-moderate severity	Fluconazole 200–400 mg/d for 6–12 months
Severe or immunocompromised	Same as CNS disease
Central nervous system (CNS disease)	
Induction/consolidation	Amphotericin B 0.7–1.0 mg/kg/d plus flucytosine 100 mg/kg/d for 2 weeks then fluconazole 400 mg/d for 10 weeks
Maintenance/suppressive	Fluconazole 200–400 mg/d
AIDS	12 months and CD4 count >150 cells/ml
Other immunosuppression	6–12 months

Source: Data from Sang MS, Graybill RJ, Larsen RA, et al. Practice guidelines for the management of cryptococcal disease. Clin Infect Dis *30:710–718, 2000.*

Indications for Treatment

Pneumonia

For asymptomatic patients without extrapulmonary disease, antifungal therapy may be withheld for up to a month if patients can be followed closely. Increasing size or numbers of lesions would be indications for treatment. For symptomatic patients, those who are immunocompromised, and patients showing progression during observation, treatment is advised.

Meningoencephalitis

Treatment is indicated in all cases.

Extrapulmonary Dissemination, without Meningoencephalitis

Treatment is indicated in all cases.

Selection of Antifungal Agent

Pneumonia

For nonimmunosuppressed patients, fluconazole 200 to 400 mg/d for 3 to 6 months is recommended, and itraconazole 200 to 400 mg/d is an alternative. In more severe cases amphotericin B and flucytosine should be given as recommended for meningitis (see below). Treatment guidelines for meningitis should be followed in immunosuppressed patients.

Meningitis

Amphotericin B 0.7 to 1.0 mg/kg/d and 5-flucytosine 100 mg/kg/d should be given for 2 weeks (induction) followed by fluconazole 400 mg/d for 10 weeks (consolidation). 5-flucytosine accelerates sterilization of the CSF and reduces the risk for relapse. Lipid preparations of amphotericin B are less toxic than the standard formulation and are recommended in patients with renal impairment or those who are thought to be at increased risk for amphotericin B nephrotoxicity. Fluconazole alone is not recommended as induction therapy. Itraconazole 200 mg twice daily is an alternative in patients unable to take fluconazole for consolidation therapy. Aggressive management of elevated intracranial pressure through removal of large volumes (about 25 ml) of CSF is essential to achieve the highest survival. Addition of interferon-γ led to clinical improvement in two patients with CD4 lymphopenia unresponsive to amphotericin B.

In patients with AIDS or other immunosuppressive conditions, so-called maintenance or suppressive treatment with fluconazole 200 mg/d is recommended. Itraconazole is inferior to fluconazole for chronic maintenance therapy and is not advised. If itraconazole is used, 200 mg twice daily is recommended. Amphotericin B 1 mg/kg one to three times weekly is another alternative maintenance regimen.

With HAART, two small prospective studies and one larger retrospective study suggested that maintenance therapy can be safely stopped in selected patients. Criteria for withdrawal of maintenance therapy include treatment with fluconazole for at least 1 year and HAART for at least 6 months, a CD4 count of more than 150 cells/ml, and a viral load of

less than 50 copies/ml. Patients require careful monitoring for relapse and continued response to HAART. Resumption of antifungal therapy is recommended if the CD4 count falls below 100 cells/ml. Monitoring serum cryptococcal antigen may be useful, as rising would support resumption of antifungal therapy.

For immunosuppressed patients without AIDS, a 6- to 12-month course of fluconazole is recommended. As in patients with AIDS, careful follow-up is required after antifungal therapy is stopped. In some patients who relapse following such a course of therapy, lifelong maintenance therapy may be appropriate.

Disseminated/Extrapulmonary, without Meningoencephalitis

Trials have not been performed evaluating treatment of non-CNS extrapulmonary disease, and recommendations are based upon experience of the IDSA guideline committee. Recommendations outlined above for pneumonia should be followed in nonimmunosuppressed patients and for meningitis in those who are immunosuppressed.

Role of Fluconazole Resistance

Resistance may be a cause for fluconazole failure. The minimum inhibitory concentration (MIC) of fluconazole required to inhibit greater than 90 percent of strains of *C. neoformans* was 8 μg/ml, which is the breakpoint for defining resistance. In another recent report, nearly one-half of isolates from Spain were resistant to fluconazole. Relapse or treatment failure has been reported in cases with MICs of 25 μg/ml or more.

Newer Antifungal Agents

Alternatives to itraconazole and fluconazole are needed for patients who fail or do not tolerate those agents. Voriconazole and ravuconazole are slightly more active in vitro than posaconazole, with MIC_{90s} of 0.12 to 0.25 μg/ml. Voriconazole penetrates CSF, but not as well as fluconazole. Furthermore, strains with high-level resistance to fluconazole may be cross-resistant to voriconazole. Posaconazole was effective in a murine model of cryptococcal meningitis, but has not been studied in humans, while voriconazole has not been studied in either. There are, however, a few case reports supporting their potential effectiveness. Neither would appear to offer advantages over fluconazole, however. The echinocandins are not active in vitro, have not been studied in animal models, and are not recommended in patients.

Prevention

Although fluconazole and itraconazole reduced the incidence of cryptococcosis in patients with AIDS, prophylaxis is not recommended, largely because of the low attack rate. Other reasons include unlikely cost-effectiveness, limited impact on survival, and potential to induce fluconazole resistance among other fungi. One study reported a survival benefit, however, supporting prophylaxis for populations at unusually high risk.

HISTOPLASMOSIS

Histoplasmosis is the most common endemic mycosis and a major cause of morbidity in patients who live in endemic areas. Progressive disseminated histoplasmosis is an important complication of AIDS and, more recently, of treatment with tumor necrosis factor-α (TNF-α) inhibitors. Understanding of the clinical syndromes and untreated course of the infections is essential in the diagnosis and management of patients with histoplasmosis. Improved laboratory tests have made it possible to rapidly diagnose the more severe cases. Expanded treatment options are available using newer triazole antifungal agents and liposomal formulations of amphotericin B.

Mycology

Histoplasma capsulatum grows as a mold in the soil and converts to a yeast in the tissues (Fig. 132-3). Microconidia measuring 2 to 4 μm in diameter are the infectious particle in the mold-phase of the organism. *H. capsulatum* also grows as a mold on fungal media in the laboratory. Definitive identification of a mold as *H. capsulatum* is made by DNA probe or exoantigen detection. At temperatures above 35°C, *H. capsulatum* grows as a yeast, which is the pathogenic form found in the tissues. The yeast measures about 2 to 5 μm and exhibits narrow-based budding.

Epidemiology

H. capsulatum is endemic in areas of North and South America (see Fig. 132-1) but can be found throughout the world. Bird and bat excrement enhance growth of the organism by accelerating sporulation. Cases outside the endemic region may have been acquired by exposure during travel or prior residence in the endemic area, or exposure to microfoci containing the organism within the nonendemic area. In the endemic areas over 50 percent of individuals exhibit histoplasmin skin test positivity as evidence of past histoplasmosis, and over 500,000 new cases occur annually.

Pathogenesis

Infection develops when conidia are inhaled and germinate into yeast. In many cases primary infection is asymptomatic and goes undiagnosed. Clinical illness most often follows exogenous infection or reinfection. With development of cell-mediated immunity during the first month following initial infection, interferon-γ and IL-12 arm macrophages to kill the fungus and halt progression of the disease. TNF-α also is very important for immune defense against *H. capsulatum*. These defense mechanisms are sufficient to control the infection in immunocompetent individuals, explaining the subclinical or self-limited course characteristic of acute histoplasmosis.

Reactivation of latent infection may account for some cases occurring in individuals with past histoplasmosis who become immunocompromised. Studies showing a low

incidence (less than 0.5 percent) of histoplasmosis following organ transplantation, in patients with AIDS, or following treatment with TNF inhibitors, however, suggest reactivation is rare.

Clinical Manifestations

Heavy exposure can cause severe illness even in healthy subjects. Low-level exposure is more common, however, and usually causes asymptomatic infection or clinically self-limited infection. The common self-limited presentations include acute and subacute pulmonary histoplasmosis, pericarditis, and rheumatological syndromes.

Asymptomatic Infection

In endemic areas, over one-half of residents exhibit histoplasmin skin test reactivity by age 20. In most of these cases, infection was presumed to have been asymptomatic. Most asymptomatic cases are identified as an incidental finding on chest radiographs or computed tomography (CT) scans performed for other reasons. The most common findings are enlarged mediastinal or hilar lymph nodes or pulmonary nodules. The main significance of such findings is the need to differentiate them from malignancy or tuberculosis. Asymptomatic infection also may be identified by demonstration of seropositivity during evaluation of another condition.

Pulmonary Syndromes

Acute Pulmonary Histoplasmosis

Following heavy exposure, patients present with diffuse pulmonary involvement often causing respiratory insufficiency. Chest radiographs usually show diffuse interstitial, reticulonodular infiltrates, nodular, or patchy air-space disease, but a miliary pattern suggestive of hematogenous dissemination may be seen (Fig. 132-4). Initial radiographs may appear normal, evolving to show infiltrates over the next few weeks. Mediastinal adenopathy is common. Evidence for extrapulmonary dissemination is present in less than 25 percent of cases. While patients may recover without therapy, recovery may be slow, respiratory failure may develop, and some infections may be fatal.

Subacute Pulmonary Histoplasmosis

More commonly, the inoculum is small and the presentation is subacute. Patients present with fever, cough, and chest pain. Chest radiographs show mediastinal lymphadenopathy with patchy infiltrates. Most patients recover in a few weeks but some experience persistent fatigue.

Chronic Pulmonary Histoplasmosis

Chronic pulmonary histoplasmosis occurs in patients with underlying lung disease and is characterized by persistent or recurrent pulmonary symptoms, progressive lung infiltrates, fibrosis, and cavitation. Upper lobe infiltrates and cavities are characteristic, resembling the findings in tuberculosis. Progression is manifested by cavity enlargement, formation of new cavities, spread to other areas of the lungs, and bronchopleural fistula. Bacterial pneumonia, *Aspergillus* superinfection, and malignancy also must be considered in evaluation of new masses or infiltrates.

Nodules

Nodules need to be differentiated from malignancy. Calcification suggests histoplasmosis, but does not exclude malignancy. Conversely, absence of calcification, does not exclude histoplasmosis. Positive positron emission tomography (PET) scan, assumed to support malignancy, is common in histoplasmosis. Rarely nodules may cavitate, but cavitation of nodules does not represent chronic pulmonary histoplasmosis and does not require therapy. Nodules also may rarely enlarge up to 2 mm/y, but enlargement is not caused by progressive infection and is not a basis for treatment. Calcification occurs in the necrotic central and surrounding fibrous tissue. An approach to the evaluation of pulmonary nodules has been reviewed.

Broncholithiasis

Lymph nodes and pulmonary granuloma calcify and may erode into adjacent bronchi causing hemoptysis or obstruction. Patients may expectorate rocklike particles of tissue and experience recurrent and severe hemoptysis, bronchial obstruction, or tracheoesophageal fistula.

Relationship to Sarcoidosis

Sarcoidosis and histoplasmosis share several clinical and radiographic findings. Angiotensin-converting enzyme (ACE), sedimentation rate, C-reactive protein, and immunoglobulin elevation occur in both conditions. Noncaseating granulomas are seen with each, and caseation, which is more typical of histoplasmosis, also occurs in sarcoidosis. Histoplasmosis is one of the most common infections that must be excluded before sarcoidosis is diagnosed to prevent mistakes in patient management, most notably administration of immunosuppressive therapy to patients with active histoplasmosis.

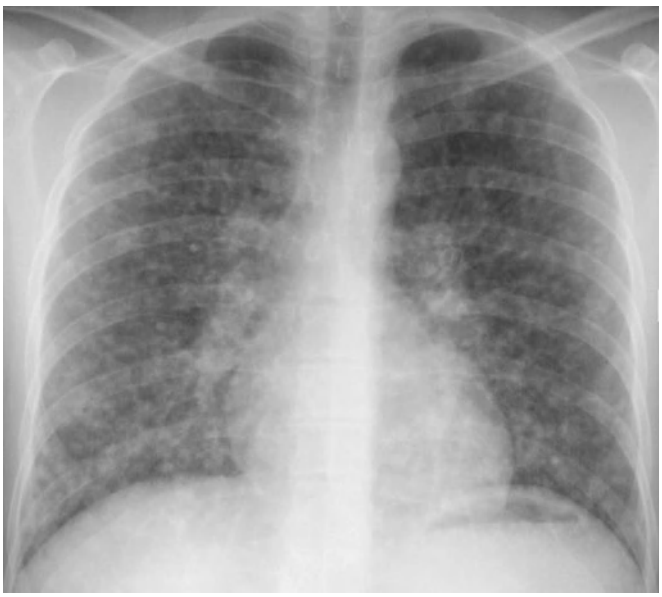
Mediastinal Syndromes

Mediastinal Adenitis

Mediastinal lymph node involvement is present in most cases of acute and subacute pulmonary histoplasmosis. Although usually asymptomatic, chest pain is the most common manifestation. Rarely, the airways, esophagus, or superior vena cava (SVC) may be impinged, causing obstructive symptoms. Airway obstruction is more likely in children because the airways are less rigid.

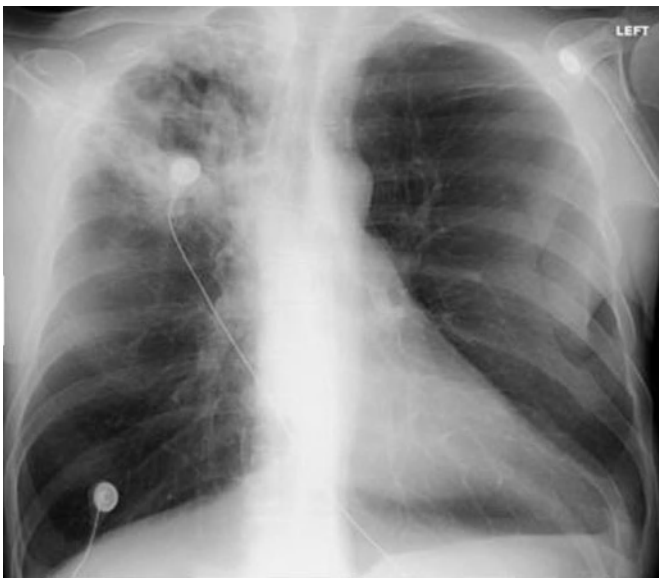
Mediastinal Granuloma

Histopathology shows a necrotic central core, often containing yeast, surrounding caseating and noncaseating granuloma, fibrous tissue, and a thin-walled (less than 5 mm) capsule. The fibrosis is less exuberant than in fibrosing mediastinitis, and does not invade adjacent structures. Symptoms



A

B



C

D

Figure 132-4 *A*. Chest radiograph of acute diffuse histoplasmosis after large inoculum exposure. *B*. Computed tomography of subacute histoplasmosis with mediastinal adenopathy. *C*. Chest radiograph of cavitary histoplasmosis. *D*. Pulmonary arteriogram showing obstruction of pulmonary artery to right upper lung caused by fibrosing mediastinitis.

are usually caused by compression of the SVC, esophagus, or airways, and in some cases the nodes liquefy and drain into adjacent structures. Disruption of the capsule, either spontaneous or caused by surgery, may create fistula to the airways, pericardium, skin, or esophagus. Esophageal involvement may result in diverticulum formation.

Mediastinal Fibrosis

Mediastinal fibrosis represents an exuberant scarring reaction to mediastinal histoplasmosis. The SVC is most commonly involved, but the fibrosis also may occlude airways, pulmonary arteries or veins, or esophagus, and invade the thoracic duct, recurrent laryngeal nerve, or atrium in rare

cases. Chest radiographs show subcarinal or superior mediastinal widening, while CT scans reveal fibrotic restriction and invasion of mediastinal structures and calcification of the lymph nodes. Recurrent and often serious hemoptysis results from lung or airway damage and vascular compromise. Respiratory failure ensues in one-third of cases.

Other Inflammatory Syndromes

Rheumatological Syndromes

Patients with subacute histoplasmosis may experience arthritis or arthralgia accompanied by erythema nodosum, a manifestation often misdiagnosed as sarcoidosis. Chest radiographs usually show mediastinal lymphadenopathy and focal pulmonary infiltrates, but may be normal. These findings represent a systemic inflammatory response rather than disseminated infection, and are managed by anti-inflammatory treatment, not antifungal therapy. The illness may recur when treatment is stopped.

Pericarditis

Pericarditis is another inflammatory complication of primary histoplasmosis, occurring in less than 10 percent of cases. Findings include chest pain, pericardial friction rub, and occasionally signs of pericardial tamponade. Chest radiographs usually show mediastinal lymphadenopathy and increase in the cardiac silhouette, while CT scan and echocardiogram may show pericardial effusion. These patients respond to anti-inflammatory treatment but may require drainage of the pericardial fluid for management of tamponade. Late constriction is rare.

Progressive Disseminated Histoplasmosis

Progressive disseminated histoplasmosis (PDH) occurs in about 1 in 2000 cases, usually in patients who are immunosuppressed or at the extremes of age. Treatment with TNF-α inhibitors is a common predisposing condition. PDH develops during the first few months of infliximab therapy, and later following etanercept, but vigilance for PDH should be maintained throughout the course of immunosuppression.

Fever and weight loss are the most common findings in PDH. Examination reveals hepatomegaly or splenomegaly in about one-half of cases and lymphadenopathy in one-third. A syndrome resembling sepsis may be seen in cases with severe immunosuppression, in whom corticosteroids are given for presumed inflammatory or autoimmune disease, or in which diagnosis is delayed. Meningitis or focal brain lesions occur in about 10 percent of cases. Other common sites of dissemination include the oral mucosa, gastrointestinal tract, skin, and adrenal glands in 5 to 10 percent of cases. Chest roentgenograms are abnormal in 70 percent of patients, usually showing diffuse interstitial or reticulonodular infiltrates, and less often a miliary pattern.

In patients with AIDS and PDH in which HAART is initiated, an immune reconstitution syndrome has been reported. Manifestations have included worsening of hepatic enzymes, hepatic abscesses, lymphadenitis, arthritis, uveitis, and intestinal obstruction.

Diagnosis

Diagnostic modalities were recently reviewed, and are summarized in Table 132-3. Histopathology, cytology, and antigen detection are most useful for rapid diagnosis in patients with acute pulmonary and progressive disseminated histoplasmosis, cases that require therapy. A serological test for antibodies forms the basis for diagnosis in subacute manifestations in most cases. Serology or culture of respiratory secretions usually provides the basis for diagnosis of chronic pulmonary histoplasmosis. To achieve a high sensitivity for diagnosis by culture, multiple specimens must be obtained,

Table 132-3

Diagnostic Studies in Histoplasmosis

Test	Acute Pulmonary	Subacute Pulmonary	Chronic Pulmonary	Mediastinal Granuloma or Fibrosis	Progressive Disseminated
Antigen	75	25	<25	<25	90
Fungal stain	20	<25	40	25–50	50
Culture	40[154]	<25	75	<25	85
Serology	25–75	95	100	70	75

Note: In acute pulmonary histoplasmosis, the sensitivity of antibody detection ranges from about <25% during the first 2 weeks of illness to 75% by the sixth week.
Source: Data derived from Williams B, Fojtasek M, Connolly-Stringfield P, et al: Diagnosis of histoplasmosis by antigen detection during an outbreak in Indianapolis, Ind. Arch Pathol Lab Med *118:1205–1208, 1994.*

often requiring invasive procedures. Culture results may not be available for up to 1 month, limiting their use for diagnosis of severe disease.

Antigen Detection

Detection of antigen in the body fluids offers a valuable approach to rapid diagnosis in patients with PDH and acute pulmonary histoplasmosis, providing results within 24 to 48 hours. Antigen is found in urine of over 90 percent of patients with PDH and 80 percent with acute diffuse pulmonary disease. Sensitivity is improved using a new second-generation antigen assay, developed to prevent false-positive results in organ transplant patients treated with human anti-rabbit antibodies. Antigen detection in urine is less sensitive in subacute pulmonary and chronic pulmonary histoplasmosis. Detection of antigen in BAL fluid may improve the sensitivity for diagnosis of these pulmonary syndromes. Antigen may be found in CSF in 50 percent of patients with *Histoplasma* meningitis. Positive results caused by cross-reacting antigens occur in patients with African histoplasmosis, blastomycosis, paracoccidioidomycosis, and *Penicillium marneffei* infection. Antigen levels decline during treatment and increase with relapse, providing a tool for monitoring therapy.

Histopathology

Fungal staining permits rapid diagnosis but has a lower sensitivity than antigen detection. The highest yield is from bone marrow. Fungal stain of BAL is positive in 70 percent of cases of diffuse pulmonary histoplasmosis in patients with AIDS with PDH. The sensitivity of fungal stain of sputum or BAL in patients with other types of pulmonary histoplasmosis has not been reported but appears to be low. Yeast may be seen in peripheral blood smears in patients with severe PDH. *Pneumocystis carinii, Candida glabrata, Blastomyces dermatitidis, Toxoplasma gondii,* and *P. marneffei* may be misidentified as *H. capsulatum.*

Serological Tests

Antibodies to *H. capsulatum* measured by immunodiffusion or complement fixation develop in most patients. Antibodies first appear 4 to 8 weeks following exposure and persist for several years. Also, the antibody response is greater in patients with heavy exposure and/or more severe clinical disease. Patients with asymptomatic or mild infection, and those who are immunocompromised, may not mount an antibody response. In a study of dogs with naturally acquired chronic disseminated histoplasmosis, immunosuppression with corticosteroids, azathioprine, and cyclophosphamide precipitously reduced antibody levels in animals that were seropositive before immunosuppression.

Serology is most useful in patients with subacute manifestations of histoplasmosis (pulmonary, rheumatological, pericarditis, mediastinal syndromes) and chronic pulmonary infection, positive in 90 percent of such cases. Sensitivity is higher while specificity is lower using complement fixation rather than immunodiffusion methods. Complement fixation titers greater than or equal to 1:32 are more suggestive of active infection but titers of 1:8 to 1:16 should not be disregarded. Cross-reactions occur in patients with other fungal diseases. Also, antibodies persisting following prior histoplasmosis may cause confusion in patients with other lung diseases.

Fungal Cultures

Cultures provide the strongest proof for histoplasmosis but are limited by low sensitivity in self-limited infections and delayed growth (2 to 4 weeks). Cultures are most useful in patients with chronic pulmonary histoplasmosis and PDH. Sputum production is rare in patients with acute pulmonary histoplasmosis, but organisms can be cultured from BAL or other bronchoscopy specimens in some cases. In chronic pulmonary histoplasmosis patients commonly expectorate sputum, and organisms can be found in sputum or bronchoscopy specimens in 60 to 85 percent of cases. Multiple specimens must be cultured to achieve the highest yield. In PDH, the highest yield is from bone marrow or blood, positive in over 75 percent of cases, and in BAL of patients with pulmonary infiltrates. Cultures are usually negative in pulmonary nodules and mediastinal nodes representing subacute or old healed lesions despite demonstration of yeast by histopathology.

Polymerase Chain Reaction

Several laboratories report diagnosis of histoplasmosis by polymerase chain reaction (PCR) on tissues or body fluids. PCR was positive on only 8 percent of urine specimens with elevated *Histoplasma* antigen. PCR is less sensitive than fungal stain for examination of tissue specimens. Currently PCR does not appear to be useful for diagnosis of histoplasmosis.

Histoplasmin Skin Test

Skin tests are not useful diagnostically because of high-background rates of skin test positivity (50 to 80 percent) in endemic areas, false-positive results in patients with other fungal diseases, and false-negative results in PDH. Furthermore, skin tests boost antibody levels, compromising interpretation of serological tests. Skin test reagents are no longer available in the United States. In vitro interferon-γ production upon exposure of mononuclear cells to *Histoplasma* antigen, however, is a surrogate for skin test reactivity.

Exclusion of Histoplasmosis in Workup of Patients with Suspected Sarcoidosis

Considering the similarity between the two conditions, and the risk for progression of histoplasmosis during immunosuppression for presumed sarcoidosis, active histoplasmosis must be excluded before immunosuppressant therapy is initiated. Fungal cultures of BAL, transbronchial lung biopsy, blood, and other sites of suspected involvement should be performed. BAL and urine should be tested for *Histoplasma* antigen, and serum should be tested for anti-*Histoplasma* antibodies. If mediastinal node or lung biopsy is performed, fungal histopathology and culture should be ordered. Biopsy of

other extrapulmonary tissues, when performed, also should be examined for *Histoplasma* by histopathology and culture. Demonstration of yeast by histopathology or elevated levels of *Histoplasma* antigen provide strong evidence for histoplasmosis, and would support delay in immunosuppressive therapy until active histoplasmosis could be excluded. Elevated anti-*Histoplasma* antibodies also should raise concern about active infection, but they may persist several years after the initial infection, and would not exclude a diagnosis of sarcoidosis. If immunosuppressive therapy was initiated in patients with laboratory findings suggestive of histoplasmosis, the patient should be followed closely for evidence of progression of histoplasmosis. Also, if patients with suspected sarcoidosis initially respond to immunosuppressive treatment but later relapse, testing for histoplasmosis should be repeated, as immunosuppression may have accelerated the progression of pulmonary or disseminated histoplasmosis.

Treatment

Most infections are asymptomatic or clinically self-limited, requiring no therapy. Furthermore, treatment has only been studied in PDH and chronic pulmonary histoplasmosis, precluding assessment of effectiveness in the other syndromes. While treatment in cases of acute pulmonary histoplasmosis appears to be effective, patients usually recover without therapy, and studies showing that therapy hastens the response or reduces morbidity have not been conducted. Furthermore, the subacute pulmonary, inflammatory, and mediastinal syndromes are unlikely to be influenced by antifungal treatment as the fungal burden is usually low and the manifestations may not be caused by the residual organisms but rather by the inflammatory response or mass effects of the enlarged nodes.

Indications for Treatment

Acute Pulmonary Histoplasmosis

Patients with symptomatic acute pulmonary histoplasmosis appear to benefit from antifungal therapy (Table 132-4). Adjunctive therapy with corticosteroids may hasten recovery in such patients. Amphotericin B 0.7 to 1.0 mg/kg/d would be preferred as initial therapy in patients who are more severely ill. Itraconazole, 200 mg once or twice daily, is recommended in patients with milder illnesses, and following response to amphotericin B. A 6- to 12-week course is recommended in the absence of PDH, which should be excluded. In cases with PDH, 6 to 12 months of therapy is recommended.

Subacute Pulmonary Histoplasmosis

Patients with subacute pulmonary histoplasmosis usually recover without treatment, and there have been no studies to determine if treatment alters the course or prevents complications. Nevertheless, treatment is reasonable in patients who show no improvement of symptoms after a month of observation. Oral therapy with itraconazole would be appropriate, 200 mg once daily for 6 to 12 weeks.

Table 132-4

Indications for Treatment of Histoplasmosis

Definite
Acute pulmonary, symptomatic
Chronic pulmonary/cavitary progressive
Disseminated
Uncertain
Subacute pulmonary, persistent >1 month
Mediastinal syndrome, persistent >1 month
Inflammatory syndrome, on corticosteroids

Chronic Pulmonary Histoplasmosis

Treatment improves survival, reduces symptoms, promotes radiographic healing, and eradicates *H. capsulatum* from the sputum. Most patients with chronic pulmonary histoplasmosis can be managed without hospitalization and respond well to treatment with itraconazole 200 mg once or twice daily for 12 to 24 months. Amphotericin B 0.7 to 1.0 mg/kg/d is recommended for initial therapy in patients with more severe respiratory insufficiency to achieve a more rapid response.

Mediastinal Adenitis and Granuloma

Patients with obstructive symptoms or fistula caused by mediastinal granuloma should be treated, but whether treatment alters the outcome remains unknown. Itraconazole, 200 mg daily for 6 to 12 weeks, is recommended, after which imaging studies should be repeated to assess response. If the enlarged nodes show reduction in size, therapy might be continued for a total of 3 to 6 months. Surgery should be considered if symptoms persist and are sufficiently bothersome. Antifungal treatment or resection of enlarged mediastinal lymph nodes to prevent fibrosing mediastinitis is not indicated since progression of enlarged mediastinal nodes to fibrosing mediastinitis has not been documented.

Mediastinal Fibrosis

Antifungal treatment is not thought to improve the outcome of mediastinal fibrosis, but therapy with itraconazole, 200 mg daily for 6 to 12 weeks, is commonly tried on at least one occasion and is not unreasonable considering the seriousness of this complication. Occasionally patients benefit from placement of stents in pulmonary vessels or the SVC. Stenting of the airways is not recommended because of the risk for growth of inflammatory tissue causing obstruction of the stent. Surgery is associated with a high mortality and limited efficacy, and should be discouraged. In patients with no other options, care should be taken to select a surgeon experienced with this rare manifestation of histoplasmosis.

Broncholithiasis

Surgical therapy is required for patients with significant hemoptysis or recurrent pneumonia and for repair of fistulae. Antifungal therapy would not be expected to reduce the symptoms since active infection is uncommon in such cases.

Inflammatory Syndromes

Rheumatological syndromes and pericarditis are noninfectious, inflammatory manifestations and respond to anti-inflammatory therapy. Antifungal therapy is not indicated unless the bone, joint, or pericardium are sites of disseminated infection, or if corticosteroids are used for treatment of the inflammatory syndrome.

Disseminated

Treatment is indicated in all patients with PDH. The mortality of untreated disseminated histoplasmosis is 80 percent but can be reduced to less than 25 percent with therapy. Amphotericin B 0.7 to 1.0 mg/kg/d, liposomal amphotericin B 3 mg/kg/d, and itraconazole 200 mg once or twice daily are highly effective. A total duration of 12 to 24 months is recommended in most cases. Among the new antifungal agents, posaconazole appears to be most effective in treating histoplasmosis.

Selection of Antifungal Agents

Amphotericin B may act more rapidly than other antifungal agents. Amphotericin B is recommended for severe cases and women who are pregnant. In patients with AIDS who also have PDH, liposomal amphotericin B (AmBisome) is more effective than standard amphotericin B, with more rapid resolution of fever, higher overall response, better survival, and lower toxicity. Liposomal amphotericin B, 3 to 5 mg/kg/d, is preferred for patients with severe or moderately severe PDH. Treatment can be changed to itraconazole after the patient improves, usually in 3 to 14 days.

Itraconazole is highly effective in most mild to moderately severe cases of PDH and in chronic pulmonary histoplasmosis. Itraconazole capsules require an acidic gastric environment for solubilization and should be given with food or cola. Medications that reduce gastric acidity should be avoided. Itraconazole solution is a good alternative in patients who require gastric acid suppression or who have low blood levels while taking the capsule.

Itraconazole blood levels should be measured after 5 to 7 days of therapy with a sample obtained just before a dose to assure that levels are detectable at trough, and if levels exceed 10 μg/ml by bioassay or 6 μg/ml (combined itraconazole and hydroxy-itraconazole) by high pressure liquid chromatography (HPLC), dosage may be reduced. For those with levels below 1 μg/ml, the oral solution provides better absorption and increases the blood concentration.

Hepatic enzyme inducers reduce itraconazole concentrations and should be avoided. Itraconazole also inhibits intestinal and hepatic cytochrome P450 3A4, causing accumulation of several drugs and increasing their toxicity. As the list of contraindicated medications continues to evolve, physicians should review the drug interactions before starting itraconazole and when new medications are added to the regimen. Furthermore, itraconazole is eliminated by hepatic metabolism and may be ineffective in patients receiving medications that induce cytochrome P450 enzymes. Itraconazole also may cause congestive heart failure and should be avoided in patients with heart disease unless the benefit outweighs the risk. If itraconazole is used in patients with cardiac disease, careful follow-up for development of heart failure is essential, and if heart failure develops, itraconazole should be stopped.

Fluconazole is less active in vitro than itraconazole in histoplasmosis. In patients with AIDS and PDH treated with 800 mg/d of fluconazole for 12 weeks followed by 400 mg/d indefinitely, failure occurred in up to one-half of patients within 6 months. Isolates from patients who failed fluconazole exhibited at least a fourfold reduction in susceptibility to fluconazole in over two-thirds of cases.

Newer Antifungal Agents

Posaconazole and voriconazole are active against *H. capsulatum*, and posaconazole was effective in an experimental model of histoplasmosis. However, voriconazole MICs are higher than itraconazole and posaconazole, and fluconazole treatment induced an increase in MIC to voriconazole (submitted for publication). A few patients have been treated with voriconazole, with inconsistent results, while posaconazole was highly effective, and appears to be the preferred alternative to itraconazole. Echinocandins are not active in vitro or effective in murine models and have not been studied in patients with histoplasmosis.

Maintenance Therapy

Lifelong maintenance therapy was the standard of care in patients with AIDS complicated by PDH before the advent of HAART. With HAART, maintenance therapy can be discontinued in patients who have received at least 1 year of itraconazole, antigen levels less than 4 units in urine and serum, and a CD4 count greater than 150 cells/ml. As with cryptococcosis, patients must be carefully monitored for relapse and continued response to HAART. Resumption of antifungal therapy is recommended if the CD4 count falls below 100 cells/ml or if antigen levels in urine or serum increase, providing evidence of relapse.

Prevention

Patients at high risk for dissemination should avoid activities that expose them to *H. capsulatum*, such as caving or remodeling old buildings inhabited by bats or birds. Hand washing reduces the risk for acute histoplasmosis among persons exposed while crawling in a bat-inhabited cave, while use of loose-fitting paper masks does not. A placebo-controlled study using itraconazole, 200 mg daily, in persons with AIDS demonstrated reduction in the incidence of histoplasmosis. However, since the introduction of HAART, the incidence of

these infections has declined, and is too low to justify prophylaxis. Prophylaxis may be reasonable in areas where the combined incidence of systemic fungal infections exceeds 10 cases/100 patient-years.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is the most serious of the endemic mycoses, often failing therapy. Furthermore, large outbreaks in Arizona and southern California, increasing population in the southwestern states, and travel have placed large numbers of persons at risk. *Coccidioides immitis* is listed as a "Select Agent" of bioterrorism, complicating its use in the clinical and research laboratory.

Mycology

Coccidioidomycosis is caused by the pathogenic fungus, *Coccidioides,* which includes two species, *C. immitis* and *Coccidioides posadasii.* Except for different geographical locations (*immitis* in California and *posadasii* in Arizona), the laboratory properties, virulence factors, pathogenesis, clinical findings, diagnostic approach, and treatment are the same, hence, *C. immitis* will be used to refer to both species in this section.

C. immitis is highly virulent, causing infection upon exposure to only a few conidia and severe disease with larger inoculum. *C. immitis* has been designated as a select agent by the Centers for Disease Control, requiring that it be destroyed upon identification in the laboratory except at facilities approved for handling select agents. *C. immitis* grows as a mold with septate hyphae in the soil and on culture media and as an endosporulating spherule in the tissues of patients. Its arrow-shaped arthroconidia are 2.5 to 4 × 3 to 6 μm in size and are the infectious particles found in soil.

C. immitis converts to an endosporulating spherule at 37° to 40°C. Spherules measure 30 to 60 μm in diameter and contain numerous 2 to 5 μm endospores (see Fig. 132-3). Growth on fungal media occurs rapidly (less than 5 days) and identification may be possible by the 10th day.

Epidemiology

Coccidioidomycosis occurs in a spotty distribution in the southwestern US, northern Mexico, and Central America (see Fig. 132-1). Growth is enhanced by bat and rodent droppings. Climates in the endemic areas are characterized by hot summers, mild winters, and arid conditions. Exposure is heaviest in the late summer and fall when the soil is dry and conditions are windy, especially following rainy winters. In the United States 100,000 new cases occur annually.

Cases often are identified in construction or agricultural workers and archaeologists or students doing projects in the desert, conditions associated with exposure to soil, but winds carry the spores for miles exposing persons with no direct contact with contaminated soil. Cases often are identified outside the endemic area in travelers or past residents of the endemic area, often years after exposure. Coccidioidomycosis also is a threat to laboratory personnel working with the organism outside of biosafety cabinets.

Coccidioidomycosis is a serious opportunistic infection in immunosuppressed patients, including those with AIDS, bone marrow transplantation recipients, and organ transplantation recipients, those who are receiving immunosuppressive treatment, including TNF-α inhibitors, and those with other immunodeficiency conditions.

Pathogenesis and Pathology

Infection occurs following inhalation of arthroconidia of the mycelial phase of the fungus or reactivation of latent infection during immunosuppression. Reactivation is less common than new infection as a cause for infection in immunocompromised individuals. Person-to-person transmission does not occur and exposure by direct inoculation is rare. Transmission by transplantation of an infected allograft has been reported and causes rapidly progressive disease in the recipient.

In the lungs, the arthroconidia enlarge to form thick-walled spherules, which contain multiple endospores. Spherules rupture releasing endospores, which spread locally and disseminate hematogenously. Cellular immunity and neutrophils both are involved in host defense in coccidioidomycosis. Patients with deficient cellular immunity experience severe progressive forms of coccidioidomycosis.

C. immitis produces several mixed pyogranulomatous reactions in the tissues. but, unlike *H. capsulatum*, it is an extracellular pathogen. The neutrophil response and caseous necrosis may lead to development of large abscesses, which often require surgical drainage. Abscesses also may spontaneously rupture or produce fistulas. Tissue and blood eosinophilia often are prominent. Inflammation is less pronounced in patients with AIDS. Fibrosis may be prominent in the lungs or meninges, and as in histoplasmosis, healed lesions frequently calcify.

Clinical Findings

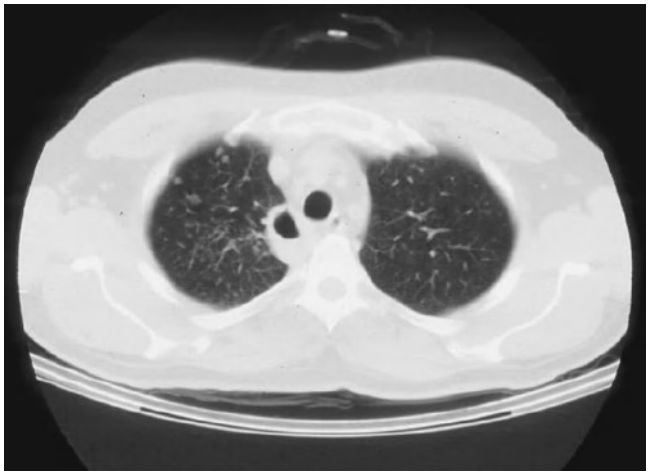
Coccidioidomycosis is asymptomatic in over one-half of cases, and in the remainder symptoms appear 1 to 4 weeks following exposure. In symptomatic cases, a pulmonary illness is most common. While most immunocompetent patients recover without treatment, in some outbreaks over one-fourth of patients experienced severe disease requiring hospitalization, nearly 5 percent developed disseminated disease, and 2 percent died. Disseminated disease is more common in those with underlying immunosuppression.

Primary Pulmonary Infection

Symptoms develop within a few weeks following exposure, depending on the intensity of the inoculum and the immunity of the patient. Low inoculum exposure in the

A

B



C

Figure 132-5 *A*. Chest computed tomography (CT) of cavitary peripheral nodule in acute coccidioidomycosis. *B*. Chest radiograph of diffuse infiltrates in disseminated coccidioidomycosis. *C*. CT of nodular masslike infiltrate that has cavitated.

nonimmunocompromised host usually results in a localized pneumonia, which is often misdiagnosed as community-acquired bacterial pneumonia. In an outbreak following an earthquake, over 80 percent of cases were misdiagnosed as community-acquired pneumonia.

Localized Pneumonia

Symptoms include pleuritic or dull chest pain, nonproductive cough, fever, and malaise. Headache also is common. Macular rash, erythema nodosum, and erythema multiforme are common. A constellation of fever, arthralgia, and erythema nodosum is referred to as "desert rheumatism." Infection is more severe in older persons, those with diabetes, and smokers. Chest radiographs show patchy infiltrates, often with mediastinal adenopathy. Pulmonary nodules occur in about 20 percent of cases and thin-walled cavities in 10 percent, which are usually asymptomatic and clear without therapy (Fig. 132-5). Rarely cavities rupture into the pleural space causing pyopneumothorax, bronchopleural fistula, or empyema. Less commonly pericardial effusions also may be seen.

Diffuse Pneumonia

Diffuse pneumonia may follow large inoculum exposure in the nonimmunocompromised host, and often causes respiratory failure. A miliary pattern, representing hematogenous or lymphangitic dissemination throughout the lungs, although rare, portends a high mortality, and likelihood of extrapulmonary dissemination. Patients with diffuse or miliary infiltrates may develop septic shock, which also carries a poor prognosis.

Chronic Progressive Fibrocavitary Pneumonia

Chronic fibrocavitary infection similar to histoplasmosis and tuberculosis may be seen in coccidioidomycosis. This manifestation is seen in patients with underlying lung disease and tends to progress without treatment, as in histoplasmosis.

Disseminated Disease

Progressive disseminated disease occurs in less than 0.5 percent of cases overall but it is reported in nearly one-half of cases occurring in patients with underlying

immunosuppression. Disseminated disease is often first recognized years following exposure. Risk factors for disseminated disease include nonwhite race, extremes of age, and pregnancy.

Pulmonary involvement is common. Chest radiographs usually show diffuse reticulonodular or miliary infiltrates, but focal pulmonary lesions, nodules, cavities, adenopathy, and pleural effusions also may be seen (see Fig. 132-2).

The extrapulmonary sites commonly involved are skin, bone, joints and meninges, and a shock syndrome associated with respiratory failure has been described. Bone involvement was more common in African Americans while skin and CNS disease occurred more often in Filipinos. Less frequently involved extrapulmonary sites include lymph nodes, liver, peritoneum, kidneys, epididymis, prostate, testes, retina, ears, larynx, heart, thyroid, adrenal, and pituitary glands, esophagus, and pancreas.

Meningitis occurs in up to one-fourth of patients with disseminated coccidioidomycosis, usually presenting within the first month of infection. Patients complain of headache, nausea, vomiting and confusion, and CSF shows lymphocytic pleocytosis. Meningitis carries a poor prognosis and tendency to relapse, despite long-term maintenance therapy. Abscesses may develop in the brain or spinal cord.

Diagnosis

A battery of tests including fungal stain, culture, and serology are useful for diagnosis of coccidioidomycosis (Table 132-5). The sensitivity of these methods is affected by the extent of exposure, immune status of the patient, and the type of infection.

Antigen Detection

Antigen-detection assays for *C. immitis* have been described, but have not been refined for clinical use. Research is ongoing to develop a clinically useful antigen-detection assay for rapid diagnosis of coccidioidomycosis.

Cytology or Histopathology

The sensitivity for examination of sputum is low but may be improved by bronchoscopy, if lesions in the lung or airways can be biopsied, or with BAL. Cytology was positive in 35 percent of culture-positive bronchoscopy specimens for patients with pneumonia, more so with diffuse (46 percent) versus focal (26 percent) infiltrates. In a study of severe diffuse pneumonia in patients with AIDS, Papanicolaou smear was positive in 9 or 14 BAL specimens, compared to KOH wet mount in only 3, calcofluor white stain in 2, and culture in 12. Histopathology is positive on needle-biopsy specimens from lung nodules in about one-half of cases. The sensitivity in extrapulmonary lesions has not been reported but presumably is high, except for meningitis.

Serology

Serological tests are positive in 90 percent of clinically recognized cases, and the magnitude of response correlates with the extent of the infection. Serology is usually negative in asymptomatic cases and often negative in those with mild illness, including thin-walled cavities and nodules. Some report reduced sensitivity in the immunosuppressed host. In patients with AIDS and severe pneumonia, however, serology was positive in only 7 of 13 in one report. In another study of patients with diffuse pneumonia, serology was positive in about two-thirds of cases. Sensitivity may be increased by concentrating the specimen first. Detection of antibody in CSF is invaluable for diagnosis of meningitis. The test proved positive in over 80 percent of cases, while cultures were positive in less than one-third.

The immunoglobulin M (IgM) response can be measured by tube precipitation (TP) or agar gel diffusion (IDTP) and is positive in 50 percent of acute cases during the first week and over 90 percent by the end of the first month of the illness, fading over the next 6 months. However, in an outbreak in

Table 132-5

Diagnostic Studies in Coccidioidomycosis

Test	Acute Pneumonia, Focal	Acute Pneumonia, Diffuse	Nodule or Cavity	Chronic Fibrocavitary	Disseminated (Crum et al, 2004)
Papanicolaou smear or histopathology	<25%	64% (Sarosi et al, 2001)	50% (Forseth et al, 1986)	35% (Sarosi et al, 1970)	>75%
Culture	<10% (Rosenstein et al, 2001)	86% (Sarosi et al, 2001)	10% (Forseth et al, 1986)	95% (Sarosi et al, 1970)	39% (Rosenstein et al, 2001)
Serology	90% (Pappagianis, 2001)	54% (Sarosi et al, 2001)	<50% (Smith & Saito, 1957)	95% (Sarosi et al, 1970)	95% Rosenstein et al, 2001)

Kern County, California, the IDTP test was positive in only 23 percent of patients with mild pneumonia, 39 percent with severe pneumonia, and 21 percent with disseminated disease.

The immunoglobulin G (IgG) response measured by complement fixation (CF) or immunodiffusion (IDCF) follows the IgM and peaks during the fourth month of illness, and then slowly fades. In the Kern County outbreak, CF was positive in 94 percent of patients with mild pneumonia, 91 percent with severe pneumonia, and 94 percent with disseminated disease. CF titers correlate with the extent and severity of infection, and titers greater than or equal to 1:32 suggest dissemination. While CF titers greater than or equal to 1:32 are more common in disseminated versus pulmonary coccidioidomycosis, titers were less than or equal to 1:16 in nearly 25 percent of disseminated cases in a recent report. CF titers greater than 1:32 are also common in patients with chronic pulmonary coccidioidomycosis.

IgM and IgG antibodies also can be measured by enzyme immunoassay (EIA). IgM results were positive in 72 percent of patients with mild pneumonia, 65 percent with severe pneumonia, and 67 percent with disseminated disease in Kern County. However EIA results do not correlate well with CF titers and specificity in fungal controls has not been fully examined. If the EIA test is used, positive results should be verified by immunodiffusion (ID) and/or CF.

Antibody titers decline with treatment, assisting in monitoring therapy and identifying relapse. Serial testing is also indicated in patients who are not receiving therapy, as rising titers suggest progressive infection and support evaluation to exclude dissemination.

Culture

Although few data are available, cultures of respiratory specimens are thought to be infrequently positive in patients with acute pneumonia. The sensitivity of culture for diagnosis of the other pulmonary syndromes also is uncertain because culture positivity was a basis for inclusion in the published studies. Interestingly, cultures were positive in less than 10 percent of needle-biopsy specimens in which spherules were seen by histopathology. Cultures of skin or bone lesions were positive in more than 95 percent of cases of disseminated coccidioidomycosis, while blood, urine, and CSF cultures are positive infrequently, except in renal transplant patients. However, among all disseminated cases, culture was positive in only 39 percent in one study, and the diagnosis was based on serology in the remainder.

C. immitis poses a risk in the laboratory, and must be handled in a biosafety cabinet using biosafety level 3 precautions. Furthermore, as a select agent of bioterrorism, cultures must be destroyed upon identification in laboratories that are not approved for handling them.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) methods have been described but have not yet been studied sufficiently to recommend them for routine use. Their sensitivity, specificity, and accuracy compared to standard methods are unknown.

Coccidioidin or Spherulin Skin Test

Skin test reagents are no longer commercially available. Production of interferon-γ by peripheral blood mononuclear cells upon incubation with *Coccidioides* antigen provides similar information, however, but is not commercially available.

Treatment

Guidelines for treatment have recently been updated. Most infections are asymptomatic or self-limited pulmonary infections, and require no treatment in the absence of immunosuppression. Before withholding treatment, however, patients must be evaluated carefully for the extent of disease and evidence for extrapulmonary dissemination, and in some cases bone scan to identify skeletal lesions and lumbar puncture to assess CNS symptoms may be indicated. In patients in which treatment is withheld, radiographic and clinical follow-up at 3- to 6-month intervals for 2 years is recommended to identify evidence for progressive infection.

Indications for Treatment

Acute Uncomplicated Pneumonia

Some physicians recommend treatment to prevent long-term complications, but most recommend observation without therapy (Table 132-6). Circumstances warranting treatment include immunosuppression, other chronic diseases or conditions affecting recovery from the acute infection, such as diabetes, pregnancy, age greater than 55 years, African American or Filipino descent, and severity of illness. Indicators of severe illness include weight loss greater than 10 percent, intense night sweats for more than 3 weeks, infiltrates involving more than one-half of one lung or portions of both lungs,

Table 132-6

Indications for Treatment of Coccidioidomycosis

Chronic progressive fibrocavitary pneumonia
Disseminated

** Special circumstances include underlying immunosuppression, other chronic disease affecting outcome (e.g., diabetes, heart, or lung disease), age >55 years, pregnancy, Filipino or African ancestry, severe manifestations, infiltrates > one-half of one lung or portions of both lungs, complement fixing antibody titer ≥ 1:32, inability to work, symptoms > 2 months.*

prominent or persistent hilar adenopathy, inability to work, and symptoms persisting for more than 2 months.

Persistent Cavities or Nodules

Five to ten percent of patients with acute pulmonary coccidioidomycosis will develop nodules or cavities, which often are asymptomatic, and require no therapy. Symptoms may include pain, hemoptysis, and those associated with bacterial superinfection. Antifungal therapy is appropriate in patients with persistent symptoms for more than 2 months, in conjunction with antibacterial antibiotics if super infection is suspected. Treatment also is recommended in those with lesions contiguous with the pleura, or exhibiting progressive enlargement. Excision should be considered if the cavity does not decrease in diameter in response to therapy, or persists after 2 years of observation. For cavities that rupture into the pleural space, optimal therapy requires surgical closure by lobectomy and decortication, and antifungal therapy. In patients who are too ill to undergo extensive surgery, chest tube drainage may be appropriate.

Chronic Progressive Fibrocavitary Disease

Antifungal treatment is recommended in patients with chronic progressive fibrocavitary disease.

Extrapulmonary or Disseminated

Treatment is indicated in all patients with disseminated coccidioidomycosis. More controversial is the role of antifungal therapy in the immunosuppressed host with serological, radiographic, or clinical evidence of prior coccidioidomycosis. Death from coccidioidomycosis was reduced by antifungal therapy used as secondary prophylaxis in solid organ transplant patients with a history of symptomatic coccidioidomycosis up to 5 years before transplantation, supporting a recommendation for preventive treatment.

Selection of Antifungal Agents

Amphotericin B 0.7 to 1.0 mg/kg/d is indicated in severe cases, immunosuppressed patients with diffuse pneumonia, and during pregnancy. The lipid formulations are recommended in patients who cannot take the standard formulation because of underlying renal disease or amphotericin-induced nephrotoxicity.

Itraconazole and fluconazole are effective in milder cases. In patients with bone disease, outcome was better with itraconazole. Recommended dosages for fluconazole and itraconazole are 400 mg/d for nonmeningeal disease. Drug interactions and inadequate drug exposure occur more often with itraconazole than fluconazole.

Treatment for meningitis is less effective than for other forms of coccidioidomycosis. Fluconazole 400 to 1000 mg per day is recommended because of its excellent penetration into CSF in conjunction with amphotericin B intravenously in more severe cases. Toxicities may be greater using doses above 400 mg daily, however. Some physicians also administer amphotericin B intrathecally.

Newer Antifungal Agents

The newer triazoles exhibit in vitro and in vivo activity against *C. immitis* and there are a few reports of successful treatment with posaconazole and voriconazole, including cases with meningitis. Despite poor in vitro activity, caspofungin demonstrated efficacy in animal studies; but its effectiveness in patients has been inconsistent, discouraging its use.

Duration of Therapy

In patients with acute pulmonary coccidioidomycosis, a short course of therapy (e.g., 2 to 4 months) may be sufficient. Patients should be re-evaluated before treatment is stopped to identify evidence for chronic infection or extrapulmonary dissemination, in which case treatment should be continued for 12 to 18 months. Treatment should be continued indefinitely for patients with meningitis or those with severe underlying immunodeficiency states. Relapse has been reported in a patient with AIDS with a CD4 count greater than 300 cells/ml who discontinued fluconazole.

Adjunctive Surgical Therapy

Surgical debridement or resection of infected tissue often is necessary as an adjunct to antifungal therapy. Chronic foci of pulmonary necrosis or cavitation may require resection to prevent progression or relapse. Soft-tissue, joint, or bony abscesses may require drainage or debridement.

Prevention

Patients with diseases that impair cellular immunity probably should avoid activities involving dust or soil, areas experiencing active outbreaks, and the desert during dry and windy periods. Antifungal prophylaxis for high-risk patients is not recommended. Some, however, would recommend screening for coccidioidomycosis by chest radiograph and serology before initiating TNF-α inhibitor therapy, and treatment of those with positive results. Efforts to develop a vaccine have been unsuccessful to date.

BLASTOMYCOSIS

Blastomycosis is the least common of the endemic mycoses. Although recognized in immunocompromised individuals, in whom manifestations are more severe, it is less common than histoplasmosis or coccidioidomycosis in this setting. Unfortunately, the diagnosis is often overlooked until late in the course of the disease, when the patient is severely ill and the prognosis is poor.

Mycology

Blastomyces dermatitidis is a thermally dimorphic fungus producing mycelia with 2 to 10 μm dumbbell-shaped conidia at 25°C and doubly retractile, broad-based budding yeasts varying in size from 8 to 30 μm at 37°C (see Fig. 132-3). Isolation

of *B. dermatitidis* in the mycelial form from cultures may require several weeks. Definitive identification is made using DNA probes or exoantigen tests.

Epidemiology

B. dermatitidis is found in microfoci near water that is enriched with animal excreta, and its endemic distribution overlaps that of histoplasmosis (see Fig. 132-2). The organism has been isolated from soil in areas inhabited by farm animals and from beaver lodges or dams. Decaying organic matter enhances its growth in the environment. Several common source outbreaks have been reported, usually associated with outdoor activities such as hunting, camping, or canoeing in wooded or swampy environments.

Pathogenesis and Pathology

Pulmonary disease follows inhalation of conidia and often is accompanied by hematogenous dissemination. Neutrophils are first recruited to sites of infection, followed by lymphocytes. Cellular immunity plays a lesser role in defense in blastomycosis than in histoplasmosis, but disease is more severe in immunosuppressed individuals.

Pathologically, blastomycosis is characterized by granuloma formation with central microabscesses, so-called pyogranulomas, but not by caseation as seen in histoplasmosis or tuberculosis. Histological changes in the skin may resemble those of squamous-cell carcinoma or keratoacanthoma. Calcification is uncommon.

Clinical Manifestation

Following exposure, the incubation period ranges from 2 to 10 weeks, but usually is less than 1 month, although diagnosis is often delayed. In up to one-half of cases the infection is asymptomatic, and in symptomatic cases pneumonia is most common. The importance of consideration of blastomycosis in the differential diagnosis of community-acquired pneumonia was dramatically illustrated by the recent report of fatal outcome in several children.

Pneumonia

Patients exhibit fever, cough, dyspnea, chest pain, and often expectorate purulent sputum. Fibrocavitary disease, as seen in histoplasmosis and coccidioidomycosis, is uncommon in blastomycosis, occurring in only 6 percent of cases. Radiographic findings included nodules, focal infiltrates or consolidation, lung masses, and diffuse infiltrates (Fig. 132-6). Areas of consolidation may resemble cancer, leading to lung resection. Mediastinal lymphadenopathy and calcification are uncommon. The radiographic findings in patients with acute blastomycosis and those with chronic disease are similar, except that cavities and consolidation are more common in patients with chronic and diffuse infiltrates in acute infection.

Acute Respiratory Distress Syndrome

Although acute respiratory distress syndrome (ARDS) may be the presenting manifestation of blastomycosis, in most patients it follows a chronic illness. Patients may have underlying diseases or be otherwise healthy, and about one-half exhibit extrapulmonary dissemination. Pathology is characterized by dense consolidation, microabscesses, hyaline membranes, and alveoli packed with yeast forms. Mortality is high, with death occurring in less than a week following presentation in most cases.

Disseminated Blastomycosis

Dissemination is rare in acute pulmonary blastomycosis but common in those who are undiagnosed and manifest chronic illness. Skin lesions are the most common manifestations, followed by bone, genitourinary, and CNS involvement. Other sites include the sinuses, ears, eyes, thyroid gland, heart, pericardium, pancreas, spleen, liver, and adrenal glands.

Immunocompromised Host

Blastomycosis is more aggressive in this group, with a mortality of nearly 30 percent. CNS involvement or ARDS was reported in 5 to 10 percent of cases. Except perhaps for increased mortality and a tendency to relapse, the clinical findings are similar to that in nonimmunocompromised individuals.

Diagnosis

Fungal stain, cytology, or antigen detection provides the first evidence for the diagnosis in most cases (Table 132-7). Culture, although usually positive, does not permit early diagnosis because growth may be slow. Serology using recombinant antigens promises to be useful in blastomycosis.

Antigen Detection

Antigen can be detected in the urine and/or serum of 92 percent of patients with disseminated or pulmonary blastomycosis. Antigen also can be detected in BAL specimens from patients with pulmonary blastomycosis and CSF of those with CNS involvement. Antigen declines with treatment and rebounds with relapse, guiding treatment decisions.

KOH, Cytology, or Histopathology

Cytology and KOH exhibit variable sensitivity in different laboratories. The sensitivity is similar in pulmonary and extrapulmonary specimens, ranging from below 50 percent to over 90 percent. Bronchoscopy may improve the sensitivity in pulmonary cases with negative results on sputum specimens. The organism also may be identified by GMS or PAS stain in most cases.

Mycology

Definitive diagnosis requires isolation of the organism by culture and identification by exoantigen testing or nucleic acid

hybridization. Cultures are positive in two-thirds to three-fourths of cases, but rarely provide the basis for initial diagnosis because of slow growth.

Serology

Serology using recombinant antigens may assist in diagnosis of blastomycosis. While older methods using crude antigens are neither sensitive nor specific, an immunoassay using recombinant WI-1/Bad1 protein is more accurate. An EIA using Bad1 protein is under investigation.

Polymerase Chain Reaction

PCR methods have been described but have not yet been studied sufficiently to recommend them for clinical use.

Treatment

Treatment is indicated in most symptomatic patients, according to published guidelines and recent reviews.

Indications for Treatment

Treatment is indicated in all patients with diffuse pneumonia, disseminated disease, underlying immunosuppression, or persistent symptoms more than a month following acute infection (Table 132-8). In some cases of acute pneumonia, the course is self-limited and resolves without treatment. Some authorities recommend treatment for all cases, but if observation is under consideration, the following conditions should be met: mild illness and absence of immunosuppression or extrapulmonary dissemination. Furthermore, such patients should be followed carefully for several years for evidence of progression or dissemination.

Whether pregnancy alters the course of infection in the mother is unknown, but there is risk for transplacental transmission to the fetus. Treatment of the mother may reduce the risk for transmission to the fetus. Amphotericin B is recommended as the triazoles are contraindicated because of embryo toxicity and teratogenicity.

Table 132-8

Indications for Treatment of Blastomycosis

Acute pneumonia, moderately severe or severe
Acute pneumonia, mild if not improving after 1 month observation
Disseminated infection
Immunocompromised host

Selection of Antifungal Agent

Amphotericin B 0.7 to 1.0 mg/kg/d is recommended for initial therapy in severe cases and itraconazole for others. In patients who improve with amphotericin B, treatment could be changed to itraconazole 200 to 400 mg daily. Fluconazole is less effective than itraconazole and should be reserved for those unable to take itraconazole.

Newer Antifungal Agents

Voriconazole and posaconazole are active against *B. dermatitidis* and effective in a murine model of blastomycosis. Neither has been studied in humans, but there are a few reports of successful therapy with voriconazole. The echinocandins showed variable activity in vitro but have not been studied in animal models or humans, and are not recommended.

Duration of Therapy

Treatment should be continued for at least 6 months, until clinical and laboratory findings have normalized including antigen levels in urine and serum, and radiographic abnormalities have resolved or at least stabilized to represent residual healed lesions. Some experts recommend chronic maintenance treatment for patients with AIDS or other underlying immunosuppressive conditions. Experience in AIDS is insufficient to assess the safety of discontinuation of maintenance. If maintenance therapy is stopped, the patient should be followed clinically for relapse, and antigen levels should be monitored. Treatment should be resumed if CD4 counts decline below 100 cell/mm or antigen levels rise.

Pneumocystis Pneumonia

Jay A. Fishman

Despite significant advances in our understanding of the treatment and pathophysiology of *Pneumocystis* infection, *Pneumocystis carinii* remains an important pathogen in the immunocompromised host. Since the original association of this organism with epidemics of interstitial plasma cell pneumonitis of young, malnourished children, *P. carinii* has been identified as a cause of pneumonia in a broad range of immunocompromised hosts. The incidence of *Pneumocystis* pneumonia has decreased with appropriate deployment of antimicrobial prophylaxis in appropriate hosts and with the advent of highly effective antiretroviral therapy (HAART) in HIV-infected individuals. PCP remains an important syndrome in HIV-infection in the developing world, with high mortality and often in association with tuberculosis. *Pneumocystis* pneumonia (PCP) has also remained an important syndrome as the survival of immunocompromised individuals has increased after organ and hematopoietic stem cell and bone marrow transplantation, and with the broader use of immunosuppressive therapies in connective tissue and other immune disorders. The proposed change in nomenclature, renaming of *Pneumocystis carinii* as *Pneumocystis jiroveci,* reflects the increase in knowledge about the organisms responsible for this syndrome in different host species and has generated significant controversy among scientists, clinicians, and journal editors. Advocates and detractors alike agree that *Pneumocystis* pneumonia or PCP should be used to describe disease caused by this organism in humans. For this discussion, and in the absence of a clear consensus, the term *P. carinii* is retained for both the human and non-human forms of the organism.

HISTORY AND BACKGROUND

The cyst form of *P. carinii* was described in 1909 (Chagas) and 1910 (Carini) as a part of the life cycle of the trypanosome. It was described in 1912 (Delanoe and Delanoe) as a unique organism infecting the lungs of rats. *P. carinii* was not described in humans until 1942 (van der Meer and Brug), and was not associated with human disease until 1952 (Vanek and Jirovec), when it was found in association with "plasma cell interstitial pneumonitis" in malnourished children and neonates. Small epidemics of plasma cell interstitial pneumonitis had been noted in children in orphanages in Europe in the 1930s. In the 1950s, studies of the immune system led

to the recognition of congenital immune deficiencies and the development of immunosuppressive therapies. At that time, *P. carinii* was recognized in patients receiving corticosteroids and chemotherapeutic drugs, and in immunosuppressed rats receiving corticosteroids. The first case of *PCP* was reported in the United States in 1956.

The increasing incidence of PCP led to epidemiologic and therapeutic studies of the disease by the Centers for Disease Control (CDC) in 1970 and in 1974, based on the provision of the sole therapeutic agent available at that time (pentamidine methanesulfonate) by the CDC. Clusters of *P. carinii* have been reported at a variety of clinical oncology and transplant centers. However, the development of pyrimethamine and sulfadoxine and of trimethoprim (TMP) and sulfamethoxazole (SMX) for the treatment and prevention of *Pneumocystis* infection greatly reduced the occurrence and the morbidity of the infection. These agents are now generally used in a fixed combination (TMP-SMX, cotrimoxazole). *P. carinii* became the first disease-defining illness associated with AIDS in the 1980s, causing over one-fourth of community-acquired pneumonias in HIV-infected persons and more than 200,000 cases of *PCP* occurring since 1979 seen without the use of antibiotic prophylaxis and antiretroviral therapy in the HIV-infected population. Fortunately, as with other AIDS-defining illnesses, effective HAART for HIV-infection has resulted in the dramatic reductions in the incidence of PCP in regions in which such therapies are available. PCP remains a frequent complicating infection in areas without access to HAART, including mycobacterial and endemic fungal pneumonias.

STRUCTURE AND LIFE CYCLE

In humans and animals, three forms of the organism have been identified: trophozoite, cyst, and sporozoite (or intracystic bodies) (Fig. 133-1). The trophozoite, 2 to 5 μ in diameter, is either round or sickle-shaped and contains a nucleus, mitochondria, and vacuoles; it also includes pseudopodia and filopodia, used in limited motility. The cyst usually measures between 3 and 6 μ in diameter. Its cell wall consists of three layers, and its cytoplasm contains eight small pleomorphic intracystic (oval) bodies (sporozoites). Two other cystic forms have been described, but these are probably intermediates including empty or developing cysts (Fig. 133-1). Many small surface projections (tubular expansions) form a branching network over the surfaces of the cysts and the trophozoites. The role of these projections is unknown.

In the alveolus, *Pneumocystis* are covered with a variety of glycoproteins derived from both the organism and the environment. Specific and nonspecific immunoglobulins, albumin, surfactant proteins, laminin, fibronectin, and other serum and lung proteins coat the surface. The organism itself produces a relatively limited array of surface glycoproteins that share antigenic epitopes; these are 110 to 120, 55 to 60, 40 to 50, and 20 to 27 kd in molecular weight. These, and some minor components, are found on both animal- and human-derived organisms. *P. carinii* from different species share antigenic epitopes in addition to carrying unique epitopes. Of note is that most adult patients with *Pneumocystis* pneumonia carry antibodies to the major epitopes of the

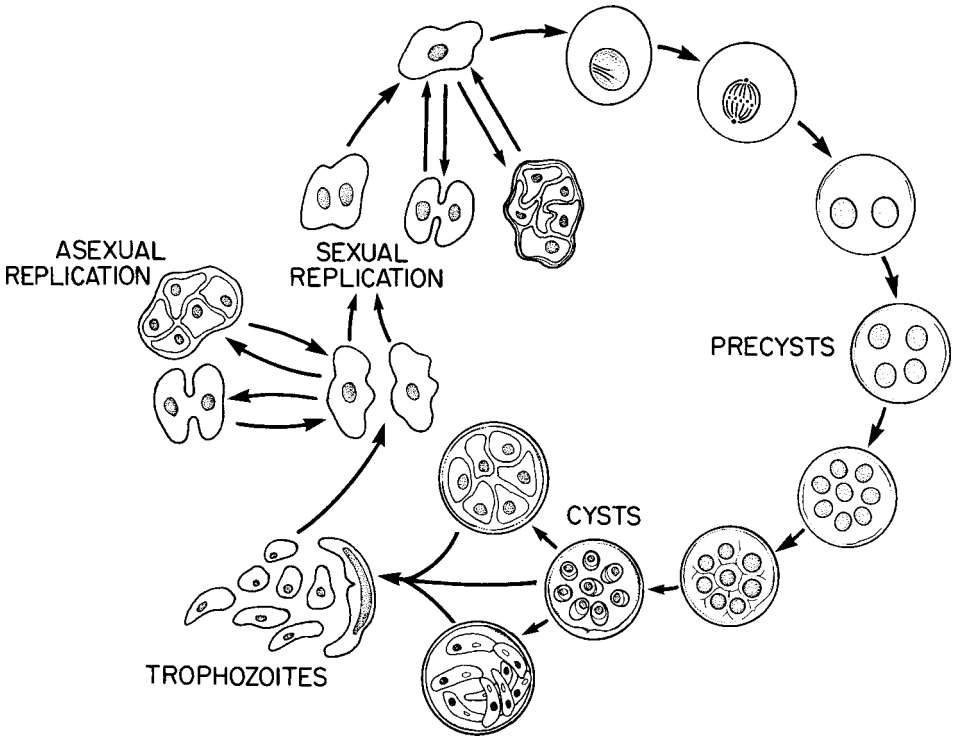

Figure 133-1 The life cycle of *Pneumocystis carinii.*

organism. The cell wall contains cholesterol but no ergosterol and does not appear to synthesize sterols de novo; this accounts for the lack of susceptibility to many of the antifungal antibiotics. The presence of chitin in the cell wall is controversial. The surface of *P. carinii* is carbohydrate rich with glucose, mannose, and β-1,3-glucan, which may play a role in phagocytosis of the organism by macrophages. The surface also contains carbohydrate-binding moieties, which may play a role in attachment to epithelial or surfactant layers.

The life cycle of *Pneumocystis* is poorly understood (Fig. 133-1). Many of the studies of the life cycle have used organisms derived from infected animals and passaged on a feeder cell layer of epithelial or fibroblastoid cells in tissue culture. Continuous growth has not been achieved in this system, and the human-derived organism has not been grown consistently in vitro. Success with axenic or cell-free cultivation of *P. carinii* has been limited. It is now believed that the sporozoites (daughter forms) emerge from the cyst to develop into trophozoites; some of the trophozoites mature to form cysts and then repeat the cycle. This sequence is far from settled, however, and both sexual and asexual intermediate stages have been postulated. It is likely that some differences exist in *Pneumocystis* growth in different hosts and with different immune defects.

Research on *Pneumocystis* has been hampered by the difficulties encountered in propagating the organism in vitro. Studies have been performed on organisms derived from immunosuppressed rodents, which spontaneously develop PCP. Hughes and coworkers have used this model to demonstrate the aerosol transmission of *P. carinii.* Cell culture techniques are not useful diagnostically, because of the difficulty in culturing the organism from infected human tissues. *Pneumocystis* is occasionally grown as a contaminant in viral cultures of bronchial lavage fluid on a variety of feeder cell lines.

TAXONOMY AND MOLECULAR BIOLOGY

Phylogenetic data support the identification of *P. carinii* with the fungi (*Rhizopoda, Myxomycetes, Zygomycota, Schizosaccharomyces, Neurospora, Candida,* and the red yeasts in various studies), based on conserved mRNA sequences. The presence of separate genes encoding the thymidylate synthase and dihydrofolate reductase of *P. carinii,* the presence of a cyst wall rich in β-glucan that stains with periodic acid–Schiff and silver stains, the poorly developed mitochondria, the absence of typical protozoan intracellular organelles, and the airborne spread of infection all support this taxonomic position. The neutral lipid fraction of *P. carinii* includes a variety of phytosterols shared by plants and fungi, including *Physarum* species. However, the appearance of the organism with a thick-walled cyst with internal sporozoites and ameboid trophozoites, the absence of ergosterol, susceptibility to antibiotics used in the treatment of protozoan infections (pentamidine, atovaquone, sulfamethoxazole), and the existence of antigenic variation in the major surface glycoprotein (gp120, gpA, MSG) lend credence to identification with the protozoa.

Based on these observations, it was likely that a new phylogenetic category is needed within the *Ascomycota* for *Pneumocystis.* Difficulty in ascribing *Pneumocystis* to one or another family may be further complicated by the apparent exchange of membrane lipids and perhaps glycoproteins between *P. carinii* and host cells. This may allow the adaptation of *P. carinii* to the host environment, decrease the effectiveness of the immune response, and enhance survival by decreasing the membrane synthetic demands of the organism. Unique cell wall components (glucans, phytosterols) and synthetic pathways (e.g., topoisomerases) may participate in the pathogenesis of infection due to *P. carinii* and may provide targets for the development of new antibiotics.

The existence of different strains of *Pneumocystis* has been demonstrated using pulsed-field gel electrophoresis to establish chromosomal patterns. It appears that infections are often clonal, although multiple strains may coexist in the infected person. Characteristic chromosome patterns have not yet been associated with specific virulence or host characteristics. Characteristic shifts in the telomeric ends of the chromosomes suggest that genetic exchange is ongoing between chromosomes, as occurs in the mechanism of antigenic variation by movement of genetic cassettes noted in the subtelomeric region of the trypanosomes.

P. carinii expresses both unique and some common antigens in different host species. Surface antigens have been characterized at the glycoprotein and molecular levels. The major surface glycoprotein (MSG) represents the main humoral immunogen in the rat model, although other antigens (gp45–55) may have importance in human infection. Several MSG types (up to three) have been observed simultaneously in single infected humans and animals with monoclonal antibody staining and genetic characterization. Because some antigens are shared between glycoproteins of differing sizes and between species, it is unclear whether a single organism can express more than one MSG or switch MSG expression during the life cycle. The MSG appears to represent a large family of related genes (more than 30), many of which are located in tandem repeated arrays in the subtelomeric regions and may contribute to the generation of the variety of antigenic types.

Data from a number of laboratories, including our own, suggest that each genomic copy of an MSG includes an upstream highly conserved expression site and a unique segment downstream that encodes the differing antigenic characteristics of each clone. The organization of the joining region between the conserved and variant segments contains alternating conserved and variant segments, whose function remains to be determined. It is not yet clear whether the conserved intron-exon structure represents a splicing system related to that of the African trypanosomal variant surface glycoprotein, which allows the serial expression of a variety of antigenic types. No evidence for active switching of genotypes has been developed to date (e.g., under selective immune pressure).

However, the presence of splicing is suggested by the absence of genomic intergenic regions in the mRNA transcripts encoding cloned MSGs.

EPIDEMIOLOGY OF INFECTION DUE TO *PNEUMOCYSTIS*

Over the past 50 years, *PCP* has been transformed from a medical curiosity into an important respiratory infection that affects four categories of immunocompromised host: (1) *congenital,* caused by inborn immune defects in antibody-synthesizing capacity and/or in the cellular mechanisms responsible for delayed hypersensitivity; (2) *induced,* by immunosuppressive therapy, especially corticosteroids in the treatment of hematopoietic malignancies; (3) *acquired,* occurring as an identifying opportunistic pathogen in HIV infection or with exogenous immune suppression; and (4) *nutritionally deficient with epidemic infection,* seen primarily in neonates and infants.

P. carinii causes pneumonia in persons with a wide variety of underlying immune deficiencies (Table 133-1). Studies performed in immunosuppressed animals and clinical experience indicate that T-cell immune defects predominate in individuals with *P. carinii* infection. Passive transfer of immune T lymphocytes is protective against *PCP* in mice, whereas transfer of immune globulin alone is only partly protective.

The relative risk of infection with *Pneumocystis* is predictable in most hosts in which this infection occurs. For example, the risk of *Pneumocystis* pneumonia is greatest in the first 6 months after transplantation, after 3 to 6 months of oral corticosteroid therapy, and during periods of increased immune suppression, for example, during the use of bolus corticosteroids or antilymphocyte therapies for graft rejection (Table 133-2). Disease occurring outside the hosts or timeframe predicted on the basis of the predicted degree of immune suppression should suggest an excess epidemiologic hazard or immune deficiency. PCP has also complicated the syndrome of rapamycin lung an idiosyncratic syndrome of diffuse pulmonary infiltrates in solid organ transplant recipients receiving sirolimus-based immune suppression. In AIDS, risk for PCP increases with the progressive fall of the CD4-positive lymphocyte counts to below 200 per cubic centimeter or to less than 20 percent of the total lymphocyte pool. The correlation with T-lymphocyte numbers is such that the rate of infection nearly doubles with a drop in CD4-positive lymphocyte counts from between 100 and 200 to below 100/cm^2. The presence of thrush has also been shown to be an independent predictor of risk for PCP in patients with HIV as a previous bout of PCP. Rarely, PCP occurs at CD4 counts greater than 200 cells/mm and prophylaxis should be offered to such patients starting around the level at which PCP occurred. The occurrence of PCP infection in persons not

Table 133-1

Conditions Associated with *Pneumocystis* Pneumonia

Acquired immunodeficiency syndrome (AIDS) (without HAART)
Chemotherapy (especially corticosteroids)
Radiation therapy
Organ transplantation
Prematurity
Malnutrition (protein and calorie)
Malignancies (especially hematopoietic)
Congenital immune deficiency diseases (cellular and/or humoral)
Collagen vascular disease
Hematologic disorders
Cushing's syndrome
Nephrotic syndrome

Table 133-2

Reported Attack Rates for PCP by Underlying Condition in Patients Not Receiving Prophylaxis

Underlying Disorder	Attack Rate (%)
Acute lymphoblastic leukemia	6.5–42.9
Severe combined immunodeficiency syndrome	27–42
Rhabdomyosarcoma	4–25
Wegener's granulomatosis	3.5–12
Hodgkin's disease	1.3
Collagen vascular disease	<2
Primary or metastatic central nervous system tumor	1.3–1.7

in these categories should suggest exposure to infected persons, other immunosuppressive effects (e.g., coinfection with cytomegalovirus, lymphoma, neutropenia), or in the HIV-infected person, a rapid progression of viral infection with the accompanying decline in systemic immune function. The spectrum of patients developing PCP has changed with the advent of highly active antiretroviral therapy (HAART) for HIV infection and the routine use of prophylaxis for most patients with hematological malignancies or after organ transplantation. In most HIV-negative, immunocompromised patients, the risk of disease is of the order of 5 to 15 percent. The major risk factors for PCP are reflected in a retrospective study of 116 HIV-negative patients with PCP of which 30.2 percent had hematologic malignancies, 25 percent were organ transplant recipients, 22.4 percent had inflammatory disorders, 12.9 percent had solid tumors, and 9.5 percent had other conditions. Corticosteroids use was reported in 90.5 percent of these patients. The median daily dose was 30 mg of prednisone; however, 25 percent of the patients had received as little as 16 mg/day of prednisone. The median duration of corticosteroid therapy before the diagnosis of PCP was 12 weeks. However, 25 percent of the patients developed PCP after 8 weeks or less of corticosteroid use.

In children, epidemiologic studies suggest that PCP may occur as a result of concomitant viral infections and were prominent among infants who die unexpectedly in the community. Beard et al. demonstrated that different strains of *Pneumocystis* appeared to be present in specimens obtained from infants compared with those from HIV-infected adults, suggesting that different strains were circulating among immunocompetent infants and in HIV-infected adults.

The natural reservoir of infection remains unknown. Aerosol transmission of infection has been demonstrated in animal models, and clusters of infections have developed in clinical settings—for instance, between HIV infected persons and renal transplant recipients. *P. carinii* DNA has been detected by polymerase chain reaction (PCR) in the air of hospital rooms, bronchoscopy suites, and clinics used by infected subjects. The frequency of infection varies both by institution and geography. For example, it appears that the incidence of *Pneumocystis* in AIDS patients is much lower in Africa than in the United States. However, this may reflect limited diagnostic capabilities and the morbidity associated with the endemic level of tuberculosis and diarrheal pathogens in Africa, rather than a reduced epidemiologic exposure. The use of PCR technology suggests that carriage of *P. carinii* in African AIDS patients is, in fact, common.

The prevalence of infection with *P. carinii* in patients with AIDS prompted a large effort to develop diagnostic serologic tests that might be applied to the general population. Serologic testing has reinforced the view that subclinical infection is common and that a reactivation of latent infection is often a factor in the pathogenesis of *PCP*. However, in studies of rats cured of *Pneumocystis* pneumonia by trimethoprim-sulfamethoxazole (TMP-SMX), immunosuppression alone does not result in recurrent infection if the animals are maintained in a sterile environment. Recent molecular studies in animals and humans using a variety of genetic probes, including probes for *P. carinii,* ribosomal mRNA internal transcribed spacer regions have suggested that *both reinfection and the reactivation of latent infection are significant factors in the incidence of disease.*

Most people have serologic evidence of exposure by age 4. The rate of identification of organisms in autopsy studies is less than 8 percent. An autopsy series from patients with malignant lymphoma or leukemia demonstrated a 5 percent incidence of identification of pulmonary *P. carinii,* compared with a less than 0.5 percent incidence in immunologically normal subjects. Thus, while the isolation of patients infected or potentially infected with *P. carinii* from immunologically normal patients (who are likely to be seropositive for *Pneumocystis* antigens) is not essential, uninfected, immunocompromised patients should not be exposed to persons with active PCP.

A clear correlation with circulating viral loads in AIDS is not established. Historically, the rate of *Pneumocystis* pneumonia in AIDS was halved by the use of zidovudine for the duration of the effective antiviral effect of this agent. More pronounced effects have been observed in individuals who regain immune function for more than 6 months under HAART therapies; such patients should be able to avoid primary prophylaxis. The rate of infection appears to double in homosexual males with AIDS when compared with intravenous drug users. In the absence of effective prophylaxis or HAART, more than 80 percent of AIDS patients are expected to develop *Pneumocystis* pneumonia.

Corticosteroid use, neutropenia, and lung transplantation are also major predisposing factors in the development of infection. However, in most non-AIDS patients, the risk of disease is around 5 to 15 percent, depending on the nature and duration of the immune suppression. In the solid organ transplant recipient, chronic immune suppression that includes corticosteroids is most often associated with *Pneumocystosis* (Fig. 133-2). Bolus corticosteroids and cyclosporine may also contribute to the risk for *Pneumocystis* pneumonia. Active infection due to cytomegalovirus (CMV) may also enhance the growth of *Pneumocystis* in any affected population (Figs. 133-3*D* and 133-5*B*). Whether CMV directly stimulates the proliferation of *Pneumocystis,* acts systemically as an immunosuppressive agent, or is simply a fellow traveler in the immunocompromised host remains to be settled. The clinical association of CMV with *P. carinii* may reflect similarities in the susceptible hosts or subtle shifts in the alveolar microenvironment.

Clinically symptomatic infection may emerge during the weaning of immunosuppressive agents or as a part of the immune reconstitution syndrome seen with HAART in AIDS. This is consistent with the limited inflammatory response generated by the organism in the susceptible host. Patients with *PCP* generally have both antibodies and T lymphocytes directed at the organism at the time of presentation. Thus, the assumption has been made that such immunities are not protective, the correlates of protection (the target antigens) have

Davis Allen, Jr., New England Deaconess Hospital.)*

not yet been identified, antigenic variation has "switched" the antigens expressed on the surface of the organisms, or protection rests with the cellular immune control of alveolar macrophage function. In the presence of *P. carinii*, cytokine production and phagocytosis by alveolar macrophages are abnormal. Surfactant proteins A and D, members of the collectin family, are increased during *Pneumocystis* pneumonia in patient and animal models, while surfactant lipids are reduced. These changes may contribute to diminished uptake of organisms by resident macrophages.

CLINICAL PRESENTATION

The hallmark of infection due to *P. carinii* is the presence of marked hypoxemia, dyspnea, and cough out of proportion to physical or radiologic findings. In the transplant recipient or the person undergoing corticosteroid therapy, *Pneumocystis* pneumonia is generally acute to subacute in development and often masked by other processes, including allograft rejection or infection. In the AIDS patient with first episode of infection, the evolution is more gradual (often 2 to 5 weeks) and constitutional symptoms and weight loss are prominent. Subsequent infections may evolve more rapidly. In the cancer patient receiving chemotherapy or in the organ or bone marrow transplant recipient, the use of corticosteroids, prior lung infection, abnormal pulmonary lymphatics (after heart, lung, or liver transplantation), and neutropenia may contribute to the absence of radiologically apparent disease. The rate of development of clinical infection is exacerbated by the presence of preexisting lung disease or other infections (e.g., CMV, *Legionella*, mycobacteria) (Fig. 133-2) or allograft rejection (in lung transplantation recipients). In the organ transplant recipient, *Pneumocystis* pneumonia occurs approximately 2 to 4 months after the initiation of immune suppression or during periods of increased immune suppression (pulsed steroids, antilymphocyte therapies, CMV infection). The incidence of infection varies between institutions and with the prophylactic regimens employed. In some series of patients

Typical alveolar exudative pattern from the lung of an adult with *Pneumocystis* pneumonia after therapy with corticosteroids. Swelling of the alveolar epithelial cells and interstitial edema are seen. Inflammatory response in interstitium is minimal (H&E stain, × 500). *C*. *Pneumocystis* in the form of thick-walled cysts within the foamy exudate (displayed by Gomori's methenamine-silver nitrate stain and brilliant green counterstain, × 1250). *D*. Cytomegalovirus inclusion bodies in alveolar macrophages in a patient with *Pneumocystis* pneumonia (H&E stain, × 720). *E*. *Pneumocystis* cysts in cytologic preparation of induced sputum from an AIDS patient (silver stain, × 1250). *F*. *Pneumocystis* pneumonitis. Typical chest radiograph showing bilateral, diffuse interstitial infiltrates extending from hilar area.

receiving lung transplants the rate of asymptomatic isolation of *P. carinii* approaches two-thirds of the total. Of these, up to half are expected to develop symptomatic disease without treatment.

In AIDS patients without HAART, the presentation of *Pneumocystis* pneumonia is often complicated by a variety of factors. Prophylaxis with aerosolized pentamidine or other antibiotics may delay or alter the presentation of disease. As in most immunocompromised hosts, coinfection may accelerate the progression of disease or alter the radiographic pattern; in particular, CMV, *Histoplasma capsulatum, Legionella* spp., and mycobacterial species may contribute to the constitutional symptoms, hypoxemia, and the locality of pulmonary lesions.

Acute exposure to *Pneumocystis* is rarely documented; in animal models, inoculation of *P. carinii* induces a neutrophilic infiltrate that is rapidly (2 to 3 days) replaced with lymphocytes and macrophages. Similarly, in transplant recipients and despite therapy with cyclosporine, *Pneumocystis* induces lymphocyte- and neutrophil-predominant infiltration into the lungs acutely, followed by macrophage infiltration and clearance of organisms. This contrasts with the macrophage- and neutrophil-predominant infiltrates seen in AIDS patients with acute disease. The lymphocytes are primarily T lymphocytes with normal CD4/8 ratios. *Coinfection with CMV and other pathogens will be detected in more than half of* Pneumocystis-*infected patients.* The nature of the immune suppression determines the types of other opportunistic pathogens that coinfect the compromised host. Thus, fungal coinfection has increased as cyclosporine has replaced high-dose corticosteroids in transplant recipients. The expected mortality due to *Pneumocystis* pneumonia is increased in patients taking cyclosporine when compared with other immunocompromised hosts.

EXTRAPULMONARY PNEUMOCYSTOSIS

Pneumocystis was known to cause extrapulmonary disease in the pre-AIDS era, but metastatic infection to significant degrees has been observed only in patients with untreated AIDS. Few cases of systemic infection due to *P. carinii* have been observed in patients receiving systemic prophylaxis with TMP-SMX, while the diagnosis is occasionally not considered in patients using pentamidine prophylaxis. Pulmonary disease may be minimal or absent in such patients. In our hands, blood samples from up to half of the patients with *Pneumocystis* pneumonia have PCR evidence of circulating DNA from this organism. In addition to the liver and spleen, sites of extrapulmonary disease have included eye, ear, lymph nodes, thymus, skin, mastoids, ascites, GI tract and omentum, pleura, kidney, bone marrow, pancreas, and adrenal glands, and it has been reported as a cause of thromboembolic disease. Vasculitis has been reported due to *P. carinii* as a cause of ischemic necrosis of digits.

The presentation of extrapulmonary infection is generally a mass lesion with accompanying fever, sweats, and malaise. Visual loss may accompany retinal lesions, hepatitis with liver impairment, and ascites and GI tract obstruction with peritoneal and omental lesions. By computed tomographic (CT) scan, many nonenhancing, low-attenuation masses, often with necrosis and/or hemorrhage, may be seen in the liver or spleen (Fig. 133-2). Calcification may occur at the edge of such necrotic lesions during the acute infection, often in the hepatic or renal parenchyma. Histopathology will demonstrate granulomas with giant cells, calcification, or cavities. Distant sites may also contain the same frothy hyaline material seen in the alveoli in pulmonary disease (Fig. 133-3). *P. carinii* will be seen adherent to the blood vessel walls, with myointimal inflammation and thrombosis.

Dual infections may occur with any organism, including mycobacteria, *Histoplasma, Legionella,* fungi, or common bacteria. Unless superinfection has occurred or splenic rupture or other life-threatening condition is imminent, systemic treatment of multiple small abscesses due to *Pneumocystis* infection should be adequate without surgical intervention.

RADIOGRAPHY

The Chest Radiograph

The chest radiograph plays a central role in the diagnosis of *PCP* (Figs. 133-4 and 133-5). However, no radiographic pattern is pathognomonic for *Pneumocystis* infection, any more than for the other atypical pneumonias—interstitial processes on chest radiograph that present with hypoxemia and fever, but without sputum production. The radiographic pattern depends on the patient's underlying or accompanying disease, state of immunosuppression, and duration of infection. Sometimes the chest radiograph is normal despite overt pulmonary disease. More often, the early stage of *PCP* is manifested by fine, bilateral, perihilar, diffuse infiltrates that progress to an interstitial alveolar butterfly pattern; from the hilar region, the infiltrates spread to the apices or bases. Despite therapy, this pattern is often succeeded in 3 to 5 days by progressive consolidation, the appearance of air bronchograms, and complete opacification of the lung fields.

As in many of the atypical pneumonias, unusual courses and patterns are seen: nodules, unilateral infiltrates, or even lobar consolidations (Figs. 133-4 and 133-5). Small pleural effusions also occur. Distortions in pattern are commonly produced by prior radiation, drug-induced pulmonary injury, or concurrent infection with other organisms. The patient with recurrent disease may develop chronic interstitial markings, small cysts, or honeycombing on chest radiograph. The distribution of cysts in pneumocystosis, when present at all, is more often diffuse, while peripheral or apical bullae are often seen without infection in intravenous drug abusers. Rarely, cavitary disease is seen in the absence of other pathogens;

Figure 133-4 Atypical pattern of *Pneumocystis* with *Mycobacterium avium-intracellulare* in a Haitian woman with AIDS. *A*. Diffuse pulmonary infiltrates before treatment of *Pneumocystis* infection. Arrow indicates small abscess cavity. *B*. After treatment for *Pneumocystis,* many small cavities persist (arrow). *C*. Transbronchial lung biopsy of initial infiltrate reveals *Pneumocystis* cysts (silver stain, × 760). *D*. Open lung biopsy after therapy for *P. carinii* included areas of pneumonitis atypical for *Pneumocystis* (upper), which contain *M. avium-intracellulare* (arrowheads, lower) (Kinyoun acid-fast stain, × 950.)

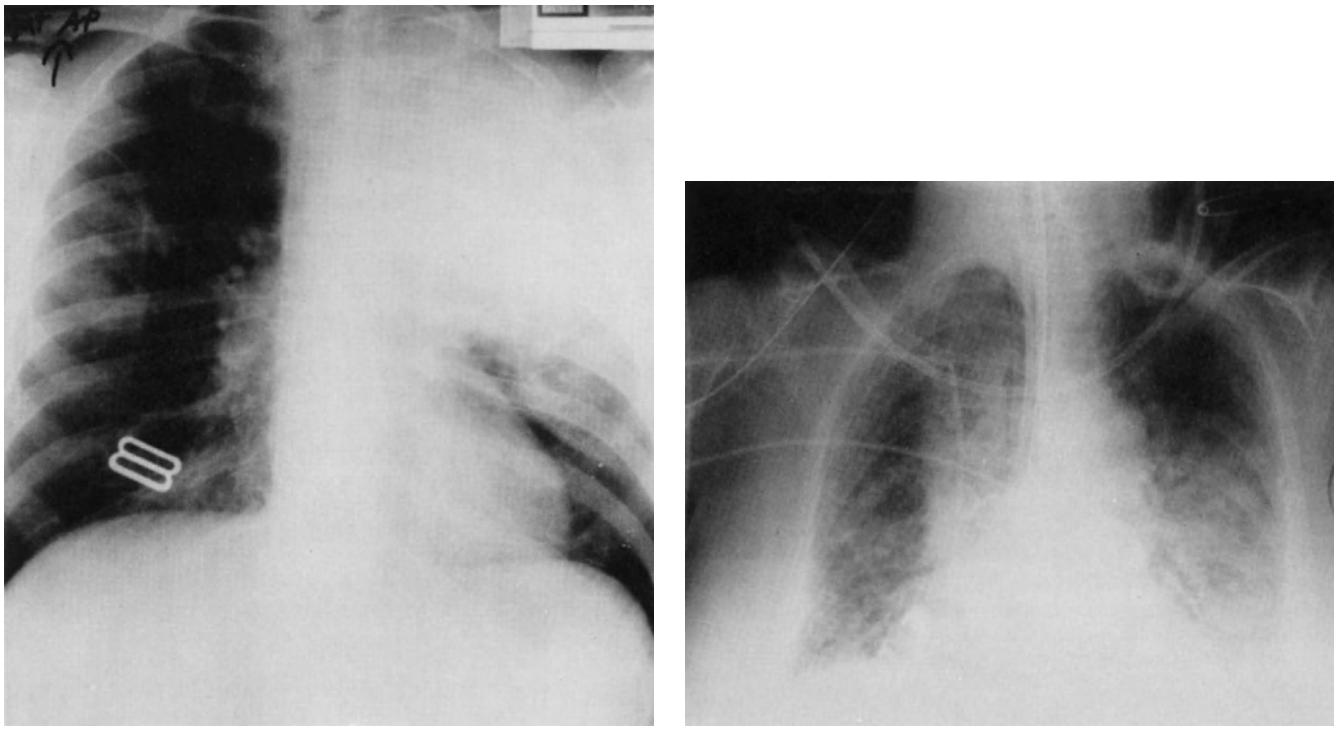
however, *P. carinii* can superinfect fungal or mycobacterial cavities.

The use of aerosolized pentamidine for the therapy and prophylaxis of *Pneumocystis* pneumonia in AIDS created some new problems in the diagnosis and treatment of pneumocystosis (Fig. 133-5). The disease may present largely or solely in the upper lobes on chest radiograph. Similar disease may be seen without pentamidine use, suggesting a predilection of infection for the upper lobes. Cystic changes are more common in patients undergoing prophylaxis who develop *Pneumocystis* pneumonia. The development of spontaneous pneumothoraces may indicate the recurrence of *P. carinii* in the upper lobes despite ongoing prophylactic therapy. Pneumothorax may also complicate the management of intubated patients with *Pneumocystis* pneumonia; active pneumonia or fibrosis in the upper lobes is usually implicated. Undiagnosed, this complication is responsible for a 50 percent mortality rate. Dense consolidation of tissues may suggest dual infection, often with a bacterial agent.

In lung transplant patients, rejection and infection often produce abnormal chest radiographs. In the first month, rejection of the transplanted lung will cause radiographic changes in up to 75 percent of patients. These changes include nodular and interstitial infiltrates in the perihilar area and the lower lobes, which may progress to consolidation. These changes may also occur with infection, of which CMV is the most common. CMV may be indistinguishable from organ rejection without biopsy. After the first month, rejection less often yields radiographic changes (about 25 percent), and the radiographic findings of infection are similar to those of other immunocompromised hosts.

Inflammation Imaging

Nuclear medicine scans are generally nonspecific and add little to the diagnosis of pulmonary pneumocystosis. However, a normal scan will generally exclude diffuse pulmonary infection due to *Pneumocystis*. Gallium citrate, technetium,



A *B*

Figure 133-5 Atypical pneumocystosis. *A*. Upper-lobe pneumonia in an AIDS patient on prophylactic aerosolized pentamidine therapy for a history of *Pneumocystis* pneumonia. The patient had both *P. carinii* and *Legionella pneumophila* infections. *B*. Persistent pulmonary infiltrates in a patient undergoing chemotherapy for non-Hodgkin's lymphoma. Despite 21 days of therapy for *P. carinii,* oxygenation and pulmonary infiltrates failed to improve. An open lung biopsy revealed cytomegalovirus pneumonitis (which responded to therapy with ganciclovir) and drug-induced interstitial fibrosis.

indium-immunoglobulin, white blood cell, and diethylenetriamine penta-acetate (DTPA) scans are abnormal in more than 90 percent of patients with *Pneumocystis* infection. These may be most useful in following the resolution of infection. Gallium scintigraphy can be entirely normal for patients with opportunistic pneumonia with or without AIDS. Conversely, AIDS patients may have abnormal gallium scans in the absence of other infection. Gallium scans often become abnormal before the radiographic appearance of pulmonary disease. Lymph node uptake alone may indicate the condition formerly referred to as AIDS-related complex (ARC), due to HIV infection. Diffuse pulmonary uptake may indicate occult infection in the asymptomatic patient, which would allow early intervention for therapy or prophylaxis. The cost of routine gallium scanning for AIDS patients probably outweighs utility when compared with the judicious use of antiviral or anti-*Pneumocystis* antibiotics based on CD4 cell counts, viral load measurements, or other clinical data. The pattern of lymphoid interstitial pneumonitis (LIP) in children with AIDS is indistinguishable from that of *Pneumocystis* pneumonia.

Some centers make a presumptive diagnosis of *PCP* in the patient with AIDS when a decrease in diffusing capacity (Dlco) is coupled with an abnormal chest radiograph and gallium scan. The clearance of radiolabeled inhaled DTPA is also increased in *PCP* (as in other pulmonary infections). Although these tests are usually abnormal in *PCP*, they lack specificity.

Imaging with radiolabeled (indium) human immunoglobulin (IgG) has proved to be a useful adjunct to the diagnosis and treatment of *Pneumocystis* pneumonia, for two reasons. First, the IgG scan is more sensitive to inflammatory changes than is the gallium scan. This allows the detection of superimposed focal pulmonary processes due to other pathogens in addition to the diffuse pattern seen in *P. carinii*. This sensitivity also allows the IgG scan to be used to follow the resolution of infection in response to therapy, which has not been possible with gallium. Second, the IgG scan has been useful in detecting unsuspected extrapulmonary foci of infection; this may be important in the management of AIDS patients with disseminated *P. carinii* or other processes. The IgG scan is not useful in the neutropenic patient or the uremic patient with dysfunctional neutrophils.

Other Diagnostic Techniques

The chest CT scan will detect interstitial and micronodular disease not visible on routine chest radiographs. Further, the CT and magnetic resonance imaging (MRI) scans

and ultrasound imaging are better suited to the definition of pneumocystomas occurring outside the lung (discussed above; see Fig. 133-2).

LABORATORY FINDINGS

A number of nonspecific indicators of pulmonary processes have been used in the presumptive diagnosis of *Pneumocystis* pneumonia. In general, the patient will have a PO_2 less than 60 mmHg and a respiratory alkalosis. The serum lactic dehydrogenase (LDH) enzyme will be elevated in most cases of *Pneumocystis* pneumonia (over 300 IU/ml), with high levels (over 600 to 700 IU/ml) carrying a poor prognosis in the setting of histologically confirmed infection. Lymphoma, other diffuse pneumonias, and LIP may also raise the LDH level. Respiratory distress and respiratory failure requiring intubation carry a poor prognosis. The marked hypoxemia of *Pneumocystis* pneumonia is accompanied by a PaO_2– PaO_2 gradient rise; gradients over 30 mmHg at the start of therapy are associated with a high mortality (and are an indication for the use of adjunctive corticosteroid therapy). Both LDH and the arterial oxygenation gradient will return to normal with successful therapy. Another nonspecific indicator of lung injury in *PCP* is the angiotensin-converting enzyme (ACE) level (also elevated by smoking and sarcoidosis, among other causes). While pulmonary function testing may reveal abnormalities in oxygen exchange and compliance in *Pneumocystis* pneumonia, they are not useful diagnostically. Arterial blood gas measurements are helpful in the management of patients with regard to decisions about intubation and the use of corticosteroids as an adjunct to initial antibiotic therapy (see Therapy, below). Corticosteroids are of greatest use in nonintubated patients with PaO_2 of less than 75 mmHg and greater than 35 mmHg on room air, or a hypoxemia ratio (PaO_2/FiO_2) of less than 350 and greater than 75.

SPUTUM EXAMINATION AND HISTOLOGIC DIAGNOSIS

The diagnosis of *PCP* depends on the identification of characteristic organisms on examination of pulmonary specimens (Table 133-3). The methods used in making the diagnosis have been changed by the use of the induced sputum

Table 133-3

Diagnostic Techniques for *P. carinii*

Technique	Yield	Complications	Comments*
Routine sputum	Poor	Rare	Cultures needed
Induced sputum	30–75%	Rare	First choice; excellent in AIDS
Transtracheal aspiration	Fair (with experience)	Common: bleeding, subcutaneous air	Rarely worthwhile
Gallium scan	Nonspecific	Injection site of infected patients	Positive in >95%
Bronchoalveolar lavage (BAL)	>50% (>95% in AIDS)	Bleeding, aspiration fever, bronchospasm	Wedges terminal BAL with immunofluorescence
BAL/brushing	As for BAL alone	As for BAL	Not useful for *P. carinii*
BAL/transbronchial biopsy	>90% (all patients)	See BAL; pneumothorax	Impression smears; cultures/ pathology
Open lung biopsy	>95% (all patients)	Anesthesia, air leakage, altered respiration, wound infection	"Gold standard" noninfectious/ infectious processes; large sample
Needle aspirate	≤60%	Pneumothorax, bleeding	Best in localized disease

* *All sample should be cultured and stained for bacteria (including mycobacteria), fungi, and viruses, and examined for protozoa. Optimal procedures will depend on the locally available expertise.*

examination and bronchoscopic alveolar lavage (BAL) without biopsy, and by immunofluorescent staining using monoclonal antibodies to *P. carinii*. As a result, the morbidity associated with diagnostic procedures has been reduced and the diagnosis of simultaneous pathogens by these methods is decreased.

The initial step in the diagnosis of *PCP* is the realization that the patient is at risk for opportunistic infection. The first procedure should be a routine sputum examination for bacterial, mycobacterial, and fungal stains and cultures. Subsequently, the choice of diagnostic test depends on the status of the patient (ability to cooperate with sputum induction), the distribution of pulmonary disease, and the urgency of diagnosis. Given a single procedure, a more invasive test may be preferred. The diagnostic test of choice is the induced sputum examination, coupled with direct immunofluorescent staining for *P. carinii* and for mycobacterial smears and cultures. Some bacteria and fungi may not survive the hypertonic saline used for induction, and the yields for these pathogens do not exceed those of routine sputum samples. Induced sputum may be collected after 20 to 30 minutes of exposure to aerosolized hypertonic saline or water, or after oral hydration.

Before the availability of immunofluorescent antibody staining techniques, smears were prepared from the mucoid, nonpurulent portion of the specimen and stained with Giemsa or Diff-Quik stain (for intracystic bodies or sporozoites and trophozoites; see Fig. 133-6) or with toluidine blue O or silver, which stains the cyst wall. Because cysts represent only 5 to 10 percent of the organism burden, many laboratories prefer the Giemsa to the more complex silver stain, but Giemsa-stained smears are more difficult to read. In experienced hands, these stains should detect *P. carinii* in up to 85 percent of AIDS patients and in up to 60 percent of other immunocompromised patients. Proper induction and smearing techniques are critical to success.

The staining method of choice for sputum as BAL specimens is direct immunofluorescent staining with monoclonal antibodies (Fig. 133-6). This method is costly, but significant cost savings may be achieved in terms of specimen preparation and examination time. Rapid staining with immunofluorescent monoclonal antibodies directed against surface antigens of *P. carinii* has a high degree of specificity and a sensitivity for screening of sputum smears. This technique may detect 10 to 15 percent of *Pneumocystis* infections beyond the standard histologic stains (Fig. 133-2). Some of the commercially available antibodies produce high backgrounds and some nonspecific staining; each laboratory must optimize the fluorescent staining technique. Smears may be improved through use of mucolytic agent (Mucomyst, dithiothreitol) just before preparation.

As with PCR testing, the heightened sensitivity of immunofluorescent staining, coupled with the use of either induced sputum or bronchoscopic lavage samples, may detect "infections" that are not of clinical significance. The meaning of a few organisms on smear in a patient with fever and cough may not be clear. Owing to the broad antibacterial spectrum of TMP-SMX, response to therapy is only a partial confirmation of the existence of *PCP*. AIDS patients often have residual (dead) organisms in their sputum for many weeks after successful treatment. However, organisms found in the non–AIDS-immunosuppressed patient should suggest disease meriting therapy. Insignificant "colonization" of the respiratory tract before therapy has not been demonstrated; significant numbers of organisms have not been found by BAL in asymptomatic AIDS patients. Of note is that a negative smear does not indicate the absence of *P. carinii*. With use of ribosomal sequence–derived primers on pulmonary specimens, the PCR has more than 98 percent specificity and sensitivity, compared with 78 percent sensitivity for immunofluorescence on the same samples. Serologic tests are useful only for epidemiologic studies.

The *histopathology* of *Pneumocystis*-infected lung is usually distinctive enough to be diagnostic even when organisms cannot be identified. In the adult, the disease appears to be predominantly alveolar. The airspaces are filled with a foamy eosinophilic exudate and appear honeycombed. The intra-alveolar exudate consists of organisms, large amounts of surface glycoprotein, proteinaceous exudate from the lungs, and debris of macrophages and inflammatory cells. At the same time, the alveolar interstitium is infiltrated by polymorphonuclear leukocytes and lymphocytes (Fig. 133-3). Patchiness in the distribution of disease within the lungs is common. In contrast to the adult disease, *Pneumocystis* pneumonia in malnourished infants has a major interstitial component: The interstitium is filled with fluid, plasma cells, and lymphocytes; these formed elements seem to overflow into the airspaces, which are also filled with a frothy eosinophilic exudate. In both forms, the organisms usually appear intermingled with alveolar macrophages in the alveolar exudate (Fig. 133-3). By light microscopy, trophozoites predominate numerically (in more than 90 percent of the organisms), but cysts are more readily identified.

The earliest indication of disease is the presence of organisms adjacent to the epithelial layer. Cysts or clumps of trophozoites may be seen, with a minimal inflammatory infiltrate. As the number of organisms increases, epithelial injury occurs. The mechanism of alveolar epithelial cell injury is uncertain. The organism preferentially adheres to and injures the surface of type I alveolar epithelial cells, while the adjacent type II cells undergo hyperplasia. Desquamation of alveolar epithelial cells occurs early in the course of disease; denuded basement membrane is occasionally seen. Epithelial injury is followed by mononuclear cell infiltration in the interstitium. Organisms may be seen within vacuolated alveolar macrophages, as well as free in the proteinaceous and cellular debris that fills the airspace (Fig. 133-3).

In AIDS, the interstitial inflammation is less marked than in other adult forms of *Pneumocystis* pneumonia, and greater numbers of both cysts and trophozoites are seen in the alveoli. While HIV-infected alveolar macrophages appear to bind organisms normally, internalization of *P. carinii* may be impaired and clearance of organisms delayed. Many dead macrophages are found in BAL samples from HIV- and

Figure 133-6 Rapid staining of sputum and biopsy specimens for *P. carinii: A.* Impression smear (touch preparation) from the cut surface of a human lung biopsy stained with Diff-Quik stain reveals the nuclei of clumped trophozoites (arrowheads) and of the sporozoites within cysts (arrows). *B.* Human *P. carinii* cysts in an induced sputum specimen that has been stained with fluoresceinated monoclonal antibodies raised to the 116-kd surface antigen of human *P. carinii.*

Pneumocystis-infected lungs. In children with AIDS, the appearance is similar to that of adult AIDS, with the addition of some degree of plasma cell infiltration of the interstitium. Although hyaline membranes may line alveoli, they are not diagnostic of infection with *Pneumocystis,* since oxygen toxicity, alveolar proteinosis, or ARDS can evoke similar changes. These may coexist with *Pneumocystis* infection. In pediatric AIDS, lymphocytic interstitial pneumonitis, without evidence of an infectious origin, and bacterial pneumonia may mimic or coexist with *PCP.*

The *Pneumocystis* cyst wall is displayed by a variety of staining techniques. Of these, the Gomori methenamine silver nitrate method (which stains organisms brown or black) is most reliable, even though it is susceptible to artifacts and does not stain intracellular bodies (Fig. 133-3). Sporozoites and trophozoites are stained by polychrome stains,

particularly the Giemsa stain. The Giemsa, Wright, toluidine blue O, and Grocott's rapid silver stain techniques are most useful in dealing with lung imprints, BAL fluid, and pulmonary aspirates. Rapid polychrome staining (Diff-Quik) and a rapid silver staining technique have proved useful in screening smears (Fig. 133-6). When a silver stain is used, a counter stain such as Gram, Wright, Giemsa, hematoxylin, or trichrome may be required to identify intracystic bodies and to distinguish cysts from red blood cells and yeasts. Up to 97 percent of the organisms are trophozoites. Thus, silver stain substantially underestimates the organism burden.

Even when chest radiography indicates that *PCP* has cleared, interstitial fibrosis is likely to be found at rebiopsy or autopsy. Unfortunately, the contribution of *Pneumocystis* to the residual fibrosis is often obscured by the tendency of superimposed infection, therapeutic agents, or intervening radiation therapy to elicit inflammatory responses in the interstitium. Subsequent infections are likely to present with more rapid progression to hypoxemia due to persistent restrictive lung disease. In AIDS patients, pulmonary interstitial fibrosis has been observed in up to 27 percent of autopsy and biopsy series, and emphysematous changes are also common. These changes do not appear to be associated with prior *Pneumocystis* infection. A pathogenic role for chronic or recurrent viral (HIV, CMV) infections or immunologic injury has been postulated.

The demonstration of CMV by culture is not helpful in regard to the presence of CMV *disease.* Coinfection due to CMV and *P. carinii* is common, however, and may necessitate treatment for both entities. Nucleic acid diagnostics (hybridization and/or PCR) are used routinely at some centers; the interpretation of positive results remains uncertain because of the high degree of sensitivity of the test. PCR may be best used to determine the risk of *Pneumocystis* infection in patients who might otherwise not receive prophylaxis. Preliminary data support the hypothesis that systemic dissemination is common during infection in AIDS patients (up to 50 percent have *Pneumocystis* DNA in the blood), but it is generally well controlled by resident phagocytes.

INVASIVE DIAGNOSIS OF PNEUMOCYSTOSIS

In the immunocompromised patient with significant pulmonary disease, the inability to make a diagnosis of infection on examination of the induced sputum, or the failure to respond to appropriate therapy, should lead to a more invasive diagnostic procedure: BAL (with biopsies if possible), radiologically guided needle aspiration (for accessible cystic or mass lesions), or open lung biopsy. The choice of the specific test depends on the clinical condition of the patient and the expertise available at the institution (Table 133-3).

Invasive procedures for the diagnosis of *PCP* fall into several categories: tracheal aspiration, fiberoptic bronchoscopy, transthoracic aspiration, and open lung biopsy. Attempts to avoid the use of invasive procedures by resorting to empiric therapy run a great risk of inappropriate medications and undesirable side effects, as well as delaying effective therapy. Pulmonary specimens obtained by invasive approaches should be processed for bacterial (including mycobacteria, *Nocardia, Actinomyces,* and *Legionella*), fungal, and viral evaluation in addition to making slides for rapid staining with fluorescent antibodies, toluidine blue O, silver, Diff-Quik, Giemsa, or Wright stain. Early diagnosis can be made and therapy initiated on the basis of such smears, especially in AIDS.

Tracheal Aspiration

The yield from this procedure is generally low, and the hazards, particularly in inexperienced hands, are high. In intubated patients, respiratory secretions should be carefully smeared on slides, stained, and examined. If the physician or the microbiology technician has had little experience with *Pneumocystis* smears, and direct immunofluorescence techniques are not available, fiberoptic bronchoscopy or open lung biopsy is indicated for the immunocompromised patient with pulmonary disease, followed by methenamine silver staining of the tissue sections.

Fiberoptic Bronchoscopy

The importance of knowing the success rate of the institution as a basis for selecting the optimal invasive technique is illustrated by published reports of diagnostic yields from fiberoptic bronchoscopy. In proven instances of *PCP* in non–AIDS-immunocompromised hosts, the reported yields range from 5 to 95 percent. As a rule, institutions with a large experience with *PCP* are very successful in identifying the organism. Indeed, when bronchial lavage and transbronchial lung biopsies are part of the diagnostic procedure, the success rate exceeds 90 percent. The yield has been even higher in AIDS, and lavage alone (i.e., without biopsy), coupled with immunofluorescent staining of the specimens, will be successful in up to 95 percent of cases. In these patients, lavage specimens must be gathered from a wedged bronchoscope with at least 50 ml of physiological saline for alveolar washings. Lavage should be performed from the upper lobes if diffuse disease is present. The diagnostic yield in HIV-infected persons with pulmonary symptoms is more than 60 percent: 18 percent with *P. carinii* and another pathogen, 16 percent with *P. carinii* alone, and 25 percent with other infectious causes, including *Histoplasma, Cryptococcus,* mycobacteria, and other bacteria. Trophozoites predominate in bronchial washings, so Giemsa or Diff-Quik staining should be performed routinely to back up other staining methods. In general, lung biopsy is not essential for the diagnosis of *PCP* in AIDS patients. Patients suspected of harboring multiple pathogens may still benefit from any of the more invasive procedures. Although bleeding from the biopsy site is common (in up to 25 percent of

patients), it is rarely life threatening if the coagulation indices are normal.

Percutaneous Needle Aspiration

High success rates in finding *P. carinii* have also been reported in patients with *PCP* (up to 60 percent), particularly when aspiration of localized radiologic infiltrates is performed under fluoroscopic guidance. Needle aspiration is also advantageous when a focal process (e.g., abscess) is peripherally located in the lung parenchyma. Pneumothoraces occur in up to one-third of patients as a result of the procedure. In approximately 20 percent of pneumothoraces, insertion of a chest tube will be necessary.

Lung Biopsy

Thoracotomy followed by open lung biopsy or VATS (video-assisted thoracoscopic biopsy) affords the most unequivocal avenue for diagnosis. Although the patient may be quite ill by the time this step is taken, in the hands of skilled surgeons these procedures are safe, even for the intubated patient and provide histologic information that may allow the separation of significant infection of the lower respiratory tract from colonization of the upper respiratory tract by a variety of respiratory pathogens. This information may be critical to therapeutic decision making, as in the use of antiviral agents in the treatment of CMV infection. Thoracoscopic biopsies can often be performed as minimally invasive procedures.

Often, accurate diagnosis in the non-AIDS patient may require invasive procedures despite the excellent yields of sputum induction and immunofluorescence (Table 133-3). One element in the choice of procedure depends on the clinical state of the patient: patients who have an uncorrectable coagulopathy are poor candidates for either bronchoscopy with biopsy or open lung biopsy. Patients with atypical presentations or unique epidemiologic exposures have a higher incidence of dual processes or non-*Pneumocystis* infections. Institutions unfamiliar with the proper technique for sampling or handling specimens for the diagnosis of *Pneumocystis* infection should probably use open lung biopsies, which are likely to be more rewarding. Because disease caused by *PCP* may progress rapidly, the likelihood of success in treatment is greatest at the outset. Therefore, invasive procedures to disclose the organism and any secondary infections should be undertaken early in the course of the disease.

The demonstration of *Pneumocystis* organisms is necessary for diagnosis in the transplant recipient. No more than 15 to 25 percent of pulmonary infiltrates are caused by *P. carinii* in the non-AIDS patient, although regional and underlying disease-specific variations exist. Empiric therapy is more reasonable in the AIDS patient not receiving prophylaxis, as *PCP* occurs in up to 90 percent of such persons; however, dual infections remain common. Empiric therapy in the transplant recipient may delay specific treatment for other opportunistic pathogens and subject the patient to avoidable toxicities of TMP-SMX or pentamidine. Demonstration of infection due to *P. carinii* should lead to successful treatment, barring superinfection or ARDS.

PROPHYLAXIS AND PROPHYLACTIC STRATEGIES

In the pre-AIDS era, the prevention of *PCP* was associated with time-limited antibiotic use in the setting of prolonged neutropenia due to cancer chemotherapy. Because many of the chemotherapeutic regimens included corticosteroids, the incidence of *Pneumocystis* pneumonia was predictably high. Prophylactic TMP-SMX was pioneered by Walter Hughes and his colleagues at the St. Jude's Children's Research Hospital for use in children with hematopoietic malignancies and severe combined immunodeficiency (SCID) syndrome. This combination agent became the standard for prophylaxis in the AIDS era as well. In pre-HAART AIDS, such prophylaxis was lifelong rather than time-limited. In general, prophylaxis can be stopped in patients with undetectable viral loads for at least 6 to 12 months and CD4 counts that surpass 200 for that period. Without HAART, more than 60 percent of those cured of *PCP* in AIDS will suffer a recurrence within 1 year. The increased incidence (50 to 60 percent) of side effects due to TMP-SMX in AIDS when compared with patients without AIDS (10 to 20 percent) has led to the development of alternative regimens for prophylaxis against *P. carinii.* Among non-AIDS patients, routine prophylaxis should be reserved for centers or patient groups that are known to have a fixed high incidence of disease (i.e., about 3 to 5 percent of susceptible hosts), or for persons with recurrent *Pneumocystis* disease.

The use of appropriate prophylaxis should prevent *Pneumocystis* pneumonia. In AIDS patients and in transplant recipients, the failure to utilize appropriate prophylaxis is generally a reflection of the toxicities associated with the necessary medications or a failure in compliance due to the large number of medications these patients may be expected to consume. Prophylaxis should be maintained in the stable transplant patient for at least 6 months after surgery. In lung transplantation and in stem cell transplant recipients with significant graft-vs.-host disease or overall poor recovery, prophylaxis is for at least a year and generally for the duration of treatment. It should be noted that in transplant centers without a fixed, high incidence of *Pneumocystis* pneumonia, prophylaxis may be reserved for patients in whom chronic, high-level immune suppression, especially with corticosteroids, is needed to maintain graft function. If immune suppression cannot be reduced after a course of treatment for *Pneumocystis* pneumonia, prophylaxis should be maintained indefinitely. In Europe, where immunosuppressive regimens are often less intense, such reductions may not be feasible. Prophylaxis should be reinstituted with increases in immune suppression, including those resulting from pulse steroids or antilymphocyte therapies in transplantation, CMV infection

in AIDS or transplantation, treatment of graft-vs.-host disease following bone marrow transplantation, new-onset neutropenia, or similar conditions.

In untreated HIV infection, adults and adolescents with CD4 counts of fewer than 200 cells/mm^2 (or 15 to 20 percent of the total lymphocyte number), unexplained fever for more than 2 weeks, a history of oropharyngeal candidiasis, or rapid progression of disease, as measured by rising viral titers or falling CD4 counts, should receive prophylaxis. Prophylaxis in HIV-infected children is recommended for CD4 counts of fewer than 1500 cells/mm^2 for less than 11 months, fewer than 1000 cells/mm^2 between 1 and 5 years, or fewer than 500 cells/mm^2 after age 5, and in any child in whom the CD4 percentage falls to less than 24 percent. The greatest risk for children may be at 3 to 6 months of age, making the identification of the HIV-infected infant critical to survival.

Prophylaxis is needed against many opportunistic infections in AIDS and other compromised patients. Very few HIV-infected persons are capable of completing a long-term (36 months) course of any particular agent. The median time to switch of therapies that have begun with either TMP-SMX or dapsone is approximately 2.5 years, with approximately 20 percent of patients requiring several (two or more) changes in prophylactic regimen. Thus, over time, more patients receive less adequate therapies. Prophylaxis has a significant impact on survival, quality of life, and hospitalization frequency. Benefits (about 9 to 12 months' survival) are less marked outside North America, where the incidence of *Pneumocystis* pneumonia is lower.

Resistance of *P. carinii* to antibiotics has been proposed based on clinical failures while receiving prophylaxis. Resistance *may* develop in association with mutations in the dihydropteroate synthase gene of *P. carinii*. Predictably, the use of prophylaxis both for *P. carinii* and for yeasts and the resultant improved survival of HIV-infected persons have increased the relative frequency of other causes of pulmonary disease in transplant recipients, including both infections (e.g., CMV, azole-resistant fungi, mycobacteria) and noninfectious processes.

Trimethoprim-sulfamethoxazole (TMP-SMX, cotrimoxazole) is the agent of choice for the prevention of *Pneumocystis* infection in any patient who can tolerate this fixed-combination agent. At a dose of one single-strength tablet per day (80 mg TMP and 160 mg SMX), a wide variety of opportunistic infections are prevented, including *P. carinii, Toxoplasma gondii, Listeria monocytogenes, Nocardia asteroides, Isospora belli,* and susceptible bacteria, including pneumococci, *Haemophilus influenzae,* community-acquired staphylococci, and some enteric gram-negative rods. While the protection against *T. gondii* is incomplete in AIDS patients (80 to 90 percent effective) at this dosage (generally a double-strength tablet a day might be used in seropositive persons without a history of *T. gondii* infection), breakthrough infection has not been seen in transplant recipients or in cancer patients. Studies of low- and high-dose regimens for prophylaxis (single- or double-strength TMP-SMX) in HIV-positive subjects suggest no advantage to the higher dose (no disease in either group when compliant) and earlier occurrence of toxicity in the high-dose group.

Drug toxicity is commonly observed even with low-dose regimens, especially in the form of mild bone marrow suppression. Such bone marrow toxicity is notable in combination with other marrow suppressive agents (e.g., azathioprine, ganciclovir, Cytoxan, allopurinol), malnutrition, or infection (HIV, mycobacteria, or cytomegalovirus). For *Pneumocystis* prevention, it is equally effective, given the slow replication of the organism, to administer the antibiotics on 3 days a week. Toxicity has been related to serum levels of the sulfa component in AIDS. Some patients will not tolerate any dose of sulfa drugs, owing to significant rash (occasional Stevens-Johnson syndrome), hepatitis (particularly in liver allograft patients), eosinophilic nephritis, or neutropenia. Generally, significant toxicities evolve within the first month of therapy. Hyperkalemia may be observed in the setting of normal renal function as a result of trimethoprim interfering with the secretion of potassium in the renal distal tubule. This is reversible and more common during therapy than with prophylaxis. In general, neutropenia should not be treated with folate, which has been associated with treatment failures. Both oral and intravenous desensitization regimens will allow the use of TMP-SMX in many patients otherwise intolerant of the combination. Reintroduction of TMP-SMX at reduced dose is often tolerated in AIDS patients not severely intolerant of this agent. This is generally preferable to the use of any alternative agent. Non-AIDS immunocompromised patients appear to be less able to tolerate desensitization.

Alternative regimens are available for the patient intolerant of TMP-SMX. The use of prophylaxis with aerosolized pentamidine isethionate (300 mg every 3 to 4 weeks) was pioneered in AIDS patients and is well tolerated in organ transplant recipients. Pentamidine aerosol prophylaxis is generally effective after the second or third dose administered by experienced personnel with a nebulizer, producing droplets in the range of 1 to 3 μ. The Fisons nebulizer has also been used with an alternative schedule of five 60-mg doses over 2 weeks, followed by 60 mg every 2 weeks. Because the distribution of drug may not reach the upper lobes, or because the growth of *Pneumocystis* may be favored in the upper lobes, adjusting patient positioning during inhalation may be useful.

Breakthrough infection has been observed in some patients receiving aerosolized and intravenous pentamidine prophylaxis (particularly in the upper lobes). These breakthroughs are in patients receiving primary prophylaxis after transplantation or in AIDS patients who have not yet received two or more doses of antibiotic (i.e., in the first 8 to 10 weeks), in CMV-infected persons, or in secondary prophylaxis after incomplete clearance of infections. In single-lung transplant recipients, prophylactic failures have been observed in the residual (native) lung despite successful protection of the allograft. When breakthrough occurs, diagnosis by noninvasive means is often complicated by reduced organism numbers; biopsy may be required. The use of *intravenous* pentamidine (300 mg every 3 to 4 weeks) for prophylaxis has been

successful, with the single exception of disease occurring in transplant patients coinfected with CMV or receiving antilymphocyte globulins for graft rejection, or in AIDS patients with rapidly progressive disease and/or infected with CMV.

Cough and bronchospasm are the common side effects of aerosolized pentamidine therapy; they are generally reversible with bronchodilator therapy. Less often, pneumothorax and hypoglycemia or hyperglycemia are noted. Transient, mild hypoglycemia or nausea is more common after intravenous administration than with the aerosolized method. The use of pentamidine prophylaxis requires the simultaneous administration of a second antibiotic (e.g., quinolone) for antibacterial prophylaxis in transplant recipients—which is not required in patients receiving TMP-SMX.

In general, alternative prophylactic agents have been preferred to pentamidine. In AIDS patients, dapsone (diaminodiphenylsulfone), with or without trimethoprim or pyrimethamine, is in wide use in a variety of combinations. In general, neutropenia (especially in the G6PD-deficient host), hepatitis, and rash are limiting for each of these regimens, and they offer no benefit over low-dose TMP-SMX. Because of a long half-life, dapsone may be administered in doses of 50 to 100 mg per day to 100 mg per week. Breakthrough infection has been observed in AIDS patients at 50 mg per day, but toxicity begins to be limiting at 100 mg a day. Therefore, pyrimethamine is administered weekly (25 or 50 mg) to supplement dapsone in a dose of 50 mg a day. It should be noted that significant excess mortality (almost twofold) occurred in AIDS patients receiving 50 mg a day of dapsone alone in a comparison trial with aerosolized pentamidine for secondary prophylaxis. Trials of dapsone at doses of 100 mg two or three times per week show equivalence to pentamidine therapy; doses of 100 mg per day are equivalent to TMP-SMX therapy. Trimethoprim may replace pyrimethamine in this regimen (100 to 200 mg per day) in patients with creatinine clearances over 15 ml per min. The incidence of intolerance to dapsone—65 to 70 percent—is roughly equivalent to that for TMP-SMX. Up to half of the patients who discontinue prophylactic therapy with either of these agents will be able to tolerate the other drug. This strategy is not recommended for any person with severe allergic reactions, including desquamation to sulfa drugs, persistent bone marrow suppression, G6PD deficiency, or severe hepatitis. Toxicities observed with dapsone are long-lived and may limit utility, especially in liver transplantation recipients. Dapsone alone does not protect against toxoplasmosis—necessitating dual therapy for prophylaxis.

Fansidar (weekly) has been used successfully to prevent pneumocystosis. Atovaquone (formerly BW566c80) has been approved by the FDA for the treatment of mild to moderate *P. carinii* infections and may be equally useful for prophylaxis because it is well tolerated, undergoes enterohepatic circulation without metabolism, and has a long half-life. The drug has been reformulated as a liquid to improve bioavailability. Large-scale toxicity studies have not been performed in the non–HIV-infected host. In AIDS patients receiving 750 mg orally (three tablets) three times a day, some breakthrough infections have been observed. Rash, nausea, and elevated liver transaminases were occasionally documented. Experience suggests that the bioavailability in AIDS patients is one-half to one-third that in other compromised hosts. Prophylactic doses of reformulated liquid drug in the range of 1000 to 1500 mg a day exceed the MIC in serum for *P. carinii* in transplant recipients, but higher doses (1500 to 2250 mg a day) may be needed in AIDS patients. The incidence of side effects is quite low in either population. Some patients complain about the flavor and color of atovaquone liquid (which stains clothes), but many find it preferable to aerosolized pentamidine. In small numbers of transplant recipients, interactions of atovaquone with cyclosporine and other toxicities have been insignificant; prospective randomized comparative studies are under way.

Patients receiving prophylaxis for toxoplasmosis (sulfadiazine, triple sulfa, clindamycin/primaquine, atovaquone) generally have also been protected against *P. carinii.* Transplantation recipients receiving quinolone for postoperative prophylaxis will be at the same risk for *Pneumocystis* pneumonia as the general transplant population.

TREATMENT OF *PNEUMOCYSTIS* PNEUMONIA

The incidence of *Pneumocystis* infection in AIDS patients has led to the development of a number of newer options for the treatment of this infection in all susceptible hosts (Table 133-4). Treatment should be initiated as soon as the suspicion of *Pneumocystis* infection is entertained. The short-term use of treatment (48 hours) will not impair the diagnosis of infection if, for example, bronchoscopic or laboratory support services are unavailable. It is likely to be more useful clinically to obtain specimens for *P. carinii,* mycobacteria, *Legionella,* fungi, and routine cultures when these can be properly handled by the clinical laboratory. Further, because the pneumonia can be rapidly progressive, early therapy is essential. Treatment of *Pneumocystis* should be successful if a 14- to 21-day course of therapy is tolerated.

The incidence of adverse reactions to antibiotics, necessitating switching of agents, is increased in the organ and marrow transplant recipient, as it is in AIDS patients. In general, side effects in transplantation are related to synergistic drug toxicities. For example, the bone marrow suppression seen in infection with CMV and treatment of this infection with ganciclovir may be further exacerbated with TMP-SMX. Generally, elevations in liver function tests in the liver transplant recipient or depression in the leukocyte count in the marrow recipient due to therapy with TMP-SMX is of concern in the transplant recipient but may be tolerable in other hosts. Nephrotoxicity is common in transplant recipients (both renal and extrarenal) receiving therapy with TMP-SMX, even with adjustment of dosing for renal dysfunction. Thus, while the incidence of intolerance by transplant recipients to one or another agent is somewhat less than the 50 percent seen

Table 133-4

Treatment of *P. carinii**

Agent(s)(route)†	Dose	Options†
Trimethoprim and sulfamethoxazole (TMP-SMX) (IV/PO)	15 mg/kg/day TMP (to 20) 75 mg/kg/day SMX (to 100)	Treat through rash: reduce TMP or SMX by one-half; desensitize; first choice
Pentamidine isethionate (IV)	4 mg/kg/day 300 mg/day max.	Lower dose (2–3 mg/kg) after loading; IM not advised
Dapsone (PO) with TMP (PO/IV)	100 mg/day 15–20 mg/kg/day (900 mg)	Methemoglobinemia, G6PD; *may* be tolerated in sulfadizaine allergy
Clindamycin (IV/PO) diarrhea and primaquine	450–600 mg q6h 15–30 mg base qd	Methemoglobinemia, (pyrimethamine for primaquine)
Trimetrexate (IV) with folinic acid (Not available)	30–45 mg/m/day 80–100 mg/m day	Leukopenia, anemia, thrombocytopenia; relapse common
Pyrimethamine (PO) with sulfadiazine (PO)	Load 50 mg bid × 2d, then 25–50 mg qd Load 75 mg/kg, then 100 mg/kg/day	Not studied fully in clinical trials
Piritrexim (IV) with folinic acid	Max. 4 gm in two doses; up to 8 g	
Atovaquone (PO) suspension	750 mg (PO) tid to 1500 bid	Variable absorbance, improved with fatty food; rash, GI intolerance

*Adjunctive therapies *(see text): Corticosteroids (high dose with rapid tapering), possibly γ-interferon, granulocyte-macrophage colony–stimulating factor.*
†*Based on clinical judgment of physician; some agents are not FDA approved for this indication.*

in AIDS patients, significant toxicity remains a common feature of therapy. As was noted, resistance to antibiotics has not yet been demonstrated by *P. carinii*. Thus, changing antibiotics *other than for toxicity* does not appear to be indicated. While there are patients who appear to do better on one agent than another, it is much more common to recognize a second process (infection, tumor, allergy, ARDS) as complicating *Pneumocystis* pneumonia than a resistant infection. The chest radiograph is a less reliable indicator of failure than is oxygenation. Adding pentamidine to TMP-SMX offers no advantage over simply switching agents. Indeed, animal experiments suggest the possibility of antagonism between these agents when used in combination. As a rule, patients who need to be switched from co-trimoxazole to pantamide, or vice versa, do not fare as well as those who can be treated for 14 to 21 days with either agent alone. The success rate with either pentamidine or TMP-SMX for initial treatment is around 60 to 80 percent. Adjunctive therapies (see below) may also be more useful than switching agents.

The proper duration of therapy has not been studied but is generally 14 to 21 days in all patients. Residual organisms persist after treatment for a number of months (up to 3), but the role of these organisms in recrudescent or persistent infection is not clear. Following treatment with TMP-SMX, most residual organisms are dead; relapse in the non–AIDS-immunocompromised patient should not be expected *as long as immunosuppression can be reduced* (notably, with steroid therapy).

Trimethoprim-sulfamethoxazole is the agent of choice for the treatment of *Pneumocystis* pneumonia and extrapulmonary disease in all hosts. This combination antibiotic has the advantage of excellent tissue penetration, the most rapid clinical response of anti-*Pneumocystis* agents (3 to 4 days), and bioavailability from oral therapy comparable with that of parenteral administration. Survival without intubation and mechanical ventilation appears to be greater with TMP-SMX than with pentamidine (by up to 20 percent). The incidence of some of the side effects is related to serum concentrations and is also greater than with other agents. In part, this is a reflection of the use of dosage schedules derived for children in adults and in the setting of abnormal renal function. The proper dosing in adults has not been completely studied. Therapy is initiated at 15 to 20 mg/kg per day of the TMP component (100 to 150 mg/kg per day of SMX), divided into three or four doses. Therapy should be initiated intravenously if there is uncertainty about GI function or marked hypoxemia. Peak levels are obtained about 2 h after oral dosing and should approach the range of 100 to 150 μg/ml of SMX (5 to 15 μg/ml TMP). Levels of over 200 μg/ml of SMX are associated with a higher incidence of side effects, especially bone

marrow suppression. After a clinical response is observed, the dosing can be reduced to 10 to 15 mg/kg per day, in divided doses.

Therapy can be continued (with adjustments) despite mild side effects (rash, transaminase elevations, neutropenia) tolerable to the patient and physician. Dose reduction will often eliminate toxicity in AIDS patients. Desensitization to TMP-SMX may be used in the patient with mild intolerance. With renal dysfunction, dosing must be reduced; daily dosing is sufficient (3 to 5 mg/kg per day) for a glomerular filtration rate of 10 to 50 ml/min. Renal impairment developing in a patient taking TMP-SMX should prompt a search for urinary eosinophils and an assessment of the need for further therapy with this agent. Nephrotoxicity occurs frequently in the renal transplant recipient on full-dose therapy; this toxicity is both idiosyncratic and dose related. Nephrotoxicity often occurs without demonstrable urinary eosinophils, perhaps as a reflection of the use of corticosteroids for immune suppression. In these patients, interstitial eosinophils may be found on renal biopsy. The transplanted liver is particularly susceptible to TMP-SMX toxicity (eosinophilic infiltrates, hepatocyte necrosis, bilirubinemia) and may be confused with, or complicate treatment for, early rejection or systemic infection. The side effects of TMP-SMX are generally those of sulfa allergy: rash (including Stevens-Johnson syndrome), transaminase elevation, neutropenia, thrombocytopenia, erythema multiforme exudativum, and nephrotoxicity. The bone marrow suppression is marked in patients with underlying hematologic disorders; folinic acid supplementation is rarely useful and should be avoided in patients with acute leukemia.

Dapsone (100 mg orally per day), in place of SMX and in combination with oral TMP (15 mg/kg per day), is an effective alternative therapeutic regimen. Many AIDS patients intolerant of sulfamethoxazole will tolerate dapsone, which is metabolized by the liver (half-life at least 30 hour). However, the long half-life and side-effect profile in the non-AIDS patient (hemolysis in G6PD deficiency, rash, hepatitis) may be particularly disadvantageous in the transplant recipient. Manifestations of sulfa and TMP toxicity may be masked by corticosteroids. Similarly, side effects of azathioprine (hepatitis, macrocytic anemia, neutropenia, hepatic veno-occlusive disease) may be accentuated by TMP-SMX. In AIDS, the toxic side effects of TMP-SMX are generally those of the sulfonamide; however, trimethoprim allergy is not uncommon, and allergies to the "carriers" in the various preparations of TMP-SMX (dyes, coatings, filler) have also been reported. Both components of TMP-SMX interfere with folate metabolism. Leukopenia, thrombocytopenia, and anemia caused by co-trimoxazole are generally relieved by folinic acid, whereas drug rash, fever, azotemia, and increased blood levels of transaminases will reverse only when therapy is stopped. Folinic acid should not be used in patients with acute leukemia.

Pentamidine isethionate is the first alternative agent for the treatment of *Pneumocystis* pneumonia. Pentamidine isethionate was first administered intramuscularly during an epidemic of the infantile form of the disease. It decreased mortality from 50 to 3.5 percent of those affected. Subsequently, less dramatic effects were obtained with this agent in older children and adults: survival rates of 25 to 85 percent have been reported following its use. Pentamidine is now judged to be about 70 percent effective. Pentamidine isethionate may be administered either intravenously or intramuscularly, although only the intravenous route is currently recommended. Complications with early therapy occurred in up to 50 percent of patients, notably sterile abscesses at the site of intramuscular injection. Intravenous pentamidine isethionate is given by slow (1- to 2-h) infusion in 5 percent glucose solution as a single dose of 4 mg/kg per day. Evidence exists that lower doses (3 mg/kg per day) are equally effective. Pentamidine achieves therapeutic levels in the lungs slowly (in 5 to 7 days), owing to high levels of extrapulmonary tissue binding. Slow accumulation of pentamidine in pulmonary tissue may account for the delayed onset of activity when compared with TMP-SMX. However, increased serum levels and a long serum half-life and gradual accumulation in the lungs may play a role in the continued therapeutic effect after the cessation of therapy. Because this agent has a long serum half-life (6.4 hour) and delayed excretion due to extensive tissue binding (more than 240 hour), pentamidine tends to accumulate during therapy. The reduction of symptoms by pentamidine may be due, in part, to suppression of the secretion of tumor necrosis factor by alveolar macrophages as well as to treatment of infection. Pentamidine has largely been supplanted by TMP-SMX for therapy of *Pneumocystis* infection in the non-AIDS patient. But pentamidine continues to be used for infection in patients with adverse reactions to trimethoprim or to sulfonamides.

Idiosyncratic side effects include transient hypoglycemia, pancreatitis, diabetes (after prolonged therapy, with or without prior pancreatitis), pancytopenia, hypotension, and renal dysfunction. These side effects are exacerbated by intravenous administration and in the presence of decreased renal function. Pentamidine should be avoided in pancreas transplant recipients, owing to the potential for islet cell necrosis. New diamidine compounds under development may have significantly superior therapeutic and side-effect profiles when compared to the parent molecule.

Alternative regimens have been developed as a reflection of toxicities observed in AIDS patients treated with either TMP-SMX or pentamidine. Atovaquone (750 mg orally three times a day) has been approved by the FDA for the treatment of mild to moderately severe *Pneumocystis* pneumonia. Atovaquone is a hydroxynaphthoquinone and inhibitor of electron transport with a prolonged serum half-life (at least 70 hours). Absorption is enhanced by fatty foods and decreased by diarrhea and in AIDS patients. Bioavailability has been improved by reformulation as a liquid form. Comparative trials between atovaquone (tablets) and TMP-SMX suggest that TMP-SMX is the preferred agent in patients who tolerate this therapy. Up to 7 percent of HIV-infected patients develop limiting toxicity on atovaquone (compared to 20 percent for TMP-SMX); however, significantly more patients failed therapy owing to lack of response in the atovaquone group than

in the TMP-SMX group. When pentamidine was compared with atovaquone for therapy of mild to moderate infection, lack of response was observed in 29 percent of atovaquone patients and 19 percent of pentamidine patients. However, atovaquone was better tolerated. Like TMP-SMX, atovaquone may clear *P. carinii* from the lungs in patients who complete a course of therapy better than other alternative agents, reducing the rate of relapsed infection.

Trimetrexate (NeuTrexin, US Bioscience, 45 mg/m per day) is no longer being manufactured. Trimetrexate is a dihydrofolate reductase inhibitor and is lipid soluble, with a serum half-life up to 34 hours. It will produce severe neutropenia in the absence of folinic acid supplementation (80 mg/m per day) which should be continued for 3 to 5 days after cessation of trimetrexate. Side effects include fever, rash, leukopenia, and transaminase elevation. Infection relapse in AIDS patients has been somewhat more frequent than with other therapies. Piritrexim is pharmacologically similar to trimetrexate but has been most useful in combination with a sulfonamide.

The combination of clindamycin (600 to 900 mg intravenously every 6 to 8 hours) and primaquine (15 to 30 mg base per day orally) is effective in mild to moderate infection, with the main side effect being *Clostridium difficile* colitis. Pyrimethamine (50 to 100 mg a day by mouth after 100- to 200-mg load) and sulfadiazine or trisulfapyrimidines (4 to 8 g a day) are also effective, but require folinic acid (10 mg a day) supplementation. Pyrimethamine will decrease the renal clearance of creatinine without attaining the glomerular filtration rate. The newer macrolides (azithromycin, clarithromycin) have little efficacy alone but appear to enhance the efficacy of sulfamethoxazole. However, this combination provides little benefit over TMP-SMX. The utility of DFMO (α-difluoromethylornithine) has not been established. The presence of the target enzyme in *P. carinii* (ornithine decarboxylase) suggests that efficacy is possible, but it binds the drug less well than the host enzyme. Newer agents under study include the echinocandins (glucan synthase inhibitors), which block formation of cysts, the 8-aminoquinolines, the dicationic substituted bis-benzimidazole (pentamidine derivatives), isoprinosine, bilobalide (a sesquiterpene from *Gingko biloba* leaves), quinghaosu albendazole, proguanil, terbinafine, guanyl hydrazones, and some nonquinolone topoisomerase inhibitors.

Adjunctive therapies to the treatment of *Pneumocystis* pneumonia include corticosteroids and, potentially, colony-stimulating factors. Delayed response to therapy or the inability to reduce immune suppressive therapy may allow progressive disease despite appropriate therapy for *Pneumocystis* pneumonia. Given the risks of nosocomial superinfection associated with intubation for assisted ventilation, the use of adjunctive corticosteroids was developed to prevent the early deterioration of AIDS patients with documented *Pneumocystis* pneumonia. The use of corticosteroids (prednisone, 40 to 60 mg three or four times a day, orally or intravenously) in the first 72 hour after admission may reduce pulmonary inflammation to a degree sufficient to avoid intubation. When studied in AIDS patients, the use of corticosteroids in patients with a PaO_2 of 35 to 72 mmHg or with a hypoxemia ratio of 75 to 350 was of significant benefit in terms of preventing deterioration in oxygenation in the first 7 days of therapy, mortality, and the avoidance of intubation (50 percent reduction). After such therapy, the exercise tolerance and survival of patients were also improved. Steroid tapering is necessary to avert relapse of pulmonary inflammation. Patients experience an increase in oral thrush and herpes simplex after 2 to 3 weeks of therapy and tapering. The impact of corticosteroids in the non–AIDS-compromised host and in AIDS patients failing initial therapy appears to be similar. However, the utility of additional steroids in the transplant or cancer patient has not been subjected to a controlled clinical trial.

Cytokines, including γ-interferon, have been shown to reduce the amount of *Pneumocystis* found in animal models of disease without greatly increasing the inflammatory response. The colony-stimulating factors (CSF), including those for the monocyte/macrophage (M-CSF), granulocytes (G-CSF), and granulocyte/macrophage (GM-CSF) lineages, have come into use to supplement immunity in the immunocompromised host. G-CSF has been used successfully in many of our neutropenic cancer and organ transplant recipients without adversely affecting the transplanted organs. GM-CSF has been used with systemic antifungal therapy in patients with acute fungal infections with some success. Preliminary data suggest that M-CSF and GM-CSF may be useful in enhancing the clearance of *P. carinii* by resident alveolar macrophages. Some investigators have endorsed the use of aerosolized pentamidine in addition to standard anti-*Pneumocystis* therapy. Some theoretical advantage may accrue to local administration.

The response to therapy is generally excellent in patients who receive a diagnosis before respiratory failure. The ability to reduce immune suppression or to supplement the immune response (see above) also improves the rapidity of clearance of infection. The failure to observe clinical improvement by days 4 to 5 (TMP-SMX) or 5 to 7 (pentamidine) should suggest the presence of another process: fibrosis, ARDS, dual infection (especially CMV), abscess, bronchial obstruction, drug allergy, and carcinoma. Bronchoscopic lavage and biopsy for microbiology and pathology, or chest tomography (CT scan), may be revealing in these patients.

Viral Infections of the Lung and Respiratory Tract

John Treanor

GENERAL PRINCIPLES

Viral infections of the upper and lower airways have a major impact on health. Acute respiratory illnesses, largely caused by viruses, are the most common illness experience for otherwise healthy adults and children. The National Health Interview Survey suggests that such illnesses are experienced at a rate of 85.6 illnesses per 100 persons per year, and account for 54 percent of all acute conditions exclusive of injuries. A total of 44 percent of these illnesses require medical attention, and result in 287 days of restricted activity, 94.4 days lost from work, and 182 days lost from school per 100 persons per year. Estimates from family-based surveillance suggest that

approximately one-fourth of these illnesses result in consultation with a physician. Illness rates for all acute respiratory conditions are highest in young children; children below the age of 9 are estimated to experience between five and nine respiratory illnesses per year, whereas adults experience between three and five such illnesses.

Mortality due to acute viral respiratory infection in otherwise healthy individuals in economically developed countries is relatively rare, with the exception of epidemic influenza. However, acute respiratory infection is a major cause of childhood mortality in developing countries, and it is estimated that 4.5 million children under 5 years of age die annually from acute respiratory infection. Viruses are identified in about 3 to 40 percent of cases of respiratory disease in this setting, and are estimated to play a contributing role in approximately 20 to 30 percent of deaths. In addition, new and emerging respiratory viruses such as the coronavirus associated with severe acute respiratory syndrome (SARS) and potentially pandemic avian influenza A viruses, pose a continuing threat.

Epidemiology

Many of the viruses associated with acute respiratory disease display a significant seasonal variation in incidence. Although the exact seasonal arrival of each virus in the community cannot be predicted with precision, certain generalizations are useful diagnostically and in planning control strategies. For example, influenza and respiratory syncytial virus epidemics both occur predominantly in the winter months, with a peak prevalence in January to March in the northern hemisphere. Parainfluenza virus type 3 (PIV-3) infections show a predominance in the spring, whereas types 1 and 2 (PIV-1 and PIV-2) cause outbreaks in the fall to early winter. Rhinoviruses may be isolated throughout the year, with increases in frequency in the spring and fall. The peak prevalence of enteroviral isolations is in late summer and early fall, whereas adenoviruses are isolated at roughly equal rates throughout the year. The herpes viruses also do not show significant seasonal variation in incidence, except for varicella, which occurs throughout the year, but more commonly in late winter and early spring.

The reasons for these seasonal changes are not entirely clear. One mechanism may involve seasonal effects on virus transmissibility either because of more favorable environmental conditions for virus survival or behavioral changes that increase transmission, such as indoor crowding. Heretofore unknown effects of season on host susceptibility or response to infection could also play a role.

Characteristics of the Viruses

Classification

Viruses of importance in the respiratory tract include both those considered to be principal respiratory viruses, whose replication is generally restricted to the respiratory tract, and others in which respiratory involvement is part of a generalized infection. Virus classification depends in part on the type and configuration of the nucleic acid in the viral genome, the characteristics of the viral structural proteins, and the presence or absence of a lipid-containing envelope surrounding the virus particle (Table 134-1). The number of distinct antigenic types in each of the virus families varies. For example, the adenovirus and rhinovirus groups are composed of large numbers of antigenically (serotypically) distinct immunotypes, but other groups, such as paramyxovirus and coronavirus, are composed of only a limited number of immunotypes. As a general rule, it appears that immunity is longer lasting, and reinfection with the same virus type less common, in groups with many immunotypes than in those with only a few. The degree of antigenic stability of the virus is another important factor in determining frequency of reinfection. This characteristic is particularly important for influenza type A virus, which periodically undergoes both minor and major changes in its surface antigens.

Transmission

The routes by which the different respiratory viruses spread from person to person are still not established with certainty. Rhinovirus and respiratory syncytial virus spread, at least in part, by direct hand contact with contaminated skin and environmental surfaces. This is followed by self-inoculation of infectious virus onto the nasal mucosa or conjunctiva. Others, including influenza, measles, and varicella-zoster viruses, spread at times in small-particle aerosols. Many viruses may spread by means of large-particle aerosols over short distances (1 meter). The relative importance of the various transmission routes under natural conditions for each virus is unknown.

A number of respiratory viruses have been documented to cause outbreaks of infection in closed populations. In hospitals, nurseries, day care centers, and homes for the elderly, secondary spread to staff members and other patients may occur. Such outbreaks have been observed for viruses that appear to be spread by small-particle aerosols, including measles and varicella-zoster virus, and for those spread by direct contact with infectious secretions, such as respiratory syncytial virus, rhinoviruses and coronaviruses, where there is frequent close contact between patients and staff.

Pathogenesis of Infection

The initial sites of infection and pathogenesis differ for the various virus groups. Some, such as rhinovirus, are associated mainly with upper respiratory tract involvement. Others, such as influenza, commonly invade the lower airways and sometimes pulmonary parenchyma in addition to causing upper airway disease. The viruses also differ in the amount of damage produced in the cells lining the respiratory tract. Extensive damage to the respiratory epithelium is a characteristic feature of influenza virus infection, but biopsy studies show little evidence of nasal epithelial damage in persons with rhinovirus colds. Instead, colds are related both to virus damage to the respiratory tract and to the host responses to

Common Respiratory Viruses

Virus	Family	Genome	Seasonality	Diseases	Vaccine	Antivirals
Influenza virus	Orthomixoviridae	ss RNA (−)	Yes (winter)	Influenza, croup, bronchitis, pneumonia	Yes	Yes (oseltamivir, zanamivir)
Respiratory syncytial virus (RSV)	Respiroviridae	ss RNA (−)	Yes (winter)	Bronchiolitis, pneumonia	No	Yes (ribavirin)
Metapneumovirus (hMPV)	Respiroviridae	ss RNA (−)	Yes (winter)	Bronchiolitis, pneumonia	No	No
Parainfluenza virus (PIV)	Paramyxoviridae	ss RNA (−)	Yes (winter)	Croup (PIV1), pneumonia (PIV3)	No	No
Measles	Paramyxoviridae	ss RNA (−)	No	Croup, pneumonia	Yes	No
Rhinovirus	Picornaviridae	ss RNA (+)	Yes (spring, rail)	Common cold	No	No
Coronavirus (CoV)	Coronaviridae	ss RNA (+)	No	Common cold (OC43), pneumonia (HuCoV-SARS)	No	Yes (interferon alpha?)
Sin nombre virus	Bunyaviridae	ss RNA (+/−)	No	Pneumonia	No	No
Adenovirus	Adenoviridae	ds DNA	No	Croup, pneumonia	Yes	No
Herpes simplex virus	Herpesviridae	ds DNA	No	Pneumonia	No	Yes (acyclovir, famciclovir)
Varicella zoster virus	Herpesviridae	ds DNA	No	Pneumonia	Yes	Yes (acyclovir, famciclovir)
Cytomegalovirus	Herpesviridae	ds DNA	No	Pharyngitis, pneumonia	No	Yes (ganciclovir cidofovir)
Epstein-Barr virus	Herpesviridae	ds DNA	No	Pharyngitis	No	No
Bocavirus	Parvoviridae	ss DNA (+/−)	No	Bronchiolitis, colds	No	No

infection, including immunologic events, release of mediators of inflammation, and neurogenic reflexes.

An additional important feature of respiratory virus infections is their effect on the resident bacterial flora of the upper airways. Respiratory virus infections have been found to alter bacterial colonization patterns, increase bacterial adhesion to respiratory epithelium, and reduce mucociliary clearance and phagocytosis. These impairments of host defenses by virus allow colonization by pathogenic bacteria and invasion of normally sterile areas, such as the paranasal sinuses, middle ear, and lower respiratory tract, resulting in secondary infection.

A summary of the specific viral etiologies most commonly associated with syndromes of upper respiratory

Table 134-2

Virus-Associated Respiratory Tract Infections

Clinical Syndrome	Associated Viruses
Common cold	Rhinovirus, other picornaviruses, RSV, PIV, coronavirus, adenovirus
Pharyngitis	Rhinovirus, influenza, EBV, CMV, HSV, HIV
Tracheobronchitis	Influenza, adenovirus, rhinovirus
Croup	PIV1, PIV2, influenza, adenovirus, measles
Bronchiolitis	RSV, hMPV, HuCoV-NL63, bocavirus
Pneumonia: Adults	Influenza, adenovirus, RSV, PIV, measles, VZV, sin nombre virus, HuCoV-SARS
Children	RSV, PIV, influenza, measles, adenovirus, rhinovirus, CMV
Immunocompromised	CMV, HSV, VZV, adenovirus, RNA viruses

tract infection is given in Table 134-2. The following sections briefly summarize the important points of viral respiratory tract infections.

THE COMMON COLD

Clinical Features

The term "cold" really does not constitute a single entity, but rather a group of similar illnesses of differing cause. However, all colds include symptoms of rhinitis with variable degrees of pharyngitis. Predominant associated symptoms include nasal stuffiness, sneezing, runny nose, and sore throat. Patients often report chills, but fever is not a typical feature of uncomplicated colds. Cough and hoarseness are variably present and may be more frequent in the elderly but, other lower respiratory tract signs and symptoms are not typical of colds and should raise suspicion of other entities.

Physical findings are nonspecific and most commonly include nasal discharge and pharyngeal inflammation. More severe disease, with higher fever, may be seen in children. Although colds are generally self-limited, symptoms may last for a surprisingly long period of time, with a median duration of illness of approximately 9 to 10 days in adults. Recognized complications of colds include secondary bacterial infections of the paranasal sinuses and middle ear, and exacerbations of asthma, chronic bronchitis, and emphysema. Colds are frequently associated with involvement of the middle ear, likely due to eustachian tube dysfunction. Colds are associated with symptomatic otitis media in approximately 2 percent of cases in adults, and in a higher proportion in young children.

Colds are also associated with detectable abnormalities of the paranasal sinuses, which may or may not be evident clinically. Mucosal thickening and/or sinus exudates have been observed in as many as 77 percent of subjects with acute colds. These abnormalities are transient and usually not associated with symptoms, although they may persist 21 days or longer. However, clinically manifest acute sinusitis is seen in a small (0.5–5 percent) proportion of individuals with naturally occurring colds.

Clinical colds in atopic individuals may be more severe or more likely to result in wheezing than in normal individuals, and rhinoviruses have been identified as major causes of asthma exacerbations in children and adults. The mechanism of this increased susceptibility is unclear, but may be related to an altered immune response to infection. Rhinovirus colds may increase asthma by augmenting airway allergic responses such as histamine release and eosinophil influx after antigen challenge. Rhinoviruses have also been identified as important causes of exacerbations of chronic obstructive pulmonary disease (COPD).

Viral Etiologies and Differential Diagnosis

Epidemiologic studies have established that the great majority of common colds are associated with infection with the human rhinoviruses or other picornaviruses. Other agents frequently associated with common colds include coronaviruses OC43 and 229E, and, in adults, parainfluenza and respiratory syncytial virus, with a variety of other agents implicated occasionally. The clinical characteristics of illness due to each of these viruses are similar, and a specific viral etiology generally can not be deduced on clinical grounds alone. Epidemiologic studies have indicated that on an annual basis, any one antigenic type of virus is responsible for less than 1 percent of all colds.

The differential diagnosis of individuals presenting with typical signs and symptoms is not extensive. However, in the presence of additional signs or symptoms that are not part of this clinical description, such as high persistent fever, signs of respiratory distress, or lower respiratory tract disease, alternative diagnoses should be sought. Allergic causes should be considered in individuals who present with recurrent symptoms restricted to the upper respiratory tract.

Pathogenesis

Studies of the pathogenesis of the common cold have largely focused on rhinoviruses, the most commonly implicated

viral etiology. Transmission of most of the viruses responsible for the common cold is by direct contact, with inoculation of virus into the upper respiratory tract. In situ hybridization studies of nasal biopsy specimens from rhinovirus-infected subjects demonstrate that infection is largely confined to relatively small numbers of ciliated nasal mucosal epithelial cells, although occasional nonciliated cells are also infected. Sloughing of these epithelial cells is seen in naturally occurring colds, but the epithelial lining remains intact, with structurally normal cell borders. Infection is associated with significant increases in the numbers of polymorphonuclear leukocytes in nasal mucosa and secretions, probably due to elaboration of IL-8 by infected cells. Although rhinoviruses are not able to grow efficiently at body temperature, virus can be detected within cells of the lower airway even in uncomplicated colds in healthy subjects.

In general, the number of infected cells appears to be quite limited, even in fairly symptomatic individuals, and there is no clear correlation between the level of virus replication or the number of cells infected, and the level of symptomatology. These results have suggested that virus-induced cellular injury is not the direct cause of symptoms in rhinovirus colds, but rather that inflammatory mediators play an important role. Analysis of the nature of the mucosal exudate during rhinovirus colds suggests that the nasal secretions during the initial response to rhinovirus infection are predominantly the result of increased vascular permeability, as demonstrated by elevated levels of plasma proteins in nasal secretions, whereas later glandular secretions (lactoferrin, lysozyme, and secretory IgA) predominate. Similar observations have been made in allergic rhinitis. However, in contrast to the situation in allergic rhinitis, histamine does not appear to play a role in the induction of symptoms in colds, as nasal histamine levels do not increase, and therapy with selective H1 antihistamine is not effective. Nasal secretion kinin levels do correlate with symptoms in natural and experimental colds, and intranasal administration of bradykinin mimics the induction of signs and symptoms in the common cold, including increased nasal vascular permeability, rhinitis, and sore throat.

Diagnostic Tests

Rapid diagnostic tests have been developed for many of the viruses associated with the common cold. By using specific primers, most of the responsible viruses can be detected in nasal secretions by reverse-transcriptase-polymerase chain reaction (RT-PCR), or other nucleic acid–based tests. Since there is no specific therapy and the clinical characteristics of colds due to different viruses are similar, use of techniques for specific viral diagnosis in the common cold is generally limited to the research setting.

Treatment and Prevention

The recommended treatment for colds is to use individual remedies to treat specific symptoms. Symptoms of sneezing and rhinorrhea can be alleviated with nonselective sedating antihistamines such as brompheniramine, chlorpheniramine, or clemastine fumarate. The effect is probably due to the anticholinergic properties of these drugs but treatment with selective H1 inhibitors is not effective. Studies of pseudoephedrine have demonstrated measurable improvements in nasal air flow consistent with a decongestant effect. In previously healthy children and adults, there is no danger from the routine use of cough suppressants, although they should be used cautiously in patients with serious underlying COPD. Cough syrups containing expectorants are of unproved value in common colds, although guaifenesin may reduce the cough reflex.

Symptomatic therapy with systemic anticholinergic drugs or anticholinergic-sympathomimetic combinations has not been shown to confer any benefit, non to be associated with significant side effects. In addition, the use of the decongestant phenylpropanolamine is associated with an increased risk of hemorrhagic stroke, and this drug has been removed from over-the-counter cold remedies.

Topical application of vasoconstrictors such as phenylephrine or ephedrine provides relief of nasal obstruction, but may be associated with a rebound of symptoms upon discontinuation if used for more than a few days. Thus, nasal sprays containing decongestants should be used for no more than 3 days. Topical application of ipratropium, a quaternary anticholinergic agent that is minimally absorbed across biologic membranes, reduces rhinorrhea significantly in naturally occurring colds. This agent probably exerts its major effect on the parasympathetic regulation of mucous and seromucous glands.

There has been considerable interest in the development of antiviral agents for the common cold. Several problems confront the successful development of such an antiviral agent. Because of the numerous etiologic agents, the ideal drug would require a wide spectrum of activity. In addition, many drugs that appear to have excellent in vitro activity have failed in clinical trials, apparently because they did not reach sufficient levels within the nasal mucosa where virus replication occurs. Finally, because symptoms in colds are not clearly related to the level of virus replication, a successful treatment strategy may also require use of drugs to antagonize the effects of the inflammatory mediators described herein.

LARYNGITIS AND PHARYNGITIS

Clinical Features

Pharyngitis is a common complaint of both adults and children, and is one of the more common reasons for seeking outpatient medical care. In general, this syndrome refers to individuals who present with the primary complaint of sore throat, and should probably be reserved for those individuals who manifest some objective evidence of pharyngeal inflammation as well. The clinical manifestations of pharyngitis are dominated by the specific causative agent. However, generally

the syndrome can be divided into those cases in which nasal symptoms accompany pharyngitis, which are predominantly viral in nature, and those cases without nasal symptoms, which have a somewhat more diverse spectrum of etiologic considerations, including both group A and nongroup A streptococci, chlamydia (strain TWAR), mycoplasma, and other agents.

Viral Etiologies and Differential Diagnosis

Rhinovirus colds are frequently accompanied by pharyngitis, although objective signs of pharyngeal inflammation are uncommon. Adenovirus infections are frequently associated with pharyngitis, and a specific syndrome of pharyngoconjunctival fever, consisting of fever, pharyngitis, and bilateral conjunctivitis is associated with adenovirus types 3 and 7. A variety of enteroviral serotypes are associated with febrile pharyngitis. Herpangina is a specific Coxsackie virus-induced pharyngitis in which small (1- to 2-mm) vesicular lesions of the soft palate rupture to become small white ulcers. Pharyngitis is a typical component of acute influenza in which individuals experience the sudden onset of systemic symptoms of fever, myalgias, and malaise accompanied by upper respiratory signs and symptoms, including pharyngitis. Primary oral infection with herpes simplex virus may present with pharyngitis, typically with vesicles and shallow ulcers of the palate, and cervical lymphadenopathy.
