Foreword I

Dr. David Shepro has compiled an outstanding book on Microvascular Research that summarizes the state-of-the-art advances in this exciting field and points to the future horizons in this interdisciplinary area of great important in health and disease.

The book starts with a Section on Basic Science that covers the molecular and cellular bases of endothelial cell structure and function; roles of various molecules and cells in regulating vascular development; *in vitro* models ranging from zebrafish to mammalian and human systems; physiological regulation of permeability, vascular tone and hemodynamics, and the process of transendothelial transport in relation to endothelial junctions and adhesion molecules. This Basic Science Section provides an excellent foundation and underpinning for the subsequent Sections.

The second Section presents the current knowledge on Microvascular Adaptation in Organs, including the heart, central nervous system and eye, gastrointestinal tract, hematopoietic system, kidney, liver, lung, lymphatics, pancreas, skeletal muscle, skin, and reproductive systems. The comprehensive presentations in this Section point out the uniqueness of each organ/tissue and at the same time provide insights into the similarity in microvascular adaptation among different organs and tissues. This organ-level treatment of microvascular physiology leverages on the molecular and cellular approaches in the Basic Science Section and set the stage for the Sections on Pathology and Therapy that follow.

The third Section on Pathology covers the microvascular basis of pathological changes seen in various disease states. Some of the clinical conditions are well-documented as stemming from microvascular abnormalities, e.g., thrombosis and hemostasis, diabetes, inflammation, wound healing, etc. With the expansion of knowledge on microvascular research, there is now increasing evidence that the microvasculature also plays a significant role in Alzheimer's disease, arthritis, transplant rejection, tumor growth and metastasis, etc. This book provides an in-depth analysis of the role of microvasculature in a variety of pathological conditions.

The fourth Section on Therapy provides new insights into the great potential of applying the fruits of microvascular research to clinical conditions such as fluid treatment of hemorrhagic shock, the betterment of delayed preconditioning, therapeutic use of statins, therapeutic angiogenesis, and the delivery of molecular and genetic therapeutic agents to vascular endothelium. This Section points to the translational potential of microvascular research to enhance human health and combat disease.

The fifth Section on New Research Modes and Procedures presents a stimulating and inspiring view of the vista of microvascular research. It covers important recent advances such as DNA microarray, tissue engineering, endothelial biomarkers, knockout/transgenic models, mathematical models, and proteomics, as well as stem cells and their therapeutic promises. This Section provides a great ending of the book with the exciting future of microvascular research.

In summary, this book provides a comprehensive and logical progression from basic science through organ adaptation to pathology and therapy, ending with new research approaches. It is the most definitive book ever written on Microvascular Research and it is a must for all researchers and students in this field.

Dr. Shepro's superb background and experience made him uniquely qualified to edit such a state-of-the-art treatise on Microvascular Research. He has made important contributions to microvascular research, publishing over 200 peer-reviewed articles and four books. He is a Founding Editor and the Editor-in-Chief of *MICROVASCULAR RESEARCH: An International Journal*. In this capacity, Dr. Shepro has a marvelous knowledge of the leading scientists working at the frontiers of microvascular research, and hence he was able to gather such a stellar group of authors contributing to

this wonderful book. As a member of the microvascular research community, I wish to congratulate Dr. Shepro and the contributors to this book for their outstanding accomplishments and to thank them for disseminating their precious knowledge to everyone working on this subject. This book undoubtedly will have a major impact on the further advancement of this important field.

Shu Chien, M.D., Ph.D.
University Professor of Bioengineering
and Medicine
Chair, Department of Bioengineering
University of California, San Diego
La Jolla, California, U.S.A.
March 2005

Foreword II

The present compilation of articles on the topic of Microvascular Research is both the most comprehensive and most current of the works ever written on this subject. Its breadth is dazzling and the assembled cast of contributors is a Who's Who of the field's best minds. There is virtually no area of scientific discovery relevant to the structure, function and pathology of the microvasculature that is not addressed in this text. Together Drs Shepro and D'Amore have logged more that 75 years of research in vascular biology and their knowledge of the field and of the top scientists in this field is unparalleled.

The volume starts with the basic biology of the cells that comprise the microvascular bed and moves from there to vascular development and permeability, *in vivo* models, peri-vascular transport and on to the role of the microvasculature in specific organ beds as well as in human disease. What is noticeable is the extremely large list of human diseases that are caused or influenced by alterations in the microvasculature. One begins to think that the list of diseases that are *not* influenced by microvascular alterations must be considerable shorter. Of course, a large amount of the research on microvessels over the past 35 years has been conducted on the topic of tumor angiogenesis and this topic is well covered in this volume.

It is remarkable to see how much progress has been made in microvascular research over the past few years and how much information is now known. In some cases, the text reveals new progress on topics that have been studied for decades. Among these are the relationship of the endothelium with the extracellular matrix, endothelial metabolism, endothelial heterogeneity, the distinction between developmental vessel formation and pathologic vessel formation, the traditional experimental models such as the chick chorioallantoic membrane and hamster cheek pouch, the maintenance of vascular tone and the regulation of microvascular hemodynamics, a long-term interest of Dr. Shepro.

At the same time, there are a variety of new areas of microvascular research that have burst onto the scene in just the last few years and these, too, are wonderfully represented in this volume. Among these are the role of ephrins as signaling mediators in vascular cells, the ability of zebrafish to function as model system for vascular biology, the effect of mechanical signals on microvascular structure and function, and the extraordinary new work on VEGF and VEGF antagonists that is leading to important new treatments for both cancer and for vascular diseases of the eye.

If there is a message that emanates from this book as a whole, it is the concept that blood vessels have a crucial yet differing role in the function of virtually every tissue and in the pathogenesis of a host of diseases. No longer is it sufficient to consider blood vessels as passive tubes that merely carry nutrients to tissues. Rather the microvessels are a vital part of every tissue that interact mechanically, biochemically and metabolically with the parenchymal cells of the tissues they support. The communication is elaborate and goes in both directions, from the vessels to tissue and vice versa. If you study the vasculature, you must look at it from the context of the tissue in which it occurs. If you study any specific tissue, you must understand its relationship with the microvessels that inhabit it. Reading this volume allows a new appreciation of these interactions.

It should be noted that Dr. D'Amore began her career as a graduate student in Dr. Shepro's laboratory and is now one of the leading investigators in the field of vascular biology. Perhaps they didn't realize at the time that they would one day put together a volume as definitive and thoughtful as this one. One only hopes that there is a graduate student in Dr. D'Amore's laboratory who can be counted on to update this volume in ten or twenty years.

Bruce Zetter, Ph.D.
Charles Nowiszewski Professor of Cancer Biology
Children's Hospital
Harvard Medical School
Boston, Massachusetts

Introduction

Rationale and Reader's Guide

I can safely state that no one truly comprehends the physiology and pathophysiology of the microvasculature. In a large measure, this less than desirable state is the result of an explosion of new scientific data that creates paradoxically [or maybe poetically] a concomitant explosion of ignorance. But challenges enhance curiosity. Regardless how far scientists' understanding may be from the natural laws that regulate microvessel functions, we share an incumbency to accumulate and disseminate, by whatever means, current new concepts based upon the latest tested investigations. Hence, the *Biology and Pathology Microvasculature Research* in printed and electronic formats. As Lord Florey once stated: "I do not think there is any sharp line between physiology and experimental pathology," hence the subtitle.

In 1967, at a Boston conference the *Microcirculation as Related to Shock*, (D. Shepro and G.P. Fulton, Eds. Acad. Press, 1968) Robert Ebert, then dean of Harvard Medical School, summarized the proceedings in his keynote address that: "*in shock all physiological parameters are disturbed but if there is a common denominator it would be the microcirculation.*"

Endothelium is metabolically one of the most active tissues in the body . . . probably second only to nervous tissue. Microvessels bridge the subcellular to the cellular to the organ to the system. **The breaching of the microvascular barrier is part and parcel of every disease. An inflammatory response, initially localized by microvessels, is frequently a persistent parameter of every disease.** Hence, whatever the therapeutic intervention, continuous attenuation of this defense mechanism, when awry, is required. As a closing but not a final argument, one important current concept is that there are specific *microvascular diseases* that to a large extent are independent of events in other parts of the cardiovascular system; e.g. angina with patent coronary arteries, cardiac slow flow states, long flight induced edema. Some scientists have speculated that the first stage of all forms of dementia is a breakdown of the blood brain barrier.

In the past, writers and publishers at some point had to agree on an endpoint, regardless of the manuscript's blemishes, and submit what was on hand for publication. As the "*ink dried*," the accumulated responses from critics and readers and new information would form the basis to kick-off a new edition, more frequently than not, years after the initial publication. Informatics technology, in all research endeavors, adds a new dimension to publishing, namely instant editing when the need arises, whether it be daily, weekly, quarterly, biannually. Because the editors and publishers are mindful of the fact that the currency of each scientific publication devaluates rapidly, the electronic version of *Microvascular Research* will be updated frequently. If "break throughs" should occur, an epilogue can be added immediately or reverse, obsolete "facts" and speculations that do not dovetail with new documented data can be immediately deleted.

The readers will quickly note that each presentation is limited to about 10–15 printed pages, unusual especially for review articles, and with a limited annotated (author's) bibliography. This editorial decision is based upon the realization that investigators are swamped with data and with the new tools to share information, speed has become an essential parameter. Global updating is so easily and readily available that, *less can be an advantage*. Given the space constraints, our contributors are challenged to provide the readers with their best objective and subjective take on the state of their sub-discipline. The redeeming fall-out of condensation is that lengthy introductions, redundant citations, speculations beyond the call, are eliminated. The creative sifting and contracting prior to submitting an article serves as a *needle's eye*.

A Perspective on Historical Recordings

In keeping with the editorial consensus that brevity can be a virtue and in light of the speed of scientific discoveries [see Rationale], a classical account that chronologically recapitulates microcirculatory milestones is not included in the volume. Some readers will regard this decision as an

intellectual miscalculation; that without a record of discoveries there is blinding ignorance. Yet, it is an accepted fact of academia that recorders of events cannot prevent their imaginations from slipping into their "factual accounts." The noted historian Pieter Geyl states "history is an argument without end". For example: W*ho was the first to posit the existence of capillaries and their connecting role: Erisistratus? Galen? Malpighi? Harvey? Leeuwenhoek? Boerhaave? Henle?* The winner of the paternity title will go to the histiographer of your choice. Fortunately, a wealth of microcirculatory data are readily available in paper and electronic format, which lessens the need for such a chapter in the Encyclopedia. However, to accent the editors' recognition and appreciation of history, an illustration may provide the wherewithal to unravel one scientific puzzle in the history of microvascular research.

Why did it take over a century for scientists to appreciate the heterogeneity and high metabolic activity of the ubiquitous endothelial cell [not to mention the pericyte]? Elie Metchnikoff (1883), at the Pasteur Institute, in describing his new theory on inflammation that laid the foundation for the modern concept of this defense mechanism, stated:

"Movement [contractility] of endothelial cells plays an important role in the formation of stomata during inflammation as Klebs thought and as I imagined and stated in my first paper on inflammation."

Another Nobel laureate, August Krogh, described and illustrated endothelial cell motility in "The Anatomy and Physiology of Capillaries" [1922], the publication of his Sterling Lectures given at Yale University. Although both works are highly quoted, the scientific concepts that they embrace were virtually ignored in endothelial research until a scant 30 years ago. In 1966, the laureate Lord Florey, in his address entitled, "The Endothelial Cell", honoring the noted pathologist Sir Roy Cameron, spoke exclusively on the morphology of these cells. Presciently, he concluded that his was an interim report and "*I should expect to see in the next ten years a rich harvest of new [functional] knowledge. . . .*"

Again the question—why the achievements of three laureates, whose collective contributions significantly codified microvascular biology, were largely ignored? One explanation certainly can be argued on the importance of technology over imagination; that in the life sciences technology has always played a dominant role (review the history of the microscope) in contrast to Newton's and Einstein's science, where imagination was dominant. In other words, the technology for accurately profiling mural cells was unavailable. But in this scientific teaser I believe the answer lies in the incandescence of another stellar scientist, Earnest H. Starling, whose hypothesis on fluid transport still remains a major physiological principal. But for years this monumental work may have put blinders on investigators regarding the true nature of the microvascular wall. The Starling quotation in part supports this opinion:

"We have no sufficient evidence to conclude that endothelial cells of capillary walls take any part in the formation of lymph" [1896]

The elegance of Starling's hypothesis and research on filtration was so convincing that for decades microvascular physiologists devoted their efforts, for the most part, to fine tuning his formula. I hasten to add that this opinion does not diminish Starling's achievements and legacy an iota. Newton's unique contributions were eventually and correctly challenged and even the theories of Einstein, the genius of the 20th century, are now under scrutiny.

I would add one very personal speculation (a chronicler's prerogative) that might explain why Starling ignored other scientific data that could have affected his unilateral view of the microvessel wall as a passive barrier. Notwithstanding their correspondence on science and other matters, Starling did not appear to appreciate Krogh's experimental data. My perception is that he viewed Krogh as a junior level scientist and I "*imagine*" he was a tad jealous of his Danish colleague's talents.

In summary, I respectfully suggest to those who are interested in the historical analysis of microcirculation to select the format that best matches their interest. The chronological approach is the most common and of course should include examples from ancient oriental cultures as well as those from western civilization. Another choice would be to select the superstars of different eras. For example, Andreas Vesalius's "**De Humani Corporis Fabrica**" could be the starting point of modern science since this publication marked the deathknell for skewing scientific data to comply with authority (Aristotle; Galen). Vesalius's work was based on careful observations. Would there have been a Harvey [17 century] without a Versalius [16 century]? Advances in technology, such as the history of the microscope, can also be an artful approach to chronicle advances in microcirculatory knowledge. Whatever your choice, the endpoint will be similar.

Acknowledgements

I thank all of the contributors, the editors who developed and shaped the contents of these volumes, our Elsevier Editor, Noelle Gracy, who inaugurated the project, and provided often needed encouragement, notwithstanding a transfer to Holland and a *maternity leave*. And to Karen Dempsey, at Elsevier, San Diego, who managed to organize our input, in bits and pieces, into a professional, valuable

publication—always positive in her responses and never displays an “ounce of static.” To my assistant, Christina Pitcher-Cozzone, for her “can do” handling of correspondence and almost daily revisions of contributors, titles and contents. Lastly, my gratitude to my wife, Marilyn, for her encouragement whenever I whined about the problems of a head editor and who did not complain about lengthy disappearances to my computer during the final stages of production.

Editorial Board Members

Herbert B. Hechtman, M.D.

Dr. Hechtman is Professor of Surgery at Harvard Medical School and Brigham and Womens Hospital. His laboratory's areas of research include the consequences of ischemia and inflammatory reactions in the lungs.

Rakesh K. Jain, Ph.D.

Rakesh K. Jain is Andrew Werk Cook Professor of Tumor Biology, Department of Radiation Oncology, Harvard Medical School and Director of the Edwin L. Steele Laboratory of Tumor Biology at Massachusetts General Hospital. Dr. Jain is regarded as a leader in the areas of vascular and interstitial biology of tumors and is known for integrating tumor biology with bioengineering. He is a member of the Institute of Medicine and the National Academy of Engineering of the U. S. National Academies.

Joseph A. Madri, Ph.D., M.D.

Joseph A. Madri received his BS and MS in Biology from St. John's University, NY and his Ph.D. in Chemistry and an M.D. from Indiana University. He is a Professor of Pathology at Yale University with appointments in the Medical School and Graduate School of Arts & Sciences. His areas of interest include vascular and cardiac development, angiogenesis, immune cell-endothelial cell interactions, and extracellular matrix biology.

CHAPTER 1

Endothelin in the Microvasculature

Matthias Barton

University of Zurich School of Medicine, Medical Policlinic, Department of Medicine, University Hospital Zurich, Switzerland

Introduction

Vascular activity of a peptide secreted from endothelial cells was discovered in the mid-1980s. In 1988, Yanagisawa and collegues published the sequencences of the gene and the peptide, which belongs to a peptide family structurally related to vasoconstrictor snake venoms. According to their cellular origin, the peptides were named *endothelins*. The predominant isoform, endothelin-1, is the most potent vasoconstrictor known and also promotes cell growth throughout the cardiovascular system. Endothelin is synthesized from its inactive precursor, big-endothelin, by endothelin-converting enzymes and other peptidases, and in mammals signal transduction is mediated through activation of two G-protein-coupled endothelin receptors. The endothelin system is activated in conditions associated with vascular injury and disease. This chapter discusses the role of endothelin in the microvasculature for some of the clinically most prevalent entities, atherogenesis, inflammation, and cancer development.

Endothelins: Vasoactive Peptides

After the discovery of endothelium-derived relaxing factor, later identified as nitric oxide [1], the vascular activity of a peptide secreted from endothelial cells was described in the mid-1980s [1,2]. In 1988, the gene sequencence of a 21-amino acid protein was identified [3] and found to be structurally similar to snake venoms, the sarafatoxins. The protein was named *endothelin* based on its cellular origin, and it soon turned out that three functionally different isoforms exist [4]. In the late 1990s, additional endothelin isoforms consisting of 31 and 32 amino acids were discovered [5, 6]. The predominant isoform of the endothelin peptide family, endothelin-$1_{1–21}$, is the most potent vasoconstrictor known in terms of duration of action and potency and also stimulates cell growth throughout the cardiovascular system. In the vasculature, endothelin is synthesized from its inactive precursor, big-endothelin, by endothelin-converting enzymes and other peptidases (Figure 1). In mammals, endothelin signaling is mediated through activation of two high-affinity, G-protein-coupled endothelin receptors [5, 6]. Endothelin ET_A receptors predominantly promote vasoconstriction and growth, whereas activation of the ET_B receptor—which is highly expressed in endothelial cells—is mainly coupled to the release of the vasodilators and growth inhibitors nitric oxide and prostacyclin [5]. ET_A receptors preferably bind endothelin-1, whereas the ET_B receptor binds all three isoforms with equal affinity.

Regulatory Role of Endothelin for Microvascular Function

Expression of endothelin receptors in the microvasculature differs from the expressional pattern observed in larger vessels. Specifically, the endothelin ET_A receptor—which is rarely detected in macrovascular endothelial cells—is expressed in microvascular endothelium. Microvascular endothelial cells are also structurally different from endothelial cells in other parts of the vascular tree. They differ in terms of abundency of cytoskeleton stress fibers, metabolic activity, and number of tight junctions [7]. Also, microvascular endothelial cells contain more vesicles. These cell organelles play a central role for endothelin synthesis: Endothelin-converting enzyme-2 protein expression is localized to endothelial cell vesicles, structures that store

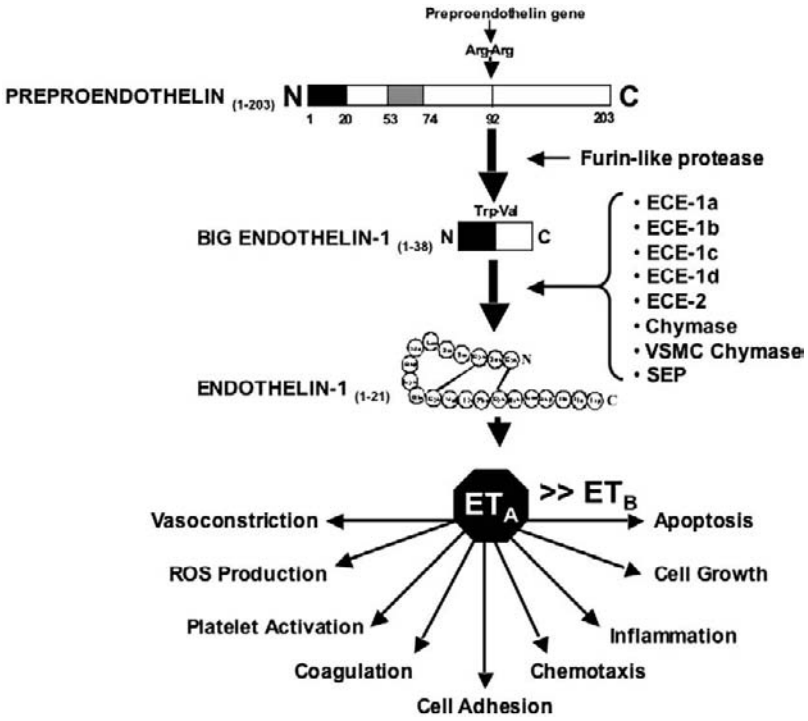

Figure 1 Biosynthesis and multiple functions of endothelin-$1_{(1–21)}$ in the cardiovascular system. Preproendothelin-1 messenger RNA is translated into preproendothelin-1, a 203 amino acid peptide, which is further cleaved by furin convertases to the inactive precursor, big-endothelin-$1_{(1–38)}$. Several enzymes, including endothelin-converting enzymes (ECE), cleave big-endothelin-1 to the active 21-amino acid peptide, endothelin-1. and release mature endothelin-1 upon stimulation. In vitro work suggests that endothelin also has important functions for capillary formation under normal and pathological conditions. Furthermore, endothelin-1 leads to activation of cytokines in circulating blood cells and also in resident cells such as endothelial cells or vascular smooth muscle. This activation includes induction of interleukin-6, nuclear factor kappa B, and C-reactive protein, effects that in turn can be enhanced by other cytokines under certain conditions. Thus, inflammatory changes and subsequent increases in vascular permeability are key factors determining microvascular injury mediated by endogenous endothelin-1.

Endothelin and the Microvasculature in Disease

Carcinogenesis and Angiogenesis

Autocrine endothelin receptor signaling controls growth of different types of tumor cells, including ovarian cancer melanoma, Kaposi sarcoma, colon carcinoma, prostate cancer, and bone metastases of tumors [8]. In most cancer cells, growth responses involve activation of ET_A receptors. In addition, angiogenesis provides an important means to increase blood supply of the tumor growth and metastasis. Proliferation and wound healing of endothelial cells is mediated by ET_B receptors. Therefore, endothelin-1 via ET_B receptors may act as an angiogenic peptide, providing additional avenues for cancer cells to increase blood supply and disseminate. By controlling expression of vascular endothelial cell growth factor (VEGF) in an autocrine fashion, endothelin-1 also acts as an important inducer of angiogenesis, thereby stimulating tumor cell proliferation. In consequence, endothelin-1 can be considered an essential factor for tumor growth, neovascularization, and metastasis. ET_A receptor blockade has been shown to inhibit tumor growth directly and to exert antiangiogenic effects by inhibiting VEGF production and by acting on vascular smooth muscle cell and on microvascular channels lined by tumor cells (Figure 2). Moreover, because ET_A receptors are expressed by microvascular endothelial cells, inhibiton of these receptors is likely to play a role for capillary formation and growth as well. It is therefore not surprising that targeting of endothelin receptors currently appears to be a promising new anticancer strategy.

Inflammation and Vascular Permeability

Hypoxia represents a strong stimulus inducing both transcription and protein synthesis of endothelin-1. Moreover,

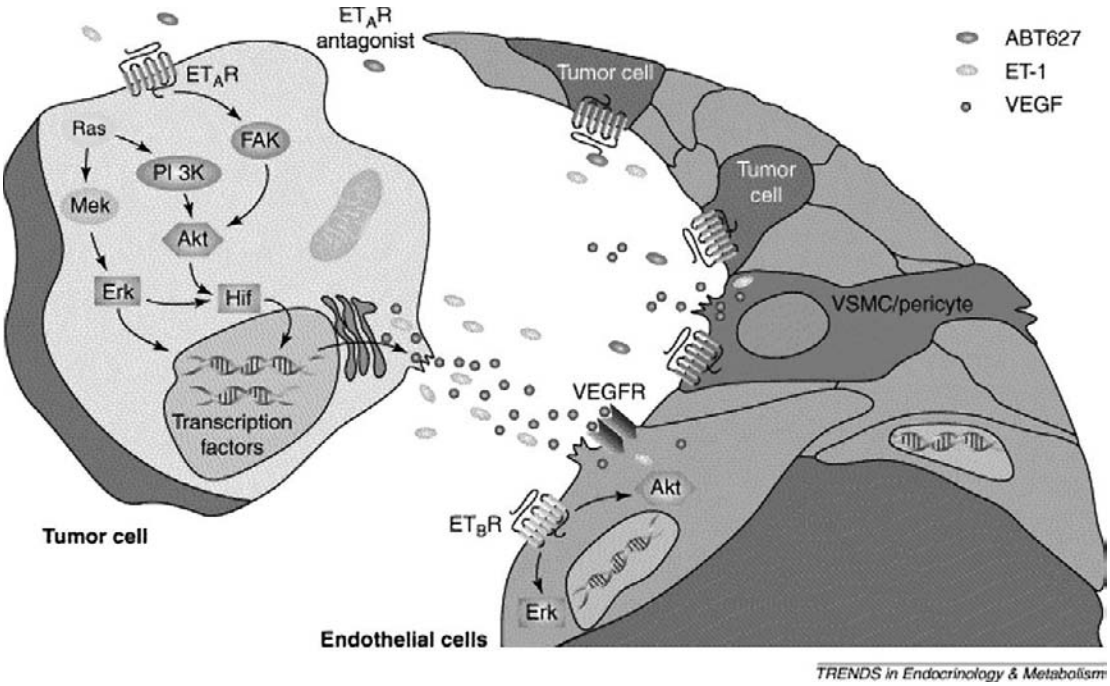

Figure 2 Proposed Overview of the Possible Role of Endothelin Signaling in Tumor Angiogenesis. This process involves a series of linked signaling pathways that typically begins with upregulation of the synthesis of angiogenic factors, such as ET-1 and VEGF, that are released by tumor cells. ET_A receptor (*ET_AR*) activation by ET-1 could promote angiogenesis by increasing VEGF production through HIF-1-dependent mechanisms. ET-1 binds to specific ET_B receptors (*ET_BR*) on endothelial cells and to ET_A receptors on pericytes/vascular smooth muscle cells or on tumor cells lining vessels (vasculogenic mimicry). ET_A receptor blockade (*ABT627*) could exert antiangiogenic effects by inhibiting VEGF production and by acting on VSMC and on microvascular channels lined by tumor cells. Another cascade of signaling events is then initiated, which leads to the formation of new tumor vessels. *Erk*, extracellular signal-related kinase; ET-1, endothelin-1; Mek, mitogen-activated protein kinase kinase; *Akt*, protein kinase B; Hif, hypoxia-inducible factor-1; VEGF, vascular endothelial cell growth factor; VEGFR, vascular endothelial cell growth factor receptor. oxidative stress associated with reperfusion further increases endothelin synthesis. There is now evidence suggesting that endothelin-1 directly contributes to vascular inflammation and microvascular permeability [9, 10]. Although the latter function is usually attributed to mediators such as histamine or VEGF, endothelin may not only contribute to tissue edema but also induces rolling and adherence of leukocytes to the capillary wall [11] (Figure 3). This results in inflammation, blood hyperviscosity, and microcirculatory stasis, leading to a substantial decrease in microcircular O_2 extraction and cell dysfunction. These changes can be prevented to a large extent by endothelin receptor blockers targeting the ET_A receptor, a treatment that has been shown to substantially reduce microcirculatory dysfunction in the myocardium [10, 12], brain [11], and intestine. Activation of the microvascular endothelin system and its direct and indirect effects are therefore responsible for cell injury, particularly in conditions associated with ischemia.

Atherosclerosis and Hypercholesterolemia

Cardiovascular risk factors such as increases in blood pressure, increased plasma levels of cholesterol or glucose, or lack of female sex hormones—all of which accelerate the development of atherosclerosis—result in activation of the endothelin system in vitro and in vivo [5, 6]. Recently, several studies have demonstrated that changes in microvasculature may importantly contribute to atherogenesis. Experimental evidence from John Cooke's laboratory suggests that enhancing angiogenesis may accelerate rather than limit the atherosclerotic disease process. Elegant studies by Lerman and coworkers [10, 13] have investigated some of the regulatory processes by which endothelin-dependent microvascular changes may contribute to early atherogenesis [13]. Even in the absence of structural injury, hypercholesterolemia, one of the cardinal risk factors for atherosclerosis, results in vascular inflammation, increased microvascular permeability [10], and adventitial neovascularization (Figure 5B). These alterations are associated with induction of VEGF expression (Figure 5D). Interestingly, increased microvascular permeability, adventitial neovascularization, as well as VEGF expression can be fully prevented by blocking ET_A receptors [10, 13]. Similarly, prevention of myocardial inflammation, infarction, and fibrosis in atherosclerotic mice by endothelin ET_A receptor blockade has been demonstrated [12], and beneficial effects on structural changes in mesenteric resistance vasculature of

mice with atherosclerosis have been reported (Table I). It is not known whether the microvascular changes described mechanistically translate into the inhibition of advanced human-like atherosclerotic lesions observed after ET_A receptor blockade [14], but it is likely that anti-inflammatory and antiangiogenic effects of endothelin blockade play an essential role.

Capsule Biography

Dr. Barton is Associate Professor of Cardiology at the University of Zürich School of Medicine, Switzerland. He is currently Attending Physician at the Department of Medicine and Director of Research of the Medical Policlinic at the University Hospital Zurich. The research in his laboratory focuses on atherogenesis, obesity, as well as vascular and renal biology. His research is supported by grants from the Swiss National Foundation (SNF), the Deutsche Forschungsgemeinschaft, and the University of Zürich.

CHAPTER 2

Control of Cell Motility by the Cytoskeleton and Extracellular Matrix

Amy Brock and Donald E. Ingber
Harvard Medical School and Children's Hospital, Boston, Massachusetts

Introduction

Most past work in the area of angiogenesis and vascular development has focused on the importance of cell growth control. However, directional motility—the process by which endothelial cells migrate in a spatially oriented manner—is equally critical for tissue expansion and vascular pattern formation. For example, angiogenic factors can stimulate 2 millimeters of capillary outgrowth in normally avascular tissues (e.g., cornea) under conditions in which cell proliferation is inhibited; this occurs exclusively through endothelial cell elongation and directed movement. Repair of the endothelium after endarterectomy also involves migration of large vessel endothelium, and failure to reconstitute the continuous cell monolayer can lead to thrombus formation and vessel occlusion. Thus, it is critical that we unravel the mechanism by which local cues from the cell microenvironment drive cell migration in order to understand angiogenesis and other vascular disease processes. But how do cells interpret, integrate, and respond to information from their local environment and decide in which direction to move? This is a complex problem in light of the fact that their environment contains multiple soluble, insoluble, and mechanical stimuli that may provide conflicting signals to individual cells.

In this chapter, we review the current understanding of how cells sense these local signals and choose a direction in which to execute purposeful locomotion, with particular focus on the role of the cytoskeleton and mechanical interactions between cells and their extracellular matrix (ECM). Insights into this mechanism have been made possible by recent development of new microtechnologies and tools that allow analysis of how microscale changes in physical parameters, such as ECM structure, topography, and mechanical compliance, impact directional cell motility and associated cytoskeletal signaling mechanisms.

Directional Motility

Directional cell migration on ECM is critical during all phases of embryonic development. For example, neural crest cells emigrate along a path defined by basement membrane fibrils during development of the nervous system. The ureteric bud epithelium migrates from the nephric duct toward the metanephric mesenchyme to induce the formation of the adult kidney. Formation of the vascular system follows a similar paradigm and is characterized by tandem cell migration during angiogenesis and migration of cell sheets during the expansion and repair of large vessels.

Angiogenesis relies on the tight control of endothelial cell migration through the balance of angiogenesis inducers and inhibitors. This dynamic, multistep process involves retraction of pericytes from the abluminal surface of the capillary, release of proteases that degrade the ECM surrounding the preexisting vessels, and endothelial cell migration in the direction of an angiogenic stimulus that is mediated by ongoing deposition (and degradation) of new ECM components. This is followed by cell proliferation, which facilitates further extension of the growing capillary

sprouts. Eventually, these structures locally slow down their rate of ECM turnover, accumulate a basement membrane, and reorganize into quiescent, hollow, capillary tubes. Recruitment of pericytes and smooth muscle cells further stabilizes these newly formed blood vessels.

In the adult, cell migration during angiogenesis is critical for normal function of the female reproductive system as well as wound healing and the immune response. Directed cell movement is also a feature of the tissue remodeling that occurs during postnatal developmental processes, such as branching morphogenesis of the mammary epithelial ductal system and elongation of the ureters in the renal system. In the subventricular zone, an area of the brain containing neural stem cells, neurogenesis occurs throughout adulthood, with the majority of these new neurons migrating anteriorly into the olfactory bulb, traveling a distance of several millimeters in a highly directed manner to reach their destination. Thus, understanding of the mechanism by which directional cell movement is controlled has important implications for many developmental systems.

Cell motility also is a central component of various pathological conditions and as such may represent a common target for drug development. Tumor expansion requires the proliferation and directional migration of endothelial cells as blood vessels are recruited to supply a solid tumor with oxygen. If this angiogenic process is inhibited, the tumor must rely on preexisting blood vessels, and its growth will be checked at a maximum size of approximately 1 to 2 millimeters in diameter because of diffusion limitations. Metastatic tumor cells also acquire the ability to migrate out of the primary tumor into the vasculature and subsequently invade a secondary location. In the vascular system, misdirected endothelial cell migration is a key factor in vascular anomalies, intimal hyperplasia secondary to endarterectomy, and chronic inflammatory diseases such as arthritis and atherosclerosis.

The Migratory Process

Migration is initiated as a cellular response to chemotactic gradients of soluble mitogens and haptotactic gradients of insoluble adhesive (ECM) molecules in the local microenvironment. Cell movement is mediated by the extension of thin, flat, membrane protrusions from the leading edge of the cell (Figure 1). These outward extending membrane processes are filled with a loose network of actin filaments and are known as *lamellipodia*; they are also sometimes referred to *membrane ruffles* when they are oriented perpendicular to the plane of the adhesive substrate. In some cells, formation of these membrane processes is accompanied or preceded by extension of long, thin protrusions filled with rigidified (cross-linked) bundles of actin filaments, known as *filopodia*, that act like moving cantilevers or fingers that explore the surrounding substrate. In fact, cells may extend and retract multiple filopodia and lamellipodia as they explore their microenvironment, suggesting that this process is a key regulatory event in directional migration and pathfinding.

First identified as the primary organelles of cell motility by Abercrombie in 1971, lamellipodia are sites of active actin polymerization, and their formation requires the local recruitment of a whole array of molecular components to mediate cytoskeletal reorganization. These include actin filament nucleating factors such as Arp 2/3 and SCAR; filament depolymerizing proteins such as cofilin; barbed-end capping proteins; and actin monomer binding factors such as profilin. Filopodia also form as a result of actin polymerization; however, these filaments are cross-linked into long, stiff bundles that can extend to up to tens of micrometers in length.

Other key structural elements in migrating cells are the adhesive contacts where the cells tightly attach to the underlying ECM. In migrating cells, the formation of these local

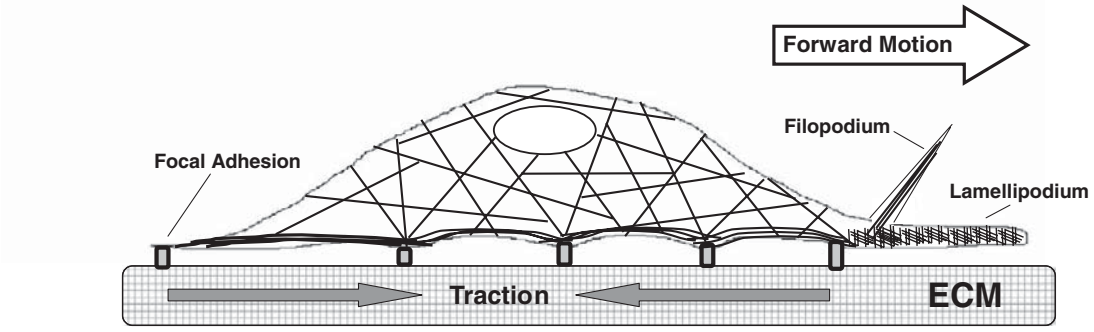

Figure 1 Diagram of a Migratory Cell. As the attachment sites between the intracellular cytoskeleton and the extracellular matrix (ECM), focal adhesions (*gray ovals*) transmit cell tractional forces to the substrate. In migrating cells, the formation of these local adhesive structures behind the leading edge stabilizes the extension of actin-based protrusions, such as lamellipodia and filopodia. The thin, sheet-like lamellipodium is characterized by a tight network of actin filaments and may be accompanied or preceded by the extension of filopodia containing rigid, cross-linked actin bundles. Forward motion requires direction extension of these processes from the leading edge, as well as exertion of cell tractional forces on the ECM substrate that help both propel the cell forward and release the cell's trailing adhesions.

adhesive contacts, known as *focal adhesions*, at the leading edge of the cell helps stabilize the actin-based membrane protrusions. ECM regions beneath these spot weld-like focal adhesions also act as traction sites that resist tensional forces that are generated via actomyosin interactions in the cytoskeleton. This buildup of isometric forces restructures and stiffens the actin cytoskeleton behind the leading edge of the cell, thereby providing a stable platform from which the actin filaments that form filopodia and lamellipodia can assemble.

Importantly, cells also must be able to exert tractional forces and pull against their fixed ECM adhesions in order to propel the cell body forward and produce purposeful locomotion. During this process, the cell must generate enough motive force to overcome the resistance of the stiffness of its own cytoskeleton and of the ECM adhesions at its trailing edge (Figure 1). The extension of lamellipodia and the formation of new adhesions at the leading edge must also be spatially and temporally coordinated with detachment of adhesions in the trailing edge and release of the tail to result in net forward movement of the entire cell.

Control of Motility by ECM

It is well known that ECM plays a central role in microenvironmental control of cell motility based on its ability to chemically mediate cell adhesion. In addition, capillary endothelial cells must increase ECM degradation to initiate cell outgrowth and also must maintain ongoing ECM synthesis and deposition to sustain progressive cell migration during both angiogenesis and healing of large vessel endothelial monolayers. Importantly, recent work has revealed that the physical properties of the ECM, including its surface topography and mechanical compliance, also can significantly impact cell movement.

Compared with cells on rigid ECM substrates, cells on flexible substrates coated with the same ECM protein display increased rates of both lamellipodial activity (protrusion and retraction) and locomotion. Cells also prefer to move from regions of low to high mechanical rigidity. In addition, they move faster along edges of adhesives surfaces than in their central regions, and along microengineered grooves or thin lines than on flat ECM substrates. Furthermore, when individual cells are constrained to polygonal ECM-coated adhesive islands with angular edges (e.g., squares, triangles, pentagons, hexagons, trapezoids), they preferentially extend lamellipodia and filopodia from their corners. Thus, cells apparently can sense micrometer-scale changes in topography and subtle alterations in ECM mechanics, and they respond by changing both their cytoskeleton and migratory behavior. This knowledge could have important implications for engineering of artificial matrices for tissue engineering applications.

Studies of endothelial cell clusters cultured in a three-dimensional collagen gel have demonstrated directly that force application can promote capillary outgrowth. These experiments also showed that matrix-transduced tensional forces in stretched collagen gels are sufficient to control *directional* outgrowth as the growing capillaries extend along the tension field lines that stretch between neighboring cells. Part of this response is based on the ability of the outgrowing endothelial cells to sense and respond to the direction of ECM fibrils that become aligned by the cell-generated forces.

The mechanism by which changes in ECM mechanics influence cell motility is less clear, largely because it has been difficult to study this process until recent years. Qualitative analysis of the traction forces exerted by migrating cells was first carried out by observing the pattern of wrinkles produced by fibroblasts cultured on deformable substrates (e.g., fibrin clots, collagen gels, silicon rubber substrates). Since that time, increasingly sophisticated methodologies have improved the quantification and spatiotemporal resolution of cell-based forces. For example, polyacrylamide gels with different degrees of cross-linking now allow substrate stiffness to be varied as an independent parameter in cell culture studies. The added use of fluorescent microbeads embedded in the gels as fiducial markers permits the direct quantitation of traction forces that are exerted by adherent cells. Combination of this method of "traction force microscopy" with micropatterning techniques also has allowed control of the position where cells exert these tractional forces, as well as analysis of the impact of varying this position on cell behavior.

These techniques have generated new and sometimes surprising insights. For example, it has recently been demonstrated that the small nascent focal adhesion complexes at the leading edge of a cell can exert stronger traction forces than larger, more mature focal adhesion plaques. In individual cells that are physically constrained to single square ECM adhesive islands, the localized distribution of focal adhesions corresponds precisely to the corner regions where the cell exerts greatest tractional forces on the substrate, deposits ECM (fibronectin) fibrils, and extends new migratory processes (lamellipodia and filopodia). Moreover, lamellipodia extension can be inhibited by dissipating cytoskeletal tension generation.

Biochemical Signaling Mechanisms

Over the past decade, great advances have been made in our understanding of the chemical factors that drive cell motility, as well as the biochemical signaling cascades that mediate cellular responses, as described in several excellent recent reviews (see Bibliography). In particular, the Rho family of small GTPases, consisting of Rho, Rac, and Cdc42, have been shown to regulate signal transduction pathways that link extracellular signals through membrane receptors to changes in cytoskeletal structure and organization that drive cell locomotion. For instance, in 1992, Hall and coworkers demonstrated that constitutively active (GTPase-deficient) mutants of Rac induce lamellipodia

assembly in fibroblasts, whereas active Rho and Cdc42 mutants promote formation of stress fibers and filopodia, respectively. Similar effects have been observed in various endothelial cells as well.

In fact, Rac has been found to be essential for the migration of all cells examined thus far. Studies in macrophage, for example, have demonstrated that downregulation of Rac activity stalls cell migration while downregulation of Cdc42 renders cells unresponsive to the direction of a chemotactic gradient, causing them instead to move via a random walk. Studies utilizing fluorescence resonance energy transfer (FRET) microscopy have revealed that while Rac protein is distributed homogeneously throughout migratory fibroblasts, the active GTP-bound form is localized to the leading edge of the cell. Rac and Cdc42 may therefore act locally to govern where actin polymerization is activated at the periphery of the cell.

Analysis of Rho GTPase signaling has revealed a vast array of downstream effector proteins (at least 60 at present) that regulate many different cell processes. Rac is activated by guanine nucleotide exchange factors (GEFs) such as Trio, Vav, and Sos-1 and repressed by GTPase-activating proteins (GAPs) such as chimerin. Several factors downstream of Rac act on cytoskeletal structure and other aspects of cell migration. Perhaps the best characterized of these effectors is p21-activated kinase (Pak), a serine/threonine kinase that is activated upon binding to the GTP-bound form of Rac or Cdc42. Pak provides a direct link from Rac to cell motility through phosphorylation and activation of LIM kinase, which phosphorylates and represses the actin depolymerizing factor, cofilin. Pak may also regulate cell traction forces by promoting myosin light-chain phosphorylation and increasing cytoskeletal contractility, although these results have been controversial and may depend on the cell type examined.

The Rho GTPases also impact directional migration through the regulation of focal adhesion dynamics. In migrating cells, Rac is required for the formation of new focal adhesion complexes at the leading edge of the cell, whereas Rho is essential for the maturation of these nascent adhesive contacts into fully developed focal adhesions. Rac may regulate adhesion turnover indirectly by antagonizing Rho through its downstream effector Pak1, which localizes to focal adhesions upon activation. The mechanism by which Pak1 regulates adhesion dynamics is not yet clear but may involve the action of LIM kinase or the phosphorylation of myosin light chain.

Mechanical Signaling Mechanisms

But how do changes in ECM mechanics or in the level of tractional forces cells exert on their focal adhesions influence cell motility? Focal adhesions are critical to the migratory process because they are sites of attachment between the ECM, transmembrane adhesion receptors (known as integrins), and the actin cytoskeleton, which stabilize lamellipodia and transmit propulsive forces. In addition, the cytoskeletal backbone of the focal adhesion acts as an orienting scaffold for a vast array of signaling molecules. They also are sites where the mechanical and biochemical signals that regulate cell migration are integrated inside the cell.

The temporal and spatial organization of focal adhesion assembly is only partially understood; nevertheless, it is clear that physical forces significantly impact this process. The application of force to newly formed integrin-cytoskeleton linkages promotes additional focal adhesion assembly, and hence mechanically reinforces the connection, by inducing force-dependent signaling events inside the cell. For example, cytoskeletal tension exerted on the ECM via new adhesion sites results in the maturation of small nascent adhesive contacts (“focal adhesion complexes”) into larger, more highly organized anchoring structures (classic “focal adhesions”). The earliest events in the assembly process include activation of receptor and nonreceptor tyrosine phosphatases, and the subsequent sequential recruitment of talin and paxillin, followed by slower recruitment of vinculin and FAK. The presence of tensin and zyxin may indicate a late stage of adhesion assembly or a transition to a different type of adhesion site that assembles only after the leading edge has stabilized.

To date, more than 50 different signaling molecules have been reported to be associated with focal adhesion sites, and further investigation into the functional consequences of this molecular heterogeneity is ongoing. In addition, the dynamic aspect of adhesion assembly and disassembly will need to be examined in the future. The lifetime of an adhesion is on the order of tens of minutes, whereas the exchange rates of its individual structural components appear to be on the order of seconds to minutes. The local mechanical compliance of the ECM also may spatially regulate the strength, size, number, and molecular composition of the cell-ECM adhesions, and thus it may be a major source of spatial heterogeneity in adhesion complexes. For example, treatment of cells with HL-7 to inhibit actomyosin contractility results in the rapid loss of phosphotyorosine from focal adhesions, followed by disassembly of the complex on a slower time scale. These findings suggest that tension applied through the actomyosin system may trigger local tyrosine phosphorylation events that are required for the subsequent assembly of adhesion complexes.

Micromanipulation studies utilizing magnetic or optical micromanipulation techniques have unequivocally demonstrated that changes in the balance of forces transmitted across cell surface integrins play a key role in organization of the focal adhesions that mediate cell motility. Application of physical stresses to integrins results in the recruitment of focal adhesion proteins, actin filaments, signaling molecules, and mRNA to the site of force application. Focal adhesions also respond rapidly to mechanical perturbations and may actively regulate their dynamics to control their strength, size, and spatial distribution. For example, application of fluid shear stresses to the apical membranes of confluent endothelium results in almost immediate focal

adhesion remodeling at the cell base, with preferential addition of new components in the direction of the applied stress.

It is now clear that directed motility within developing tissues, such as vascular networks, is controlled by local changes in cellular force balance. Mechanical perturbation of tissues or their underlying ECM results in the transmission of forces across integrin receptors, restructuring of the CSK, and activation of various signal transduction cascades in a force-dependent manner. Recent work in Drosophila has confirmed that the migratory motion of cell layers similarly generates mechanical forces that shape the digestive tract. During development of this tissue, movements of the posterior and anterior mesoderm cells compress neighboring stromodeal precursor cells. This mechanical stress results in the translocation of Armadillo transcription factor to the nucleus, where it upregulates expression of *Twist*, a gene required for invagination of the stromodeum. In cells expressing a mutant form of *Twist*, these events can be rescued by the application of an external mechanical force (using a micropipette). Thus, mechanical force per se clearly can impact cell migration in a developmentally relevant way.

Future Directions

A great deal is known about the signaling molecules that invoke the motile response, but the mechanism by which this response becomes spatially localized within the cell to determine the site where motile structures, such as lamellipodia and filopodia, are generated is less well characterized. Future work in this area will rely on advances in imaging technology and new probes to permit the real-time visualization of activated states of signaling molecules with improved spatial resolution. As directional migration also requires the integration of microenvironmental information, including ECM composition, topography, and mechanics, systems that maintain or reproduce these parameters in vitro will greatly facilitate future study of migration within the physical and spatial context in which it normally proceeds.

Glossary

Cytoskeleton: the network of protein filaments in the cytoplasm of eukaryotic cells that gives the cell shape, guides intracellular transport, and coordinates its movement and growth. Its most abundant components are actin microfilaments, microtubules, and intermediate filaments.

Focal adhesion: the localized, spot weld-like attachment site between the cytoskeleton and extracellular matrix that anchors the cell to its adhesive substrate. Attachment is mediated by tightly clustered, transmembrane integrin receptors and a variety of structural and signaling protein components.

Lamellipodia: flat, sheet-like, membrane protrusions supported by an intracellular meshwork of actin filaments that are extended outward at the leading edge of a migrating cell.

Capsule Biographies

Amy Brock, a graduate student in the Biomedical and Biosciences (BBS) program at Harvard University, is completing her Ph.D. dissertation on cell motility in the laboratory of Dr. Ingber.

Dr. Ingber has made significant contributions to the fields of angiogenesis, matrix biology, and mechanoregulation, and cellular engineering. He is the Judah Folkman Professor of Vascular Biology in the department of Pathology at Harvard Medical School, and Senior Investigator in the Vascular Biology Program at Children's Hospital in Boston, Massachusetts. His work is supported by grants from the NIH. NASA, DARPA, ARO and DOD.

CHAPTER 3

Ultrastructural Morphometry of Capillary Basement Membrane Thickness

Edward C. Carlson
School of Medicine and Health Sciences, University of North Dakota

Introduction

Capillary Basement Membrane Morphometry Defined

Morphometry is a precise method of measurement that employs conventional morphological methods to estimate the physical dimensions of an unbiased population of biological structures. The structures may be quite large and visible to the naked eye or they may be small and require substantial magnification. In order to measure capillary basement membranes (CBMs), transmission electron microscopic (TEM) methods are applied to tissue samples. The samples must be selected without bias and carefully prepared, accurately measured, corrected for plane of section, and statistically analyzed to provide a faithful numerical description of the measured CBM population.

Historical Background

Basement membranes (BMs) were identified first in the mid-19th century. They were described as homogeneous and sometimes fibrillar extracellular sheets that supported the digestive and respiratory systems, and as continuous matrix barriers between mucous membranes and their underlying capillaries. These remarkably accurate accounts formed the bases of textbook descriptions of BMs until the 1950s, when the advent of TEM provided substantially increased image resolution of biological samples.

Subsequent TEM studies coupled with the development of new methods to isolate BMs led to biochemical and immunochemical analyses, which showed that BMs were comprised largely of collagen, noncollagenous glycoproteins, and proteoglycans assembled in a network that resulted in the electron-dense layer (*basal lamina*) imaged by TEM [1]. Studies of isolated BMs substantially increased our understanding of the production, assembly, and degradation of their molecular components. Importantly, it was shown that although most BMs comprised similar molecular subunits, they were not identical, and a nonunitary concept of BM composition was generally adopted.

BMs also varied widely in their location and morphological presentation, including width (thickness). Some (e.g., the lens capsule and Descemet's membrane in the eye) were extremely thick and could be removed from their underlying tissues with a dissecting microscope. Others, including those of most blood capillaries, were very thin and could not be imaged clearly by light microscopic (LM) techniques. It is now recognized that regardless of location and width, TEM techniques are required to provide adequate images for accurate BM measurements, and this is especially true for the microvasculature where CBMs are particularly narrow.

Although BMs exhibit slow turnover rates, they are nevertheless dynamic structures, and their thickness is altered with age, physiological state, or pathological environment. For example, many microvascular BMs are thickened in diabetes mellitus, leading to renal, retinal, and neurological disorders. Interestingly, BMs of nonvascular tissues (e.g., renal tubules) also show thickness increases in diabetes. Accordingly, it is believed that although BMs from various tissue types are differentially thickened during normal aging or in disease states, the mechanisms leading to such thickening may be similar.

Because CBM thickness is widely regarded as a biomarker for aging and a hallmark for chronic complications of diabetes, numerous studies have centered on this parameter. The purpose of this chapter is to provide the reader with background information regarding the morphological heterogeneity of CBMs, and specifically with some methods by which their thickness may be accurately measured.

Ultrastructural Definitions

Basement Membranes

BMs were first defined by LM as extracellular layers subjacent to epithelia. Because the practical limit of LM resolution is approximately 0.2 μm, these BMs necessarily included considerable quantities of stained ground substance and reticular (small collagen) fibers in addition to the narrow (~100 nm) electron-dense basal lamina of TEM. Nevertheless, these early descriptions were accurate, and subsequent TEM studies confirmed their histological locations and demonstrated that basal laminae consistently colocalized with BMs described by LM.

Subsequently, the term BM was taken over by the electron microscopists, who widened the definition considerably to include a ubiquitous network of basal laminae always closely associated with cell surfaces. Moreover, BMs and basal laminae became synonymous terms for extracellular membranes that formed physical boundaries for a large and uncompartmented connective tissue space. BMs separated the space from nonconnective tissue cell types including epithelia, muscle, and nerve, while connective tissue cells (except adipocytes) were free in the tissue space uncovered by BMs. TEM also provided substantial substructural BM detail, including three distinct layers not recognizable by LM. These included a central, dense layer *(lamina densa)* flanked by two layers that were more electron-lucent *(laminae rarae).*

Capillary Basement Membranes

TEM analyses of many tissues show that all capillaries are surrounded by CBMs that closely subtend their endothelial cell layers. Simple capillaries are surrounded by BMs (basal laminae) composed of a central lamina densa separated from the endothelium by a lamina rara (Figure 1a). Capillaries decorated by perivascular cells (pericytes) are more complex. As in simple capillaries, basal laminae surround the endothelium, but they often split to enclose one or more pericytes as well. In these, CBMs separate endothelial cells from the connective tissue space and subendothelial BMs shared by perictyes, and endothelial cells often fill the narrow space between them (Figures 1b, 1c and 2).

Even more structural sophistication is demonstrated by renal glomerular capillaries, pulmonary alveolar capillaries, and capillaries of the central nervous system (including the retina). In these, both CBM surfaces are demarcated by cell

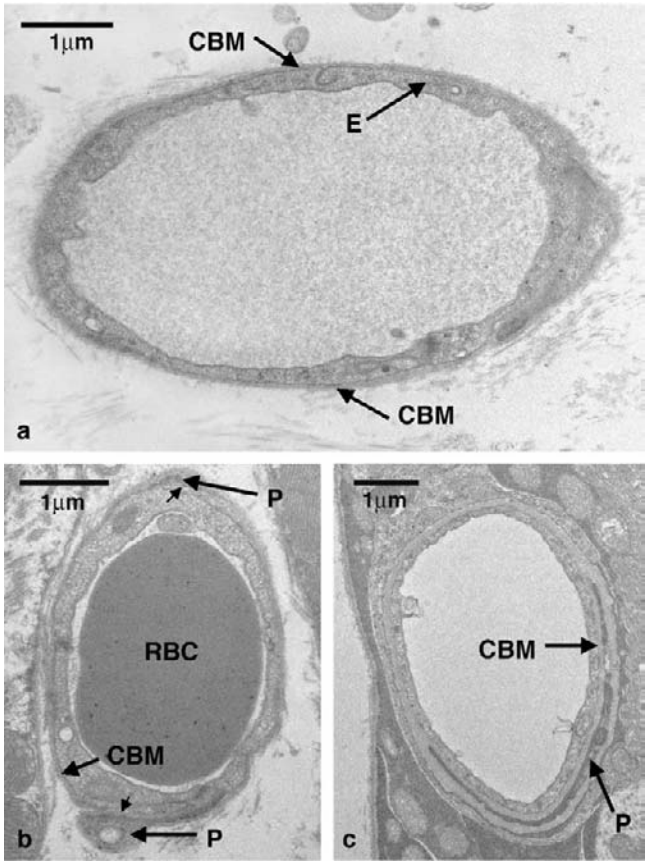

Figure 1 Transmission electron micrographs of sections through capillaries. **(A)** Simple capillary from rat skeletal muscle. A continuous capillary basement membrane (CBM) subtends the endothelium (E) and separates it from the connective tissue space. **(B)** Bovine skeletal muscle capillary surrounded by basement membrane (CBM) and decorated by pericytes (P). A shared basement membrane (*arrows*) separates pericytes from the endothelium. RBC, red blood cell, (c) Rat retinal capillary near the vitreo-retinal border. A pericyte (P) shares the basement membrane (CBM) with the endothelium for nearly half of the capillary circumference.

membranes. In the kidney, glomerular BMs are flanked by capillary endothelial cells and podocytes; in the lung, pulmonary alveolar BMs intervene between capillary endothelium and the alveolar epithelium, and in the CNS (retina), CBMs are sandwiched between endothelial and glial (Müller) cells in a highly complex microvasculature that often includes single or multiple layers of perictyes (Figures 1c and 2).

With these structural complexities, an important question relates to the definition of CBM. In this regard, most investigators consider the CBM as the BM subjacent to the capillary endothelium, regardless of whether it is shared by other cell types.

CBMs have membranous or sheet-like shapes and are relatively narrow in one dimension (width) compared to the other two (area). Although both dimensions are subject to changes that may have physiological or pathological significance, width (thickness) is by far the simplest to estimate. Accordingly, investigators have applied various

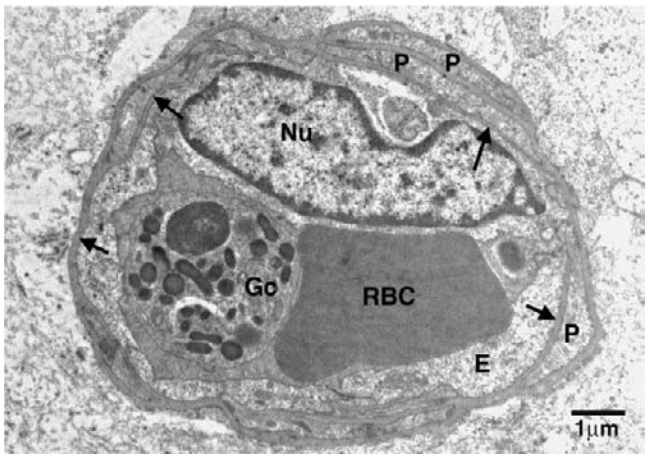

Figure 2 Transmission electron micrograph of section through complex bovine retinal capillary surrounded by numerous pericytes (P). Capillary basement membrane (*arrows*) surrounds the endothelium and often is shared by pericytes. Within the lumen are a red blood cell (RBC) and a granulocyte (Gc). Nu, endothelial cell nucleus.

morphometric techniques in an effort to determine BM thickness in normal and diseased tissues.

Capillary Basement Membrane Thickness in Health and Disease

TEM studies of CBMs in humans and other vertebrates show that regardless of animal age or health, they are continuous along the length of the microvessel and closely adhere to their parent cell types as described previously. CBM thickness, however, is widely variable within and between tissue types both in health and disease.

It is now clear that in many tissues, CBM thickness is a normal function of age and is considered a biomarker for aging. However, thickness increases with age are not seen in all tissues and all animal models, and few rigorous studies have been carried out to address this issue. Nevertheless, most investigators believe modest increases in CBM thickness are a normal age-related process. In certain disease states, however, CBM thickening is excessive and is considered a diagnostic hallmark. This is especially true in chronic stages of diabetes mellitus where most CBMs are thickened, and glomerular and retinal CBMs show remarkable thickness increases in humans and animal models of the disease [2]. In fact, it is fair to say that most CBM thickness studies have been carried out in diabetics in an effort to identify possible patterns that could point to potential molecular regulators of BM thickening. Of these investigations, a large percentage has focused on capillaries in the retina and renal glomerulus, where their diabetic sequelae often lead to retinal degeneration and blindness and/or renal decompensation and death. Moreover, because diabetes often has been cited as a disease of premature aging, recent studies have sought metabolic mechanisms that might possibly explain both normal, benign, age-related CBM thickness increases as well as those of diabetic BM disease.

Several mechanisms are implicated in the pathogenesis of microangiopathy leading to diabetic CBM thickening. These have been reviewed recently [3] and include hyperglycemia-induced increases in Type IV collagen synthesis, decreased expression of matrix metalloproteinases (MMP-2 and 3), and increased tissue inhibitors of metalloproteinase (TIMP). Vascular endothelial growth factor (VEGF) also may be involved because treatment with anti-VEGF antibodies reduces glomerular BM thickening. Also, oxygen radicals/oxidative stress and advanced glycation end products (AGEs) may play a role because aminoguanidine (which inhibits AGE formation, but also has antioxidant properties) attenuates diabetic nephropathy. In addition, the polyol enzymatic pathway is stimulated by hyperglycemia and has been implicated in the chronic sequelae of diabetes. In this regard, hyperpermeability is an early feature of diabetic microangiopathy and is reduced by aldose reductase inhibitors. Because hyperglycemia apparently increases the generation of reactive oxygen species (ROS), activates aldose reductase, and induces AGE-formation, it has been postulated that ROS production may represent a common underlying element in several pathways leading to diabetic microvascular damage, including increased CBM thickness.

Clearly, CBM thickness is an important parameter in a wide variety of biological and medical investigations. Moreover, because thickness changes necessarily alter CBM functional capacities, it is important to accurately measure their physical dimensions in order to identify patterns of change that might offer insights into molecular mechanisms regulating their form and function.

Capillary Basement Membrane Morphometric Methods

The goal of any morphometric study is to produce a numerical description that is as faithful as possible to the object described. This requires close attention to several techniques that potentially could bias the outcome.

Data Sampling

Whenever structural data are sought, a very important question regards sampling procedures. This begins at the level of selecting patients or animals for study, and rules for independent sampling must be strictly obeyed. If bias is introduced at any of the sampling levels (e.g., populations of patients or animals, blocks of tissue, visual fields, sites of measurement), then the study will be flawed and of no value. For example, with some CBM measuring techniques, it is essential that tissue sections be cut perpendicular to the long axis of the capillary. Unfortunately, this has not been closely monitored in many studies, which may explain conflicting data derived from different laboratories.

Tissue Collection and Preparation

Because CBM morphometry requires resolution at the level of ultrastructure, careful TEM techniques must be employed to consistently prepare the tissue for observation [2]. In this regard, whenever possible it is most appropriate to fix the tissue by intravascular perfusion. This should be done as quickly as possible following anesthesia and should include freshly prepared buffered fixatives. Tissues should be harvested and minced quickly, post-fixed in buffered OsO_4, and further dehydrated before embedding. A blinded (unbiased) method should be employed for choosing cured tissue blocks for sectioning. Also, the technical person responsible for generating sections, making electron micrographs, and measuring CBMs should be unaware of the source of the tissue.

Regardless of the method utilized for CBM measurement, it is advantageous to make ultrathin sections that are normal to the long axis of capillaries. In this regard, it is possible to embed some tissues (e.g., peripheral nerve, skeletal muscle, retina, ocular choriocapillaris) in epoxy blocks so that most of its microvessels are oriented perpendicular to the cutting surface. For others, however (e.g., kidney, lung, pancreas), this is not possible, and they must be sectioned randomly. Nevertheless, an effort at perpendicularity should be made by cutting thick (1 μm) sections first to determine tissue orientation and position by LM before proceeding with ultramicrotomy.

Microscopy and Micrography

As an initial preparatory step, the TEM should be stabilized (constant beam current) and calibrated using a standard cross-grating grid (e.g., 2,160 lines/inch) photographed under the same conditions and magnification used for the tissue sections.

Before CBM micrography is carried out, care must be taken to randomize visual fields selected for TEM. Consistency is critical in this regard, and whatever methods are chosen to eliminate selection bias should be applied rigorously to all sections. For example, for selecting skeletal muscle CBMs, it might be decided to utilize only those grid squares that are completely filled with tissue and only those in which the capillaries are cut primarily in cross section (i.e., where they are circular or only slightly elliptical).

Either TEM photomicrographs or digital images may be utilized for ultrastructural morphometry, but regardless of the mode chosen, all parameters (e.g., TEM and enlarger magnifications) must remain constant throughout the study.

Measuring Capillary Basement Membranes

Irrespective of the method used to physically measure CBMs, a most important point regards randomization of measurement sites. A clear plastic grid is helpful in this process (Figure 3). It can be superimposed on the photographic paper during the enlarging procedure [4], and decisions regarding sites of measurement can be determined by noting where the endothelium intersects with the sampling line grid (Figure 2). This eliminates site selection bias because measurements are made only at preselected points, and it also ensures remarkably consistent numbers of measurements per linear CBM distance.

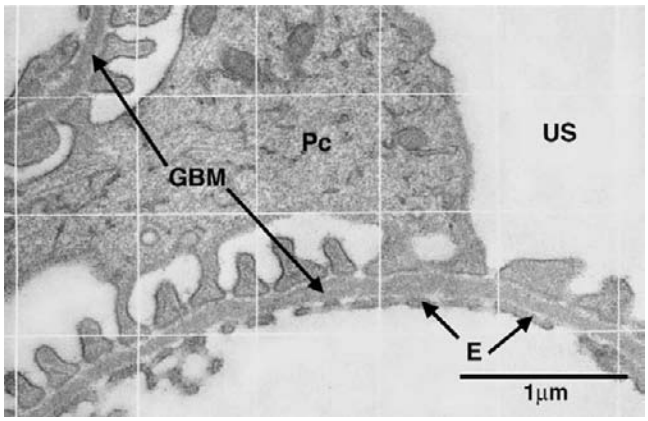

Figure 3 Transmission electron micrograph of renal glomerulus superimposed with a sampling grid. Perpendicular measurements are made at points where the grid intersects with the endothelium. Pc, podocyte; E, endothelium; GBM, glomerular basement membrane; US, urinary space.

Removing Right-Sided Skew and Calculating True CBM Thickness

By definition, CBMs are tube-like, and any series of parallel cuts through them generally will not cross precisely perpendicular to the long axis of the vessel. In fact, because many CBMs are highly folded (e.g., glomerular BM), many cuts will be partially *en face*. As a result, distributions of CBM measurements usually exhibit a right-sided skew. This phenomenon can be eliminated by measuring CBMs only where they are cut in cross section (i.e., only where adjacent endothelial cells show crisp plasmalemmae). However, this process is painstakingly slow and unnecessary because of a major advance in membrane morphometry called the orthogonal intercept method for determining membrane thickness. It was developed in 1979 by Jensen and associates and employs a measuring ruler [5] with a logarithmic scale indicating nine classes of increasing length. The ruler can be a simple transparent plastic device or it may be numerically defined using a digitizing tablet interfaced with a computer designed to measure length [2]. In either case, numbers of measurements in each class are recorded, and their harmonic mean is calculated and then multiplied by $8/3\pi$ [6]. This final calculation is designed to remove the expected right-sided measurement distribution skew [7] and to yield a true CBM thickness.

Statistical Analysis

Statistical studies of true CBM thickness derived from orthogonal intercepts are somewhat problematic because the data from many CBM measurements tend to collapse into a single number and the sample size becomes very small. Accordingly, data from different CBM types can be presented simply as ranges and medians. Alternately, true CBM thickness values can be derived from a specific number of animals, tissue samples, or micrographs, with each set representing one *n*. In a recent study [2], the latter method was chosen, with one set of 20 electron micrographs (approximately 100 measurements) representing one *n* (true CBM thickness data point). Standard deviations of these can be calculated, and distributions of control and experimental samples statistically compared using an unpaired *t*-test. In those instances where data fail to meet parametric testing assumptions of equal variance and normal distribution, nonparametric tests may be employed.

Interpreting the Data

The goal of all scientific data collection should be to generate credible information that can be interpreted in light of previous investigations. In the case of CBM morphometry, however, this is difficult because, as pointed out by Osterby [8], most early CBM thickness studies did not employ unbiased sampling methods—an obvious drawback to their credibility. Nevertheless, attempts must be made to compare and contrast new data with that from previous studies.

Future CBM thickness studies must be centered on unbiased samples and carried out by rigorously controlled methods. However, correlation with previous work will continue to be extremely difficult for reasons cited previously. Moreover, recent data strongly suggest that large differences exist in CBM thickness between and within individuals and between and within tissue types. This real CBM thickness variation demands that conclusions be drawn from investigations with large sample sizes prepared and analyzed under rigorous conditions. Fortunately, excellent progress has been forthcoming in the efficiency of TEM techniques and in development of appropriate morphometry software, which should be advantageous in future experimental design.

Conclusions

CBM thickness is altered with age, physiological conditions, and in several disease states—most notably diabetes mellitus. This important parameter can best be derived from well-controlled, state-of-the-art TEM morphometry studies carried out on capillaries selected by unbiased sampling methods. Given the known wide variation in CBM thickness within and between tissue types, large sample sizes will be critical for accurate estimation of CBM thickness. Recent technical advances make such studies possible, and it is hoped that new investigations will identify patterns of CBM thickness change from which can be inferred possible molecular mechanisms of metabolic dysfunction, and ultimately that these can be controlled or eliminated through therapeutic intervention.

Glossary

Basement membrane: Continuous electron-dense sheets of extracellular materials composed of collagenous and noncollagenous glycoproteins and proteoglycans, and located wherever nonconnective tissue cells border the connective tissue space. Many basement membranes thicken with age as well as in several disease states, notably diabetes mellitus.

Capillary: A small microvascular channel, generally less than 10 µm in diameter, that connects arterioles and venules; they comprise endothelial lining cells occasionally overlaid by perivascular cells (pericytes) and are surrounded by basement membrane.

Morphometry: A precise method of measurement employing conventional morphological methods to estimate the physical dimensions of an unbiased population of biological structures. The structures may be quite large and visible to the naked eye or they may require substantial magnification for measurement.

Ultrastructure: Structural elements of cells and tissues that require electron microscopic observation; it generally includes structures smaller than 0.2 µm.

Capsule Biography

Edward Carlson is professor and chairman of the Department of Anatomy and Cell Biology at the University of North Dakota School of Medicine and Health Sciences, in Grand Forks, North Dakota. He received his Ph.D. from the University of North Dakota and previously served as a faculty member in Departments of Human Anatomy at the University of Arizona, and the University of California at Davis, Schools of Medicine. The author's principal research interests include the morphology and cell biology of basement membranes in health and disease.

CHAPTER 4

IL-7 Receptor and Microvascular Endothelial Cells

[1]Danuta Dus, [1]Agnieszka Krawczenko, and [2]Claudine Kieda

[1]Ludwik Hirszfeld Institute of Immunology and Experimental Therapy, Polish Academy of Sciences, Wroclaw, Poland
[2]Centre de Biophysique Moléculaire (CNRS), Orléans, France

Interleukin 7 (IL-7) is a stromal cell–derived cytokine that is critical for B- and T-lymphocytes development. It was originally isolated as a murine pro-B cells growth factor and called lymphopoietin-1. Interleukin 7 functions primarily as a growth- and antiapoptotic factor in the early stages of B- and T-cell development. When bound by proteoglycans, it could exert a local biological activity. It was also shown that IL-7 is a potent endothelial growth factor and has an impact on the process of lymphangiogenesis, enhancing the expression of lymphatic markers on human endothelial cells.

Receptor for IL-7

Structure

Interleukin-7 can act on various cells through its receptor IL-7R. IL-7R is a heterodimer that consists of an α chain (CD127) that specifically binds IL-7 and the common γ chain γ_c (CD132), which is also a component of several other cytokine receptors: IL-2, IL-4, IL-9, IL-15, and IL-21. Interleukin-7 receptor is a member of the hematopoietin/cytokine receptor superfamily; both IL-7Rα and γ_c have a pair of conserved extracellular cysteine residues and an extracellular Trp-Ser-X-Trp-Ser motif and lack intrinsic tyrosine kinase activity (Figure 1). The α chain of IL-7R can also bind thymic stromal-derived lymphopoietin (TSLP), a cytokine that is important in early stages of B- and T-cell development. IL-7Rα is a type 1 membrane glycoprotein. It has a 220-amino acid extracellular domain, a 25-amino acid transmembrane fragment, and a 195-amino acid cytoplasmic tail. The mature protein has an observed molecular weight of about 75 kDa, although the predicted molecular weight is 49.5 kDa; the difference is probably caused by post-translational modification of one or more of the six potential N-linked glycosylation sites. The α chain exists in membrane-bound and soluble forms. Soluble forms of the IL-7R are produced by alternative splicing of the IL-7R gene, which is located on human chromosome 5p13 and mouse chromosome 15. The murine IL-7 receptor shows 64 percent sequence identity with the human protein. For high-affinity binding of IL-7, necessary for cell survival or proliferation signal transduction, both α and γ_c chains are required (Figure 1). On T cells, high- and low-affinity receptors are expressed according to the state of activation of the cell.

Signal Transduction

Interleukin 7 can signal through several nonreceptor tyrosine kinases associated with the cytoplasmic tail of the receptor. This includes the JAK/STAT pathway, Src family kinases ($p59^{fyn}$ in mice and $p59^{fyn}$ and $p53/p56^{lyn}$ in humans), and PI-3 kinase. In T lymphocytes, the MAPK family (p38) is also involved. IL-7 activates JAK1 and JAK3 kinases, which are also activated by the cytokines that share the γ_c receptor subunit. JAK kinases can further activate signal transducers and activators of transcription (STAT1, STAT3, and STAT5), which in turn translocate to the nucleus and activate DNA transcription. It has been demonstrated that stimulation of the pro-T cells by IL-7 results in clathrin phosphorylation. Because clathrin is involved in internalization of many receptors, its phosphorylation by IL-7 may affect the internalization of the IL-7 receptor. The disorder in JAK-mediated signal transduction is a cause for the immunodeficiency syndrome severe combined immunodeficiency (SCID). The mutation in the JAK3 kinase gene as well as in the α chain gene of the IL-7 receptor results in autosomal, recessive SCID, whereas mutation in the γ_c chain gene causes X-linked SCID (SCID-X).

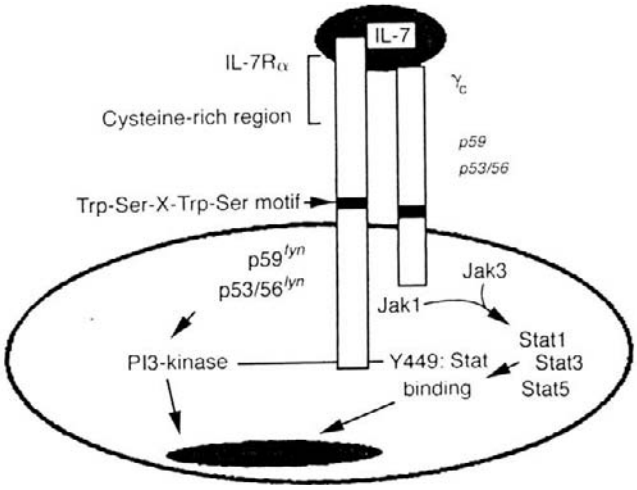

Figure 1 The Schematic Structure of IL-7R. The receptor for IL-7 consists of a specific α chain and a common γc chain. The IL-7Rα is also a part of thymic stromal lymphopoietin (TSLP), whereas the γc chain is present in other cytokines such as IL-2, IL-4, IL-9, IL-15, and IL-21. The cellular signaling upon binding of IL-7 to IL-7R can be mediated by the JAK/STAT pathway, PI-3 kinase, or Src kinases family. Reprinted from "Biological and clinical implications of interleukin-7 and lymphopoiesis" by P. M. Appasamy from *Cytokines, Cellular & Molecular Therapy*, www.tandf.no/ccmt, 1999, **5**, 25–39, by permission of Taylor & Francis AS.

Other details describing the structure of IL-7R and IL-7 signaling have been reviewed elsewhere [1–3].

IL-7R Distribution

The presence of IL-7R was reported mainly in hematopoietic human and murine cell systems and selected myeloid cells. The IL-7Rα chain is present on bone marrow progenitor cells, lymphoid T and B precursors, and on most mature T cells. Recently, its presence on epithelial cells and neurons, as well as on human microvascular endothelial cells and some tumors, was reported.

After IL-7 binding, IL-7R transduces several biological signals, playing an important role in the function of the immune system. The cytokine, *via* its receptor, supports the maturation and augment proliferation of pre-B and pre-T cells. Murine B lymphocyte development is critically dependent on IL-7 availability. The interleukin-7 receptor is essential for Peyer's patches (PP) development. Lymphoid organ-specific mesenchymal tissue that possesses IL-7R is involved in the initial phase of PP formation. Accumulating evidence indicates that both PP and lymph nodes (LN) originate from a common precursor, characterized by the presence of IL-7R. The precursor differentiation into LN or PP, and their further functional properties, are controlled by the local environment.

The Presence of IL-7R on Endothelial Cells

The endothelium is a type of highly specialized, structurally and functionally heterogenous mesodermal-derived epithelium. Microvascular endothelium controls the body compartmentation and homing of lymphocytes into lymphoid as well as nonlymphoid sites, in a tissue-specific manner. Selectins (E- and P-) and other endothelium-specific adhesive molecules called addressins (ligands for selectins) initiate the process of leukocytes' adhesion to the vascular wall. Under the chemoattractive influence of endothelium-presented chemokines, activated leukocytes adhere firmly and finally transmigrate through the vascular wall to the surrounding tissues. Endothelial cells play fundamental roles not only in normal processes such as wound healing but also in pathological ones such as atherosclerosis, inflammation, and cancer progression and metastasis.

In 1993 it was shown that murine endothelial cells from peripheral lymph nodes could be specifically activated by IL-7. In cells grown in the presence of IL-7, expression of lectin adhesion molecule and a selective induction of addressin (MECA 79 antigen) expression were noticed. These observations strongly suggested the presence of IL-7R on murine endothelial cells. Further study revealed that human endothelial cells possess the receptor for IL-7. The α chain of the receptor (IL-7R) was detected in five endothelial cell lines, derived from peripheral or mesenteric lymph nodes, lung, and appendix.

It has been postulated that there is a close association of the hematopoietic and endothelial developmental lineages because they both arise from a common precursor, the hemangioblast. Hence, the fact of the presence of an IL-7 receptor on hematopoietic as well as on endothelial cells may support this hypothesis.

Activity of IL-7 on endothelial cells is achieved through activation of its specific receptor, resulting in induction of adhesion molecules and/or cytokines. It could be hypothesized that IL-7, activating endothelial cells, may act indirectly, inducing the production of another growth factor such as VEGF or bFGF; however, no evidence supports this hypothesis. It has also been shown that IL-7 can induce signal transduction events in cells that do not express IL-7R because of the ability to involve other surface receptors such as FLT3 and c-kit.

IL-7R in Cancer

Because IL-7 is a known lymphocyte growth and differentiation factor, it also participates in the development of several hematological malignancies. However, the IL-7 receptor mRNA has also been detected in many nonhematological tumor in vitro cell lines. IL-7 was found to be a potent growth factor for breast cancer cells. Breast cancer cell lines, cancer tissue biopsies, and normal breast tissue express IL-7R mRNA. Moreover, the expression of IL-7R and its signaling molecules is higher in tumor tissue of patients with a poor clinical outcome. The aberrant expression of IL-7, IL-7R, and their signaling complex may influence the proliferation of breast cancer cells and disease progression, supporting lymphangiogenesis of the solid tumors.

Capsule Biographies

Danuta Dus, Ph.D. hab., is a head of Laboratory of Cellular Interactions at the Institute of Immunology and Experimental Therapy at the Polish Academy of Sciences in Wroclaw, Poland; Agnieszka Krawczenko, Ph.D., is an assistant professor at the Laboratory of Cellular Interactions. The scientific activity of the laboratory concerns predictive markers of metastasis. The aims of the study are molecular mechanisms engaged in the process of mutual interactions of tumor cells with endothelial cells at the site of tumor cell extravasation, which determine the organ specificity of metastatic secondary growth. The work is supported by the Ministry of Scientific Research and Information Technology, The State Committee for Scientific Research (KBN), and by The Foundation for Polish Science (FNP).

Claudine Kieda, Ph.D., is heading the Cell Recognition: Endogenous Lectins team in the Centre for Molecular Biophysics in Orléans, France. The laboratory is focusing on molecular mechanisms of cellular interaction between endothelium and circulating cells leading to invasion. She first discovered endogenous lectins in lymphocytes; her actual special interests are glycoconjugates and their receptors as key recognition signals in inflammation and metastasis. She was awarded the CNRS bronze medal, and her work is supported by ARC, CNRS, and private foundations such as Jérôme Lejeune.

CHAPTER 5

Matrix Metalloproteinases, Tissue Inhibitors of Metalloproteinases, and the Microvasculature

Cecilia A. Fernández and Marsha A. Moses

Vascular Biology Program, and Department of Surgery, Children's Hospital, Boston, and Department of Surgery, Harvard Medical School, Boston, Massachusetts

An accumulating body of evidence suggests that the remodeling of the extracellular matrix (ECM) during angiogenesis is accomplished largely through the activity of the matrix metalloproteinases (MMPs). MMPs form a large family of metal-dependent proteolytic enzymes, which have been classified on the basis of their substrate (i.e., the ECM components that they degrade) specificity. There are four major classes of MMPs: collagenases, gelatinases, stromelysins, and membrane-type MMPs. The activity of MMPs is the rate-limiting step in ECM turnover. MMP activity is regulated at three different levels: transcription, activation of MMPs from their inactive (latent) proenzyme form, and by the activity of their endogenous inhibitors, the tissue inhibitors of matrix metalloproteinase (TIMPs) [1].

Matrix Metalloproteinases

MMPs have been implicated in promoting angiogenesis as well as tumor growth and metastasis. Capillary endothelial cells (EC), under the influence of angiogenic mitogens, secrete MMPs, and the proteolytic activity of these enzymes facilitates the sprouting of EC out from the parent venule as well as the migration of these cells at the leading edge of the new capillary sprout through the ECM during angiogenesis (Figure 1). For example, MMP-2 activity has been shown to be concentrated at the invadopodia of a variety of cell lines. In addition, MMP activity is required for cancer cell migration and invasion through extracellular spaces as well as for the cell's ability to invade a nearby blood vessel, extravasate at a distant site, and then to finally invade the distant tissue in order to seed a new metastatic lesion. MMPs have also been shown to cleave membrane-bound growth factors, such as HB-EGF and TGFβ, as well as to release angiogenic mitogens (bFGF) deposited in the matrix.

Recent studies have demonstrated that MMPs are also important at the earliest stages of the angiogenic program called the *angiogenic switch*. In a model of tumor progression that recapitulates the earliest events associated with the onset of neovascularization, our laboratory has shown that MMP-2 is a critical component of the angiogenic switch. In this study, both MMP-2 protein and activity were significantly upregulated during the transition from a preangiogenic to an angiogenic tumor [2]. Since that report, other groups have shown that MMP-9 may be a regulator of the angiogenic switch in a pancreatic tumor model [3]. Taken together, these data support the conclusion that MMP activity is one of the earliest and most sustained activities in angiogenesis. Because MMP activity is required for angiogenesis and tumor growth, it is not surprising that MMPs can be found in the urine of cancer patients and that they are independent predictors of disease status [4]. MMPs were reproducibly detected in the urine of cancer patients and correlated with disease status but were not found in the urine of healthy age-matched, sex-matched controls or in the urine of patients who showed no evidence of disease at the time of sampling and testing.

These studies highlight the importance of MMPs as regulators of angiogenesis and subsequent tumor progression. Based on these data, MMP activity represents a potentially powerful target for cancer therapy. In fact, it has been shown that a shift in the proteolytic balance in favor of the MMP inhibitors would effectively block angiogenesis, and several synthetic inhibitors of MMPs have been tested in clinical

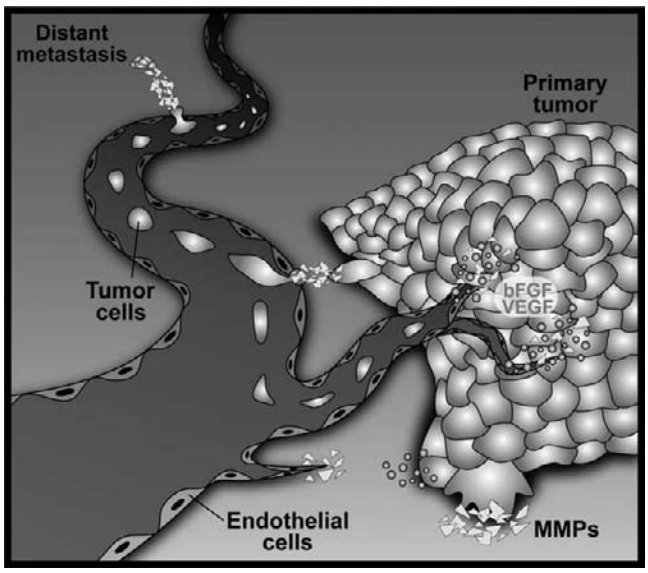

Figure 1 Role of MMPs in angiogenesis, tumor growth and metastasis.

trials designed to determine their efficacy in the treatment of solid tumors and metastasis. Unfortunately, the indiscriminate use of synthetic MMP inhibitors has proven to be less successful than originally anticipated and has also resulted in side effects that preclude their use at therapeutically effective doses. Current clinical trials are testing certain of these inhibitors in combination therapies. However, it is possible that their broad specificity and, in some cases, limited bioavailability may ultimately mean that this generation of synthetic MMP inhibitors will not be as promising as once hoped. In light of these disappointing outcomes, there is renewed interest in the endogenous MMP inhibitors, which, although larger in size, may offer advantages over synthetics, with respect to both a reduction of cytotoxicity and their lack of immunogenicity as a function of their being a part of a naturally occurring protein.

Although MMPs are routinely regarded as being proangiogenic molecules, MMPs have also recently been shown to process antiangiogenic fragments from their inactive parent molecule, suggesting that they can also function as negative regulators of angiogenesis. For example, we have shown that MMP-2 can proteolytically cleave plasminogen to yield the endogenous inhibitor, angiostatin. Other groups have reported that, depending on tumor type, additional MMP family members also share this activity. Similarly, MMPs have been shown to participate in the processing of endostatin from collagen XVIII.

Tissue Inhibitors of Metalloproteinases

There are four known endogenous inhibitors of MMPs that have been cloned to date: TIMP-1, -2, -3, and -4. These four members of the TIMP family have been shown to inhibit active MMPs equally well, although some limited degree of specificity exists. For example, TIMP-2 binds preferentially to MMP-2, whereas TIMP-1 binds to MMP-9 with higher affinity than to other MMPs. The amino acid sequence of TIMPs is highly conserved (~45%) and includes 12 cysteine residues that form 6 disulfide-bonded loop structures. The junction of the first three loops has been identified as the MMP inhibitory site by both biochemical and structural studies. In fact, the first three loops expressed alone as a truncated protein have been shown to be sufficient to inhibit MMP activity. These three loops have been popularly referred to as the N-terminal domain. The C-terminal domain, comprising the remaining three disulfide-bonded loops, is more variable among the TIMP family members in terms of its primary structure and is believed to confer some of the specificity observed for certain TIMPs [5]. For example, interactions between the C-terminal domain of TIMP-2 and the PEX domain of MMP-2 are thought to stabilize the enzyme inhibitor complex, as well as to promote pro-MMP-2 activation in a trimeric complex with MT1-MMP.

It is becoming increasingly clear that TIMPs are multifunctional proteins that affect a variety of cellular activities, such as cell growth and apoptosis. Most prominent among these functions is the ability of certain TIMPs to regulate vascular and tumor cell growth. For many years, this potential has been predicated on their ability to directly inhibit the MMP activity by binding to the enzymes' active site. Since the first report that TIMPs could inhibit angiogenesis in vitro and in vivo [6], it has largely been assumed that all TIMPs inhibit angiogenesis. However, recent studies now illustrate important differences in the ability of these family members to be bona fide inhibitors of angiogenesis in vivo. Although TIMP-1, TIMP-2, and TIMP-3 are all inhibitors of capillary EC migration, only TIMP-2 has been shown to inhibit the proliferation of normal capillary endothelial cells [7]. TIMP-1 has actually been found to be a modest stimulator of capillary EC proliferation as well as angiogenesis in vivo, whereas TIMP-3 has no significant effect on normal capillary EC proliferation. TIMP-4 has not yet been tested in these systems.

These results led us to hypothesize that the antiproliferative effects of TIMP-2 are, in fact, a unique feature of this TIMP and represent a second antiangiogenic activity in this molecule. Recently, it has been reported that this second antiangiogenic site which is responsible for directly inhibiting capillary EC proliferation, is housed in the C-terminal domain of TIMP-2 and, more specifically, in Loop 6. (Figure 2) Interestingly, while the antiproliferative domain of TIMP-2 was a potent inhibitor of corneal neovascularization when angiogenesis was stimulated by the exogenous addition of an angiogenic mitogen, the MMP-inhibitory domain resulted in only modest inhibition that was not statistically different from a mutant form of the protein that lacked MMP inhibitory activity [8]. In fact, synthetic MMP inhibitors, such as BB-94, do not inhibit angiogenesis in this system, nor do monospecific, MMP-2 immuno-

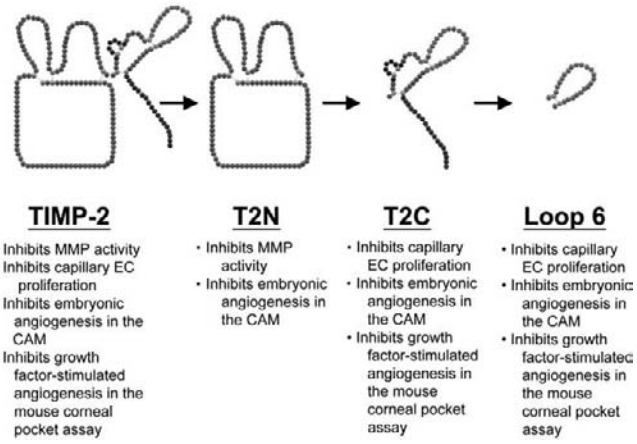

Figure 2 Uncoupling of the anti-angiogenic domains of TIMP-2. TIMP-2 possesses two structurally independent anti-angiogenic domains, T2N and T2C. T2N inhibits MMP activity but not capillary endothelial cell proliferation, while T2C inhibits capillary endothelial cell proliferation but not MMP activity. T2N inhibits embryonic angiogenesis *in vivo* as demonstrated in the chick chorioallantoic membrane (CAM) assay, while T2C inhibits *both* embryonic and mitogen-stimulated angiogenesis, as demonstrated in the CAM and in the mouse corneal pocket assays. The anti-proliferative activity of T2C has been further isolated to Loop 6 of TIMP-2. This 24 amino acid domain is, in and of itself, a potent inhibitor of angiogenesis *in vivo* as shown in the two distinct *in vivo* models.

neutralizing antibodies. These results suggest that direct MMP inhibition alone may not be sufficient to inhibit the robust angiogenesis associated with pathological neovascularization[8].

It is possible th.at the antiproliferative effects of TIMP-2 are the result of its interaction with the PEX domain of MMP-2. As mentioned previously, TIMP-2 has been shown to participate in the cell surface activation of pro-MMP-2, and the C-terminal domain alone has been shown to inhibit this process, presumably by hijacking pro-MMP-2 from the activating complex. This interaction has now been shown to be mediated by the C-terminal tail of TIMP-2, in that a mutant form of the TIMP-2 carboxy-terminal domain containing the C-terminal tail of TIMP-4 did not result in the inhibition of pro-MMP-2 activation [9]. Given these results, it is unlikely that the antiangiogenic effects of Loop 6, which is not involved in these interactions, is the result of indirect MMP inhibition.

Much remains to be learned about the multifunctional and sometimes contradictory activities of TIMPs. For example, TIMP overexpression in cancer cell lines has been shown to result in decreased tumor growth and tumor cell colonization in some systems, while stimulating tumor growth in other systems. Similarly, whereas certain TIMPs inhibit apoptosis, others have been shown to promote it. These effects often vary depending on the specific TIMP and cell type tested and the method of gene delivery utilized. These studies continue to teach us that the physiological *context* in which these inhibitors and their cognate enzymes function plays a key role in determining their ultimate effect in vivo both with respect to regulating the vasculature as well as other important physiological systems.

Glossary

Angiogenesis: The process of new capillary formation from a pre-existing vessel.

Matrix metalloproteinases (MMPs): A multigene family of metal-dependent enzymes, whose activity is considered to be a rate-limiting step of extracellular matrix degradation. The growing family of MMPs is currently composed of 28 members.

Tissue inhibitors of metalloproteinases (TIMPs): A family of endogenous inhibitors of metalloproteinases. Four family members have been cloned and expressed to date.

Capsule Biography

The authors are research scientists in the Vascular Biology Program at Children's Hospital and Harvard Medical School. Dr. Moses is an Associate Professor in the Department of Surgery at Harvard Medical School. Work from this group demonstrated for the first time that the inhibition of MMP activity resulted in the inhibition of angiogenesis and subsequent tumor growth, and that MMP activity was critical for the switch to the angiogenic phenotype. They have published extensively on the role of MMPs and TIMPs in the regulation of vascular growth and angiogenesis.

CHAPTER 6

Matrix Metalloproteinases and Their Inhibitors

Iwona Fijalkowska and Rubin M. Tuder

Divisions of Cardiopulmonary Pathology and Pulmonary and Critical Medicine, Departments of Pathology and Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland

Introduction

As important as the inner organelles of the cell, the extracellular matrix (ECM) plays fundamental roles in cell function. The molecular framework of the extracellular matrix serves several functions in cell-to-cell communication and integration of environmental cues to a cell's differentiation and fate. We have learned that the extracellular matrix is as plastic and dynamic as the cells that produce them. Critical in this molecular and structural plasticity is the ability to cleave the underlying molecular matrix units, which is accomplished by a vast array of enzymes with a wide spectrum of substrate specificities. Metalloproteases (MMPs) or matrixins refer to a wide superfamily of enzymes that requires the presence of a highly conserved zinc-binding motif for catalysis [1, 2]. MMPs are functionally, structurally, and at the DNA sequence homology related to a collagenase found in the tail of a tadpole undergoing metamorphosis, which was the first member to be described within this rapidly expanding superfamily of enzymes. By cleaving the molecular extracellular framework surrounding cells, MMPs contribute to cell renewal and tissue formation, both in the embryo and in the adult system. Their action continues in critical biological processes, such as tissue remodeling, would healing, and angiogenesis. Furthermore, there is growing evidence that, despite their enzymatic activity, MMPs also act as cellular regulatory factors in areas of cellular signaling, growth, differentiation, and death. These broad functions modulate or control interactions of a cell with its immediate surroundings and with its external environment.

In this chapter, the authors aim at summarizing the newest knowledge on the role of MMPs in physiological and pathophysiological processes, with an emphasis in vascular and pulmonary vascular biology.

Molecular Structure

Currently a total of 23 enzymes out of 29 MMPs have been identified in humans. Five MMPs are shorter isoforms of full-length enzymes, and one is annotated as MMP-like1 protein. Additionally, several plant and nonvertebrate MMPs have been found and characterized.

All MMP family members share a similar multidomain structure. The general structural pattern consists of a prodomain, a catalytic domain, a hinge region, and a hemopexin domain. The prodomain comprises a signal peptide [of about 20 amino acids (aa)] and a propeptide region, of about 80 aa. The signal peptide is cleaved off the molecule during its transport through the endoplasmic reticulum for cell release. The propeptide contains two specific regions, which as based on their biochemical properties, mechanistically account for the activation of the zymogen (i.e., latent form) to the active MMP. These two regions consist of a protease-sensitive sequence located in the second out of three helices and a unique, cysteine-switch motif PRCGXPD, within the peptide tail.

The catalytic domain (of about 170 aa) consists of five β-sheet and three α-helix structures linked by a connecting loop. Three calcium ions and one structural zinc atom strengthen and stabilize the structure. The active site with its characteristic metal-binding motif HEXGHXXGXXH is located near the C-terminus, a highly conserved (56% to 64%) portion of the protein. The second zinc atom, also known as the active zinc, is coordinated by three histidines

present within this motif. The substrate binding region is located adjacent to the active site. Unlike the active site, the binding pocket reveals a high level of sequence variability among the different MMP classes, and thus accounts for the specificity of substrate recognition by the MMPs.

The hemopexin-like domain consists of four hemopexin-like repeats (containing about 210 aa) and occupies the C-terminal part of the molecule. Each repeat has a four-bladed β-propeller fold, with a single stabilizing disulfide bond between blades I and IV. Because these domains are also found in many other proteins, for instance in integrins, it is thought that they can also be involved in protein–protein interactions. The hemopexin domain connects to the catalytic domain via a proline-rich polypeptide hinge region of 10 to 70 aa. The hemopexin-like domains are determinants of substrate specificity of each enzyme The function of the hinge region is not fully understood.

Although all MMP family members have a similar overall structural motif, their molecular weight ranges from 28,000 to 92,000 da and suggests the existence of different levels and patterns of glycosylation, as well as some structural diversity. Whereas some enzymes lack certain domains, others have additional inserts that modulate but not drastically alter their functions. For instance, MMP-7 and MMP-26 lack the hemopexin domain, whereas MMP-2 and MMP-9 have an insert of three fibronectin type II domains in the vicinity of the catalytic site. NMR studies have indicated that the inserts consist of two antiparallel β-sheets, connected with a short α-helix. and are stabilized by two disulfide bonds. Domains 2 and 3 are thought to be structurally flexible, which can facilitate simultaneous interactions with multiple sites in the ECM.

Several members of the MMP family exhibit additional structural features that allow classifying them into a separate subgroup of membrane-type MMPs (MT-MMPs). Within their polypeptide linker that connects the prodomain with the catalytic domain, there is a sequence R-X-R/K-R, which seems to be essential for specific post-translational processing of these proteinases. Also, their C-terminal region has a 70 to 100 aa hydrophobic polypeptide tail that inserts in the cell membrane, terminating with a short cytoplasmic tail. These enzymes are anchored in a cell membrane. So far, six membrane-type proteases have been characterized [2].

Each MMP exhibits a unique set of structural and functional characteristics. For instance, MMP-23 lacks the cysteine switch motif and the hemopexin domain. Instead, it has a unique cysteine and proline-rich region, the IL-1 type II receptor-like domain, and a furin-susceptible region. MMP-23 is activated in the Golgi-like MT-MMP, but it does not have a transmembrane domain. It is released in active form, but it may associate to the cell membrane via the N-terminal part of the propeptide.

MMPs can be grouped according to different common properties, varying from primary sequence homologies, substrate specificity, or site of action. One such approach is based on grouping by DNA homology using the resources of the human genome project database, or as based on the search for proteins with homologous catalytic domain of MMPs. Relevant amino acid sequences were detected after analyses of alignments that revealed 29 different proteins stemming out from the same ancestor. Based on this approach, MMPs could be ordered into five subfamilies: nonfurin-regulated MMPs, gelatinases, transmembrane MMPs, GPI-anchored, and others. A similar clustering, with minor differences, was obtained when catalytic domain or hemopexin sequences were compared [3].

Based on the differences in substrate specificity, MMPs can be classified into six subgroups: collagenases, gelatinases, stromyelisins, matrilysins, membrane-type MMPs, and others [2]. Based on the site of action, there are two groups of enzymes: secreted into the extracellular matrix and transmembrane proteins. Table I summarizes groups of MMPs.

Activation of Metalloproteinases

The final products of MMP gene translation are inactive forms of enzymes such as zymogens or proMMPs. Functionally, the active form of MMPs requires exposure of the active catalytic center, which occurs via a series of conformational changes.

The active site containing a zinc-binding motif and surrounding amino acids consists of a cleft along the catalytic domain. In the latent form of the enzyme, the polypeptide tail of the prodomain region covers the catalytically competent cleft. The inhibitory cysteine with its sulfhydryl group acts as a fourth ligand and thus blocks accessibility to the active zinc atom. Cleavage of the protease-sensitive region in the prodomain causes translocation of the polypeptide tail away from the cleft, which upon removal of the cysteine from the active region, exposes the active zinc in coordination with a water molecule. The removal of the inhibitory prodomain exposes the substrate binding region located close to the active site. When the substrate binds and comes close to the active site, the carbonyl group of the substrate peptide bond replaces the water molecule and coordinates the active zinc. The glutamic acid located within the MMP active domain and adjacent to active zinc acts as a proton acceptor from water and provokes a nucleophilic attack on the peptide bond of substrate [5].

MMP activating factors include proteolytic enzymes that digest a protease-sensitive region in the prodomain. Glutathione and other thiol-modifying agents in general, chaotropic agents, SDS, reactive oxygen, NO, heat, or low pH can also perturb the molecular interaction between the inhibitory cysteine and the active zinc, causing activation of MMPs. MMP activation is a multistep process, involving initially the partial removal of the peptide from the prodomain by any of the above listed agents, culminating with the full removal of activation peptide of intermediate molecules.

Membrane-type MMPs contain a specific sequence between the propeptide and the catalytic domain that is susceptible for furin or furin-like proprotein convertases

Table I Groups of Human MMPs.

Enzyme	GENE	Domains	Substrate
Collagenases			
MMP-1, Interstitial collagenase, collagenase 1	11q22–q23	Pre-Pro(SH)-Cat(Zn)-Hinge-Hemopexin(S-S)	Aggrecan, collagens I, II, III, VII, VIII, X, XI, enactin, fibronectin, gelatin, IGFBPs, laminin, link protein, myelin basic, tenascin, vitronectin, α1-AC, α2-M, α1-PI, casein, C1q, fibrin, fibrinogen, IL1β, ProTNFα
MMP-8, Neutrophil collagenase, collagenase 2	11q21–q22	Pre-Pro(SH)-Cat(Zn)-Hinge-Hemopexin(S-S)	Aggrecan, collagens I, II, III, α2-M, α1-PI, C1q, fibrinogen, substance P
MMP-13 Collagenase 3	11q22.3	Pre-Pr(SH)-Cat(Zn)-Hinge-Hemopexin(S-S)	Aggrecan, collagens I, II, III, VI, IX, X, XIV, fibrillin, fibronectin, gelatin 1, osteonectin, α2-M, casein, factor XII, fibrinogen, proMMP2, ProTNFα
Gelatinases			
MMP-2, Gelatinase A	16q13	Pre-Pro(SH)-Cat-3xFnII(Zn)-Hinge-Hemopexin(S-S)	ADP-ribose polymerase (in vitro) [ref 64 S1], collagen I, III, IV, V, VII, IX, X, XI, decorin, elastin, entactin/nidogen, fibrillin, fibronectin, fibulins, gelatin1, IGFBPs, laminin, α1-AC, α1-PI, C1q, fibrin, fibrinogen, IL1β, ProTNFβ, plasminogen substance P
MMP-9, Gelatinase B	20q11.2–q13.1	Pre-Pro(SH)-Cat-3xFnII(Zn)-Hinge-Hemopexin(S-S)	Aggrecan, collagens IV, V, XI, XIV, decorin, elastin, fibrillin, gelatin1, laminin, link protein, myelin basic, osteonectin, vitronectin, α2-M, α1-PI, casein, C1q, fibrin, fibrinogen, IL1β, ProTNFα, Pro TNFβ, plasminogen, substance P
Stromelysins			
MMP-3, Stromelysin 1	11q23	Pre-Pro(SH)-Cat(Zn)-Hinge-Hemopexin(S-S)	Aggrecan, collagens III, IV, V, VII, IX, X, XI, decorin, elastin, entactin/nidogen, fibrillin, elastin, fibronectin, gelatin1, IGFBPs, laminin, link protein, myelin basic, osteonectin, tenascin, vitronectin, α1-AC, α1-PI, C1q, E-cadherin, fibrin, fibrinogen, IL1β, ProTNFα, plasminogen,substance P, T-kininogen
MMP-10, Stromelysin 2	11q22.3–q23	Pre-Pro(SH)–Cat(Zn)-Hinge-Hemopexin(S-S)	Aggrecan, collagens III, IV, V, elastin, fibronectin, gelatin1, link protein, casein, fibrinogen
MMP-11, Stromelysin 3	22q11.2	Pre-Pro(SH)FurinSite-Cat(Zn)-Hinge-Hemopexin(S-S)	IGFBPs, α2-M, α1-PI
Matrilysins			
MMP-7, Matrilysin 1, pump-1	11q21–q22	Pre-Pro(SH)-Cat(Zn)	Aggrecan, collagens I, IV, decorin, elastin, entactin/nidogen, fibronectin, fibulins, gelatin1, laminin, link protein, myelin basic, osteonectin, tenascin, vitronectin, α1-PI, casein, E-cadherin, fibrinogen, Pro-α-defensin, Fas-ligand, Pro(TNF)-α
M**MP-26**, Matrilysin 2, endometase	11p15	Pre-Pro(SH)-Cat(Zn)	Collagen IV, fibronectin, gelatin1, α1-PI, fibrinogen
Membrane-Type MMPs			
MMP-14, MT1-MMP	14q11–q12	Pre-Pro(SH)FurinSite-Cat(Zn)-Hinge-Homopexin(S-S)-TM-Cytoplasmic tail	Aggrecan, collagens I, II, III, elastin, entactin/nidogen, fibronectin, gelatin 1, laminin, vitronectin, α2-M, α1-PI, Factor XII, fibrin, fibrinogen, ProMMP2, ProTNFα
MMP-15, MT2-MMP	15q13–q21	Pre-Pro(SH)FurinSite-Cat(Zn)-Hinge-Homopexin(S-S)-TM-Cytoplasmic tail	
MMP-16, MT3-MMP	8q21	Pre-Pro(SH)FurinSite-Cat(Zn)-Hinge-Homopexin(S-S)-TM-Cytoplasmic tail	Collagen III, fibronectin, ProMMP2
MMP-17, MT4-MMP	12q24.3	Pre-Pro(SH)FurinSite-Cat(Zn)-Hinge-Homopexin(S-S)-GPI anchor	
MMP-24, MT-MMP	20q11.2	Pre-Pro(SH)FurinSite-Cat(Zn)-Hinge-Homopexin(S-S)-TM-Cytoplasmic tail	
MMP-25, MT6-MMP	16p13.3	Pre-Pro(SH)FurinSite-Cat(Zn)-Hinge-Homopexin(S-S)-GPI anchor	

Table I Continued

Enzyme	GENE	Domains	Substrate
Others			
MMP-12, macrophage metalloelastase	11q22.2–q22.3	Pre-Pro(SH)–Cat(Zn)-Hinge-Hemopexin	Aggrecan, collagens I, IV, decorin, elastin, entactin/nidogen, fibronectin, gelatin 1, laminin, myelin basic, tenascin, α2-M, α1-PI, Factor XII, fibrinogen ProTNFα, ProTNFβ, plasminogen
MMP-19, RASI-1	12q14	Pre-Pro(SH)–Cat(Zn)-Hinge-Hemopexin	Collagens I, IV, fibronectin, gelatin 1, tenascin, casein
MMP-20, enamelysin	11q22.3	Pre-Pro(SH)–Cat(Zn)-Hinge-Hemopexin	amelogenin
MMP-23, cysteine array MMP (CA-MMP)	1p36.3	Pre-Pro(SH)-FurinSite-Cat(Zn)-Cys-rich-Ig-like	
MMP-27, CMMP	11q24	Pre-Pro(SH)–Cat(Zn)-Hinge-Hemopexin	
MMP-28, epilysin	17q21.1	Pre-Pro(SH)FurinSite-Cat(Zn)-Hinge-Hemopexin(S-S)	

Enzymes MMP-22 from chicken, MMP-18 and MMP-21 from Xenopus have been omitted.

Abbreviations: Pre, preprodomain, signal peptide; Pro(SH), prodomain with a zinc-ligating thiol (SH) group; FurinSite, specific sequence susceptible for furin cleavage located within Prodomain; Cat(Zn), catalytic domain with active zinc; 3xFnII, three Fibronectin-like domains inserted into a catalytic domain; Hinge, hinge region, linker polypetide; Homopexin(S-S), hemopexin domain with four propeller domains and a disulfide bridge between the first and fourth domain; TM, transmembrane region of protein; C, cytoplasmic tail, intracellular region of MMp expressed on the cell surface; GPI, glycophosphatidyl inositol anchoring domain; Cys-rich, cystein and proline rich domain; Ig-like, immunoglobulin like domain. This table is based on [2, 4].

cleavage. During post-translational processing, these enzymes recognize and cleave within this sequence, thus activating MT-MMPs. Once transported through the Golgi network, activated MT-MMPs remain as surface enzymes at the cell membrane. Internalization of the enzyme can occur within 60 minutes after initial cell membrane exposure. This might represent a rapid response for relocalizing active MT1-MMP at the leading edge of the cell during migration.

Active MMPs and MT-MMPs degrade several components of ECM molecules. Their targets include other proteinases, proteinase inhibitors, clotting factors, chemotactic molecules, latent growth factors, growth factor–binding proteins, cell surface receptors, and cell–cell adhesion molecules. In addition, they may act via cell receptors, as for instance α2β1 integrin, thus affecting cell survival. Hence, the mechanisms of in vivo activation and inhibition of proMMPs are of high physiological importance. It was suggested that activation may take place on the external cell surface, where plasma plasminogen, together with its uPA/uPAR complex, is converted into plasmin, and plasmin then removes part of the propeptide of a freshly secreted MMP zymogen. Membrane-type MMP also plays a role in MMP activation by cleaving the rest of the propeptide. There is some evidence that this process is mediated by a specific MMP inhibitor (TIMP) that has high affinity to both the MT-MMP and MMP zymogen, keeping the complex docked on the cell surface. The adjacent MT-MMP, which is not occupied by a TIMP, then partially cleaves MMP zymogen, which in turn can auto-activate to the fully active form. Recently, a new activating agent was revealed that offers an additional control of MMP function called the SIBLINGS proteins. Also, it was found that blood proteins involved in coagulation/fibrinolysis cascade, such as Activated Protein C, can directly activate MMPs.

Specific Inhibitors of Metalloproteinases: TIMPs

MMPs can be inhibited by α-2 macroglobulin, a general proteinase inhibitor of very broad spectrum, by inhibitors of complexed progelatinase and TIMP, and by TIMPs themselves. Tissue inhibitors of metallo-proteinases (TIMPs), the key inhibitors of MMPs in vivo, have four members (TIMPs 1 to 4) that share 41 percent to 54 percent sequence identity. They are small proteins with molecular weight that ranges between 27-kDa and 29-kDa. Each TIMP is built with one polypeptide chain that folds into two domains: N-terminal domain (about 125 aa) and C-terminal domain (about 65 aa). The interaction between TIMP and MMP or MT-MMP occurs via the binding of its four N-terminal residues to the catalytic cleft in MMP, one of them being the inhibitory cysteine. Additionally, the C-terminal region of TIMP binds with high affinity to the C-terminal part of MMP, thus interfering, which intensifies the interaction so much that the complexes are stable even in 0.1 percent SDS. The stoichiometry of complexes is 1 : 1.

The role of TIMP in the activation and inhibition of MMP seems to be dual. Experimental data show that low or moderate levels of TIMP2 promote activation of MMP2 in breast tumor cells, whereas higher levels inhibit it. These contrasting findings may be explained by the fact that high levels of TIMP saturate MT-MMP, thus blocking its ability

to activate proMMP. It was found that TIMPs additionally have some cell–growth–promoting or cell growth–inhibiting activities. Molecules of TIMP were found in nuclei of fibroblasts and breast carcinoma cells. By analogy to their interaction with MMPs, their role in other physiological or pathophysiological processes can also be dual [6].

Because overactive MMPs are associated with many pathological states, the equilibrium between active enzymes and their inhibitors plays a crucial role in maintaining the proper level of metalloproteinase activity.

MMP Genes and Regulation of Expression

Genes coding MMPs were localized on chromosomes 11, 14, 16, 20, and 22. Genes coding several secreted, soluble proteases form clusters. For instance, the long arm of chromosome 11 harbors sequentially (oriented from the most centromeric to the most telomeric regions) genes coding for MMP-8, MMP-10, MMP-1, MMP-12, MMP-7, and MMP-13. In contrast, the genes coding for membrane-type MMPs were localized on different chromosomes; MMP14 (MT1-MMP) maps to human chromosome 14, MMP15 (MT-2-MMP) to human chromosome 16, and MMP16 (MT-3-MMP) to human chromosome 8.

A paradigm of MMP gene structure and organization is the MMP-12 (human macrophage elastase) gene. It is similar to the genes of stromelysins and collagenases because it has the same location to chromosome 11q22.2–22.3 and similar, highly conserved exon size and intron–exon borders. It is 13-kilobase (kb) long, composed of 10 exons and 9 introns. It was determined that MMP-12 (macrophage elastase) and MMP-3 (stromelysin 1) genes are physically linked within the 62-kb region. The promoter region of the MMP-12 gene contains several features common to other MMP genes, including a TATA box 29 nucleotides upstream to the transcription initiation site, an AP-1 motif located about −70 kb upstream, and a PEA3 element. The PEA3 is a conserved Polyoma Enhancer A binding protein site, and the AP-1 is an Activation Protein 1 binding element. Both are regions of DNA that bind directly to these transcription factors. Other regulatory elements within different MMP genes include GC-Sp-1 binding site, SBE-SIAT binding element, c/EBP-β-CCATT/enhancer binding protein β, OSE-2 (osteoblast specific element-2), SPRE (stromelysin-1 PDGF responsive element), TRE (octamer binding protein), Sil (silencer sequence), NF-kβ (nuclear factor kβ), NF-1 (nuclear factor-1), and RARE (retinoic acid responsive element). Some of these sites overlap. For instance, the phorbol ester-responsive element is located within the AP-1 binding region.

Under normal conditions, the level of MMPs is rather low and increases with the need for ECM remodeling. Thus, the MMP genes are susceptible to external induction, which occurs with participation of the regulatory elements listed above. Regulation at the translational level may occur via modulation of mRNA or via second messenger signaling.

The agents affecting gene expression are inflammatory cytokines, growth factors, hormones, phorbol esters, oxidant stress, and mechanical injury or aging. They act through the whole variety of intracellular signaling pathways, including mitogen-activated protein kinases. These pathways may cross-react with each other, resulting in a broad spectrum of intermediating proteins (enhancers, co-regulators, or inhibitors) that in turn form complexes with transcription factors. These complexes eventually bind to AP-1 or other regulatory elements in the promoter region of the MMP gene.

A good example of the level of complexity is transforming growth factor (TGF)-β. TGF-β is a potent regulator of many genes that carry AP-1 motifs in their promoters. It generally induces expression of MMP inhibitors (TIMPs) and expression of genes coding for ECM proteins that are substrates for MMPs, but suppresses synthesis of MMPs 1, 3, and 9. For its suppressive activity, TGF-β binds to its transmembrane receptor and activates the cascade of phosphorylation of Smad family proteins. These proteins can then be translocated to the nucleus, where they bind to a TGF-β inhibitory element (TIE). This is a sequence: 5′-GAATTGGAGA-3′, located 245 bp upstream of the transcription site and upstream of the AP-1 site in the MMP-1 promoter. TIE is considered to be a constitutive repressor of the MMPs. In carcinoma cells, TGF-β has an opposite effect, in that by acting through a protein kinase C and tyrosine kinase signaling pathways, it enhances expression and synthesis of MMP-13 [7, 8].

Angiogenesis

MMPs play critical roles in different areas related to vascular biology, particularly angiogenesis, which involves intimate interaction between the vascular cells and their surrounding matrix. MMP-mediated remodeling with degradation of ECM components by proteolytic cleavage rearranges or removes mechanical barriers, thus allowing cell migration and cell growth. Because of the presence of MMPs in virtually any tissue and because of activity directed to a broad spectrum of substrates, MMPs play a crucial role in embryonic development and organogenesis. For review, see recent publications [9].

Vascularization, de novo vessel formation, begins when fibroblast growth factor isoforms produced by endodermal cells induce paraxial and lateral plate mesoderm to form angioblasts and hematopoietic cells. Cells differentiated into angioblasts can either remain at a specific site of origin or migrate to distant locations to form a regional vascular plexus. Within the plexus, endothelial cells proliferate and form capillaries, which may foster further vessel formation, known as angiogenesis. These processes are regulated on several levels, one of which is the endothelial receptors tyrosine kinase TIE-2 and TIE-1 and interactions of vascular endothelial growth factors with their receptors VEGF-R2 and VEGF-R1 located on the cell surface. It is believed that

the VEGF-R2 receptor mediates early-stage endothelial cell differentiation, whereas VEGF-R1 is responsible for formation of lumen in newly created capillaries. Knock-out animals lacking either of these factors died in embryonal stage from abnormal vascularization.

Angiogenesis consists of formation of new capillaries by two processes: one by splitting of a native vascular structure, also known as *intussusception*, and the other by sprouting. Splitting requires the proliferation of endothelial cells inside the existing vessels. This process can be induced either by formation of transcapillary pillars (folding capillary walls) that eventually tear the native vessels or by direct action of proteases that degrade the wall enzymatically. In the site of injury, a new vessel can be formed.

Sprouting occurs when endothelial cells from the original cluster migrate through the basement membrane of the vessel wall, invade the surrounding tissue, anchor in a new place, and proliferate. In both instances, before any move, endothelial cells release proteases that remodel ECM, thus facilitating translocation of cells from the parent venule. Lack of synthesis or inhibition of collagen-degrading enzyme prevents new vessel formation. Indeed, mice deficient in MMP-2 (gelatinase A, degrades collagen) had reduced retinal angiogenesis.

It has been recently proposed that postnatal vasculogenesis originates from endothelial progenitor cells differentiated from bone marrow stem or precursor cells. Angioblasts were found in and isolated from the peripheral blood of adult species, and the series of transplantation experiments revealed that they maintained specific endothelial cell features and were eventually incorporated into foci of neovascularization. Matrix metalloproteinase-9 (MMP-9, gelatinase B), induced in bone marrow cells, mediated the transfer of endothelial and hematopoietic stem cells from the quiescent to proliferative niche by releasing soluble Kit-ligand, a specific signal that induced stem cells to differentiate and mobilize to circulation [10].

Although the nature of the triggering signal in the angiogenic sprouting remains unknown, it is known that angiogenic stimuli, such as fibroblast growth factor (FGF), vascular endothelial cell growth factor (VEGF), or vascular permeability factor (VPF), are the most potent inducers of MMP synthesis in endothelial cells. Additionally to growth factors and cytokines, modifying action of other molecules has been reported. These molecules are side products or intermediates of proteolytic cleavage of ECM proteins (matrikines), and cryptic segments within larger proteins revealed by conformational changes or partial hydrolysis (matricryptins). Among this group of mediators of angiogenesis, some are worth mentioning: angiostatin and kringle 5 (proteolytic fragments of plasminogen), endostatin and restin (proteolytic fragments of collagen XVIII an XV), the 16 kDa N-terminal fragment of prolactin, an N-terminally truncated platelet factor 4 (PF4), vasostatin originating from calreticulin, kininostatin corresponding to the high-molecular-weight kininogen domain 5, the cleaved form of the serpin antithrombin (AT), a noncatalytic carboxy-terminal hemopexin-like domain of MMP-2 (also known as PEX), several noncollagenous domains from type IV collagen, thrombospondins, secreted protein acidic rich in cysteine (SPARC), and anastellin corresponding to the first type III repeat in fibronectin [11].

Under physiological conditions, new vessel formation is a process triggered by signals from neighbor cells or ECM, balanced by MMP synthesis, activation and inactivation mechanisms, and modulated by tissues or blood flow or blood products, depending on or benefiting from a well-maintained circulatory system. The lack of appropriate inhibition at any level results in excessive expression or overactivity of the MMPs and causes pathological states. The most severe pathological states are tumors, cancer, arthritis, atherosclerosis, nephritis, tissue ulcers, and fibrosis. For instance, there is evidence that MMP-2 is involved in the switch to the angiogenic phenotype, one of the earliest events during the transition of a tumor from the preneoplastic to the tumorigenic phenotype.

MMPs and Pulmonary Vascular Diseases

MMPs have been extensively involved in pulmonary diseases, including interstitial lung disease, emphysema, asthma, and in the context of this review, pulmonary hypertension. Pulmonary hypertension concerns the elevation of pulmonary artery pressures above 25 mmHg mean pulmonary artery pressures. Pulmonary hypertension may occur as an idiopathic disease, known historically as primary pulmonary hypertension (or, currently, as idiopathic pulmonary hypertension), or associated with underlying clinical conditions such as congenital heart malformations with left-to-right shunting, collagen vascular diseases, HIV infection, liver diseases, interstitial lung processes, or chronic obstructive pulmonary disease. Clinically, pulmonary hypertension can be divided as mild to moderate, when the pulmonary artery pressures rise to levels not more than 40 to 45 mmHg, and severe, if the pressures are equivalent to those in the systemic circulation. The severe forms of pulmonary hypertension ultimately kill as a result of right heart failure. The underlying morphological basis of pulmonary hypertension is an alteration in the number or size of medial, smooth muscle cells (hyperplasia or hypertrophy, respectively), and in growth of myofibroblasts into the intima. In a selected group of patients with severe disease, endothelial cells undergo growth, forming plexiform lesions. In aggregate, these cellular alterations are known as *pulmonary vascular remodeling*.

Degradation of components of ECM releases matrix-bound growth factors or creates fragments originated from degraded matrix proteins, resulting in biologically active mediators. The integrated action of these growth factors or active protein fragments may induce vascular cell growth and vascular remodeling. Increased elastolytic activity in pulmonary arteries was postulated as a potential mechanism leading to pulmonary vascular remodeling. Experimental

pulmonary hypertension caused by monocrotaline, an alkaloid that causes pulmonary artery endothelial cell injury and pulmonary hypertension, was associated with enhanced elastolytic activity. Similar observations were then extended to the chronic hypoxia model of pulmonary hypertension. The mediator of this elastolytic activity appeared to be a serine protease called endogenous vascular elastase, and if blocked with an elastase inhibitor, pulmonary hypertension was prevented [12].

The interaction between the action of the vascular elastase and MMPs was further dissected in studies employing pulmonary arteries of pulmonary hypertensive lungs caused by monocrotaline, grown in organ cultures. These explants demonstrated increased gelatinase activity (mostly MMP2), which could be blocked by treatment with the broad-spectrum MMP inhibitor GM6001. GM6001 also inhibited tenascin (a growth factor for smooth muscle cells) expression, increased vascular cell apoptosis, decreased cell proliferation, and finally, caused a reduction of medial thickness [12]. This line of work agrees with other hypotheses. It is proposed that, during chronic hypoxia, pulmonary arteries undergo cycles of extracellular collagen synthesis and degradation, ultimately contributing to pulmonary vascular remodeling. Pulmonary vascular oxidative stress with formation of peroxynitrite can induce MMP activation, such as of MMP-1, -2, -8, and -9. There is evidence of oxidative stress in experimental hypoxic pulmonary hypertension and in pulmonary arteries of patients with idiopathic pulmonary hypertension [13]. Also, there is evidence that chronic hypoxia activates MMP-2 and MMP-13, which might degrade elastin and fibrillar collagen, respectively. The corollary of this paradigm is the protection against pulmonary hypertension and pulmonary vascular remodeling afforded by the MMP inhibitor Batismat. In summary, these data ascribe a pathogenetic role for serine proteases and MMPs in the process of pulmonary vascular remodeling, which is most pertinent to the monocrotaline model of pulmonary hypertension.

However, other investigations revealed a diametrically opposite function for MMPs in pulmonary vascular remodeling associated with pulmonary hypertension. Armed with the rationale that regression of pulmonary vascular remodeling requires proteolytic processing of the ECM in pulmonary arteries, Vieillard-Baron et al. demonstrated that TIMP-1 inhibition of MMPs worsened hypoxia-induced pulmonary hypertension. It is difficult to pinpoint the cause of this discrepancy with regard to the pathobiological importance of matrix proteases in pulmonary vascular remodeling, but it is conceivable that TIMP-1 may have an unforeseen effect on pulmonary vascular remodeling that is independent of its MMP-inhibitory effect.

Conclusion

MMPs and matrix proteases are critical effectors of cell responses. This function is ever more pertinent to dynamic states in which cells have to interact with their surrounding matrix to perform physiologic functions, or in disease states. Blood vessels undergo dynamic changes of their component cells to adapt to stresses or maladapt and cause disease. MMPs are intimately involved in these processes, but as apparent with the data presented herein, manipulation of MMP activity to modify the course of diseases may lead to adverse and unforeseen consequences.

Glossary

Metalloproteases: Protein molecules (enzymes) that require the presence of metal ion bound to their sequence to maintain a proper structure that allows their functional activity. The main function of metalloproteases is to activate or to inactivate (inhibit) other proteins (substrates), usually by cutting off one or more of their fragments.

Multidomain structure: Domains are regions in a protein molecule that are determined by amino-acid sequence and that form defined, functionally distinct units. Thus, multidomain structure is specific for and characterizes a particular protein. If several proteins have similar multidomain structure, it means these proteins may also have similar functions.

His interests are focused on pulmonary pathology and molecular mechanisms responsible for pulmonary diseases. His grants are supported by the NIH/NHLBI, AHA, and other foundations.

Dr. Iwona Fijalkowska is a Research Associate in Cardiopulmonary Pathology in the Department of Pathology, Johns Hopkins University School of Medicine. Her scientific interests cover protein chemistry and protein–protein interactions in angiogenesis and hemostasis.

CHAPTER 7

VEGF-A and Its Isoforms

Eric B. Finkelstein and Patricia A. D'Amore
Schepens Eye Research Institute, Harvard Medical School, Boston, Massachusetts

Vascular endothelial growth factor-A (VEGF) is one of the most important regulators of physiological and pathological angiogenesis, as demonstrated by genetic studies in which deletion of a single VEGF allele resulted in embryonic lethality caused by defective blood vessel formation. VEGF is an endothelial cell (EC) mitogen that serves as a mediator of angiogenesis and vessel permeability. As such, VEGF is essential for tumor growth and angiogenesis and is involved in ocular neovascularization characteristic of diabetic retinopathy and retinopathy of prematurity. VEGF belongs to a family of growth factors that includes VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placental growth factor (PlGF). This chapter focuses on isoforms of VEGF-A resulting from alternative splicing. Therefore, throughout the text, VEGF-A will be referred to as VEGF.

VEGF is active as a homodimer by binding two receptor tyrosine kinases: VEGF receptor-1 (VEGFR1; Flt-1) and VEGF receptor-2 (VEGFR2; Fkl-1; KDR). VEGFR2 is primarily associated with the mitogenic and angiogenic activities of VEGF, whereas VEGFR1 is thought to be a reservoir for VEGF in solution, thereby regulating its availability. VEGF activity is regulated on many levels, including transcriptionally by cytokines and oxygen tension, and by alternative splicing of the VEGF gene to produce multiple isoforms that differ in their bioavailability and bioactivity. Increasing evidence suggests that VEGF isoform levels may be a major mechanism by which VEGF activity can be regulated physiologically and pathologically.

VEGF Isoform Structure

The VEGF gene is comprised of eight exons separated by seven introns (Figure 1). Exons one through five and eight are common to all isoforms. The first five exons encode for domains involved in α-helical dimerization, a signal peptide cleaved following secretion (exons 1 and 2), and sites for VEGFR1 (exon 3) and VEGFR2 (exon 4) binding (Robinson and Stringer, 2001). VEGF is alternatively spliced to produce several isoforms that vary in amino acid number in all species studied to date (Table I). Variability among the isoforms results from the inclusion of exons six and/or seven (Figure 1).

The most abundant human isoform in most tissues is VEGF165, and as a result, the most is known about this isoform. There have been several studies of VEGF145 and VEGF121, but few have focused on VEGF189 or VEGF206 because of their low abundance and reported difficulties producing them in pure form. Many of the studies described in the following sections have utilized recombinant human VEGF121 or VEGF165, whereas studies of VEGF189 or VEGF206 have utilized in vitro–produced extracellular matrix (ECM), to which these isoforms are bound.

Several additional VEGF isoforms have been described, including murine VEGF115 (Robinson and Stringer, 2001), expressed in immortalized fibroblasts, with 37 novel carboxyl-terminal amino acids relative to VEGF120. Human VEGF183 uses an alternative splice donor site 18 nucleotides upstream of the common splice site between exons 6a and 6b, which results in six less amino acids than VEGF189 [1]. Other isoforms have been reported, including VEGF162 with angiogenic activity, VEGF165b that may negatively regulate VEGF165, and VEGF148 with unknown biological activity. The significance of these isoforms awaits further investigation.

VEGF and the ECM

Interactions with HSPG and the ECM

VEGF isoforms have variable affinities for heparan sulfate proteoglycans (HSPGs) on the cell surface and/or within the ECM (Robinson and Stringer, 2001). VEGF121 has lowest affinity, VEGF145 and VEGF165 have similar

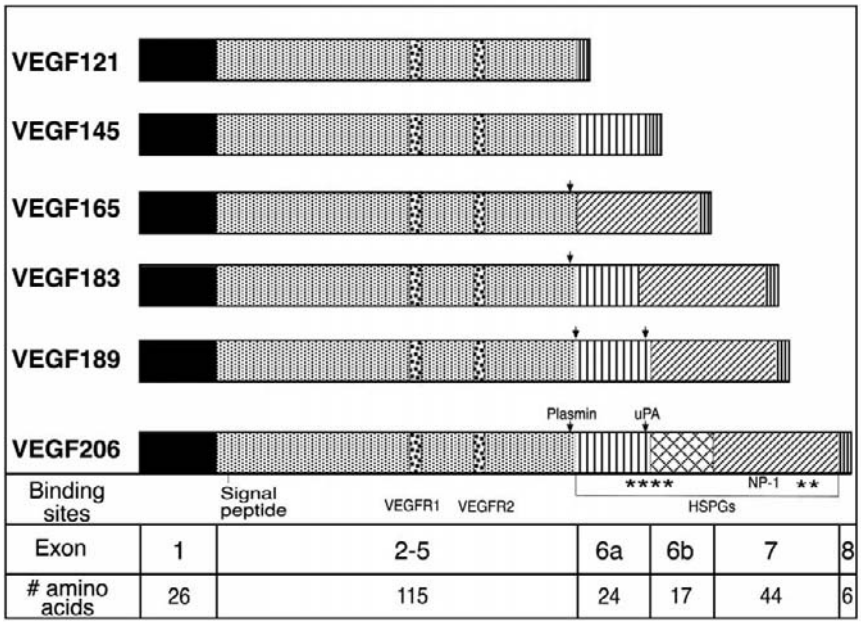

Figure 1 Isoforms of Human VEGF-A Generated by Alternative Splicing. Alternative splicing of human VEGF-A has been reported to generate several isoforms. These isoforms differ by the inclusion or exclusion of domains encoded by exons six and seven. The location of a signal peptide and VEGF receptor (VEGFR1 and VEGFR2) binding sites common to all isoforms are indicated on VEGF206. HSPG binding sites common to isoforms with exons six and seven are indicated (*), as is the neuropilin-1 binding site (NP-1). Finally, arrows indicate sites of potential proteolytic processing by either plasmin or uPA. The exons and number of amino acids in each exon is indicated at the bottom of the figure.

Table I VEGF Isoforms from Alternative Splicing in Species Studied to Date.

Species	VEGF-A Isoforms (number of amino acids)
Human	121, 145, 165, 183, 189, 206
Mouse	115, 120, 164, 188
Quail	122, 146, 166, 190
Rat	120, 164, 188
Bovine	120, 164

Table II Biochemical Properties of Human VEGF Isoforms.

Isoform	Exons	MW (kDa)	Acidic or basic	Heparin binding
121	1–5, 8	34	Weakly acidic	no
145	1–5, 6a, 8	41		yes
165	1–5, 7, 8	46	basic	yes
183	1–5, 6a*, 7, 8	46		yes
189	1–5, 6a, 7, 8	52	basic	yes
206	1–5, 6a, 6b, 7, 8	~60	basic	yes

Molecular weight (MW) based on the sum of monomer band sizes.
* indicates that exon 6a is truncated.

affinities, and VEGF189 and VEGF206 have the highest affinities for HSPG (and heparin in vitro) (Table II). The high affinity of VEGF189 and VEGF206 is a result of the presence of exons 6 and 7, which mediate binding to HSPGs (Figure 1). Exon 6a in VEGF145 mediates ECM binding independent of HSPGs because of a cell surface retention sequence. The affinity of a VEGF isoform for HSPGs is directly correlated with its diffusibility (Figure 2). As a result, the smallest isoform (VEGF121) is secreted and freely diffusible. Approximately 50 percent of intermediate-sized isoforms (VEGF145 and VEGF165) diffuse from producing cells (based on their presence in conditioned media), whereas the remainder are cell and/or ECM associated. Finally, the largest isoforms (VEGF189 and VEGF206) are secreted from producing cells but completely sequestered within the ECM with low amounts bound to the cell surface (Figure 2). Similar to VEGF189 and VEGF206, most of VEGF183 remains bound to the cell surface [1], suggesting it has a high affinity for HSPGs. Although most of the isoforms can bind HSPG and/or the cell surface, they can be released as soluble, biologically active molecules.

Release of VEGF from the ECM

Addition of heparin to cells stably expressing VEGF165 resulted in a two- to fourfold increase in the level of VEGF in conditioned media. Therefore, VEGF165 can be released from the cell surface and/or ECM by heparin. A similar

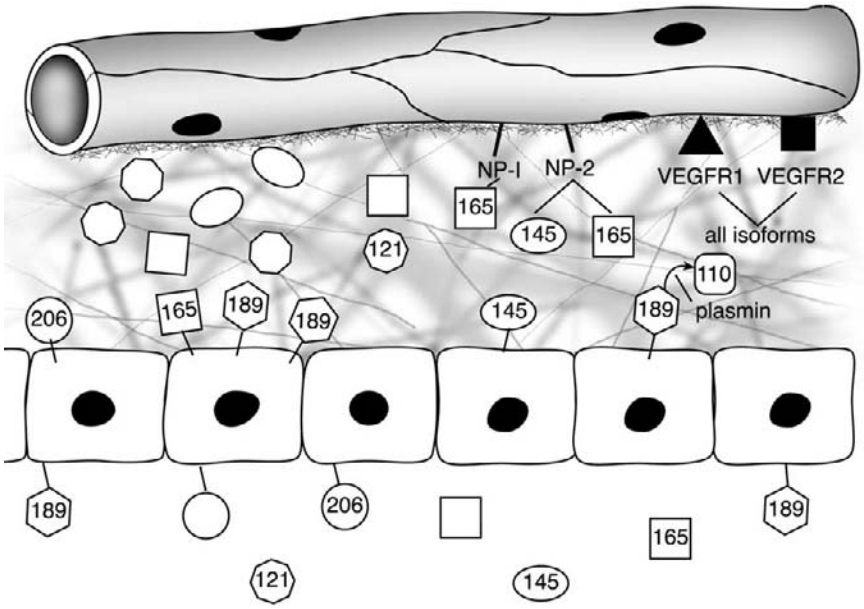

Figure 2 Diffusibility or Cell-Association of VEGF Isoforms. VEGF is depicted as being produced by an epithelial cell layer and diffusing towards endothelial cells, where it binds to the neuropilins (NP-1 or NP-2) or to VEGF receptors (VEGFR1 or VEGFR2). VEGF isoforms are diffusible to different degrees, with VEGF121 completely diffusible, while VEGF189 (or VEGF183) and VEGF206 remain bound to the cell surface and/or within the extracellular matrix. VEGF189 (and 206) can be cleaved by plasmin to generate a diffusible form, VEGF110.

effect was observed for heparinase. All VEGF isoforms within the ECM or on the cell surface can be rapidly released by proteolytic cleavage with plasmin, a serine protease (Robinson and Stringer, 2001). Plasmin cleavage produces a 110 amino acid (aa) fragment (Figure 2) that can bind VEGFR2 but not heparin. This 110 aa fragment is active as an EC mitogen and vascular permeability factor similar to VEGF121, with activity reduced fiftyfold relative to VEGF165. Plasmin cleavage results in a second smaller, heparin-binding fragment without mitogenic activity because the VEGF receptor-binding domains are absent. Thus, the carboxyl-terminal heparin-binding domains of VEGF are essential for full mitogenic activity, as their deletion by proteolytic cleavage or alternative splicing significantly reduces activity. VEGF189 and perhaps VEGF183 and VEGF206 are also processed by the serine protease urokinase type plasminogen activator (uPA) near the carboxyl terminus of the domain encoded by exon six. This results in a truncated VEGF (uPA-VEGF189) with activity similar to native VEGF165. These processing steps are required for mitogenic activity and binding toVEGFR2, but not for binding to VEGFR1.

VEGF–Receptor Interactions

In addition to modulating isoform bioavailability, heparin can alter bioactivity through the VEGF receptors. Low concentrations of heparin can enhance binding of VEGF165 to VEGFR2, while high concentrations of heparin can inhibit this interaction. Binding of VEGF121 to VEGFR2 is unaffected by heparin. Heparin can inhibit interactions of VEGF121 and VEGF165 with VEGFR1, suggesting that HSPGs are necessary for VEGFR1 activity. In addition to heparin, exon seven of VEGF binds a class of receptors, known as neuropilins (Figure 1; neuropilin-1: NP-1; neuropilin-2: NP-2). NP-1 binds VEGF165 but not VEGF121, and is thought to serve as a VEGF coreceptor to potentiate signaling through VEGFR2. As such, NP-1 has a lower affinity for VEGF than VEGFR2. In support of the coreceptor concept, a peptide corresponding to exon seven can inhibit VEGF165 activity by approximately 60 percent (to a level similar to VEGF121) likely by blocking VEGF–NP-1 interactions [2]. NP-2 binds VEGF165 and VEGF145 and can mediate VEGF145 signaling.

Isoform Expression

In human tissues, VEGF121, VEGF165, and VEGF183 are expressed in virtually all cell types examined, with the notable exception of EC. VEGF145 is restricted to cell lines derived from female reproductive tract carcinomas and the placenta, and VEGF206, originally isolated from a fetal liver cDNA library, has been found in the placenta.

Investigation of VEGF isoform expression during murine development suggested that the isoforms are developmentally regulated. Quantitative analysis of isoform expression in developing and adult murine tissues revealed that while all VEGF isoforms are expressed in embryonic mouse

organs, the relative levels of each isoform varied from organ to organ over developmental time [3]. In the developing lung, heart, and liver, VEGF188 levels increased from embryonic day 13 to day 18 to account for more than 50 percent of the total VEGF mRNA, and remained high in the adult. In contrast, there were only slight increases in VEGF120 and VEGF164. Little VEGF188 was expressed in the developing or adult brain, with no change detected. In adult organs, lung had the highest relative level of VEGF188, while eye, small intestine, and ovary had the lowest VEGF188 level. VEGF164 was predominant in brain, muscle, eye, and kidney. Finally, VEGF120 was highest in uterus, skin, and ovary [3]. Differences in expression levels of VEGF isoforms in developing and adult organs are an indication that the isoforms have specific functions during developmental and adult angiogenesis.

Isoform Function

In Vitro Bioactivity

All VEGF isoforms, including the cell-associated forms, are active as EC mitogens by signaling through VEGFR2. Recombinant VEGF189 and VEGF206 are unable to stimulate endothelial cell mitogenesis, because of protein folding that masks regions necessary for receptor binding. However, ECM derived from cells expressing VEGF189 or VEGF206 induces EC to proliferate, demonstrating that VEGF trapped in the ECM is an active mitogen.

In Vivo Bioactivity: Developmental

The first definitive demonstration that the various VEGF isoforms serve distinct functions in vivo was provided by analysis of mice that were engineered to express single VEGF isoforms [4]. Earlier analysis of VEGF isoform expression in adult tissues indicated that heart and lung expressed the highest levels of VEGF188. Consistent with this observation, mice that express only the soluble VEGF120 are born at a reduced frequency (indicating embryonic lethality), and those that develop to term die rapidly after birth as a result of defective pulmonary and/or cardiac development. Analysis of vessel density in a limited number of mice that lived up to two weeks revealed that whereas vessel density in wild-type mice increased threefold within a week following birth, there was no increase in vessel density in VEGF 120/120 over the same time frame. These results demonstrate that the isoforms are in fact functionally distinct. In particular, these data illustrate that VEGF120 is not able to substitute for the missing VEGF188. Although the mechanistic explanation for the resulting developmental abnormalities has not been elucidated, it is appealing to speculate that expression of an isoform that is entirely soluble (i.e., has no capacity to bind to matrix) may be ineffective in establishing a gradient that is necessary to induce postnatal angiogenesis.

Pulmonary development was also markedly defective in VEGF120/120 mice. These mice have delayed airspace development, and quantitation of air–blood barriers revealed that the 120/120 mice not only had as few as 30 percent of the air–blood barriers as their wild-type littermates, but that the architecture of barrier structures was abnormal. Whereas in the normal air–blood interface the pulmonary epithelium is closely apposed to the capillary endothelium, the pulmonary capillaries in the VEGF120/120 mice were separated from the alveolar lumens by up to three cell layers. Interestingly, the heterozygous (120/+) mice display intermediate phenotypes.

Although these observations indicate distinct functions for the individual isoforms, they do not clarify the mechanisms whereby these different functions are mediated. Some insight into the possible means by which the isoforms act is provided by localization studies. VEGF isoform production in the lung appears to be developmentally regulated [3], with VEGF188 levels relatively low until it dramatically increases at around embryonic day 16, the late canalicular and late saccular phases of lung development, when alveolar structures are forming. In addition to the temporal correlation between VEGF synthesis and pulmonary capillary formation, there is a clear spatial correlation. In situ hybridization has shown that VEGF is produced specifically by the type 2 pneumocytes, cells intimately associated with the forming vasculature. These findings strongly indicate that the intimate association between the source of the VEGF and the target cells directs the formation of the blood–air barrier. Furthermore, the fact that a majority of the VEGF produced by the pulmonary epithelium is VEGF188, an isoform that is not freely diffusible but remains locally sequestered, adds further strength to this hypothesis of the paracrine regulation of alveolar formation.

Abnormalities in the formation of other tissues and organs have been described in the isoform-specific mice. Retinal vascularization in mice that express only VEGF120 is severely impaired; there is a dramatic reduction in the formation of the primitive vascular network, reduced remodeling, and a persistence of the hyaloid vasculature [5]. Mice expressing only VEGF188 also exhibit abnormal retinal vascularization. Although the primitive vessel plexus is normal at postnatal day 3 (P3), vessel number is reduced by half only two days later (P5), with ephrin staining indicating a loss of the arterial component. As for the VEGF120 mice, a persistent hyaloid vasculature appears to migrate into the retina by P9, perhaps compensating for the regression of the arteries. More recent investigations into the relative contribution of VEGF isoforms to pathologic retinal neovascularization have revealed that retinal vessel development is normal in VEGF120/188 (VEGF164-deficient) mice [6].

The relative contribution of the various VEGF isoforms to skeletogenesis has also been investigated. Analysis of mice expressing only VEGF120 leads to the suggestion that VEGF is involved in at least three aspects of bone formation, including vessel ingrowth into the perichondrium and primary ossification center, stimulation of vessel growth and

osteoclast migration into hypertrophic cartilage, and induction of osteoblast activity in both intramembranous and endochondronal bones [7].

Thus, VEGF isoforms appear to play critical and rate-limiting roles in the formation of a wide range of tissues and organs. The continued, tissue-specific expression of VEGF isoforms in adult organs [3] suggests that these functions may persist in mature organs and tissues.

In Vivo Bioactivity: Pathologic Models

To date, there have been few comparative studies on the function of VEGF isoforms, but differences clearly exist. Overexpression of VEGF121 and VEGF165 in a brain tumor model led to rapid vessel growth and breakdown (hemorrhage) around tumors, whereas VEGF189 overexpression led to tumors with a similar extent of vascularization as the other isoforms, but no hemorrhage [8].

Tumor cell lines expressing a single mouse VEGF isoform have been used to study the role of the isoforms during tumorigenesis [9]. VEGF-null fibroblasts were immortalized by transfection with SV40 large T antigen and transformed by infection with *H-ras*. The fibroblasts were then infected with plasmids encoding individual VEGF isoforms under control of the CMV promoter and used to generate fibrosarcomas in mice. Relative to VEGF-null cells that formed small, poorly vascularized tumors, VEGF164-expressing transformed fibroblasts completely rescued tumor growth, VEGF188 failed to rescue tumor growth, and VEGF120 had a partial effect. However, although VEGF188 did not rescue tumor growth, tumors were more vascularized compared to VEGF120 tumors [9]. The authors proposed a model in which the isoforms act cooperatively during tumor vascularization with soluble forms acting at a distance to promote blood vessel recruitment, while ECM-bound forms act locally to expand the capillary bed within the tumor [9].

These results and others suggest that VEGF-A isoforms have different abilities to induce vascularization, tumor growth, and blood vessel leakiness in multiple models. However, all models to date have utilized overexpression systems with VEGF under the control of nonphysiological promoters such as the CMV promoter. Therefore, although these results strongly indicate differential functions for VEGF isoforms, the absence of endogeneous VEGF regulatory elements makes the data difficult to extrapolate. Development of models in which VEGF is under the control of its endogeneous regulatory elements would greatly enhance our understanding of the contribution of VEGF isoforms to vascularization during developmental and pathological processes.

Overexpression is not an issue in studies that have utilized mice that express single VEGF isoforms. A second set of pathologies in which VEGF isoform function has been studied is ocular neovascularization, including diabetic retinopathy and retinopathy of prematurity, two leading causes of blindness in which ischemia leads to aberrant retinal blood vessel proliferation. One study utilized mice that express single VEGF isoforms (see above). VEGF164 is derived from leukocytes, is more proinflammatory than VEGF120, and is preferentially induced during ocular neovascularization [6]. Using a mouse model of retinopathy of prematurity, it was found that administration of a VEGF164-specific neutralizing reagent (aptamer) blocks leukocyte adhesion and pathologic neovascularization, with no effect on retinal revascularization or physiological (developmental) neovascularization [6]. When all VEGF isoforms were blocked, revascularization and physiological neovascularization were also affected. In mice with only VEGF120 and VEGF188 (VEGF164-deficient), retinal development was normal, similar to the aptamer results, suggesting that VEGF164 has a primary role in pathologic but not developmental vessel growth [6]. These data suggest that VEGF164 is essential for pathological retinal neovascularization, but not physiological revascularization, which can progress under the influence of only VEGF120 and VEGF188. Thus, in this ocular angiogenesis model, an inhibitor specific for VEGF164 has been developed, which eliminates the features of pathological neovascularization (i.e. leukocyte adhesion, vascular tufts) while allowing the ischemic retina to become revascularized normally.

Conclusion

It is clear that the VEGF isoforms differ in their biochemical properties. Analysis of several model systems has demonstrated that individual isoforms can differentially affect both developmental and pathological angiogenesis. Further work is necessary to elucidate the precise roles of each isoform. Such work may eventually make it possible to specifically target individual isoforms during pathological angiogenesis.

Glossary

CMV: Cytomegalovirus promoter, a ubiquitous, strong promoter often used in overexpression studies.

Exons: The coding sequences of genes. In mammalian cells, exons within genes are interrupted by introns, which are noncoding sequences.

HSPGs: Heparin sulfate proteoglycans.

Ischemia: A condition in which tissues become oxygen deficient as a result of several pathological conditions. As a result, the tissue is relatively hypoxic, leading to upregulation of the VEGF gene.

Isoforms: Different forms of a protein, derived from a single gene that result from alternative splicing.

Capsule Biographies

Patricia A. D'Amore received her Ph.D. from Boston University and completed a postdoctoral fellowship at Johns Hopkins Medical School. She is currently Professor of Ophthalmology and Pathology at Harvard Medical School, a Research Associate at Children's Hospital, and a Senior Scientist at the Schepens Eye Research Institute in Boston.

Eric B. Finkelstein earned his Ph.D. in 2001 at the SUNY Upstate Medical University in Syracuse, New York, working in Dr. Thomas J. Poole's laboratory on the role of VEGF in blood vessel morphogenesis. He is currently a postdoctoral fellow in Dr. D'Amore's laboratory in Boston, studying endothelial cell differentiation and the function of VEGF isoforms.

CHAPTER 8

Ephrins and the Unveiling of Distinct Arterial and Venous Microcirculations

Jeffrey M. Gelfand and Guillermo García-Cardeña

Center for Excellence in Vascular Biology, Departments of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts

Introduction

When William Harvey boldly challenged centuries of medical orthodoxy in 1628 by proclaiming that blood circulated throughout the body, he still had trouble explaining one critical concept: how arteries actually connected to veins. For with no way to magnify the vessels, all the great experimenter could conjure up was the old idea that there must be some sort of vascular pores arterial blood seeped through [1]. The Italian anatomist, Marcello Malpighi, was therefore quite surprised just 30 years later when he trained the lens of his new-found microscope onto the fine vascular architecture of a frog's lung and found not pores, as he had expected, but rather an entirely new class of veritable microvessels—which became known as "capillaries"—as the definitive connection shuttling blood between arteries and veins [2].

For more than 300 years, scientists have understood capillaries to be just as Malpighi described them that day in Bologna—as a third class of blood vessels distinct in form and function from their arterial and venous counterparts. However, recent research on a novel class of cell-signaling molecules known as ephrins, some of which reliably mark either arteries or veins on a molecular level, suggests that this traditional view of capillaries may no longer be sufficient, as capillary vessels seem to exhibit clear arterial-venous identities of their own. These identities are defined by the differential expression of members of the Ephrin-B family down to the level of the smallest microvessels, demonstrating that the microvasculature, far from just being a homogenous collection of nonarterial, nonvenous capillaries linking arterioles to venules, consists rather of two discrete arterial and venous continuums: the *arterial microcirculation* and the *venous microcirculation*. These new observations of arterial and venous microcirculatory identities likely reflect previously uncharacterized genetic, morphologic, and functional differences within the microvasculature, and should provide a novel conceptual framework for the study of vascular biology and the treatment of angiogenesis-dependent disease.

Cell Signaling via Ephrins and Eph Receptors

The ephrins, and their Eph receptors, are a novel class of proteins that enable cells to send signals to one another. Although long known to be key mediators in brain formation, ephrin signaling is also essential for the proper development of new blood vessels. Because some subsets of these important signaling molecules exhibit the additional property of localizing exclusively either to arteries or veins, ephrins have also begun to serve as the first reliable molecular marker capable of distinguishing arterial from venous identity.

In 1987 researchers working with *e*rythropoietin-*p*roducing *h*epatocellular carcinoma cells happened to discover a new kind of tyrosine kinase receptor, which they accordingly named the *Eph* receptor [3]. With 15 subtypes subsequently identified (EphA1–9 and EphB1–6), Eph receptors now constitute the largest family of tyrosine kinase receptors in vertebrates [4]. Tyrosine kinase receptors participate broadly in many pathways controlling cell

growth and differentiation. Unlike traditional tyrosine kinases, however, where soluble hormones and growth factors travel as ligands from cells much farther away, ephrin ligands are bound to the cell surface and can activate Eph receptors on neighboring cells only when their mutual cell membranes draw close enough to interact. As a result, Ephrin/Eph receptor signaling is particularly well-suited for mediating physical cell-to-cell interactions such as repulsion and attraction.

Ephrin ligands are classified into two groups: Ephrin-As and Ephrin-Bs. The six known Ephrin-As are tethered to the cell membrane by a chemical moiety known as the glycosylphosphatidyl inositol (GPI) anchor. The three Ephrin-B ligands, on the other hand, extend both inside and outside the cell as transmembrane proteins with active cytoplasmic tails. In general, EphA receptors tend to bind Ephrin-As, and EphB receptors bind to Ephrin-Bs.

Even more unusually for tyrosine kinase–based systems, ephrin ligands can also function as receptors unto themselves, thereby enabling a unique mode of two-way, bidirectional signaling between neighboring cells. The bipartite structure of the Ephrin-B protein particularly lends itself to this duel function, with its extracellular portion serving as the ligand to activate "forward" signaling in Eph-expressing cells, while its cytoplasmic tail controls "reverse" signaling within its own cell [5]. The mechanism for how Ephrin-A ligands may also participate in reverse signaling is, however, unknown.

In neural development, where most Ephrin/Eph research originally concentrated, Ephrin/Eph cell-to-cell signaling has proven to be fundamental to the way axons, the signal-carrying end of nerve cells, navigate their way to specific locations in the nervous system. The best-studied model is one called the retinal-tectal projection, in which axons from visual neurons in the retina migrate to an important visual relay center in a part of the brainstem known as the tectum (the superior colliculus in humans). The axons appear to navigate by way of particular gradients, where, for instance, different EphA receptor concentrations influence anterior/posterior mapping and various EphBs affect dorsal/ventral patterning. Ephrin/Eph signaling exerts its effects by mediating repulsion and attraction between neurons within these gradients. Axonal migration in other parts of the brain also relies, in part, on Ephrin/Eph signaling, as does neural crest cell migration in the early embryo [6]. The very recent observations that EphB receptors also function in the adult brain beside excitatory NMDA glutamate receptors, and may even affect synaptic plasticity, could suggest an additional, and as-of-yet uncharacterized, role for Ephrin/Eph receptors in higher-order processes such as memory formation as well [7].

Angiogenesis Requires Ephrin Signaling

In the vasculature, ephrins are essential to the proper development of new blood vessels, particularly in the process of angiogenesis, where new vessels form from existing vascular templates. Although the mechanism remains unknown for how ephrin signaling actually influences angiogenesis, a role mediating attraction and repulsion between developing arteries and veins is strongly suspected.

Blood vessels form embryonically in two discrete stages. During vasculogenesis, endothelial cell precursors first form into a crude template known as the primary capillary plexus, which serves as the first branches of the future vascular tree. In the subsequent process of angiogenesis, this plexus then remodels into a mature vascular network by sprouting off new vessels and pruning others, with the balance between pro- and antiangiogenic factors as the guide. This angiogenic developmental program can be physiologically reactivated when needed, as in wound repair and menstruation, but it can also be pathologically co-opted in many diseases. As Judah Folkman first proposed in the early 1970s, most solid tumors, for instance, must recruit their own blood supply from the host using angiogenic factors in order to grow larger than 1 to 2 millimeters in size [8]. Many other diseases are also increasingly being recognized as angiogenic-dependent, including macular degeneration, endometriosis, and rheumatoid arthritis, and others like psoriasis also appear to have strong angiogenic components to their pathophysiology. Ephrin-signaling may play a role in most, if not all, of these physiologic and pathologic forms of angiogenesis, and may therefore prove to be an important and novel target for the treatment of angiogenic-dependent diseases.

Most notably, in a 1998 report by Wang, targeted mutagenesis of vascular Ephrin-B2 in a mouse model proved to be lethal at embryonic day 11 because of defects in angiogenesis. Because Ephrin-B2 localizes to arteries as opposed to veins, whereas its EphB4 receptor sits primarily on venous cells, the hypothesis began to emerge that Ephrin-B2/EphB4 signaling between nascent arteries and veins is required for angiogenesis to proceed properly in murine development [9]. This model received even more experimental support when Gerety and Wang subsequently revealed that EphB4 mutant mice had exactly the same defective-angiogenic phenotype as the Ephrin-B2 mutants [10]. The question remained, however, whether Ephrin-B2 on endothelial cells as well as smooth muscle mesenchymal cells were both necessary for mediating angiogenesis. To distinguish between their relative roles, Gerety and Anderson crossed Tie2-Cre mice with Ephrin-B2/lox mice to selectively knock out Ephrin-B2 in endothelial cells. What they discovered was that the endothelial cell–specific knockout led to angiogenic defects which were "indistinguishable" from the conventional combined endothelial and mesenchymal Ephrin-B2 knockout, demonstrating that the endothelial expression of Ephrin-B2 alone is necessary and sufficient for its angiogenic funciton [11]. The role of Ephrin-B2 signaling in the pathologic angiogenesis of tumors is as of yet unknown, but if it mediates signaling between developing arteries and veins in the nascent tumor vasculature, much like its postulated role in development,

blocking arterial Ephrin-B2 may be a potent antiangiogenic therapeutic target.

Members of the Ephrin-A family also appear to play a direct role in mediating angiogenesis, although through very different mechanisms. In 1995 Pandey demonstrated that TNF-α, a potent proinflammatory as well as proangiogenic factor, exerts its downstream angiogenic effects by inducing Ephrin-A1 ligands to bind EphA2 receptors on endothelial cells as part of its signal transduction [12]. More recent studies suggest that tumor cells often develop the ability to express Ephrin-A1 ligands, which then bind to EphA2 receptors on endothelial cells to help induce angiogenesis. Accordingly, antibodies targeted to the EphA2 receptor have been shown to inhibit tumor angiogenesis and tumor growth in vivo in models of RIP-Tag pancreatic islet cell carcinoma and 4T1 mammary adenocarcinoma, specifically by blocking endothelial cell migration [13]. Whether any other members of the Ephrin-A family in the vasculature also contribute to angiogenesis remains to be determined.

Because metastastic potential in most tumors partially depends on angiogenic potential, Ephrins and their Eph receptors are also being studied as possible markers of tumor behavior. Several studies report associations between certain Eph and Ephrin subtypes in a variety of tumor cell lines, but more research needs to be done in this area before any estimations of their utility can be made.

Ephrins Reveal Distinct Arterial and Venous Microvascular Identities

Perhaps the most important conceptual role for Ephrins, however, stems not from what they do, but rather from on which cells they act. While studying the functional role of Ephrins in the nervous system, Wang et al. happened to notice that the Ephrin-B2 ligand localizes to distinct subsets of blood vessels in the developing mouse embryo. Further analysis revealed that this staining pattern was a result of the differential expression of Ephrin-B2 in the arterial, as opposed to venous, endothelium of the vasculature [9]. Subsequent studies by Shin and García-Cardeña et al. and Gale et al. went on to demonstrate that this Ephrin-B2 expression pattern persists into adulthood and extends not just within the endothelium, but into smooth muscle cells and pericytes as well [14, 15]. Most important, they also observed that differential arterial Ephrin-B2 expression extends into even the smallest diameter vessels, suggesting for the first time that the microvessels of capillary networks may have arterial and venous identities of their own. This differential expression was evident in vessels of multiple tissues, including pancreas, muscle, fat, kidney glomeruli, brain, liver, adrenal cortex, and adrenal medulla. Intriguingly, Ephrin-B2 also appears to differentiate arterial from venous vessels in several models of both normal and pathological angiogenesis, including marking subsets of vessels sprouting into the cornea from the limbus artery in a model of VEGF-induced angiogenesis, as well as subsets of microvessels in wounded tissue undergoing healing. Strikingly, approximately half of the vessels present in the microvasculature of different types of mouse tumor models also expressed Ephrin-B2, suggesting that the tumor vasculature may also consist of distinct arterial and venous microcirculatory components. Taken together, these studies for the first time challenged the classical view that quiescent as well as remodeling capillaries have neither arterial nor venous identities of their own, and strongly suggested that the expression of Ephrin-B2 may also be important for the formation of new vascular circuitries.

The Implications of a New Microvascular Paradigm

Since the time of Malpighi in the late 17th century, scientists have understood capillary networks to consist of a unique class of tiny “hair-like” microvessels linking arterioles to venules. Part of what distinguished capillaries operationally from all other vessel types was that they were neither arterial nor venous and could therefore function as a vascular crossroads for gas and metabolite exchange at the tissue level. In the late 1970s and early 1980s, however, a series of studies out of Czechoslovakia on enzyme histochemistry began to challenge this long-standing presumption of capillary arterial-venous neutrality. In 1979, Lojda realized that because the enzyme alkaline phosphatase histochemically stained arterioles, and dipeptidylpeptidase IV (DPPIV) highlighted venules, staining for both of these enzymes together would help illuminate the entire capillary bed [16]. With this new staining method, Lojda was able to divide the capillary bed histologically into three distinct portions—an alkaline phosphatase section, a DPPIV section, and a third “transitional” zone in which both enzymes were present—revealing for the first time molecular differences within the microvasculature. Throughout the 1980s and early 1990s, a handful of studies revealed additional evidence of capillary heterogeneity with even more molecular markers, but these markers only lasted during specific windows of development. Not until the late 1990s did Ephrin-B2 prove to be the first reliable molecular marker of arterial identity from the largest down to the smallest vessels and persisting from development into adulthood. Much like Lojda’s enzymes, Ephrin-B2 even more clearly maps out specific subsets of capillaries as arterial versus venous, providing the strongest challenge yet to the long-standing idea of capillaries as its own class of nonarterial, nonvenous blood vessel.

The new picture that is now emerging of microvascular identity is one of distinct arterial and venous microcirculations. These circulations are defined by the differential expression of molecular markers such as Ephrin-B2, which delineate an arterial continuum from arteries to arterioles, all the way down to corresponding microarterial capillary seg-

ments, and a venous continuum extending from veins to venules to corresponding microvenous capillary segments. These continuums display their own unique genetic, morphologic, and, perhaps, functional identities, and raise a host of new questions for the study of vascular biology and treatment of many human diseases: Why, for instance, do activated immune cells in the blood escape only through postcapillary venules and not through arterioles? Many vasculitic processes, on the other hand, exhibit specific arterial versus venous predispositions for the site of inflammation. Both giant cell and Takayasu's arteritis, for instance, occur only in large arterial vessels, and Kawasaki's disease in medium-sized arteries, but the many small-vessel vasculitic processes, such as microscopic polyangiitis and Wegener's granulomatosis, have much less exclusive propensities. Would more directed studies of these many vasculitic processes reveal any segregration between microarterial and microvenous capillary segments and perhaps provide new clues to their mysterious pathogenic processes? In genetic disorders such as CADASIL, where mutations in Notch-3 lead to migraines, mood changes, strokes, and, ultimately, vascular dementia, why are only small arterioles affected? Are there any corresponding syndromes defined by defects in the genes of the venous microcirculation? And as the tumor microvasculature appears to consist of roughly half microarterial and half microvenous vessels, how important in the end is arterial and venous identity in forming a functioning tumor vasculature? Similarly, what would happen if either the arterial or venous development of the tumor vasculature were blocked? And do chemotherapeutic or antiangiogeneic agents specifically target the arterial or venous microcirculations? Research into Ephrins is providing the first window into answering these questions.

Much like Malpighi's microscopy and its ability to reveal an entire class of vessels that even William Harvey did not imagine, the study of Ephrins has begun to serve as the first example of a 21st-century molecularly-guided microscopy powerful enough to reveal unexpected heterogeneity within even Malpighi's own capillary microvessels. The missing link in Harvey's circuit appears to be defined neither by pores, nor even liminal capillaries, but rather by "microarteries" and "microveins" bridging together distinct arterial and venous circulations.

CHAPTER 9

Endothelial Heterogeneity

Mary E. Gerritsen
Frazier HealthCare Ventures, Palo Alto, California

Introduction

The following paragraph written by a Malaysian student studying in America aptly captures the concept of regiospecific heterogeneity, the topic of the present chapter:

America is not homogeneous, neither is its heterogeneity immediately apparent. Rather, as so many of my American friends have been so keen to enlighten me, American people differ from state to state. The mainstream American culture of fast-food chains, shopping malls and pop music is there for the world to see. But it is the only uniting factor across their vast homeland. A person from Iowa is vastly different from a person from California. Even in Virginia alone, those who lived in the northern part of the state near Washington, DC are totally different from those who grew up in central Virginia where Sweet Briar is located. Taken as a whole, America is bursting with ethnic and cultural diversity, but in reality, it is small pockets of homogeneity that combine to form a picture of unparalleled heterogeneity.[1]

The vascular endothelium lines the blood vessels of the body, and in humans, the estimated number of individual cells constituting this lining is somewhere on the order of $1–6 \times 10^{13}$. Like Americans, the mainstream "endothelial culture" of blood, tissue, and nutrients is there for all to note. These uniting factors do not, however, reveal the vast differences of specific circulations [1, 2]. Several vascular human diseases are exquisitely restricted to specific types of vessels. Vasculitis often shows a marked predilection for specific arteries, veins, or capillaries; tumor cells may metastasize to selective vascular beds, and atherosclerosis is generally restricted to the larger arteries.

Although scientists initially thought the endothelial cell layer was essentially an inert barrier between the blood and the tissue, this extensive "organ" is now known to carry out a diverse array of specialized functions which can vary markedly from one organ to another. Today the endothelium is viewed as a dynamic, mutable, heterogeneous, distributed organ with essential secretory, synthetic, metabolic, and immunologic functions. The picture of "unparalleled heterogeneity" is revealed as follows.

[1] Thoughtfully penned by a Citizen of the World; http://www.jellybeans.blogspot.com/2002_12_01_jellybeans_archive.html

Endothelial Architecture

Endothelial heterogeneity is a term that has been coined to describe the diversity and regional specificity of endothelial cells at different sites in the vasculature. The concept that endothelial cells are not identical is not new; variations in the structure of capillary endothelium led to the first subclassification of endothelial cells into "continuous," "fenestrated," and "discontinuous" [3, 4] (Figure 1). Endothelia of the continuous type are the most prevalent and are found in the walls of arterioles, capillaries, and venules of skeletal, smooth and cardiac muscle, the mesentery, skin, connective tissue, lung, brain, and eye, as well as lining the major conduit vessels (large arteries, veins). These endothelial cells are characterized by occluding (tight) junctions. Fenestrated endothelia are found in the exchange vessels of secretory and excretory organs such as endocrine and exocrine glands, in the capillaries lining the gastric mucosa, the glomerular and peritubular capillaries of the kidney, as well as in the synovium and choroid plexus. (Actually, the capillary endothelial cells of the synovium exhibit a continuous morphology on the side facing away from the synovial fluid and a fenestrated morphology on the opposite side.) Fenestrated endothelial cells are characterized by numerous small "windows" (i.e., small transcellular openings ranging from 50 to 80 nm in diameter). At the ultrastructural level, differences in the fine structure of the fenestrae are revealed. In some organs, the fenestrae appear open; in others the fenestrae are

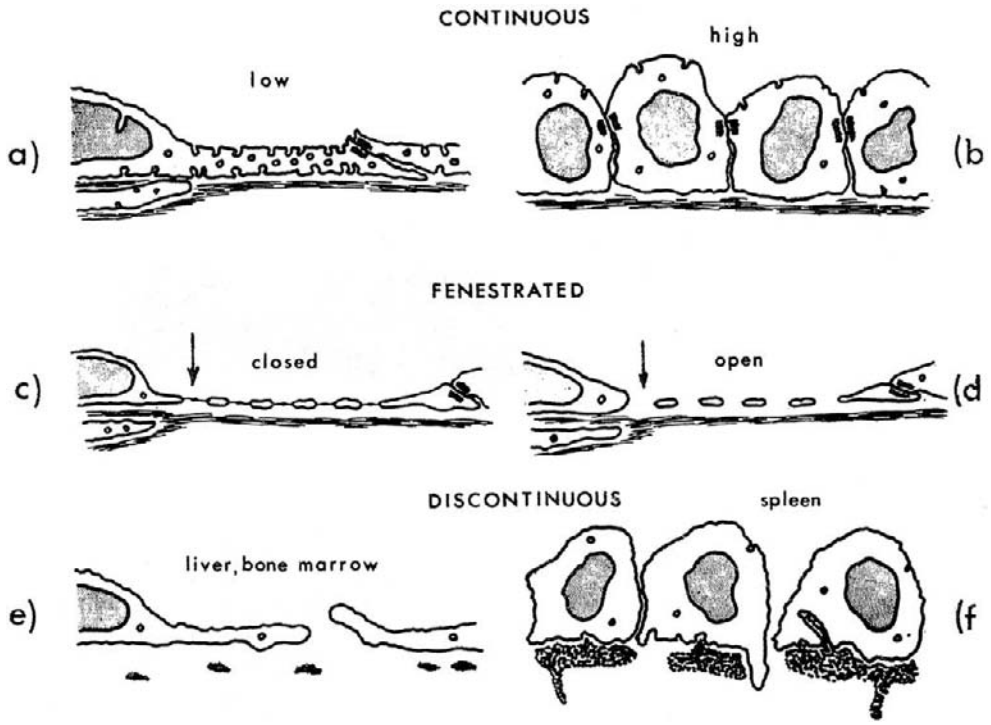

Figure 1 Classification of the endothelial cells of different capillaries according to their continuity. Three main types are distinguished (i.e., continuous, fenestrated, and discontinuous) and for each, two main varieties are represented. Little detail is shown because considerable variations exist from organ to organ; in fact, almost each organ can be said to have its own type of capillary endothelium. The scheme is based on information derived from mammalian studies. **Panels a, b:** The endothelium has no recognizable openings. The low variety **(a)** is found in striated muscle, myocardium, central nervous system, smooth muscle of digestive and reproductive systems, and subcutaneous and adipose tissue. The high variety **(b)** is typical of the postcapillary venules of the lymph nodes and thymus; a similar endothelial appearance is also seen in large arteries when they are contracted. **Panels c, d:** The endothelium has intracellular fenestrae (*arrows*) either closed **(c)** as in endocrine glands, choroids plexus, ciliary body, and intestinal villus, or open **(d)** as in the renal glomerulus. **Panels e, f:** The endothelium are discontinous, containing intercellular gaps. These vessels are often refered to as "sinusoids" and are typical of liver, bone marrow, and spleen; in each of these sites, they differ in structural detail. (Reprinted with permission from Figure 1 [4].)

"closed" by thin, membranous diaphragm-like structures. Fenestrae are not fixed structures; their frequency and location can be influenced by cytokines, ischemia reperfusion, growth factors, and other stimuli. An extreme form of fenestrated endothelia, termed *discontinuous endothelia*, are found in the sinusoids of the liver, spleen, and bone marrow. These endothelia have irregular outlines and calibers and highly fenestrated structures; in the liver, the fenestrae are often clustered to form sieve plates, and none of the fenestrae are closed with diaphragms (Figure 1).

Endothelial Glycocalyx

Endothelial diversity goes far deeper than appearance alone. In recent years, scientists have begun to appreciate the breadth of endothelial specialization, at the biochemical, metabolic, and immunological level. The endothelial surface is a highly specialized feature. This is the "face" the endothelial cell presents to the nutrients and formed elements of the blood, and not surprisingly, this surface exhibits remarkable specificity. One exquisitely localized property is the composition of the endothelial glycocalyx, in which differences have been revealed by the binding patterns of labeled lectins. For example, wheat germ agglutinin (WGA), when perfused through the vasculature of mice or rats, will bind to the luminal surface of endothelial cells in capillaries and arterioles, but not in venules (Figure 2). This selectivity is impressively abrupt; capillary endothelial cells will bind WGA strongly, whereas immediately adjacent venular cells do not. WGA interacts with N-acetylglucosamine and sialic acid glycoconjugates; thus the display of these glycoconjugates is highly regional [6].

Endothelial Lymphocyte and Leukocyte Interactions

The expression of homing receptors involved in lymphocyte homing illustrates another aspect of endothelial surface specificity, providing the so-called "zip code" for cell trafficking. For example, in the mouse, lung-specific endothelial adhesion molecule (Lu-ECAM-1) is expressed exclusively by pulmonary postcapillary endothelial cells and in some venules in the spleen; mucosal addressin cell

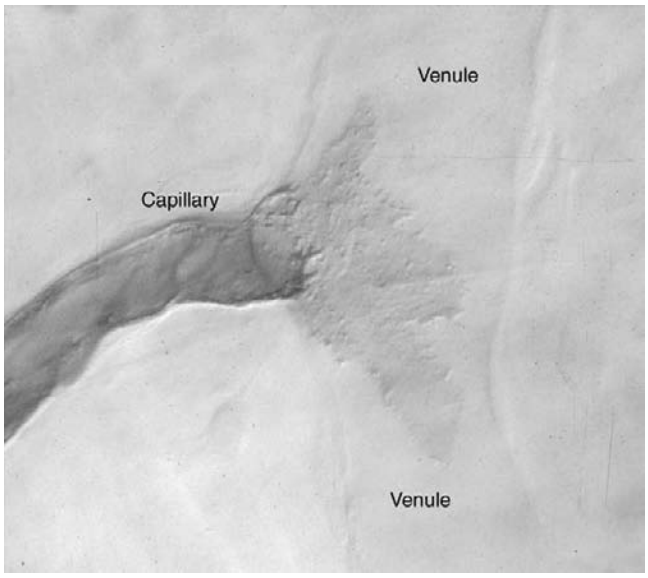

Figure 2 Staining of microvessels in rat trachea by postfixation perfusion of biotinylated wheat germ agglutinin (WGA) lectin, followed by reaction with DAB peroxidase. WGA lectin binds to the luminal surface of capillary endothelial cells, but not to that of venular endothelial cells, showing abrupt heterogeneity of cell surface glycosylation. Micrograph shows WGA binding to an endothelial cell that extends from the capillary into the postcapillary venule. (Photomicrograph kindly provided by Dr. Gavin Thurston, Regeneron Pharmaceuticals, Inc.)

Table I Different Markers of Endothelial Specialization [1, 5].

Marker	Preferential Expression
Ephrin-B2	Arterial endothelial cells
P-glycoprotein (mdr 1a)	Brain endothelial cells
Glut-1	Brain endothelial cells
CD73/transferrin receptor	Brain endothelial cells
LuECAM	Lung venular endothelial cells
GlyCAM-1	HEVs
NF-HEV	HEVs
MECA79	HEVs, chronically inflamed EECs
VAP-1	HEVs, endothelial cells in large vessels
VAP-2	HEVs, venules
CD34/Sgp90	One form, specifically glycosylated is restricted to HEVs
MadCAM-1	Peyer's patches, mesenteric lymph node HEVs, venules in intestinal lamina propria, spleen sinus
EphB4	Venous endothelial cells
Flt-4	Lymphatic endothelial cells
LYVE-1	Lymphatic endothelial cells
Podoplanin	Lymphatic endothelial cells
Prox-1	Lymphatic endothelial cells
Desmoplakin	Lymphatic endothelial cells

adhesion molecule-1 (Mad-CAM-1) is expressed primarily on high endothelial venules in Peyer's patches; GlyCAM-1 is also restricted to high endothelial venules. Postcapillary venules are the site of leukocyte adhesion and emigration, partly because of regio-specific cell adhesion molecule expression. For example, P-selectin is constitutively expressed by venular endothelial cells in most organs; however, it is absent or present only at very low concentrations in arteriolar and capillary endothelial cells. In vivo, the leukocyte adhesion molecules VCAM-1 and E-selectin are also selectively expressed by venular endothelial cells when activated by inflammatory cytokines or other mediators. Other factors contributing to this "local zip code" include the selective secretion of certain chemokines, cytokines, and differences in shear stress (see following sections for further discussion of physical forces). Table I summarizes the expression of several vascular bed–specific endothelial cell markers.

Vascular Permeability

The early topographic studies of Majno [7] were the first to recognize that the topical application of histamine or serotonin to the rat cremaster muscle selectively induced permeability in the venules. The list of inflammatory mediators that selectively induce venular responses is impressive and includes substance P, leukotriene B4, bradykinin, tumor necrosis factor, lipopolysaccharide, and ischemia-reperfusion injury. Moreover, these venular-specific responses have been observed in many organs, including cremaster muscle, diaphragm, trachea, cheek pouch, skin, bladder, stomach, pancreas, and intestine. At least some of this specificity is a result of different densities of the specific receptors for these mediators on venular endothelial cells; there may be additional contributing factors such as differences in downstream signal transduction. There are remarkable differences in the baseline permeability of different vascular beds to low-molecular-weight compounds as well as to large proteins. The exchange of these molecules across the endothelium can occur through the endothelium (by specific transporters, or by "vesicular transport") or between endothelial cells (i.e., at the endothelial junction). Obviously, the architecture of the endothelial junction plays a critical role in the roles of these different exchange pathways. There are also differences in the expression of different transporters and plasmalemmal vesicles from one vascular bed to another. For example, plasmalemmal vesicles are rarely seen in brain endothelia, yet are relatively frequent in the endothelial cells of the lung and diaphragm. The endothelium of the brain, which forms the so-called blood–brain barrier, plays a particularly important role in regulating the transport of solutes from the apical to basal surface; brain endothelial cells have specific transport systems for certain nutrients such as glucose (Glut-1) and amino acids. The endothelium of the brain also expresses the multidrug-resistance protein P-glycoprotein (*mdr1a*), an

active transporter that transports low-molecular-weight molecules from the basal to apical surface, thus protecting the cells of the central nervous system from accumulating potentially neurotoxic molecules. Organs with discontinuous endothelia, such as the liver capillaries, are quite permeable, and albumin escapes at a rate several fold greater than from less permeable continuous-type capillaries of muscle and skin.

Vascular Reactivity

Endothelial cells are the source of some potent molecules that influence the contractile state of vascular smooth muscle cells, including the vasodilators nitric oxide (NO), prostaglandin (PG)PGI_2, endothelial-derived hyperpolarizing factor (EDHF), adrenomedullin, and the potent vasoconstrictor, endothelin-1. PGE_2, made predominantly in microvascular endothelial cells, may be a vasodilator or vasoconstrictor, depending on the concentration, interactions with other autocoids, and the vascular bed. The balance of these factors is an important determinant of the control of vascular tone and tissue perfusion; considerable heterogeneity of responses exists among vessels of different size from different anatomic origins and different species.

Endothelial Junctions

As discussed previously, differences in endothelial cell-to-cell junctions in different vascular beds has long been recognized. During the last two decades, much has been learned about the biochemical and molecular constituents of the endothelial junction and their regulation. The inter-endothelial adhesive structures include tight, adherens, and gap junctions, in which the surface proteins occludin, claudins, cadherins, platelet endothelial cell adhesion molecule (PECAM), CD99, and junctional adhesion molecules (JAMs) are specifically incorporated. Tight junctions, defined structurally as closely opposed neighboring plasma membranes that appear to be tightly fused, are especially well developed in the brain and retina; occludin and claudin are the cellular marker proteins of this type of junction.

Adherens junctions, defined morphologically by a cytoplasmic plaque structure of electron-dense material on the plasma membrane of adjacent cells, are ubiquitously expressed in endothelia of all vascular beds; cadherins, in particular vascular endothelial (VE)-cadherin, are the endothelial marker protein for this type of junction. Gap junctions are characterized by their morphological appearance as a patch on which the membranes of two adjacent cells are separated by a uniform narrow gap of 2 to 4 nm; connexins, in particular connexins (Cx) Cx37, Cx40, and Cx43, are the marker protein for this type of junction. This "gap" is spanned by channel-forming proteins (the connexins) that allow inorganic ions and other small water-soluble molecules to pass from the cytoplasm of one cell to another; gap junctions thus couple cells both electrically and metabolically.

There is considerable heterogeneity in the expression of some of these junction-associated molecules. For example, occludin, a structural component of the tight junction, is highly expressed in epithelial cells and in brain endothelial cells, yet barely detectable in endothelial cells of most other organs. Junctional adhesion molecule (JAM)-B (JAM-2, VE-JAM) is highly localized to the intercellular boundaries of high endothelial venules; JAM-A (JAM-1) is more highly expressed in brain endothelia, whereas JAM-C (JAM-3) is more broadly expressed in endothelia of different vascular beds. JAM-1 may be an organizer of occludin clustering, thus contributing to the establishment of tight junctions in certain endothelial cells. In the kidney, the expression of claudin 5, a component of tight junctions, is restricted to arterial endothelial cells but undetectable in veins and capillaries. Other junctional molecules such as vascular endothelial cadherin (VE-cadherin) and the connexins seem to be more ubiquitously expressed.

Metabolism

The total surface area of the vascular endothelium is impressive: 100 to 700 m^2. This surface provides an interface for nutrient transport, metabolism of bloodborne substances, and secretion of chemokines, cytokines, vasoactive peptides, enzymes, and other biologically active factors. The lung, because of its large surface area and its position as recipient of the entire cardiac output, is an important site of metabolism of both native molecules and xenobiotics. The architecture of the pulmonary capillaries, sandwiched between adjacent alveolae, provides a system in which blood flows through these vessels as if between sheets, providing for maximal exposure of the capillary blood to alveolar gases. Surprisingly, relatively little is known about the potential expression of specific metabolic enzymes in pulmonary capillary endothelia.

Endothelial Cells as a Source of Growth Factors

Endothelial cells from the bone marrow are capable of promoting long-term multilineage hemopoiesis, in particular myelopoiesis and megakariocytopoiesis. The ability of these cells to support hemopoeisis may be a result of their ability to constitutively produce certain growth factors such as colony stimulating factors 1 and 2, fibroblast growth factor, leukemia inhibitory factor, transforming growth factor β, platelet-derived growth factor, interleukin-6, and kit ligand.

Endothelial Cells and Physical Forces

In addition to biochemical activation, the endothelial lining is constantly subjected to biomechanical stimuli (i.e., shear stresses, strains, and hydrostatic pressures), generated by the pulsatile flow of the blood. The fluid mechanics of blood flow in the vasculature is complex; in arteries it involves pulsatility at high pressures, yet in veins it is quasi-

steady and at low pressure. Flow patterns in the vicinity of curvatures and branch points create regions of turbulence in arteries; however, turbulence in veins is generally not seen. Flowing blood subjects the endothelium to two orthogonal components: viscous friction and distension. The frictional force per unit area acts tangential to the vascular wall and is known as wall shear stress. The distending force acts perpendicular to the wall and is essentially equal to the fluid pressure. The shear stress and the pressure stretch the wall, producing both longitudinal and circumferential strain. Endothelial cells are known to sense and respond to all of these hemodynamic challenges. Flow patterns dictated by vascular anatomy are now thought to play a crucial role in the origin of atherosclerotic lesions. These lesions have a predeliction to occur at or near vessel bifurcations, regions exposed to nonuniform, complex flow. Interestingly, in vitro and in vivo studies comparing the effects of nonuniform complex flow to time-averaged, uniform flow, such as laminar shear stress, have revealed a remarkable difference in phenotype. Disturbed or turbulent flow is associated with the generation of reactive oxygen species by endothelial cells, followed by the expression of endothelial inflammatory markers, augmented endothelial turnover, and increased endothelial cell death. In contrast, the more uniform flow is associated with minimal endothelial cell turnover, low levels of apoptosis, and the expression of antioxidants and anti-inflammatory genes. There are quite likely inherent differences in the ability of endothelial cells at different vascular sites to respond to biomechanical forces; this is a relatively understudied aspect of endothelial heterogeneity.

Endothelial Cells and the Basement Membrane

The basal lamina is a flexible, thin (40 to 120 nm thick) mat of specialized extracelluar matrix that separates the endothelium from the underlying tissue; it is composed mainly of type IV collagen, heparan sulfate proteoglycan, laminin, and nidogen/entactin (although the total number of proteins known to make up the basement membrane is at least 50). This so-called mat is far from inert or just structural; the basal lamina can influence cell metabolism, organize proteins in adjacent plasma membranes, induce proliferation, serve as a filter, act as a depot for various growth factors and other proteins, and importantly, serve as a specific highway for migrating leukocytes. Most basement membranes appear similar at the level of the electron microscope, but their composition is unique to each tissue. This molecular inequality is an important contributor to the differentiated state of the endothelial cell. The basement membrane of bone marrow sinusoids shows a distinctive structure: it is discontinous, lacks a network organization, and consists of irregular masses of amorphous material. It is also unusually abundant in chondroitin sulfate proteoglycans and poor in heparan sulfate proteoglycan. This composition may facilitate disassembly and reassembly of basement membrane material as maturing hemopoietic cells pass through the sinusoidal wall. Tumors produce basement membrane components that promote angiogenesis, and additionally, cryptic domains within basement membrane molecules (such as the collagens) can be exposed during proteolytic degradation; some of these possess antiangiogenic activity [8].

Endothelial Cells and Pericytes

Pericytes, a type of mural cell associated abluminally with endothelial cells in capillaries and in some postcapillary venules, exhibit considerable variability in their relative association with endothelial cells in different tissues (for a review, see Ref. [9]. For example, capillaries of the retina, lung, and skeletal muscle exhibit more pericytes and "coverage" of endothelial cells than capillaries found in endocrine tissues such as the adrenal gland. Pericyte coverage of newly formed blood vessels is also thought to play a role in the stabilization of these structures; the vasculature of tumors is poorly invested with pericytes.

Endothelial Cell Proliferation

Endothelial cells isolated from various microvascular beds have been traditionally more difficult to maintain in culture than their counterparts from larger vessels such as the aorta, saphenous vein, and umbilical vein. This is likely a consequence of multiple contributing factors: differences in growth factor synthesis and in growth factor receptor expression and signal transduction, harsher experimental conditions used to isolate the cells, and potential differences in the nutritional requirements (e.g., amino acids, carbohydrates, vitamins). A perusal of PubMed will quickly identify all of these as candidates, and more, in one or several publications. There are regional differences in endothelial "proliferative" states in vivo as well. For example, endothelial cells at sites of disturbed flow (e.g., branching of blood vessels, areas of curvature) exhibit a higher rate of BrDU labeling or proliferating cell nuclear antigen expression (indices of proliferation) compared to cells in adjacent regions of the vasculature exposed to laminar flow. Endothelial cells at the site of a wound, ischemia-reperfusion injury, or in reproductive organs such as the ovary or mammary gland undergo phenotypic changes consistent with the development of an angiogenic phenotype. The phenotypic characteristics of the endothelial cells in tumors are a hot topic of current research: the vision of specifically targeting the tumor vasculature offers an incredible therapeutic opportunity for the treatment of many solid tumors. A major contributor to the switch to the "angiogenic phenotype" is vascular endothelial growth factor (VEGF), a potent mitogen, morphogen, and motogen for endothelial cells. Moreover, VEGF is a potent inducer of vascular permeability. Proliferating or angiogenic endothelial cells display different antigens, altered basement membrane composition, altered junctional morphology, and numerous transendothelial channels. Recent studies now indicate that there may

also be vascular bed–specific endothelial cell growth factors; for example, endocrine gland–derived VEGF (EG-VEGF) is an endothelial cell mitogen selective for endocrine gland endothelial cells.

Genetic Diversity of Endothelial Cells

Several approaches have been used to identify endothelial differences on a genomic scale, including differential display, suppressive subtractive hybridization, serial analysis of gene expression, and DNA and oligonucleotide microarrays [10–14]. Such studies have identified potential tissue-specific endothelial cell transcripts from cerebral, lymphatic, arterial versus venous, lung, nasal polyp, skin, and myometrial cells. At present these studies are too preliminary to cite the markers as fact, but they offer considerable promise for an improved molecular understanding of endothelial heterogeneity.

Capsule Biography

At the time this review was written, Dr. Gerritsen was working as an independent consultant for several biotech and venture capital firms. Currently she is the Senior Director of Molecular and Cellular Pharmacology at Exelixis Inc. She has held the positions of Senior Director, Vascular Biology, at Millennium Pharmaceuticals (2001–2002); Associate Director, Cardiovascular Research, at Genentech Inc. (1997–2001); Group Leader, Inflammation, at Bayer Corporation (1990–1997) and Associate Professor, Physiology, New York Medical College, 1985–1990. Her work has focused on the biology of the endothelium.

CHAPTER 10

Portholes on a Vessel: Endothelial Fenestrae

Sofia Ioannidou, Steven J. Samuelsson, and David T. Shima
Eyetech Research Center, Eyetech Pharmaceuticals, Inc.

Precise regulation of blood–tissue interchange is critical for proper integration of organ physiology with the cardiovasculature. Accordingly, microvascular endothelial cells, the primary barrier to free blood–tissue exchange, adopt highly specialized features and behaviors to mediate and monitor the flux of macromolecules and fluids across the vascular wall. For example, the vascular endothelium of the blood–brain and the blood–retinal barriers is fortified by tight junction components that restrict access of fluid and blood components to sensitive neural tissues. The other extreme of endothelial barrier differentiation is that of lymphatic vessels, an endothelium with numerous gaps between cells enabling uptake of extravascular fluid for clearance, transport, and return to the circulation. Finally, organs mediating endocrine, absorptive, or filtrating functions have a demand for abundant but more regulated fluid and macromolecule exchange and thus are supported by a highly specialized vascular endothelium containing numerous plasma membrane pores, the fenestrae (Figure 1). Derived from the Latin word for window, the term *fenestra* is used in this context to describe an opening in the vessel wall that connects the luminal and extravascular space. In this chapter, fenestrae structure, function, and pathophysiological relevance are discussed in detail.

Fenestrae Structure

Morphology and Architecture

Ultrastructural studies have described fenestrae as transcellular circular pores with an average diameter of approximately 60 nm (although they can be as large as approximately 125 nm within the liver sinusoidal endothelium). Fenestrae are encountered in the most attenuated regions of the endothelium, where the cell profile is as little as 40 nm, and span the entire thickness of the cell without disrupting the continuity of the cell membrane (Figure 2). The substances that traverse the pore never encounter the contents of the cytoplasm and are transported in a rapid and presumably energy-efficient manner. This is in contrast to transcytosis, which involves the coupling of energy-rich endocytic and exocytic events. In most vascular beds, the fenestrae contain a diaphragm composed of approximately eight radial fibrils converging in a central knob, which further dissects the pore into 5- to 6-nm openings (Figure 3).

Fenestrae are known to occur in clusters of approximately 50 to 100, termed *sieve plates*, which are encircled by a microtubule-rich border. Within a sieve plate, fenestrae are found in a near-linear arrangement, with precise spacing between each pore, implying the presence of a complex intracellular scaffolding to support such order. Whether individual fenestrae, or the sieve plates, are stable structures that persist throughout the lifetime of a differentiated cell or dynamic structures that are rapidly turned over, is currently unknown.

Chemical and Molecular Composition

Palade and the Simionescus pioneered the study of fenestrae composition in the 1960s, 1970s, and 1980s by demonstrating that cationized ferritin (CF) preferentially deposited within a glycocalyx visible on the luminal aspect of the fenestral diaphragm. Capitalizing on this initial observation, they used the CF interaction as a probe for the molecular nature of fenestrae, by monitoring its disappearance following treatment with enzymes of defined speci-

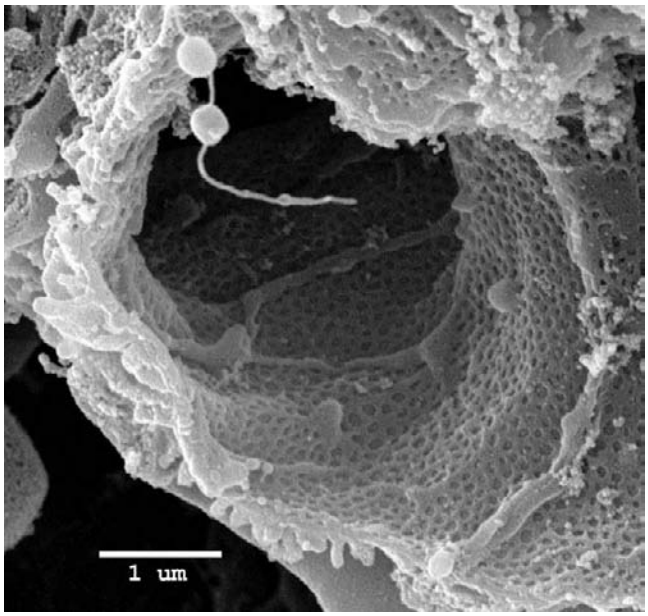

Figure 1 A scanning electron micrograph from a freeze-fractured glomerulus shows a view down the lumen of a fenestrated capillary. The endothelium appears to have a colander-like structure that permits passage of materials from the blood to the glomerular capsule. ficity. Sensitivity to proteases and certain glycosidases as well as affinity for lectins suggested that acidic glycoproteins and proteoglycans could account for CF-decorated anionic sites on the diaphragms. However, the differential sensitivity to heparinase and heparitinase in the fenestral diaphragms of the intestine and choriocapillaris, respectively, together with variable results in lectin-binding studies in these tissues, highlight organ-specific differences in the glycocalyx composition: heparan sulfate proteoglycans presumably form part of the diaphragms in the intestine, while the closely related molecule heparin is thought to localize on diaphragms of the choriocapillaris. Moreover, binding of CF to fenestral diaphragms is absent altogether in the bone marrow and the fetal liver.

Recent studies by Stan and colleagues identified an endothelial cell-specific protein, Plasmalemmal Vesicle 1 Protein (PV-1) as the first known component of the fenestral diaphragm. PV-1 is a 60-kDa Type II transmembrane glycoprotein that is believed to form homodimers that constitute the primary structural component of the diaphragm. It should be noted that PV-1 and the diaphragm are not unique to fenestrae but also reside within endothelial cell caveolae and transendothelial channels.

Fenestrae Biogenesis

The inability to maintain fenestrated endothelium in tissue culture and the difficulty in quantifying and manipulating the appearance of fenestrae both in vivo and in vitro have greatly hampered the study of their biogenesis. Until recently, the induction of fenestrae in cultured endothelial cell lines has been reported to yield numbers that are three to four orders of magnitude lower in density than normally observed in vivo. Nevertheless, a small number of key studies published throughout the last three decades have highlighted several extracellular and intracellular determinants that may be involved in the differentiation program of a fenestrated endothelial cell.

Endothelial Cell Microenvironment

Fenestrated microvessels are in constant contact with the extracellular matrix, both in the form of routine basal lamina or, in some cases, elaborate, thickened matrix such as the basement membrane of the kidney glomerulus or the multilamellate Bruch's membrane, which separates pigmented retina from the choriocapillaris (Figure 4). Extracellular matrix could simply provide a structural scaffold to facilitate the extreme shape changes and cell attenuation that accompanies the fenestrated phenotype. However, a more active, instructive role for the extracellular matrix has been proposed to explain, for example, the presence of fenestrae only in the regions of the choriocapillaris that are immediately adjacent to Bruch's membrane. In vitro experiments examining the effects of a variety of extracellular matrices suggest that fenestrae formation is supported by specific matrix components, which mimic the situation observed in vivo.

Signal Transduction Pathways

The first attempts to reprogram the fenestrae differentiation program in cultured endothelial cells relied on the use of potent and relatively nonspecific initiators of intracellular signaling cascades on isolated bovine adrenal cortex endothelial cells. Phorbol myristate acetate, an activator of protein kinase C isoforms and a potent differentiation agent for some cell types, promoted a change in the shape of endothelial cells accompanied by a five-fold increase in the frequency of diaphragmed fenestrae (approximately six fenestrae per $100\,\mu m^2$). Similarly, treatment of cultures with retinoic acid led to a threefold increase in the surface density of fenestrae, while transforming growth factor β led to a sevenfold decrease in their density. The physiological relevance of these signaling pathways remains to be established.

The angiogenic growth factor, vascular endothelial growth factor (VEGF), is the strongest candidate for a signaling protein that induces fenestrae formation. VEGF is an endothelial-specific mitogen and motogen, and was originally identified as a vascular permeability factor, approximately 50,000 times more potent than histamine. Although VEGF is greatly downregulated after the completion of embryonic vasculogenesis and angiogenesis, it is continuously and highly expressed in epithelial cells adjacent to fenestrated endothelium. Moreover, fenestrae have been

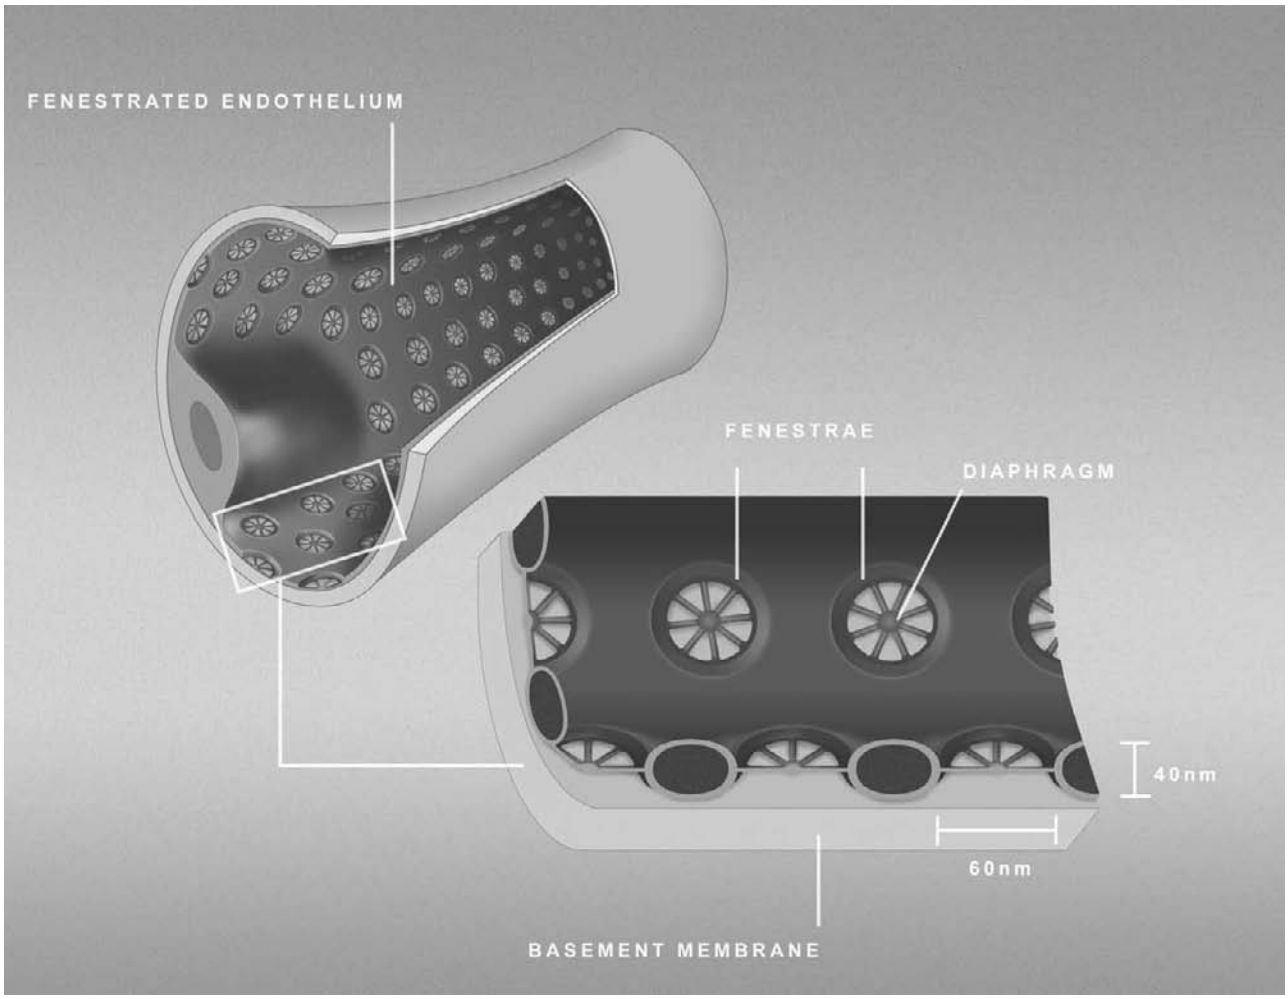

Figure 2 Schematic representation of a capillary with fenestrated endothelium and underlying basement membrane. Fenestrae are found only at the most attenuated regions of endothelial cells, where the nucleus and organelles are excluded and the distance from apical to basal plasma membrane is as little as 40 nm. They occur in groups and are arranged in a near-linear fashion with precise spacing between them. *Inset* shows the fenestral pore to be 60 nm in diameter, with an effective size of 5 to 6 nm when apertured by a diaphragm. Biol.* **100**, 418–428.] (see color insert)

observed in the neovasculature of tumors and in the normally continuous endothelium of the retina during diabetic microangiopathy, both pathological situations that are functionally linked to the local upregulation of VEGF. In fact, in vivo studies have demonstrated that VEGF can induce fenestrae within 10 minutes in the continuous endothelium of skeletal muscle and skin, when applied topically or injected intradermally, and in vitro studies using capillary endothelial cells further reinforce the ability of VEGF to promote fenestrae biogenesis. It is still unknown to what degree overall VEGF-induced permeability can be attributed to fenestrae formation, since VEGF also triggers the appearance of other structures implicated in permeability, such as caveolae and vesiculo-vacuolar organelles (VVOs), and regulates the gating properties of endothelial junctions.

Cytoskeleton

The importance of cytoskeletal remodeling in fenestrae biogenesis has been suggested from in vitro studies examin-

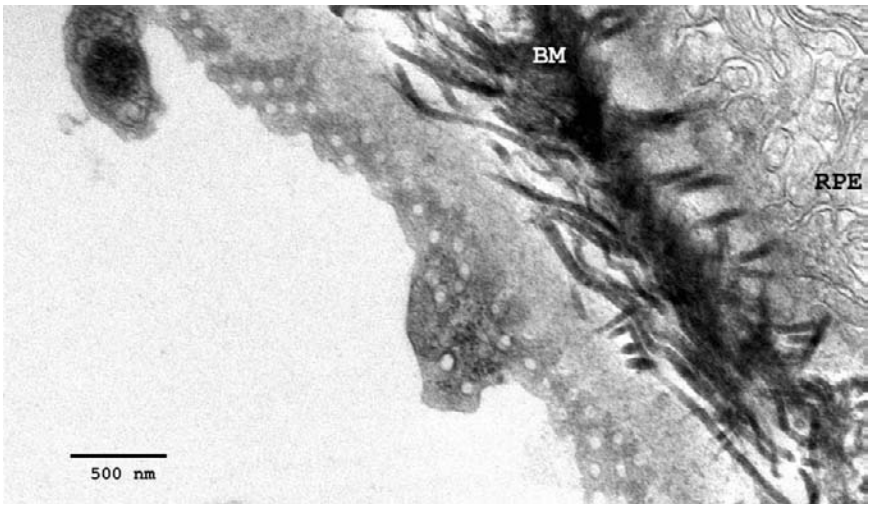

Figure 4 Fenestrated endothelium of choriocapillaris. This image reveals the close association of diaphragmed pores to Bruch's membrane (BM) and microvillar base of retinal pigmented epithelium (RPE). (We thank associate Eunice Cheung for this data.) (see color insert)

ing the effect of agents that disrupt actin microfilament assembly on highly fenestrated liver sinusoidal endothelial cells. Latrunculin A, which depolymerizes actin filaments through the sequestration of actin monomers, as well as Cytochalasin B, which leads to disassembly by capping the fast-growing end of actin filaments, both led to a two- to threefold increase in the number of fenestrae within 30 to 60 minutes. The physiological relevance of this data was recently supported by experiments showing that a dominant negative version of the small GTP-binding protein Rac could block VEGF-driven fenestrae formation during corneal angiogenesis, putatively through interfering with the reorganization of the actin cytoskeleton.

General Concepts for Fenestrae Formation

Researchers have used the limited amount of experimental data to generate several conceptual models (not mutually exclusive) to guide research in the area of fenestrae biogenesis.

Caveolae Give Rise to Fenestrae

Fenestrae and caveolae share structural features, common tissue distribution, a relationship to the VEGF signaling cascade, and a common putative role in the regulation of vascular permeability. In one of the earliest hypotheses for fenestrae formation, investigators postulated that caveolae may give rise to fenestrae in a process involving fusion of a budding caveolar vesicle with the adjacent plasmalemma. The discovery that PV-1 was common to the diaphragms that reside in both fenestrae and the caveolae of endothelial cells further supported this model. Current evidence, however, emphasizes more differences than similarities in the nature of the two organelles. General compositional differences between the two organelles were first highlighted in tracer perfusion studies showing that caveolar diaphragms (also referred to as stomatal diaphragms) lacked anionic sites among other molecular determinants that were present within the fenestral diaphragm. Furthermore, exclusion of the main structural component of caveolae, caveolin-1, from fenestrae in vivo and in vitro, and the recent finding that knockout mice completely lacking caveolae still have fenestrae, provide compelling evidence for distinct origins of caveolae and fenestrae. However, the existence of a common structural precursor that differentiates to give rise independently to fenestrae and caveolae still remains a valid point for consideration.

A Putative Role for the Diaphragm in Fenestrae Formation

The presence of a diaphragm in fenestrae is variable; it is found in the fenestrated capillaries of the intestine, the choriocapillaris, the choroid plexus, and endocrine organs, while it is absent from the more permeable microvessels of the kidney glomerulus and the liver sinusoids. Diaphragmed fenestrae, however, do initially appear within the vessels of developing fetal glomerulus, which has raised speculation on a role for the diaphragm in fenestrae biogenesis, in addition to its putative role in gating the pore. Achieving a precise circular opening and facilitating the extreme membrane curvature at the rim of fenestrae, where apical and basal plasma membranes come together, could be functions of the protein-rich diaphragm.

Apical-Basal Plasma Membrane Fusion Following Actin Displacement

Data demonstrating that actin microfilament disassembly triggers fenestrae biogenesis have spawned a model whereby removal of the actin-rich cortex beneath the plasma membrane is required to allow close apposition and fusion of apical and basal plasma membranes. Cortical actin removal has been shown to be an important prerequisite to

membrane fusion during exocytosis, while removal of organelle-bound actin has been suggested to accelerate mammalian endosome and yeast vacuole membrane fusion. Whether the cytoskeleton also plays an instructive role in fenestrae formation remains to be established.

Fenestrae Function

Selectivity of the Barrier

Attempts to investigate the permeability properties of fenestrae were initiated by Clementi, Palade, Simionescu, and Pino using tracer perfusion studies. Horseradish peroxidase (~4 nm in diameter) proved to be readily permeable through diaphragmed fenestrae of the intestinal mucosal capillaries and the ocular choriocapillaris, whereas larger tracers such as ferritin (~11 nm in diameter), or dextrans and glycogens, were variably permeable. These findings fit remarkably well with data developed by Bearer and Orci, who determined that the presence of a diaphragm transected the 60-nm fenestrae into multiple channels of approximately 5 nm in diameter.

Whether permeability through fenestrae is a passive process or is facilitated by specific molecular interactions between components of the pore and traversing substances remains an open question. Although somewhat speculative, future studies in this area may benefit by examining the structure and function of the nuclear pore, a remarkably analogous structure consisting of two lipid bilayers fused to create a seamless circular opening. Transport of molecules between the cytoplasm and the nucleoplasm is chaperoned by proteins of the nuclear pore that first recognize specific export or import signals on potential cargo molecules and then act as shuttling factors in a process regulated by the GTPase, Ran. So far, selectivity within the fenestrae has only been shown with respect to molecular charge, as inferred from studies demonstrating the particularly high affinity of cationic substances for fenestral diaphragms.

Fenestrae and Organ Function

Although there is sparse direct evidence of a major physiological role for fenestrae, several functions can be safely attributed to them simply on the basis of their physical properties and their distribution within normal vasculature and during neovascular disease. Fenestrae are postulated to mediate the bidirectional exchange of water, solutes, and small macromolecules between blood and tissues. More specifically, fenestrae are believed to function (1) in the filtration of blood within the choroid plexus that gives rise to cerebrospinal fluid; (2) in the access of endocrine hormones to the bloodstream, such as the release of steroid hormones by the adrenal cortex; (3) in the supply of nutrients to, and removal of waste from, the outer retina by the underlying choriocapillaris; (4) in the ultrafiltration of blood to create primary urine within the kidney glomerulus; and (5) in the filtration of potentially hazardous substances in the blood at the liver sinusoids.

Fenestrae are also observed in normally nonfenestrated vascular beds in association with unwanted angiogenesis and other cardiovascular pathologies. The appearance of fenestrae in the neovasculature of tumors, retinal vessels in diabetic retinopathy, and capillaries of inflamed tissue, such as arthritic joints, coincides with clinical and experimental findings for vascular leakage and edema and implies that fenestrae contribute to the deregulation of vascular permeability. Fenestrae diameter has also been found to alter in conjunction with liver dysfunction, such as cirrhoses, and in kidney disease, such as pre-eclampsia.

Challenges for the Future

The lack of molecular tools, quantitative methods, and suitable model systems have slowed progress on fenestrae research and, to date, the bulk of our knowledge is still largely anecdotal and rich with assumption. A primary challenge for the future is to begin relating definitive functional properties of the fenestrae to the abundant ultrastructural information that has been collected over the past five decades. Recent advances in the fields of genomics and proteomics combined with the development of promising in vitro models for fenestrae formation are expected to open the way for (1) fascinating endothelial cell biology, (2) the potential to create light microscopic and biochemical methods to supplement ultrastructural analyses, and (3) the development of specific antagonists of fenestrae function to elucidate its contribution to cardiovascular function.

Glossary

Caveolae: Flask-shaped invaginations (50 to 100 nm in diameter) at the cell membrane implicated in endocytosis, cholesterol trafficking, and signal transduction. Also known as *plasmalemmal vesicles*.

Diaphragm: Variable feature of fenestrae and caveolae consisting of radial fibrils converging in a central knob. It is thought to consist of proteins, and its only known component to date is plasmalemmal vesicle 1 (PV-1) protein.

Fenestrae: Transcellular circular pores (60 to 70 nm in diameter) that occur in clusters in attenuated endothelia and are implicated in capillary permeability.

Vascular endothelial growth factor (VEGF): Growth factor expressed as several spliced variants and involved in vasculogenesis, angiogenesis, and vascular permeability.

CHAPTER 11

Neuropilins and the Vasculature

Roni Mamluk and Michael Klagsbrun

Departments of Surgical Research and Pathology, Vascular Biology Program, Children's Hospital and Harvard Medical School, Boston, Massachusetts

The development, patterning, and stabilization of the vasculature depends on several key steps, including the proliferation and migration of endothelial cells (EC) and the differentiation and recruitment of their supportive mural cells. These processes are regulated by the surrounding cells and tissues that secrete various growth factors, cytokines, and chemokines that activate EC receptors. It has been recently recognized that one of these EC receptors is neuropilin (NRP). Neuropilins (NRP1 and NRP2) are receptors for the vascular endothelial growth factor (VEGF) family, members of which are potent regulators of EC migration, EC proliferation, and angiogenesis. Previously, it was shown that VEGFs act via VEGF receptor tyrosine kinases, but it now appears that VEGF activity is also modulated by NRPs, which have no kinase activity. This article focuses on the role of NRPs in the vasculature and describes NRP structure, gene expression, regulation, and biological function.

Introduction

NRP1 and NRP2 are mediators of neuronal guidance and angiogenesis. NRPs bind members of the class 3 Semaphorin family, regulators of neuronal guidance, and members of the VEGF family of angiogenesis factors. Fujisawa and colleagues first identified NRP1 in 1991 as an adhesion molecule in developing nervous tissue; it was shown to be a 130- to 140-kDa highly conserved type 1 transmembrane glycoprotein. A second gene, NRP2, was identified in 1998 that had a 44 percent amino acid homology with NRP1.

A possible role of NRP1 in blood vessel development was first noted when NRP1 was overexpressed in mice. Besides ectopic sprouting and defasciculation of neurons, the mice also exhibited excess blood vessels. Subsequently, it was reported that NRP1 knockout mice exhibited various vascular abnormalities along with neuronal defects. The molecular connection of NRP1 to angiogenesis was noted when Klagsbrun and colleagues reported that VEGF, a major angiogenesis factor, was a ligand for NRP1 and NRP2.

Neuropilin Structure

Domains

NRPs are glycoproteins with a relatively large extracellular domain (860 amino acids), a transmembrane domain, and a relatively short cytoplasmic domain of about 40 amino acids. The extracellular domain consists of five subdomains, which are referred to as a1, a2, b1, b2, and c. The a1a2 and b1b2 domains are involved in ligand binding and cell adhesion. The c domain is thought to function as a site for homo- or hetero-dimerization of NRP1 and NRP2. The function of the short cytoplasmic domain, which is highly conserved, is not clear. A neuropilin interacting protein (NIP) has been identified that contains a PDZ domain. It binds to the C-terminal three amino acids of NRP1 (S-E-A-COOH).

In addition to full-length NRPs, some cell types express truncated NRP isoforms. These naturally occurring proteins contain only the a1a2 and b1b2 subdomains, are soluble, and are secreted by cells. The soluble NRP molecules are produced by premature truncation within introns and as a result are characterized by having intron-derived 3′ nucleotides and C-terminal amino acid sequences.

Neuropilin Binding Sites for Ligands

NRPs can bind multiple ligands, which can be categorized into three groupings: the class 3 semaphorins, the VEGF family, and various transmembrane proteins. Semaphorins have a sema domain that binds to the NRP a1a2

domain and an Ig-basic C-terminal domain that binds to the b1b2 domain. VEGF family members bind NRPs with a high degree of specificity. Placental growth factor-2 (PlGF-2), VEGF-B, and VEGF-E bind NRP1 but not NRP2. On the other hand, $VEGF_{145}$ and VEGF-C bind NRP2 but not NRP1. Domain binding sites have been determined for $VEGF_{165}$ and PlGF-2, both of which bind to the b1b2 domain. The binding sites of VEGF-B, VEGF-C, and VEGF-E on NRP have not been determined.

Heparin, which enhances both $VEGF_{165}$ and PlGF-2 binding to NRP1, binds the b1b2 domain. Heparin and heparan sulfate may play a critical role in EC NRP function by forming a complex of $VEGF_{165}$ or PlGF-2, NRP1b1b2, and heparin that facilitates ligand binding to NRP1. Because the b1b2 domain is a binding site for Sema3A, $VEGF_{165}$, and PlGF-2, there may be a structural basis for competitive inhibition of the different NRP1 ligands. For example, Sema3A competes $VEGF_{165}$-induced EC migration and $VEGF_{165}$ inhibits Sema3A-induced growth cone collapse, suggesting overlapping binding sites in the b1b2 domain.

The third category of NRP1 ligands are transmembrane proteins, including plexins A, L1, VEGFR-1, VEGFR-2, and heparan sulfate proteoglycans (HSPG). These bind to the NRP1 extracellular domain, but the subdomains involved have not yet been determined.

Endothelial Cell Neuropilin

Neuropilin Expression

Cultured EC express both NRP1 and NRP2. However, NRPs are expressed in vivo on specific EC types. For example, it has been demonstrated that there are differential embryonic blood vessel expression patterns for NRP1 and NRP2 in the avian vascular system. In the avian vasculature, NRP1 and NRP2 are both expressed in blood islands, which are the earliest vascular structures. However, once arteries and veins differentiate, NRP1 is expressed in arterial EC and in mesenchyme surrounding developing arteries, whereas NRP2 is expressed only in the venous EC. Similar expression patterns were reported in mice. In the developing mouse skin and retina, NRP1 is predominantly expressed in EC of arteries and arterioles. NRP2 expression was restricted to EC of veins at E10, but from E13 and on, NRP2 was downregulated in veins and highly expressed on lymphatic EC.

Neuropilin-Mediated VEGF Activity in Endothelial Cells

NRP1 appears to be a co-receptor for VEGFR-2 in cultured EC. When co-expressed in cells with VEGFR-2, NRP1 enhances the binding of $VEGF_{165}$ to VEGFR-2 and $VEGF_{165}$-mediated chemotaxis as compared to cells expressing VEGFR-2 only. Conversely, inhibition of $VEGF_{165}$ binding to NRP1 inhibits its binding to VEGFR-2 and its mitogenic activity for EC. $VEGF_{165}$ binds NRP1 via its exon 7–encoded peptide, whereas it binds VEGFR-2 via its exon 4–encoded peptide. $VEGF_{165}$ may form a bridge between the two receptors, facilitating a better presentation of $VEGF_{165}$ to VEGFR-2 (Figure 1). Support for this model was shown in immunoprecipitation studies where NRP1 and VEGFR-2 were co-immunoprecipitated only in the presence of $VEGF_{165}$. However, other reports have suggested that NRP1 can directly interact with VEGFR-2.

Semaphorin-Mediated Neuropilin Activity in Endothelial Cells

NRPs bind class 3 semaphorins, regulators of neuronal guidance. Semaphorin 3A (Sema3A), which is the best characterized semaphorin, repels axons, collapses dorsal root ganglion neuronal growth cones, and regulates migration of cortical neurons in an NRP1-dependent manner. These effects are mediated by small GTPases such as Rho A and Rac, which induce actin depolymerization. NRPs do not appear to directly activate signaling pathways in neurons. Instead, signaling is mediated by the interactions of a Sema3A/NRP1 complex with plexins, which are transmembrane signaling receptors. NRP1/plexin complex formation enhances Sema3A binding to NRP1. L1, a neuronal adhesion molecule, has also been demonstrated to be a component of the Sema3A receptor complex (Figure 1).

Sema3A binds EC via NRP1 and inhibits the motility of EC and capillary sprouting from rat aortic ring segments in an in vitro angiogenesis assay. The inhibition of EC motility by Sema3A is competed by $VEGF_{165}$. $VEGF_{165}$ and Sema3A are also antagonists in neuronal survival/apoptosis assays. Thus, a balance of semaphorins and $VEGF_{165}$ can modulate both EC and neuronal activities.

The role of semaphorins in vascular development has been analyzed in several models, and they have been shown to be regulators of vascular development. In chick limb development, overexpression or sequestering of Sema3A abrogated both vascular and neuronal patterning. In addition, it has recently been shown that in the chick embryo, EC express Sema3A, which autoregulates EC motility and vascular morphognesis via NRP1 and Plexin A1 complexes.

In zebrafish, semaphorins regulate the pathway of dorsally migrating angioblasts, which are NRP1-positive endothelial precursor cells that migrate to generate the dorsal aorta. Ubiquitous overexpression or knockdown of Sema3a1 protein interrupted dorsal migration of angioblasts and retarded development of the dorsal aorta, resulting in severely diminished blood circulation. Thus, Sema3a1 is a key regulator of early zebrafish vascular development.

In mice, however, transgenic studies seem to indicate that Sema3A does not play a role in regulating the vasculature. An initial report demonstrated that blood vessels developed normally in the limbs of Sema3A knockout mice. Consistent with this observation, transgenic mice overexpressing a

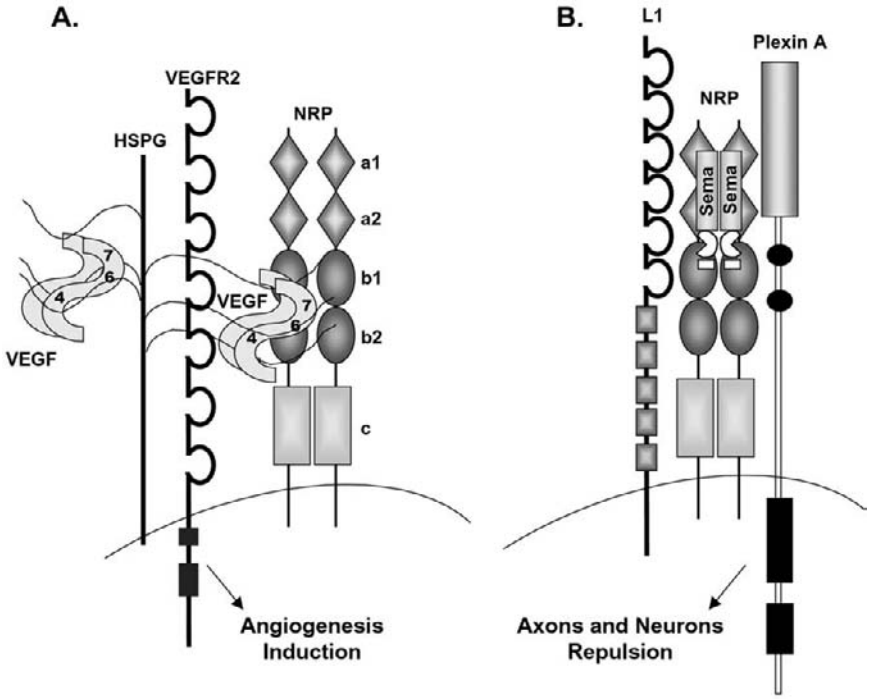

Figure 1 A Schematic of Neuropilin Signaling Complexes. **(A)** In this model, $VEGF_{165}$ bridges NRP1 (via axon 7) and the tyrosine kinase receptor VEGFR-2 (via exon 4). There are no direct NRP1/VEGFR-2 interactions. $VEGF_{165}$ and NRP1 also bind HSPG. The NRP1 binding site for $VEGF_{165}$ and HSPG is the b1b2 domain. It is suggested that the formation of a complex between $VEGF_{165}$ and the three receptors enhances $VEGF_{165}$ binding to VEGFR-2, which initiates the cellular signaling cascade, and as a consequence enhances $VEGF_{165}$ activity such as chemotaxis of endothelial cells and angiogenesis. **(B)** Sema3A binds to the a1a2 and b1b2 domains of NRP1. NRP1 binds to the transmembrane proteins plexin A and L1. The complex formation enhances the binding of Sema3A to NRP1, and subsequently plexin A induces the signaling events that lead to repulsion of axons and of neuronal cells.

mutated NRP1 that cannot bind Sema3A exhibited normal vasculature. On the other hand, in a different mouse background, Sema3A knockouts showed vascular defects in the head and had abnormal trunk blood vessels. These discrepancies as to whether Sema3A does or does not regulate the vasculature could be a result of the use of different developmental models and methodologies and will hopefully be reconciled in the future.

Neuropilin Function in Developmental Angiogenesis

Mice

There is strong evidence from transgenic mouse studies that NRPs mediate angiogenesis. Mice overexpressing NRP1 were embryonic lethal and displayed several vascular abnormalities, such as excess capillaries and blood vessels, dilation of blood vessels, hemorrhage, and malformed hearts. The chimeric embryos appeared redder than their normal counterparts, suggesting that blood vessels were leaky, which was possibly caused by enhanced vascular permeability activity of $VEGF_{165}$. It was concluded that expression of NRP1 was essential not only for neuronal development but also for development of the cardiovascular system.

The physiological role of NRPs in angiogenesis has also been determined using knockout mice. It was demonstrated that NRP1-deficient mutant mice were embryonic lethal between E12.5 to E13.5. In yolk sacs and embryos the vascular networks of large and small vessels were disorganized, the capillary networks were sparse, and normal branching did not occur. In the central nervous system (CNS), capillary invasion into the CNS was delayed and the capillary networks that were in the CNS were disorganized and had degenerated. The mutant embryos showed abnormal heart development, including lack of some of the branchial arch–related great vessels, and dorsal aorta and transposition of the aortic arch. The development of heart outflow tracts was also disturbed.

In another approach, the role of NRP1 in the vascular system was demonstrated by deleting NRP1 specifically from EC. Mutant mice were embryonic lethal by mid- to late gestation, with abnormal vasculature throughout the embryo. The larger vessels were intact, but medium and

small vessels were missing. In the developing brain the vessels appeared larger and underdeveloped with very little branching, suggesting a defect in remodeling and branching of the primary vessel plexus. Taken together all of these data indicate that NRP1 is a critical receptor required for angiogenesis. On the other hand, NRP2 knockouts were viable into adulthood and did not display any abnormal vascular development.

More recently, double NRP1/NRP2 knockouts were reported. Transgenic mice, in which both NRP1 and NRP2 were targeted, died in utero at E8.5 and their yolk sacs were totally avascular. Mice that were homozygous for one gene but heterozygous for the other were also embryonic lethal and survived to E10 to E10.5. The vascular phenotypes of these mice were abnormal. The yolk sacs, while of normal size, displayed the absence of branching arteries and veins, the absence of a capillary bed, and the presence of large avascular spaces between the blood vessels. The embryos displayed blood vessels that were heterogenous in size, large avascular regions in the head and trunk, and unconnected blood vessel sprouts. The embryos were about 50 percent the length of wild-type mice and had multiple hemorrhages. These double NRP1/NRP2 knockout mice had a more severe abnormal vascular phenotype than either NRP1 or NRP2 single knockout mice. Their abnormal vascular phenotype resembled those of VEGF and VEGFR-2 knockouts. It appears that NRPs are early genes in embryonic vessel development, with overlapping functions that are required for normal blood vessel formation.

Zebrafish

The zebrafish is an excellent system for analyzing vascular development. Zebrafish intersegmental vessels correspond to mammalian capillary sprouts, whereas the axial vessels correspond to larger blood vessels, such as arteries and veins (Figure 2A, control). The zebrafish NRP1 gene (*znrp1*) was isolated, and the zNRP1 protein was shown to be a functional receptor for human $VEGF_{165}$. Whole-mount in situ hybridization showed that transcripts for *znrp1* during embryonic and early larval development were detected mainly in neuronal and vascular tissues. Knockdown of zNRP1 by using specific antisense oligos (Morpholino) in embryos resulted in severe defects in angiogenesis, including impaired circulation in the intersegmental vessels and dorsal longitudinal anastomotic vessel (DLAV) (Figure 2). However, circulation via the trunk artery and vein axial vessels, which are formed by vasculogenesis, was not affected. When zNRP1 and VEGF morpholinos were co-injected into embryos at concentrations that individually did not significantly inhibit blood vessel development, the result was a potent inhibition of blood cell circulation via both intersegmental and axial vessels. These results demonstrated that VEGF and NRP1 act synergistically to promote a functional circulatory system. These results may provide a physiological demonstration that NRP1 regulates angiogenesis through a VEGF-dependent pathway.

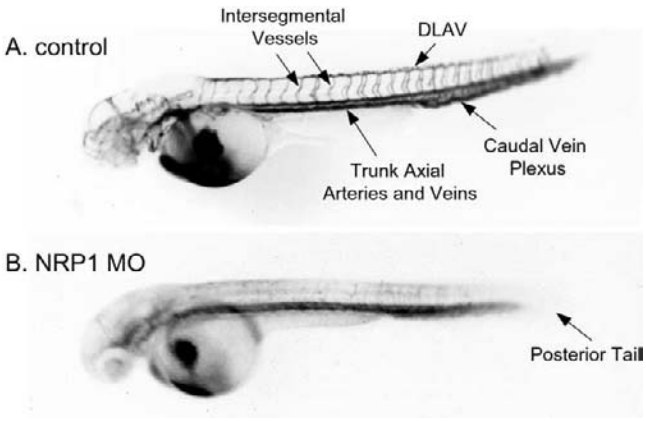

Figure 2 NRP1 Knockdown in the Zebrafish: Microangiography. Fish embryos were injected with antisense morpholino (MO) or controls at the one- to four-cell stage. To visualize blood vessels flow, FITC-dextran was injected into the cardinal vein 56 hours postfertilization. **(A)** Normal circulation of the zebrafish. Injected with the four-base mismatch morpholino control. **(B)** In zebrafish injected with anti-zNRP1 morpholino, blood flow via intersegmental vessels, DLAV, caudal vein plexus, and posterior vein is diminished. Axial vessel flow, however, is not affected.

Neuropilin in Pathological Angiogenesis

Tumor Angiogenesis

Many tumor cell types express NRP1 and NRP2 and bind $VEGF_{165}$. NRPs are the only VEGF receptors expressed by these tumor cells, so that any $VEGF_{165}$ activity must be mediated by NRPs. In several clinical studies, NRP1 and NRP2 expression was correlated with increased aggressiveness, malignancy, and/or hypervascularity. For example, NRP1 was upregulated in primary sporadic prostate tumors at different clinical stages. The correlation between NRP1 overexpression with advanced disease suggested that NRP1 overexpression might be a marker of aggressiveness.

The function of NRP1 in tumor cells has been analyzed directly by expressing NRP1 in tumor cells under the control of a tetracycline-inducible promoter. Concomitant with increased NRP1 expression in response to tetracycline, tumor cell migration and $VEGF_{165}$ binding was increased. However, induction of NRP1 did not affect tumor cell proliferation. When rats injected with rat prostate carcinoma cells were fed tetracycline, NRP1 synthesis was induced in vivo and tumor size was increased by up to sevenfold, compared to control. The tumors were characterized by markedly increased microvessel density, increased EC proliferation, dilated blood vessels, and notably less tumor cell apoptosis compared to noninduced controls. In addition, tumors overexpressing NRP1 retained higher levels of VEGF, possibly because of "trapping" by NRP1. It was concluded that NRP1 expression results in enlarged tumors associated with substantially enhanced tumor angiogenesis.

On the other hand, sNRP1 is a tumor antagonist. Tumors of rat prostate carcinoma cells overexpressing recombinant

sNRP1 in vivo were characterized by extensive hemorrhage, damaged vessels, and apoptotic tumor cells. Because sNRP1 inhibits ^{125}I-VEGF$_{165}$ binding to EC and VEGF$_{165}$-induced tyrosine phosphorylation of VEGFR-2 in EC in vitro, this tumor phenotype may be caused by VEGF$_{165}$ withdrawal and lack of bioavailability. Withdrawal of VEGF$_{165}$ from tumors has previously been shown to result in vascular damage, EC apoptosis, hemorrhage, and extensive tumor necrosis.

Vascular Injury and Disease

NRPs are more highly expressed in the developing embryo as compared with the normal adult, but are induced following injury such as ischemia. Several pathologies that are characterized by ischemia-induced angiogenesis have shown NRP1 upregulation. For example, in the adult mouse, NRP1 expression in ischemic brain was significantly upregulated as early as two hours and persisted at least 28 days after focal cerebral ischemia. There was a marked increase in NRP1 expression in EC of cerebral blood vessels at the border and in the core of the ischemic lesion after seven days. These results suggest that upregulation of NRP1 may contribute to neovascular formation in the adult ischemic brain. In another mouse ischemia model system, very little NRP2 expression was observed in normal blood vessels after birth. However, NRP2 expression was induced in newly sprouting blood vessels in response to ischemia in a hind limb model in which the femoral artery was occluded. Increased NRP1 expression was also detected in pathological retinal neovascularization induced by ischemia. In this case, expression of NRP1 and VEGFR-2 was co-localized in the area of neovascularization.

Summary

Substantial evidence based on cell culture and transgenic mouse studies indicates that NRPs are novel and significant regulators of blood vessel development. During embryonic development, NRP expression occurs early, in the blood islands of the yolk sac. NRP expression is required for the normal branching and organization of large vessels and capillaries in the developing embryo. In the developing heart, NRP1 is required for normal formation of the large vessels. In the adult, NRP expression is generally reduced, but it is strongly upregulated in blood vessels in response to vascular injury. Tumor cells are among the highest expressers of NRPs, and overexpression of NRP1 enhances tumor angiogenesis and progression. The significance of direct VEGF binding to tumor cells is unknown but might involve enhancement of tumor cell migration and survival. On the other hand, whereas overexpression of full-length NRP1 in tumor cells enhances tumor angiogenesis, overexpression of sNRP1 suppresses it.

It is now well established that NRPs are crucial for vascular development and angiogenesis. In the future, goals will include determining the molecular mechanisms by which NRP regulates EC functions and elucidating the role of NRPs in normal physiology and in pathology.

Glossary

Angiogenesis: The formation of new blood vessels that sprout from preexisting blood vessels.

Axonal guidance: Also know as *axonal pathfinding* and *neuronal guidance*. The process by which neuronal axons move to their destinations in response to chemorepellants and chemoattractants, such as the semaphorins.

Vasculogenesis: The formation of blood vessels from endothelial cell precursors, for example, arteries and veins.

Capsule Biography

Dr. Klagsbrun is a professor in the Vascular Biology Program at Children's Hospital Boston and Harvard Medical School. He is well known for his work on vascular growth factors and their receptors. His studies on vascular molecules such as basic FGF, HB-EGF, neuropilin, and semaphorin have greatly furthered our understanding of how the vascular system is regulated and how tumor growth may be inhibited. His work is supported by grants from the National Cancer Institute.

Dr. Mamluk completed her post doctorate in the laboratory of Professor Klagsbrun. She focused her research on understanding the role of neuropilins, soluble NRPI and VEBFR-2 in vascular function and development. Currently she is conducting research for a biotechnology company aimed at developing new protein therapeutics to inhibit tumor angiogenesis.

CHAPTER 12

Receptor Tyrosine Kinase Signal Transduction in the Microvasculature

Marie B. Marron and Nicholas P. J. Brindle
Department of Cardiovascular Sciences, University of Leicester, United Kingdom

Introduction

Receptor tyrosine kinases (RTKs) have essential roles in the formation, maintenance, and function of the microvasculature. Vasculogenesis and angiogenesis, involving differentiation, migration, proliferation, and survival of endothelial cells, as well as microvascular regression, inflammation, and permeability are all controlled by RTK signaling pathways. Being able to understand how these pathways work will provide new opportunities for therapeutic manipulation of the microvasculature relevant to a wide range of diseases, from inflammatory diseases to tumor growth and tissue ischemia. In this chapter, signaling pathways utilized by four of the key families of RTKs of the microvasculature are outlined. Because of space constraints, we have focused on RTKs in the endothelium. Signaling pathways controlling the specialized functions of the microvasculature are best studied in the physiologically appropriate cell types. Although data from nonvascular cells can be extremely valuable in guiding understanding, such cells may lack key components of signaling or effector pathways, co-receptors, and signaling cross-talk important in the mechanisms by which the RTKs exert their effects in vascular cells. We have, therefore, focused on RTK signaling pathways demonstrated in endothelial cells rather than extrapolated from findings in nonvascular cells.

RTKs are activated by ligand-induced clustering. This permits transphosphorylation of regulatory tyrosine residues in the RTKs, activating kinase activity and inducing phosphorylation of additional tyrosine residues. These phosphotyrosines act as docking sites for SH2 and PTB domains in intracellular signaling molecules, leading to their recruitment to the RTKs. Such signaling molecules may then become activated by phosphorylation or protein-to-protein interactions and initiate a signaling cascade linking the RTK to effector mechanisms. In the following sections, these signaling cascades are reviewed with respect to the microvasculature. Where amino acid numbers are given, they refer to positions in the human sequences.

Signaling by VEGF Receptors

The vascular endothelial growth factors (VEGFs) have central roles in initiating blood vessel formation by both stimulating angioblast differentiation and activating angiogenesis from existing vessels. There are six members of the VEGF ligand family: VEGF-A to VEGF-E and placental growth factor (PlGF). These ligands signal via three VEGF-RTKs: VEGF-receptors-1 to 3. VEGF-A is the predominant form of the ligand and can bind all three receptors, whereas PlGF and VEGF-B recognize only VEGFR-1, and VEGF-E is specific for VEGFR-2. VEGF-C and D bind VEGFR3 and to some extent VEGFR2. All three RTKs have a similar overall structure, with a ligand binding extracellular domain containing seven immunoglobulin-like repeats and intracellular domain comprising a juxtamembrane sequence, tyrosine kinase domain with kinase insert, and carboxy-terminal tail. VEGFR-3 is mainly confined to lymphatic endothelia, where it has important roles in lymphangiogenesis. The

principal VEGF-RTKs of the microvasculature are VEGFR-1 and VEGFR-2, which are the focus of this section. Because most endothelial cells express both VEGFR-1 and -2, defining the specific roles and signaling events mediated by each receptor in response to VEGF has been challenging. One way to address this issue has been by overexpression of chimeric receptors, allowing specific activation of each receptor, or the expression of each receptor individually in cells that do not normally express VEGFRs. Such approaches are useful, but care is required in extrapolating to the situation in primary endothelial cells expressing physiological levels of receptors. Some of the discrepancies reported in signaling by VEGFRs may be a result of these limitations.

VEGFR-1 Signaling

Of the two microvessel VEGF-RTKs, VEGF-A binds with highest affinity to VEGFR-1. However, this receptor appears to have relatively low kinase activity, and VEGF-A-activated increase in kinase activity or autophosphorylation of VEGFR-1 is difficult to detect in endothelial cells. One function of the receptor may therefore be to act as a negative regulator of VEGF-A activity by sequestering the ligand and preventing it from activating VEGFR-2.

In addition to any role in regulating VEGF-A availability, VEGFR-1 does have signaling activity. Transgenic mice expressing a truncated form of VEGFR-1, lacking the intracellular domain, exhibit normal developmental angiogenesis but have compromised pathological angiogenesis, indicating involvement of the intracellular VEGFR-1 signaling domain. VEGFR-1-specific ligands also activate distinct patterns of gene expression, again consistent with the receptor having discrete signaling activity. The signaling pathways utilized by VEGFR-1, however, are poorly understood. Phosphorylation has been observed in baculovirus expressed intracellular domains of the receptor and in cells overexpressing VEGFR-1 in response to VEGF-A. The principal phosphorylation sites identified in these studies were Y1169, Y1213, and Y1333. VEGF-A activation of nonoverexpressing endothelial cells increases Y1213 phosphorylation. PLCγ, Nck, and Crk bind to phosphopeptides containing the Y1333 site, and SHP2, phospholipase Cγ (PLCγ), and Grb_2 bind to Y1213 phosphopeptides. Increased tyrosine phosphorylation of PLCγ, Crk, and SHP_2 has also been observed in response to VEGF-A stimulation in cells overexpressing VEGFR-1. These data suggest that the receptor could modulate Ca^{++}/DAG (via PLCγ) and Ras/Raf pathways (via SHP_2/Grb_2), although more work is necessary to establish interaction of the receptor with these intermediates in endothelial cells expressing physiological levels of receptor in their normal cellular background.

VEGF-A and the VEGFR-1-specific ligand PlGF appear to have some distinct effects on VEGFR-1 in endothelial cells expressing normal levels of the receptor. The two ligands induce different patterns of gene expression and activate phosphorylation of different tyrosine residues in the receptor. In contrast to the effects of VEGF-A on Y1213, PlGF activates phosphorylation of Y1309. The signaling and functional consequences of Y1309 phosphorylation have yet to be defined. Such differential effects of ligands on the receptor provide a means for distinct activities of the ligands on endothelial cells and raise the important question of the mechanism for ligand-specific phosphorylations in VEGFR-1.

There is cross-talk between VEGFR-1 and VEGFR-2. Specific activation of VEGFR-1 by PlGF enhances VEGF-A-activation of VEGFR-2 by a mechanism involving transphosphorylation of VEGFR-2 by VEGFR-1. The two receptors exist as homomeric complexes and preformed heteromeric complexes in endothelial cells.

In summary, VEGFR-1 has apparently low kinase activity and can act to sequester VEGF-A and regulate signaling by VEGFR-2. Specific ligands for VEGFR-1 can modulate signaling via VEGFR-1 by displacing sequestered VEGF-A and enhancing VEGFR-2 activity by transphosphorylation. Such activities are likely to be involved in the enhancement of VEGF-induced angiogenesis by PlGF. In addition, VEGFR-1 does have distinct signaling capability responsible for regulating specific gene expression profiles, and probably other effects in endothelial cells.

VEGFR-2 Signaling

The limited ability to detect VEGFR-1 activation has led to the suggestion that the principal receptor mediating the effects of VEGF-A in endothelial cells is VEGFR-2. The receptor has been implicated in VEGF-induced endothelial migration, proliferation, and differentiation, as well as the pro-inflammatory and permeability effects of the ligand. Reported sites of tyrosine phosphorylation in VEGFR-2 include Y951, Y996, Y1054, Y1059, Y1175, and Y1214. Of these, Y1175 and Y1214 appear to be primary sites of phosphorylation, and Y1175 has been confirmed in endothelial cells expressing physiological levels of receptor.

Specific activation of VEGFR-2 in nonoverexpressing endothelial cells provides an antiapoptotic signal requiring phosphatidylinositol-3-kinase (PI-3K) and Akt. The activity of Akt is stimulated by VEGF in endothelial cells in response to VEGFR-2-specific ligands, and PI-3K and Akt are both activated via VEGFR-2 in cells overexpressing the receptor. The precise way in which PI-3K is activated by VEGFR-2 is not clear, but in some studies the receptor was found to associate directly with the p85 subunit of PI-3K (pY801, pY1175), whereas in others p85 was bound to focal adhesion kinase (FAK) recruited to pY1214 of VEGFR-2, or VEGFR-associated protein (VRAP), which is recruited to pY951. Intriguingly, the antiapoptotic activity of VEGF appears to involve the interendothelial adhesion molecule VE-cadherin. In cells from mice lacking the intracellular domain of VE-cadherin, coupling between VEGFR-2 and Akt is impaired and interaction between VEGFR-2 and p85 is decreased. Further work will be required to define the

mechanism by which VE-cadherin modulates VEGFR-2 association with p85.

The signaling pathway by which VEGF induces endothelial migration via VEGFR-2 is unclear. The pathway is likely to involve FAK and PLCγ, both of which interact with VEGFR-2 and have been implicated in VEGF-stimulated endothelial migration in studies using mutant receptors and inhibitors. VEGF activation of endothelial proliferation occurs via a signaling pathway involving VEGFR-2 activation of PLCγ following its recruitment to pY1175. The resulting generation of diacylglycerol (DAG) activates protein kinase C (PKC), which in turn stimulates Raf and the Erk pathway.

VEGF markedly increases vascular permeability, and use of receptor-specific ligands indicates this is mediated via VEGFR-2. Again, however, the signaling mechanisms involved are not yet understood. There is good evidence that PLCγ-mediated DAG generation and Ca^{++} mobilization contribute to increased nitric oxide (NO) generation, leading to elevation of cGMP and increased vascular permeability. In addition, Akt, activated via VEGFR-2 as described previously, has also been implicated. One action of the Akt is to phosphorylate endothelial nitric oxide synthase (eNOS) on serine1177 and increase NO production. The PLCγ pathway appears to predominate in the first few minutes of VEGF-induced vessel permeability, after which the Akt pathway becomes more important. The downstream events mediating the effects of cGMP on permeability have yet to be clearly defined. The lack of effects of VEGF on vascular permeability in transgenic mice lacking p60Src and p62Yes indicate that these members of the Src family of intracellular tyrosine kinases also participate in the permeability signaling pathway, although exactly how is not yet known. Acute increased permeability of microvessels in response to VEGF can occur through formation of fenestrae, which is stimulated by VEGF, and increased transcellular flux. Clear definition of the mechanisms by which fenestrae form and transcellular flux increases will allow delineation of the missing links between the VEGFR-2-NO signaling pathway and increased permeability. Figure 1 summarizes in schematic form some of the best elucidated VEGFR-2 signaling pathways.

Signaling by FGF Receptors

There are more than 20 FGFs, and the best studied of these are FGF-1 and FGF-2. The FGFs signal via four FGF RTKs, FGFR-1 to FGFR-4, and variants of these receptors arise by alternative splicing. These receptors have a similar overall structure, with extracellular domains containing two or three immunoglobulin repeats and an alternatively spliced sequence rich in acidic residues and serines, the acidic box. The intracellular domains comprise a juxtamem-

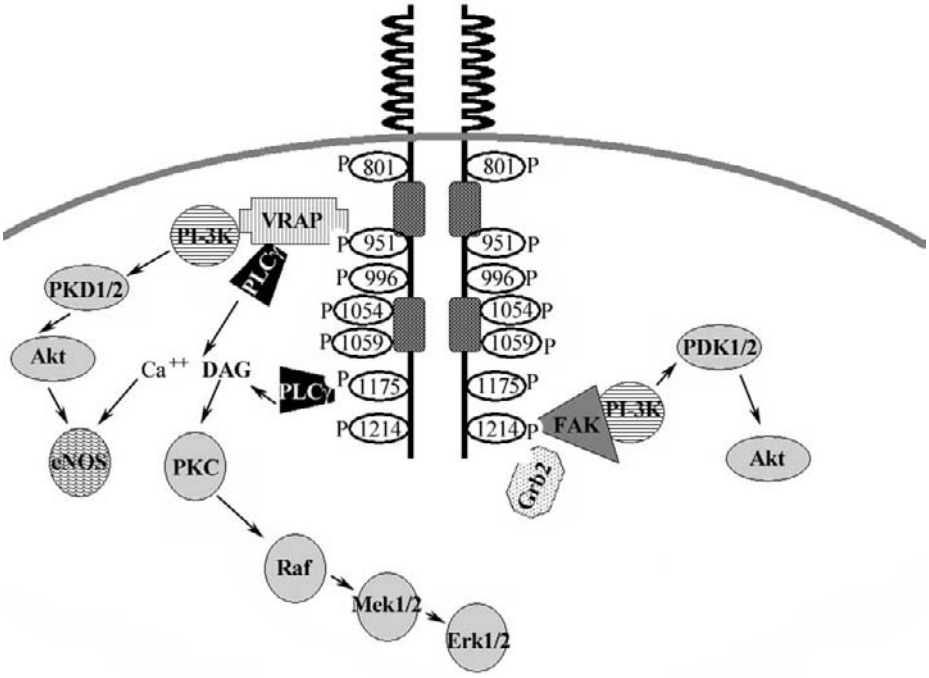

Figure 1 Overview of VEGFR-2 Signaling. Schematic representation of VEGFR-2 illustrating main sites of tyrosine phosphorylation. Shaded boxes in the intracellular portion of the receptor denote the kinase domain. Signaling intermediates, PLCγ, Grb2, FAK, and VRAP, known to interact with VEGFR-2, are shown adjacent to the phosphotyrosine residues to which they bind. Arrows indicate downstream pathways reported in endothelial cells to be initiated from signaling molecules recruited to VEGFR-2. VEGFR-2-activated PLCγ acts on phosphatidylinositol 4,5-bisphosphate to generate DAG and the Ca^{++} mobilizing second messenger inositol 1,4,5-trisphosphate (IP_3). Increased intracellular Ca^{++} may also occur via an IP_3-independent route.

brane region, tyrosine kinase domain with kinase insert, and carboxy-terminal tail. In contrast to the VEGFR family, receptors for FGF are expressed by a wide range of cell types. FGFR-1 has been shown clearly to have a role in microvessel formation and maintenance. FGFs stimulate endothelial proliferation, migration, and organization into capillary tubes.

Activation of FGFR-1 results in phosphorylation of the juxtamembrane Y463, Y583/585 in the kinase insert, Y653/654, Y730, and in the carboxy-tail Y766. Several signaling pathways are activated by FGFR-1, including the PI-3K pathway and stimulation of Src family kinases. The best-elucidated pathways are those leading to PKC activation and ERK1/2 stimulation, linking FGFR-1 to endothelial proliferation. Phosphorylation of Y766 is important for both of these pathways. This phosphotyrosine provides a site for recruitment and activation of PLCγ, leading to generation of inositol 1,4,5-trisphosphate (IP_3) and DAG with subsequent PKC stimulation.

FGFR-1 is linked to the Ras/ERK1/2 pathway and proliferation via a multisubstrate adaptor FRS2. In some studies, this adaptor has been found constitutively associated with the juxtamembrane region of FGFR-1 via the FRS2 PTB domain, although in a phosphotyrosine-independent manner. Activation of FGFR-1 results in markedly increased phosphorylation of FRS2, creating recruitment sites for Grb2 and Shp2. Grb2 is associated with the guanine nucleotide exchange factor SOS that activates Ras, thereby initiating the Raf/ERK1/2 cascade. In endothelial cells, stimulation of FRS2 phosphorylation by FGFR-1 requires the adaptor protein Shb that binds to phosphorylated Y766 in FGFR-1. This adaptor does not interact directly with FRS2 but associates with Shp2, providing an indirect link. Further work will determine the mechanism by which Shb mediates FGFR-1 phosphorylation of FRS2. These signaling events are illustrated in Figure 2. Additional, undefined pathways exist in endothelial cells for FGFR-1 activation of the ERK1/2 pathway.

In several cell types, the adaptor protein Gab1 is recruited to FGFR-1-activated FRS2 via its interaction with the SH3 domain of Grb2. FGFR-activated phosphorylation of Gab1 then creates a binding site for the SH2 domain of the p85 regulatory subunit of PI-3K, resulting in activation of PI-3K and Akt. Although not yet directly demonstrated, it is likely that a similar pathway is responsible for the FGF-activation of PI-3K/Akt in endothelial cells.

The Ephs and Ephrins

The Eph family of RTKs comprise 15 members. They are activated by ligands, the ephrins (of which there are 9), which are cell surface bound. This system functions in short-range cell-to-cell communication. The ephrins are

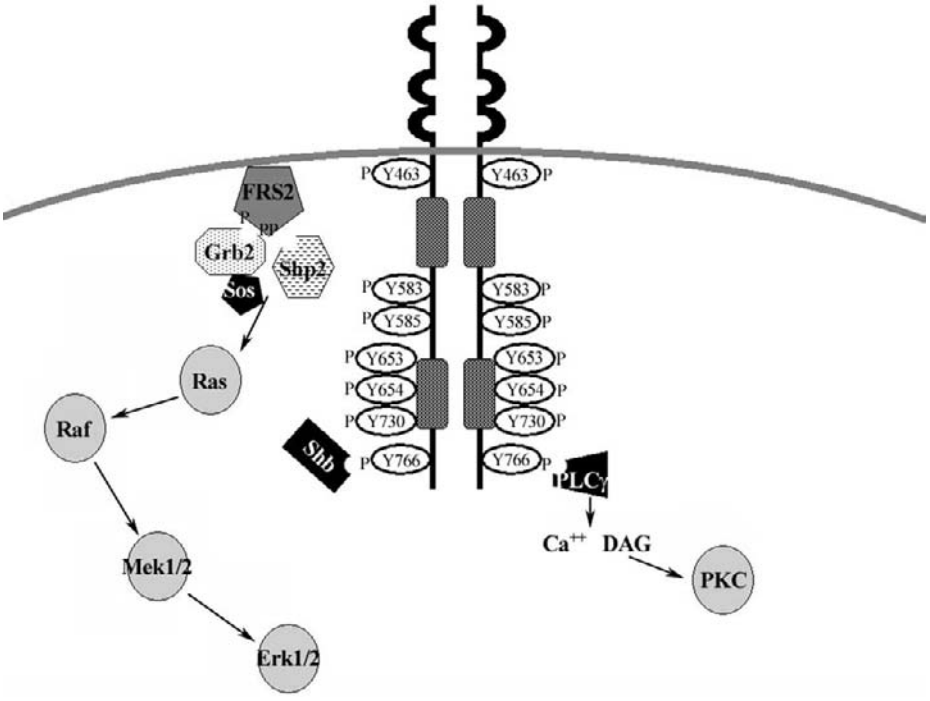

Figure 2 FGFR-1 Signaling in the Endothelium. This schematic figure shows the main tyrosine phosphorylation sites in FGFR-1. Shaded boxes in the intracellular portion of the receptor denote the kinase domain. Signaling intermediates are shown adjacent to phosphotyrosine residues to which they bind. The adaptor protein FRS2 may be constitutively associated with the juxtamembrane region of FGFR-1. Maximal phosphorylation of FRS2 requires binding of Shb to pY766. Shp2 has been found to be constitutively associated with Shb and may act to link Shb with FRS2 phosphorylation. The pathways shown are those for which clear evidence exists in endothelial cells.

divided into two subtypes: (1) those bound to the cell surface by glycosylphosphatidyl inositol (GPI) linkages, class A ephrins, and (2) those with transmembrane domains, class B ephrins. Two subtypes of Eph have also been defined, generally EphAs bind class A ephrins and EphBs class B ephrins. EphB2, EphB3, and EphB4 as well as the ligands ephrinB1 and ephrinB2 have been implicated in microvessel formation. Transgenic mice deficient in EphB4 or ephrinB2 have defects in vasculogenesis and compromised angiogenic remodeling. Deficiency of EphB2 and EphB3 also results in defective vessel remodeling, although because of some functional compensation, the single knockouts do not have a defective vascular phenotype. These phenotypes are consistent with the known involvement of the Eph/ephrin system in regulating cellular repulsion, adhesion, and migration. The broadly reciprocal expression of EphB4 in venous endothelium and its ligand ephrinB2 in arterial endothelium suggest involvement in suppression of mixing between the two cell types, again in accord with roles in regulation of adhesive and repulsive interactions.

The Eph receptors all possess a glycosylated extracellular region consisting of an N-terminally located ligand-binding site, a cysteine-rich domain, and a dimerization motif contained within two fibronectin III–like repeats. The intracellular region follows the single transmembrane spanning domain and consists of a juxtamembrane region and a single tyrosine kinase domain, each of which contain tyrosines that when phosphorylated act as docking sites for downstream signaling molecules. The C-terminus has a PDZ binding motif to which PDZ motif containing proteins bind. These may act as scaffolds for the assembly of multiprotein signaling complexes at the membrane. There is a sterile alpha motif (SAM) domain just before the C-terminus, which may regulate dimerization of the receptors.

The membrane-bound ephrin ligands present in a clustered state to the Eph receptors. The extent of clustering may determine the level of activation of the Eph receptor. Importantly, the ephrins also have signaling capacity, and the class B ligands become tyrosine phosphorylated on binding their receptors. Thus, both EphB receptors and ephrin-B ligands are involved in bidirectional signaling.

Eph/Ephrin Signal Transduction

A large number of adaptor proteins, namely, SLAP, Grb2, Grb10 Crk, and Nck, together with cytoplasmic signaling proteins such as RasGAP, Src, Abl, LMW-PTP, PLCγ, and PI-3K, have been shown to interact with Eph receptors and their ligands in studies on patterning in the nervous system. These studies have established Eph/ephrin signaling in controlling neural cell morphology and architecture, attachment, and motility. In contrast, very little is known about Eph/ephrin signaling pathways in the endothelium and microvasculature. However, the adaptor protein Crk has been strongly implicated in ephrinB1-induced membrane ruffling and focal complex assembly in endothelial cells. EphrinB1 induces phosphorylation of EphB1 in human endothelial cells and activates both Rac1, resulting in membrane spreading, and Rap1, which mediates stabilization of focal complexes. These events depend on the adaptor function of Crk, which has been shown to associate with Ephs following their activation in other cell types. Ephrin-B1 transduces signals to modulate integrin-mediated cell attachment and migration in endothelial cells and promotes angiogenesis in vivo, although the signaling pathway has yet to be clearly defined. EphB2 and EphB4 have been shown to recruit p120RasGap on activation and suppress VEGFR- and Tie2-mediated endothelial migration, but again further work will be required to establish the precise signaling cascades involved.

Signaling by the Tie Receptor Tyrosine Kinases

The Tie family comprises two members: Tie1 and Tie2. Both of these RTKs are essential for blood vessel formation and maintenance. There have been no ligands yet identified for Tie1, and relatively little is known about the cellular functions and signaling pathways utilized by this receptor. Tie1 does inhibit endothelial apoptosis and promote vessel survival. Several ligands, the angiopoietins, have been identified for Tie2. Of these, angiopoietin-1 (Ang1) and angiopoietin-2 (Ang2) have been best characterized. Ang1 is an activator of Tie2, and Ang2 can activate Tie2 or antagonize the effects of Ang1 depending on the cellular context. Tie2 inhibits endothelial death, promotes endothelial migration, suppresses microvessel regression, inhibits vascular inflammation, and promotes microvessel integrity.

Structurally, Tie1 and Tie2 share several key features. The extracellular domain consists of two immunoglobulin-like domains separated by three epidermal growth factor motifs and followed by three fibronectin III–like repeats. Intracellularly, the receptors each contain a tyrosine kinase domain interrupted by a kinase insert region.

Tie1 Signaling

Studies examining Tie1 signaling have utilized chimeric receptors in which the extracellular domain of Tie1 is replaced by that of a receptor with known ligand. Using this approach, Tie1 exhibits a very limited ability to undergo phosphorylation and appears to have a low kinase activity in comparison with Tie2. Nevertheless, the receptor does interact with the adaptor Shp2 and the p85 subunit of PI-3K. The latter interaction initiates an antiapoptotic signaling cascade via Akt. Tie1 also interacts with Tie2, and a pool of preformed Tie1:Tie2 hetero-oligomers exist in endothelial cells.

Tie undergoes regulated ectodomain cleavage in which the extracellular domain of the receptor is proteolytically released. This generates an intracellular fragment containing the tyrosine kinase domain. This fragment may have

signaling functions. Ectodomain cleavage of Tie1 is stimulated by VEGF.

Tie2 Signaling

Several phosphorylation sites have been identified in Tie2, including Y992 in the activation loop of the kinase and Y1102, Y1108, and Y1113 in the carboxy-terminal tail of the receptor. Y1108 has been confirmed as a phosphorylation site in Ang1-activated endothelial cells. Ligand-activated phosphorylation of Y1108 results in recruitment of the multiple adaptor protein Dok-R and its tyrosine phosphorylation. This recruitment entails localization of Dok-R to the membrane via interaction of Dok-R PH domain with membrane phosphoinositide lipid products generated by PI-3K, and binding of the adaptor to pY1108 via its PTB domain. Maximal activation of Dok-R tyrosine phosphorylation by Tie2 therefore depends on Y1108 phosphorylation and activation of PI-3K. Phosphorylated Dok-R recruits the adaptor Nck and p21-activating kinase (Pak) that constitutively associates with it. Pak activity is stimulated in this complex of Tie2/Dok-R/Nck/Pak. This cascade mediates Tie2-stimulated endothelial motility.

The antiapoptotic activity of activated Tie2 is mediated via the PI-3K/Akt pathway. Phosphorylation of Y1102 on Tie2 creates a binding site for the p85 subunit of PI-3K. This leads to activation of PI-3K and Akt and suppression of apoptosis. Tie2 activation also stimulates tyrosine phosphorylation of FAK, and this depends on PI-3K activity. Other signaling intermediates have been reported to interact with phosphorylated Tie2, including Grb2, ShP2 Grb7, and Grb14. Further work will be required to delineate the precise involvement of these molecules in Tie2 activity. Tie2 also recruits the NFκB regulatory protein ABIN-2. This recruitment is dependent on Tie2 phosphorylation and is activated by Ang1 in endothelial cells. Interaction between Tie2 and ABIN-2 appears important in the anti-inflammatory effects of Tie2, although the signaling pathway involved has yet to be clearly defined. Tie2 signaling pathways are summarized in Figure 3.

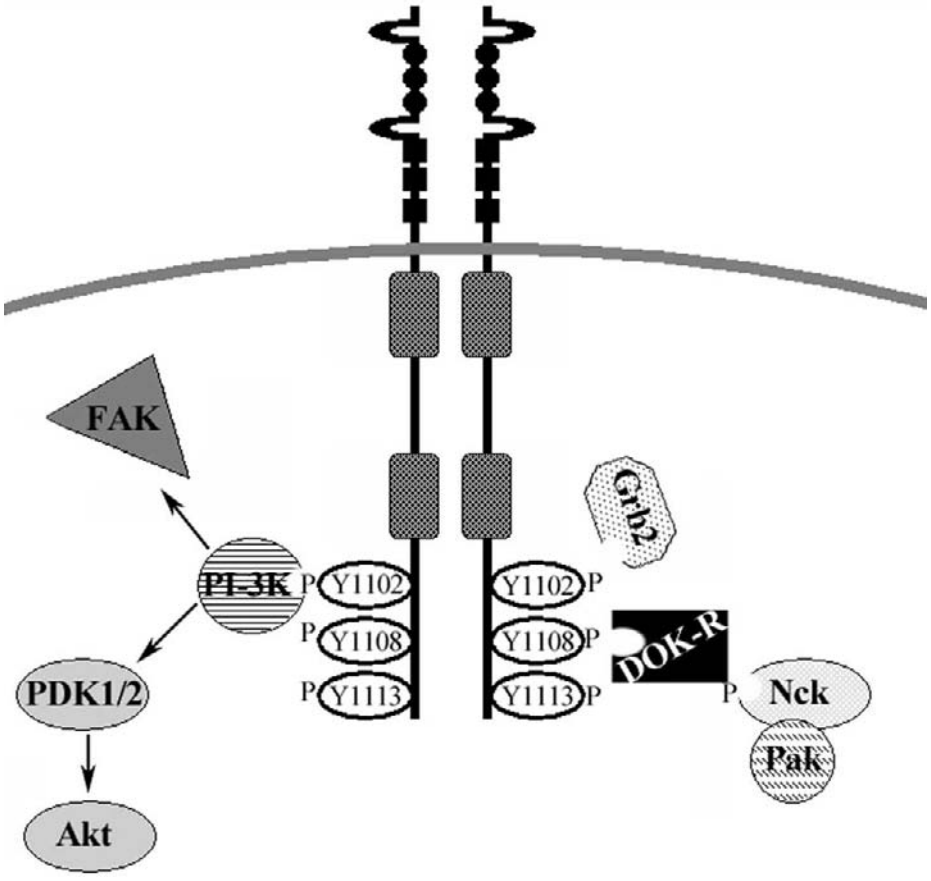

Figure 3 Tie2 Signaling Pathways. In this schematic figure, the three main phosphorylation sites in the carboxy-terminal of Tie2 are shown together with signaling intermediates reported to interact with the receptor. Shaded boxes in the intracellular portion of the receptor denote the kinase domain. Optimal DOK-R recruitment requires interaction with pY1108 in Tie2 via the DOK-R PTB domain and membrane localization via DOK-R PH domain binding to phosphoinositide lipid products generated by PI-3k action. Tie2-mediated phosphorylation of DOK-R provides a recruitment site for Nck binding. Pak is constitutively associated with Nck. Other intermediates have been found to bind Tie2 in a phosphotyrosine-dependent manner; however, their roles in Tie2 action and downstream Tie2-initiated signaling cascades have yet to be defined in endothelial cells.

Conclusion

Despite the importance of RTK signal transduction cascades in microvessel development and function, it is clear that there are large gaps in our understanding of these cascades in microvascular cells for each of the RTKs reviewed. A more comprehensive knowledge of events at the receptor, downstream pathways, and linkage with effector mechanisms is needed for each of the microvascular RTKs. Important questions also remain on the specificity of signaling cascades in the microvasculature, how different RTKs can activate the same signaling pathway but have different effects on the cell. For example, VEGF and Ang1 both activate the Akt pathway, but VEGF stimulates proinflammatory gene expression and Ang1 suppresses this via a mechanism that requires Akt activation. Differences in spatial, temporal, and quantitative aspects of signal cascades as well as the profile of signaling events elicited by each receptor is likely to underlie some of the specificity in signaling. The cell is required to integrate many signals into the physiological setting. An important challenge is to understand how the different RTK signaling pathways coordinate, both with each other and with non-RTK pathways. Such coordination is likely to involve interactions between cascades within the cell as well as regulation at the level of ligand and receptor. For example, VEGF impacts Tie signaling by inducing proteolytic cleavage of Tie1, and heterooligomeric complexes of VEGFR1:VEGFR2 and Tie1:Tie2 provide mechanisms for cross-talk between receptors of the same family. The specialized functions and architecture of the microvasculature provide an opportunity to gain fundamental insights into mechanisms of signal transduction and how they regulate tissue morphogenesis and maintenance. Such insights may provide new strategies for treatment of ischemic disease, cancer, and inflammatory conditions.

Glossary

Adaptor protein: (also called adapter protein): A protein that can act as a binding intermediate. Adaptor proteins bind to one protein, for example an activated receptor, and provide binding sites for the recruitment of other proteins.

Autophosphorylation: The phosphorylation of a protein by itself. Receptor tyrosine kinases are said to undergo autophopshorylation following ligand activation. In fact, ligand binding enhances RTK dimerization or oligomerization, allowing individual RTKs within the complex to be phosphorylated by other RTKs also in the complex (transphosphorylation).

PTB domain: Phosphotyrosine binding domains are between 100 and 170 amino acids and bind phosphotyrosine, usually flanked by an asparagines-proline-X amino peptide. PTB domains in some proteins appear to have broader binding specificity, including nonphosphorylated sequences.

SH2 domain: SH2 domains comprise approximately 100 amino acids and bind phosphotyrosine-containing peptides. The specificity of SH2 binding is determined by the amino acid residues flanking the phosphorylated tyrosine.

SH3 domain: A protein module binding proline-rich peptides.

CHAPTER 13

Eicosanoids and the Pulmonary Microvasculature

Ivan M. Robbins and Brian W. Christman

Department of Medicine, Division of Allergy, Pulmonary and Critical Care Medicine, Vanderbilt University School of Medicine, Tennessee

Introduction

All cell membranes, including those of the pulmonary endothelium, are composed in large part of phospholipids structurally derived from glycerol. In addition to serving a barrier function, these compounds are metabolized by a family of phospholipases, which liberates precursors of biologically active compounds that act in both an endocrine and paracrine fashion to alter physiologic responses. These phospholipids are enriched in the sn-2 position with arachidonic acid, a 20-carbon alkane with four double bonds. Metabolism of arachidonic acid proceeds by oxygen insertion catalyzed by several different enzyme families, including cyclooxygenase 1 (COX-1) and cyclooxygenase 2 (COX-2), yielding an unstable intermediate prostaglandin (PG) H2. Further metabolism of this compound depends on the complement of available enzymes in a given cell type (e.g., prostacyclin synthetase in endothelial cells and thromboxane synthase in platelets), but can result in formation of a variety of prostaglandins, including PGD_2, PGE_2, $PGF_{2\alpha}$, prostacyclin (PGI_2), and TxA_2. In the vascular bed of the lung, the predominant prostaglandins made by vascular endothelium are prostacyclin and PGE_2. Smooth muscle cells in lung vessels are net producers of both thromboxane A_2 and prostacyclin.

It is also possible for arachidonic acid to be metabolized by lipoxygenases (yielding leukotrienes and lipoxins) and specific cytochrome P450 enzymes [yielding epoxyeicosatrienoic acids (EETs), and stereospecific hydroxyeicosatetraenoic acids, (HETEs)]. Alternately, during situations of enhanced oxidant stress, reactive oxygen species can directly interact with arachidonic acid esterified to membrane phospholipids to form isoprostanes (IsoPs), compounds analogous to prostaglandins but with different stereochemistry (Figure 1). All of these molecules derived from arachidonic acid are known as *eicosanoids*.

In vitro studies document that specific enzymes critical for synthesis of unique prostaglandins and leukotrienes are restricted in their cell distribution. As such, the appearance of end products in biological samples allows inference about which cells have been activated in vivo. In the case of intact tissues and organs perfused with blood containing cells with different metabolic capacities, additional opportunities for mediator synthesis are created. For example, early in the pulmonary inflammatory process, upregulation of adhesion molecules facilitates neutrophil binding to pulmonary vascular endothelial cells. Neither cell in isolation is capable of metabolizing arachidonic acid into cysteinyl leukotrienes (LTC_4, LTD_4, LTE_4). However, an unstable epoxide intermediate, LTA_4, can be formed by the actions of 5-lipoxygenase in the neutrophil and transferred to the endothelial cell because of intimate cellular apposition. The endothelial cell lacks 5-lipoxygenase but does contain abundant LTC_4 synthase and is able to complete formation of a cysteinyl leukotriene [1]. Such transcellular biosynthesis with transfer of arachidonic can also occur between platelets and endothelium to facilitate formation of prostacyclin. This is part of the biochemical basis for the beneficial effects of antiplatelet agents, such as aspirin, in prevention of myocardial infarction and stroke. Such processes emphasize the dynamic and complex nature of pulmonary vascular eicosanoids biosynthesis and, with waxing and waning of cell apposition, allows some plasticity in the eicosanoid synthetic capability of the lung.

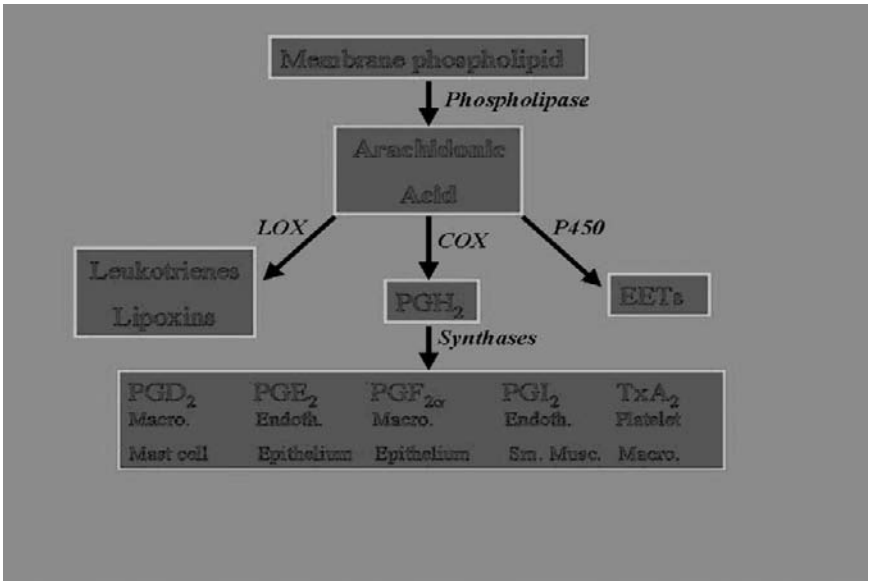

Figure 1 Enzymatic metabolism of membrane phospholipid, via arachidonic acid, to form eicosanoids. Specific enzymes are shown in italics (LOX = lipoxygenase; COX = cyclo-oxygenase; P450 = cytochrome P450; "Synthases" includes PGD synthase, PGE synthase, PGF2 isomerase, prostacyclin synthase, and thromboxane synthase. (see color insert)

The pulmonary microvasculature serves not only as an important source of prostaglandins but also as a major site of metabolism of these molecules. The standard bisenoic prostaglandins (PGE_2, PGD_2, $PGF_{2\alpha}$) are rapidly metabolized (60% to 90%) on first passage through the lung. This proceeds via oxidation of the 15-hydoxyl function followed by reduction of the 13,14-double bond, resulting in the respective 15-keto-13,14-dihydro metabolites [2]. Presumably such rapid metabolism by the lung limits systemic effects of prostaglandins generated in the splanchnic circulation. However, during periods of oxidant stress, such as in prolonged hyperoxia, or when lung endothelial function has been compromised (e.g., sepsis with ARDS), transpulmonary clearance of PGE_2 has been shown to be markedly reduced. Such loss of the normal, homeostatic clearance function of the pulmonary vascular bed may result in significant alteration in function of systemic organs during times of prostaglandin overproduction. Interestingly, metabolism of both prostacyclin and thromboxane A_2 tends to occur via both spontaneous hydrolysis, which curtails the circulating half-life of both autocoids to a few minutes, and hepatic metabolism by beta oxidation pathways in the liver.

The biological effects of prostaglandins depends on binding to specific cell surface receptors. There are subtypes of many of the prostaglandin receptors, which may signal by entirely different mechanisms. For example, of the four different E-prostaglandin (EP) receptors, one signals by altering calcium flux, two increase cellular cyclic adenosine monophosphate (AMP) levels, and one decreases c-AMP [3]. Relative regional differences in density of such receptors on target tissues and effector cells modulates the effects of eicosanoids on vascular tone and microvascular fluid and solute exchange. In addition, the structural similarity that exists between the different eicosanoids can result in "receptor promiscuity"—high levels of a structurally similar eicosanoid ligand can activate a related receptor. In vivo and in vitro studies have documented such cross-talk between PGD_2 and the thromboxane (TP) receptor and between the prostacyclin and the EP receptor.

As described previously, a wide array of eicosanoid metabolites, often with opposing actions and synthesized by multiple cell types, are produced in, and act on, the pulmonary microvasculature. The predominant endothelial cell product is prostacyclin, a key endogenous vasodilator that results in rapid elevation of intracellular c-AMP after binding to its receptor. This in turn activates protein kinase A and decreases intracellular calcium concentration, leading to relaxation of smooth muscle. Both vasoconstrictors (angiotensin II) and vasodilators (nitric oxide) have been shown to increase the synthesis of prostacyclin. In addition, increased shear force is a potent stimulus for prostacyclin synthesis by endothelium. Of note, in precapillary PAH, the ordinary pulsatile capillary flow in the lung is lost. This may contribute to the decrease in synthesis observed in many forms of pulmonary arterial hypertension (PAH).

Prostacyclin has additional properties that are important. These include inhibition of platelet aggregation and effects on muscle growth and cardiac contractility [4]. PGI_2 is a well documented inhibitor of platelet aggregation, which is mediated, similar to its vasodilatory actions, through an increase in intracellular c-AMP. Importantly, prostacyclin does not inhibit initial platelet adhesion at the site of vessel wall injury and thus allows hemostasis without vessel occlusion. When used in pharmacological doses for the treatment of PAH (see following discussion), although bleeding time

increases, clinical evidence of excessive bleeding in patients does not occur. PGI_2 also modulates leukocyte adhesion to abnormal vascular surfaces, preventing local leukostasis and limiting inflammation. The intracellular increase in c-AMP resulting from engagement of PGI_2 to its receptor has also been shown to inhibit DNA synthesis in vascular smooth muscle cells. Direct inotropic effects of prostacyclin have been demonstrated in animal studies evaluating isolated ventricular muscle preparations, and clinically important improvement in cardiac output following administration of epoprostenol, the synthetic salt of prostacyclin, has been reported in patients with pulmonary hypertension receiving chronic therapy.

Thromboxane A_2 (TxA_2) is the principle eicosanoid produced by platelets, but significant production in alveolar macrophages and monocytes occurs as well, especially when they are activated [5]. TxA_2 has properties opposite to those of PGI_2 in that it is a potent vasoconstrictor and promotes platelet aggregation and smooth muscle growth, the latter possibly through a protein kinase C-linked pathway. Numerous triggers of platelet activation, including acute lung injury, endotoxemia, shear force, and procoagulant alterations of the endothelial surface, lead to increased TxA_2 synthesis.

It is well known that PGD_2 causes bronchoconstriction. Its effects on the pulmonary vasculature are less well documented, but in sheep PGD_2 causes vasoconstriction, likely through binding to the TxA_2 receptor. Conversely, and similar to prostacyclin, PGD_2 also inhibits DNA synthesis in vascular smooth muscle cells, but this is independent of an increase in c-AMP. In humans, whether PGD_2 has a beneficial or deleterious effect on the development, maintenance, or regression of pulmonary arteriopathy is unknown. PGD_2 also may tend to oppose platelet aggregation.

Leukotrienes, eicosanoid products resulting from the action of lipoxygenases on arachidonic acid, are potent mediators of inflammation with well-documented involvement in the pathogenesis of asthma. Recently, increased levels of 5-lipoxygenase and 5-lipoxygenase activating protein have been found in small and medium-sized pulmonary arteries by immunohistochemical staining of lung tissue from patients with pulmonary hypertension [6]. These results, in combination with the finding of increased leukotriene E4 in lavage fluid from newborn infants with persistent pulmonary hypertension, suggests a possible role for leukotrienes in pulmonary vasculopathies.

Isoprostanes, the result of nonenzymatic, free-radical catalyzed peroxidation of arachidonic acid, are excellent markers of in vivo oxidant stress. Evidence of lipid peroxidation has been found in numerous vascular disorders, including pulmonary vascular disease. Isoprostanes may also cause vasoconstriction and modulate platelet function, possibly by binding to receptors for TxA_2. Furthermore, they can stimulate proliferation of endothelial cells and synthesis of endothelin-1, an exceptionally potent endogenous vasoconstrictor and smooth muscle mitogen. Previously believed to be exclusively formed by cyclo-oxygenases, a recent study indicates that as much as 30 percent of PGD_2 is synthesized via the isoprostane pathway. This suggests that oxidant stress can increase prostaglandin production by two independent mechanisms: (1) facilitation of enzymatic catalysis by COX, and (2) direct peroxidation of arachidonate-containing phospholipids with phospholipase (or PAF acetylhydrolase) induced release of prostanoids.

A large body of information has examined the role of eicosanoids in endotemia and acute lung injury [7]. Increased levels of the major metabolite of thromboxane, a powerful vasoconstrictor and platelet aggregating cyclo-oxygenase product produced exuberantly by platelets, have been demonstrated in experimental models of endotoxemia. However, neither inhibition of thromboxane A_2 synthesis nor blockade of the TP receptor abrogates the decrease in vascular barrier function (10#26,69,74). Furthermore, platelet depletion does not significantly modify the pulmonary vascular permeability response to endotoxin in chronically instrumented, nonanesthetized sheep. Both humans and large animals develop pulmonary hypertension following endotoxemia. Brigham and coworkers administered *E. coli* endotoxin to awake, chronically instrumented sheep and noted a two-phased response consisting of an early phase of acute pulmonary hypertension, characterized by increased flow of lung lymph that was relatively low in protein. This was followed by a longer phase of increased vascular permeability (i.e., high lymph/plasma protein ratio), during which mean pulmonary pressure remained only slightly elevated. Both analytical and pharmacologic studies using cyclo-oxygenase inhibitors suggest that thromboxane A_2 mediates the early pulmonary vasopressor response but does not play a role in the later alteration in microvascular permeability.

Pulmonary Arterial Hypertension

A major disorder involving the pulmonary microvasculature and eicosanoids is pulmonary arterial hypertension (PAH). PAH primarily affects the small pulmonary arteries with a diameter of less than 100 microns. Pathological changes include medial hypertrophy, intimal proliferation, in situ thrombosis, and plexiform lesions, the latter likely a disordered attempt at neovascularization. PAH may occur without an associated disorder, primary pulmonary hypertension (PPH), or in association with connective tissue disease, congenital heart disease, portal hypertension, HIV infection, or use of appetite suppressants. Disruption of the endothelial lining of the microvasculature in PAH is associated with changes in the local milieu of protein and lipid mediators. Whether these changes are causative or secondary to the pathological changes is uncertain. It is noteworthy that similar pathological changes have been found in the microvasculature of patients undergoing thromboendarterectomy for treatment of large-vessel thromboembolic pulmonary hypertension, suggesting that small-vessel vasculopathy can result from multiple processes.

More specifically, alterations in the production of eicosanoid mediators have been demonstrated in animal models of pulmonary hypertension and in PAH. Although several eicosanoid products can affect the pulmonary microvasculature, PGI_2 and TxA_2 appear to play the largest role in vascular homeostasis. Both compounds are rapidly metabolized within seconds to minutes, and therefore, circulating levels of both prostacyclin and TxA_2 are extremely low (< 4 pg/mL). This implies that these eicosanoids are primarily synthesized locally in the pulmonary vasculature, and perturbations in the local environment are associated with changes in mediator production.

In an animal model of pulmonary hypertension using calves exposed to hypoxia at high altitude, investigators found decreased synthesis of PGI_2 compared to control animals. More recently, studies using in situ hybridization and Western blots have demonstrated a decrease in prostacyclin synthase in both large and small pulmonary arteries from patients with PAH. Additional studies in mouse models support a pivotal role for prostacyclin in the development of pulmonary hypertension. In a prostacyclin receptor knockout model, mice exposed to hypoxia developed more severe pulmonary hypertension and vascular remodeling compared to control animals. Conversely, when exposed to hypobaric hypoxia, transgenic mice with overexpression of prostacyclin synthase produced more prostacyclin and histologically exhibited nearly minimal medial hypertrophy in precapillary arteriole vessels compared to significant changes in control animals.

In patients with pulmonary vascular disease, with PPH or related to connective tissue disease, we found increased urinary metabolites of TxA_2 when corresponding metabolites of prostacyclin were decreased, so the overall ratio of TxA_2/PGI_2 was significantly increased compared to control subjects [8]. These findings have subsequently been confirmed in patients with PAH related to congenital heart disease. Although TxA_2 is usually synthesized by platelets (and to a lesser extent by other circulating cells), vascular synthesis of TxA_2 has been demonstrated, at least in systemic arteries. This abnormal production of TxA_2 may be even more marked in PAH where an abnormal vascular lining promotes platelet binding and activation. Combined, these studies, in humans and in animal models, suggest that the pathogenesis and/or maintenance of pulmonary hypertensive vascular disease may involve alterations in the production of PGI_2 and TxA_2.

Clinical Modulation of Eicosanoids in Pulmonary Vascular Disease

Attempts to treat PAH with pharmacological doses of epoprostenol (the synthetic salt of prostacyclin), 100 to 1,000 times that normally made endogenously, began in the early 1980s based on epoprostenol's vasodilatory properties. Because of the short half-life in vivo, epoprostenol must be continuously infused via a central venous catheter; acute clinical deterioration has been reported with acute interruption of the drug. Nevertheless, use of epoprostenol has been approved for the long-term treatment of PAH based on improvement in pulmonary hemodynamics, quality of life, and survival documented in a randomized, clinical trial [9]. Currently, epoprostenol is used to treat all forms of intrinsic PAH as well as other disorders that can affect the pulmonary microvasculature, such as distal chronic thromboembolic disease that is not amenable to operative treatment or sarcoidosis with diffuse vascular involvement.

Intravenous epoprostenol has dramatically improved the outcome of patients with PAH, most impressively in patients with PPH. Results in patients with the scleroderma spectrum of disease are not as impressive, perhaps because they have a systemic disease and are generally older than patients with PPH. Compared to historical controls or to survival predicted by the NIH PPH Registry survival equation, survival with epoprostenol is significantly improved [10]. However, not all patients respond to therapy, and one third of patients with PPH still die within three years of starting treatment. This may be explained by the fact that although most patients improve clinically, hemodynamics remain markedly abnormal. After one year of therapy, mean pulmonary artery pressure only decreases 10 to 15 mmHg, and pulmonary vascular resistance remains five to six times normal. Rarely do patients demonstrate normalization of pulmonary hemodynamics. This indicates that while most patients improve clinically, the fundamental pathological remodeling process in the precapillary pulmonary vessels is not significantly affected.

Since the approval of epoprostenol, other prostacyclin analogues have been evaluated in the treatment of PAH. Beraprost, an oral analogue of prostacyclin, was originally used in uncontrolled studies in Japan that purported to show efficacy in PPH. More recently, two randomized, placebo-controlled studies have been performed. One was a three-month study that demonstrated improvement in six-minute walk distance. The other was a 12-month study that initially showed similar clinical improvement at 3 and 6 months. However, by 9 months of treatment, no clinical benefit was apparent, indicating that long-term benefit can not be maintained with the oral preparation. Iloprost is another longer-acting prostacyclin analogue, given intravenously and by inhalation, the latter of which requires 6 to 10 treatments per day. A recent multicenter, placebo-controlled three-month trial involving patients with PAH and inoperable chronic thromboembolic disease demonstrated improvement in a combined endpoint with inhaled iloprost. Although the treatment was effective in some patients, the frequency of the treatments makes this therapy difficult to use. Finally, treprostinil, a subcutaneously delivered analogue, has been studied in the largest randomized, placebo-controlled study in PAH. Modest improvement was found in six-minute walk distance with treprostinil. Local pain at the infusion site, related to binding of the prostacyclin analogue to pain receptors, limited the dose escalation in most patients in the study and has been an impediment to widespread use of

treprostinil; however, those able to increase to greater doses experienced greater clinical improvement.

The mechanism of action of prostacyclin and its analogues remains uncertain. As noted previously, most patients continue to exhibit significant pulmonary hypertension despite treatment, indicating that vasodilation is unlikely to play a major role. Much of the benefit from epoprostenol may result from inotropic effects leading to improved right ventricular contractility. Increases in c-AMP, while important during acute use of epoprostenol, are unlikely to be sustained during long-term use. In cell culture studies of both proximal and distal pulmonary artery, smooth muscle growth was inhibited by a variety of prostacyclin analogues, which correlated with increases in c-AMP. However, levels peaked by 30 minutes and declined by 4 hours. We have measured c-AMP levels in plasma in patients receiving therapy with epoprostenol and found no increase compared to baseline values.

Provision of pharmacologic doses of prostacyclin has effects on other mediator systems. Investigators have shown that chronic infusion of epoprostenol decreases circulating levels of endothelin-1, which may account for some of the beneficial action of prostaglandins. Others have shown improvement in platelet aggregation and markers of endothelial injury, such as circulating levels of von Willebrand factor with long-term epoprostenol treatment. Interestingly, in preliminary studies, despite epoprostenol's potent effects on platelet aggregation, the drug does not appear to decrease excretion of thromboxane metabolites in patients with PPH. This suggests that much of the increase in thromboxane generation in patients with PPH may derive from cells other than platelets. More recently, epoprostenol has been reported to decrease markers of oxidative damage in lung tissue samples from patients with PPH.

Use of thromboxane receptor antagonists or synthase inhibitors have been unsuccessful, perhaps because TxA_2 is not a pivotal mediator in the maintenance of the microvascular remodeling in PAH. Inhibition of thromboxane synthase with an oral agent was initially studied in the late 1980s and showed very modest improvement in resting hemodynamics. More recently, use of a combined thromboxane synthase inhibitor/receptor antagonist, terbogrel, was evaluated in a randomized, placebo-controlled study. Unfortunately, the study was stopped prematurely because of an unexpected adverse event, severe leg pain, that developed in approximately 25 percent of patients. In addition, there was no clinical or hemodynamic improvement in patients who completed the study, although TxA_2 metabolite levels in serum (reflecting platelet capacity) and in urine (reflecting total body thromboxane production) decreased significantly with drug treatment. Furthermore, urinary prostacyclin metabolites increased, supporting the concept of endoperoxide shunt from platelet to endothelium at the vascular interface. Inhibition of PGD_2 or modulation of leukotriene synthesis (or receptor blockade) or treatment with antioxidants (e.g., vitamins C and E) has not been studied in PAH.

A combination of empiric clinical trials of modulation of prostaglandin balance, translational research in patients with pulmonary vascular disease, and ongoing basic investigations of endothelial and smooth muscle biology have yielded clinically useful results over the last decade. Epoprostenol, and perhaps stable analogues of prostacyclin, have a beneficial effect in patients with PAH, particularly those with PPH. However, despite improvement in both quality of life and survival with pharmacological doses of prostacyclin, it is clear that the fundamental abnormalities of growth and disordered angiogenesis are not substantially altered by this therapy. Future studies spanning the spectrum from basic to clinic research are needed to determine more precisely the role of eicosanoids in pulmonary vascular disease.

Glossary

Cyclo-oxygenase: An enzyme protein complex present in most tissues that catalyses two steps in prostaglandin biosynthesis and produces prostaglandins and thromboxanes from arachidonic acid.

Eicosanoid: A class of oxygenated, endogenous, unsaturated 20-carbon fatty acids derived from arachidonic acid after it is cleaved from membrane phospholipids. They include prostaglandins, leukotrienes, thromboxanes, and hydroxyeicosatetraenoic acid (HETE) compounds. They exert their actions by binding to specific cellular receptors.

Epoprostenol: A prostaglandin that is biosynthesized enzymatically from prostaglandin endoperoxides generated by the action of cyclo-oxygenase in human vascular tissue. It is a vasodilator and a potent inhibitor of platelet aggregation. The sodium salt has also been used as a pharmaceutical (Flolan), to treat primary pulmonary hypertension.

Pulmonary arterial hypertension: A disorder primarily affecting the small precapillary pulmonary arteries and occurring either as an idiopathic illness [primary pulmonary hypertension (PPH)], or in association with other disorders including congenital heart disease, connective tissue diseases (especially scleroderma), liver disease, human immunodeficiency virus infections, and use of appetite suppressants. Characteristic pathologicial changes include smooth muscle medial hypertrophy, intimal proliferation, in situ thrombosis, and the development of plexiform lesions.

Capsule Biographies

Dr. Robbins has directed the Adult Pulmonary Hypertension Center at Vanderbilt University since 2001. His research has focused on the mechanism of action of epoprostenol in the treatment of pulmonary hypertension, and he has been the lead investigator at Vanderbilt in numerous clinical trials evaluating new medications for the treatment of pulmonary hypertension. His work is supported by grants from the NIH.

Dr. Christman trained in internal medicine and pulmonary/critical care medicine at Vanderbilt University, where he is currently Vice-Chair of Medicine at Vanderbilt University and Chief of the Medical Service for the VA Tennessee Valley Health System. His laboratory uses both basic and clinic research approaches to decipher contribution of the urea/nitric oxide cycle and eicosanoid pathways in modulating both liver/lung injury after endotoxemia and pulmonary hypertension. His work is supported by an NIH Program Project Grant from the NIH National Heart Lung and Blood Institute and by a grant from the NIH National Cancer Institute.

Vascular Development: Vasculogenesis and Angiogenesis

CHAPTER 14

Role of platelet-derived growth factors in the microvasculature

Christer Betsholtz and Holger Gerhardt

Department of Medical Biochemistry, University of Göteborg, Medicinaregatan 9A, Box 440, SE 405 30 Göteborg, Sweden

Introduction

Platelet-derived growth factor (PDGF) is a family of dimeric ligands that bind to and activate two cell surface receptor tyrosine kinase subunits, PDGFRα and PDGFRβ. Four different ligand chains (PDGF-A, B, C and D) assemble into five different dimeric combinations (AA, AB, BB, CC and DD). Binding of bivalent ligands leads to receptor subunit dimerization. The apposition of the receptor kinase domains leads to reciprocal receptor subunit phosphorylation, further activating the tyrosine kinases and creating docking sites for down-stream signal transducers.

One of the first biological functions demonstrated for PDGF was its mitogenic activity on cultured vascular smooth muscle cells (vSMC) [1]. The PDGF preparations used for these early studier were derived from platelets and consisted mainly of PDGF-AB heterodimers. Subsequently it was demonstrated that vSMC carry both PDGFRβ and PDGFRα. In vitro studies also demonstrated that cultured vascular endothelial cells produce PDGF A and B. Thus, early in vitro findings provided indications that PDGFs and their receptors play a role in the vasculature. However, the focus was placed on large vessels and the potential function of PDGF as a "wound healing" hormone for the vascular wall and surrounding connective tissue. For example, PDGF was suggested to be of central importance in the "response to injury" model of atherosclerosis championed by Russell Ross and co-workers.

Subsequent in vitro studies argued for PDGF signaling to have a role also in the microvasculature. In co-culture studies, endothelial cells promoted pericyte migration—a function that was attributed to PDGF. Moreover, pericyte contact with the endothelial cells inhibited proliferation of the latter, and TGFβ was implicated in this function [2, 3].

Roles of PDGFs in the Microvasculature Revealed by Genetic Studies

Lessons from PDGF-B and PDGFRβ Knockouts

PDGF-B and PDGFRβ null mice both die at late gestation from microcirculatory deficiency involving generalized microvascular hemorrhage and edema [4, 5]. Closer analysis revealed that these mice fail to recruit pericytes to their microvasculature in many but not all organs [6, 7]. The acute cause of death of the PDGF-B and PDGFRβ null mice is likely circulatory failure. Live born mutants die from respiratory distress within minutes to hours after birth.

CNS Pericytes

The central nervous system (CNS) microvasculature has a remarkably high density of pericytes in comparison with most other capillary beds. The CNS is also one of the organs most strongly affected by genetic PDGF-B or PDGFRβ deficiency. CNS vessels develop by angiogenic sprouting from the perineural vascular plexus. In this process, the invading endothelial cells express PDGF-B and the pericytes PDGFRβ. In the absence of either ligand or receptor, pericyte co-recruitment largely fails, resulting in <5% of the normal number of brain pericytes. In spite of this cellular deficiency, the endothelial sprouting process proceeds relatively normally, establishing an intracerebral circulation that allows prenatal CNS growth and differentiation. At early

stages (E10–14), only mild abnormalities in vessel patterns are observed in associated with a 2-fold increase in endothelial cell number [8]. However, at late gestation, the microvasculature displays more advanced morphological aberrations. Focal dilations and microaneurysms rapidly expand and rupture, leading to multiple sites of hemorrhage and edema. At the cellular level, this correlates with endothelial hyperplasia and abnormal differentiation. Notably, the endothelial luminal membrane surface is oversized and multiple cytoplasmic folds protrude into the vascular lumen. There are also abnormalities in the endothelial adherence junctions and multiple signs of increased vascular permeability. These observations suggest that PDGF-B signaling through PDGFRβ is critical for pericyte recruitment to the CNS microvasculature. Moreover, they show that pericytes, in turn, deliver important signals within the microvessel wall that regulate endothelial proliferation and differentiation. At the level of integrated functions, pericytes thereby support microvascular integrity and homeostasis. At a gross anatomical level, pericytes appear to exert control of the capillary diameter.

Mesangial Cell Recruitment

Mesangial cells are pericyte-like cells of the kidney glomerulus. PDGF-B and PDGFRβ null embryos both fail to recruit pericytes into the developing glomerulus [4, 5, 9]. As a result, the single capillary loop that invades the nascent glomerular epithelial cleft fails to develop into a complex tuft of vessels. Instead, it dilates into an aneurysm-like structure filling out the glomerular space. During glomerulus development, PDGF-B is expressed in the invading endothelium, whereas the mesangial cells express PDGFRβ. A paracrine PDGF-B signal from the endothelium thus promotes mesangial cell co-recruitment into the glomerulus, and the mesangial cells in turn deliver signals that promote glomerular capillary branching and splitting (intussusception). The role of the mesangial cells thus differ somewhat from the brain pericytes, since the overall vessel branching pattern in the brain does not seem to be influenced by the pericytes. However, there are also similarities in that the pericyte/mesangial cell absence in both organs leads to loss of capillary diameter control.

Placenta Pericytes

Placenta pericytes, like glomerular mesangial cells, appear to function in intussusceptive vessel splitting, leading to the formation of complex high-density vascular tufts. Possibly, such specialized pericytes are of particular importance where high vascular densities are needed to fulfill systemic functions (filtration, excretion, absorption etc). Both the kidney and the placenta exert such functions, and the vessels densities are therefore tailored to serve demands of the whole organism, rather than local needs. PDGF-B and PDGFRβ null mice show about 50% reduction in the number of placenta pericytes, and an associated impairment of the formation of fetal vessel tufts in the labyrinthine layer of the placenta (where fetal and maternal vessels meet) [10].

Other Locations

Other organs that show a marked (>50%) pericyte deficiency in PDGF-B or PDGFRβ null embryos include skin, heart and lung. Interestingly, the major population of liver pericytes, the perisinusoidal cells (Ito cells), is unaffected by PDGF-B or PDGFRβ deficiency, and therefore has to develop through other mechanisms. Ito cells also do not express appreciable levels of PDGFRβ (mRNA), at least prenatally, and the sinuisoidal endothelium does not detectably express PDGF-B. Also the axial arteries constitute a site at which the number of vSMC/pericytes appears to be unaffected by PDGF-B or PDGFRβ deficiency. The origin of these vSMC is believed to be the immature mesenchyme surrounding these vessels. Upon an *inductive* cue, presumably presented by the endothelial cells, the mesenchymal cells condensate around the vessel and turn on a SMC differentiation program. This *circumferential* recruitment of vSMC/pericytes is thus independent of PDGF-B/Rβ, whereas the subsequent *longitudinal* recruitment to new vessels formed by angiogenic sprouting requires paracrine endothelial-to-pericyte signaling using PDGF-B and PDGFRβ. Although dispensable for the vSMC *induction* around the axial arteries, PDGFRβ is required for the postnatal maintenance and/or expansion of this vSMC population, as shown by chimeric analysis [11].

Lessons from Conditional PDGF-B Knockouts

Using Cre-lox techniques, vascular endothelium- and neuronal-specific PDGF-B knockouts have been generated [12, 13]. The latter did not reveal observable defects in the brain microvasculature in spite of neurons being a major source of PDGF-B in the CNS. However, the endothelium-specific knockout resulted in pericyte deficiency, confirming the endothelium as the critical source of PDGF-B in pericyte recruitment [12, 14].

Evidence for the Local Importance of Pericytes

The endothelial PDGF-B gene deletion was not complete. Instead, it resulted in a chimeric situation where wild-type vessel segments alternated with PDGF-B deficient segments. In contrast to the PDGF-B null mutants, the endothelium-specific knockouts survived into adulthood, allowing analysis of postnatal angiogenesis. The chimeric nature of the mutant made it possible to spatially correlate pericyte deficiency with microvascular abnormality. This was important, as the role of systemic influences (e.g. heart and placenta defects) on microvessels formation could not be ruled out in the studies of the null mutants. It could therefore be concluded that pericytes control the function of neighboring endothelial cells. Possibly this control involves paracrine growth factors, cell adhesion and junction molecules, and pericyte-derived extracellular matrix molecules.

Retinal Angiogenesis

The survival of the endothelium-specific knockout made it possible to analyze retinal angiogenesis, an early postnatal

process. As in other parts of the CNS, pericyte recruitment in the retina was shown to be dependent on endothelial PDGF-B. Studies using neutralizing PDGFRβ antibodies confirmed this conclusion [15].

PERICYTES AND DIABETIC RETINOPATHY

The chimeric nature of the endothelial PDGF-B deletion was inter-individually variable, allowing for analyses of the retinal vascular abnormalities at different states of pericyte density ranging from almost normal (≈70% of normal) to near complete deficiency (<10% of normal). Animals where the average pericyte density in the CNS was lower than 50% invariably developed proliferative lesions in the retinas that were reminiscent of diabetic retinopathy. This result was striking since diabetic retinopathy in both humans and animals has been associated with pericyte loss within the microvessel wall. It is not known, however, whether the pericyte loss constitutes a causal event in the pathogenesis of the retinopathy, or whether it is just correlative with the process. The results from the endothelium-specific PDGF-B knockouts show that independently of a diabetic challenge, pericyte deficiency may cause progressive vascular changes that mimic diabetic retinopathy. The data may also provide an explanation as to why diabetic rodents only develop mild signs of retinopathy and never proliferative disease; pericyte loss in these models is usually substantially lower that 50%.

Lessons from PDGF-B Retention Motif Knockouts

PDGF-B carries a basic stretch of amino acids in its C-terminus referred to as the "retention motif". A similar motif is found in PDGF-A and in different members of the VEGF family, where it is included or excluded by alternative splicing. In PDGF-B the retention motif may remain or be deleted from the precursor depending on proteolytic processing. The basic motifs of the PDGF-B/VEGF family have affinity for heparin and heparan sulphate proteoglycans (HSPGs) and probably serve the same function as analogous motifs in other growth factor families, namely to help generating gradients or depots of factor in the extracellular space. This may ensure graded signaling, or sequestering of the factor in the ECM for release or redistribution by proteolytic cleavage in situations of inflammation.

PDGF-B RETENTION IS REQUIRED FOR PROPER INTEGRATION OF PERICYTES IN THE VESSEL WALL

Deletion of the retention motif in PDGF-B resulted in viable mice (PDGF-B ret/ret mice), however, with severe retinopathy [16]. Other signs of microvascular dysfunction were evident as well, including brain microaneurysms and breakage of the blood brain barrier, as well as glomerular defects and proteinuria. All these problems appear to relate to abnormal pericyte and mesangial cell recruitment. Although there was a significant reduction in the number of pericytes in these mice, the degree of reduction did not seem to explain the severity of the phenotype; endothelium-specific knockouts with a similar decrease in pericyte numbers had much milder retinal and glomerular pathology. The severity of the PDGF-B ret/ret mutants was instead proposed to result from abnormal pericyte integration within the microvessel wall. Notably, pericytes are normally very tightly associated with the abluminal endothelial cell surface. In PDGF-B ret/ret mutants, pericytes were instead partially or fully detached from the endothelial cells. Likely this abrogates the normal communication between the pericytes and the endothelium, leading to a state that resembles the absence of pericytes. In the eye, the dissociated pericytes also form sheets of fibroblast-like cells at the retinal surface, which may contribute to contraction and detachment of the retina.

PDGF-B AND THE RECRUITMENT OF TUMOR PERICYTES

There are several possible explanations for the detachment of pericytes from the microvessels in PDGF-B ret/ret mice. One possibility is that a graded presentation of PDGF-B is required from the endothelium in order to guide pericyte migration along the abluminal endothelial surface. If the pericyte fails to recognize that the source of PDGF-B is endothelial, they may migrate more randomly, leading eventually to their detachment from the endothelial surface. Another possibility is that a directional presentation of PDGF (i.e. from the endothelium) is needed to polarize the pericyte, forcing unequal distribution of cell and matrix adhesions molecules, or deposition of matrix itself. Such polarization may promote adherence of the pericyte to the endothelium and/or ensure that the pericyte is properly embedded within the microvascular basement membrane. These possibilities, which are not mutually exclusive, are attractive also considering the uneven expression of PDGF-B in the vascular endothelium. The recent finding that the expression is concentrated to specialized endothelial cells situated at the sprout tip (endothelial tip-cells) [17] suggests that the location of the PDGF-B source is critical.

Studies of pericyte recruitment to tumor vessels have provided additional strong support for the idea that directional presentation of PDGF-B is important in the process of pericyte recruitment. In tumors transplanted on PDGF-B ret/ret mice, few pericytes were recruited, and they were partially or fully detached from the endothelium [18]. However, when PDGF *levels* were compensated by secretion from the tumor cells rather than the endothelium, the number of pericytes in the tumor vessels increased significantly, but the integration of the pericytes in the vascular wall failed. Since the tumors produced the wildtype form of PDGF-B (including the retention motif) it could also be excluded that the integration defect depended on a putative change in the signaling properties of the mutant PDGF-B. Instead, the most plausible explanation is that the PDGF-B protein has to be presented directionally from the endothelium, and that the retention motif helps associating the secreted PDGF-B protein to the endothelial surface or within the periendothelial matrix to facilitate such presentation.

Lessons from PDGFRβ Signaling Mutants

Using homologous recombination in ES-cells, Soriano and collaborators have generated an extensive allelic series of endogenous signaling mutations in PDGFRβ. Mice carrying these mutations show a different range of cardiovascular defects. Taken together, these analyses confirm the importance of PDGFRβ signaling in vSMC and pericyte recruitment and in the development of a functional cardiovascular and renal excretory system. However, the analyses also came up with several surprises concerning the relative importance of the different signaling pathways downstream of PDGFRβ.

PDGFRβ Signaling and Cell Function in Vitro

PDGFRβ has been the subject of intense biochemical analysis. It is extensively autophosphorylated upon ligand binding, leading to the formation of up to thirteen phosphotyrosine residues that engage in coupling to at least ten different SH2-domain containing proteins. These molecules include Src family kinases, PI3 kinase (PI3K), Shc, RasGAP, STATs, Grb2, Grb7, SHP-2, PLCγ, and Nck. Their engagement leads to the initiation of several different cellular functions in cultured mesenchymal cells, including proliferation, migration, and extracellular matrix synthesis. In vitro, a certain degree of specificity has been noticed between the signaling pathway engaged and the cellular response. For example, PI3K signaling has been strongly linked to cytoskeletal rearrangements and cell migration. Since analysis of the PDGF-B and PDGFRβ null mutants suggests a role for these proteins in pericyte migration and proliferation, it was hoped that the distinct signaling mutations in the endogenous PDGFRβ gene would separate between the putative multiple roles of PDGFRβ signaling in pericyte/vSMC recruitment. However, as discussed in more detail below, it appears that the various signaling pathways engaged downstream of PDGFRβ exert additive rather than distinctive effects in microvascular development.

PDGFRβ Unable to Signal Through PI3K and PLCγ

Surprisingly, mice homozygous for a mutation that encodes a PDGFRβ protein lacking the two PI3K-binding phosphotyrosine residues displayed no overt phenotype [19]. When challenged, however, they display a reduction in the capacity to resolve an experimentally induced tissue edema. Thus, PDGFRβ signaling may be implicated in the control of tissue interstitial fluid pressure (IFP). Increased IFP is a general feature of solid tumors and PDGF-B or PDGFRβ inhibiting compounds seem to be able to reduce tumor IFP, which in turn facilitates the delivery of substances, including cytostatic drugs, to the tumor [20]. The mechanism by which PDGFRβ regulates IFP is not clear, however it is plausible to assume that it involves pericyte or fibroblasts mediated contraction of the ECM. Hence, PDGFRβ-mediated PI3K signaling may have its major role in cell contraction in the adult tissues, rather than in cell migration in embryonic development. Recent analysis using embryonic CNS pericyte density as readout also demonstrates that PDGFRβ-mediated PI3K signaling takes part in determining the rate of expansion of the pericyte population [21, 22]. Hence PI3K signaling may also be involved in the control of pericyte progenitor proliferation in vivo.

Mice carrying mutant PDGFRβ unable to signal through both PI3K and PLCγ are likewise without an overtly abnormal phenotype [23]. However, when challenged with an experimental injury to the glomerulus, they display exaggerated pathology. Although it is unclear how the change in pathogenesis relates to defective PDGFRβ signaling, it likely involves recruitment or function of mesangial cells, since these are the only cells in the developing glomerulus known to express PDGFRβ. Since the overall growth rate of the pericyte population is decreased in the combined PI3K/PLCγ mutants, one might speculate that the proliferation of the mesangial cells is likewise negatively affected, and that this may slow down repair of the injured glomerulus and, in turn, enhance a pathological response.

PDGFRβ With Multiple Pathways Defects

Additional mutations removing 5 and 7 phosphotyrosine residues, respectively, in PDGFRβ led to overt vascular defects in several organs, in particular when combined with a PDGFRβ null allele to reduce the level of PDGFRβ expression [21, 22]. These phenotypic abnormalities coincided with a substantial (>50%) reduction in pericyte numbers. The PDGFRβ allelic series generated by Soriano and co-workers hence provides a series of mutant animals with a progressive decrease in the pericyte density. This decrease is even further aggravated in animals where the mutant alleles occur in combination with the PDGFRβ null allele.

A mutant has also been created in which the intracellular domain of PDGFRβ was replaced with that of PDGFRα [24]. While homozygous carriers of this mutation lack overt phenotype, mice carrying one hybrid receptor and one null allele, showed spontaneous pathology similar to that observed in the mutant lacking 7 phosphotyrosines. This demonstrates that PDGFRα signaling can only partially compensate for PDGFRb signaling in vSMC/pericytes, in agreement with biochemical analysis.

Pericyte Density and Its Relationship to Organ Pathology—Concluding Remarks

Analogous Phenotypic Consequences of PDGF-B and PDGFRβ Mutagenesis

Several interesting conclusions may be drawn from comparing the various mouse lines that have been generated by mutagenesis at the PDGF-B or PDGFRβ loci. Not surprisingly, perhaps, the range of phenotypes that is seen in the two mutant series is similar. Both the ligand and receptor series display a gradual reduction in pericyte density, and a phenotypic outcome ranging from normal (no phenotype in the unchallenged state) to overt pathology in the eye, heart

and kidney, with the eye displaying the most profound pathology. Interestingly, the relationship between overall degree of pericyte reduction and the resulting pathology was also similar. Both series produced mutants with pericyte reduction ranging from <50 to >90%, and overt phenotypic changes in the eye appear in mutants with more than 50% reduction in the pericyte density. Thus, substantial pericyte reduction appears to be tolerated in organ development, with most organs (in which pericytes depend on PDGF-B/PDGFRβ signaling) tolerating 50% reduction or more. The exception is the eye, which has the highest known normal pericyte density, suggestive of a critical and perhaps unique function for these cells. Intriguingly, development of many organs, including the brain, can be completed relatively normally, even when there is up to 90% reduction in pericyte density. However, these mice have many signs of brain microvessel dysfunction and pathological responses in the astroglia. When mice with 50% reduction or less are exposed to a pathological challenge, such as glomerulonephritis or diabetes, there is an exaggerated pathological microvascular response, however.

Not only pericyte numbers, but also their association with the endothelium seems to matter, as illustrated by the PDGF-B retention deficient mice. Probably, a graded, or directional, presentation of PDGF-B by the endothelial cells is required to ensure that the pericytes become correctly associated with the endothelial cells and their basement membrane. Thus the extracellular compartmentalization of PDGF-B seems to be as important for pericyte recruitment as the formation of gradients or depots of VEGF-A in the guidance of endothelial sprouts [17, 25].

Do the Other PDGF/Receptors Play a Role in the Microvasculature?

No other PDGF/PDGFR member is as strongly implicated in microvascular assembly or function as PDGF-B and PDGFRβ. PDGFRα knockouts display defects in the cardiac outflow tract [26, 27] that may relate to a primary defect in the neural crest. Likewise, other neural crest-derived populations of vSMC and pericytes may be affected in the PDGFRα knockouts, particularly in the rostral part of the embryo. Again the critical signaling events involving PDGFRα likely take place before the crest-derived vSMC/pericyte populations are specified. An additional location where PDGFRα signaling might determine the fate of a progenitor of the vSMC/pericyte population is the kidney. Here, PDGFRα null mutants become progressively depleted of interstitial mesenchymal cells. However, these mutants also partially lack mesangial cells in the kidney glomeruli in spite of the fact that PDGFRβ is the dominant receptor in these cells. Thus, it is possible that the mesangial progenitors are in part (or fully) recruited from the PDGFRα positive interstitial mesenchyme [28].

While PDGF-A and -C signaling through PDGFRα may have indirect effects on microvascular development, the function of PDGF-D remains elusive. The strong similarities between PDGF-B and PDGFRβ null mutants may suggest that PDGF-D has no or little effect during development. However, it is possible that PDGF-D serves mainly postnatal functions, and that some of these functions may involve the microvasculature. Detailed expression analysis and genetic ablation of PDGF-D in mice will help answering these questions.

Glossary

PDGF: Platelet-derived growth factor. A family of five dimeric ligands (AA, BB, CC, DD and AB) composed of four constituent chains (A, B, C, D) encoded by different genes. PDGF was originally found in platelets and assumed to exert a wound healing function, but is currently know to be expressed by a multitude of cell types and exert numerous important roles, particularly during organogenesis.

PDGFR: Platelet-derived growth factor receptor. A family of two transmembrane receptors (α and β). They are structurally related receptor tyrosine kinases with 5 extracellular Ig domains and a split intracellular kinase domain. The PDGFRs dimerize upon ligand binding, autophosphorylated, and thereby engage several classical signaling pathways, including **••**.

Pericyte: A mural cells of the vessel wall that shares basal lamina with the endothelium. Pericytes are vascular smooth muscle lineage cells that express several of the markers of smooth muscle.

Capsule Biography

Dr Christer Betsholtz is professor of Medical Biochemistry at Göteborg University since 1993. His laboratory has explored the physiological roles of the PDGF family members for more than 20 years, which has recently led into the areas of angiogenesis and, in particular, the mechanism of recruitment and function of pericytes. His work is supported by several research councils and foundations in Sweden and Europe.

Dr Holger Gerhardt is a former post doctoral fellow in Betsholtz' group and newly appointed junior group leader at Cancer Research UK, London. His previous work on avian neural development, together with a more recent focus on angiogenesis, has led him into new exciting areas of angiogenic sprout guidance in the central nervous system. He is supported by the Cancer Research UK.

CHAPTER 15

Basic Concepts of Intussusceptive Angiogenesis

Valentin Djonov and Peter H. Burri
Institute of Anatomy, University of Berne, Switzerland

Sprouting and Intussusceptive Angiogenesis

Angiogenesis is a fundamental process of microvascular growth and expansion implicated in different physiological and pathological processes. It can occur by two main mechanisms: sprouting and intussusception. Although both mechanisms lead to creation of new vascular segments, they involve different morphogenic mechanisms and probably are regulated by different factors.

Sprouting angiogenesis is characterized by local vasodilation, followed by increased vascular permeability. After proteolytic degradation of the basement membrane, the endothelial cells migrate into the extracellular matrix and proliferate. After internal reorganization, the sprouts form a vascular lumen and get connected to other capillary segments. Sprouting is a relatively sluggish process. At least three to five days are needed before the newly formed capillary loop is perfused and integrated into the vascular system.

In intussusceptive angiogenesis, the capillary system expands and grows by the insertion of new capillary meshes into the existing network.

The Basic Concept of Intussusception

Nonsprouting angiogenesis by intussusception was first described in the capillary bed of neonatal rat lungs by Caduff and coworkers [1]. Analyzing scanning electron micrographs of lung vascular corrosion casts, the authors detected a multitude of tiny holes with diameters up to 2 µm. Serial sectioning of lung tissue followed by transmission electron microscopy revealed these structures to correspond to transluminal tissue pillars [1, 2]. Four consecutive steps for pillar formation have been postulated:

- *Phase I:* Simultaneous protrusions of opposite capillary walls into the vessel lumen lead to the creation of an interendothelial contact zone across the capillary lumen.
- *Phase II:* Reorganization of the interendothelial cell junctions followed by central perforation of the sandwich-like structure composed of two basal membranes and two endothelial leaflets.
- *Phase III:* Formation of the interstitial pillar core by invasion of cell processes of pericytes and myofibroblasts; appearance of collagen fibrils. During these first three phases, the transluminal pillars are still very slender, mostly with diameters less than 2.5 µm.
- *Phase IV:* The pillars increase in girth by further deposition of material and cells, but without changes in their basic structure.

The concept of intussusception is schematically represented in Figure 1.

In the meantime, it could be demonstrated that transcapillary tissue pillars could be produced by several alternative mechanisms to the one described above. For details, the reader is referred to a recent review [3].

To describe the new angiogenic process, the authors coined the term *intussusception* to convey the meaning that creation of new capillary segments occurs by insertion of transcapillary pillars (i.e., by growth "within itself"). They postulated that the microvasculature of the developing lung was predominantly growing by intussusception, a phenomenon that had not been described hitherto and termed it intussusceptive microvascular growth (IMG) [1, 2].

The complex spatial structure of transluminal pillars, their small size, and the need of three-dimensional analysis

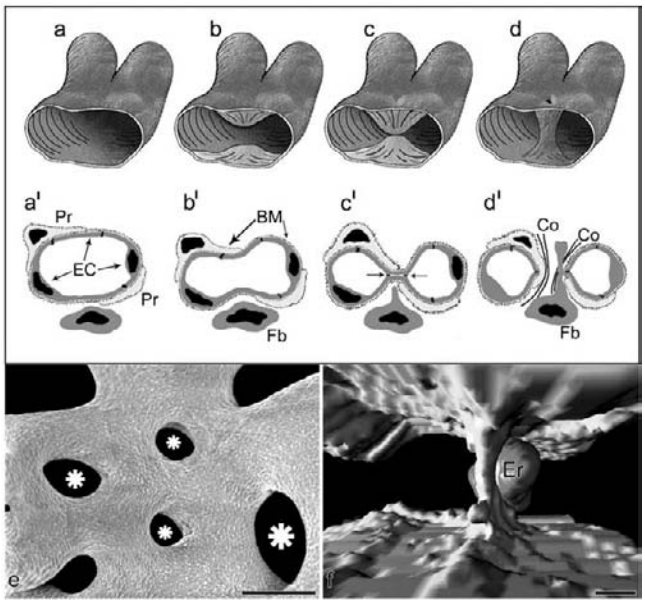

Figure 1 Three-dimensional **(a–d)** and two-dimensional **(a′–d′)** drawings illustrating intussusceptive pillar formation. The process begins with the protrusion of opposite capillary walls into the vessel lumen **(a, b, a′, b′)**. After establishing an interendothelial contact **(c, c′)**, the endothelial bilayer and the basement membranes (BM) are perforated centrally. The newly formed pillar increases in girth after being invaded by pericytes (Pr) and fibroblasts (Fb), which produce collagen fibrils (Co) **(d, d′)**. Corresponding three-dimensional visualization of transluminal pillars in capillary plexus of chicken CAM. In corrosion casts of blood vessels, newly formed transcapillary pillars appear as small holes (*asterisks*) **(e)**; three-dimensional reconstruction of a pillar based on transmission electron microscopic analysis of serial sections **(f)**. An erythrocyte (Er) is seen behind the pillar. Bars: e and f = 5 µm. (a–d′). Reproduced from Kurz et al. 2003 [8] and (e, f) from Djonov et al. 2000 [4] with the authors' and publisher's permission. (see color insert)

for their visualization may explain why intussusception was overlooked in the past. The only reliable methods to recognize transluminal pillars safely are vascular corrosion casting visualized by scanning electron microscopy, serial sectioning for light or transmission electron microscopy followed by three-dimensional reconstruction (Figure 1) or, alternatively, confocal laser microscopy [4–7]. Other methods, such as nuclear magnetic resonance, microcomputer tomography, angiography, and ultrasonics even adapted for small objects do not have the resolution (below 1 µm) needed for visualizing pillars.

Hallmarks of Intussusception

Intussusception is a widespread phenomenon that occurs in the vascular systems of all species and organs investigated so far. Some essential characteristics, which distinguish it from sprouting, are discussed in the following sections.

Intussusception Can Occur Only in a Perfused Vascular Bed

All commonly used in vitro and in vivo experimental tools, such as three-dimensional collagen gels, corneal implants, tumor implantation, wound healing, and embryonic grafting, will originally induce capillary sprouting during early tissue neovascularization. Intussusception would not be expected to occur initially in these models because (1) the facts that the tissue has first to be "colonized" by endothelial cells and (2) the absence of blood flow. Our own investigations indicated that hemodynamic factors are essential players in regulatory mechanisms of intussusception [7]. This could be an additional reason why intussusception has not been recognized until recently.

Blood Vessel Segments Are Generated More Rapidly by Intussusception than by Sprouting

As mentioned previously, sprouting is a relatively sluggish process, requiring a few days for initiation, implementation, and finally integration of the newly formed segments into the vascular system. Using improved in vivo monitoring combined with histological and ultrastructural analyses of serial tissue sections, pillar formation has been demonstrated to require a period of four to five hours for completion. Under conditions of artificially accelerated blood flow, this period was reduced to one hour only [4, 5, 7]. This swiftness could explain how the capillary network of the eye choroid or of the chorio-allantoic membrane (CAM) of the chicken could increase 25 and 100 times, respectively, in disk surface just within a few days. The augmentation of the vascular exchange surface area and vascular volume was much higher even. Similarly, in the lung vasculature during the early postnatal period, the capillary volume and surface area increase thirty-fivefold and twentyfold, respectively [4, 5, 7–9].

Intussusceptive Microvascular Growth Is Achieved with a Low Rate of Endothelial Proliferation

Our own morphometric investigations on the lung and CAM, as well as data from the literature, indicate that the intussusceptive process is associated with low endothelial proliferation. This means that capillary beds growing by intussuception achieve their rapid expansion by redistributing the preexisting total endothelial cell volume by thinning and spreading of the cytoplasmic leaflets. This was confirmed by our comparative studies of different organs before and after the onset of intussusception, as well as by reports in the literature [3–5, 8, 9].

Capillaries Formed by Intussusception Are Less Leaky

Intussusception is characterized by physiological levels of vascular transpermeability. This is an essential condition for uncompromised tissue and organ function. This

important benefit could be the reason why after the formation of the primary capillary plexus by vasculogenesis or sprouting, additional vascular growth and remodeling during both embryonic development and postnatal life occurs by intussusception. The low transpermeability could furthermore be an essential factor for the resistance to chemotherapy treatment in tumors growing predominantly by intussusception [6].

Intussusception Is Energetically and Metabolically More Cost Effective

In contrast to sprouting, massive cell proliferation, extensive basement membrane degradation, and invasion of the surrounding tissue is not required in intussusception. Intussusception represents a phenomenally simple angiogenic mechanism possessing a high morphogenic potential and plasticity, and which is simultaneously energetically and metabolically more economical. This would explain why intussusceptive microvascular growth is triggered immediately after the formation of the primitive capillary plexus by vasculogenesis or sprouting.

Three Facets of Intussusceptive Angiogenesis

The term *intussusceptive angiogenesis* circumscribes a host of processes that are involved in generation, growth, and final remodeling of vascular entities with diverse morphological and functional outcomes. Although chronologically sequential, the processes overlap both in space and time, affecting different components of the vascular bed.

Intussusceptive Microvascular Growth: Expansion of Capillary Plexuses

Intussusceptive microvascular growth (IMG) represents a widespread phenomenon, by which capillary plexuses expand by simultaneous scattered pillar formation and successive pillar enlargement. By these means, new microvascular segments arise without dramatic changes in the dimensions and functional characteristics of their components (Figure 2). IMG favors the rapid expansion of the primitive capillary plexuses, thus providing a large surface area for the exchange of oxygen, carbon dioxide, and nutrients. As mentioned previously, IMG was first observed in the growing postnatal lung [1] and then in the microvasculature of many other tissues and organs, both in normal and pathological microvascular growth, such as retina, kidney, CAM, liver, intestines, stomach, excretory glands, spleen, skeletal muscle, heart, brain, in a model of tissue repair, during the cyclic vascular changes in the endometrium, in cerebral vascularization after stroke, and during tumor angiogenesis. Intussusception is a widespread, practically ubiquitous phenomenon that occurs in the vascular systems

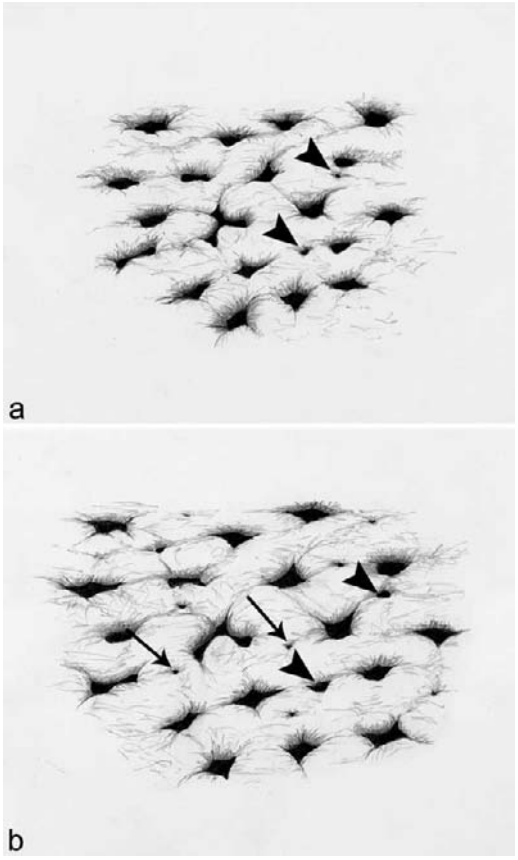

Figure 2 Drawing representing the process of intussusceptive microvascular growth (IMG). The capillary plexus expands from its initial stage in **(a)** to status **(b)** by insertion of new pillars (*arrows*) and by enlargement of already existing ones (arrowheads).

of all species thus far investigated, including rat, mice, rabbit, chick, fish, and human. Actually, in many older reports dealing with different angiogenic aspects, it is possible to recognize the well-documented signs of intussusception; they were, however, not recognized as a mechanism of angiogenesis. It is now evident that IMG represents a general and ubiquitous mechanism of capillary growth, by which the capillary beds of organs, which arise initially by sprouting and/or vasculogenesis, can undergo rapid expansion without any compromise in vascular physiology or function thanks to low vascular permeability and a low rate of endothelial cell proliferation [3, 6, 8, 9].

Intussusceptive Arborization: Formation of a Feeding Vascular Tree

Intussusceptive arborization (IAR) represents a mechanism whereby preferentially perfused segments of a capillary plexus can be transformed into terminal arterioles or collecting venules, patterning in this way a hierarchic vascular tree. IAR is initiated by the formation in the capillary bed of double rows of lined-up “vertical” tissue pillars, which demarcate future feeding vessels. These pillars undergo reshaping into narrow tissue septa that progres-

sively fuse to delineate a new vascular entity. The remaining connecting bridges are "severed" by the formation of "horizontal" folds, the feeding vessels being thereby definitively separated from the capillary plexus. As a result of this process, a complex arterial and venous vascular tree arises to form a second layer of draining and feeding vessels (Figure 3).

IAR provides the vasculature with an important angioadaptive mechanism. Any capillary plexus expansion is associated with an increase in the mean capillary path length between arteries and veins, with deleterious consequences for gas and nutrient exchange. The formation of new terminal supplying and draining branches is necessary, and this is achieved via IAR. The IAR process could be observed in all investigated organs and systems, but for easy demonstration it is mostly shown in nearly two-dimensional capillary beds, such as the chloroid of the eye and the chicken CAM. In these models, the de novo segregated arterial and venous vascular trees form an easily detectable second layer atop the capillary plexus [3–5, 8–9].

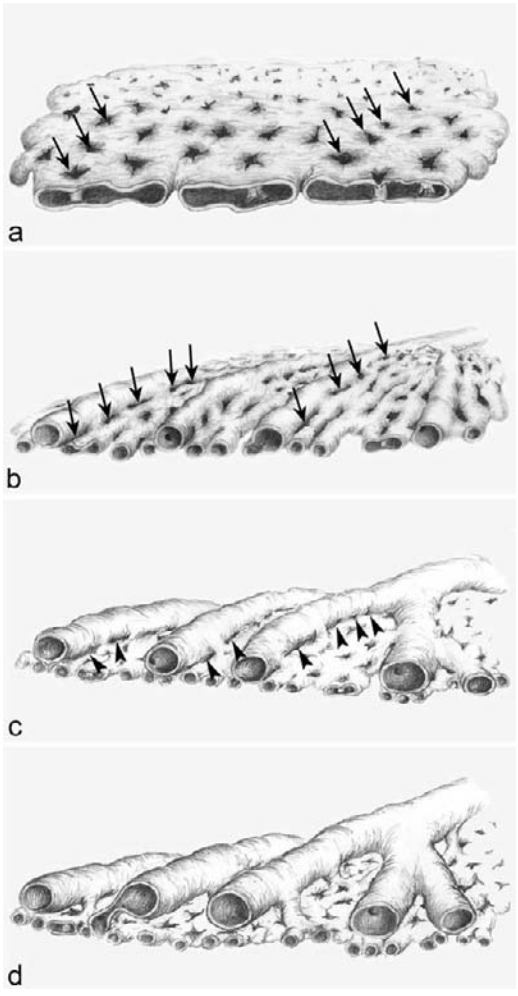

Figure 3 Drawing representing the process of intussusceptive arborization (IAR). Within a capillary plexus, a series of "vertical" pillars arise (*arrows in* ***a***), demarcating the pathway of future feeding vessels. These pillars undergo reshaping and fusion to form narrow tissue septa (*arrows in* ***b***). "Horizontal" pillars and folds are then formed (*arrowheads in* ***c***), which separate the feeding vessels from the capillary plexus **(d)**. Adapted from Djonov et al. 2000 [5], with the authors' and publisher's permission.

Intussusceptive Branching Remodeling: Optimization of Branching Geometry and Vascular Pruning

Intussusceptive branching remodeling (IBR) refers to the process by which the branching geometry of supplying vessels is modified, thereby optimizing the pre- and postcapillary flow properties. IBR can also lead to the removal of putative supernumerary branches (vascular pruning), thereby optimizing the efficiency of the blood supply and the hierarchy of the vascular tree. Implementation of IBR is accomplished via transluminal pillars and folds, which are inserted close to the bifurcation sites of arteries and veins of up to 120 μm in diameter. These structures appear de novo and are capable of rapidly changing the vascular geometry and the hemodynamic properties at the affected branching points.

The pillars located close to bifurcation points enlarge (alternately elongate into flat longitudinal folds) until they merge with connective tissue in the branching angle (Figure 4). Thus, IBR narrows the branching angle by relocating the branching point more proximally. This may represent an important adaptive response to the continually increasing blood flow and blood pressure during embryogenesis and growth. Second, IBR optimizes the hemodynamic conditions at bifurcation sites by remodeling the diameter of one or both branches (mainly by "pillar augmentation"). Consequently, IBR yields a branching pattern that approximates the ideal hemodynamic condition predicted by Murray's Law of minimal power consumption and constant shear stress. Third, IBR is implemented in the process of vascular pruning by the successive asymmetric formation of pillars. The subtotal lumen obstruction of one of the daughter branches followed by reduction in blood flow probably contributes to the regression, retraction, and ultimate atrophy of the affected branch (Figure 4) [7–9].

From the mechanisms of IAR and IBR, detected more recently, it appears that the intussusceptive angiogenic principle represents an important morphogenetic machinery affecting all components of vascular beds: as the expansion of capillary beds (IMG), the segregation of small arteries and veins (IAR), and finally the optimization of the branching geometry and vascular pruning by IBR.

Sprouting and Intussusception: Two Complementary Angiogenic Mechanisms

Structural investigations have revealed that the vasculature of different organs of chicks and rats, such as CAM, lung, heart, endometrium, eye, kidney, and yolk sac, undergoes two main phases of development. The *early, sprouting phase* is characterized by the appearance of multiple capillary sprouts, which are responsible together with

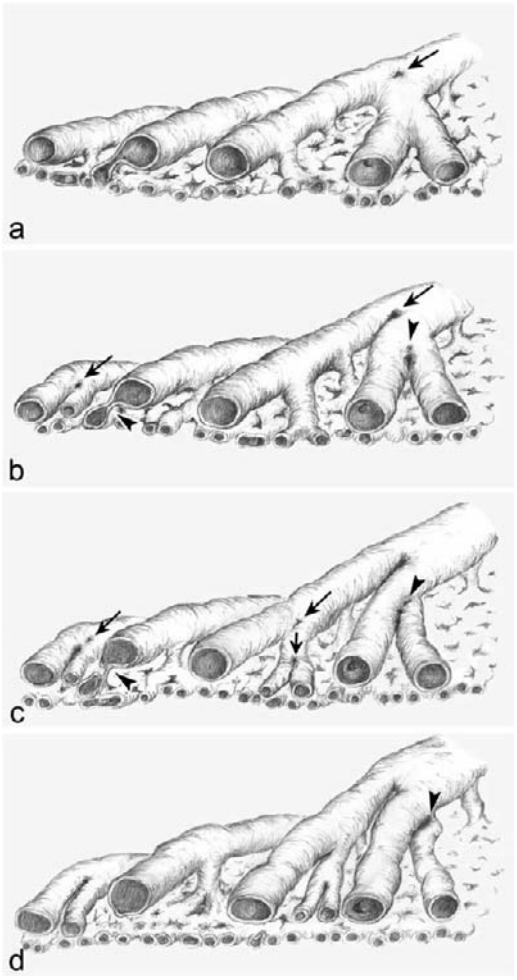

Figure 4 Drawing representing intussusceptive branching remodeling (IBR). The insertion of transluminal pillars at branching points is followed by their merging with the connective tissue in the branching angle (*arrows*). This process allows to adapt the depth of the branching angle and the diameters of the two daughter vessels. Moreover, intussusceptive branching remodeling leads to vascular pruning by repetitive eccentric formation, thickening, and fusion of pillars (*arrowheads*). Adapted from Djonov et al. 2000 [5], with the authors' and publisher's permission.

vasculogenesis for tissue neovascularization, forming the primary capillary plexuses. During the *second, intussusceptive phase*, capillary sprouting is superseded by pillar formation. Further vascular growth and remodeling occurs by intussusception as a result of advantages listed in the section on hallmarks of intussusception.

Summary

Intussusceptive angiogenesis is a general and ubiquitous formative process of the vasculature. The formation of tissue pillars across the vascular lumen has three distinct consequences depending on the pillar location. It results in rapid expansion of the capillary networks (= IMG), it implements vascular tree formation (= IAR), and/or it leads to dynamic adaptations and remodeling of the vascular bed (= IBR). It plays a crucial role in embryonic blood vessel formation, growth, tissue repair, and tumor angiogenesis.

Taking into consideration that numerous pro- and antiangiogenic agents act in complex vascular beds formed mainly by intussusception, it is evident that better understanding of the intussusceptive angiogenesis, and especially its regulatory mechanisms, will open the way for development of novel therapeutic strategies.

Capsule Biographies

Peter H. Burri is Professor Emeritus of Anatomy. He was the head of the Section for Developmental Biology at the Institute of Anatomy of the University of Berne, Switzerland, and became the Chairman of the Institute from 1993 to 2003. His primary research interest was lung development, growth, and regeneration. His research on angiogenetic mechanisms developed directly from the lung studies. Dr. Burri's work has constantly been supported by the Swiss National Science Foundation.

Valentin Djonov is Assistant Professor at the Institute of Anatomy of the University of Berne, Switzerland. After completing research in tumor biology in the lab of Professor Friis, he joined the group of Dr. Burri in 1995 and started work on intussusceptive angiogenesis. He is now leading the research group in this field. Dr. Djonov's work is supported by the Swiss National Science Foundation and the Bernese Cancer League.

CHAPTER 16

Vascular Permeability Factor/Vascular Endothelial Growth Factor (VPF/VEGF, VEGF-A)

Harold F. Dvorak

Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts

VEGF-A is the founding member of the VPF/VEGF family of proteins that also includes VEGFs B, C, and D as well as placenta growth factor (PlGF) and a related viral protein, VEGF-E. VEGF-A, the subject of this chapter, has critical roles in vasculogenesis and pathological and physiological angiogenesis, acting through receptors (VEGFR-1, VEGFR-2, and neuropilin) that are expressed on vascular endothelium as well as on certain other cell types. The product of a single gene, VEGF-A is alternatively spliced to form several proteins of different lengths, properties, and functions. Originally discovered as a potent vascular permeabilizing factor (VPF), VEGF-A is also an endothelial cell motogen and mitogen, profoundly alters the pattern of endothelial cell gene expression, and protects endothelial cells from apoptosis and senescence. Recently, VEGF-A has been found to have additional critical roles in hematopoiesis, in expansion and differentiation of bone marrow endothelial cell precursors, and in development and maintenance of the nervous system. The functions of other VPF/VEGF family members have been less well characterized. However, VEGFs C and D are essential for development of the lymphatic system, VEGF-B has a role in the development of coronary arteries, and PlGF has important roles in pathological angiogenesis.

VEGF-A Structure

VEGF-A is a highly conserved, disulfide-bonded dimeric glycoprotein of Mr ~45 kD. It shares low but significant sequence homology with platelet-derived growth factor (PDGF) and, like PDGF, has cysteines that form integral inter- and intra-chain bonds. Crystal structure reveals that the two chains that comprise VEGF-A are arranged in antiparallel fashion with binding sites at either end. Upon reduction, VEGF-A separates into its individual chains and loses all biological activity.

The human VEGF-A gene is located on the short arm of chromosome 6 and is differentially spliced to yield predominant isoforms that encode polypeptides of 206, 189, 165, and 121 amino acids in human cells (corresponding murine proteins are one amino acid shorter) (Figure 1). Other splice variants (183, 165b, 145) have also been described. The several major VEGF-A isoforms have distinct physical properties. VEGF-$A^{120/1}$ is acidic, freely soluble, and does not bind heparin. By contrast, the 164/5 and 188/9 isoforms have increasing basic charge and bind heparin with increasing affinity; in fact, VEGF-A^{165} was originally purified on the basis of its affinity for heparin. Heparin, heparan sulfate, and heparinase all displace the larger VEGF-A isoforms from proteoglycan binding sites in tissues; proteases such as plasmin have a similar net effect, cleaving the C-terminal portion of bound VEGF-A to generate a biologically active peptide. In several situations in vivo, liberation of bound VEGF-A from cells or cell matrix is the necessary trigger that initiates angiogenic activity. The different VEGF-A isoforms have largely identical biological activities in vitro, but there is increasing evidence for distinctive functions in vivo; for example, mice

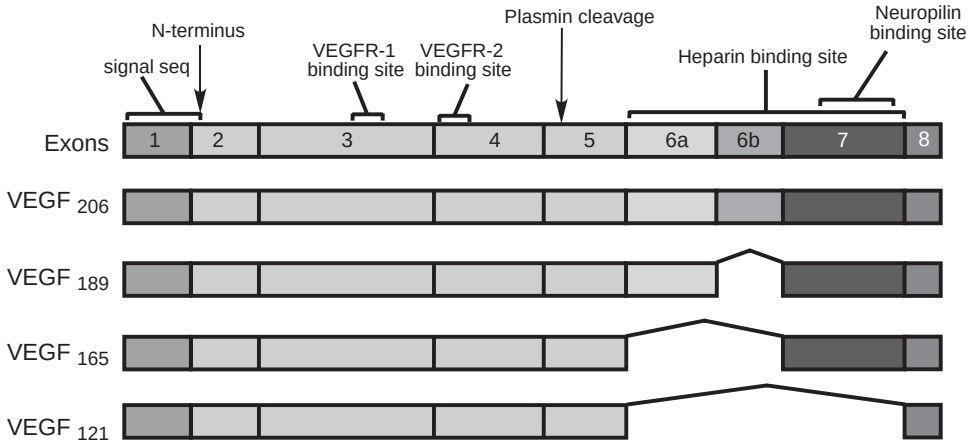

Figure 1 VEGF-A Gene Structure. VEGF-A has eight exons, the first of which encodes a hydrophobic leader sequence, typical of secreted proteins. The 206 amino acid VEGF-A isomer is encoded by all eight exons. VEGF-A^{189} lacks a portion of exon 6, whereas VEGF-A^{165}, frequently the predominant isoform, lacks all of exon 6. VEGF-A^{121} lacks both exons 6 and 7. VEGF receptor and heparin binding sites are as indicated. [Republished with permission from Cross et al. (2003), *Trends in Biochemical Sciences* **28**, 488.] (see color insert)

expressing only the 120 or 188 isoforms develop severe vascular anomalies.

VEGF-A Receptors and Signaling Pathways

VEGF-A mediates its effects primarily by interacting with two high-affinity transmembrane tyrosine kinase receptors: VEGFR-1 (Flt-1) and VEGFR-2 (KDR, Flk-1) (Figure 2). Cultured endothelial cells have approximately 3,000 copies of VEGFR-1, which binds VEGF-A^{165} with a K_d of approximately 10 pM; they have more numerous copies of VEGFR-2, which binds VEGF-A^{165} with somewhat lower affinity (K_d of 75 to 125 pM). A truncated soluble form of VEGFR-1 (sFlt) that results from alternative splicing is found in serum and retains VEGF-A binding activity. sFlt has recently been implicated in pre-eclampsia, a serious complication of pregnancy. A third, nonkinase receptor, neuropilin (NRP-1) has been found; NRP-1 potentiates VEGF-$A^{164/5}$'s binding to VEGFR-2. Neuropilin had been known as a receptor for the semaphorin/collapsin family of neuronal guidance mediators, and it is also expressed widely on nonendothelial cells. VEGF-$A^{164/5}$, B, E, and PlGF bind to NRP-1, but VEGF-$A^{120/1}$ does not (Figure 2); this inability may explain some of the abnormalities in mice engineered to express only the VEGF-A^{120} isoform. Two other members of the VPF/VEGF family (VEGF-B and both isoforms of PlGF) bind to VEGFR-1, whereas VEGFs C, D, and E bind to VEGFR-2.

Mice null for any of the three VEGF-A receptors are embryonic lethals. VEGFR-1 null mice die at day 8.5 to 9.0 as a result of vessel obstruction by an overgrowth of endothelial cells. VEGFR-2 knockout mice die at a similar stage of development because of failure of endothelial and

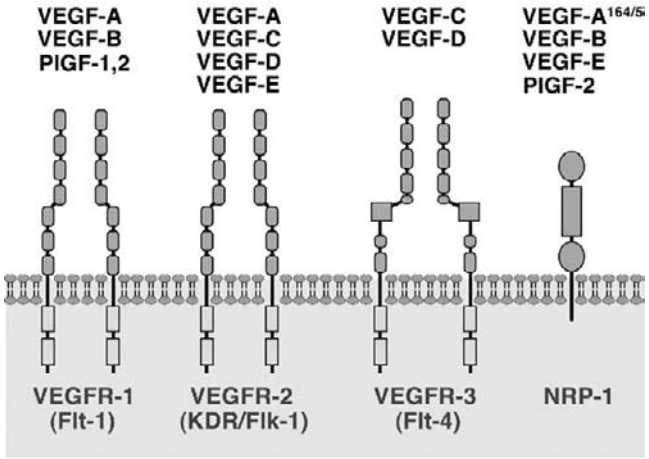

Figure 2 Binding Specificities of the VPF/VEGF Ligand Family Members and Their Receptors. VEGFR-1 and VEGFR-2 are expressed on vascular endothelial cells as well as on some other cell types; VEGR-3 is expressed on lymphatic endothelium in the adult but also on some tumor vessels. NRP-1 is expressed on vascular endothelium, neurons, and some tumor cells (see text for further details). [Republished with permission from H. Dvorak (2002), *Journal of Clinical Oncology* **20**, 4368.] (see color insert)

hematopoietic precursor cells. NRP-1 null mice also die from a failure of vascular development.

VEGFR-1 and VEGFR-2 are widely expressed on normal vascular endothelium, and expression is upregulated in tumor blood vessel endothelium and in that of other examples of pathological angiogenesis induced by VEGF-A. The mechanisms responsible for receptor overexpression are not yet fully understood, but hypoxia, which stimulates VEGF-A expression (see following discussion), may also upregulate VEGF receptor expression.

Recent reports indicate that VEGF-A receptors may also be expressed on tumor cells, raising the possibility of an

autocrine loop that might stimulate tumor cell growth and migration. VEGFR-1 is additionally expressed on a population of hematopoietic stem cells and myeloid progenitors as well as on monocytes/macrophages, spermatogenic and Leydig cells, uterine smooth muscle cells, and osteoclasts. VEGFR-1 has an important role in mediating hematopoietic cell development and recruitment, particularly that of monocytes, and mediates VEGF-A-induced monocyte (but not endothelial cell) motility. As noted previously, VEGFR-1 null embryos die as a result of an overgrowth of endothelial cells, implying, along with data from cultured endothelial cells, that this receptor exerts a negative regulatory effect on the VEGF-A activities governed by VEGFR-2 signaling. VEGFR-2 is expressed on bone marrow endothelial cell progenitors, megakaryocytes, uterine smooth muscle cells, and lymphatic endothelium.

Although binding to VEGF-A with high affinity, VEGFR-1 induces only minimal stimulation of kinase activity in vascular endothelium; as a result, downstream signaling pathways have had to be worked out in endothelial cells that were engineered to overexpress this receptor. Much more is known about the signaling pathways initiated through VEGFR-2 (Figure 3). Upon binding to VEGFR-2, VEGF-A initiates a cascade of events that begins with receptor dimerization and autophosphorylation followed by phosphorylation of numerous downstream proteins. Very recently, G proteins have been implicated in VEGF-A signaling. Most of the biological activities mediated by VEGF-A on endothelial cells (e.g., proliferation, migration, vascular permeability, antiapoptosis) are mediated through VEGFR-2 signaling. VEGFR-2 also has an important role in the development of endothelial cell precursors present in the bone marrow and circulating in blood.

Biological Activities

VEGF-A is essential for the development and organization of the vascular system (vasculogenesis) and for both physiological and pathological angiogenesis. Mice lacking even one copy of the VEGF-A gene are embryonic lethals. VEGF-A mediates its complex functions by exerting specific biological activities.

Increased Microvascular Permeability

VEGF-A was originally discovered in the late 1970s because of its ability to increase the permeability of microvessels (primarily postcapillary venules) to circulating plasma and plasma proteins. It is responsible for the nearly

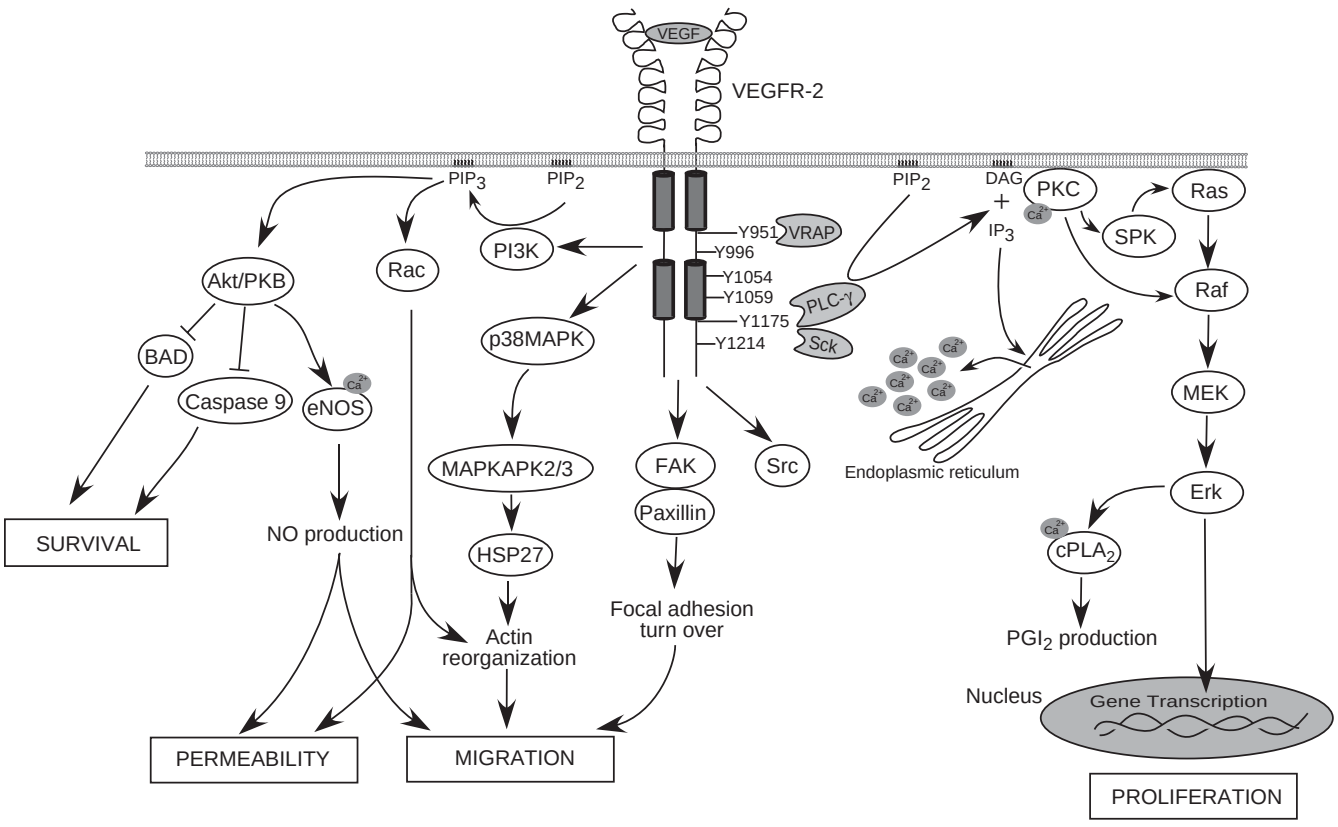

Figure 3 Schematic Diagram of VEGFR-2 Signaling. Ligand binding to the extracellular domain induces dimerization, autophosphorylation of specific intracellular tyrosine residues, and a series of downstream phosphorylations and other events that lead to endothelial cell survival, migration, proliferation, and increased permeability. [For further details, see Cross et al. (2003), *Trends in Biochemical Sciences* **28**, 488, from which this diagram is republished with permission.] (see color insert)

universal hyperpermeability of tumor blood vessels. Permeability becomes evident within a minute following injection of VEGF-A protein into skin and continues for approximately 20 minutes. VEGF-A is among the most potent vascular permeabilizing agents known, acting at concentrations below 1 nM and with potency some 50,000 times that of histamine on a molar basis.

VEGF-A induces venular permeability by its action on endothelial cells, the primary barrier to the extravasation of plasma proteins, but there has been debate about the pathway that circulating macromolecules follow in traversing endothelium. The earlier view had been that vasoactive agents cause endothelial cells to pull apart, creating an interendothelial cell gap through which macromolecules could extravasate. Although supported by data using cultured endothelial cells, evidence for an intercellular extravasation pathway in vivo is not convincing. More recent studies have shown that macromolecules cross tumor and normal venular endothelium primarily by means of a transendothelial cell pathway that involves vesiculovacuolar organelles (VVOs) (see Chapter 46 by A. Dvorak and D. Feng for a detailed discussion of VVOs). VEGF-A also induces endothelial fenestrations that provide an additional transcellular pathway for solute extravasation.

The increased microvascular permeability induced by VEGF-A leads to tissue edema, a characteristic of tumors, healing wounds, and other pathologies in which VEGF-A is overexpressed. Extravascular fluid accumulation is particularly prominent in tumors growing in body cavities such as the peritoneum (ascites tumors). Plasma protein leakage has several consequences. One of these is activation of the clotting system via the tissue factor pathway, leading to deposition of a fibrin gel that retards clearance of edema fluid and results in locally increased interstitial tissue pressure, a characteristic feature of many solid tumors. Deposited fibrin also provides a provisional stroma for endothelial cell and fibroblast migration that supports the angiogenesis and fibrogenesis necessary for generating mature stroma (desmoplasia in the case of tumors or scar formation in wound healing).

Other Biological Activities on Vascular Endothelium

VEGF-A has multiple effects on vascular endothelium that become apparent over the time frame of hours to days. These include striking changes in cell morphology and cytoskeleton, accompanied by stimulation of endothelial cell migration and division. At the molecular level, VEGF-A reprograms endothelial cell gene expression, causing the increased production of several different proteins, including the procoagulant tissue factor, fibrinolytic proteins (urokinase, tPA, PAI-1, urokinase receptor), matrix metalloproteases, the GLUT-1 glucose transporter, nitric oxide synthase, numerous mitogens, and antiapoptotic factors (e.g., bcl-2, A1, survivin, XIAP). VEGF-A also serves as an endothelial cell survival factor, protecting endothelial cells against apoptosis (L. Benjamin) and senescence. In addition, the Jain laboratory has shown that VEGF-A upregulates the expression of endothelial adhesion molecules on vascular endothelium, including E-selectin, ICAM-1, and VCAM; this favors inflammatory cell attachment and extravasation. Recently, the Ferrara laboratory has identified another activity of VEGF-A, that of paracrine release of hepatotrophic molecules from sinusoidal liver endothelium, a function mediated through VEGFR-1.

Effects of VEGF-A on Cells Other Than Vascular Endothelium

There is increasing interest in activities that VEGF-A exerts on nonendothelial cells that express VEGF receptors as VEGF-A stimulates monocyte chemotaxis and proliferation of uterine smooth muscle. VEGF-A also has reported effects on lymphocytes, granulocyte-macrophage progenitor cells, osteoblasts, Schwann cells, mesangial cells, and retinal pigment epithelial cells. In development, VEGF-A drives angioblasts and primitive vessels toward arterial differentiation and attracts filopodia of both endothelial cells and neurons, causing these cells to move in the direction of a VEGF-A gradient. VEGF-A receptors have now been reported on some tumor cells, raising the possibility that VEGF-A exerts autocrine effects that enhance tumor cell motility and survival.

Expression of VEGF-A in Normal Physiology and in Pathology

VEGF-A is constitutively expressed in the cells of many normal tissues and at higher levels in several types of epithelium (renal glomerular podocytes, adrenal cortex, breast, and lung), in cardiac myocytes, and in activated macrophages. It is also expressed at high levels in the physiological angiogenesis of ovarian follicular development, in corpus luteum formation, and in endochondral bone formation.

VEGF-A is overexpressed by the vast majority of solid human and animal carcinomas, where it is thought to be the prime mover of tumor angiogenesis. Most VEGF-A in solid tumors is expressed by the malignant cells, but tumor stroma can also synthesize VEGF-A. More recently, VEGF-A has been found to be expressed in lymphomas and hematological malignancies. VEGF-A is also overexpressed in at least some premalignant lesions (e.g., precursor lesions of breast, cervix, and colon cancers); furthermore, expression levels increased in parallel with malignant progression. An association between VEGF-A expression and benign tumors is less well established, in part because the latter have been less carefully studied. However, pituitary adenomas and benign hemangiomas rarely overexpress VEGF-A, whereas uterine leiomyomas and malignant vascular tumors do so.

VEGF-A is overexpressed in many other examples of pathological angiogenesis, including wound healing (e.g.,

in healing skin wounds, myocardial infarcts, and strokes), chronic inflammation (e.g., delayed hypersensitivity, rheumatoid arthritis, psoriasis), and various retinopathies. In all of these examples, VEGF-A is thought to be largely responsible for the accompanying angiogenesis.

Regulation of VEGF-A Expression

Several mechanisms regulate VEGF-A expression, including oxygen concentration, low pH, oncogenes and tumor suppressor genes, cytokines, hormones, and a variety of other mediators.

Oxygen Concentration and Low pH

Hypoxia potently upregulates VEGF-A expression, both by stabilizing its message and by increasing message transcription. Transcriptional regulation is mediated through hypoxia-inducible factor 1 (HIF-1), a heterodimeric protein transcription factor. One HIF-1 component, HIF-1α, is rapidly degraded under normoxic conditions by the ubiquitin pathway; however, when stabilized by hypoxia, HIF-1α dimerizes with HIF-1β, and the complex binds to and activates a hypoxia-responsive element in the VEGF-A promoter. Hypoxic regulation of VEGF-A expression is likely important in healing wounds and has been demonstrated in some tumors. However, many tumors express VEGF-A constitutively at high levels even under normoxic conditions, and therefore, regulation is achieved by other means, such as those discussed as follows.

Low pH, another hallmark of tumors and ischemic tissues, also upregulates VEGF and does so independently of HIF-1.

Oncogenes and Tumor Suppressor Genes

Several oncogenes (*src*, *ras*) and tumor suppressor genes (*p53*, *p73*, von Hippel Lindau [*vHL*]) modulate VEGF-A expression and in this way can modulate tumor growth. Cells transfected with mutant *src* or *ras* oncogenes express increased amounts of VEGF-A mRNA and protein. The *vHL* tumor suppressor gene is part of the protein complex that targets specific proteins, including HIF-1α, for ubiquitinylation and proteolysis. Therefore, when *vHL* is absent or inactivated, HIF-1α is stabilized even under normoxic conditions with resulting upregulation of VEGF-A and perhaps other members of the VPF/VEGF family. The *p53* and *p73* genes suppress VEGF-A transcription.

Cytokines and Other Mediators

Numerous growth factors, cytokines, and lipid mediators upregulate VEGF-A expression in different cells, including EGF, TGF-α, FGF-2, TGF-β, PDGF, keratinocyte growth factor, TNF, interleukins 1 and 6, insulin-like growth factor 1, HGF, and prostaglandins E1 and E2. These findings are likely to be important in autocrine regulation of VEGF-A expression in vivo in that many tumors that express VEGF-A also express other cytokines and their receptors (e.g., TGF-α, FGF-2, EGF).

Hormones

VEGF-A is expressed by many cells that make steroid hormones (adrenal cortex, corpus luteum, Leydig cells) and by cells that are under hormonal regulation (e.g., the cycling uterus and ovary). Circulating VEGF-A levels and presumably VEGF-A expression correlate with estrogen receptor positivity in breast cancer. VEGF-A is also expressed by peptide hormone-producing cells such as thyroid follicular cells, and its production in culture is upregulated by agents such as insulin, dibutyryl c-AMP, and the IgG of Graves' disease. Thyroid-stimulating hormone upregulates VEGF-A mRNA expression in human thyroid follicles and promotes VEGF-A secretion in several thyroid cancer cell lines.

Other Agents

Several other chemicals, proteins, and processes can augment VEGF-A expression or activity by direct or indirect means, including thrombin, platelet aggregation, shear stress, acidosis, lysophosphatidic acid, and adenosine. On the other hand, dexamethasone downregulates or prevents cytokine- (but not hypoxia-) induced upregulation of VEGF-A expression.

The New Blood Vessels Induced by VEGF-A

VEGF-A, and particularly its 164/5 isoform, is thought to be the most important mediator of pathological angiogenesis, including that induced by tumors, wounds, and inflammation. However, all of these complex entities involve the activities of multiple cytokines. Recently, it has been possible to tease apart those aspects of the angiogenic response that are attributable solely to VEGF-A by expressing VEGF-A^{164} in an adenoviral vector (Ad-VEGF-A^{164}). Upon introduction into mouse tissues, infected host cells express VEGF-A^{164} protein within a few hours and continue to secrete it at fairly constant levels for approximately two weeks. VEGF-A^{164} induces a highly reproducible, time-ordered sequence of events that is qualitatively similar in all tissues studied. Local microvessels become hyperpermeable to plasma proteins, resulting in tissue edema and deposition of extravascular fibrin. By 18 hours, enlarged, thin-walled, pericyte-poor, hyperpermeable, and strongly VEGF receptor-positive "mother" vessels develop from preexisting venules (Figure 4). Such mother vessels are characteristic of many tumors, healing wounds, and so forth and form according to a three-step process: (1) proteolytic degradation of the noncompliant (nonelastic) vascular basement membrane; (2) detachment of pericytes from basement membrane; and (3) transfer of VVO membranes to the

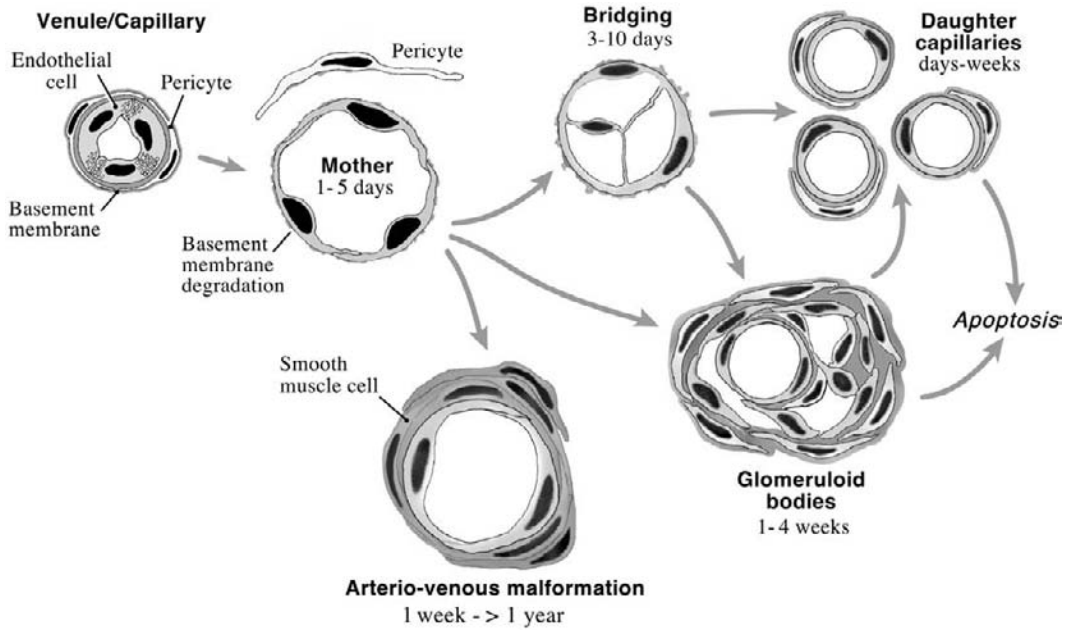

Figure 4 Schematic diagram summarizing the progression of the angiogenic response that follows introduction of a VEGF-A^{164}-expressing adenoviral vector in vivo. Mother vessels develop and may evolve into glomeruloid bodies, vascular malformations, and daughter capillaries. Finally, as VEGF-A^{164} expression wanes, glomeruloid bodies undergo apoptosis, whereas malformations achieve VEGF-A independence and persist indefinitely. [Republished in modified form from Pettersson et al. (2000), *Laboratory Investigation* **80**, 99]. (see color insert)

plasma membrane, allowing endothelial cells to thin and spread over the enlarged surface area that was made possible by basement membrane degradation.

Mother vessels are transitional structures that generally persist as such for only a few days (Figure 4). They may divide into smaller channels by projecting transluminal endothelial cell "bridges" into and across mother vessel lumens; these divide blood flow into smaller channels that separate from each other over time, forming individual smaller-caliber "daughter" capillaries. Mother vessels also evolve to form glomeruloid bodies, poorly organized conglomerates of endothelial cells and pericytes that are also found in tumors such as glioblastoma multiforme. Other mother vessels acquire a coating of smooth muscle cells and/or fibrosis and take on the appearance of arteriovenous vascular malformations. Taken together, these findings show that VEGF-A is sufficient to generate the mother vessels, glomeruloid bodies, and vascular malformations found in various human pathologies.

In addition, VEGF-A^{164} is also able to induce a modest degree of arteriogenesis and to generate abnormal "giant" lymphatics that are characterized by very large size and poor function. Lymphatics of this description occur in patients with Crohn's disease and in lymphangiomas (lymphatic malformations).

Clinical Significance of VEGF-A

Patients with large tumor burdens and widespread metastatic disease have increased levels of circulating VEGF-A, often multiples of those found in normal individuals. Although not useful as a screening tool, increasing serum VEGF-A levels may signify increased tumor growth, recurrence, or metastatic spread in individual patients. There is debate about whether plasma or serum levels are more meaningful because platelets sequester VEGF-A and because plasma $\alpha 2$ macroglobulin binds it and makes it unavailable to at least some antibodies. Also, both megakaryocytes and leukocytes synthesize VEGF-A. Therefore, serum levels reflect not only VEGF-A of tumor origin but also that released from platelets and leukocytes, making it difficult to establish a range of normal values. VEGF-A levels are also elevated in malignant effusions and in the urine of patients with bladder cancer.

Treatments that reduce VEGF-A expression or inhibit its action have been advanced as an antiangiogenesis approach to cancer therapy. Antibodies that neutralize VEGF-A strikingly inhibit tumor growth in mice and have recently shown success in prolonging the life of colon cancer patients when used in combination with chemotherapy. Conversely, VEGF-A has been used in attempts to induce the growth of new blood vessels in ischemic tissues (e.g., myocardial infarctions, peripheral vascular disease), but there are many reasons for caution. Very recently, reduced VEGF-A has been implicated in amyotrophic lateral sclerosis and in certain neurovascular disorders.

Glossary

Angiogenesis: The development of new blood vessels from preexisting blood vessels.

Vasculogenesis: The development of blood vessels from angioblasts as in development.

Vesiculo-vacuolar organelles (VVOs): Interconnected chains of uncoated cytoplasmic vesicles and vacuoles that span the entire thickness of venule endothelial cell cytoplasm from lumen to albumen. VVOs serve as a pathway for macromolecular extravasation and as an intracellular store of plasma membrane that can be transferred to the cell surface to allow rapid plasma membrane expansion and vessel enlargement.

Capsule Biography

Dr. Dvorak has served as chair of the Department of Pathology at Beth Israel Deaconess Medical Center and as Mallinckrodt Professor of Pathology at the Harvard Medical School since 1979. The recipient of the 2002 Rous-Whipple Award from the American Society for Investigative Pathology, his laboratory focuses primarily on the angiogenic response in health and disease. His work is supported by grants from the NIH and the National Foundation for Cancer Research.

CHAPTER 17

Endothelial Progenitor Cells, Vasculogenesis, and Their Contribution to New Blood Vessel Formation in the Adult

John Glod and Howard A. Fine

Neuro-Oncology Branch, National Cancer Institute, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, Maryland

Introduction

It is well established that the de novo formation of blood vessels in the embryo is accomplished by the process of vasculogenesis. Endothelial progenitor cells (EPCs) or angioblasts are formed from more primitive mesodermal precursors and migrate into areas of vessel formation, where they are incorporated into the vascular wall and differentiate into mature endothelial cells (ECs). Vasculogenesis is contrasted by angiogenesis, a process classically thought to be the exclusive means of new vessel formation in the adult. Angiogenesis consists of the replication of mature endothelial cells that are resident in established blood vessels. These cells provide a supply of endothelium for the budding and branching of new vessels from the old. However, evidence has accumulated over the past decade that vasculogenesis is not limited to the prenatal period but is also an important component of new vessel growth in the adult. This chapter summarizes the current body of work on circulating endothelial progenitor cells as building blocks of adult neovasculature.

Despite the recent burst of interest in the concept of vasculogenesis in the adult animal, evidence that an endothelial precursor is present in the adult circulation has a long history. In 1932, Hueper and Russell reported on "Capillary Tube Formation in Tissue Cultures of Leukocytes." This was followed by several reports in the 1950s of hematopoietic cells adopting characteristics of endothelial cells in vitro, and numerous publications have described the participation of blood-derived cells in the re-endothelialization of vascular grafts. Several studies suggested that the new endothelial layer was not a result of migration of cells from preexisting vessels. These early reports suggested the presence of circulating cells that could form endothelium. Several possible hypotheses could explain this finding.

Mature Endothelial Cells in the Circulation

One possibility is that mature endothelial cells are present in the circulation and can participate in neovascularization. In 1970, Gaynor and colleagues identified endothelial cells in the circulation of rabbits after exposure to endotoxin. A body of evidence has since accumulated, demonstrating the presence of mature endothelial cells in the circulation after various types of vascular injury. However, it is unlikely that these cells contribute significantly to vasculogenesis. Two pieces of data that argue against mature ECs participating in vasculogenesis are their extremely low prevalence in the blood (1 to 3 per milliliter of blood) and their limited proliferative capacity based on in vitro assays.

The prevailing evidence indicates that these circulating mature ECs are not the cells responsible for vasculogenesis in the adult. Nevertheless, the presence of increased mature ECs in the circulation may be useful as a marker for vascular injury.

Endothelial Progenitor Cells from the Bone Marrow

Another hypothesis regarding the potential reservoir for circulating endothelial progenitors is that they arise from the bone marrow. The potential for hematopoietic cells to contribute to endothelial formation is supported by the close relationship between endothelial cells and hematopoietic cells in development. Endothelial progenitors (angioblasts) and hematopoietic progenitors both arise from mesodermal precursors in the blood islands during early embryonic development. The angioblasts develop at the perimeter of blood islands in the yolk sac of the embryo, whereas hematopoietic precursors are formed in the center of the blood island. A common precursor for both hematopoietic precursors and angioblasts has also been described by Risau et al. in 1995 using in vivo studies in zebrafish and in vitro differentiation experiments. Embryonic angioblasts and hematopoietic stem cells also share several markers, including Flk-1, Tie-2, and CD34. These hint at the close ties between ECs and hematopoietic cells, suggesting that circulating endothelial progenitors may be generated from bone marrow cells. This line of reasoning ultimately led to the isolation and characterization of circulating EPCs.

Isolation and Characterization of Circulating Endothelial Progenitors from Adult Peripheral Blood

Circulating endothelial progenitors have been defined as highly proliferative cells that are derived from the bone marrow with the capacity to adopt endothelial characteristics in vitro and incorporate into neovasculature and differentiate into mature endothelial cells in vivo. Asahara, Isner, and colleagues published the first description of circulating endothelial progenitor cells in an adult in 1997. In this initial description, human peripheral blood mononuclear cells enriched for expression of the markers Flk-1 (VEGFR2) and CD34 were found to have the capacity to develop traits of mature endothelial cells when cultured. The conditions used to produce this phenotype attempted to recapitulate an angiogenic environment by including bovine brain extract in the culture medium. The cells expressed endothelial characteristics such as the markers CD31, Tie-2, Flk-1, von Willebrand Factor (vWF), and endothelial nitric oxide synthetase (ecNOS). The cells also took up DiI-labeled acetylated low-density lipoprotein (DiI acLDL) and lost the hematopoietic cell surface marker CD45. This initial work was a prelude to several studies in the area that have used a variety of culture conditions to induce the expression of endothelial traits in bone marrow–derived cells. The starting populations of cells that have been used in these experiments can be roughly divided into two categories: hematopoietic stem cells and monocytes. (See Table I for a summary of these experiments.)

Several groups have reported that cells with one or more of a constellation of markers CD133, CD34, and the vascular endothelial growth factor receptor flk1 (VEGFR2) identifies a subpopulation of circulating cells with endothelial potential. These cells have been isolated both from the bone marrow and peripheral blood and been found to adopt endothelial characteristics in culture. Upon culture with angiogenic cytokines such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and others, the precursor endothelial cells lose the expression of hematopoietic stem cell markers CD133 and CD34 and begin expressing the endothelial markers VE-Cadherin, von Willebrand factor, and *Ulex europaeus* agglutinin-1 (UEA-1) binding. Additionally, these cells are able to show some functional endothelial characteristics in vitro, including uptake of acLDL and tube formation in matrigel.

Another hematopoietic cell population that has been shown to adopt endothelial characteristics in vitro and participate in neovasculature formation in vivo are peripheral blood monocytes. The ability of a monocyte fraction of cells to assume endothelial characteristics in vitro was first demonstrated in 2001 by Haaraz and colleagues and has been subsequently repeated in other studies. As with the CD34+/CD133+/FLK1+ cells, monocytes require culture under angiogenic conditions to express endothelial traits. These cells were found to express the EC markers von Willebrand factor, VE-Cadherin (CD144), endoglin (CD105), thrombospondin receptor (CD36), VEGFR1, and VEGFR2. However, unlike the CD34+/CD133+/FLK1+ derived cells, the monocyte-derived cells continue to express myeloid markers such as CD45 and CD14, even as they begin showing endothelial characteristics.

Contribution of Circulating Cells to Neovasculature

In their initial report of endothelial progenitor cells Asahara and colleagues showed that following systemic injection, endothelial progenitors incorporate into sites of vessel growth and repair in rodent hind limb ischemia models. Other investigators have since repeated this finding. Several experimental designs have been used to document this process, although each design has possible pitfalls. The supply of endothelial progenitors has varied between experiments. Both undifferentiated early progenitor cells and cells that have been differentiated in vitro to a more endothelial-like phenotype have been delivered systemically and directly into areas of vessel growth. Additionally, bone

marrow transplant studies have been performed to document the incorporation of bone marrow–derived cells into a growing endothelium. The methods of marking the endothelial progenitors have also differed and include dye labeling, green fluorescent protein (GFP) expression, use of transgenic donor animals expressing GFP or β-galactosidase, and identification of the Y chromosome in sex-mismatched donor/recipient pairs. Some criticisms of these studies have been the possibility of dye uptake by other native cells and the inherent difficulty in demonstrating that a cell is functionally incorporated into the vasculature as opposed to spatially located in the vasculature. Despite these criticisms, the ability of several groups to derive essentially the same conclusions using varied experimental methodologies make the data compelling.

Although the potential for circulating cells to incorporate into new vasculature appears to be established, there continues to be debate on the relative importance of angiogenesis versus vasculogenesis in the adult. An effort has been made to quantitate the relative amount of endothelium derived from circulating cells versus mature local endothelial cells using rodent bone marrow transplant models. Several groups have used this strategy and found wide ranges of donor versus recipient contribution to new vascular endothelium. In different experimental situations, the donor contribution ranges from 0 to 95 percent (see Table II). The comparison of these experiments is complicated by the use of different models of adult vascular formation ranging from tumors to limb ischemia and by other factors such as differences in the extent of bone marrow engraftment and accuracy with which transplanted cells are differentiated from host cells. Several studies in human transplant patients have also been published. Host contributions to endothelium in donor hearts ranging from 0 to –25 percent have been

Table II. Contribution of Bone Marrow–Derived Cells to Neovasculature in Mouse Transplant Models. The contribution of bone marrow–derived cells in various models of neovascular growth in the adult mouse has been determined using murine transplant models. The wide range of bone marrow–derived cells illustrates possible differences in the contributions of angiogenesis versus vasculogenesis with different experimental conditions.

demonstrated, and recipient-derived endothelial cells have been reported in transplanted kidneys and livers. Transplanted bone marrow has also been found to contribute to endothelium in recipients. There are wide variations in the reported relative contribution of circulating cells to new vascular endothelium even among different patients in the same study. This variation in transplant patients as well as rodent bone marrow transplant models suggests that many factors influence the interplay between angiogenesis and vasculogenesis and also illustrates the complexity and variability of these experiments.

Factors That Influence the Numbers of Circulating Endothelial Progenitors

The wide range of estimates on the relative contribution of bone marrow–derived cells to neovasculature suggests that this contribution may vary depending on the conditions in a particular experiment or the biological/clinical situation. One prevailing theme in the literature is the absence or low level of bone marrow–derived cells incorporated into quiescent endothelium, while higher percentages of marrow–derived cells are reported in proliferating vasculature. Other than this broad generalization, factors that may influence the relative contributions of angiogenesis and vasculogenesis to neovessel formation in different circumstances remains unclear. One variable that may play a role is the number of circulating endothelial progenitors.

In a broad sense, the number of circulating endothelial progenitors is increased by vascular injury. More specifically, the levels of several cytokines have been found to influence the numbers of circulating EPCs. Not surprisingly, VEGF was one of the first substances identified that increases EPC number. Increased plasma levels of VEGF in adult mice and humans has been shown to increase EPCs. Other chemokines such as platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), and interleukin-8 (IL-8) have also been shown to promote the migration of endothelial cells to sites of injury. G-CSF, GM-CSF, and erythropoietin, cytokines already in use clinically to promote mobilization of hematopoietic cells, can also increase EPCs. EPC mobilization can also be increased by HMG-CoA reductase inhibitors (statins). Further dissection of the mobilization of circulating EPCs by Heissig and colleagues shows that mobilization of both hematopoietic and endothelial precursors is dependent on MMP-9-mediated release of soluble kit ligand (sKitL) in the bone marrow.

Are Circulating Cells Critical to the Formation of New Vasculature?

Although numerous studies have demonstrated that circulating endothelial progenitors may be involved to a greater or lesser extent in vessel formation in the adult, few have unequivocally demonstrated their necessity in this process. Mice with reduced gene dosages of the Id transcription factors are unable to support neoangiogenesis in tumors. Rafii and colleagues demonstrated that bone marrow transplantation with wild-type marrow could reconstitute tumor angiogenesis in $Id1^{+/-}Id3^{-/-}$ mice. Not only were these studies the first to imply that marrow–derived cells are involved in new vessel formation in the adult, but they also demonstrated that these cells are critical for this process of new vessel formation. In this work, approximately 90 percent of the tumor vessels were found to contain cells derived from the donor bone marrow.

Clinical Studies Using Bone Marrow–Derived Cells to Augment Neovascularization

Although our knowledge is still in its infancy, the biology of circulating EPCs has begun to show some therapeutic promise. In early animal experiments, the injection of

human bone marrow–derived EPCs improved revascularization in rodent hind limb ischemia models. Local injection of EPC or CD34+ cells into the ischemic myocardium of rats has also been shown to improve the recovery of cardiac function after the injury. The use of EPCs in revascularization has progressed to clinical trials. The delivery of autologous bone marrow cells was shown to improve revascularization in patients with ischemic limbs in the Therapeutic Angiogenesis using Cell Transplantation Study. Several clinical trials have also shown benefit to the local delivery of EPCs in the treatment of myocardial infarction.

Using Bone Marrow–Derived Cells in Antiangiogenic Strategies

Using EPCs to impede vascular growth is also being investigated. Ferrari and colleagues used bone marrow–derived cells to deliver a conditional cytotoxic gene to tumor vasculature. This approach resulted in a significant decrease in tumor growth. Other laboratories have used similar methods to impede tumor growth. The depletion of circulating endothelial progenitors is also being studied as an approach for the treatment of cancer. Preclinical experiments demonstrated the necessity of endothelial progenitors in tumor growth, and low-dose chemotherapy has been shown to decrease the number of circulating endothelial precursors. This treatment strategy is currently being evaluated in clinical trials.

Conclusion

Significant advances in our understanding of the role of bone marrow–derived cells in the formation of new vasculature have occurred in the last decade. Despite these advances, however, large gaps in our understanding of this biology remain. The population(s) of cells involved continue to be unresolved, and the methods of isolation of circulating endothelial progenitor cells remain to be standardized. There continues to be controversy regarding the importance of bone marrow–derived cells in neovasculature and the relative contribution of vasculogenesis versus angiogenesis in the adult. Other important questions such as a detailed description of the mechanisms of homing to areas of vascular growth and the role and ultimate fate of the endothelial progenitor cells that have incorporated into neovasculature in vivo remains to be elucidated. It is becoming clear that understanding the biology of circulating endothelial progenitor cells is critical to understanding the mechanisms of vessel formation, a process important in many pathological and physiological processes. Continued advances in this area are likely to pay significant clinical dividends in the future.

Glossary

Angiogenesis: The growth of new blood vessels from preexisting vasculature.

Endothelial progenitor cell: A precursor cell with the potential to develop into a mature, functional endothelial cell.

Vasculogenesis: The formation of new blood vessels from the aggregation of endothelial progenitors.

His research focuses on the role of bone marrow–derived cells in the growth and repair of vasculature in the brain.

CHAPTER 18

Pericytes and Microvascular Morphogenesis

Ira M. Herman
Tufts University, School of Medicine, Boston, Massachusetts

Overview

During the past few years, the cellular mechanisms regulating microvascular morphogenesis have come under close scrutiny. In consideration of the important role that cell-to-cell and cell-to-matrix interactions play in regulating these developmental and disease-related processes, researchers have taken advantage of the technology and approaches founded in genetics and cell biology in their efforts aimed at revealing the molecular mechanisms controlling developmental and pathologic angiogenesis. Although significant inroads have been made with regard to the molecular and cellular details that govern endothelial seeding of early organ primordia or the regulatory role that pericytes play in microvascular physiology, there is currently little knowledge regarding the molecular and cellular events regulating vascular morphogenesis, including the signals regulating the recruitment and local differentiation of pericytes. Presumably, the early inductive events that stimulate vascular endothelial growth are also linked to the subsequent rounds of vascular remodeling seen in association with vascular proliferative disorders (e.g., tumor-induced angiogenesis, diabetic retinopathy, age-related macular degeneration). Collectively, these vascular morphogenetic events are characterized by the (1) growth/differentiation of vascular endothelial cells, (2) subsequent immigration and/or colonization of microvessels with pericytes, and (3) incipient dedifferentiation, loss, or death of pericytes that initiates or sustains the vascular pathophysiologic state. Based on our work and experiments carried out in our colleagues' labs, it seems quite likely that pericyte growth and differentiation are critically dependent on autocrine signals, cues that emanate from the microvascular endothelium and information arising from the associating extracellular matrix components present in the capillary basement membrane. In turn, these homotypic and heterotypic cellular interactions (i.e., endothelial–endothelial, endothelial cell–pericyte, and pericyte–astrocyte) and the interactions that occur between these cells and the surrounding extracellular matrix dictate where, when, and how vascular cell growth and differentiation ensue. Moreover, acute or chronic perturbations in these molecular and cellular signaling pathways will play pivotal roles in developmental or pathologic angiogenesis.

Microvascular Morphogenesis

The vasculature forms via two processes: vasculogenesis and angiogenesis. In vasculogenesis, endothelial cell (EC) precursors called *angioblasts* associate to form early vessel tubes. Tissues that are vascularized by this process are generally of endodermal origin and include lung and pancreas as well as the heart tube and dorsal aorta. In the process of angiogenesis, small blood vessels form by budding and sprouting from larger, extant vessels. Tissues of ectodermal and mesodermal derivation, such as the kidney, brain, and retina, are thought to be vascularized primarily via angiogenesis. In addition, angiogenesis appears to be the predominant means of neovascularization during events such as wound healing and during pathologies such as proliferative diabetic retinopathy. Whether vessels form by angiogenesis or vasculogenesis, the primitive vessels are subsequently remodeled. Remodeling is a poorly understood event that involves growth of new vessels and the regression of others, as well as changes in lumen diameter and vessel wall thickness, to suit the local tissue needs.

Although there are fundamental differences between angiogenesis and vasculogenesis, these two processes share several common regulatory features.

Until recently, information regarding the regulation of angiogenesis and vasculogenesis came from classic embryological studies. During the past decade, cell and molecular analyses have divulged several vessel-specific receptors and their corresponding high-affinity ligands. These include the isoforms of VEGF and its receptors, flk1, flt1, and neuropilin-1; platelet-derived growth factors A and B (PDGF) and their receptors α and β; angiopoietins (ang) 1 and 2 and their receptor tie-2; and transforming growth factor β (TGF-β) and the TGF-β receptors 1 and 2 [1–3]. This database, when combined with the ability to genetically manipulate vascular development and differentiation using mouse genetic approaches, has begun to provide important insights into the molecular mechanisms that regulate vessel growth and remodeling. Although our knowledge of the molecules involved in the assembly of mature, quiescent blood vessels is far from complete, observations to date do permit some speculation regarding how vascular cells take advantage of these developmental and differentiative signaling pathways to assemble a physiologically functional vasculature [1, 3].

Receptor Kinases Regulate Microvascular Growth and Differentiation

One specific area of interest in vascular signal transduction has been the recent identification of receptor tyrosine kinases (RTKs), which coordinate signaling cascades integral to angiogenic phenomena. At least five transmembrane receptor kinases have been shown to possess an expression pattern that is predominantly endothelial, and these can be conceptually subdivided into two groups. One group, or subfamily, encodes the VEGF receptors, flt-1, flk-1, and flt-4, whereas the second group encodes the TEK and Tie receptors. Both groups share structural homology with extracellular Ig and cytoplasmic split-kinase motifs. Because expression patterns vary with developmental time and space, there has been considerable speculation as to whether the differential expression of each RTK is important in dictating when or how the vascular endothelial lineage is specified. Based on the very early and predominantly overlapping expression patterns of flk-1 compared with the subsequent onset of TEK and tie-1 expression during embryonic development, it has been suggested that these signaling pathways are necessary for establishing the embryonic vasculature. Analysis of dominant-negative mutations in the murine TEK gene reveal its essential role in fostering endothelial proliferation in vivo, but not in the derivation of the endothelial lineage from angioblastic precursors. When considering the recurrent rounds of neovascularization seen during normal development or accompanying adult-onset, ischemia-induced ocular angiogenesis, it is also quite likely that the regulated expression of the fibroblast, platelet-derived growth factor, as well as the vascular endothelial growth factor (VEGF) families are also of pivotal importance for endothelial as well as pericyte proliferation [3, 4].

Receptor Tyrosine Kinases: Endothelial–Pericyte Interactions?

Biochemical analyses and gene cloning studies have clearly demonstrated the importance of the fibroblast growth factor family in fostering endothelial growth and angiogenesis. Although it has been established that bFGF (FGF-2) is a component of select subendothelial basement membranes in vivo (as well as a component of the endothelial extracellular matrix in vitro), its mode of release as well as its accumulation and function in the matrix remain somewhat equivocal. Because matrix (heparin)-bound FGF envelops populations of quiescent endothelial cells, others and we have suggested that it acts as a wound healing or survival agent, being released following tissue injury. However, if FGF-2 acts only in an autocrine or paracrine role to stimulate endothelial proliferation, then it is difficult or impossible to explain the exceedingly low rate of endothelial turnover observed in microvascular beds that possess FGF-2-enriched basement membranes, let alone its presence in the extracellular compartment despite any convincing evidence of local injury or cell death. These important observations have led us to postulate other critical roles for FGF signaling in vascular cells [5]. Specifically, is it possible that the recruitment and/or local differentiation of retinal pericytes are regulated by endothelial-produced and matrix-associated growth regulators (i.e., FGF-2).

As has been well studied, the pericyte resides within the basement membrane in association with the microvascular endothelial cell. Although the pericytes' contribution to the basement membrane, per se, has not been critically established, the strategic location of this mural cell population within the basement membrane places it in a position capable of participating in unique heterocellular signaling, events that may be essential for their sustained growth and/or survival [6, 7]. Work in the field has demonstrated a role for PDGF in potentiating vascular smooth muscle and pericyte proliferation.Vascular endothelial cell (EC) production of PDGF is seemingly regulated by injury and repair, because quiescent EC populations fail to produce measurable PDGF levels in vitro. In vivo, PDGF and PDGF RTK mRNA have been localized within pericyte-deficient capillaries, but it is unknown whether such an autocrine signaling loop is responsible for stimulating endothelial cell cycle progression. Recently, work from our laboratory has revealed that FGF-2 acts as a principal regulator of pericyte growth during the development and/or remodeling of the microvasculature [5]. These observations demonstrate a critical role for FGF signaling not only in microvascular

development but in the pathological morphogenesis occurring during disease as well.

Modulation of pericyte contractile phenotype is by serine/threonine kinase signal transduction, TGFβ-1, and the extracellular matrix. TGFβ-1, which is a member of the transforming growth factor gene family and represents the prototype of this multimember family, coordinates a variety of activities, including the regulation of growth, differentiation, and extracellular matrix production. Its widespread expression during embryonic development points to the important role that TGFβ-1 plays in orchestrating epithelial–mesenchymal interactions, angiogenesis, chrondro-, and osteogenesis. Only recently, through the targeted disruption of TGFβ-1, have these essential role(s) been mapped. TGFβ-1 signals through two transmembrane serine/threonine kinases, STKI and STKII, which function together and share about 40 percent homology with each other [2]. Each STK possesses an extracellular cysteine-rich domain responsible for fostering ligand binding, a single transmembrane domain, and an intracellular serine/threonine kinase domain responsible for intracellular signaling. It has been demonstrated that binding of TGFβ-1 to STKII causes receptor phosphorylation, allowing association and phosphorylation of STKI, therein forming a functional heteromeric complex capable of downstream signaling. In vivo phosphorylation occurs within a stretch of five clustered threonines and serines (TTSGSGSG) within the GS domain, a conserved stretch of 30 amino acids that are unique to STKI. Mutations that either (1) inactivate the STKI kinase domain, (2) eliminate the STKI phosphorylation sites, or (3) alter the STKII cysteine-rich region involved in recognition of TGFβ-1 all prevent STKI phosphorylation and TGFβ-1 signal transduction. Elucidation of the downstream targets for STKI and STKII may unveil important new insights in TGFβ-1 signaling during embryonic development, cellular differentiation, and the response to injury. Our recent discovery that TGFβ-1 signaling may orchestrate the onset of pericyte differentiation as well as control pericyte extracellular matrix production not only indicates the putative importance of STK signaling during retinal microvascular development, but, in consideration of the known alterations that occur in retinal capillary permeability, basement membrane composition, and vascular cell growth/differentiation during diabetes, it seems evident that aberrations in TGFβ-1 signal transduction may also be critically involved in regulating pericyte de-differentiation during disease onset [5, 8].

Despite recent in vitro demonstrations that pericytes can dramatically inhibit endothelial growth in a TGF-β-dependent pathway, little evidence indicates that the reverse is also true (i.e., that pericyte growth or contractile phenotype can be modulated by endothelial-produced, matrix-associated growth regulators). Early work helped establish the important role that the endothelial-derived extracellular matrix plays in modulating retinal pericyte growth state and contractile phenotype [5, 9]. Most interesting and perhaps critical to our more current understanding of matrix dynamics and pericyte signal transduction is the demonstration that collagen IV–enriched, endothelial-synthesized extracellular matrix fosters pericyte proliferation. In these growth-potentiated pericyte cultures, smooth muscle contractile proteins cannot be detected [5, 9]. Similarly, when pericytes are stimulated to proliferate under the control of exogenously added FGF-2 and heparin (both of which are components of the endothelial-derived matrix), α-smooth muscle actin expression is also repressed (as cells proliferate).

Not only do these observations suggest that the growth state of the cells and their resultant contractile phenotype are inversely related, but the data also suggest the phenotypic similarity that exists between vascular smooth muscle and pericytes, both with respect to the molecular events controlling contractile phenotype as well as cell cycle progression. It is tempting to speculate that control of either pericyte growth or differentiation is the sum total of the positive and negative signals that originate in the vascular basement membrane, with each signaling pathway having as targets the regulators of cell cycle progression. In fact, reports in the literature state that stimulation of growth by FGF-2 is mediated by phosphorylation of the retinoblastoma susceptibility gene product, RB, which is thought to restrict cell cycle progression through late G1. It has also been demonstrated that TGFβ-1 may inhibit cell proliferation by preventing RB phosphorylation. We presume that both of these important signaling pathways are in place in the microvasculature (Figure 1). Furthermore, in consideration of the role that TGFβ-1 signal transduction plays in fostering retinal pericyte differentiation (presumably via induction of smooth muscle gene transcription), it seems possible that other downstream targets are also affected. For example, TGFβ-1 signaling in pericytes and/or endothelial cells could account for the excessive accumulation of type IV collagen in diabetic basement membranes. In turn, reduplication of the basement membrane may cause the loss of contact of endothelial cells from pericytes. Concomitantly, pericyte phenotypic modulation would ensue, resulting in de-differentiation, loss of smooth muscle contractile proteins, and a failure to restrain endothelial cells in their growth-arrested state. These de-repressed endothelial cells would then begin proliferating and retinal angiogenesis would ensue. In this model (Figure 1), we would postulate that pericyte phenotypic modulation (de-differentiation), together with local alterations in the extracellular matrix (rather than pericyte death), serve as early signals that elicit the recurrent rounds of endothelial proliferation observed during diabetes-induced neovascularization. This hypothesis is supported by the observations that, in humans, only a modest decrement in pericyte number is seen in proliferative diabetic retinopathy (~20% to 30%). Our collective data would strongly suggest that the pericytes are present in the proliferative retinopathic vasculature, but these cells are neither fully contractile nor in intimate contact with their endothelial neighbors (Figure 1).

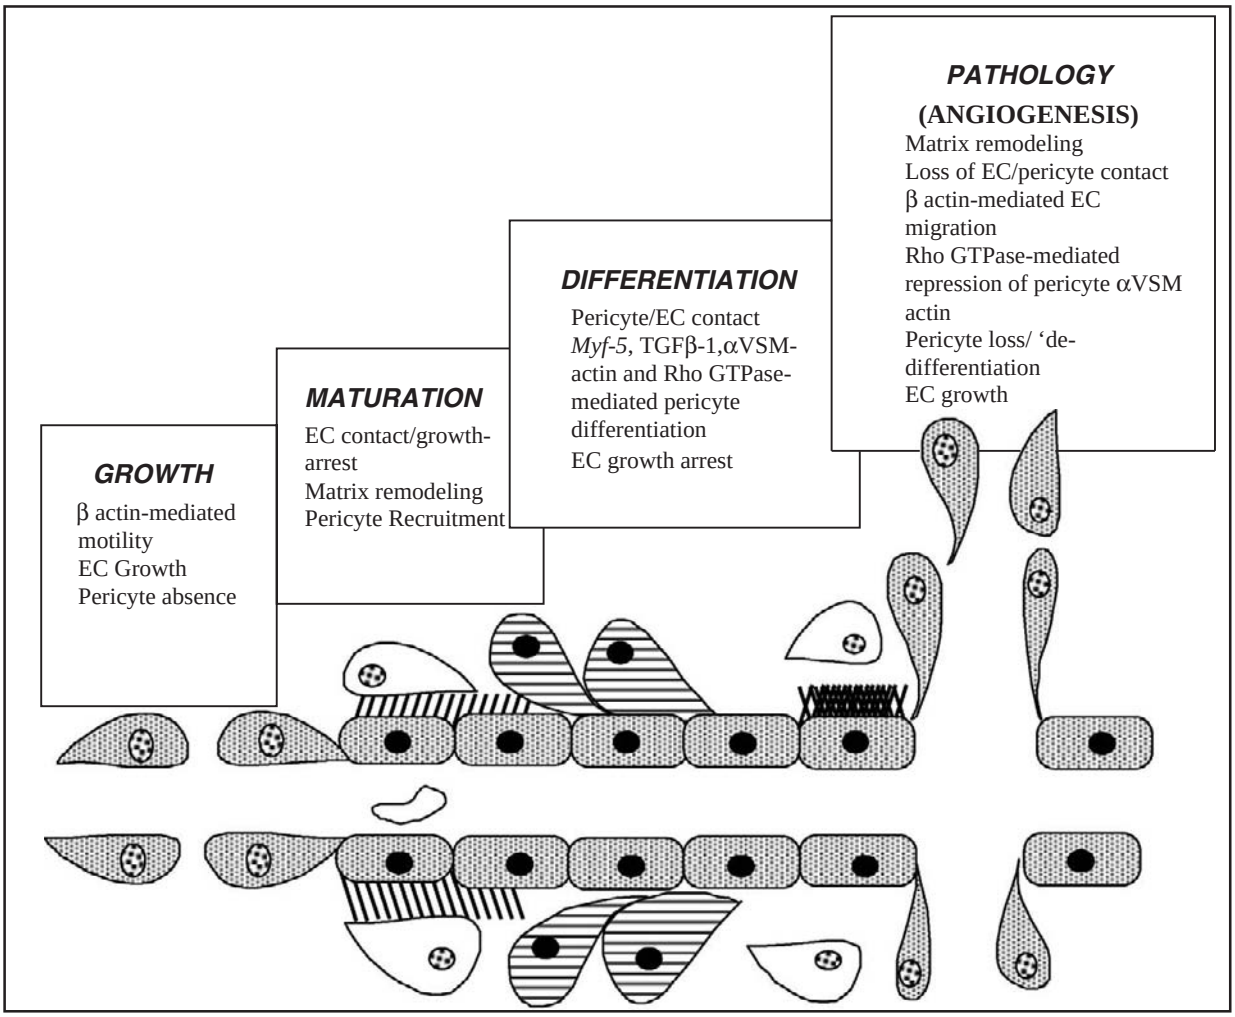

Figure 1 Model depicting microvascular morphogenesis during developmental and pathologic angiogenesis.

Pathologic Angiogenesis: Recapitulation of Microvascular Development

Development of the retinal vasculature is tightly regulated and highly dependent on cell-to-cell and cell-to-matrix interactions. For example, during retinal development, astrocytes transiently express VEGF as they migrate across the ganglion cell layer, preceding the formation of the superficial layer of retinal microvessels. Müller cells also express VEGF and direct a deeper layer of retinal microvascular morphogenesis. Blinding diseases, such as diabetic retinopathy, age-related macular degeneration, or neovascular glaucoma are directly related to aberrant angiogenic responses, which deploy common features of developmental angiogenesis, including ischemia and increased vascular permeability. For example, in diabetic retinopathy, pathological changes in the retinal vasculature yield proliferation of endothelial cells, and the loss or de-differentiation of pericytes is believed to be causally linked to the pathologic angiogenic cascade.

The correlation between the absence of pericytes and retinal neovascularization in diabetic retinopathy led to the hypothesis that pericytes exert a suppressive influence in capillary growth. Pericytes and endothelial cells share and coproduce a common basement membrane through which direct cell-to-cell contact can be achieved. Consistent with this concept was the ultrastructural observation that pericyte association with the developing capillary marked the cessation of vessel growth. Pericyte growth and recruitment is positively regulated by PDGF-β, and recently it was reported that endothelium-restricted ablation of PDGF-β generates viable mice with extensive inter- and intra-individual variation in the density of pericytes throughout the CNS, including retina. This strong inverse correlation between pericyte density and the formation of a range of retinal microvascular abnormalities suggests that pericyte

depletion may be sufficient to cause retinopathy, at least, in mice. Evidence suggests that at least some of the retinal pericytes are lost during nonproliferative diabetic retinopathy as a result of apoptosis, presumably secondary to hyperglycemic episodes. However, based on earlier work carried out in the lab, we also suspect that pericyte loss is caused by their de-differentiation and concomitant dissociation from the retinal endothelium. We further speculate that pericyte apoptosis might ensue as a result of either mechanism; alterations in the retinal microvascular basement membrane are also likely to be contributory, all events leading to a similarly dysfunctional retinal microvasculature. Although these mechanisms by which pericytes suppress endothelial cell proliferation and/or stabilize capillaries have not been completely elucidated, coculture of pericytes with endothelial cells indicate that growth inhibition is achieved in a contact- and TGF-β-dependent process. It is our working hypothesis that signaling through the retinal microvascular isoactin network orchestrates the retinal microvascular remodeling required for developmental and pathologic retinal angiogenesis. Ongoing experiments will not only directly test this hypothesis, but results will also reveal the molecular switches controlling developmental and pathologic angiogenesis.

The Isoactin Network Drives Retinal Microvascular Morphogenesis

Coordination of cell shape and motility during retinal microvascular morphogenesis occurs principally through molecular cascades that signal isoactin expression, isoprotein sorting, and cytoskeletal reorganization. Both the assembly state as well as the molecular composition of the isoactin network expressed in vascular cells is tightly regulated. Furthermore, actin cytoskeletal control mechanisms arise through specific protein–protein interactions that sequester isoactin monomers, foster filament cross-linking, or alter polymerization kinetics [10]. Clearly, selective subcellular or cell-specific functions are afforded through the specific expression and sorting of multiple actin isoforms encoded by distinct, structurally related genes [11].

There are multiple lines of genetic, cellular, and biochemical data demonstrating functional diversity of the actin isoforms. Functional distinction is evidenced by altered expression profiles, biophysical properties, cellular localization, and overexpression studies. For example, in retinal pericytes or vascular smooth muscle cells that are actively dividing, nonmuscle isoactins are prevalent; however, when the cells are contractile, α-VSM actin (among other smooth muscle–specific proteins) prevails [9]. Expression of αVSM actin is strongly regulated during wound contraction, as seen in myofibroblasts, during mesangial cell damage in hypertension, and in de-differentiated, intimal vascular smooth muscle cells present in atherosclerotic lesions. This regulated pattern of vascular cell isoactin expression mediates the developmental and disease-related motile- and contractile-mediated events.

Rho GTPases Signal Isoactin-Dependent Cytoskeletal Remodeling

More recently, we have recognized the pivotal role that the Rho GTPases and their downstream signaling effectors play in regulating retinal microvascular shape, motility, and contractile potential [12, 13]. As has been well documented, activation of Rho GTPase in other cells has been shown to cause the bundling of actin filaments into stress fibers, along with the clustering of focal adhesion complex proteins. Like all GTPases, Rho GTPases act as molecular switches, which cycle between an inactive GDP-bound and an active GTP-bound state, and the ratio between these two forms depends on the activity of regulatory factors. GTPase-activating proteins (GAPs) promote the inactive state of the GTPase by increasing the GTPase's intrinsic rate of nucleotide hydrolysis, while guanine nucleotide dissociation inhibitors (GDIs) interfere with both the exchange of GDP for GTP and the hydrolysis of bound GTP. Guanine nucleotide exchange factors (GEFs) promote the active GTP-bound state and tether the GTPases to specific subcellular locations in order to generate an active signal. Biological implications of these findings are wide ranging, and Rho GTPases, together with family members, rac and Cdc42, play key regulatory roles in cell movement, axonal guidance, as well as multicellular morphogenetic processes involving changes in cell polarity and angiogenesis [3].

Two protein families appear to be required for contractility through Rho-induced assembly of stress fibers and focal adhesions: the Rho-associated kinases (ROCK) and the Dia members of the formin family. These include ROCK1 and ROCK2 as well as mDia1 and mDia2. Activation of ROCK appears to be necessary, but is not sufficient, for stress fiber formation. Inhibition of ROCK using the inhibitor Y-27632 prevents stress fiber formation, whereas a constitutively activated mutant of ROCK1 promotes the formation of stellate actomyosin filaments, which do not resemble stress fibers. Through its downstream phospho-substrates, ROCK can signal isoactin reorganization by multiple mechanisms (e.g., ROCK has been shown to phosphorylate and thereby inactivate MLC phosphatase, thus resulting in an increase in phosphorylated MLC). In addition, ROCK1 can also play a pivotal role in generating contractile force by stabilizing filamentous actin cross-links through a LIM-kinase-dependent phosphorylation of the actin depolymerizing protein, ADF-cofilin, which is inactivated by phosphorylation. In turn, this may also influence cellular ATP levels, which may also be important in regulating cellular contractility, as has recently been demonstrated for retinal pericytes [14]. For the microvasculature, we believe that these molecular signaling cascades are essential elements controlling developmental and pathologic angiogenesis and offer a newfound

awareness for the molecular and cellular mechanisms regulating microvascular morphogenesis.

Glossary

Capillary: A microvascular blood vessel interposed between the arterial and venous microcirculation, which has a lumenal diameter between 5 to 8 micrometers (i.e., wide enough to permit the passage of one red blood cell to pass, one at a time).

Cytoskeleton: The structural organelle of living cells, which comprises structural and contractile protein components. The cytoskeleton is usually comprised of three distinct filament systems: the thin filaments (actin filaments), the intermediate filaments (desmin or vimentin filaments), and the microtubules (made up of the protein, tubulin).

Morphogenesis: A term referring to the structural development of an organism or a part thereof (e.g., in the formation of the blood vascular system).

Pericyte: The mural (wall) cell of the capillary and postcapillary venule, which has been shown to possess contractile and structural properties similar to the vascular smooth muscle cell and which has been demonstrated to influence vascular endothelial cell growth.

Capsule Biography

Dr. Herman is currently Professor of Cellular and Molecular Physiology at Tufts University School of Medicine, where he also holds appointments as Professor of Cell Biology and Anatomy as well as Professor of Ophthalmology. For more than two decades, work in the Herman laboratory has been instrumental in revealing the molecular and cellular mechanisms regulating vascular remodeling during development and disease. For this work, Dr. Herman has been the recipient of numerous awards, including grants from the NIH, American Heart Association, and pharma.

CHAPTER 19

PDGF-B and Pericyte Recruitment

Michael J. Jarzynka and Shi-Yuan Cheng
University of Pittsburgh Cancer Institute, Pennsylvania

Vasculogenesis and Angiogenesis

Blood vessels are formed by two processes: vasculogenesis and angiogenesis. Vasculogenesis involves the de novo formation of blood vessels that occurs mostly during embryogenesis. Angiogenesis is a process comprising the development of new blood vessels from pre-existing vessels. Angiogenesis takes place during embryogenesis and is often associated with physiological conditions including wound healing and the reproductive process as well as pathological conditions such as arthritis, diabetic retinopathy, periodontal disease, psoriasis, and cancer.

Blood vessel formation is closely linked with hematopoiesis. The hemangioblast is a common precursor to endothelial and hematopoietic cells. During vasculogenesis, hemangioblasts aggregate to create blood islands. These blood islands are composed of hematopoietic stem cells and angioblasts that further differentiate into hematopoietic cells and endothelial cells, respectively. Endothelial cells form the inner lining of blood vessels and generate tube-like structures that connect to form an primitive network of capillaries. Next, vascular remodeling such as pruning and sprouting occur, resulting in a mature vessel network.

The vasculature is composed of capillaries, arterioles, and venules. The microvasculature is made up of endothelial cells and mural cells. Mural cells are vascular support cells in which pericytes constitute a major portion (Figure 1). Larger blood vessels such as arteries and veins differ slightly from the microvasculature in that they contain endothelial cells, smooth muscle cells (differentiated pericytes), fibroblasts, collagen, and elastic fibers. Pericytes and smooth muscle cells form a layer surrounding the developing vascular tube, facilitating the formation of a mature vessel.

Various growth factors modulate a variety of pathways during vasculogenesis and angiogenesis. For example, fibroblast growth factor (FGF) is responsible for the generation of hemangioblasts during vasculogenesis. Vascular endothelial growth factor (VEGF) initiates the differentiation of angioblasts into endothelial cells. Additionally, VEGF stimulates endothelial cell proliferation, migration, and sprouting, leading to endothelial tube development and eventually new vessel formation. These newly formed vessels are immature and leaky, requiring further processing. Growth factors such as angiopoietin-1 (Ang1), transforming growth factor-β (TGF-β), and platelet-derived growth factor (PDGF) are responsible for the maturation and stabilization of the newly formed vessels. PDGF facilitates the recruitment of pericytes to encase the endothelial cell layer, reinforcing the vessel. Lack of pericytes leads to leaky blood vessels that are structurally defective.

Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) family plays important roles in angiogenesis. PDGF is an approximately 30 kilodalton (kDa) protein consisting of four related polypeptide chains (-A, -B, -C, and -D) that exist in dimeric form as a result of disulfide bonds between cysteine residues contained within the peptides. PDGF can form homodimers (-AA, -BB, -CC, and -DD) as well as a heterodimer (-AB). The c-sis/PDGF-2 gene on chromosome 22q that encodes PDGF-B in humans is homologous to the v-sis of the Simian sarcoma virus, which is significant because it is an oncogene.

The PDGF family of proteins binds to and signals through membrane-bound receptor tyrosine kinases (RTKs), of which there are two isoforms: PDGF receptor (PDGFR)-α (170 kDa) and -β (190 kDa). Similar to their ligands, the PDGFR also form homo- or heterodimers: PDGFR-αα, -αβ, and -ββ. PDGFR-α and -β arise from two different gene products and have various binding affinities for their PDGF ligands. For example, PDGF-AA binds only the -αα

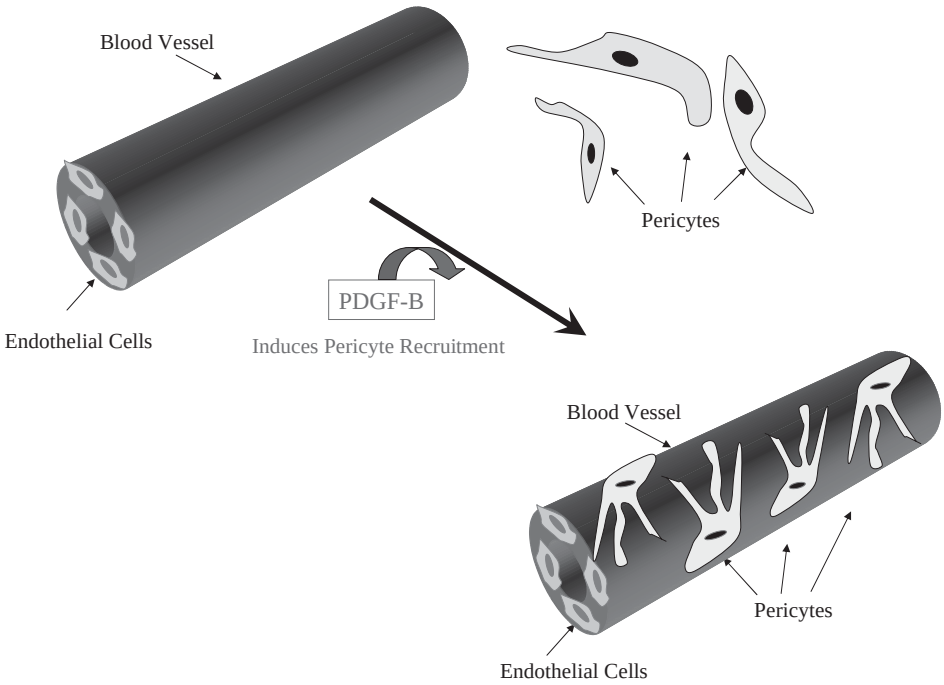

Figure 1 Schematic Representation of Pericyte Recruitment to a Newly Formed Vessel. PDGF-B released from endothelial and other types of cells acts as a chemoattractant by stimulating PDGFR-β on vascular support cells called pericytes. This stimulus causes the recruitment of pericytes that encase and structurally stabilize the growing vessel. (see color insert)

receptor homodimer, whereas PDGF-BB interacts with -αα and -αβ receptors but has the highest binding affinity for the -ββ receptor. The PDGF-AB heterodimer preferentially binds to -αα and -αβ receptors. PDGF-CC and PDGF-DD interact with the -αα and -ββ receptors, respectively. All of the receptor subtypes are comprised of five immunoglobulin-like extracellular domains containing a ligand-binding site, a single hydrophobic transmembrane domain, and an intracellular domain containing residues with tyrosine kinase activity (Figure 2).

Binding of ligand induces receptor homo- or heterodimerization depending on cellular expression of the receptor subtype and ligand present. In a process known as *autophosphorylation*, the kinase portion of each receptor monomer phosphorylates tyrosine residues within the intracellular domain of its dimeric partner. Afterward, additional phosphorylation events occur at other locations within the intracellular domain of the receptor. These phosphorylated tyrosine residues serve as docking sites for signaling molecules that contain SH2 domains such as PI-3 (phosphatidylinositol-3) kinase, Src (cellular counterpart of the Rous sarcoma virus gene, v-src), Grb2/Sos1 (growth factor receptor-bound protein 2/son of sevenless 1), Stat (signal transducer and activator of transcription), GAP (GTPase activating proteins), and PLC-γ (phospholipase C-γ), leading to modulation of cellular processes and gene expression. Cellular functions including mitogenesis, chemotaxis, and apoptosis are regulated based on the broad range of signaling cascades to which the PDGF receptors couple.

PDGF-B, Pericyte Recruitment, and Vessel Maturation

PDGF-B is the most characterized member in the PDGF family. Although first discovered as a secretory product of platelets during coagulation, PDGF-B is also expressed in many other cell types, such as endothelial cells, macrophages, smooth muscle cells, fibroblasts, glial cells, neurons, tumor cells, and possibly others. Expression of PDGF-B is constitutive in immune and nerve cells, whereas inducible expression of PDGF-B most likely occurs in other cell types. The actions of PDGF-B can occur via paracrine and autocrine pathways. PDGF-B is involved in many physiological functions, such as wound healing, inflammation, gestation, and differentiation.

PDGF-B triggers mural cell recruitment to sprouting vessels and proliferation of certain cell types during angiogenesis. Pericyte recruitment is believed to occur through the secretion of PDGF-B by endothelial cells, stimulating the PDGFR-β on pericytes, leading to migration of these cells to nascent capillaries of the developing microvasculature. In vitro, PDGF-B induces smooth muscle cell migration and proliferation. In addition, PDGF-BB has been shown to increase the expression of PDGFR-β in endothelial cells, eliciting endothelial cell proliferation, resulting in angiogenesis amplification in vitro.

In 1994, two studies revealed the roles of PDGF-B and PDGFR-β in vasculogenesis and angiogenesis during murine development. Soriano demonstrated that PDGFR-β gene knockout impaired kidney development in mice

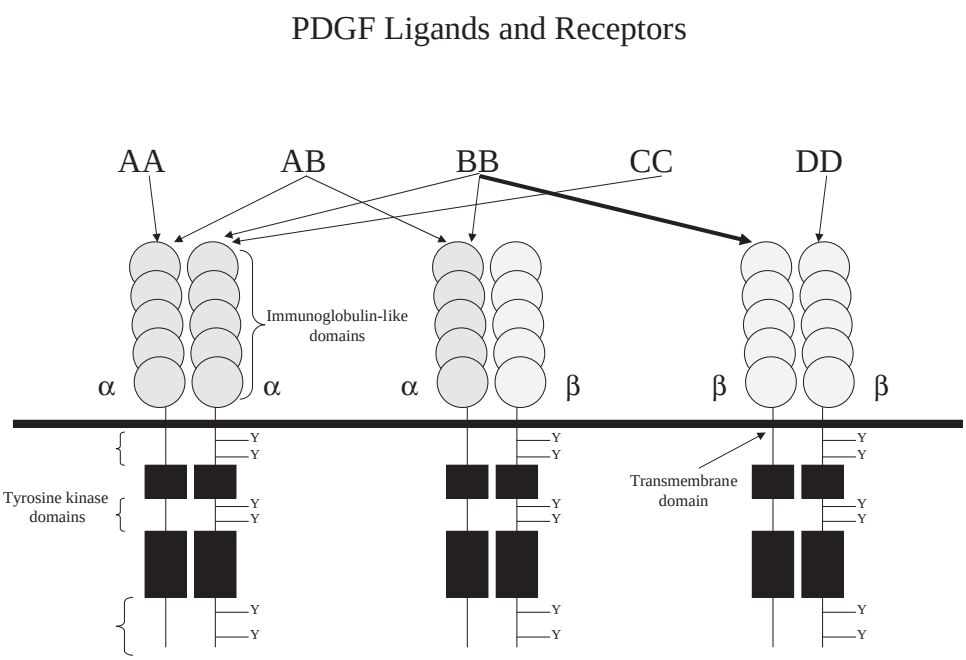

Figure 2 Schematic Representation of the Binding of PDGF Ligands to Their Respective Receptors. PDGF-AA binds only the -αα receptor homodimer. PDGF-BB binds to the -αα and -αβ receptors but has the highest binding affinity for the -ββ receptor. PDGF-AB preferentially binds to -αα and -αβ receptors. PDGF-CC and PDGF-DD interact with the -αα and -ββ receptors, respectively. The binding of PDGF to the extracellular immunoglobulin-like domains of its cognate receptors induces receptor homo- or heterodimerization, stimulating tyrosine phosphorylation in the intracellular kinase domains. The phosphorylated tyrosines trigger downstream signaling events to occur cellular events such as mitogenesis, chemotaxis, and apoptosis. (-Y, tyrosine residues) (see color insert)

because of glomerular development irregularities secondary to an absence of mesangial cells, cells that are structurally and functionally related to pericytes. In addition, hematologic abnormalities such as anemia, thrombocytopenia, erythroblastosis, and arteriolar dilation were also present. The other study performed by Betsholtz and group utilized PDGF-B-deficient mice that displayed a similar phenotype and died perinatally as a result of hemorrhage. In 1997, the effects of PDGF-B deficiency were further characterized, indicating that lack of pericytes during vessel growth produces microvascular aneurysms and related these findings to possible pathological complications seen in diabetes mellitus. These studies demonstrated the importance of PDGF-B signal-ing through the PDGF-β receptor in promoting the recruitment of pericytes to developing vessels thereby increasing their stability.

The Role of PDGF-B in Tumor Angiogenesis and Progression

Normal PDGF-B function is critical in physiological events such as embryonic development and wound healing. However, aberrant PDGF-B or PDGFR-β function has been implicated in several disease states depicted by excessive cell growth, including atherosclerosis, fibrosis, glomerulonephritis, liver cirrhosis, rheumatoid arthritis, and tumor progression.

Various types of human cancers have been shown to have increases in PDGF-B and/or PDGFR-β expression, affecting tumor growth and angiogenesis. Overexpression of PDGF and PDGF receptors has been observed in brain tumors, gastric carcinoma, lung cancer, melanomas, neuroendocrine tumors, ovarian cancer, pancreatic cancer, and prostate cancer. For example, in glioma pathogenesis, the degree of expression of PDGF-B correlates with increasing glioma tumor grade. In addition, increased expression levels of PDGF-B and PDGFR-β have been observed in tumor-associated endothelial cells in grade IV glioblastomas. Interestingly, the PDGFR-β was not expressed in the glioma cells. Additional studies comparing PDGFR-β expression in normal brain tissue and glioma tissue have demonstrated increased expression only in the tumor-associated endothelial cells. However, no detection of PDGFR-β was seen in the normal brain tissues and glioma cells. From these data, it can be presumed that PDGF-B acts on the PDGFR-β on the tumor-associated endothelial cells, stimulating glioma angiogenesis and progression.

Several in vitro studies have attempted to decipher the mechanisms behind PDGF actions on endothelial cells. PDGF-BB has been shown to have an increased potency to induce chemotaxis in rat brain capillary endothelial cells as compared to PDGF-AA. Further studies have demonstrated

that reorganization of the cytoskeletal protein actin is responsible for this chemotactic effect. Additional mechanisms are involved in PDGF-B effects on endothelial cells, specifically the effect on VEGF. PDGF-B augments VEGF expression and secretion by stimulating the PI-3 kinase signal transduction cascade on PDGFR-β-expressing endothelial cells. In addition, a variety of human glioma cell lines stimulated with PDGF-B have been shown to increase VEGF secretion. Thus, PDGF-B enhances glioma angiogenesis and growth by stimulating VEGF expression in the tumor endothelia, increasing endothelial cell migration and mitogenesis, and by promoting recruitment of pericytes into growing vessels, thus facilitating vessel assembly.

The overexpression of PDGF-B in tumor cells and PDGFR-β in endothelial cells appears to play important roles in glioma development and progression, corroborating both paracrine and autocrine pathways of PDGF-B on endothelial cell proliferation and migration. Additionally, PDGF-B may act as an angiogenic switch that upregulates VEGF and enhances vessel growth, thus promoting glioma angiogenesis. Continuous high levels of expression of PDGF-B and PDGFR-β in gliomas further upregulate VEGF in the tumor endothelium in addition to increasing the recruitment of pericytes. These events would allow rapid neovascularization in malignant gliomas to occur.

In summary, the PDGF family of proteins is critical in physiological and pathological events because of their direct effects on the state of the vasculature. As demonstrated by genetic studies, lack of PDGF-B and PDGFR-β expression disrupts normal vascular development during embryogenesis, leading to premature death. In vitro analysis reinforced the importance of normal expression levels of these proteins in cell culture. In addition, in vivo tumor xenograft models proved that overexpression of PDGF-B increased glioma tumorigenicity and angiogenesis in mice. Overall, the effects of PDGF in homeostasis and pathology are becoming clearer. Researchers will continue to develop methods to induce or abrogate PDGF signaling and apply these methods to novel therapeutic treatments of disease.

Glossary

Angiogenesis: The process of new blood vessel formation from preexisting vessels.

Chemotaxis: The chemical-induced movement of cells toward or away from other cells.

Glioma: Malignant neoplasms of the glial cells (support cells) in the central nervous system.

Pericytes: Cells associated with the walls of capillaries and other small blood vessels.

Vasculogenesis: The de novo formation of new blood vessels.

CHAPTER 20

VEGF Regulation of Morphogenesis

[1]Thomas J. Poole and [2]Eric B. Finkelstein

[1]SUNY Upstate Medical University, Syracuse, New York

[2]Schepens Eye Research Institute and Harvard Medical School, Boston, Massachusetts

Vascular endothelial growth factor (VEGF) expression and its regulation are critical for normal vascular development. Gene knockout studies in mice resulted in embryonic lethality from a failure of endothelial cell specification and blood vessel formation. Such studies have revealed an essential role for VEGF in vascular development. Animals heterozygous or homozygous for the VEGF-null mutation are embryonic lethal, demonstrating a critical role for dose regulation of VEGF during vascular morphogenesis. Additional studies in which mice were engineered to overexpress VEGF [1] or downregulate VEGF specifically in yolk sac endoderm [2] also lead to disruption of vascular patterns, a further demonstration that precise control of VEGF levels is critical for normal vascular development. Studies in the quail embryo, zebrafish, and frog have led to similar conclusions. Such studies have utilized delivery of soluble growth factor (quail, frog), delivery of soluble inhibitors (quail), and genetic knockdown with antisense or morpholinos (zebrafish, frog). All studies have demonstrated that increased or decreased VEGF levels result in abnormal vascular patterns.

Origins of the Embryonic Vascular Pattern

Vascular development is studied in several model vertebrate embryos, with different species having distinct advantages for understanding various aspects of vascular morphogenesis. Avian embryos of the chicken and Japanese quail have the advantage of accessibility in the egg or whole embryo culture, quail/chick chimeras, and a monoclonal antibody (QH-1) that labels quail angioblasts and endothelial cells. Mouse embryos from a variety of transgenic and knockout lines have been examined for vascular patterning defects, leading to the discovery of unexpected roles for several genes. Frog embryos have the advantage of ease of injection of DNA constructs for overexpression and classic tissue transplantation studies. Zebrafish embryos are nearly transparent, allowing for easy observation of the developing vasculature, and large-scale genetic screens have identified mutants with vascular pattern formation defects.

The formation of embryonic blood vessels occurs through a series of events (Figure 1). First, angioblasts (endothelial cell precursors) are induced from the embryonic mesoderm (Figure 1A), which at this stage is an epithelial cell sheet. The new angioblast initially undergoes an epithelial to mesenchymal transformation (EMT; Figure 1B), and the new mesenchymal cell migrates (Figure 1C) and coheres to other angioblasts, forming an initial solid cord of cells (Figure 1D) at sites of vessel formation (vasculogenesis). This solid cord further differentiates through unclear mechanisms to form a lumen in which a blood vessel tube is lined with endothelial cells (Figure 1E). In the case of the dorsal aorta, the first major vessel formed in the developing embryo, angioblasts originate from mesoderm directly adjacent to where they assemble in a process called *vasculogenesis type I*. In contrast, angioblasts that form the endocardium and cardinal veins migrate as individual cells or clusters that assemble at a distance from sites of angioblast origin in a process called *vasculogenesis type II*. Angiogenesis is the sprouting of new vessels from preexisting vessels. The first example of angiogenesis in the embryo

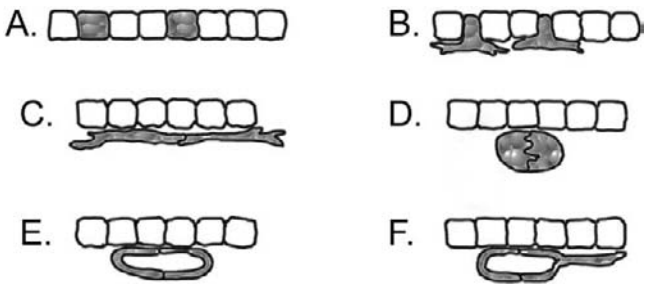

Figure 1 Initial Steps in Dorsal Aorta Morphogenesis. Embryonic blood vessels form from angioblasts that originate from the embryonic mesoderm by epithelial to mesenchymal transformation (EMT). **(A)** Two cells in a simple cuboidal epithelium acquire gene expression changes (*shaded*) that distinguish them as angioblasts. **(B)** These two angioblasts undergo EMT. **(C)** The angioblasts migrate and cohere to one another. **(D)** Two angioblasts have formed a portion of a solid cord. In the case of the dorsal aorta, a thin cord runs in the cranial-to-caudal direction. **(E)** A lumen is formed between two endothelial cells that continue to adhere at their junctions. **(F)** A sprout has formed off the vessel with the formed lumen.

is morphogenesis of the intersomitic arteries that sprout from the dorsal aorta (Figure 1F) after a lumen has formed.

Angioblast Induction

Although the role of VEGF in angioblast induction remains unclear, fibroblast growth factor 2 (FGF-2) has been implicated in angioblast induction in the quail embryo [3]. The expression of VEGF receptor 2 (VEGFR2, flk-1) resembles the expression of the quail antibody QH-1, which labels angioblasts as they undergo EMT. VEGFR2 is the first VEGF receptor expressed, suggesting that VEGF is not involved in angioblast induction. The idea that VEGF is not involved with angioblast induction fits with the phenotypes of VEGF and VEGFR2 knockout mice. In receptor knockout mice, endothelial cell precursors formed, but there were no mature endothelial cells, while in the VEGF ligand knockout mice, endothelial cells formed but failed to differentiate into a vascular pattern. Similarly, VEGFR2 mutations in zebrafish suggest a role for VEGF in sprouting and remodeling but not in initial specification of angioblasts [4].

Vasculogenesis

Morphogenetic Events

The dorsal aortae are formed by vasculogenesis. The role of VEGF in the assembly of the dorsal aorta was examined by perturbation studies in which VEGF was added or inactivated. VEGF has been inactivated by injection of soluble VEGF receptor-1/Fc hybrid protein in quail embryos [5] and by mouse or zebrafish knockout or mutation. In the quail embryo, VEGF has been added through direct injection of recombinant protein [5] or by surgical implantation of heparin chromatography beads preincubated with recombinant human VEGF165 [6], which serve as a slow-release source of VEGF (Figure 2). VEGF was delivered to somites of quail embryos with six or seven somite pairs, because somites give rise to few angioblasts. This was followed by seven hours of culture, until the embryos had 9 to 12 somite pairs. Embryos were fixed and stained as whole mounts with the QH-1 monoclonal antibody (Figure 2A). At early stages of vasculogenesis, ectopic VEGF delivery resulted in increased vascular densities such that the dorsal aorta (DA) and capillary plexus (CP) just lateral to the embryo appeared fused together, with obliteration of the avascular area (AVA) that normally separates the DA from the CP (Figures 2B and C).

The embryo and its vasculature develop in a rostral-caudal (head-to-tail) fashion, such that the most highly developed vascular pattern is located rostrally. Ectopic VEGF can affect morphogenetic events of vasculogenesis along the entire rostral-caudal axis of the embryo, resulting in hypervascularization [6]. However, qualitative differences in the vascular changes were observed at different levels. Ectopic VEGF at rostral levels resulted in an increased number of vessel branches between the DA and CP, similar to intersomitic arteries branching from the tubular dorsal aortae at this anatomic level. Moving caudal (closer to the tail), VEGF delivery at the level of a middle somite or the most recently formed somite resulted in a more generalized expansion of the vasculature. There was complete loss of the AVA, such that the DA and CP fused together (Figures 2B and C). The effect of ectopic VEGF can be seen by comparing of the side where VEGF was delivered to the opposite side, or to a control embryo (Figure 2A). These data suggest that VEGF influences multiple events of vascular morphogenesis as they occur simultaneously along the rostral-caudal axis. These include cohesion of angioblasts to form a solid cord caudally, further differentiation of the cord as a lumen forms at the middle somite level, and finally sprouting from the tubular DA at rostral levels, likely through angiogenesis (see Figure 1).

Mechanisms

There are several cellular mechanisms by which VEGF can influence endothelial cells as they form networks in vitro or in vivo. These include induction of endothelial cell proliferation or chemotaxis toward a VEGF source, where it can influence the size and pattern of blood vessels. Although it is known that increased or decreased VEGF levels in the developing embryo can profoundly affect vascular morphogenesis, to date the precise mechanism of VEGF activity remains unclear. VEGF does not induce the formation of new angioblasts from uncommitted mesoderm. Rather, it is believed to act on existing populations of angioblasts by guiding them to form a vascular pattern with vessels specifically located and of defined size. VEGF is not believed to influence the developing vasculature in our experiments by inducing endothelial cell or angioblast proliferation. The effects of VEGF were observed in as little as four hours,

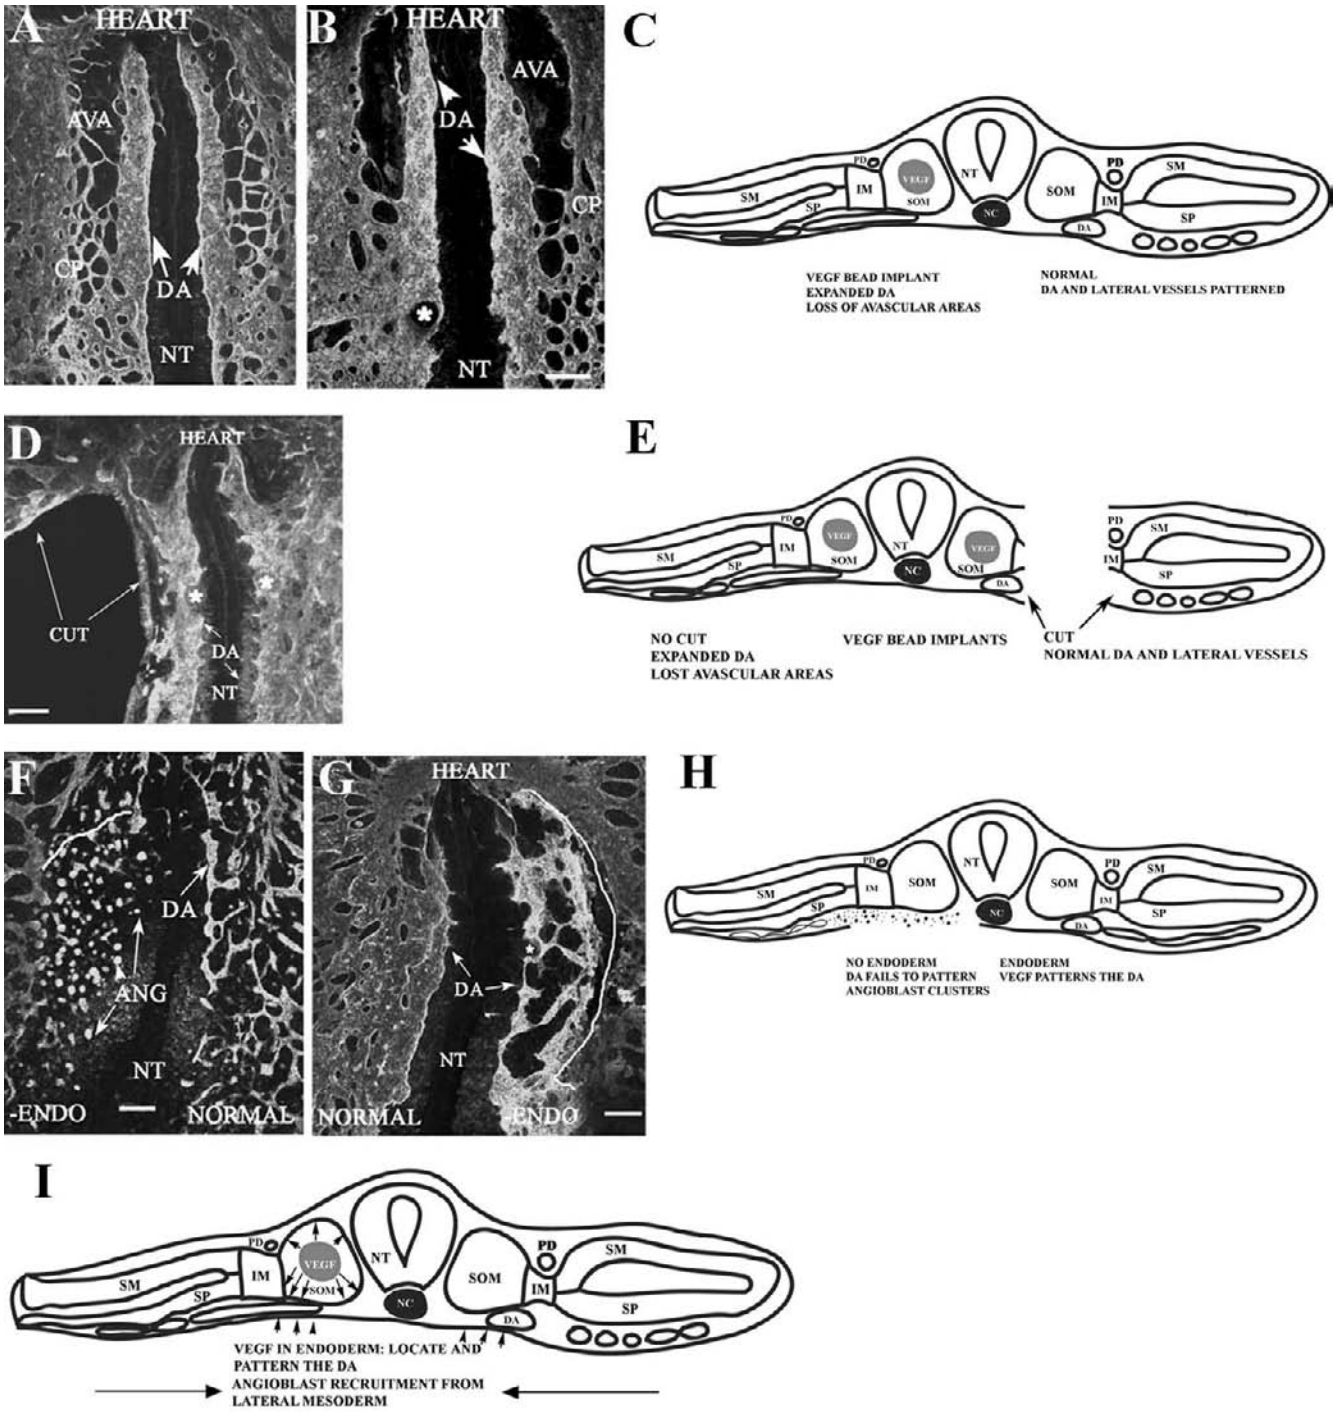

Figure 2 The Effect of VEGF and Endoderm on Angioblast Recruitment from Lateral Mesoderm to Pattern the Dorsal Aorta. Quail embryos are shown following experimental methods to study vascular morphogenesis. For each panel, the head of the embryo is up, the scale bar represents 100 μm, and asterisks (*) indicate VEGF delivery locations. **(A)** A normal quail embryo stained with QH-1. **(B)** An embryo with VEGF delivered to somite 7. **(C)** A schematic representation of the effect of ectopic VEGF on the vascular pattern, as seen in cross section. **(D)** An embryo with VEGF delivery to both sides, followed by a cut (made as indicated approximately 100 μm lateral to the midline) to separate the lateral mesoderm (a source of angioblasts) from the embryo proper, resulting in ablation of the VEGF delivery effect. **(E)** The effect of lateral mesoderm removal on the ability of ectopic VEGF to alter vascular patterns. VEGF is a chemoattractant for angioblasts from the lateral mesoderm to form the dorsal aortae. **(F)** An embryo without a VEGF bead, in which the endoderm was removed from one side. On the side without endoderm (-ENDO), the DA failed to form; rather, angioblasts (ANG) remain as single cells or clusters, compared to the unoperated (NORMAL) side of the embryo. **(G)** An embryo in which endoderm was removed from one side (-ENDO), followed by VEGF delivery on the same side. In this case, VEGF was able to partially restore the normal vascular pattern. **(H)** The effect of endoderm removal on vascular patterning. VEGF expressed within the endoderm is necessary for the proper localization and patterning of the dorsal aorta. **(I)** The role of VEGF in vascular morphogenesis. Ectopic VEGF delivery causes hypervascularization *(left)* by recruiting angioblasts from lateral mesoderm. Endogeneous VEGF within the endoderm recruits angioblasts from lateral mesoderm *(arrows)* and acts to localize and pattern the DA. In all diagrams: AVA, avascular area; CP, capillary plexus; DA, dorsal aorta; IM, intermediate mesoderm; NC, notochord; NT, neural tube; PD, pronephric duct; SM, somatic mesoderm; SP, splanchnic mesoderm; SOM, somite; VEGF, delivery site.

while the proliferation rate of quail embryo cells at the stages examined is approximately ten hours [6]. Rather, VEGF is believed to induce endothelial cells and angioblasts to undergo directed migration (chemotaxis) towards a VEGF source. Evidence for this mechanism in quail is from experiments with VEGF delivered to both sides of the embryo, followed by removal of lateral mesoderm (a tissue rich in angioblasts). After removal of lateral mesoderm, the effect of ectopic VEGF on vascular pattern formation was reduced (Figures 2D and E), suggesting that cells recruited by the VEGF to form the dorsal aorta were removed.

VEGF is known to regulate the behavior of endothelial cells during vasculogenesis, such that adding VEGF increases protrusive activity, while soluble VEGFR1 (a VEGF inhibitor) reduces protrusive activity. Protrusive activity is the extension of filopodia from endothelial cells as they extend and migrate to form a vascular pattern. This activity is necessary for endothelial cell shape changes that take place during vascular morphogenesis [5].

The Role of Endoderm

In the developing quail embryo, high levels of VEGF are expressed within the planar endoderm that underlies the DA. VEGF within the endoderm may provide a chemotactic cue to recruit angioblasts and endothelial cells from the lateral mesoderm to the midline, thereby positioning the DA. Directed cell migration of angioblasts toward an area of VEGF expression was demonstrated during development of the dorsal aorta in the frog, *Xenopus laevis* [7]. In *Xenopus*, the hypochord (an endoderm-derived midline structure that lies below the notochord) expresses predominantly the lowest molecular weight isoform of VEGF (VEGF122), a diffusible form of the growth factor. Diffusion of VEGF122 stimulates angioblast migration toward the midline of the embryo. Expression of ectopic VEGF in lateral mesoderm can divert angioblasts away from the hypochord. Vital dye labeling studies confirmed lateral mesoderm as the source of angioblasts destined to form the DA [7]. VEGF is thought to play essentially the same role in dorsal aorta formation in zebrafish [4].

In the quail embryo, removal of endoderm resulted in failure of the dorsal aorta to form (Figures 2F and H). However, unlike the situation in *Xenopus*, angioblasts were recruited to the midline, where they remained as single cells or clusters in the absence of endoderm, without undergoing cohesion to form the DA. On the contralateral side of the embryo, where the endoderm was left intact, a DA formed (Figure 2F). VEGF delivery to the side where endoderm was removed partially restored the vascular pattern and hypervascularized the control side as previously described (Figure 2G). Therefore, VEGF within the endoderm of the quail embryo locates and patterns the DA (Figure 2H). This may differ from the results in *Xenopus* because of the developmental stage when endoderm was removed in the quail (earlier removal may prevent angioblast migration), or the planar quail endoderm may function differently from the *Xenopus* hypochord. Taken together, data from lateral mesoderm removal and endoderm removal experiments in quail suggest that VEGF within the endoderm recruits angioblasts to the midline, where they undergo cellular changes under the continued influence of VEGF to form the DA (Figure 2I).

Embryonic Angiogenesis

VEGF can affect the process of embryonic angiogenesis in addition to its roles in vasculogenesis described previously. The effect of VEGF on angiogenesis has been examined in the mouse eye, where the retinal vasculature expands by sprouting as the retina grows [8]. The vascular sprout contains two types of endothelial cells: tip cells and stalk cells, which can be distinguished by differences in gene expression and morphology [9]. Filopodia of tip cells direct cell migration by sensing a gradient of VEGF, while stalk cells respond to VEGF by proliferation. VEGF induces filopodia to extend from tip cells, which are guided toward VEGF sources. VEGF antagonists inhibit these activities. This is similar to the protrusive activity of endothelial cells in the developing quail embryo, as disruption of VEGF gradients inhibits protrusive activity and migration of sprouting tip cells.

Other Functions of VEGF in Morphogenesis

In addition to its role in blood vessel morphogenesis, VEGF has been implicated as being mitogenic for other cell types, which include lymphocytes, retina pigment epithelial cells, and Schwann cells. VEGF can act as a neuron survival factor. Nerves and blood vessels are both branched structures, forming intricate networks that are often associated with each other in the same anatomic space. However, it is unknown if they form their patterns in an independent or coordinated fashion. Arteries, but not veins, specifically align with peripheral nerves. VEGF is expressed by peripheral nerves and can induce expression of arterial markers (including ephrinB2) when added to primary embryonic endothelial cells in vitro [10]. A similar effect was seen when neural cells were cocultured with endothelial cells, suggesting that neurons and Schwann cells induce ephrinB2 in primary embryonic endothelial cells by secretion of VEGF. In erbB3-/- mutant mice, Schwann cells are absent and blood vessels fail to arterialize. This is correlated with reduced nerve-associated VEGF levels, suggesting that VEGF from nerves is an arterializing factor in vivo [10]. VEGF has also been found to promote arterial fate in zebrafish [4]. Genetic studies demonstrated that VEGF acts downstream from the hedgehog signaling pathway, but upstream of Notch to specify arterial endothelial cell fate.

Use of VEGF antisense morpholinos resulted in loss of arterial markers from trunk vessels and ectopic venous marker expression in arterial vessels. This was similar to the phenotypes observed in animals with defective Notch signaling. Activated Notch induces arterial specification in the absence of VEGF, a further indication that VEGF is active upstream of the Notch pathway.

Summary

VEGF is essential for vascular morphogenesis, with precise control of its level required for normal vascular pattern formation. Results to date have focused on the role of VEGF in many organisms, using a variety of techniques. VEGF is known to be essential for forming a vascular pattern, perhaps by recruiting angioblasts and specifying the size and location of blood vessels within the embryo. Size and location may be predetermined by a VEGF gradient, before angioblast migration. However, the mechanism of VEGF activity and the signaling pathways active during vascular morphogenesis are less clear. Further studies of VEGF action in the embryo will lead to a better understanding of VEGF activity during pathological neovascularization.

Glossary

Angioblasts: The precursor cells of endothelial cells that arise from embryonic mesoderm.

Angiogenesis: The formation of new blood vessels by sprouting from existing vessels.

EMT: The process of epithelial to mesenchymal transformation.

Morphogenesis: The change in form that gives rise to the organization of cells into tissues in embryos.

Vasculogenesis: The process of vessel morphogenesis by de novo assembly of angioblasts.

Capsule Biographies

Thomas J. Poole has been studying vascular development since 1983. He has published numerous articles on the use of quail embryos and quail/chick chimeras in deciphering the origins of the embryonic vascular pattern. The current interests of his laboratory are the roles of FGF and VEGF in angioblast induction and vessel morphogenesis, and the use of arsenic in perturbation of embryonic vasculogenesis and angiogenesis.

Eric B. Finkelstein earned his Ph.D. in 2001 in Dr. Poole's laboratory, studying the role of VEGF in blood vessel morphogenesis. He is currently a postdoctoral fellow in Dr. Patricia D'Amore's laboratory in Boston, studying endothelial cell differentiation and the function of VEGF isoforms.

CHAPTER 21

The Two-Phase Model for Angiogenesis Regulation by the Extracellular Matrix

James D. San Antonio and Renato V. Iozzo
Thomas Jefferson University, Philadelphia, Pennsylvania

Introduction

Angiogenesis, the development of blood vessels from the preexisting vasculature, is recognized to play a central role in organismal development and pathologies such as tumor growth and metastasis. Two of the primary classes of molecular players in angiogenic regulation include growth factors and the extracellular matrix (ECM), the latter being the special focus of this review. The ECM scaffold that EC produce during capillary morphogenesis and in the differentiated microvasculature comprises 10 or more macromolecules, and many of these have been reported to exhibit pro- or antiangiogenic activities in their native or processed forms. Thus, at first glance, the literature presents a bewildering collection of information that appears difficult to integrate into a coherent model for the ECM regulation of angiogenesis. However, results from numerous studies suggest that a simple way to categorize the ECM control of angiogenesis is in the form of a model, wherein the intact basement membrane that promotes quiescence and differentiation comprises the first phase, and that certain conditions stimulate the endothelium to degrade the basement membrane, and encounter the second phase, the stromal or provisional matrices, including fibrillar collagens and fibrin, that promote capillary tube morphogenesis (Figures 1 and 2). The focus of this chapter is on discussing this two-phase model of angiogenesis and on deciphering the role the ECM plays in controlling and modulating this morphogenic event. Finally, we will discuss how this information may be applied to ECM bioengineering, which may be used to influence angiogenesis in vivo.

Phase I: Maintenance of Quiescence by the Basement Membrane

Insofar as angiogenesis is the process of growth of a preexisting vasculature, it is appropriate to begin our discussion with the ECM status of the quiescent, differentiated blood vessel. Basally, the capillary secretes and assembles a basement membrane scaffold, which exists in close contact with the EC that make up the capillary network (Figure 2, upper panel). The basement membrane contains several classes of glycoproteins and proteoglycans. The basement membrane conglomerate is considered to play multiple roles in the vascular system, from partitioning EC from the surrounding stroma and providing structural support to the vasculature, to creating a charge barrier between the capillary and adjacent cells and tissues. However, in addition to playing these roles, it is also clear that many of the basement membrane components may also act individually or in concert to exert significant activities on angiogenesis.

Basement Membrane Structure

The basement membrane is a highly organized, net-like molecular conglomerate. At least two modes of basement membrane construction may take place: self-assembly driven by the molecules themselves and cell-assisted processes. The two major components comprising the network are type IV collagen and laminin. Type IV collagen is proposed to self-assemble through multimerization via its N-terminal S domains and C-terminal noncollagenous domains, and lateral associations between its central col-

Figure 1 The Microvasculature and the ECM are Intimately Associated. This electron micrograph of an arteriole illustrates that EC that line the vessel lumen (Lu) are surrounded closely by circumferentially arranged smooth muscle cells (SMC) and interstitial ECM. A basement membrane, deemed to be phase I of angiogenic regulation in this review, lies between the EC and the underlying vessel components, but it is too thin to be resolved at this magnification. Interstitial collagen fibrils (Co), comprising phase II of angiogenic regulation, can be seen in abundance underneath the EC layer and throughout the media.

lagenous regions. Similarly, the laminin scaffold is thought to form through oligomerization of laminin monomers ($M_r \cong 900$ Kd), likely driven by low-affinity interactions between the N-terminal regions of the α, β, and γ arms of the monomers, and may be further modulated by the local protein and calcium concentration. The other major components of basement membranes include the glycoprotein nidogen ($M_r \cong 80$ Kd) and at least three proteoglycans, including perlecan ($M_r \cong 750$ Kd), agrin, and type XVIII collagen. In addition, type XV collagen harbors chondroitin sulfate side chains. Nidogen is proposed to serve as the molecular glue that holds the basement membrane together. Thus, the C-terminal domain of nidogen binds with high affinity to the short arm of the laminin γ chain, and through weaker affinity interactions, via its other domains, with type IV collagen and perlecan. The heparan sulfate (HS) chains of perlecan and, presumably, those of collagen XVIII and agrin, may also stabilize basement membrane structure because heparin-binding is exhibited by laminin and type IV collagen preparations. Depending on the tissue, other nonstructural components of basement membranes may include type XVIII or XV collagens, the agrin proteoglycan, or nonstructural components associated with the basement membranes such as basic fibroblast growth factor or matrix metalloproteinases (MMPs), proposed to bind to and be sequestered by the HS chain components of perlecan. All of the components of basement membranes are synthesized and secreted by EC, which may help regulate or direct its assembly. For example, disruption of the function of the cell surface β1 integrin receptor interferes with the ordered deposition of type IV collagen during basement membrane formation.

The Basement Membrane and EC Quiescence

In the quiescent capillary, EC are tightly associated with a basement membrane. It is proposed that the basement membrane may promote EC quiescence in two ways: (1) the intact matrix scaffold may exert strong differentiation-promoting activities on EC, and (2) individual basement membrane components or their proteolytic products may exert strong antiproliferative and antiangiogenic activities (Figure 2, upper and lower left panels).

Role of the Intact Basement Membrane

The most compelling evidence supporting the role of the intact basement membrane in promoting EC quiescence and differentiation is circumstantial in nature (i.e., the fact that quiescent capillaries assemble basement membranes and exist in tight association with them). Moreover, a hallmark of other differentiated cell types that, like the microvasculature, differentiate to form polarized, morphologically distinct tissues, is the production of and association with basement membranes. Not surprisingly, EC and many other cell types differentiate in vitro when cultured within or on top of basement membrane mixtures such as Matrigel. Further evidence in support of the role of the basement membrane in angiogenesis is supplied by studies that identified genes upregulated by at least two-fold in various angiogenesis systems [1]. Coincident with capillary tube differentiation in response to either type I collagen or fibrin, mRNA for various basement membrane components including laminin chains α4, β1, and β2, type IV collagen, the type XVIII collagen αI chain, and nidogens 1 and 2, are increased along with other molecules directly or indirectly related to basement membrane structure and function. The latter include collagen synthesis enzymes, MMPs 1, 2, and 9, disintegrin, and ADAMs (A disintegrin-like and metalloproteinase domain) –9, 10, and 17. More work is needed to understand how the complex basement membrane scaffold acts to promote EC quiescence. In this regard, it may be useful to consider how the basement membrane regulates differentiation in mammary epithelial cells that respond to the three-dimensional matrix environment in very defined ways, as elucidated by Mina J. Bissel and co-workers. Thus, when these epithelial cells interact with laminin, they change their cell morphology, undergo growth arrest, and in the presence of prolactin, express the differentiation marker, the milk protein β-casein. A multiplicity of cell surface receptors, including the α6β4 integrin, β1 integrins, and an E3 laminin receptor, were found to mediate these cellular responses. Whether the intact basement membrane promotes EC quiescence and the expression of EC-specific differentiation in a similar manner remains to be determined.

Role of Individual Basement Membrane Components

Most of the research probing the function of basement membranes in angiogenesis has taken the reductionistic approach of assaying the activities of individual basement

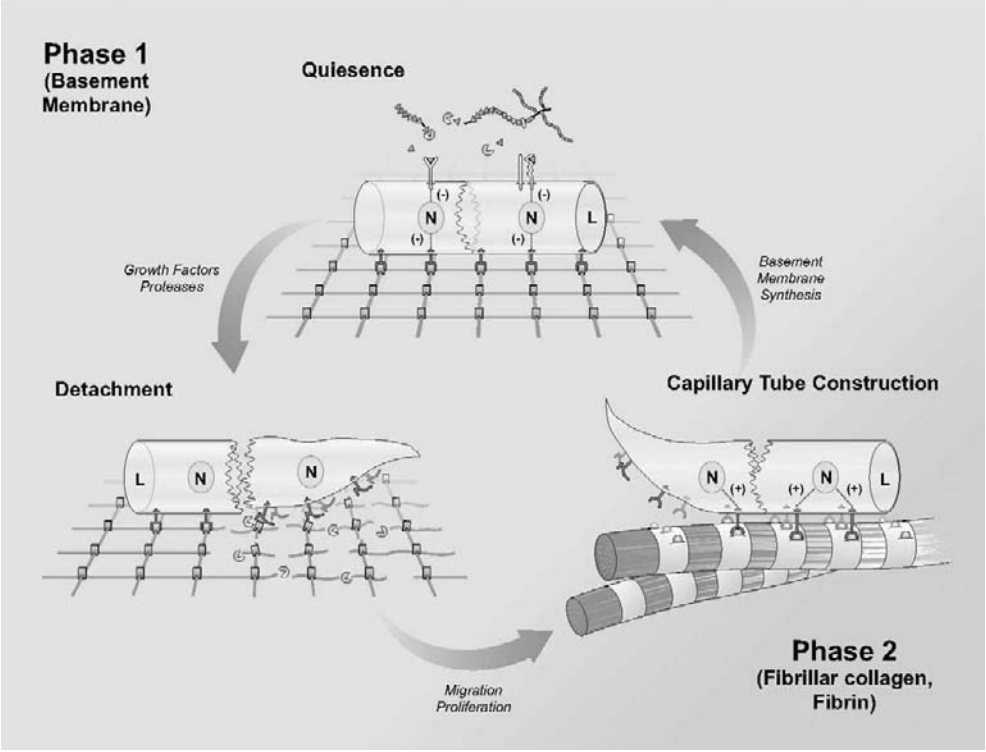

Figure 2 The Two-Phase Matrix Model of Angiogenesis Regulation. *(Phase I, Top of Diagram)* It is proposed that the basement membrane phase, shown here on an orange background, promotes EC quiescence and maintains capillary integrity in two ways: (1) via stable interactions between cell surface receptors and various basement membrane components on the basal EC side, and (2) by the release of antiangiogenic fragments of basement membrane components through the continuous low-level proteolysis and basement membrane turnover that may occur during quiescence. For the sake of clarity, this latter activity is shown only on the EC apical side, although it is presumed to occur virtually anywhere the EC has contact with the basement membrane. Antiangiogenic fragments may inhibit EC growth and migration by binding to unique receptors (cell on left) or by binding to and interfering with integrin receptor function (cell on right). *(Phase I, Bottom Left of Diagram)* Upon growth factor stimulation, or during tissue injury, massive proteolysis, likely mediated by MMPs, causes the degradation and collapse of the basement membrane, and integrins or other cell surface receptors may mediate the migration of EC into the second matrix phase (intussusception). It is proposed that the fibrillar collagen or fibrin phase, shown on a blue background, catalyzes capillary tube construction in two ways: (1) by presenting a linear, rigid scaffold that helps align EC into presumptive tubes, and (2) by presenting regularly spaced ligand-binding sites that induce clustering of EC receptors such as the $\alpha 2\beta 1$ integrin in the case of type I collagen, or VE-cadherin in the case of fibrin, that induce capillary lumen formation and perhaps the expression of genes required for the maintenance of EC differentiation. (see color insert)

membrane components, or their various domains on EC behavior. It is difficult to reconcile the relevance of these findings to angiogenesis, because it is not clear whether the various constituents of basement membranes are accessible to the EC during quiescence or throughout the various stages of capillary development. Nonetheless, these investigations will be summarized, and it will be assumed here, for the sake of simplicity, that the following findings are most relevant to two aspects of EC biology: (1) that basement membrane components may be exposed during the constant, low-level turnover of this ECM compartment, which may occur during EC quiescence (Figure 2, upper panel), or (2) alternatively, during the massive proteolysis and collapse of the matrix scaffold at the initiation of angiogenesis or blood vessel remodeling (Figure 2, lower left panel). Early approaches examined how EC responded to culture on a reconstituted basement membrane gel. It was found that tubes formed well within one day and that, although blocking laminin function in various ways inhibits tube morphogenesis, neither laminin nor type IV collagen gels alone support tube formation. These findings imply that a multiplicity of interactions among various cell surface receptors and basement membrane components are required for tube formation in response to the basement membrane, but again, it is questionable whether in vivo EC ever encounter these matrix components as individual entities rather than as complex supramolecular assemblies.

Laminin

Several groups have mapped the regions of laminin that influence various EC behaviors. For example, an RGD peptide in the α chain of laminin promotes EC adhesion. The

YIGSR sequence in the β1 chain, when substrate-bound, induces cell-to-cell interactions and promotes tube formation, and soluble peptide inhibits that process; the IKVAV sequence from the α1 chain also promotes angiogenesis. Moreover, it has been shown that MMP-2 cleavage of laminin-5 exposes a cryptic site in the γ2 subunit that promotes cell migration. Others examined the activity of a laminin-nidogen mixture and showed that it can promote EC sprouting in vitro at very low concentrations but is inhibitory at high concentrations, consistent with a quiescence-promoting function of the intact basement membrane.

Type IV Collagen

Type IV collagen contains multiple sites for EC surface binding, including to α1β1, α2β1, and α3β1 integrins. Noncollagenous (NC)-1 domains from the α1(IV), α3(IV), and αβ6(IV) chains of collagen IV support integrin-dependent EC adhesion and migration. NC1 domains from α1(IV), α4(IV), α3(IV), and α6(IV) are potent inhibitors of angiogenesis in vivo. Angiogenesis inhibitors derived from these fragments include arresten, generated from α1(IV); canstatin, generated from α2(IV); and tumstatin, a product of α3(IV) degradation. A site exists in collagen IV that is normally cryptic but may be unmasked through exposure to MMP-2. Blocking the function of this site in vivo disrupts angiogenesis and tumor growth.

Nidogen

The α3β1 integrin has been reported to bind directly to this basement membrane component, and its fragments regulate cellular adhesion. Because nidogen may be critical in stabilizing basement membrane structure, it can be speculated that once it undergoes proteolysis, the basement membrane scaffold may fall apart or may be easily breached by EC, and that nidogen's fragments may regulate EC migration into the tissue stroma.

Perlecan

This predominant proteoglycan of the basement membrane can interact with cell surfaces via its core protein, as well as modulating cell proliferation through its sequestration or release of various growth factors. EC are proposed to bind to the protein core via the α1, β1, and β3 integrin receptors. Moreover, the activity of basic fibroblast growth factor (FGF2) on cell growth and vascular morphogenesis is potentiated through its associations with perlecan and other proteoglycans. Thus, perlecan, but not syndecans or glypicans, extracted from fibroblast cultures facilitates high-affinity FGF2 binding to Chinese hamster ovary cells deficient in endogenous HS and engineered to express the FGF receptor-1, and soluble FGF receptors. Perlecan encapsulated in alginate beads is capable of binding FGF2 and promoting extensive angiogenesis in vivo. It was proposed that perlecan functions as a low-affinity co-receptor by delivering FGF2 to its high-affinity cell surface receptors. Consistent with this model, it was shown using an antisense approach that blocking of perlecan expression by colon carcinoma cells attenuated their growth, which correlated with a reduction in their responsiveness to FGF-7. Furthermore, antisense-mediated inhibition of perlecan expression in tumor xenografts of colon carcinoma cells or allografts of mouse melanoma cells showed a reduced capacity for tumorigenesis and the promotion of neovascularization in nude mice. Perlecan-mediated potentiation of growth factor action may occur via sites on either or both of the glycosaminoglycan chains and the core protein. At the cell surface, cell-associated proteoglycans such as perlecan are proposed to contribute HS chains in the formation of a ternary complex with two FGF1 molecules, and one growth factor receptor chain, to activate the growth factor receptor. Perlecan's HS chains can also serve as reservoirs or binding sites for other angiogenic factors such as MMP-7, which, when released, may initiate or help sustain EC migration during angiogenesis.

Investigations into the functional role played by the perlecan protein core in vascular development led to the discovery that the C-terminus potently inhibits EC migration and adhesion to type I collagen and capillary morphogenesis in vitro and in vivo. The C-terminal portion of human perlecan was named endorepellin to designate its antiendothelial activity. This domain blocks EC-matrix adhesion without interacting directly with the matrix components themselves. Endorepellin also binds with high affinity to EC cell surfaces, as well as to endostatin, and counteracts its antiangiogenic activity. These latter observations imply that perlecan-type XVIII collagen interactions could play a structural role in promoting basement membrane stability in some tissues, but that during basement membrane dissolution, the presence of both endorepellin and endostatin would likely not interfere with the subsequent EC migration, growth, and capillary morphogenesis, because these factors may interact and thus neutralize each other. Iozzo and coworkers have shown that endorepellin may be liberated from the perlecan core by BMP-1/Tolloid-like MMPs, and various lines of evidence are consistent with the liberation of endorepellin by cell cultures *in vitro*, and of its presence in the circulation of humans in various pathological states.

Type XVIII and XV Collagens

These collagens are members of the mutiplexin collagen family, because they carry multiple triple-helical domains interrupted by noncollagenous regions. Type XVIII collagen is a hybrid collagen-proteoglycan molecule and is a constituent of basement membranes of blood vessels, kidney, skeletal muscle, and retina, and some other tissues. This collagen carries up to four HS chains, each attached to one of four nontriple-helical domains. The widely distributed basement membrane molecule type XV collagen is highly similar to type XVIII in primary structure and domain arrangement. Type XV collagen is also a collagen-PG

hybrid molecule, but carries chondroitin sulfate, not HS chains.

An 18 Kd protein fragment of type XVIII collagen was isolated from hemangioma cell conditioned media and shown to potently inhibit EC growth in vitro, and tumor growth in vivo, and was thus named endostatin by its discoverers, Judah Folkman and coworkers. It is proposed to be liberated from the parent molecule through the action of proteases such as cathepsin L and MMPs. Endostatin was shown to potently inhibit FGF2-induced EC growth in vitro, and in the chick chorioallantoic membrane (CAM), and to nearly abolish the growth and associated angiogenesis of a variety of tumors implanted in mice. Examination of residual carcinomas in endostatin-treated mice revealed it to act not by inhibiting tumor cell growth but by increasing apoptosis sevenfold, via its inhibition of tumor-associated angiogenesis. Discontinuation of endostatin treatment resulted in the regrowth of the implanted tumors. Thus, endostatin was proposed to hold great clinical promise as a tumor dormancy factor. A later report, however, failed to observe an effect of endostatin on the FGF2-induced growth of bovine or human EC in vitro. However, these authors found endostatin to potently inhibit the VEGF-induced migration of human EC and, at very low doses, to inhibit the growth of human renal cell carcinomas implanted subcutaneously in nude mice. A third group reported an inhibition of FGF2 but not VEGF-induced angiogenesis by endostatin. Finally, drastically different results were reported when the roles of the zinc- and heparin-binding domains of endostatin to its antiangiogenic action were examined. Notably, type XV collagen also contains a C-terminal noncollagenous domain with about 60 percent sequence homology to endostatin, that does not interact with heparin or zinc, but nonetheless inhibits FGF2- or VEGF-induced angiogenesis in the CAM. In experiments where endostatin from type XVIII collagen and ES-XV were compared for their abilities to inhibit FGF2- or VEGF-induced angiogenesis, strikingly different activities were observed. Thus, the type XV collagen-derived fragments, ES-XV, and NC1 XV similarly inhibited VEGF-induced angiogenesis, but angiogenic stimulation by FGF2 was potently inhibited by NC1-XV but not by ES-XV. In contrast, whereas type XVIII endostatin and NC1 domains failed to inhibit VEGF-induced angiogenesis, endostatin, but not the type XVIII collagen NC1 domain, were active against FGF2-induced angiogenesis.

Mode of Angiogenesis Inhibition by ECM Fragments

Angiogenesis inhibitors are likely to act via distinct pathways primarily because of their diversity in structure and receptors used. For example, endostatin is proposed to interact with the $\alpha5\beta1$ integrin that triggers a signaling cascade leading to inactivation of RhoA GTPase; this subsequently may cause disruption of the actin cytoskeleton and disassembly of focal adhesions. Thus, endostatin blocks the mobility of EC, thereby preventing the early stages of angiogenesis that require cells to migrate. This process requires an intact cytoskeletal organization. Cytoskeleton dynamics are of fundamental importance for the actions of another antiangiogenic factor derived from the C-terminus of perlecan, endorepellin. Endorepellin is proposed to interact with another integrin, the $\alpha2\beta1$ that is the major receptor for collagen I, and this may lead to an intracellular increase in c-AMP, activation of protein kinase A, and subsequent dissolution of actin stress fibers and focal adhesions. Notably, collagen I exerts the opposite effect, further indicating that the $\alpha2\beta1$ integrin is directly involved in endorepellin-related signaling. Interestingly, tumstatin, a C-terminal fragment of collagen type IV, is believed to act differently by binding yet another integrin, $\alpha v\beta3$, thereby triggering a signaling cascade that leads to inhibition of EC proliferation. Therefore, a key question is whether common effector pathways are similarly modulated by the various antiangiogenic inhibitors. Endpoints for these pathways would presumably contain the most essential molecular targets for inhibition of angiogenesis. There is, thus, the need to investigate not only intracellular signaling pathways, but also the initial ECM/growth factor interactions with the surface receptors of the EC. In addition, we need to further understand the factors that alter or modulate the cell surface receptors that comprise the first lines of sensing of the angiogenesis environment by the EC.

The Transition Between the Matrix Phases: Growth Factors and MMPs Provide the One-Two Punch

It is proposed that insults such as proteolysis and wounding, or growth factor action, may provide the stimulus for basement membrane degradation or disruption; these events may induce quiescent EC to enter the second ECM phase and initiate the angiogenesis program (Figure 2, upper and lower left panels). In the case of proteases, it is widely held that MMPs, which comprise a family of at least 23 distinct endoproteinases, may be the likely players; their expression can be induced by growth factor or cytokine activity or through tissue injury. Significantly, more than half of the known MMPs have substrate specificities for one or more basement membrane components, and several of the phenotypes of mice null for specific MMPs include defective angiogenesis. Depending on the physiologic state of the vasculature, MMPs can be released by the EC or by perivascular stromal or tumor cells. Moreover, the level of MMP activity would likely determine the outcome on angiogenesis (i.e., low activities may cause limited release of antiangiogenic basement membrane fragments), but if disruption of the ECM scaffold is not significant enough to allow EC to breach the basement membrane, EC quiescence may be sustained. In contrast, high proteolytic activity would cause significant dissolution of the basement membrane, as well as promoting the release of factors, such as the heparin-binding FGFs or VEGFs sequestered by the various basement mem-

brane components, which would in turn stimulate the proliferative phase of angiogenesis. Notably, these and many others of the proangiogenic growth factors exhibit matrix-binding properties, and in some cases, require the function of cell surface or ECM proteoglycans as co-receptors for growth factor–receptor binding and activation. Although the role of proteases and growth factor action is likely crucial in promoting the progression of EC between the two ECM phases of angiogenesis, our review will not further examine these aspects because they are widely discussed elsewhere in the current literature and in this book.

Phase II: Induction of Capillary Morphogenesis by the Interstitial Matrices, Fibrillar Collagens or Fibrin

Wounding or proteolysis may be envisioned to perforate the basement membrane, a relatively thin scaffold approximately several hundred nanometers thick. Subsequently, EC would have to breach the basement membrane and migrate only small distances or, depending on the circumstances, even not at all, to encounter fibrillar collagens or fibrin (Figure 2, lower left and right panels). Thus, in many tissues the EC layer of the microvasculature or small vessels exist within several μm of light to sometimes heavy arrays of extracellular fibrillar collagens (e.g., Figure 1). During the wounding process, or in the vicinity of some tumors, fibrin may be heavily deposited throughout the tissue, and there may be cases where fibrin pools literally form adjacent to the resident ECs. Fibrillar collagens and fibrin each exert powerful proangiogenic activities on EC and are thus considered to comprise the second phase of angiogenesis regulation, and function to catalyze capillary tube construction (Figure 2, lower right panel). Because angiogenesis can occur during development in tissues lacking fibrillar collagen or fibrin (e.g., in the brain), we speculate that angiogenesis is not absolutely dependent on the presence of such polymers. Instead, we propose that fibrillar collagens or fibrin may greatly accelerate or catalyze capillary tube formation during instances when rapid revascularization is required to support tissue survival and regeneration, as in wound healing.

Type I Collagen

Type I collagen is the most abundant protein in the human body and in other vertebrates. It is synthesized by vascular cells and most other cell types and is a common and, sometimes, predominant extracellular component of many interstitial tissues. Type I collagen is synthesized as a soluble triple-helical procollagen precursor of ≅ 300 Kd, is proteolytically processed upon secretion, and assembles in a staggered fashion into the type I collagen fibril, the form most commonly found in tissues. A role for type I collagen in angiogenesis has been known for many years; initial observations showed that inhibition of collagen metabolism and cross-linking disrupted angiogenesis in vivo, and subsequently, type I collagen was shown to be an ideal angiogenic scaffold in vitro. Many investigators have developed in vitro collagen-induced angiogenesis assays. The most common type involves culturing EC within a collagen gel sandwich into which cells migrate, proliferate, undergo cell-to-cell interactions, and then form capillary-like tubes, usually within two to three days. A modification of this system was devised by our group, where an apical collagen gel is placed on a confluent EC monolayer in the presence of a serum-free medium, and tubes form as rapidly as 12 hours. Because morphogenesis occurs in the absence of significant cell migration and proliferation, we consider this to be an endpoint or tube formation assay. Using this system, we have shown that angiogenesis in response to a type I collagen gel is surprisingly specific and relies largely on interactions between the EC $\alpha 2\beta 1$ integrin receptor and only one of the three potential glycine-phenylalanine-hydroxyproline-glycine-glutamic acid-arginine (GFPGER) integrin-binding sites on the collagen fibril. This stands although the collagen fibril contains numerous sites for potential interactions with cell surfaces and their associated molecules, including those for the binding of $\alpha 1\beta 1$ or $\alpha 2\beta 1$ integrins, discoidin domain receptors, various proteoglycans, and fibronectin. Further evidence from our work suggests that $\alpha 2\beta 1$-collagen ligation correlates with activation of the intracellular signaling molecule p38MAPK and downregulation of FAK, associated with sites of focal adhesion-matrix interactions. Ongoing work attempts to determine if these signaling pathways may transduce the signal from the level of cell–collagen interactions to the intracellular signaling events that induce tube formation.

Fibrin

Fibrin is an extracellular polymer generated during thrombogenesis from the precursor fibrinogen [2]. Fibrinogen has an M_r of ≅ 340 Kd and comprises two identical subunits, each of which consists of three distinct polypeptides called the $A\alpha$, $B\beta$, and γ chains; the two halves of the molecule are associated by several disulfide bonds at the N-terminal regions. During clot formation, thrombin cleaves the A and B fibrinopeptides, and the resultant product of ≅ 45 nM in length assembles in a half-staggered fashion into fibrin polymers or fibrils. As with type I collagen, fibrin has been shown by Jose Martinez and coworkers to be a potent inducer of angiogenesis in vitro. EC monolayers exposed apically to fibrin gels form capillary-like tubes within 24 hours. It was found that an interaction between the EC VE-cadherin and the beta 15–42 sequence of fibrin was necessary for fibrin-induced tube morphogenesis.

Common Features of Type I Collagen and Fibrin Polymers

When considering whether type I collagen and fibrin act in common ways to promote angiogenesis, it may be useful

to compare the molecular and supramolecular features of these polymers. On a gross level, both polymers form classic gels, which when placed apically on EC monolayers induce capillary morphogenesis. At the level of the primary protein sequence, the two molecules share no significant homology; however, both are high-molecular-weight proteins that assemble into cable-like polymers exhibiting regular periodicities. The average type I collagen fibril diameter is 82.5 nm, the lateral repeat distance is 67 nm, and the spacing between monomers is approximately 1.0 to 1.5 nm. For fibrin, the average fibril diameter is 85 nm, the lateral repeat distance is 22.5 nm, and spacing between monomers is about 5 nm. It may be significant that the average fibril diameters are quite similar and that the other dimensions are well within an order of magnitude of each other.

We envision that these molecules may play at least two roles in promoting angiogenesis. First, both polymers present a rigid, linear substrate for cell interactions that may catalyze the side-by-side positioning of EC into tube-like arrays, a function reminiscent of that suggested by the matrical track theory of ECM-induced angiogenesis, put forth by Vernon and colleagues [3]. This theory proposes that EC may exert tractional forces on a planar, relatively homogeneous fibrillar matrix scaffold, which results in a gathering of alignment of fibrillar matrix cables between cells. These cables in turn function as matrical tracks, which guide ECs to extend processes and join together to ultimately form a polygonal cellular or capillary network. In the case of the induction of angiogenesis by a collagen gel, it is possible that the EC must first act on the three-dimensional random array of collagen fibrils within the gel to gather or align multiple fibrils together, which in turn may promote linear cell-to-cell associations. In addition, we propose that a second distinct role these polymers may play is to promote the proper spatial interactions between specific EC surface receptors and regularly repeating ligand-binding sites on the polymers, resulting in cell surface receptor clustering and the ensuing activation of signaling pathways necessary for capillary morphogenesis. It can be speculated that this event may trigger EC responses such as capillary lumen formation and the expression of genes necessary to initiate and maintain capillary differentiation. In the case of type I collagen, the $\alpha 2\beta 1$ integrin is likely involved, and for fibrin, VE-cadherin may be the relevant receptor. Such receptor clustering may be dictated by as-yet-undetermined molecular repeat distances, which may be either common to these two polymers or unique to each type of receptor–ligand interaction. In this regard, we will briefly consider only the potential mechanism of $\alpha 2\beta 1$ integrin clustering by the type I collagen fibril.

Assuming anywhere from one to three of the proposed sites for $\alpha 2\beta 1$-binding are available on the fibril surface, it may be calculated to contain from approximately 10 to 40 $\alpha 2\beta 1$ integrin receptor-binding sites across its width, and along its length, to contain such sites at 67-nm intervals. Because the region of the integrin receptor that engages type I collagen is $\cong$ 7.0 nm in diameter, across the fibril of $\cong$ 80 nm in width there is only enough space for a maximum of 10 receptors to occupy their ligand-binding sites; in this scenario the receptors clearly have the potential to be tightly arranged or clustered at the same cell surface location. On the other hand, receptors bound to sites available every 67 nm along the length of the fibril may be too sparsely distributed to promote their clustering and activation.

Another level of complexity that must be investigated is the matter of whether EC must interact with multiple collagen fibrils to initiate angiogenesis, and if so, how fibril arrangement may influence their EC interactions and capillary morphogenesis. Such information will contribute to the rational design of angiogenic polymers for various applications in tissue engineering, as discussed following. Last, it is worth addressing the fact that some other molecules, such as laminin and type IV collagen mixtures, have been reported to support tube formation in vitro, which at first glance seems inconsistent with the model described previously. However, in vivo, EC may never be exposed to high concentrations of only one or two basement membrane components, and moreover, in the intact basement membrane, many of the biologically active domains of the matrix scaffold may be inaccessible to EC. Finally, some ECM molecules, although incapable of supporting angiogenesis when present as components of the native macromolecular assembly, may be capable of engaging the appropriate cell surface receptors and thus promoting angiogenesis, when isolated and presented to EC at high concentrations.

Tissue Engineering of the Microvasculature: The ECM Holds the Key

One of the greatest current challenges in biomedical science is to refine and apply tissue-engineering technologies to correct a variety of human diseases. Among the most significant limitations to generating tissue equivalents are the difficulties inherent in endowing such implants with suitable vasculatures. Although much progress has been made in the arena of large-diameter vascular conduits, technologies to develop the microvasculature are in their infancy. However, the necessity of the microvasculature is evidenced by the observation that most cells must be within $\cong$ 100 μm or so from a capillary, and in some cases (e.g., those tissues with high metabolic rates such as skeletal or cardiac muscle myocytes), may require even greater proximity (e.g., $\cong$ 50 μm). Difficulties in engineering of the microvasculature include its complex arrangement, diminutive size, and fragility. For example, the smallest module of the microvasculature is the capillary bed, which typically consists of a thoroughfare channel that passes between an arteriole and a venule, but which also feeds a fine honeycomb-like arrangement of capillary tubes. Depending on the metabolic needs of the tissue, precapillary sphincters, arranged at the junctures between the arterioles and the capillary network, may control the flow into the capillaries. The diameters of these vessels range from $\cong$ 50 μm for arterioles (Figure 1) down to 5 or less μm for true capillaries, which do not contain associated smooth muscle cells or pericytes.

Examination of the microvasculature of even relatively modest-sized tissues (e.g., the wing of the little brown bat *Myotis lucifigus*) reveals a remarkably complex structure, containing more than 2,500 distinct blood vessels ranging anywhere from ≅4 to 75 μm in diameter. To fashion such a vasculature within an engineered tissue in a directed way seems daunting, and it would be of great advantage to tissue engineers if the assumption that the development of the vascular bed is dictated by the parenchymal tissues that surround it proves to be correct. In other words, if a tissue equivalent is seeded with the proper parenchymal and supportive cells (i.e., vascular cells and others such as fibroblasts), the capability can be created to sort and undergo morphogenesis into the proper tissue arrangement. For instance, mixtures of EC and fibroblasts cultured on cross-linked mats of chitosan-chondroitin sulfate-collagen form dermis-like tissues, complete with what appeared to be microvessels, which developed in the vicinity of fibroblast- and ECM-rich regions. However, it is currently unclear if such tissues are endowed with native-type microvasculatures. Moreover, if such a tissue equivalent were transplanted into a host animal, it is uncertain whether the vasculature of the implant would be capable of anastomosing with that of the host. As with this latter example, to date, attempts to engineer the microvasculature have largely involved use of the ECM-binding growth factors and/or ECM scaffolds as key tools.

A predominant approach toward engineering the microvasculature involves attempting to stimulate vascular regeneration by promoting the growth or regeneration of the endogenous vasculature in ischemic tissues. Such methods have mainly involved delivering angiogenic growth factors, such as FGF-2 or VEGF, to tissues either by injection or sustained polymer-based release; as mentioned earlier, these factors work in concert with extracellular or cell surface proteoglycans to exert their activities. The current literature demonstrates that such approaches hold much promise in promoting microvascular regeneration in ischemic tissues, and many reviews discuss these findings, so this topic will not be further discussed.

ECM Templates for Microvascular Engineering

Another approach attempts to provide an engineered tissue with a preformed structural template of the desired vasculature. One series of studies performed by Donald E. Ingber and coworkers has defined how the two-dimensional geometry of the ECM substrate influences EC growth and differentiation. Thus, EC were cultured on self-assembled monolayers generated by stamping microscopic patterns of alkanethiols on gold-coated substrata, resulting in micropatterns of alkanethiols that were further modified by the addition of various ECM molecules such as fibronectin. This approach allows for the generation of ECM substrata in the forms of islands, stripes, or geometric patterns of various dimensions, on which EC can be cultured and examined for their adhesive, growth, and differentiation responses. A main finding was that substrate geometry and area dictates whether an EC would adhere at all, proliferate, or undergo apoptosis. Thus, on single ECM islands of 10 μm or less, cells could not adhere; those ranging in sizes between 10 to 25 μm supported attachment but also promoted apoptosis, and on ECM islands of 50 μm or more, cells proliferated. Of particular relevance to the engineering of angiogenic scaffolds, it was further shown that EC cultured on 10-μm-wide fibronectin stripes formed vascular-like cords complete with contiguous lumens, but on 30-μm-thick stripes, the cells proliferated and did not form lumens.

Some investigators have proposed the development of three-dimensional templates for the generation of the microvasculature. One such template is described as a micro-bioreactor or angiochip. The device has as its basic design a solid-state silicon capsule or wafer containing thousands of microscopic chambers measuring 1 μm or less, which can be loaded with nanoliter volumes of bioactive agents. After filling, chambers are sealed with a thin gold layer to retain their contents until a later time. After implantation in a host, the contents of individual chambers on such chips could be selectively released by electro-dissolving the gold layers limiting the chambers. For some applications, the device may be surface-tooled and treated with an appropriate ECM scaffold to render them amenable to EC seeding before implantation. Potential uses for non-EC-seeded variety of implants would be for the sustained delivery of angiogenic or angiostatic drugs, targeted to expand or reduce the endogenous microvasculature. Angiochips preseeded with EC may be useful in promoting the outgrowth of the exogenous EC to form a new microvascular network in the host tissue, which also might anastamose with the microvascular network of the host.

Another potential approach to creating microvascular conduits was discovered using a mouse transgenic model with a targeted overexpression of chemoattractant protein-1 in the myocardium. The cardiac muscle was found to contain thin channels presumably formed by the enzymatic boring of macrophages, via their release of metalloelastase, through the tissue interstitium. To apply this phenomenon toward the rational engineering of the microvasculature will require directing the formation of channels to generate a desired microvascular configuration. Some possible approaches may include imprinting a matrix scaffold with a chemotactic gradient and seeding one end of a scaffold with macrophages. The cells may respond by boring channels through the ECM in a directed fashion, in response to the gradient. A variant of this approach would be to drive the cell-boring activities actively, using an external stimulus such as a magnetic field to spatially direct the migration of the macrophages; perhaps iron-conjugated beads may be affixed to the cells to confer their response to

the magnetic field. Subsequently, the macrophage-generated channels would have to be populated with the appropriate complement of vascular cells before its use as a tissue implant.

Rational Engineering and Use of Angiogenic Polymers

From our discussion of the basic biology of ECM-induced angiogenesis, and of the tissue engineering of the microvasculature, it is obvious that a crossroads of both bodies of knowledge is the matter of how one may define and rationally create an angiogenic polymer. The simplest approach to this end may be to design a polymer that has all of the appropriate, proangiogenic characteristics of type I collagen or fibrin, but that lacks any of their undesirable characteristics (Table I). For example, to replicate some of the common features of type I collagen and fibrin, the polymer should assume a rigid, linear shape approximately 100 nm or greater in diameter and sufficiently long (i.e., ≥ 100 μm) to simultaneously interact with or bridge two or more EC. The ideal polymer might carry a basic charge, because this will confer affinity for the strongly anionic character of the EC surface. Moreover, the polymer should contain ligand-binding sites for an appropriate EC surface receptor, such as the α2β1 integrin (i.e., GFPGER sequences), which should be distributed appropriately to promote cell–polymer interactions. From this discussion, such integrin-binding sites might be spaced no closer than 10 nm and no farther apart than 50 nm on the polymer. If the polymer is to be presented apically to cells, it should be capable of forming a classic gel or, if it must be affixed as stripes on a substrata on which EC will be seeded, one would limit their width to 10 μm or less to promote proper lumen formation. To create such a polymer, either recombinant type I collagen or fibrin could be used, in which unsuitable protein epitopes are deleted (e.g., Table I). For example, in the case of type I collagen, one might remove binding sites for ligands that have the potential to interfere directly, or through steric hindrance, with integrin receptor binding, such as fibronectin and the various collagen-binding proteoglycans such as decorin. Another approach would be to design polymers having no significant homologies to collagen or fibrin, but in which multiple integrin-binding sites are included at appropriate spacing intervals. Such super polymers may someday provide an ideal angiogenic template for a variety of tissue engineering and human therapeutic applications.

Table I Angiogenic Super-Polymers.

Physical characteristics
- Form a rigid, cable-like polymer
- Assume appropriate secondary and tertiary conformations
- Assume dimensions of ≅ 100 nm wide and ≥ 100 μm long
- Gel at physiological temperature and pH
- Carry a net positive charge

Biologically Active Determinants

Include sites:
- For binding of appropriate *integrins, distributed 10–50 nm apart, or for binding of other cell surface receptors.
- For binding of angiogenic growth factors (e.g., bFGF/VEGF)
- Necessary for polymer fibrillogenesis/assembly

Exclude binding sites for:
- Ligands that sterically disrupt EC–polymer interactions
- Proteinases, pathogens, or toxins

Exclude epitopes that are:
- Immunogenic
- Pro- or anticoagulant
- Antiangiogenic

Modes of presentation to EC
- As apical or pericellular gel
- Affixed to EC substrata in stripes/islands ≤ 10 μm wide
- Injected into tissues with vascular insufficiency/ischemia
- Incorporated into tissue equivalent scaffolds for implantation in vivo
- Genetically engineered to be expressed by perivascular cells or vascular stem cells

*Integrin-binding sites in type I collagen or collagen mimetic polymers must be triple helical.

Features and uses of angiogenic super-polymers are proposed based on common characteristics of the proangiogenic type I collagen and fibrin polymers, and on various aspects of EC biology outlined in this review. Super-polymers may include genetically engineered forms of type I collagen or fibrin, or various synthetic polymers.

Glossary

Angiogenesis: Establishment of new blood vessels by branching, budding, or remodeling of the existing vasculature. Occurs during embryogenesis and in the adult (e.g., during wound healing).

Basement membrane: Extracellular matrix scaffold secreted by EC and other cell types, comprised of laminin, type IV collagen, perlecan, and nidogen, as well as other minor components that vary depending on the tissue source. The basement membrane lies in close contact with the basal side of the EC and provides structural support and functions as a barrier separating them from the underlying perivascular cells and tissue stroma.

EC: Mesenchymal cells that comprise the lining of the cavities of the heart, blood, and lymphatic vessels.

Fibrin: A polymer that forms the fibrous stroma of blood clots. It is generated during the clotting cascade by thrombin cleavage of fibrinogen, which liberates fibrin monomers that assemble in an overlapping fashion into the cable-like fibrin polymer.

Type I collagen: A ubiquitous ECM component comprised of triple-helical monomers that assemble in a staggered fashion into cable-like collagen fibrils in the extracellular space, which confer tensile strength on many tissues of the body.

CHAPTER 22

Pericytes and Glial Cells and Vascular Development

[1]Stanley A. Vinores and [2]John D. Ash

[1]The Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, Maryland

Introduction

The retinal vasculature consists of a single layer of vascular endothelial cells, arranged to form a lumen, which are ensheathed by pericytes. In the superficial retina, these vessel structures are then ensheathed by astrocytic processes. Each cell layer is separated by a negatively charged basement membrane (Figure 1). In the deeper retina, Müller cells, rather than astrocytes, participate in the formation of the perivascular sheath. Through mechanisms that are not entirely clear, the growth, maturation, and permeability of retinal vessels are dependent on the growth and maturation of pericytes and astrocytes. A significant amount of work has been directed at determining the roles of these supporting cell types in retinal development and homeostasis, and what follows is a brief summary of the current progress. To focus this discussion, we have only included what is known for humans, mice, and rats.

Pericytes

Role of Pericytes in Maintaining Vascular Integrity

Pericytes are the vascular supporting cell type most intimately associated with the retinal vascular endothelium. They are elongated, polymorphic cells of mesenchymal origin that are sandwiched between the vascular endothelial cells and the perivascular astrocytes and are separated from each by a basement membrane, except where pericytes and endothelial cells make direct contact (Figure 1). Pericytes surround the vascular endothelium and help regulate endothelial cell growth, vessel stability, and vascular permeability. Pericyte loss, which occurs in diabetic retinopathy, is accompanied by neovascularization and vascular leakage. Pericytes contain extensive networks of intermediate filaments, which, depending on the species and tissue, consist of vimentin with or without desmin. Pericytes also contain contractile proteins, such as smooth muscle–specific isoforms of actin (α-SMA) and myosin, cyclic GMP-protein kinase, and tropomyosin, which may help in regulating blood flow [1, 2]. α-SMA, which is also found in vascular smooth muscle cells, is the most commonly used marker for the recognition and immunolocalization of pericytes [3, 4], but an RNA probe directed against PDGFβ-receptors can also be used to visualize pericytes [5].

Pericyte Development in the Retinal Vasculature

During vascularization of the rat retina, pericytes are recruited after the formation of the primary endothelial cell plexus. Pericytes migrate into the eye from arterioles branching from the hyaloid artery in the optic nerve. As the plexus matures, pericytes migrate from the arterioles toward the venules. In rats and mice, the recruitment of pericytes lags behind the formation of the endothelial plexus by several days to a week [3, 5], although some pericytes have been found in small vessels of the mouse as early as postnatal day 1 (P1)[6]. They are specifically associated with areas of the vascular network that contain collagen IV [5]. By P10, pericytes cover the primary vessel branches of the superficial retinal vascular bed in rats and by P18, they have

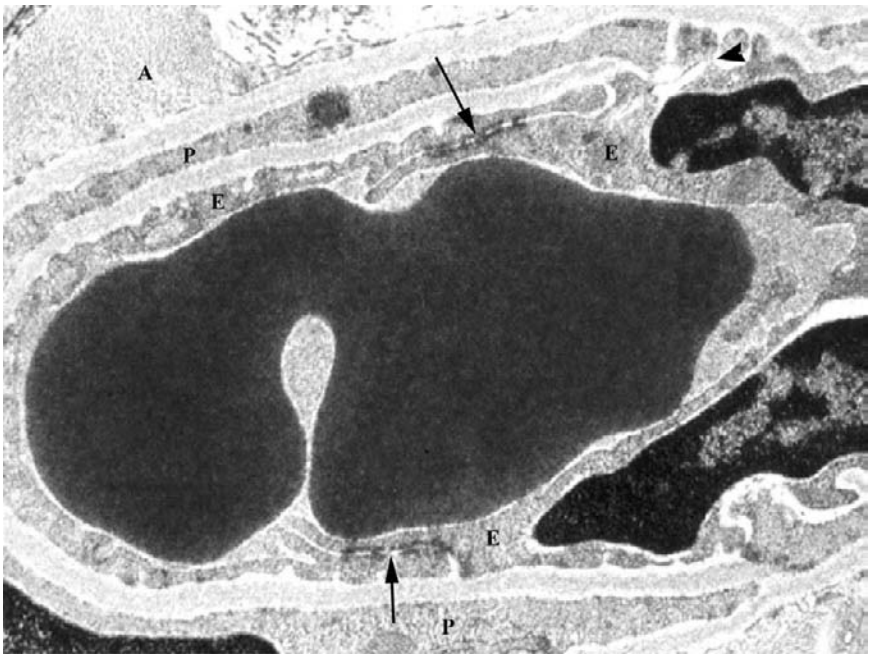

Figure 1 Ultrastructure of a normal inner retinal vessel. The tubular configuration of the vascular endothelial cells (E) forms a lumen, which contains a red blood cell. The endothelial cells are connected by tight junctions (zonula occludens) (*arrows*), which help establish the blood–retinal barrier. Pericytes (P) envelop the vascular endothelium and astrocytes (A) cover the pericytes. A basal lamina separates the astrocytes from the pericytes and the pericytes from the endothelial cells, except where there is direct cell-to-cell contact. The *arrowhead* shows a point of direct contact between a pericyte and a vascular endothelial cell. (see color insert)

reached the secondary and tertiary branches. Even though the deep capillary bed is completely formed by P10, pericytes do not cover these vessels until more than three weeks after birth, when no further vascular remodeling occurs [3]. It appears that pericytes are more involved in the maturation and remodeling of retinal vessels than in their formation. After the vasculature has formed, many of the vessels regress in more hyperoxic areas. Covering of the vascular endothelium by pericytes arrests endothelial cell proliferation and appears to stabilize the enveloped capillaries, protecting them from regressing. In mice, pericytes are always found on capillaries adjacent to the regressing segment, but never on the regressing arm [6].

The Role of PDGF-B in Pericyte Recruitment and Development

Platelet-derived growth factor-B (PDGF-B) is necessary for pericyte development, because PDGF-B-deficient mice lack pericytes [7]. Not only is PDGF-B essential for pericyte survival, but it is also critical for their migration along capillary endothelial sprouts and for normal pericyte–endothelial interactions. Pericytes are the predominant cell type in the developing retina that expresses PDGF-β receptors, which specifically bind PDGF-B. In studies where PDGF-B has been elevated during the time of vascular remodeling, either by endogenous administration [3] or because of overexpression in transgenic mice [4], the increased PDGF-B leads to a disruption of normal pericyte–endothelial cell interactions and disrupted retinal vascular development. Following intravitreal injection of PDGF-B to mice during the time of vessel remodeling, pericytes, which normally are tightly wrapped around vessels, are disorganized and often connected to more than one vessel. This leads to excessive hemorrhage followed by capillary obliteration and the widening of capillary-free zones and the formation of irregularly spaced vascular loops and capillary tangles. The retinal vasculature of these PDGF-B-treated mice is also more vulnerable to oxygen-induced damage. When PDGF-B is administered during the remodeling phase of the deep capillary plexus, but after the remodeling of the superficial plexus is complete (P18), only the deep vessels are affected [3]. Overexpression of PDGF-B in transgenic mice leads to hyperproliferation of pericytes, astrocytes, and endothelial cells. It also results in the disassociation of pericytes and vascular smooth muscle cells from vascular endothelial cells and an impairment of the formation of the deep capillary bed. These effects result in the formation of an underdeveloped vasculature in the retina. The αSMA-positive pericytes in the retinas of these mice are generally found in clusters and are usually round or oblong with a high nucleus-to-cytoplasm ratio and abundant mitochondria and rough endoplasmic reticulum [4].

Astrocytes

The Role of Astrocytes in the Development of the Blood–Retinal Barrier

Recent studies have shown that retinal astrocytes play a significant role in retinal vascular development by angiogenesis and in the induction and maintenance of the blood–retinal barrier (BRB). Glial fibrillary acidic protein (GFAP)-positive astrocytes are found in all vertebrate species that have a retinal vasculature, and the temporal-spatial development of astrocytes precedes the onset of angiogenesis in the retina [2, 5, 8]. In adults, astrocytes ensheathe the superficial retinal blood vessels (Figure 2), and their association with the vasculature is spatially and temporally correlated with the establishment of the BRB [8]. The functional role of astrocytes in establishing a blood–tissue barrier has been more clearly defined in the central nervous system and in culture (Reviewed in [9]). The end feet of astrocytes make an extensive network of cell processes that lie in close apposition to the basal surface of the microvascular endothelium. The intimate association between astrocytes and endothelial cells suggests that astrocytes may provide an inductive signal to promote the establishment of the blood–brain barrier (BBB) [9], which is analogous to the BRB. Although the exact mechanism for this induction is unknown, it can be mimicked in vitro and has been shown to require close proximity and correct cell polarity between astrocytes and vascular endothelial cells. As with the BBB, the BRB is likely to be induced by glial cells, with astrocytes providing this function in the superficial blood vessels and Müller cells in the deep capillary network. In addition to their role in establishing the BRB, retinal astrocytes also appear to play an essential role in driving the angiogenic phase of retinal vascular development through the expression of VEGF. Differentiated astrocytes are located in the retina in advance of the formation of patent vessels. In the absence of adequate blood circulation, astrocytes experience relative hypoxic conditions and have been shown to upregulate VEGF, which drives retinal vascular development by angiogenesis [2]. The association of astrocytes to retinal vessels also appears to contain their growth and provide vascular stability, and a breech of this association may result in unrestrained neovascularization and hemorrhage [10]. In order to understand the role of astrocytes in retinal vascular development, it is necessary to understand the migration, growth, and development of astrocytes in the retina.

Development of Retinal Astrocytes

Although there are significant differences between humans and mice, astrocytes in both species migrate into the retina through the optic nerve as immature astrocyte progenitors [8]. The progenitors have been defined as cells expressing Pax2 and vimentin, but not GFAP or S100 [8]. The progenitors then migrate through the nerve fiber layer toward the anterior margins of the retina. This creates a spatial and temporal pattern in which the progenitors, which are the least differentiated, are found at the leading edge of migration and the older astrocytes, which have begun to differentiate and mature, are found in the central retina. At least three stages of maturation have been described. The first stage has been defined as immature perinatal astrocytes that express vimentin, Pax2, S100, and GFAP. This is followed by the appearance of mature perinatal astrocytes that lose vimentin expression, but retain Pax2, S100, and GFAP expression. After the final stage of development, adult astrocytes are found throughout the retina and have robust expression of GFAP and S100, but have lost expression of Pax2 [8]. In mice, the interaction with the vascular endothelium seems to increase the expression of GFAP and S100 in retinal astrocytes, suggesting that this interaction may be important for the final stage of astrocyte maturation [5]. This

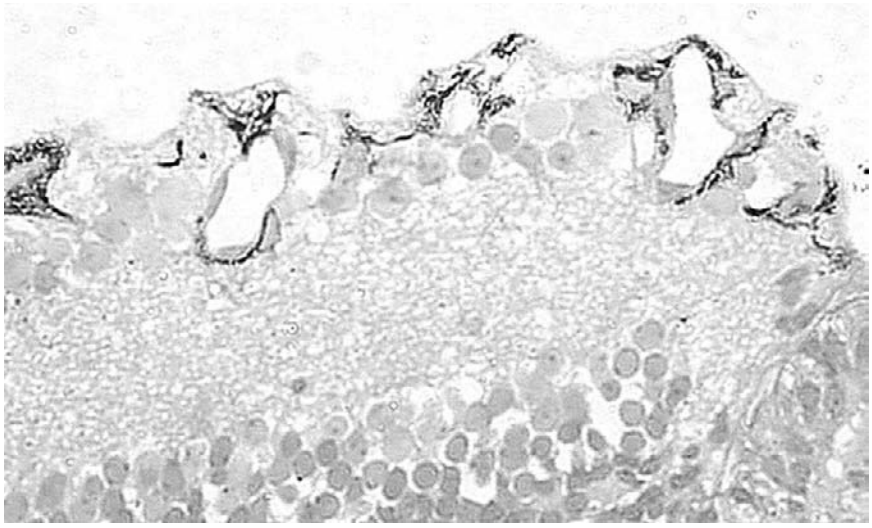

Figure 2 Immunocytochemical staining for glial fibrillary acidic protein in a P15 mouse retina decorates the astrocytic processes that encircle the vessels in the inner retina. (see color insert)

is most apparent in flat-mounted retinas from P5 mice that have been immunostained for S100 and griffonia simplicifolia isolectin B4 (GSA; Figure 3). At this stage of mouse development, S100-positive astrocytes have spread throughout the nerve fiber layer of the retina, while the developing GSA-positive vasculature has only spread throughout the central region of the retina. S100 expression is much higher in the vascular-covered central retina than in the avascular periphery.

The Role of PDGF-A in Astrocyte Migration and Proliferation

Although the inductive signals for astrocyte development have not been fully identified, the current data suggest that platelet-derived growth factor A (PDGF-A) plays an important role in their migration and proliferation. Astrocyte progenitors enter the retina well after the differentiation of retinal ganglion cells. This is perhaps a necessary sequence as astrocytes migrate into the retina through the optic nerve along the ganglion cell axons. Once in the retina, astrocyte progenitor migration may be independent of the presence of ganglion cells [11]. However, other studies have shown a direct role for ganglion cells in astrocyte development. Ganglion cells secrete PDGF-A, and astrocytes can respond to PDGF-A through the expression of PDGF receptor α (PDGFRα) [5, 12]. The simplest model suggests that astrocytes and/or their progenitors migrate into and proliferate within the retina following the chemoattractant and mitogenic signal, PDGF-A. In support of this model, studies have shown that overexpression and ectopic expression of PDGF-A from the lens results in an astrocytic hyperplasia known as a hamartoma near the optic nerve head of the retina [12]. PDGF-A has also been overexpressed in transgenic mouse retina using the neuron-specific enolase promoter and the opsin promoter [5, 13]. In both models, there was excessive accumulation of astrocytes in the retina. In each of the overexpression models, the ectopic expression of PDGF-A led to mislocalized astrocytes, suggesting that the site of PDGF-A expression is important for migration cues in normal development. PDGF-B, which can also bind and activate the PDGFRα on astrocytes, can also induce their mislocalization and hyper-proliferation [4]. Further studies have shown that disruption of PDGF-A signaling by neutralizing antibodies to PDGFRα disrupts the normal development of retinal astrocytes [5]. These studies demonstrate that PDGF-A is a potent chemoattractant and mitogen for astrocytes and that its expression is required for normal astrocyte migration in the retina. It is interesting to note that retinal vascular development is dramatically impaired in all of the mouse models overexpressing PDGF-A. These findings clearly demonstrate that growth and development of retinal astrocytes is important for the development of a functional retinal vasculature.

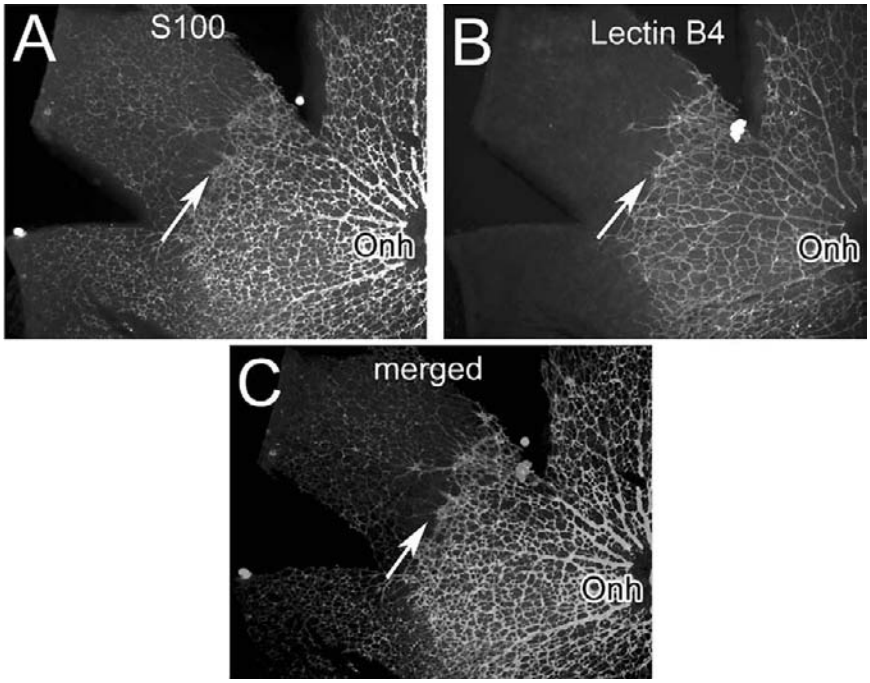

Figure 3 Immunofluorescent staining using antibodies to S100 **(A)**, which is expressed only in astrocytes in the P5 mouse retina, and fluorescence staining of the developing vasculature using Griffonia simplicifolia isolectin B4 **(B)**. S100 positive astrocytes are located throughout the retina; however, the staining intensity is higher in the central retina **(A)**. At this age, the developing vasculature covers only the central region of the retina **(B)**. The *arrow* in all panels marks the leading edge of the developing vasculature. In the merged image **(C)**, it is clear that astrocytes in contact with the vasculature have higher expression of S100 than astrocytes in the avascular periphery. (see color insert)

Glossary

Astrocyte: A neuroglial cell of ectodermal origin with processes that ensheathe vessels in the inner retina and brain, helping to establish the blood–retinal or blood–brain barrier; they represent a supporting cell type for neurons as well as the vasculature.

Pericyte: A vascular supporting cell of mesenchymal origin with contractile properties that surrounds the vascular endothelium and helps regulate vascular integrity.

Platelet-derived growth factor A: A chemoattractant and mitogen for astrocytes that is important in retinal vascular development.

Platelet-derived growth factor B: A proangiogenic factor that is necessary for pericyte survival and migration and for normal retinal vascular development.

Vascular endothelial cells: The cells that line the lumen of blood vessels.

CHAPTER 23

Hemangioma: A Model System to Study Growth and Regression of Blood Vessels

Joyce Bischoff

Vascular Biology Program, Children's Hospital Boston and Department of Surgery, Children's Hospital Boston and Harvard Medical School, Boston, Massachusetts

Hemangioma is a tumor of endothelium that occurs in 5 to 10 percent of caucasian infants. Often referred to as infantile hemangioma, it follows a unique biological course: it proliferates rapidly in the first year of life, regresses slowly during early childhood, and never recurs. These features of hemangioma distinguish it from other vascular tumors, which do not regress and can occur in adults. Like many vascular tumors, the endothelial cells that comprise hemangioma express a multitude of endothelial markers and angiogenic growth factors. Endothelial cells from hemangiomas are clonal and exhibit abnormal properties when compared to normal human microvascular endothelial cells. These findings strongly suggest that hemangiomas arise when a somatic mutation occurs, within a single endothelial cell, in a gene that controls endothelial cell proliferation and possibly responses to angiogenic stimuli. The molecular mechanisms underlying the rapid growth and the spontaneous involution of hemangioma are yet to be discovered, but when elucidated, are likely to yield unique insights into the regulation of blood vessel formation and growth.

Clinical Features of Hemangioma

Growth and Regression

Hemangiomas typically appear soon after birth, grow rapidly during the first year of life (*proliferating phase*), regress slowly from age 1 to 7 (*involuting phase*), and thereafter become a fibrofatty residuum (*involuted phase*). Hence, the life cycle of hemangioma encompasses both proliferation and regression of blood vessels and, as such, presents a unique model system to study the regulation of angiogenesis. The most common form of hemangioma appears within two weeks after birth, yet some appear fully grown at birth. These "congenital hemangiomas" fall into two subgroups: one group regresses rapidly, within months, whereas the second group fails to involute, suggesting that the life cycle of hemangioma can be compressed or extended. Understanding these variations on the more common form of infantile hemangioma will be fundamental to deciphering the mechanisms that control involution and may eventually pave the way for development of fast-acting therapies that either speed up the involution process or prevent the aberrant growth from occurring in the first place.

Location of Hemangiomas

Hemangiomas are most often cutaneous, found on the head and neck (60%), trunk (25%), and the extremities (15%). See examples of proliferating hemangiomas in Figure 1. About 20 percent of hemangiomas occur as multiple tumors. The relationship of these multifocal lesions to each other and how they differ from the more common single lesion is not understood. Visceral hemangiomas also occur, but these are rare and are likely to go undetected because most hemangiomas are small and pose no threat or complications. However, a subset of hemangiomas can grow

Figure 1 Three Examples of Hemangioma in the Proliferating Phase. The third panel is an example of multiple hemangiomas. (see color insert)

dramatically during infancy. For these children, the normally benign tumor can be devastating, causing tissue destruction, altering or impairing tissue function, and can become life-threatening. Even a relatively small hemangioma can cause significant problems for the infant depending on the location. Children with endangering or life-threatening hemangiomas are treated with corticosteroids, surgical resection, or with interferon-α. However, some hemangiomas do not respond to these drug therapies or respond so slowly that it is not clear if the drug accelerated the normal involution process. Furthermore, neurologic toxicity has been associated with interferon-α administration to infants with hemangioma.

Hypothyroidism in Hemangioma

Huang and colleagues discovered that severe hypothyroidism can be associated with large hemangiomas [1]. They showed that the likely underlying cause was ectopic expression of type 3 iodothyronine deiodinase (D3) in proliferating hemangiomas. D3 is widely expressed in fetal tissues and some tumors, but after birth, its expression is restricted to placenta and brain. D3 inactivates thyroid hormone and, in the case described by Huang and colleagues, can lead to consumption of therapeutic doses of hormone in a child with a large hemangioma. The impact of hypothyroidism during infancy is severe and irreversible; neurological damage in particular can lead to loss of three to five IQ points per month in children under one year of age with untreated hypothyroidism. Hence, the aberrant proliferation of endothelium that characterizes hemangioma can have deleterious systemic effects for a child in addition to the local tissue destruction. The discovery of hypothyroidism in hemangioma by Huang and colleagues, and subsequent case reports by others, affirms the critical importance of understanding the cellular and molecular alterations in hemangioma and the need for better fast-acting therapies.

Genetics

Most hemangiomas occur sporadically, with only rare examples of a hereditary predisposition. A large study of identical and fraternal twins, conducted by Cheung and colleagues [2], found no evidence for Mendelian inheritance, yet the authors speculated that a positive family history could reflect susceptibility to other "factors"—such as environmental or genetic factors—which in turn might lower the threshold for development of hemangiomas. Examples of factors that predispose one to hemangioma are being female (hemangiomas are three times more common in females compared to males), being fair-skinned, and being born prematurely. However, despite the preponderance of sporadic hemangiomas, Marchuk and colleagues reported evidence for inherited hemangiomas in a small number of kindreds in which hemangioma appears to be autosomal dominant [3]. An alternative scenario that could account for familial hemangiomas would be an autosomal recessive mutation, followed by acquisition of a somatic mutation in an endothelial cell. This would explain how an inherited mutation that would presumably affect all endothelial cells would only be expressed in a localized fashion.

Other Vascular Tumors

Hemangioma is often used as a generic term and applied to a wide array of vascular neoplasms and even vascular malformations. Examples of vascular tumors that have been called hemangioma are angiosarcoma, Kaposiform hemangioendothelioma, and pyogenic granulomas. Additionally, congenital tumors, such as tufted angioma and hemangiopericytoma, can be confused with hemangioma. Hemangioma is also a clearly distinct entity from vascular malformations. Several reviews and chapters have been written to clarify and classify human vascular anomalies, including infantile hemangioma, and to establish a logical

nomenclature based on clinical features, biological properties, and when possible, molecular markers. In 2000, North and colleagues discovered that infantile hemangiomas could be distinguished from other vascular tumors and vascular malformations with high confidence by immunostaining tissue sections with an anti-glucose transporter-1 (GLUT1) antibody [4]. In a retrospective study, they reported intense endothelial immunoreactivity with anti-GLUT1 antibody in 139 of 143 hemangiomas obtained from infants and young children. In contrast, endothelial GLUT1 was not detected in vascular malformation specimens, nor pyrogenic granulomas or granulation tissue specimens. Furthermore, GLUT1 was not detected in hemangioendotheliomas, a low-grade malignant endothelial tumor, and only in a few cases of angiosarcoma, a highly aggressive endothelial tumor. In a subsequent study by North and colleagues, GLUT-1 was also not detected in congenital hemangiomas, suggesting a distinct eitiology from the more common form of hemangioma. Hence, the anti-GLUT1 antibody has proven to be a valuable tool for characterizing hemangiomas among a wide array of vascular tumors.

Life Cycle of Hemangioma

Proliferating Phase: Endothelial Progenitor Cells

Proliferating hemangiomas are highly cellular, with little connective tissue and barely discernible vascular lumens; proliferating endothelial cells are easily detected by histological methods. Because the tumor comprises endothelium, it is not surprising that many studies have found high levels of endothelial-expressed proteins. In Figure 2, tissue sections from proliferating and involuting hemangioma sections were double-labeled, with antibodies directed against two well-known endothelial markers. Vascular endothelial growth factor-receptor-2 (VEGF-R2), also known as kinase insert domain-containing receptor (KDR), is the major mediator of the angiogenic effects of VEGF on endothelial cells. In addition to being expressed on mature endothelial cells, KDR is also expressed by endothelial progenitor cells (EPC). CD31, also known as platelet-endothelial cell adhesion molecule-1 (PECAM-1), is a cell-cell adhesion molecule expressed on virtually all continuous endothelium. As seen in Figure 2, KDR is abundantly expressed in proliferating hemangioma; the green fluorescent signal is evident on nascent vascular structures and on cells lining vascular channels. CD31 is also expressed in proliferating phase hemangioma; the red fluorescent signal strongly highlights vascular channels. When the two signals are viewed simultaneously, it is clear that KDR and CD31 are co-localized, providing strong evidence for endothelial cells within the proliferating hemangioma. The same immunostaining procedure was performed on involuting hemangioma specimens. KDR-positive/CD31-positive endothelial cells are evident, but the cellular density is decreased and vascular channels are more prominent. This change in endothelial morphology suggests that nascent vascular structures present in the proliferating phase differentiate into more well-defined vascular channels as the involuting phase proceeds. The speculation that proliferating hemangiomas contain primitive angioblast-like cells has been put forth by many investigators. In support of this concept, we recently reported the detection of endothelial progenitor cells (EPC) from 11 out of 12 proliferating phase hemangiomas [5]. No EPC were detected in involuting hemangiomas or in venous malformation or lymphatic malformation tissue, suggesting that the presence of EPCs in hemangioma is unique and that EPC might contribute to the pathogenesis of hemangioma. To our knowledge, our study was the first to

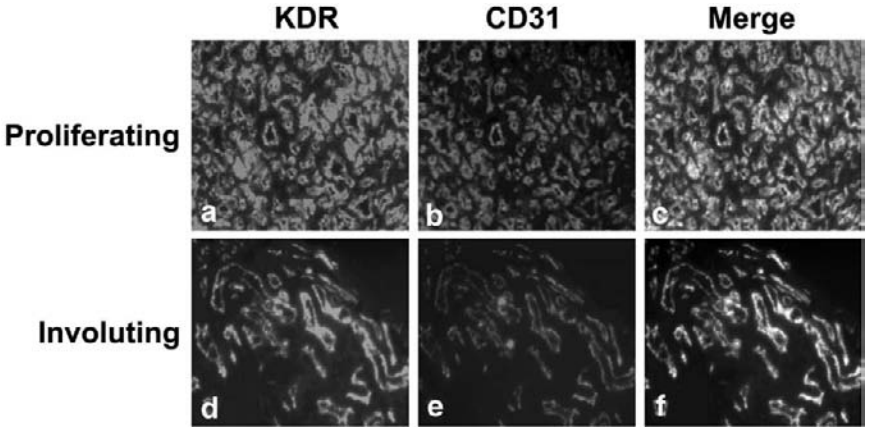

Figure 2 Expression of KDR/VEGF-R2 and CD31 in Hemangioma. Indirect immunofluorescence detection of KDR (panels a, c, d, f) and CD31 (panels b, c, e, f) in frozen sections from proliferating phase (a–c) and involuting phase (d–f) hemangiomas. In panels **a** and **d**, the green fluorescence (FITC) corresponding to KDR is seen. In panels **b** and **e**, the red fluorescence (Texas-Red) corresponding to CD31 is seen. In panels **c** and **f**, both fluorescence signals were viewed simultaneously; cells expressing both proteins are seen as yellow or yellow/orange. (Yu and Bischoff, unpublished data.) (see color insert)

show direct evidence of human EPC in a human vascular tumor.

Proliferating Hemangioma: Clonal Endothelial Cells

Two experimental approaches demonstrate that hemangioma is caused by an intrinsic defect in the endothelial cells. First, Boye and colleagues isolated hemangioma-derived endothelial cells from 10 different hemangioma tissue specimens and showed that the endothelial cells were clonal by examining X-chromosome inactivation patterns [6]. Nonendothelial fibroblast-like cells that were co-isolated from the tissue and separated from the endothelial cells were not clonal, demonstrating that the clonal expansion was restricted to the endothelial cells. In addition, the hemangioma-derived endothelial cells exhibited abnormal properties in in vitro assays that measure angiogenic activity. These results substantiate the hypothesis that hemangioma is caused by a somatic mutation in a single endothelial cell (i.e., an intrinsic defect), in a gene that controls endothelial growth and differentiation. Two other studies also support this hypothesis. Evidence for loss of heterozygosity on chromosome 5q in three out of six hemangiomas suggested a somatic mutation in this region may be the cause of sporadic hemangiomas. More recently, Walter and colleagues showed that 12 of 14 informative hemangioma lesions had nonrandom X-chromosome inactivation patterns—evidence for clonal endothelial cells—and thus, a somatic mutational event [7]. Importantly, their clonality assays were performed on DNA isolated from tissue sections, which avoids changes in cell composition that might occur during cell culture. In summary, these studies provide strong support for the hypothesis that a somatic mutation in a single endothelial cell leads to clonal expansion of dysregulated endothelial cells, resulting in hemangioma. Formal proof of the hypothesis awaits identification of the somatic mutation(s) and functional demonstration that such mutation(s) cause hemangioma.

Involuting Phase: Onset of Apoptosis

The involuting phase of hemangioma coincides with a transformation to a more lobular architecture with organized and recognizable vascular channels, which can be appreciated in Figure 2. As involution proceeds, vascular channels become larger and more prominent, and few interstitial cells are evident. Increases in perivascular cells expressing α-smooth muscle actin are consistent with the appearance of mature blood vessels. Mast cells appear to be increased in the involuting phase, and changes in extracellular matrix occur. Interferon-β in the epidermis overlying involuting and involuted hemangiomas has been proposed as a mechanism for attenuating the abnormal proliferation in hemangioma [8]. The final, involuted phase is characterized by a few remaining thin-walled vessels that resemble normal capillaries, surrounded by fibrofatty tissue.

The cellular and biochemical mechanisms that drive the involuting phase have been difficult to study because endothelial cells from involuting hemangioma do not grow in vitro [9]. Based on studies showing that increased apoptosis can offset cellular proliferation in murine tumor models, we examined cellular proliferation and apoptosis in a series of 16 hemangioma specimens from infants to children up to nine years of age, as well as normal infant skin for comparison [10]. Consistent with previous studies, cellular proliferation was high in hemangioma specimens obtained from children up to 24 months of age. Apoptosis was increased fivefold in hemangioma specimens from children one to four years of age compared to proliferating hemangioma specimens from children under one year of age, late-involuting/involuted hemangioma specimens from children over four years of age, and normal skin from infants (see Figure 3). Thus, the increase in apoptosis coincided precisely with the onset of the involuting phase. Double-labeling tissue sections for apoptosis and the endothelial marker von Willebrand Factor showed that 27 to 39 percent of the apoptotic cells were endothelial. In summary, this study suggests that regression of hemangioma involves increased apoptosis even as cellular proliferation continues. One might speculate that an agent that triggers apoptosis in proliferating endothelial cells would be an effective treatment for hemangioma.

Summary

The pathogenesis of hemangioma—its life cycle of growth and involution—is still a mystery. The studies described here support the hypothesis that sporadic heman-

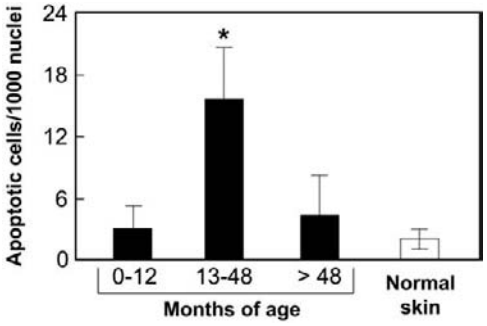

Figure 3 Increased Apoptosis Coincides with the Onset of the Involuting Phase. Apoptotic cells were quantitated using the TUNEL assay on 16 hemangioma specimens from children ranging from two months to nine years of age. Normal skin from infants and young children (n = 8) was analyzed for comparison. On average, apoptotic nuclei in eight fields, viewed at 630X magnification, were counted. Hemangiomas from children 13 to 48 months of age had a higher mean count of apoptotic nuclei compared to hemangiomas from younger children (0 to 12 months) ($p < 0.001$) and compared to hemangiomas from older children (> 48 months of age) ($p = 0.002$). There was no significant difference between younger (0 to 12 months) versus older (> 48 months) patients ($p = 0.68$). This figure is a graphical summary of data from Razon et al. (1998). *Microcirculation* **5**, 189–195.

giomas are caused by a somatic mutation in a single endothelial cell, possibly an immature endothelial cell or endothelial progenitor, that leads to clonal expansion of abnormal endothelial cells. It is likely that several somatic mutations, in one or more genes, will be discovered in individual hemangiomas, and that the assortment of mutations will reflect the differences in severity and life span of the individual tumors. Much progress has been made toward distinguishing hemangioma from the many other types of human vascular anomalies using cellular and biochemical markers. The goals now are (1) to identify the genetic defects that cause hemangiomas, so alterations in cellular signaling and function can be studied at the molecular level; (2) to develop animal models that recapitulate hemangiogenesis, so that growth and regression can be studied in vivo; and (3) to use the animal models to evaluate anti-angiogenic therapies that will either prevent growth or accelerate involution, so that better, fast-acting therapies can be provided to children with endangering hemangiomas.

Glossary

Apoptosis: A mechanism by which cell death can occur. It is characterized by morphologic changes in the nucleus and cytoplasm and chromatin cleavage at regularly spaced sites resulting in DNA fragmentation. This mode of cell death is contributes to the regulation of the size of animal tissues and in mediating pathologic processes associated with tumor growth.

Clonal expansion: A single cell undergoes multiple cell divisions to give rise to a population of descendent cells.

Endothelial progenitor cells: immature endothelial cells that co-express stem cell markers and endothelial lineage specific markers.

Immunohistochemistry: An indirect means of determining the expression and localization of a protein or antigenic determinant within a tissue. Histological tissue sections are incubated with an antibody directed against the protein of interest, followed by detection of bound antibody using a secondary antibody conjugated to a reporter.

Somatic mutations: Alterations in DNA sequence that cause defective gene products in any cell in the body except germ cells.

Capsule Biography

Dr. Bischoff is an Associate Professor in the Vascular Biology Program/Department of Surgery at Children's Hospital Boston and Harvard Medical School. Her laboratory has been investigating cellular and molecular mechanisms that cause hemangioma since 1997. In addition, her laboratory studies growth and differentiation of endothelial progenitor cells and endothelial cells that line cardiac valves.

CHAPTER 24

Window Models

Dai Fukumura
Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts

Introduction

The tissue preparations used for *in vivo* microscopy can be grouped into three classes: (1) *in situ* preparations (e.g., mouse ear skin, bat wing, human nail bed, mouse tail lymphatics), (2) acute (exteriorized) tissue preparations (e.g., hamster cheek pouch; rat cremaster muscle; mouse, rat, cat, or rabbit mesentery; internal organs such as the heart, lung, stomach, intestine, pancreas, liver, kidney, ovary, breast, spleen, lymph node, or Peyer's patch), and (3) chronic transparent windows (chambers). Each preparation has its strengths and weaknesses. *In situ* preparation does not require any invasive preparation, but accessible tissue is very limited. Acute exteriorization can be applied to virtually any tissue with variable degrees of difficulty, but the duration and frequency of the observation is limited, and the preparation procedures may affect the microcirculatory parameters.

Window models allow sufficient recovery time after the implantation and permit chronic observation thereafter. Various window models are available today, and more are being developed. This chapter discusses chronic window preparations and their usage for microcirculation research.

Chronic Window Preparations

Chronic windows developed to date include the rabbit ear chamber, dorsal skin chamber, cranial window, hamster cheek pouch, spinal window, rabbit bone chamber, mouse abdominal window, mammary window, and lung window (Table I). Each of these chronic windows has its advantages and disadvantages. For example, the rabbit ear chamber is perhaps the most optically clear. However, rabbits are expensive to purchase and maintain, and it takes four to six weeks to mature the granulation tissue before the study begins. Mice, hamsters, and rats are less expensive and require smaller quantities of reagents because of their smaller body weight. From the surgical point of view, rats and hamsters are easier to work with than mice, but the latter have many advantages. The availability of comprehensive genetic information on mice, immunodeficient and genetically engineered mice, and murine reagents such as surface markers or antibodies has made mice the most commonly used laboratory animals for modern biological research. The dorsal skin chamber in mice is the most widely used chamber preparation because the surgery is less involved than some of the other preparations and because of its longer history. The cranial window can be kept for up to a year, compared to 30 to 40 days for the dorsal skin chamber, and (along with the cheek pouch) is an immunoprivileged site. The main disadvantage of the cranial window is that, in most cases, the visualization of microvessels requires both epi-illumination and the injection of a contrast agent such as a fluorescent marker.

The Rabbit Ear Chamber

In 1924, Sandison developed the first transparent window (chamber) for implantation in the ear of a rabbit. Since then, various modifications of this model have been used for microcirculation studies. The model requires granulation tissue formation within the chamber, and during this period it is very useful for the study of the wound healing process. The chambers can be used either for normal tissue studies or for tumor implantation after the maturation of granulation tissue.

Typically, a rabbit ear chamber is surgically implanted in the 15-cm-long ears of New Zealand white rabbits (~3 kg body weight). Four holes are punched in the shaved ear: three outer perforations (3.5 mm in diameter) for the chamber positioning and a central puncture (5.4 mm diameter) for the transparent window housing. A molded plate is placed on the inside of the ear and aligned with the existing holes,

Table I Examples of Window Models for Microcirculation Studies.

Model	Species	Application
Ear chamber	Rabbits	Wound healing, tumor growth
Dorsal skin chamber	Rabbits, rats, hamsters, mice	Skin microcirculation, ischemia reperfusion, local cytokine application, wound healing, tumor growth, angiogenesis assay, tissue growth
Cranial window	Pigs, cats, rats, mice	Cerebral and pial microcirculation, local cytokine application, wound healing, tumor growth, angiogenesis assay, tissue growth
Cheek pouch window	Hamsters	Cheek pouch microcirculation, wound healing, tumor growth
Spinal window	Rats, mice	Spinal microcirculation
Bone chamber	Rabbits	Bone microcirculation, ischemia reperfusion, wound healing, stem cell homing
Abdominal window	Mice	Abdominal wall and pancreas microcirculation, tumor growth
Mammary window	Rats, mice	Tumor growth
Lung window	Rabbits, mice	Lung and pleural microcirculation, tumor growth

while a thin (~200 μm) cover of mica glass is positioned on the outside of the cartilage. A thin granulation tissue bed (with a thickness of ~40 μm and a diameter of ~5 mm) grows in the chamber, sandwiched between the molded plate and the mica glass. The granulation tissue develops at an average of 8 days after implantation, and reaches maturity at approximately 40 days after implantation.

For tumor implantation, the cover glass, which forms the top plate of the transparent chamber, is carefully removed. A tumor (such as VX2 carcinoma) is excised from the flank of a tumor-bearing host, minced, placed in 0.9 percent NaCl solution, and spread uniformly over the cover glass. The cover glass is replaced flush against the intact normal tissue. Angiogenic response is observed 3 to 4 days post-implant, and the tumor-bearing chamber is ready for intravital microscopy approximately 10 days after implantation.

For intravital microscopy, the animal is placed in a dorsal recumbent position in a cradle that restricts head movement while still maintaining proper circulation to the chamber. The ear containing the chamber is extended horizontally to the specimen plane of an intravital microscope. The chamber is secured to the microscope stage with an aluminum adapter.

The Dorsal Skin Chamber

In the 1940s, Algire adapted the Sandison chamber to the dorsal skin in mice and carried out pioneering studies of angiogenesis during wound healing and tumor growth. Algire's original design and its modifications for other species require granulation tissue growth similar to that in the rabbit ear chamber model. Although this type of dorsal skin chamber has better optical accessibility, the effects associated with the wound healing process may hamper the observation. Later development of new dorsal skin chamber design minimized such effects by using intact skin, as described below. This type of dorsal skin chamber has been used for immunocompetent as well as immunodeficient mice, rats, and hamsters. With the availability of genetically engineered animals, the mouse dorsal skin chamber (Figure 1) has the broadest range of applications.

For the implantation of a transparent chamber into mouse dorsal skin, the entire back of the animal is shaved and depilated and two symmetrical titanium frames (weight 3.2 g) are implanted so as to sandwich the extended double layers of skin. One layer of the skin is removed in a circular area approximately 15 mm in diameter, and the remaining layer (consisting of epidermis, subcutaneous tissue, and striated muscle) is covered with a circular cover glass (11 mm in diameter) incorporated into one of the frames. Following implantation of the dorsal skin chamber, animals are allowed to recover from microsurgery for 48 hours before *in vivo* microscopy studies or subsequent procedures are conducted.

To implant tissue, such as a tumor, the animals are positioned in a transparent polycarbonate tube (inner diameter: 25 mm). The cover glass is carefully removed and a small piece of tissue (approximately 1 mm in diameter) or 2 μl of dense cell suspension (~2×10^5 cells) is implanted at the center of the dorsal skin chamber. A new cover glass is then placed on the chamber.

For microscopy on a dorsal skin chamber–bearing mouse, the mouse is positioned in the polycarbonate tube. A heating tape is wrapped around the plastic tube to maintain the animal's core temperature at a constant ~37°C during the observations. To obtain microcirculatory parameters, chambers are observed under an intravital microscope, which is typically equipped with a high-sensitivity camera for fluorescence imaging.

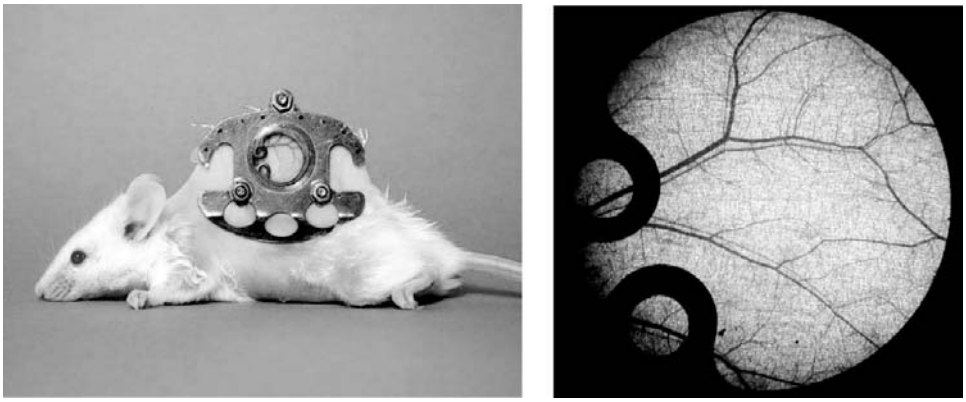

Figure 1 Mouse Dorsal Skin Chamber Model. An SCID mouse bearing a dorsal skin chamber (left) and a macroscopic image of the mouse dorsal skin chamber (right). The frame is made of titanium (3.2 g). The window is 11 mm across. (see color insert)

Figure 2 Mouse Cranial Window Model. Nude mouse bearing a cranial window (left) and a macroscopic image of the mouse cranial window (right). The window is 7 mm across. (see color insert)

The Cranial Window

The closed transparent cranial window model has been extensively used for cerebral microcirculation studies. After the recovery of central nervous system fluid and intracephalous pressure to normal levels, this model provides direct optical access to cerebral blood vessels under physiological condition. The cranial window is the most stable window model to date, allowing observation for as long as the entire natural life span of the animal; it is therefore very useful for studies requiring relatively long duration. Cranial windows are used for angiogenesis, vessel remodeling, and maturation studies. Furthermore, this model provides a natural microenvironment for primary and metastatic brain tumors. Various species, including mice, rats, cats, and pigs, are used for the cranial window model. We will describe the preparation of the mouse cranial window (Figure 2), but similar procedures are used for other species.

For cranial window implantation, a stereotactic apparatus holds the head of the animal. The skin is cut in a circular manner on top of the skull, and the periosteum underneath is scraped off to the temporal crests. A 6-mm circle is drawn over the skull, and a groove is made on the drawn circle using a high-speed air-turbine drill with a 0.5-mm-diameter burr tip. Drilling of the groove continues until the bone flap becomes loose. Using a malis dissector, the bone flap is separated from the dura mater underneath. A nick is made close to the sagittal sinus. Iris microscissors are passed through the nick. The dura and arachnoid membranes are cut completely from the surface of both hemispheres, avoiding any damage to the sagittal sinus. The window is sealed with a 7-mm cover glass, which is glued to the bone with histocompatible cyanoacrylate glue.

For implantation of tumors or tissue constructs, the cover glass is removed one week after the window implantation. A small piece of tissue is inoculated at the center of the window. Alternatively, 3 to 5 µl of a thick single cell suspension ($1–5 \times 10^5$ cells/µl) are implanted with a 28-gauge microsyringe (using a needle tip angle of 55 degrees and a depth of 1.75 mm).

For intravital microscopy, an animal is anesthetized and put on a polycarbonate plate, with the head fixed by means of a metal ring upper frontal tooth holder and a bilateral plastic ear holder. A heating pad is placed under the animal to maintain its temperature at ~37°C during *in vivo* microscopy.

Other Window Models

A spinal window has been made in rats (C5) and mice (C1 to C7) with a laminectomy. The windows were sealed with dental acrylic resin and a 7-mm cover glass (rats) or gas-impermeable transparent membrane (mice). The dorsal surface of the cervical cord was observed for leukocyte, T-cell, and platelet interaction with spinal vessels.

The rabbit bone chamber is a hollow titanium-alloy screw with quartz lenses embedded in its core. Vessels, followed by bone tissue, grow in a 100-μm-thick chamber between two flat quartz elements implanted in tibial bone. Intravital microscopy in the bone chamber has been used to study bone microcirculation, ischemia reperfusion injury in bone, and stem cell homing to bone marrow.

An abdominal window model for the mouse pancreas has been reported. A portion of the pancreas is gently exteriorized through a small laparotomy and kept within a space surrounded by the outer side of the abdominal wall, a titanium ring, and a circular glass cover slip (11 mm in diameter) held by the titanium ring. This model permits repeated observation of microcirculation in the pancreas and of the growth and treatment of pancreatic tumors.

The mammary window in rats and mice allows chronic observation of tumors growing in the breast tissue. This model requires removal of skin, nipple, and epithelium before injection of tumors and placement of an acrylic disk. Alternately, microcirculation in intact breast tissue and/or tumors grown in the breast can be observed acutely by placing a surgically prepared tissue flap in a specially designed microscope stage or chronically by using a mammary chamber similar to the mouse dorsal skin chamber.

Lung windows in New Zealand White rabbits have been used to study pulmonary microcirculation via intravital microscopy. The smaller intact pleural window involves the removal of the skin, intercostal muscles, and endothoracic fascia to expose the costal pleura, through which the lung surface is observed. The larger type of window requires the removal of the thoracic wall, including ribs, over a 3-cm distance and the implantation of a transparent window with a hollow cylinder to apply negative pressure. The lungs are inflated by positive air pressure of 6 mmHg, and the lung surface is sucked onto the window. Hemodynamics and short-term leukocyte/platelet-endothelial interactions were studied using these rabbit lung window models.

On the other hand, the chronic thoracic window model in mice allows temporal observation of the microcirculation of tumors implanted in the lung. For the implantation, a 6-mm ventral portion of the chest wall is removed, covered with a circular glass cover slip (8 mm in diameter), and sealed with biocompatible cyanoacrylate adhesive and cement mixture. Withdrawal of the remaining air in the chest cavity allows the lung to inflate and attach to the cover slip. One week later, a tumor fragment is implanted on the pulmonary pleural surface of the window. For intravital microscopy, the animal is placed in the lateral position and the chest wall is attached to adjustable arms on the stage by cranial and caudal sutures.

Utilization of Window Models

Window models generally allow long-term continuous and/or repeated observation and are thus ideal for time-course studies of physiological and pathological events. Window models are best suited for intravital microscopy and are used to study angiogenesis, microcirculation, tumor and engineered tissue growth, disease process, and treatment response.

Intravital Microscopy

Intravital microscopy is a powerful optical imaging technique that allows noninvasive monitoring of molecular and cellular processes in intact living tissue with 1 to 10 μm resolution. Sophisticated animal models, such as window models, are a prerequisite for this technique. With the use of appropriate tracers, optics, and analysis algorithms, a wide array of morphological and functional vascular parameters—such as blood and lymph vessel architectures, blood and lymph flow, vasomotion, vascular permeability, and leukocyte/platelet-endothelial interactions—can be determined by intravital microscopy. In addition, endogenous and exogenous probes, as well as genetically manipulated cells and animals, can provide other important parameters such as gene expression (promoter activity via GFP imaging), interstitial/intracellular pH, interstitial and microvascular pO_2, interstitial diffusion, convection and bindings, and extracellular matrix structure (second harmonic generation of collagen fiber).

Treatments and Manipulations

By observing the same vessels and/or regions repeatedly, window models provide accurate dynamic information on microcirculatory responses. In addition to monitoring the therapeutic effects of systemic treatments, window models are often used to assess the local effects of treatments or manipulations. For example, the occlusion of feeding vessels to the windows or the physical compression of tissues within the windows induces ischemia, followed by reperfusion after release; thus, windows are useful as models of local ischemia reperfusion. For local treatments, test compounds can be applied locally, either by topical application after removal of the cover glass or by injection through a port embedded in the window models. Alternately, a drug-containing matrix can be implanted within the window for continuous release of local treatments. Furthermore, the application of specific optical powers or wavelengths can activate certain drugs or carriers within the light-exposed area.

Cancer Research

A solid tumor is an organ-like structure that consists of cancer cells and nonneoplastic host stromal cells embedded in an extracellular matrix and nourished by a vascular network. The application of intravital microscopy techniques to tumors grown in window models (Figure 3) has provided unprecedented insights into the inner workings of this organ. It has been unequivocally demonstrated that the structure and function of tumor vessels is heterogeneous. The chaotic nature of tumor vessels forms a physiological barrier to the delivery of therapeutic molecules to tumors and hinders the efficacy of various tumor therapies. In vivo microscopy of tumor window models has revealed that certain antiangiogenic treatments can normalize the abnormal tumor vessels so that they become more efficient. Normalization of tumor vessels by antiangiogenesis treatment may overcome physiological resistance to drug delivery and accelerate treatment efficacy.

Angiogenesis Assay

To study angiogenesis, vessel remodeling, and maturation, an extracellular matrix construct containing either angiogenic factor(s) or vascular cells (such as endothelial cells, pericytes, vascular smooth muscle cells, and their precursors) are implanted in window models (Figure 4). Angiogenic matrix implants in window models allow for noninvasive, real-time measurements of angiogenic vessel structure and function, from early development to subsequent remodeling and maturation. Other types of animal models also permit chronic monitoring of vessel formation (e.g., the corneal micropocket assay in rabbits, rats and mice; the anterior chamber/iris assay in frogs, rabbits, guinea pigs, swines, goats and sheep; and the chick chorioallantoic membrane model), but these models do not typically use intravital microscopy and are thus unable to provide detailed functional information.

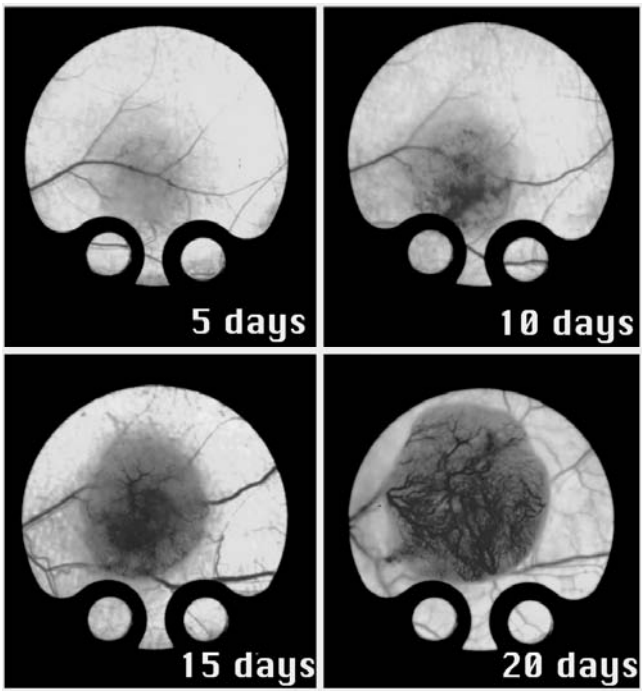

Figure 3 Angiogenesis and Tumor Growth in a Window Model. LS174T human colon cancer was implanted in an SCID mouse dorsal skin chamber. At day 5 after tumor cell implantation, enlargement of host vessels was observed, and by day 10 occasional hemorrhage and sprout formation occurred. At day 15, tumor growth and further angiogenesis became apparent. By day 20, the tumor was fully vascularized. (Adapted from Reference [3].) (see color insert)

Tissue Engineering

Tissues and organs, or their precursors (stem cells), can be implanted into window models for the study of organogenesis and/or the growth, microcirculation, and biology of the respective tissues. For example, preadipocyte implants exhibit *de novo* fat tissue formation and reveal reciprocal regulation of angiogenesis and adipose differentiation. Bone implants permit the monitoring of bone regeneration and angiogenesis as well as bone preferential metastasis such as prostate cancer. A major challenge in tissue engineering and regenerative medicine is the creation of stable vasculature. Window models provide an ideal platform for the determination of vessel development and function in an engineered tissue.

Future Perspectives

Intravital microscopy in window models has been providing useful insights into angiogenesis and microcirculation. However, two key challenges remain. First, the most widely used microscopy techniques are surface-weighted. Multi-photon microscopy can provide images at depths of up to ~700 μm, depending on the tissue and tracer used. Other optical methods, such as optical coherence tomography, can image further deeper regions. Systems and applications of these techniques have been rapidly increased recently. With more research in this area, we may someday be able to obtain dynamic images of whole organs or tissues with high spatial resolution.

The second limitation of window models is that they are currently limited to organs accessible from outside of the body. To study internal organs, surgical manipulation is required, which allows only short-term observations. The adaptation of microscopy techniques to use a fiberscope system will enable internal organs to be studied with minimum invasion. Alternately, the future advancement of optics and transponder devices may allow for both the implantation and chronic monitoring of internal organs.

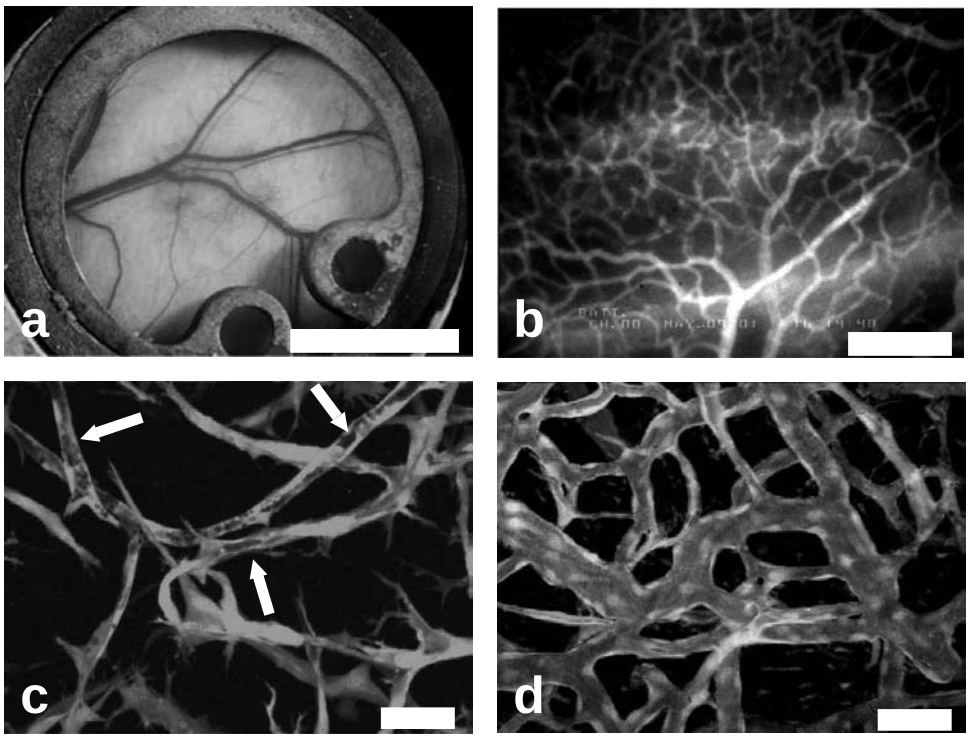

Figure 4 Vessel Formation in a Window Model. **(a, b)** Angiogenesis and vessel remodeling during adipogenesis in the mouse dorsal skinfold chamber after 3T3-F442A cell implantation. **(a)** Macroscopic image 9 days after implantation. **(b)** Intravital microscopy image of fluorescence contrast enhanced blood vessels at 28 days after implantation. **(c, d)** HUVECs and 10T1/2 cells were seeded in a 3-D extracellular matrix and implanted in a mouse cranial window. 3-D images of engineered vessels (EGFP expressing HUVEC, green; functional blood vessels contrast-enhanced with rho-dextran, red) were taken using intravital multi-photon laser-scanning microscopy. **(c)** Four days after implantation of HUVEC + 10T1/2 construct. Large vacuoles in the tubes resemble the lumens of capillaries (arrows) but they are not perfused (no red). **(d)** Four months after implantation of HUVEC + 10T1/2 construct. Engineered vessels are stable and functional. Bars indicate 5 mm (*a*), 100 μm (*b*), 50 μm (*c*, *d*), respectively. (Adapted from Fukumura, D., Ushiyama, A., Duda, D. G., Xu, L., Tam, J., Chatterjee, V. K. K., Garkavtsev, I., and Jain, R. K. (2003). Paracrine regulation of angiogenesis and adipocyte differentiation during *in vivo* adipogenesis. *Circ. Res.* **93**, e88–e97; and Koike, N., Fukumura, D., Gralla, O., Au, P., Schechner, J. S., and Jain, R. K. (2004). Creation of long-lasting blood vessels. *Nature* **428**, 138–139.) (see color insert)

With these improvements, window models will continue to offer new opportunities for discovery in microcirculation research.

Summary

Transparent window (chamber) models are widely used in microcirculation research. Because window models allow direct optical access without further surgical manipulation, they are especially useful for long-term monitoring of microcirculation by intravital microscopy. These techniques allow us to dissect physiological and pathophysiological processes during blood and lymph angiogenesis, wound healing, tissue engineering, tumor growth, and various therapies. The rabbit ear chamber, the rodent dorsal skin chamber, and the cranial window are the most commonly used window models. In addition, windows for various organs have been or are being designed. The continuing development of window models, along with progress in imaging techniques, analysis algorithms, molecular probes, and genetically engineered animals, increases the variety, accuracy, and efficacy of our data collection and further expands our knowledge of microcirculation.

Glossary

Cranial window: A transparent window in cranium of an animal.

Dorsal skin chamber: A transparent window model in dorsal skin of an animal.

Intravital microscopy: Microscopy technique for *in situ* observation of a living tissue.

Rabbit ear chamber: A transparent window model in a rabbit ear.

Transparent window (chamber) model: An animal model typically consists of a frame (e.g., titanium, mold, endogenous bone), a transparent window (e.g., glass, mica, quartz, acryl), and a tissue of interest.

Capsule Biography

Dai Fukumura, M.D., Ph.D. (Associate Professor, Edwin L. Steele Laboratory, Department of Radiation Oncology, Massachusetts General Hospital and Harvard Medical School), is a research scientist in the field of cancer and vascular biology. He has documented expertise in various animal window models and intravital microscopy. His current research interests include the role of nitric oxide in angiogenesis and microcirculation, the role of host-tumor interactions in tumor angiogenesis, growth, and metastasis, and the mechanism of vessel maturation.

CHAPTER 25

The Cremaster Muscle for Microcirculatory Studies

Robert Hester
University of Mississippi Medical Center, Jackson, Mississippi

Studies of the microcirculation have typically used thin muscle preparations that are easily dissected. The cremaster muscle has proven to be an easily prepared tissue for the study of microvascular reactivity and mechanisms for the control of striated muscle blood flow. The following will provide information about the preparation of this muscle and the associated cardiovascular parameters under both normal and pathological conditions.

Animal Models

Rats and hamsters have been used for most microcirculatory studies involving the cremaster. The first mention of the cremaster muscle for the study of blood vessels *in vivo* was presented by Grant [1]. Subsequent studies provided detailed descriptions of the dissection techniques including "hints" [2]. This manuscript also presented information about preparing the rabbit cremaster, although it was mentioned that the size of the scrotum in 2 kg rabbits was similar to 250 g rats. Therefore, although the technique is applicable to the rabbit, it is more suitable in the rat. The report by Baez [3] provided the first study using an opened cremaster, which has become the classic paper for this microcirculatory preparation. With the development of transgenic mice, the mouse cremaster has become a popular model for studying the mechanisms of inflammatory responses or control of blood flow in an animal with a modified genotype. In mice the cremaster appears to be the only microcirculatory model for skeletal muscle because of the small size of the animal.

Anatomy

Anatomically the cremaster is a muscle covering the spermatic cord and testes. The cremaster originates from the internal oblique muscle as the spermatic cord passes from the abdomen to the scrotum through the inguinal canal. The physiological role of the cremaster is to retract the testes and keep the testes warm and protect it from injury. The cremaster muscle in rodents is a thin muscle, 200 to 400 μm in thickness, comprising two muscle layers.

In adults rats or hamsters, the cremaster muscles comprise 60 to 80 percent of the total area as Type IIb fibers, which are fast-twitch glycolytic, while 10 to 16 percent are Type I slow-twitch fibers and 8 to 20 percent are Type IIa fast-twitch oxidative-glycolytic fibers [4]. This percentage has been shown to occur in both hamsters and rats, irrespective of age. The average size of the muscle fibers in young rats and hamsters averages approximately 500 μm^2 and increases to 12 to 1500 μm^2 in adult animals.

Nervous Supply

The major nerve supply to the cremaster is by both the femoral and genital branches (L1 and L2) of the genitofemoral nerve. The ilio-inguinal, the ilio-hypogastric, and the lateral cutaneous nerves also supply the cremaster, and sectioning of all four nerves is required to fully denervate the muscle. The genitofemoral nerve can be accessed by an abdominal incision and stimulated directly (0.1 ms 1–5V) to elicit contraction of the cremaster muscle. Direct field stimulation using electrodes placed across the cremaster can also be used to elicit muscle contraction.

Blood Supply

The blood flow to the cremaster is supplied by the cremasteric artery, a branch of the inferior epigastric artery. The cremaster muscle is normally supplied by a paired arteriole (~100 μm) and venule (~150 μm). These vessels branch into smaller vessels, which also give off side branches. The paired arrangement, arteriole and venule, may continue to the level of 30 to 40 μm arterioles. There is no apparent relationship between the arterioles and the orientation of the muscle fibers. Arterioles continue to branch until terminal arterioles give rise to capillaries. Groups of capillaries (modules) appear to be the basic unit of vascular architecture; that is, the flow to a group of capillaries is controlled by the diameter of the upstream arteriole, and an increase in capillary flow occurs throughout the module, not within a single capillary. Normal vascular diameters are presented below.

Dissection and Preparation

The ease of preparing the cremaster muscle is a strength of this preparation. There are only minor differences across species in the preparation of this muscle; therefore, the following directions for dissection can be easily adapted for different species.

The animal should be anesthetized with an appropriate agent, for example, sodium pentobarbital intraperitoneally (40 to 60 mg/kg, for rats and hamsters), and then supplemented with intravenous infusion, either through a jugular or femoral vein. A tracheostomy should be performed to allow removal of bronchial secretion but not to support mechanical ventilation. As with any anesthetized animal, monitoring of blood gases should be considered. Placement of a femoral or carotid arterial catheter is needed only if blood pressure is required. Core body temperature should be continually monitored with an esophageal temperature probe.

The preparation and study of the cremaster muscle requires a continuous flow of a physiological salt solution over the muscle. This is accomplished by having a small glass dripper placed over the muscle, allowing for a small continuous flow of superfusate solution during the entire dissection and experiment. A warm physiological salt solution (PSS), pH 7.35 at 34°C, containing (in mM) 131.9 NaCl, 4.7 KCl, 2.0 $CaCl_2$, 1.2 $MgSO_4$, and 20 $NaHCO_3$ is appropriate for superfusion. Because the solution is bicarbonate buffered, the superfusion solution must be equilibrated with 5 percent CO_2. The amount of oxygen in the superfusion solution has varied between different laboratories, but the oxygen delivery to the cremaster tissue should be from the blood supply. Therefore, the superfusion solution should be equilibrated with a low percentage of oxygen, 0 percent or 5 percent. Thus, the superfusion solution should be equilibrated with 5 percent CO_2, 0 percent to 5 percent O_2, with a balance of N_2.

The animal is placed on its back on a clear acrylic (Lucite® or Plexiglass®) board. The animal's feet should be secured to the board with tape and then either the left or right groin is shaved. To minimize urine contamination of the cremaster, the bladder should be emptied by gentle pressure, with a tie being placed around the penis. A round acrylic pedestal or bath with a rim of silastic or silicone elastomer (Sylgard®) allows for the cremaster to be pinned to the silastic using insect pins.

Figure 1 illustrates the basic surgical procedure. First a 5-0 suture is placed on the distal portion of the scrotum, and the suture is pulled tight to secure the cremaster for surgery. The tip of the scrotum is elevated, and the skin is cut in a distal to proximal direction. At this time the PSS should be flowing over the preparation. The connective tissue between the testicle and the skin is then cut to free the testicle. The testicle can either be removed (after ligating the blood supply) or the freed testicle is gently pushed through the inguinal canal into the abdominal cavity. The solution flowing over the cremaster will hydrate the connective tissue, allowing for a better visualization of the connective tissue for removal. The skin is then pulled proximal and either removed, secured by ties, or pinned to the silastic around the acrylic pedestal. The distal tip of the cremaster is then

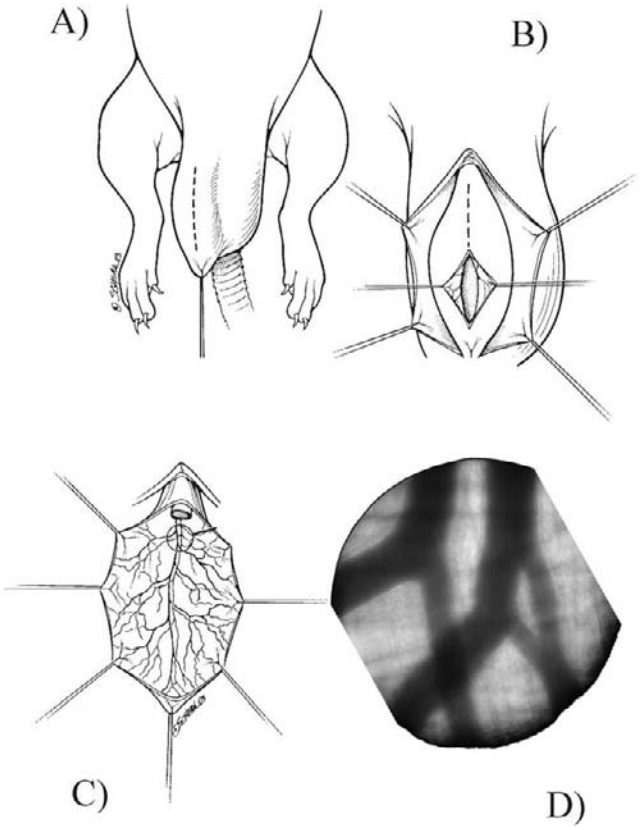

Figure 1 This figure shows the basic surgical techniques for preparation of the cremaster muscle. **(A)** A suture is placed in through the distal skin, and a distal to proximal cut is made. **(B)** The skin is retracted, the cremaster is exposed, and a distal to proximal cut is made through the cremaster to expose the testicle. **(C)** Following removal of the testicle, the cremaster is stretched over a plexiglass pedestal. Care should be taken not to overly stretch the cremaster muscle. **(D)** A microscope image of arterioles and venules.

pinned to the silastic and the cremaster is cut in a distal to proximal direction. This will free the cremaster except for a small set of blood vessels between the cremaster and the testicle. These can be occluded with forceps and gently pulled in the middle with minimal bleeding. The connective tissue is then cleared from the cremaster using fine-tipped scissors. The cremaster is then gently stretched and pinned out, starting from the distal direction. The entire animal can then be moved to the microscope for observation at higher magnification. The cremaster should be superfused with the PSS through the experimental period.

An intact cremaster preparation can be prepared by an abdominal removal of the testicle and replacement with a clear Lucite insert. Although this technique has not been used by a large number of investigators, the major advantage is that disruption of the vasculature is minimized.

Cardiovascular Parameters

Tissue Blood Flow

The preparation of the cremaster muscle requires minimal surgery. Even so, the surgery can result in a disruption of the normal blood flow. Several studies have measured total cremaster blood flow for rats and hamsters using radioactive microspheres in both the surgically dissected tissue and the contralateral undisturbed cremaster muscle (Table I). Blood flow in the dissected cremaster muscle was similar to flow in the intact cremaster and similar to flow in the biceps and gastrocnemius muscles [5]. Other studies reported higher values in the dissected cremaster muscle compared to the undisturbed contralateral muscle. From these studies, it appears that surgery results in an elevated blood flow in the cremaster, although the increased blood flow may be limited to the outside areas exposed to surgical trauma (Table I). At the current time, no measurements of blood flow in the mouse cremaster muscle have been made.

Table I Cremaster Muscle Tissue Blood Flow.

Animal	Dissected tissue blood flow ml/min/100 g	Intact tissue blood flow ml/min/100 g	Reference
Rat	10 ± 2	9 ± 2	Morff and Granger 1980 [5]
	43 ± 3	24 ± 7	Proctor and Busija 1985 [6]
Hamster	7.7 ± 2.3	3.3 ± 0.5	Klitzman and Duling 1979 [7]

Microvascular Parameters

The range of diameters of arterioles and venules are presented in the Table II. The size of each vessel will vary with the age and size of the animal. The most common method for identifying vessels is based on the feed vessel being classified as first order, and each branching vessel with a decreasing size results in an increase in order number. There are varying numbers of arterioles before capillaries, but there are at least four branching orders of arterioles before the capillaries. The terminal arterioles are located before the capillaries and because of their small size, regulate flow through the capillaries. The arterial vessels supplying the cremaster provide significant resistance such that the pressure in the first-order arterioles averages 40 percent of the systemic pressure. Arteriolar diameter, red cell velocity, and calculated blood flow for representative vessels are presented in Table III.

Models of Hypertension

There are numerous hypertensive rodent models, and the cremaster muscle has been used to determine the effects of

Table II Normal Microvessel Diameters and Pressures.

Animal	Systemic blood pressure	Vessel	Resting diameter μm	Max diameter	Microvascular pressure	Reference
Rat	91 ± 4	1st order	119 ± 7		46 ± 3	Meininger et al. 1984 [8]
		2nd order	86 ± 5		43 ± 2

hypertension on the microcirculation. Table IV provides data for baseline arterial pressures, diameters, and microvascular pressures in four models of hypertension. Venular data is not presented because the values are similar to normal values (Table I).

Advantages

As a result of the ease of preparation, the cremaster muscle preparation has been used extensively to study the microcirculation. The total time for preparation of the muscle is approximately one hour. With suitable surgical training, it is easy to have preparations that have substantial vascular tone. The muscle will contract vigorously in response to field stimulation, resulting in an increase in oxygen consumption, blood flow, and arteriolar diameter.

Disadvantages

The cremaster is not a true postural muscle, and the arrangement of the muscle fibers is different from most postural muscles. The muscle fibers run oblique to each other, and even though there are discreet areas supplied by capillaries, this delineation is not readily observable. The outside areas of the cremaster should be avoided for study because these vessels are dilated as a result of the surgical procedure.

Conclusion

The cremaster muscle has proven to be an excellent tissue for the study of the microcirculation. Its ease of dissection, along with good visibility, provide a tissue that all laboratories can use for the study of the microcirculation. The availability of different hypertension models, along with different species, allows investigators a wide range of preparations to study microcirculatory function. The use of the mouse cremaster in the study of microcirculatory function will undoubtedly lead to the development of new transgenic models.

Glossary

Arteriole: A small arteriole, one which, at its distal end, leads to a capillary.

Cremaster: One of the fascia-like muscles suspending and enveloping the testicles and the spermatic cord.

Red cell velocity: The average speed of the blood in blood vessels. The centerline velocity is measured by various optical techniques, and average blood velocity is calculated as $Velocity_{average} = Velocity_{centerline} / 1.6$.

Venule: A tiny vein which, at it most proximal end, collects blood from capillaries.

Capsule Biography

Dr. Robert Hester is a Professor in the Department of Physiology at the University of Mississippi Medical Center, Jackson, Mississippi. Dr. Hester received his Ph.D. at the University of Mississippi Medical Center and completed a postdoctoral fellowship at the University of Virginia. He has been using the cremaster muscle for the study of functional hyperemia for approximately 20 years.

CHAPTER 26

Zebrafish: A Model for Studying Microvascular Development and Function

Kameha Kidd and Brant Weinstein

Laboratory of Molecular Genetics, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland

The zebrafish is a relatively recent addition to the field of microvascular research, but it possesses a number of distinct advantages for studies of blood vessel formation in vivo including experimental and genetic accessibility and an optically clear embryo. Because of its useful attributes, the fish has already begun to contribute significantly to our understanding of key factors involved in vessel growth, differentiation, and maturation, as well as the mechanisms that guide the patterning and function of the vasculature. In this chapter we provide a historical background and brief overview of the use of the fish for studies of blood vessel formation.

Emergence of the Zebrafish as a Vertebrate Genetic Model

The zebrafish has become a popular model for research in developmental and vascular biology during the past decade, but it has actually been evolving as a model organism for more than 30 years (see Figure 1 for a timeline of important events). The late George Streisinger was probably responsible more than anyone else for developing the zebrafish into the useful model organism that it is today.

From Phage to Fish

In the late 1960s George Streisinger began working with zebrafish at the University of Oregon with the goal of developing a vertebrate genetic model system comparable to the fly. Streisinger had worked with bacteriophage at Caltech during the critical foundation period of the molecular era, when the basic DNA–RNA–protein story was being established. His studies at Caltech involved a mutational approach to evaluate the genetic code, including its structure and the process of translation in the phage. These studies helped show that in vitro proposed codons did translate to in vivo specification of amino acid sequences based on specific base sequences. The success of genetic studies such as these in phage led Streisinger and others to wonder whether more complex genetic and biological processes could also be deciphered through mutational analysis. Taking this idea forward, Streisinger and some of his Caltech colleagues decided to attempt to study the nervous system using genetic analysis. Sydney Brenner turned to *Caenorhabditis elegans* for this purpose, while Seymour Benzer turned to the fruit fly to address the questions of nervous system function and behavior. Streisinger, however, was determined to find a vertebrate genetic model and set upon the zebrafish as a vertebrate organism in which it would be feasible to use mutational analysis to dissect biological (neurological in particular) development. It was joked that he wanted to find a phage with a backbone.

Why Zebrafish?

The zebrafish possesses some of the genetic and experimental accessibility of the fly and nematode worm, but is much more closely related to mammals. Some of the general

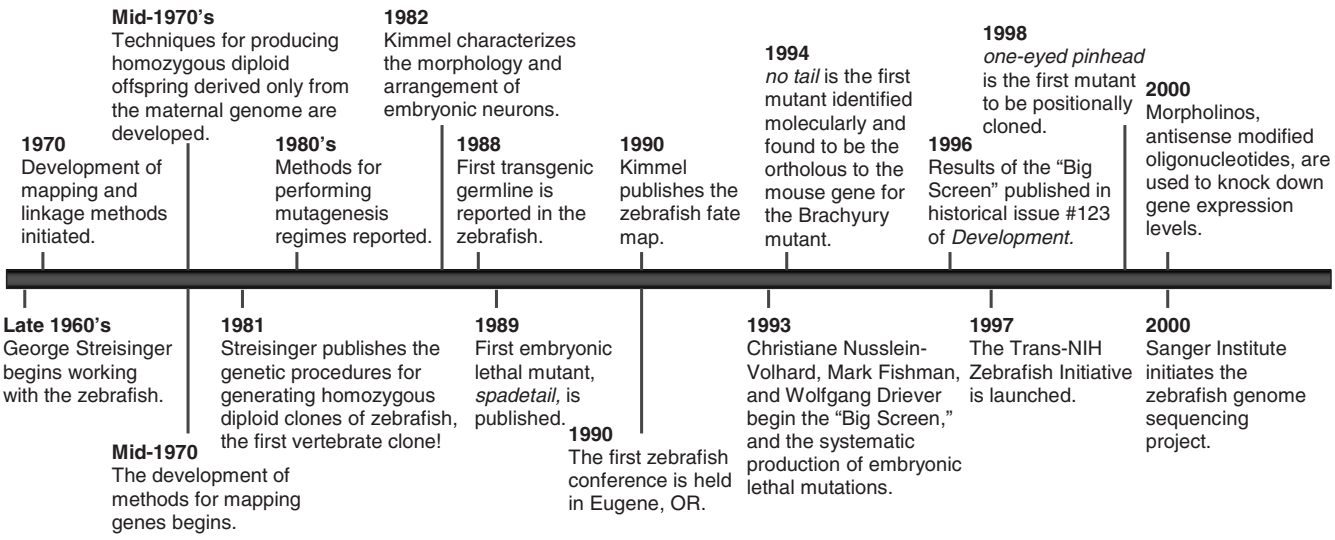

Figure 1 Major events that contributed to the success of the zebrafish. The zebrafish has been around for a number of years, but was not considered an established model for biological study until the past decade. This timeline highlights some of the major events that have contributed to the establishment of the zebrafish as a model organism. (see color insert)

features of the zebrafish that initially attracted Streisinger were the large numbers of adult fish that could be maintained in a relatively small space (adult zebrafish are only an inch long) and their year-round breeding in the laboratory. Zebrafish mature in 3 months' time, are capable of breeding every 1 to 2 weeks, and can produce hundreds of eggs per clutch. The external fertilization of the eggs permits in vitro manipulation of ploidy and fertilization for genetic analysis. Streisinger also realized the tremendous advantage afforded by the optically clear embryo of the zebrafish, facilitating screening for developmental phenotypes of interest even in organs and tissues deep within the animal.

Streisinger's Success

Streisinger's efforts to establish the zebrafish as a genetic model were not without risk. In the 1970s little was known about the conservation of regulatory pathways, and the question of translation from the fish to other vertebrates was a serious concern. Fortunately, the environment at the University of Oregon was such that Streisinger had liberty to pursue his interests without the risk of losing the support and resources provided by the "community" at Oregon, and he slowly began to make progress. He developed methods to produce haploid and diploid gynogenotes, permitting recessive mutations to be uncovered in a single generation without elaborate and time-consuming inbreeding schemes. He established a breeding program to remove lethal background mutations from strains, and developed methods to efficiently induce and recover new germ-line mutations. In 1981, Streisinger published a paper in *Nature* [1] describing the production of homozygous diploid clones of zebrafish. Meanwhile, work in other model organisms was leading to growing acceptance for forward-genetic analysis as a means of dissecting developmental processes. Arguably the most notable of these was the report published by Christiane Nüsslein-Volhard and Eric Wieschaus describing large-scale genetic analysis of *Drosophila* development [2]. As Streisinger's work with the zebrafish progressed, other faculty members at the University of Oregon also became interested in the zebrafish. In 1990 Charles Kimmel and colleagues published a cellular fate map for the zebrafish, a project that took nearly 10 years to complete [3]. This report laid the groundwork and provided tools for further studies of cell lineage and cell fate in the zebrafish. Monte Westerfield helped open the door further to other groups interested in working with zebrafish when he generated a protocol book covering the housing, handling, and laboratory use of zebrafish [4]. In 1988, Westerfield and colleagues also published the first report of stable germ-line transmission of foreign DNA in the zebrafish [5], laying the foundations for the subsequent very fruitful use of transgenic technologies in the fish.

Two additional events helped to solidify the fish as a vertebrate genetic model, by demonstrating its "relevance" to mammals and other "higher" vertebrates. The first was the molecular cloning of the zebrafish *no tail* mutant, which was shown to result from a mutation in the zebrafish homolog of the mouse *T* (*Brachyury*) gene and to cause phenotypically similar defects [6]. This demonstrated the fundamental conservation of developmental processes between these divergent vertebrate species. The second was publication of the results of the "Big Screens" carried out by two groups in Tübingen, Germany, and in Boston. Some 4,000 mutant phenotypes were identified in these screens, whose results were published in a single, historic volume of *Development* [7]. Mutants were uncovered affecting a wide variety of vertebrate developmental processes, including many modeling

human congenital diseases, and analysis of these mutants has led to many insights into the genetic pathways regulating early development. These screens demonstrated the feasibility of large-scale forward-genetic analysis of vertebrate development. Today the process of setting up and running a zebrafish screen is almost routine, and numerous genetic screens are being carried out targeting a wide variety of developmental processes.

The Postscreen Era

Interest in the use of the zebrafish greatly increased after publication of the results of the first large-scale screens in 1996, and development of additional tools and financial investment accelerated. Efforts began to develop dense genetic and physical maps of the genome, work that has led to a much more rapid turnaround time between identification of an interesting mutant phenotype and identification of the gene responsible for the phenotype. In 1997 the NIH established the Trans-NIH Zebrafish Coordinating Committee (TZCC) to help provide funding for zebrafish as a model organism for the study of vertebrate development, physiology, and disease. The efforts of this committee have been instrumental in facilitating increased and better-targeted channeling of NIH resources to the zebrafish community. A whole-genome sequencing project was initiated by the Sanger Institute, a project that has reached approximately fourfold coverage of the genome to date. Anther important advance was the development of targeted gene "knockdown" technology using antisense, morpholino-modified oligonucleotides (morpholinos, MOs) to inhibit translation or splicing of target genes of interest [8]. Suspected mutant sequences can now be confirmed with MO injections, conservation of gene function between fish and mice can be easily tested, and single and multiple gene knockdowns open the door to epistasis experiments and serve as a valuable complementary method to mutants for studying vertebrate development and disease.

The Zebrafish as a Model Organism for Studying Vessel Formation

The zebrafish is a useful model for studies of development in general, but it offers particular advantages for studies of blood vessel development, including the ability to isolate vascular-specific mutants by forward genetics and use optical imaging methods to visualize blood vessels within the living animal with very high resolution. Recently the zebrafish has begun to yield novel insights into mechanisms of blood vessel formation in vivo.

Cardiovascular Mutants in the Zebrafish

Among the mutants uncovered in the Tübingen and Boston screens were a large number with circulatory system defects. Mutations that significantly impair cardiovascular development are readily identifiable in zebrafish because of the transparency and small size of the developing zebrafish embryo, which permits easy visualization of the heart and blood vessels and allows the animal to receive enough oxygen by passive diffusion to survive for 4 to 5 days in the absence of a functional circulation. The cardiovascular mutants from these and subsequent mutant screens included a number of mutants specifically defective in the formation of blood vessels. Table I provides a list of some of the vascular-specific mutants that have been published to date, while Figure 2 illustrates the vascular defects associated with a few of these mutants. Although vascular mutants represent a relatively small subset of the mutants reported thus far, several large-scale genetic screens specifically targeting blood vessel mutants have recently been undertaken [9; also our unpublished results], and these new screens are now yielding many new vascular-specific loci, providing an important resource for future studies of vascular development in the fish.

Table I

Mutant	Phenotype	Gene	Reference
cloche	Lack endothelial and circulating blood cells	unknown	*Development* (1997) **124**, 381–389.
schwentine	Loss of angioblasts (endothelial cell precursors) and failure to undergo angiogenesis	Zebrafish ortholog of *flk 1*	*Curr. Biol.* (2002) **12**(16), 1405–1412.
gridlock	Lack trunk and tail circulation due to improper assembly of the dorsal and lateral aortae	Vascular bHLH factor related to mammalian HRT2	*Science* (2000) **287**, 1820–1824.
violet beauregarde	Massive enlargement of central cranial vessels and improper arterial–venous connections	*Alk1 (acvrl1)*	*Development* (2002) **129**, 3009–3019.
plcg(y10)	Deficient in VEGF-mediated angiogenesis and arterial differentiation	Phospholipase C-γ1	*Genes Dev.* (2003) **17**(11), 1346–1351.
kurzschluss	Branchial arteries fail to form properly and arterial–venous shunts lead to loss of circulation in the trunk	unknown	*Development* (1996) **123**, 293–302.
Out-of-bounds	Display premature sprouting and mispatterned growth of the trunk intersegmental vessels	PlexnD1	*Development* (2002) **129**, 973–982.

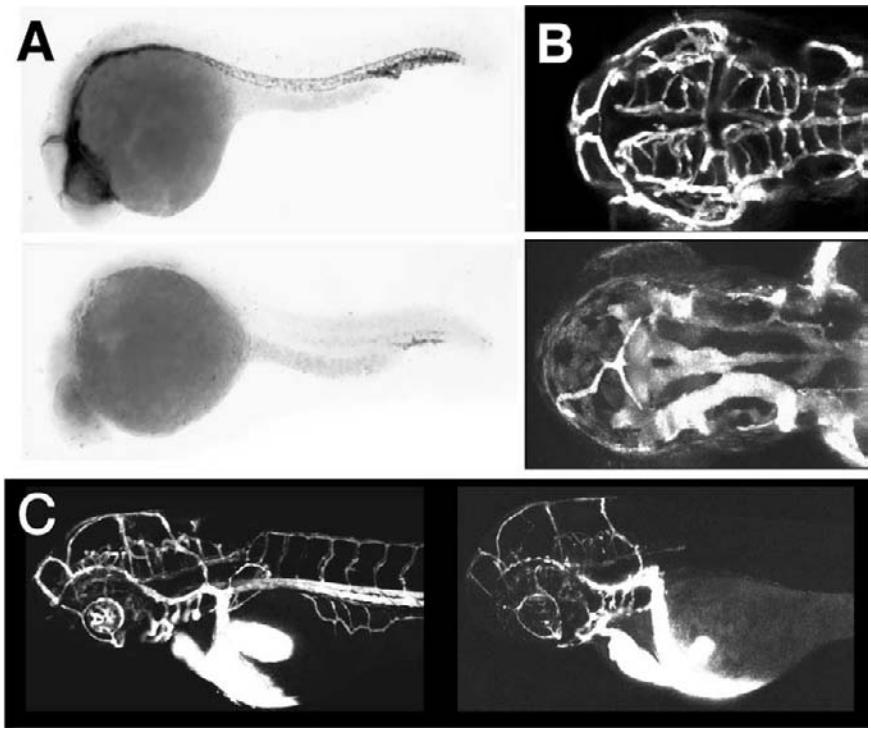

Figure 2 Vascular-specific mutants in the zebrafish. A number of different mutants have been isolated in zebrafish with defects in blood vessel formation. *Cloche* mutants lack virtually all blood endothelium (A). *In situ* hybridization of wild type (top) and mutant (bottom) embryos with vascular endothelial-specific probes such as *Fli-1* reveals a lack of vascular staining except in a small patch in the posterior trunk (24 hpf embryos, lateral views). *Violet beauregarde* mutants have defects in cranial vessel patterning (B). Mutants (bottom) display highly enlarged primary cranial vessels and reduced perfusion of secondary cranial vessels compared to wild type (top) embryos, as shown in these angiographic images (2.5 dpf embryos, dorsal views of head). *Gridlock* mutants lack caudal circulation due to a defect in proper formation of the dorsal aorta C). Mutants (right) have a normal pattern of cranial vessels but lack perfusion of more caudal vessels in comparison to wild type (left) animals (2.5 dpf embryos, lateral views of head and anterior trunk). (see color insert)

Transgenesis and Vascular Imaging in the Zebrafish

The application of transgenic technology to zebrafish cardiovascular research has provided a number of powerful tools for in vivo vascular imaging. Transgenic zebrafish lines expressing green fluorescent protein [GFP or enhanced (E)GFP] within vascular endothelial cells have been particularly useful for studying the formation of the vasculature in vivo. A germ-line transgenic expressing EGFP in the vasculature was generated using the zebrafish *fli1* promoter (Figure 3; *fli1* is a transcription factor expressed in the presumptive hemangioblast lineage, and later restricted to vascular endothelium, cranial neural crest derivatives, and a small subset of myeloid derivatives). This line expresses EGFP at high levels in vascular endothelium, permitting very high resolution long-term time-lapse analysis of developing blood vessels in vivo. Multiphoton confocal time lapse imaging of Fli-EGFP transgenic zebrafish has enabled detailed analysis of both normal vascular development and defective vessel formation due to genetic or experimental perturbations. Lawson and Weinstein [10] showed in vivo that growing blood vessels are extremely active, extending and retracting filopodial processes up to tens of microns in all directions. In a separate study Isogai et al. [11] used time-lapse imaging of Fli-EGFP animals to study how the earliest network of angiogenic vessels (consisting of intersegmental and parachordal vessels) assembles in the trunk. This study revealed a novel "two-step" mechanism for vascular network formation, with a primary vascular network forming first from artery-derived sprouts followed by emergence of a set of vein-derived secondary sprouts that interact dynamically with the primary network to generate the final functional "wiring" of the trunk network. The results of this study showed that blood flow does not play an important role in the initial assembly and gross anatomical patterning of this network, but is likely a critical determinant of the interconnections between primary and secondary vessels and their eventual arterial–venous identity. The Fli-EGFP transgenic line also permits imaging of blood vessels in adult zebrafish, as revealed in another recent study, of vascular network reassembly in the regenerating zebrafish caudal fin [12].

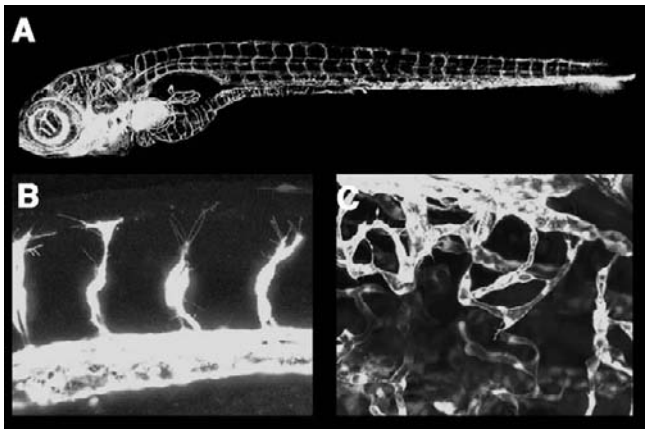

Figure 3 Blood vessels imaged in Fli-EGFP transgenic zebrafish. Vascular endothelial cells and their angioblast precursors are brightly green fluorescent in Fli-EGFP transgenic animals **(A)**. Image shown is a confocal microangiogram of a 7 day-old transgenic zebrafish. Fine cellular details can be discerned, including thin filopodial processes extending from growing intersegmental vessels in the trunk **(B)** and central arteries assembling in the zebrafish hindbrain **(C)**. Images shown are confocal microangiograms from approximately 1.5 day-old transgenic zebrafish. (see color insert)

Studying Arterial–Venous Fate Determination Using the Zebrafish

One of the recent important contributions to the study of microvasculature using the zebrafish has been the identification of molecular pathways responsible for arterial–venous (A-V) differentiation of endothelial cells. In the past, the arterial–venous fate of endothelial cells was believed to follow from physiological parameters such as differences in blood flow and pressure, but recent work has shown that early endothelial arterial–venous differentiation is in fact genetically programmed. Initial evidence that arterial and venous endothelial cells possess distinct molecular identities came from work with ephrin and Eph genes in mice. Wang et al. [13] described the expression of ephrin B2 (*Efnb2*), a member of the ephrin family of membrane ligands. Prior to the onset of flow, *Efnb2* is expressed specifically in arterial endothelial cells and is absent in venous endothelial cells, whereas the ephrin B2 receptor, Ephb4, is preferentially expressed in veins. Targeted gene deletion of each member of this ligand–receptor pair resulted in similar cardiovascular abnormalities, demonstrating their necessity, and likely direct interaction, for normal vascular development. Although these previous studies demonstrated the existence of functionally important molecular differences between arterial venous endothelial cells, they did not reveal how this fate choice was initially made. Zebrafish studies have been critical in uncovering and dissecting the functional roles of the upstream factors specifying arterial and venous endothelial cell fates, identifying a signaling cascade consisting of sequential hedgehog, vascular endothelial growth factor, and notch signaling. The discussion that follows reviews these findings.

A variety of studies in mammals and other vertebrates had revealed the specific expression of Notch signaling genes (Notch, Delta, Jagged, and so or) in arterial but not in venous endothelial cells. Murine knockout studies showed that these molecules play an important functional role in the vasculature, and their arterial-specific expression suggested they might be playing a specific role in artery formation. A number of recent studies in the zebrafish [14–16] have demonstrated that Notch signaling promotes arterial differentiation at the expense of venous differentiation during vascular development. Notch signaling was repressed in zebrafish embryos either genetically, using the neurogenic *mindbomb* (*mib*) mutant, or experimentally, by injecting mRNA encoding a dominant-negative DNA binding mutant of *Xenopus suppressor of hairless* protein. In either case, repression of Notch signaling resulted in loss of *ephrinB2a* expression from arteries and ectopic expansion of normally venous-restricted markers such as *ephb4* and *flt-4* into the arterial domain. Conversely, activation of Notch signaling [either by heat-shock promoter-driven ubiquitous expression of the Notch1a intracellular domain (Notch1a-ICD) or by Fli1-promoter driven vascular-specific expression of Notch5-ICD] suppressed expression of vein-restricted markers and promoted ectopic expression of *ephrinB2a* and other arterial markers in venous vessels. The vascular specific expression of Notch demonstrated the vascular endothelial cell-autonomy of Notch-ICD effects, confirming that Notch is in fact acting at the level of the vascular endothelial cell itself and not via indirect signals from some other, adjacent Notch-responsive cells or tissues.

Lawson and colleagues further dissected the A-V differentiation signaling hierarchy by demonstrating that sonic hedgehog (shh) and vascular endothelial growth factor (vegf) act upstream of Notch [15]. As in embryos lacking Notch signaling, embryos lacking shh or vegf fail to express ephrin-B2a within their blood vessels. Overexpression of shh promotes ectopic arterial vessel formation in the trunk, whereas overexpression of vegf via injection of vegf mRNA suppresses expression of vein-restricted markers and results in expression of ephrinB2a and other arterial markers in venous vessels. By combining activation or inhibition of each of the different signaling pathways in a series of "molecular epistasis" experiments, it was found that shh activity induces expression of vegf in the somites, which then activates notch signaling in the adjacent endothelial cells of the developing dorsal aorta, promoting arterial differentiation. Genetic screening methods were also used to identify genes functioning downstream from vegf in the zebrafish [17]. A zebrafish mutant was uncovered that was deficient in both angiogenesis and arterial differentiation as a result of a defect in phospholipase C gamma-1 (plcg1). Phospholipase C genes are known effectors of signaling via receptor tyrosine kinases such as the vegf receptor Flk1, and the vascular expression of plcg1 and vascular-specific phenotype of the mutant in this gene suggested that it might be functioning downstream of vegf signaling. Indeed, further experiments showed that plcg1 mutants were insensitive to both angiogenic and arterial differentiation responses to vegf overexpression. In support of the zebrafish findings

regarding roles for hedgehog and vegf signaling in the vasculature, recent studies in mice have also implicated shh and vegf signaling in regulating blood vessel growth and arterial differentiation [18–21], demonstrating the conservation of genetic programs between vertebrate species.

Conclusions

The lessons learned in the zebrafish are likely to be readily transferred to other vertebrate organisms, including mammals, since the complex circulatory system of the zebrafish is in most respects quite similar to that of other vertebrates. A comparison between the blood vessels of zebrafish and other vertebrates presents a striking degree of anatomical and functional conservation of vascular pattern and anatomy, suggesting that vascular development is directed by genetically programmed, evolutionarily conserved control mechanisms. Indeed, it is clear from the analysis of a variety of zebrafish orthologs of vascular-specific genes first described in other species that most of these genes have very similar spatial and temporal expression patterns in the fish. Some of the genetic control mechanisms responsible for regulating the expression of these genes and for vascular differentiation and patterning have now begun to be studied in the zebrafish. The specific advances in our understanding of the A-V differentiation pathway will be important in designing methods for directing organ-specific vessel growth for tissue regeneration, and for targeting specific vessel components for inhibition of growth. It is anticipated that our knowledge and understanding in this area will only continue to grow with the zebrafish as an integral component, resulting in the identification of novel factors and the more subtle characterization of the various vessel types and their growth.

Glossary

Clone: An exact copy of biological material such as DNA, a whole cell, or a complete organism.

Diploid: A complete set of chromosomes, present in somatic (non-sex-determining) cells, consisting of two copies of each chromosome. Human beings have 46 chromosomes in their diploid cells.

Epistasis: The ability of a gene to mask the phenotypic effects of another gene. A downstream gene is epistatic to any upstream genes that produce the same effect.

Fate map: A map of an embryo showing areas that are destined to develop into specific adult tissues and organs.

Genetic linkage map: A linear map of the relative positions of genes along a chromosome. Gene distances are determined by the frequency at which two gene loci are separated during chromosomal recombination.

Germ-line: The propagation of genetic information from one generation to the next via the germ cell. Germ-line mutation is one that has occurred in a germ cell and will be passed to the next generation. Same logic pertains to the term *germ-line transmission*.

Gynogenotes: Individuals that derive their chromosome number solely from the maternal contribution, rather than half from each parent.

Haploid: A single set of chromosomes, present in the egg and sperm cells of animals. Humans have 23 chromosomes in their reproductive cells.

Homolog: One member of a chromosome pair, or a gene similar in structure and evolutionary origin to a gene in another species.

Morpholino oligonucleotides: Short, antisense sequences of DNA (oligos) with a morpholino backbone that provides stability, and an increased life span in vivo.

Ploidy: Refers to the number of single sets of chromosomes in a given cell or organism.

Recessive mutations: Mutations affecting those genes require two identical copies to be expressed.

Capsule Biography

Brant M. Weinstein obtained his Ph.D. in 1992 from the Massachusetts Institute of Technology. He has headed the Unit on Vertebrate Organogenesis within the Laboratory of Molecular Genetics at the National Institute of Child Health and Human Development (NICHD) since 1997. His laboratory, supported by the intramural program of the NICHD, studies vascular development using the zebrafish.

Kameha Kidd received her doctorate at the University of Arizona in 2002 under the tutelage of Drs. Stuart K. Williams and James B. Hoying. She is currently a postdoctoral fellow, under the direction of Dr. Brant Weinstein, at the National Institute of Child Health and Human Development at the NIH. Her research interest is in microvascular development and organogenesis for application in therapeutic angiogenesis and tissue engineering.

CHAPTER 27

The Significance of the Nail Fold in Clinical and Experimental Studies

Hildegard Rand Maricq
Medical University of South Carolina, Charleston, South Carolina

Definition and Description of the Nail Fold

Anatomical Description

Nail fold (NF) is the skin fold surrounding the nail; it is divided into proximal and lateral portions. Since only the proximal NF has been the site of microvascular studies, the adjective is usually dropped. A sagittal section of this fold, which covers the root of the nail, is shown in Figure 1 [1].

NF has a dorsal epidermis, similar to the usual description of skin anatomy, having epidermal ridges and dermal papillae alternating along the dermo-epidermal junction. The ventral epidermis of the NF is flat, loosely adhering to the nail. Between the two epidermal layers we find the dermal connective tissue with blood vessels, nerves, and other structures, such as sweat glands. In the proximal part of the NF the dermal papillae, containing capillaries, are perpendicular to the skin surface; distally they gradually become slanted and become parallel to the ventral epidermis at the edge of the NF (Figure 1; see also Figure 4b).

The thickness of the NF, the slope of the decreasing distance between the two layers of the epidermis from the proximal NF to its edge, and the length of the NF vary considerably between individuals and also from finger to finger.

View by in Vivo Microscopy

Superficial blood vessels in the skin can be visualized by depositing oil on its surface. In an average healthy adult, there is a relatively uniform distribution of capillaries in the NF, as seen by in vivo capillary microscopy (Figure 2, bottom). Only the tips of the capillary loops are visible in the proximal NF, where they are perpendicular to the skin surface. Gradual sloping of dermal papillae in more distal NF allows visualization of capillaries partially from the side and at the edge of the NF they can be seen the best, now horizontal and showing their arterial, apical, and venular portions of the loop.

In about 5 percent of the normal young adult population, a highly visible and extensive subpapillary venous plexus can also be observed below the superficial papillary capillaries. This visible venular plexus is often associated with longer capillary loops, especially at the edge of the NF. The overall length of the NF tends to be longer in these individuals. Small sections of this plexus can sometimes also be seen in other subjects near the edge of the NF.

Place of the Nail Fold in Human Microvascular Studies

Why the Nail Fold?

Most human studies of microvasculature have used the technique of in vivo microscopy, taking advantage of the fact that superficial microvessels of the skin can be visualized by rendering the skin surface smooth by application of oil. This noninvasive method, discovered in the beginning of the 20th century, appealed to many investigators. O. Müller in 1922 published his extensive observations from a great number of areas of human skin, in both health and disease, illustrated by careful drawings that demonstrate the considerable variability of skin microvasculature from site to site.

Over time, however, NF became the favorite site because it was easy to place a finger under the microscope, and serial studies were facilitated, because the exact location of initial observations could be easily identified.

The pattern of NF capillaries varies with age. In a normal newborn baby only a plexus of microvessels can be seen;

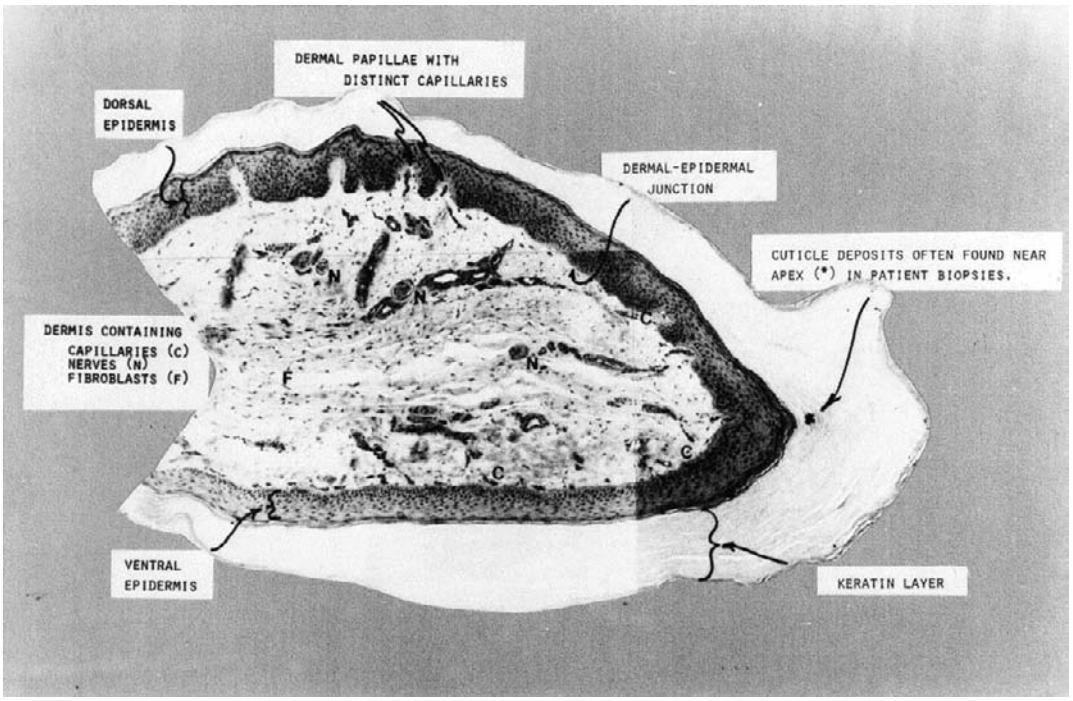

Figure 1 Sagittal section of a finger nail fold in a normal healthy subject.

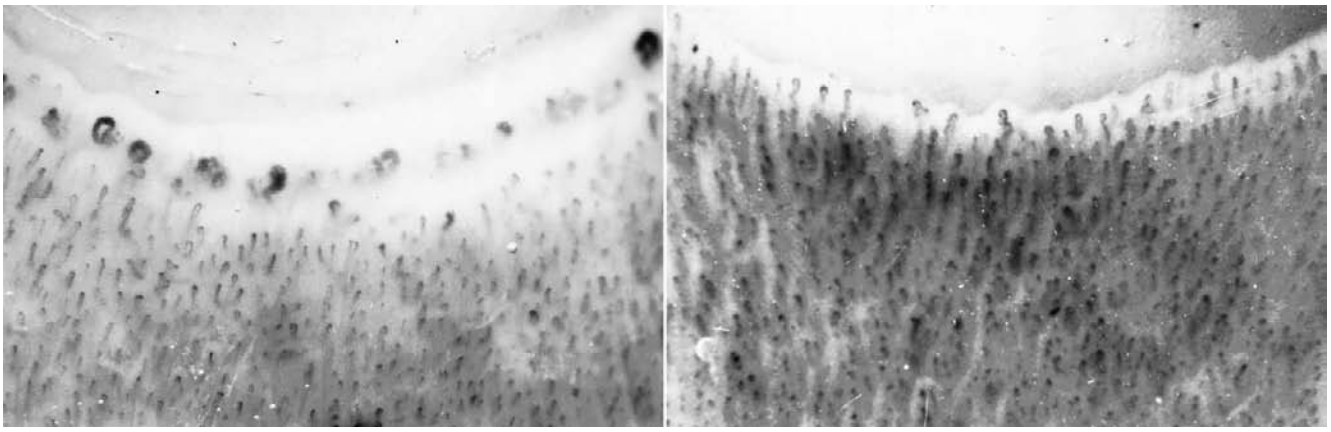

Figure 2 The wide-field view of the nail fold in a scleroderma patient and a normal control. (*Left*) Characteristic scleroderma-type capillary loops of various sizes and moderate to extensive loss of capillaries. (*Right*) Capillary distribution in the NF of a normal subject.

there are no papillary capillaries. Gradually over the first months of life a papillary layer of microvessels appears. Their density is less than in an adult and the subpapillary plexus can still frequently be seen. It appears as a polygonal network, different from the subpapillary venual plexus seen in later life. The latter appears to be a genetic trait, transmitted as Mendelian dominant, but may also be related to disease or to drugs used for treatment. In aged subjects, a decreased density of NF capillaries can occur, often associated with disease rather than aging per se.

The endrow capillaries (those in the terminal row) tend to have larger diameters than more proximally located capillaries. Because of their horizontal position, they can be seen to a greater length. Thus, it is possible to perform measurements of capillary diameters, observe red blood cell (RBC) flow, and also use minimally invasive procedures, such as capillary pressure recordings in this location.

If not otherwise indicated, NF refers to the NF of the finger, where the majority of the human microvascular studies have been performed. Not much can be found in the literature on the toe NF, despite the fact that a large number of publications are devoted to the lower leg and foot. The closest observations reported are usually from the dorsal skin of the distal phalanx of the toes, close to, but not necessarily

involving the NF and the endrow loops. Reportedly the mean width of the toe NF loops is significantly larger than in the finger.

Limiting Factors

The drawback of capillary observations in the skin, including the NF, relates to the problem of illumination: Only reflected light can be used here. Compared to microscopy performed with transmitted light, conventional capillaroscopy allows capillaries to be seen only by the presence of RBC columns within them.

Only a few investigators have been able to obtain other details. Ehring and Schumann [2] succeeded in visualizing the capillary wall of NF capillaries by using a specialized optical and illumination system of Vonwiller. Mahler et al. [3] used fluorescein-tagged human albumin that helped to visualize plasma space and thus obtain a better estimate of the total intraluminal dimensions. Conventional measurements of NF capillary dimensions have been based on RBC columns.

In addition, reflections from the oil deposited on the skin interfere with photography, as does the very limited depth of field especially at low magnification. It should also be remembered that NF is a very specialized area of the skin that may not necessarily closely reflect microvascular structure and function elsewhere in the body. Despite all these shortcomings, NF capillary microscopy has yielded considerable information on human microvasculature in health and disease.

Methods

In Vivo Microscopy

Recording of Capillaries and Their Blood Flow

Most studies of the human NF have been performed by in vivo microscopy, also called capillaroscopy, because usually the focus has been on capillaries only. A variety of microscopes, illumination techniques, and photographic systems have been used over the years to obtain well-focused, sharp still pictures.

To record capillary blood flow, by measuring RBC velocity, additional instrumentation was developed: first cinematographic, then video systems. Computer technology now allows automated analysis of these data. Normal RBC velocity ranges from 0.1 to 2.8 mm/sec, with an average of 0.6 mm/sec.

Unfortunately, the measurements are often taken from selected, nonrandom, capillaries: those that happen to be well focused. Therefore, the number of capillaries per NF and the number of nail folds studied vary.

Capillary Pressure

Instrumentation for capillary pressure measurement needs to be used in combination with capillaroscopy to properly introduce the micropipette into the capillary loop. Unlike the completely noninvasive approach just discussed, minimal trauma is necessary, because the hard keratin layer is difficult to penetrate. The normal capillary pressure ranges from 10 to 22 mmHg.

Capillary Permeability

Sodium fluorescein has been used most often to estimate capillary permeability. Although this agent also diffuses out in normal subjects, pathological changes can be estimated by the speed and pattern of this diffusion compared to healthy subjects.

Laser Doppler Blood Flow Measurements

This technique has often been performed on the dorsum of the distal phalanx, or on the proximal part of the NF concurrently with capillaroscopy. It is believed to measure skin blood flow in deeper layers and not the capillary blood flow.

More detailed information on methodology can be found in the book by Bollinger and Fagrell [4] and in a review article by Shore [5].

Biopsy

NF biopsy has been rarely performed, but, as seen in Figure 1, it can show NF structure better than the schematic illustrations often used. At higher magnification, finer details of capillary wall, dermoepidermal junction, and so on can be studied and compared to in vivo observations obtained in the same NF just before the biopsy [6].

Data Obtained

Most of the data on the NF microvasculature has been obtained from the endrow capillaries, in both morphological and function studies. Only a relatively few studies focus on the total area of NF.

Morphology

Endrow Capillaries

NF endrow capillaries show variations in shape, size, and density even in normal healthy subjects; these variations increase in pathological states. Variation is seen not only between individuals, but also between fingers. Also, within an NF not all capillaries are of the same size and shape. However, over time, in a normal subject, the overall picture of NF capillaries in a given finger has been reported to remain as constant as a fingerprint.

(a) *Shape*. A normal capillary is usually described as a hairpin-like loop. The deviant capillary loops have been described as tortuous, meandering, branched, bushy, coiled, and so on. Often the same term is used for different shapes and different terms for the same shape by

different investigators. (A better definition with adequate illustration should be used to make comparisons of results possible.) These data have been analyzed semiquantitatively by counting the number of deviant capillary loops per NF.

It should be noted here that vigorous "pushing back" of the cuticle during manicure can considerably distort the "normal" U-shaped capillaries at the edge of the NF.

(b) *Size*. Endrow loops have been classified subjectively as normal, slightly or moderately enlarged, markedly or extremely enlarged, and giant. Measurement data include diameters of arterial and venular limbs of the capillary loop, the caliber of the apical portion, the length of the capillary loop, and the total width of the loop. The ranges for normal measurements reported are arterial, 6 to 19 μm, and venular, 7 to 20 μm.

The problem here is the sampling of capillary loops: Usually they are not all studied. For any measurements, the capillaries have to be sharply focused, but because of technical difficulties this is not always the case. The other selection criteria may be the location within the edge of NF or a subjective preclassification into normal, enlarged, or giant loops.

(c) *Density*. The density is expressed as number of loops/mm. The normal range is reported as 12 to 17/mm.

(d) *Capillary hemorrhages*. These are frequently encountered in certain diseases. In normal persons, they are present only in response to obvious injury or microtrauma.

2. Total Area of NF

(a) *Density*. Capillary distribution proximal to the endrow is relatively uniform and can be measured as number of capillaries per mm^2. The normal density has been reported as 40 to 50/mm^2. A uniform decrease in capillary density in certain conditions can be measured the same way.

(b) *Localized loss of capillaries*. In some pathological conditions the loss of capillaries is not uniform: There may be an extensive loss, including the endrow and extending to a considerable distance proximally, or there may be discrete areas near the endrow. The loss may be complete, resulting in completely avascular areas, or may be relatively avascular, i.e., showing a few capillary loops but less than 8/mm^2. These areas can be measured quantitatively and expressed in mm^2.

A semiquantitative scale has also been used: slight, moderate, and extensive. A blind comparison of this scale with quantitative measurement has shown the following: slight 0.4 to 2 mm^2, moderate 2 to 4 mm^2, and extensive more than 4 mm^2 per NF.

Some authors have used the term "drop out" to note the local loss of capillaries. They refer to endrow loops only and require two "dropped-out" loops to define capillary loss or avascularity.

(c) *Visibility of subpapillary venous plexus (SPVP)*. The extent of this feature (SPVP) can be measured by a semiquantitative scale, i.e., the plexus visualization score (PVS). PVS ranges from 0 to 4 per finger and 0 to 40 per subject. Normal range is 0 to 10.

(d) *Pattern*. The view of the total NF (magnification 12 to 14×) allows us to appreciate the overall pattern of change from the normal one. The loss of capillaries is especially striking and sometimes associated with "bushy formations" (Figure 3 [7]) near the junction of avascular and normal NF capillary bed.

This total view helps to locate and identify special features to be studied with higher magnification and help to relocate them on serial studies. Observation of the total NF also makes it easier to notice the abnormal appearance of the cuticle: Normally completely transparent, it may show yellow-orange discoloration and varied patterns of outgrowing capillary hemorrhages in the cuticle.

(e) *Detection of microinjury*. The total NF observation helps to determine whether certain microvascular features are due to local trauma and inflammation rather than related to disease.

Experimental Studies

An Overview

Data presented in the previous section were obtained from NF by microvascular techniques in baseline conditions, i.e., without intervention by experimental stimuli or change in environmental conditions. Here we summarize data of microvascular responses to selected agents likely to affect the microvasculature of the NF.

Most human studies have been clinically oriented and often used for diagnosis, differential diagnosis, or correlated with laboratory data. Investigators aimed to understand pathophysiology by assuming that the same microvascular abnormalities seen in NF may be present in internal organs. They have correlated NF data with those of internal organs that were involved in a given disease, and attempted to study the prognostic significance of microvascular changes.

Selected Stimuli

COLD EXPOSURE

(a) *Whole-body exposure*. In normal subjects exposed to cold in an experimental chamber, NF capillary blood flow may slow down but will not come to a complete standstill, even after more than 30 minutes. In certain disease states, severe slowing of capillary flow occurs in NF loops within a matter of minutes and rapidly comes to a standstill in all the endrow loops and beyond. Temperatures used range from 10 to 20°C between investigators. Other factors are also important, such as time of the day, clothing, and meals.

(b) *Local cold exposure*. Cooling of the finger can be accomplished by blowing cold air on the NF, using Peltier element and other techniques, while controlling the finger skin temperature carefully to keep it in desired range and to avoid injury. A short flow stop (measured in seconds) can also occur in normal subjects.
(c) *Immersion of contralateral hand in cold water*. This has also been used but is less effective.

Reactive Hyperemia

An arterial occlusion of finger blood flow in normal subjects produces cessation of blood flow followed by reactive hyperemia overshooting the basal flow rate. This response curve can be modified in certain disease states. This test has been used with a variety of microvascular techniques, such as RBC velocity measurement and laser Doppler flux.

Response to Drugs

(a) Responses to vasomotor agonists injected IA or IV and to their antagonists.
(b) Responses to drugs used in treatment of certain diseases in which microcirculation is deemed important.

The reader can find more details on experimental studies from works of Bollinger and Fagrell and of Shore [4, 5].

Clinical Studies

An Overview

NF capillary microscopic studies have been performed in a large number of disease groups by a variety of microvascular techniques. The authors wished to determine the reason for the development and/or persistence of microvascular changes in disorders in which NF abnormalities were present. Serial studies to document progression or regression of pathological changes in the NF, as related to the evolution of the disease or to the effect of therapy, have also been performed. Data obtained from the NF studies in various diseases are presented here as a short summary.

Selected Disorders

Since NF capillaroscopic studies in human disease range from every subspecialty of medical and surgical fields to mental disorders, genetics, and epidemiology, only some selected disorders are listed here: disorders in which some concordance exist between the findings of different investigators and in which high specificity has been found for diagnosis, or microvascular findings have helped to subdivide a clinical entity or help with differential diagnosis.

1. Diabetes Mellitus

Capillary density is within normal range in both type I and II diabetes, but capillary pressure has been reported to be increased in type I, especially in those with poor glycemic control. Abnormalities in capillary perfusion have also been reported in both types of diabetes, especially in response to arterial occlusion producing reactive hyperemia. Transcapillary and interstitial diffusion of IV injected sodium fluorescein has been shown to be significantly faster in long-term diabetes than in normal controls.

2. Hypertension

Capillary density is reportedly lower (rarefaction) and capillary pressure higher in patients with hypertension; capillary flow velocity may be reduced.

3. Raynaud Phenomenon

(a) *Primary RP*. Capillary morphology is within normal range in this disorder and so is the capillary density. Capillary flow, as measured by RBC velocity, is lower than normal in baseline conditions and responds strongly to cold stimuli (local or whole body) leading to a flow stop of variable duration (measured in seconds or minutes, "complete" standstill or stop being defined differently by different investigators). During an RP attack, NF capillaries usually remain filled by RBC. Transcapillary diffusion of sodium fluorescein in NF capillaries is within normal limits.
(b) *Secondary RP*. There are a large number of disorders reportedly associated with RP, i.e., these disorders are considered primary, leading to a secondary RP. They are too numerous to review here and may or may not include microvascular studies. The most important group of secondary RP is found in connective tissue disease (CTD), especially in scleroderma (SD).

4. Scleroderma Spectrum

Scleroderma spectrum (SDS) disorders: Scleroderma (SD) and related disorders, such as CREST (calcinosis, RP, esophageal dysfunction, sclerodactyly, and telangiectasis), MCTD (mixed connective tissue disease), and UCTD (undifferentiated connective tissue disease), form a spectrum with many similarities in clinical and laboratory parameters including microvascular pathology. Dermatomyositis (DM, a closely related disease) shows similar but more acute, microvascular pathology. An overlap between SD and DM sometimes occurs.

Only in this disease group is the nail fold microvascular pathology highly specific and helpful for diagnosis. Enlarged NF capillaries have been described in other disorders, but what is characteristic here is the presence of capillaries in the NF that are enlarged in all three portions of the loop (arterial and venous limbs and the apex), resulting in a considerable increase in the total width of the loop (Figure 2, left). Other capillaries with less specific changes in size and shape may also be present.

These characteristic loops are located mainly along the edge of the NF but in an irregular manner: sometimes between quasi-normal-looking capillaries or in groups of variable size. The dimensions of these capillary loops vary considerably from slightly enlarged to giant loops; the size

Figure 3 A "bushy formation" in a patient with dermatomyositis in the active phase of the disease.

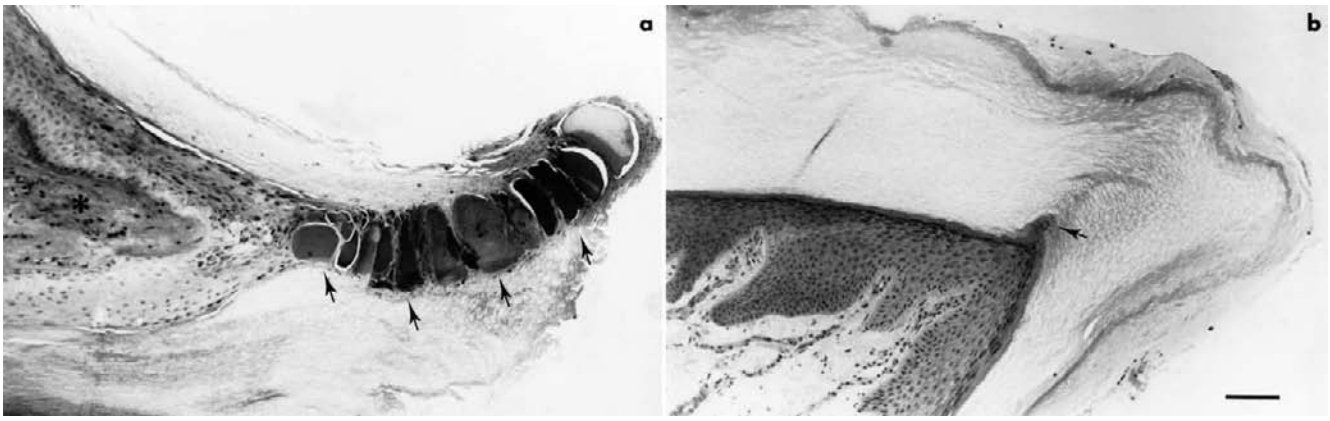

Figure 4 Cuticle deposits in a scleroderma patient compared to a normal control. (**a**) A scleroderma patient showing severe cuticle deposits (grade 6, arrows). (**b**) A normal control subject showing a grade 1 cuticle deposit (arrow), the most extreme encountered in the normal population. Bar = 100 µm.

and number of such loops vary within an NF or between NFs of the same patient. The number of capillaries per millimeter is greatly decreased because of their size, but also because they are often associated with small avascular areas along the NF edge, sometimes called dropout. However, capillary loss often extends into the proximal part of the NF and can be measured in mm^2. This characteristic pattern can be recognized even without measurements. (Pattern recognition is well known to be quite reliable.)

Other specific abnormalities, not always present but more often seen during an active phase of the disease, are "bushy formations" (Figure 3) adjacent to avascular areas (seen more often in DM than in SD).

They can be recognized even at low magnification. At higher magnification, they show many thin capillary loops springing from an arteriole or the deep end of the arterial limb. On serial photographs, they seem to be associated with filling in of an avascular area by capillaries [8]. Therefore, they are believed to be indicators of capillary regeneration. These "bushy formations" should not be confused with ramified or branched capillaries described by other authors in other disorders and even in normal subjects.

A yellow-orange discoloration of the cuticle is also associated with SD and DM. It corresponds to deposits of macromolecules (immunoglobulins, fibrinogens) in the cuticle demonstrated by biopsy (Figure 4 [6]) and reflects the

permeability change of both the capillary wall and the dermoepidermal junction. In these cases, the capillary hemorrhages, often seen in SD and DM patients, do not remain self-limited when gradually growing out with the cuticle as in normal subjects, but the heme products diffuse widely throughout the cuticle.

Studies with video microscopy after injecting sodium fluorescein show an abnormally rapid diffusion of this dye, but not with a homogenous pattern as seen in long-term diabetes, but diffusing out through only certain parts of the capillary wall.

The capillary blood flow can be slow even at an average room temperature in the classical SD and has a striking response to local or whole-body cooling, leading to a complete standstill in the whole NF area at 16°C. This can actually be better appreciated by continued watching and scanning the field of NF than by automated systems. A complete stop of capillary flow can be easily recognized by standstill of all RBCs in an NF loop by observing it for at least 1 minute. When this is repeated in other loops and the whole endrow, as well as more proximal NF, scanned for any RBC movement for a total time of about 3 minutes, a conclusion of total shutoff the NF capillaries can be reached. This has not been observed in other vasospastic conditions, such as RP; its observed flow stop is of much shorter duration, intermittent, and not present in the whole NF.

CREST, a more benign variant of SD, shows similar NF capillary abnormalities but in a slightly different pattern: Giant loops at the edge of the NF are more prominent and numerous while avascular areas are quite limited or nonexistent. These patients also show characteristic capillary telangiectases elsewhere on the fingers, especially on the finger pads. These telangiectases can be microscopic, but in most cases many are large enough to be detected with the naked eye. "Bushy formations" are absent. Their capillary blood flow response to cold is similar to that of SD.

MCTD shows SD-pattern NF capillary abnormalities and more "bushy formations" than in classical SD.

UCTD also has SD-type NF capillary patterns, but usually fewer fingers are involved and show fewer abnormalities. There are some patients, however, with active disease who show marked loss of capillaries and rapid progression to definite diagnosis of SD. Both MCTD and UCTD can show capillary flow dysfunction when exposed to cold.

DM shows more extreme avascular areas and more numerous "bushy formations" than any of the conditions described earlier; the cuticular deposits and capillary hemorrhages with diffuse extension into the cuticle are also frequent. These lesions can vary from finger to finger; patients may show even completely normal NF capillaries in some fingers, and abnormalities can return to normal in remission [8].

5. Other Connective Tissue Diseases

(a) *Rheumatoid arthritis*. An extensive visible subpapillary plexus may be present in a relatively large proportion of these patients.

(b) *Systemic lupus erythematosus.* Most patients with this disorder have NF capillaries within the normal range. In the acute phase, they may show a peculiar pattern of disappearance of all superficial (papillary) capillaries in most of the NF area, with only subpapillary venous plexus visible. The capillaries reappear in remission. SD–SLE overlaps also occur.

(c) *Discoid lupus erythematosus*. In this form of lupus, the proximal NF may be completely devoid of capillaries, showing only a prominent venular plexus; at the edge of the NF there are large looplike formations, which are probably part of the edge of the venular plexus rather than capillaries. These microvascular lesions are not present on all NFs and correspond most likely to discoid lesions occurring in the NF area.

6. Hereditary Hemorrhagic Telangiectasia

This disease is mentioned here because numerous capillary telangiectases are present on skin, lips, fingers, and NF, which may sometimes need differential diagnosis with CREST.

7. Schizophrenia

This disorder was studied by NF capillaroscopy soon after Müller's work. Many of these patients show an extensive subpapillary plexus on most of their fingers having a PVS of more than 10 (often 20 to 40 on a semiquantitative scale). This subgroup of schizophrenia also has a significantly lower finger blood flow and appear to correspond clinically to so-called process schizophrenics (those with negative symptoms). It is interesting to note that, although there is a higher than normal frequency of high PVS in both schizophrenia and RA, these disorders appear to be mutually exclusive.

Conclusions

The in vivo microvascular studies have been most fruitful clinically in SDS, not only for diagnosis and subgrouping of patients, but also in early differential diagnosis in RP subjects between primary RP and those at risk for SD. Over 90 percent of SD patients have RP, but RP usually precedes the diagnosis of SD by years. SD pattern NF capillary changes are present early and allow detection of patients at risk for SD. It has even been possible to pick out SDS patients from random samples from the general population "blindly" with the technique of in vivo microscopy and have independent confirmation of diagnosis later by clinical and laboratory examinations. This technique also allows distinction between the slowly developing CREST, acute SDS cases, and early SD with severe prognosis.

In schizophrenia research, NF capillaroscopy has been helpful to distinguish between two types of schizophrenia (those with negative versus positive symptoms) with possibly different etiopathology and prognosis.

Glossary

Capillaroscopy: In vivo microscopic examination of capillaries in the skin

Microvessels: Arterioles, capillaries, and venules

Nail fold: Skin fold surrounding the finger or toenail

Capsule Biography

Dr. Hildegard R. Maricq has been involved with interdisciplinary research centering around her interest in microcirculation since 1961. She has combined it with other disciplines, such as genetics, epidemiology, psychophysiology, and peripheral vascular physiology. She has studied microcirculation and peripheral vascular circulation in a variety of medical disorders. Dr. Maricq has headed the Microvascular Laboratory at the Medical University of South Carolina since 1975. Now a Professor Emeritus, she is still active in international epidemiological studies that include microvascular components. She was nominated Master of the American College of Rheumatology in 2001, mainly for her work in microcirculation.

CHAPTER 28

Capillaries in the Chicken Chorioallantoic Membrane

[1]Domenico Ribatti and [2]Marco Presta

[1]Department of Human Anatomy and Histology, University of Bari

[2]Unit of General Pathology and Immunology, Department of Biomedical Sciences and Biotechnology, University of Brescia, Italy

The chick embryo chorioallantoic membrane (CAM) is an extraembryonic membrane. It serves as a gas exchange surface through the eggshell and its function is supported by a dense capillary network. Because of its extensive vascularization and easy accessibility, the CAM has been broadly used to study the morphofunctional aspects of the angiogenesis process in vivo and to investigate the efficacy and mechanisms of action of pro-angiogenic and anti-angiogenic natural and synthetic molecules. Also, because of the lack of a fully developed immunocompetence system in the chick embryo, the CAM represents a host tissue for tumor engrafting suitable to study various aspects of the angiogenic and metastatic potential that characterizes human malignancies.

Developmental Anatomy of the Blood Vessels of the CAM

The allantois of the chick embryo appears at about 3.5 days of incubation as an evagination from the ventral wall of the endodermal hind gut. During the fourth day, it pushes out of the body of the embryo into the extraembryonic coelom. Its proximal portion lies parallel and just caudal to the yolk sac. When the distal portion grows clear of the embryo it becomes enlarged. The narrow proximal portion is known as the allantoic stalk, the enlarged distal portion as the allantoic vesicle. Fluid accumulation distends the allantois so that its terminal portion resembles a balloon in complete embryos (Figure 1).

The allantoic vesicle enlarges very rapidly from days 4 to 10: an extensive morphometric investigation has shown rapid extension of the CAM surface from 6 cm^2 at day 6 to 65 cm^2 at day 14. In this process the mesodermal layer of the allantois fuses with the adjacent mesodermal layer of the chorion to form the CAM. An extremely rich vascular network connected to embryonic circulation by the allantoic arteries and veins develops between the two layers. Immature blood vessels scattered in the mesoderm and lacking a complete basal lamina and smooth muscle cells grow very rapidly until day 8, giving rise to a capillary plexus. The plexus associates with the overlaying chorionic epithelium and mediates gas exchange with the outer environment.

Capillary proliferation continues rapidly until day 10 (mitotic index equal to 23 percent). Then, the endothelial cell mitotic index declines rapidly to 2 percent and the vascular system attains its final arrangement on day 18, just before hatching. Besides sprouting angiogenesis that characterizes the early phases of CAM development, late CAM vascularization is supported by intussusceptive microvascular growth in which the capillary network increases its complexity and vascular surface by insertion of transcapillary pillars. At day 14, the capillary plexus is located at the surface of the ectoderm adjacent to the shell membrane. The blood circulation and the position of the allantois immediately adjacent to the porous shell confer a respiratory function to the highly vascularized CAM. In addition to the respiratory interchange of oxygen and carbon dioxide, the allantois also serves as reservoir for the waste products excreted by the embryo—mostly urea at first, and chiefly uric acid later.

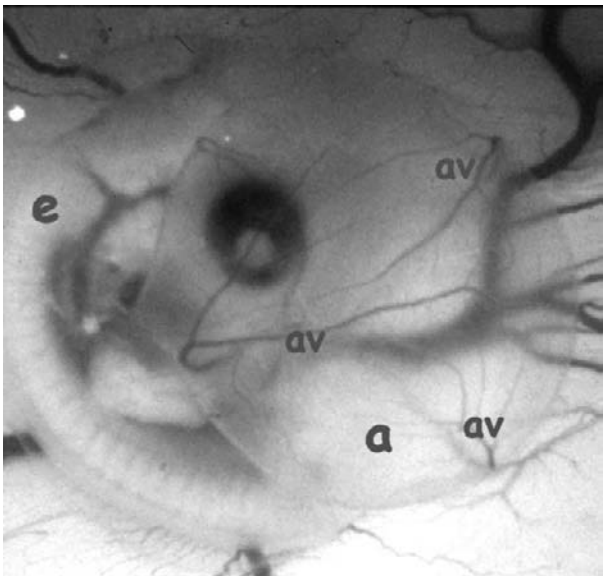

Figure 1 Allantoic sac (a) of a 5-day embryo (e) showing in ovo distribution pattern of allantoic vessels (av). Original magnification: ×25.

Structure of the Blood Vessels of the CAM

On day 4, all CAM vessels have the appearance of undifferentiated capillaries. Their walls consist of a single layer of endothelial cells lacking a basal lamina. By day 8, the CAM displays small (10 to 15 μm in diameter), thin-walled capillaries beneath the chorionic epithelium and larger vessels (10 to 115 μm in diameter) in the mesodermal layer. Large vessels have a layer of mesenchymal cells surrounding the endothelium and are completely wrapped by a basal lamina. Starting from day 12, capillaries contain endothelial cells and a few mesenchymal cells (presumptive pericytes) closely applied to the endothelial abluminal side. Desmin-positive cells are evenly distributed all over the CAM and are located in close association with the capillary plexus. The mesodermal vessels are now distinct arterioles and venules (Figure 2). In addition to the endothelium, the walls of arterioles (10 to 85 μm in diameter) contain one or two layers of mesenchymal cells and increased amounts of connective tissue. Venules (10 to 115 μm in diameter) are surrounded by an incomplete investment of mesenchymal cells. Mesenchymal cells are presumed to be developing smooth muscle cells, and the walls of arterioles also develop a distinct adventitia containing fibroblast-like cells.

At days 4 to 8 the endothelial cells form punctuate junctional appositions and a few plasmalemmal vesicles are observed. Between days 9 and 13 the arteriolar endothelium displays more extensive junctional complexes with multiple membrane contact points. In contrast to the arterioles, endothelial junctional appositions of the CAM venules remains punctuate. The venules possess multiple sites of interendothelial contact with areas of junctional dilations, while the arterioles display complex interdigitating cell junctions.

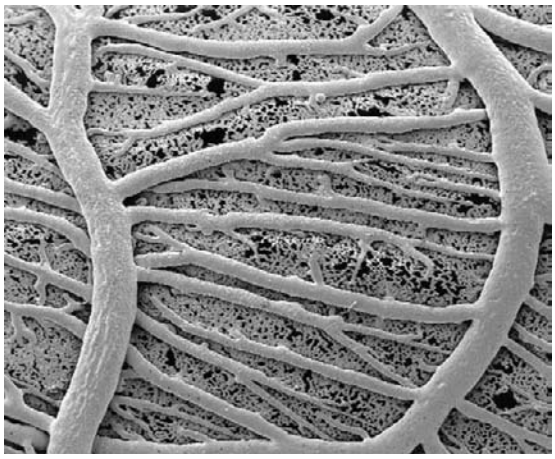

Figure 2 Image of the CAM arteriovenous and capillary systems after casting of the vasculature (provided by Dr. V. Djonov, University of Berne, Switzerland). Original magnification: ×100.

CAM arterioles and venules are accompanied by a pair of interconnected lymphatics. Veins are also associated with lymphatics and larger veins are surrounded by a lymphatic plexus. Lymph is drained by trunks of the umbilical stalk into the coccygeal lymphatics and the lymph hearts of the embryo. CAM lymphatic capillaries have no basal lamina and an extremely thin endothelial lining that specifically expresses vascular endothelial growth factor receptor-3 (VEGFR-3, Quek-2, flt-4) whereas VEGFR-2 (Quek-1, kdr, flk-1) is expressed by both vascular and lymphatic endothelial cells.

Endogenous CAM Modulators of Blood Vessel Formation

The development of the vascular system of the CAM is a complex, highly regulated process that depends on genetic and epigenetic factors expressed by endothelial and non-endothelial cells.

Endothelial cell interaction with extracellular matrix (ECM) plays an important role in angiogenesis. Accordingly, ECM modifies its properties during CAM development in terms of expression of several components (e.g. fibronectin, laminin, type IV collagen, Secreted Protein Acidic Rich Cysteine (SPARC)), distribution of specific glycosaminoglycans, and production of lytic enzymes.

Fibronectin accumulates in the ECM beneath the chorion at early stages of development when the subepithelial capillary plexus is not yet formed, possibly promoting the migration of endothelial cells merging by sprouting from the mesodermal blood vessels. In contrast, type IV collagen appears in the late stages of CAM vascular development concomitantly with the terminal differentiation of endothelial cells and maturation of basement membrane. Laminin immunoreactivity is present instead during all stages of CAM vessel formation, in keeping with its role in the early

formation and later differentiation of the subendothelial basement membrane. Finally, ialuronic acid plays a crucial role in the formation, alignment, or migration of the capillary plexus, while heparan sulfate, chondroitin sulfate, and dermatan sulfate are important in the differentiation and development of arterial and venous vessels.

In spite of the evidence that several growth factors, such as fibroblast growth factor-2 (FGF-2), VEGF, placenta growth factor (PlGF), platelet-derived growth factor (PDGF), transforming growth factor beta-1 (TGF β-1), angiogenin, and erythropoietin (Epo), stimulate blood vessel formation when applied to the CAM (see later discussion), the role of their endogenous counterparts in the development of the CAM vascular system is poorly understood. The expression of VEGFRs suggest that, in analogy with other developmental models, endogenous VEGF may play a role in CAM vascularization. Accordingly, neutralizing anti-VEGF antibodies prevent CAM vessel development. Also, direct experimental evidences implicates endogenous FGF-2 in this process.

FGF-2 protein levels change in the CAM during development and peak between days 10 and 14. At early stages of development, FGF-2 is expressed by chorionic epithelial cells and may trigger a paracrine loop of stimulation by inducing an angiogenic response in undifferentiated vessels of the CAM mesoderm. At later stages, FGF-2 mRNA expression predominates in endothelial cells forming the capillary plexus, suggesting an autocrine function in late vessel growth and maintenance. Accordingly, neutralizing anti-FGF-2 antibodies fully prevent neovascularization when applied to the CAM at day 8 of incubation. They also decrease fibroblast density within the mesoderm, but do not affect epithelial cells of the chorion and allantois. Thus, FGF-2 plays a rate-limiting role in the maturation of stroma and blood vessels during CAM development.

The proteolytic plasmin/plasminogen activator system is also involved in CAM vascularization, possibly affecting the invasive behavior of sprouting endothelium and by modulating the activity of endogenous modulators. For instance, endogenous urokinase plasminogen activator (uPA) mediates the formation of angiogenic SPARC-derived peptides, whereas exogenous uPA can induce neovascularization by increasing the mobilization of endogenous FGF-2 from ECM-associated reservoirs.

CAM as a Model to Study the Modulation of Angiogenesis

A. Tumor Angiogenesis and Metastasis

The CAM is a suitable site for transplanting tissues because the chick embryo immunocompetence system is not fully developed and the conditions for rejection have not been established. Transplants survive and develop by peripheral anastomoses between graft and original CAM vasculature or by new angiogenic vessels grown from the CAM and invading the graft. The formation of peripheral anastomoses between host and preexisting donor vessels is the main, and the most common, mechanism involved in the revascularization of embryonic grafts. At variance, the growth of CAM-derived vessels into the graft is stimulated by tumor implants.

The CAM has long been a favored system for the study of tumor angiogenesis and metastasis. Tumor grafts remain avascular for 72 hours, after which they are penetrated by new blood vessels and a phase of rapid growth begins. The rate of growth during this vascular phase is greater for implants on days 5 and 6 to decrease at later days of implantation. The CAM may also be used to assess the ability of antiangiogenic molecules to inhibit growth and neovascularization of tumor xenografts.

Studies using the tumor cells/CAM model have also focused on the invasion of the chorionic epithelium and the blood vessels by tumor cells. The cells invade the epithelium and the mesenchymal connective tissue below, intravasate into the dense bed of blood vessels, and may invade the chick embryo.

Finally, delivery of tumor cells onto the CAM allows the fine study of the effects of tumor-derived angiogenic growth factors on blood vessel structure and functionality. For instance, tumor cell lines overexpressing FGF-2 or VEGF induce a quantitatively similar vasoproliferative response when grafted onto the CAM. However, in keeping with the different ability of FGF-2 and VEGF to modulate endothelial cell morphology and vascular permeability, an increased endothelial fenestration characterizes the blood vessels of the CAM stimulated by VEGF transfectants.

B. Molecules with Angiogenic and Anti-angiogenic Activity

The CAM is used to study molecules with angiogenic and anti-angiogenic activity following their delivery in ovo (Table I). Many protocols have been envisaged to deliver macromolecules and low-molecular-weight compounds onto the CAM by using silostatic rings, methylcellulose disks, silicon rings, filters, and plastic rings. Also, collagen and gelatin sponges treated with stimulators or inhibitors of blood vessel formation have been implanted on growing CAM. The gelatin sponge is also suitable for the delivery of cell suspensions onto the CAM surface and the evaluation of their angiogenic potential. This latter experimental condition allows the slow, continuous delivery of growth factors released by few implanted cells (20,000 cells per sponge or fewer). As compared with the application on the CAM of large amounts of a pure recombinant angiogenic cytokine in a single bolus, implants of cells overexpressing angiogenic cytokines enables the continuous delivery of growth factors, following a more “physiological” mode of interaction with the CAM vasculature.

Besides in ovo experimentation, a number of shell-less culture techniques have been devised, involving cultures of avian embryos with associated yolk and albumin outside

Table I Pro-Angiogenic and Anti-Angiogenic Molecules in the CAM Assay.

Pro-angiogenic molecules	Anti-angiogenic molecules
Fibroblast growth factor-2 (FGF-2)	Anti-FGF-2 antibodies
Vascular endothelial growth factor (VEGF)	Anti-VEGF antibodies
Placenta growth factor-1 (PlGF-1)	Anti-PlGF-1 antibodies
Angiogenin	Anti-angiogenin antibodies
Tumor necrosis factor alpha (TNF-α)	Interleukin-2 (IL-2)
Transforming growth factor beta (TGF-β)	Angiostatin
Platelet derived growth factor (PDGF)	Endostatin
Erythropoietin (Epo)	Heparan sulfate
Osteogenic protein-1 (OP-1)	Modified heparins
Leptin	Heparanase inhibitors
Adrenomedullin	Protamine sulfate
CC chemokine I-309	Platelet factor-4 (PF-4)
Osteopontin/Eta-1	Pentosan polysulfate Non- or low-sulfated saccharides Arylsulfatase inhibitors Sulfated polysaccharide peptidoglycan α-, β-, γ-cyclodextrin Suramin Spironolactone Tyrosine kinase receptor inhibitors Adhesion molecule antagonists Matrix metalloproteinase inhibitors

of the eggshell. Shell-less cultures facilitate experimental access and continuous observation of the growing embryo.

Typically, an angiogenic response occurs 72 to 96 hours after stimulation in the form of an increased density of vessels that converge radially toward the implant like spokes in a wheel. Conversely, when an angiostatic compound is tested, the vessels become less dense around the implant and eventually disappear (Figure 3). Alternatively, the molecules can be directly inoculated into the cavity of the allantoic vesicle so that their activity reaches the whole vascular area in a uniform manner.

Several semiquantitative and quantitative methods are used to evaluate the extent of vasoproliferative response or angiostatic activity at macroscopic and microscopic levels. Quantification of the CAM vasculature has been performed with the use of morphometric point-count methods, radiolabeled proline incorporation to measure collagenous protein synthesis, and fractal analysis of digital images.

Many techniques can be applied within the constraints of paraffin and plastic embedding, including histochemistry and immunohistochemistry. Electron microscopy can also be used in combination with light microscopy. Moreover, unfixed CAM can be utilized for biochemical studies, such as the determination of DNA, protein, and collagen content, and for reverse transcriptase–polymerase chain reaction (RT-PCR) analysis of gene expression. Recently, studies of intracellular signaling pathways mediating the angiogenic response to growth factors and cytokines have been successfully performed. This has allowed the demonstration of the role of extracellular signal-regulated kinases (ERKs) and $\alpha_v\beta_3$ integrin engagement in FGF-2-mediated angiogenesis and of JAK2/STAT-3 pathway during neovascularization induced by GM-CSF.

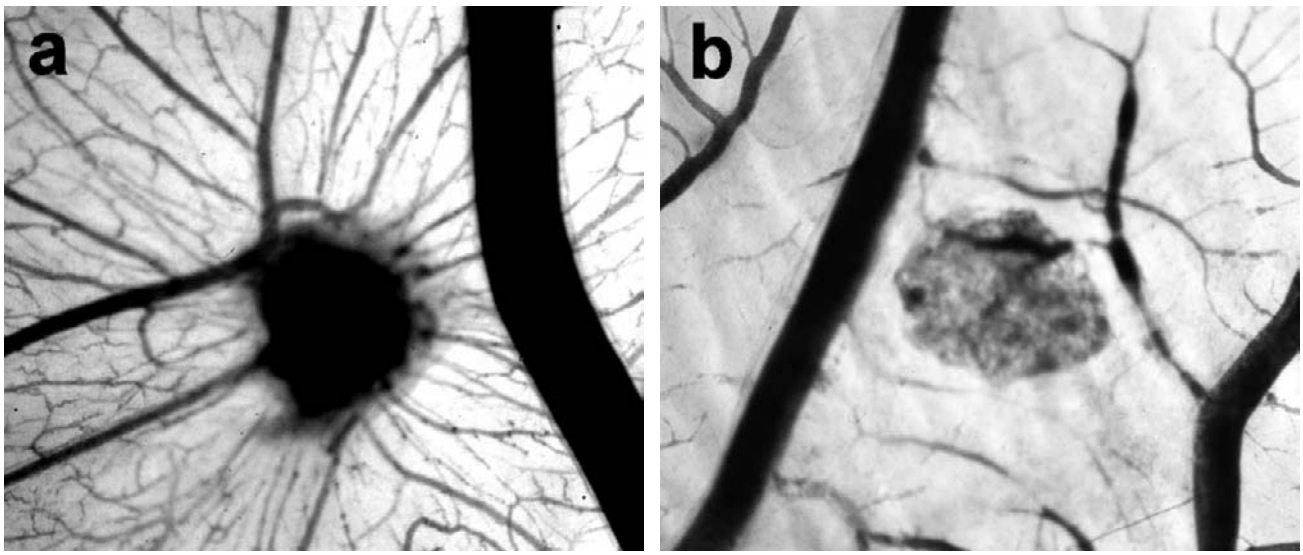

Figure 3 Modulation of CAM vascularization: numerous vessels develop radially in a "spoked-wheel" pattern toward the stimulus triggered by an angiogenic cytokine **(a)**; in contrast, very few vessels are recognizable around the implant of an angiostatic molecule **(b)**. Original magnification: ×50.

Concluding Remarks

One of the most important technical problems facing the study of angiogenesis and anti-angiogenesis is the difficulty of obtaining meaningful assessments of efficacy. In vivo angiogenesis assays, such as those performed in the CAM, have allowed important progress in elucidating the mechanisms of action of several angiogenic factors and inhibitors. Nevertheless, some limitations characterize this experimental model. Nonspecific inflammatory reactions may develop as a result of grafting, inducing a secondary vasoproliferative response hardly distinguishable from a direct angiogenic activity of the test material; rearrangement of existing vessels following membrane contraction may mimic neovascularization; and vasodilatation/vasoconstriction may result in apparent pro/anti-angiogenic effects, respectively (all these drawbacks may be overcome by detailed histological analysis). Finally, species-specific differences and the lack of avian-specific reagents (as well as limited genomic information) may represent serious disadvantages.

However, recent progress has contributed to improving the usefulness of the CAM as a model. For instance, retroviral, lentiviral, and adenoviral vectors have been used in the past few years to infect the CAM (as well as the whole chick embryo), leading to the expression of the viral transgene. This allows the long-lasting presence of the gene product that is expressed directly by CAM cells, which makes feasible the study of the effects of intracellular or membrane-bound proteins as well as of dominant-negative gene products. Such an approach will shed new light on the mechanisms of blood vessel formation and inhibition in physiologic and pathologic conditions.

Glossary

Angiogenesis: The formation of new blood microvessels from preexisting ones.

Chorioallantoic membrane: Extraembryonic membrane originated by the fusion of the mesodermal layer of the allantois with the adjacent mesodermal layer of the chorion. It mediates gas exchange between the avian embryo and the outer environment.

FGF-2: A pleiotropic growth factor endowed with a potent angiogenic activity in vitro and in vivo. It interacts with signaling tyrosine kinase receptors and heparan-sulfate proteoglycans on target cells.

VEGF: Endothelial cell growth factor crucial for embryonic vasculogenesis and angiogenesis. It acts also as a potent vasopermeability factor. It is involved in physiologic and pathologic angiogenesis.

Capsule Biography

Dr. Ribatti is Full Professor in Human Anatomy at the School of Medicine of the University of Bari. Researches in his laboratory primarily focus on the study of angiogenesis during embryonic development and tumor progression.

Dr. Presta is Full Professor in General Pathology and has headed the Angiogenesis Laboratory at the School of Medicine of the University of Brescia since 1990. Researches in his laboratory primarily focus on the mechanisms of action of angiogenic growth factors and the development of angiogenesis inhibitors. His work has been supported in part by grants from the European Union, AIRC, and MIUR.

CHAPTER 29

The Cremaster Muscle as a Microvascular Research Model

Maria Siemionow and Andrea Moreira-Gonzalez
Department of Plastic Surgery, The Cleveland Clinic Foundation, Cleveland, Ohio

Background

Despite major advances in the field of reconstructive microsurgery, complications and failures after free tissue transfer and replantation surgery remain as a significant clinical problem. The nature of these failures is often multifactorial and the pathophysiology is still not completely understood. Different research approaches and animal models were developed to improve our understanding of changes occurring at the tissue microvascular level [1].

Previously, most studies applied techniques that allowed quantifying microcirculatory perfusion by implementation of the indirect methods of measurement, such as the use of staining techniques. These methods, however, did not reveal accurate information about the dynamics of the microvascular network, which is in a constant state of change. Research discoveries improved significantly after application of modern microcirculatory techniques and models that allowed for direct in vivo observation of hemodynamics of vascular pathophysiology. These models included hamster cheek pouch, rabbit ear chamber, the cat tenuissimus muscle, bat wing, and various mesenteric preparations [1].

The rat cremaster muscle preparation has a relatively recent history of application to microcirculatory studies [2–4]. One of its advantages is that the cremaster muscle flap is structurally and functionally similar to other skeletal muscles. Thus, all changes observed in the microcirculation of this small flap could be applied to larger muscle flaps used in clinical microsurgery. Majno and Palade were the first to introduce the cremaster muscle model in their histological and electron microscopy studies on inflammation [2]. This model was accepted for microcirculatory observation by in vivo microscopy after modifications made by Grant [3]. Baez was the first to open the cremaster muscle and to detach the testicle from the flap [4]. He was then able to spread out the flap and transilluminate it under a microscope. Miller and Wiegman introduced a tissue bath to provide better control of the microcirculatory environment [5]. This standard cremaster preparation was further developed in our laboratory in such a way that the cremaster muscle was completely isolated on its neurovascular pedicle, as an island flap [6]. In this model the cremaster muscle circulation is solely dependent on one feeding artery and one outflowing vein, excluding all other sources of vascular supply. This procedure simulates the conditions encountered during surgery of free tissue transfers, where the main vessels of the flap undergo microsurgical anastomosis and changes occurring downstream from the site of vascular repair can be monitored. These microcirculatory observations can add to our understanding of variables that can directly affect flap failure and survival.

The cremaster muscle flap isolated on the neurovascular pedicle expands significantly our ability to study microcirculation in relation to (1) reactivity of the microvessels [1, 6], (2) ischemia-reperfusion injury [7], (3) assessment of microcirculatory responses to muscle denervation [8], (4) chronic observation of the microcirculation using a chamber model [7], (5) observation of the microvascular events following tumor implantation, and (6) monitoring of microvascular responses to isograft and allograft transplantation [9, 10].

Surgical Technique

Male rats weighing between 80 and 150 g are used, because at this weight range the cremaster fascia is thin enough to allow for optimal visualization of the microcirculation of the transilluminated muscle. Also, the iliac artery is

large enough to allow for controlled dissection, transection, and repair under surgical microscope magnification.

Anesthesia is induced with intraperitoneal administration of pentobarbital (60 to 70 mg/kg) with additional supplements as needed. Core body temperature is maintained between 35° and 37°C. The animal's genital area and thighs are shaved; the rat is prepped and placed in a supine position.

Isolation of the Cremaster Muscle Flap

During flap dissection the tissues should be kept moist using saline solution. An operating microscope (Zeiss OPM6-SD, Zeiss, Germany) is used for pedicle dissection and isolation. A longitudinal incision is made from the tip of the scrotum to its base. From this point the incision is carried laterally toward the anterior iliac spine. The subcutaneous tissue over the groin area and the scrotum is then carefully dissected. The cremaster is visualized as a thin tissue layer covering the testis. This dissection is continued carefully on the ventral as well as dorsal surface of the muscle until the muscle is completely detached from the scrotum. A traction suture is placed through the distal tip of the cremaster muscle to facilitate atraumatic dissection (Figure 1A). The pedicle of the flap is visualized on the dorsal aspect of the muscle. A longitudinal incision is then made on the ventral surface of the cremaster muscle flap origin including the full thickness of the muscles of the abdominal wall and is directed parallel to the inguinal ligament (IL). The vascular pedicle of the testicle and the deferens duct are exposed and ligated with 5-0 silk sutures. The testicle is pulled from the scrotum and is carefully separated from the muscle. Next the testicle is removed, and the empty cremaster muscle tube flap is now ready for dissection of the neurovascular pedicle.

Isolation of the Neurovascular Pedicle

The dissection is performed in the groin area, with exposure of the femoral artery and vein and the IL. The medial insertion of the IL is then divided from the pubic bone attachment, and the ligament is mobilized from medial to lateral, exposing the genito-femoral nerve, and the external iliac artery and vein (EIA and EIV). All nonrelevant branches of the EIA are either coagulated or ligated with 9-0 nylon sutures, leaving the intact pudic-epigastric trunk, which now provides the only blood supply to the cremaster muscle flap. The frontal wall of the cremaster muscle tube flap is then opened from proximal to distal. The remaining attachments connecting the flap to the groin region are transected and the cremaster muscle is totally isolated on its vascular pedicle, as an island muscle flap.

Preparation of the Cremaster Flap for Microcirculatory Monitoring

The animal is placed on a Plexiglas observation platform. The prepared cremaster muscle is extended and is held in place with 5-0 silk sutures (Figure 1B). The muscle is irrigated with saline solution and covered with a plastic film to avoid dehydration (Saran Wrap presoaked with distilled water overnight). Figure 1C shows the schematic map of the microvessels that can be monitored in this preparation.

Direct In Vivo Microcirculatory Observations

The cremaster muscle is then transilluminated from below and the microcirculation is observed and monitored using an intravital microscope (Nikon Optiphot-2, Japan) equipped with a color video camera (Sony CCD-IRIS, Japan), a 19-inch monitor (Sony Trinitron, Japan), and a videotape recorder (Panasonic AG-1730, Japan). Using this standardized setup, the following microcirculatory parameters can be directly observed, measured, and recorded on the videotape over time for repeated observations (Figure 2):

1. *Vessel diameter*. The diameter and the endothelial wall thickness of the cremaster arterioles and venules are measured by using a video image measurement system (VIA-150, Boeckeler, Tucson, AZ).
2. *Red blood cell (RBC) velocity*. A custom-made optical Doppler velocimeter (Texas A&M, College Station, TX) is adapted to the system. It allows the measurement of RBC velocity in millimeters per second in the main arterioles and venules of the cremaster muscle flap.
3. *Capillary density*. The capillary perfusion or functional capillary density is defined as the number of capillaries in which RBCs are constantly flowing. Three regions of the cremaster muscle flap with a good capillary perfusion and clear visualization are chosen, in the proximal, medial, and distal area of the flap. Each visual field—as seen in the monitor—represents an area of tissue of 0.18 mm^2. Nine fields in each of three flap regions are monitored and counted for a total of 27 fields, and the average number from all fields represents the overall state of capillary perfusion of the cremaster muscle microcirculation.
4. *Leukocyte–endothelial interactions*. The postcapillary venules are chosen for the observation of leukocyte behavior. These vessels have a diameter of 20 to 40 µm and are identified in the proximal, medial, and distal regions of the flap. Rolling, "sticking" (remaining stationary for more than 20 seconds), transmigrating neutrophils and lymphocytes are observed and counted during a 2-minute period in each flap region using a hand counter (Figure 2).
5. *Endothelial-edema index*. The external and internal diameters of the postcapillary venules are measured using the VIA-150. The ratio between the two numbers is defined as endothelial edema index and is used in some studies to indicate vascular occlusion caused by leukocyte aggregation within the venular lumen, causing vessel wall damage, and microvascular injury leading to increased tissue permeability.

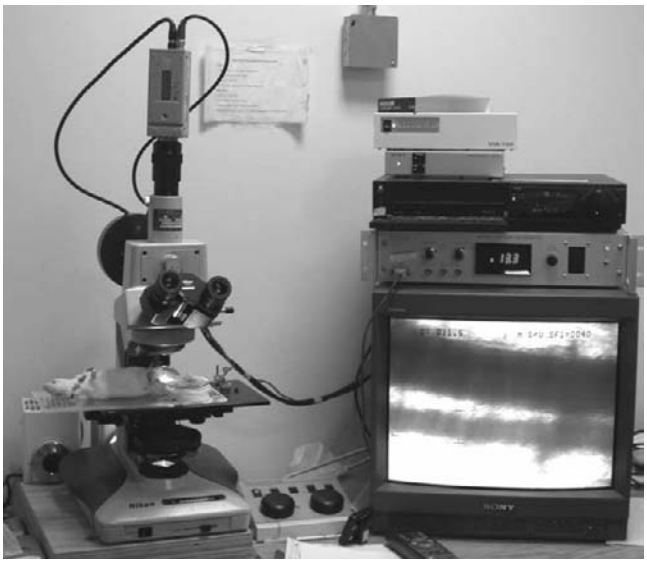

Figure 2 Intravital microscopy setup for microcirculatory monitoring. (see color insert)

6. *Thrombus formation.* The transilluminated cremaster muscle can be used to directly visualize and quantify thrombus formation. The pedicle artery is viewed with an inclinable head stereoscope (Zeiss OpMi6, Zeiss, Germany) and at the same time the downstream cremaster is observed with a compound microscope. By incorporating the two systems it is possible to image the upstream and the downstream microcirculation side by side on the same video monitor, simultaneously. This allows the correlation of thrombus formation upstream with the appearance of the dislodged platelet emboli in the downstream microcirculation.

Evaluation of the Microvascular Permeability

1. *Fluorescein microscopy setup*. A Zeiss 20T fluorescein microscope (Carl Zeiss, Germany) is used. An illumination system with a 460 to 490 nm blue light band excitation filter from a mercury arc lamp (Mercury Power Supply, Model 1200, OpticQuip Inc, NY) is used to stimulate the fluorescein isothiocyanate. The closed circuit video recording system consists of an MTI silicon-intensifying target camera (MTT SIT-68), a Panasonic AG-1290 video recorder, and a 19-inch monitor. The gain, sensitivity, and black level of the SIT camera allow the detection of very low light levels.
2. *Microvascular permeability assessment technique and analysis of macromolecule leakage.* Macromolecular leakage reflects vascular permeability. Albumin conjugated with fluorescein isothiocyanate (FITC) is injected intravenously to assess the microcirculatory permeability in the cremaster muscle flap. Postcapillary venules are selected for measurements, which are taken at zero time and after 30 minutes. The albumin appears as bright white on the video monitor. Venules without leaks look like white columns against a black background. Leaks appear as white streaks outside of the vessels. These images are digitized using a Kontron Elektronik KS 300 V2.00 image analysis system (Kontron Elektronik GmbH, Eching, Germany). Three segments in the lumen of the venule and of the interstitium are selected. An index of vascular leakage (permeability index, PI) is computed from the images. A relatively high positive PI indicates increased leakage from the postcapillary venule as result of endothelial injury. If the Kontron system is not available, the live images recorded can be captured by the computer using the Studio DC Plus software (version 3.1, Pinnacle System, Mountain View, CA) and a capture card. The images are then analyzed with the Image Pro-Plus software (version 2.1, Media Cybernetics, Silver Spring, MD).

Application of the Cremaster Muscle Island Flap for Ischemia-Reperfusion and Related Studies

There has been an increased awareness and interest in reperfusion injury or the no-reflow phenomenon. Unfortunately, the pathogenesis of this phenomenon is still not completely understood. Many hypotheses have been postulated, such as vasospasm, oxygen free radicals, platelet-plugging microthrombus formation, and changes in the vascular permeability leading to the interstitial edema. The direct observation of these highly dynamic mechanisms is important since it may explain many of the clinical events happening during postoperative follow-up in many microvascular and vascular surgery procedures.

All important parameters involved in ischemia/reperfusion injury can be evaluated using the cremaster muscle flap. They include measurements of vasospasm, vessel diameters, thrombus formation, presence of microembolism, functional capillary density, leukocytes–endothelial interaction, and microvascular leakage. Furthermore, the cremaster chamber model allows for chronic observation of the microcirculatory events, which is critical for monitoring consequences of ischemia/reperfusion.

Technique. The cremaster muscle flap dissection described earlier can be modified for application to the ischemia/reperfusion injury studies.

In order to match the events of reperfusion injury associated with the vasospastic phenomenon and decrease in capillary perfusion, the cremaster flap has been applied as a microsurgery ischemia model. Technically, the cremaster vascular pedicle is transected and re-anastomosed, and the flap is further assessed by microcirculatory monitoring An important observation from this ischemia model was the description of concept of the cremaster flap risk zones by simultaneous assessment of the site of vascular anastomosis and peripheral microcirculation. The zones were divided into the upstream risk zone (anastomotic site) and a downstream risk zone (the microcirculation) [1]. The events monitored within these zones were directly related: A process

occurring within the upstream zone such as thrombus formation was influencing events at the downstream zone, causing decrease in capillary perfusion. Other observations from this model have shown that the ischemia time that is the period needed to perform the microvascular anastomosis induced a profound vasospasm peripherally, specifically in the third-order arterioles of the cremaster flap. Some authors suggested that this mechanism is most probably related to microcirculatory response to anesthetic drugs, poor microsurgical technique of vessel repair, and tissue hypoxia and acidosis.

The cremaster flap can be also used as a clamp-ischemia model. In this model homodynamic changes occurring at the microcirculatory level following clamp application to the flap feeding artery can be compared to the ischemia-induced events during free tissue transfer procedures. The technique involves clamping the cremaster vascular pedicle for a different periods ranging from 2 to 6 hours with subsequent monitoring of the microcirculatory conditions. This was specifically of interest in studies related to ischemic preconditioning and its effects on the microcirculation. This model is also applicable for simulation of reduced flow states, in which instead of clamp application a silk suture is placed around the pedicle, reducing blood flow to the flap.

The response of leukocyte–endothelial interactions to ischemia/reperfusion injury has been extensively studied. Upon reperfusion, a cascade of events takes place, leading to activation, adherence, and transmigration of the leukocytes, ultimately resulting in decreased blood flow, increased capillary permeability, and subsequent tissue damage and microcirculatory failure. Substances such as anti-ICAM and anti-PECAM antibodies, growth factors, interferon gamma, dehydroepiandrosterone, and cyclosporin and many more have been tested in our laboratory in different experimental scenarios of tissue ischemia, reperfusion, denervation, and preconditioning. The ability to reduce the effects of the ischemia/reperfusion injury after administration of different pharmacological agents has opened new horizons in the field of reconstructive microsurgery leading to better understanding and improvement of the free tissue transfer flap survival.

Application of the Cremaster Muscle for Chronic Observation of the Microcirculation

Previously, the cremaster muscle preparation was applied only for acute microcirculatory observation lasting no longer than 6 hours [1]. However, it is well known that some of the events altering the flow hemodynamics in the flap feeding artery and peripheral microcirculation of transferred tissues can occur later most often within 72 hours and no longer than 7 days after flap transfer. Therefore, the cremaster muscle flap model was modified to allow for observation of the microcirculation for prolonged periods of time, still maintaining the accuracy of the measurements [7]. Two models for chronic observation were developed.

The Cremaster Muscle Chamber for Continuous Observation of the Microcirculation

The main advantage of the cremaster chamber application is the ability of repeated measurements of hemodynamic changes within the same muscle flap for a period of up to 3 days. This period is accepted as critical time for flap survival or failure after microvascular repair [7]. After 3 days this model is less applicable since neovascularization from the surrounding tissues takes place and can obscure visibility under intravital microscopy. Also, with prolonged chamber application there is a possibility of the cremaster pedicle stretching or damage.

Technique. The cremaster muscle island flap is dissected and spread on the bottom of the Plexiglas chamber. The muscle is bathed in saline solution, then covered with a round cover glass and with the top frame of the chamber. This keeps the flap moist and free from atmospheric oxygen throughout the experiment. The base of the chamber is fixed with a suture to the body of the animal along the inguinal canal (Figure 3). Observations start at 30 minutes following chamber application to eliminate the immediate effects of surgical trauma on the flap microcirculatory response. Hemodynamic measurements can be taken at 1-hour intervals for the first 24 hours and as needed thereafter up to 3 days after chamber application. Extension of time between the measurement intervals permits the rats to recover from the anesthesia.

In our experience, the chamber is well tolerated by the animals, and the cremaster muscle preparation remains viable during the entire observational period. There is no significant pressure exerted by the use of the chamber, as evidenced by the flow measurements. Furthermore, the

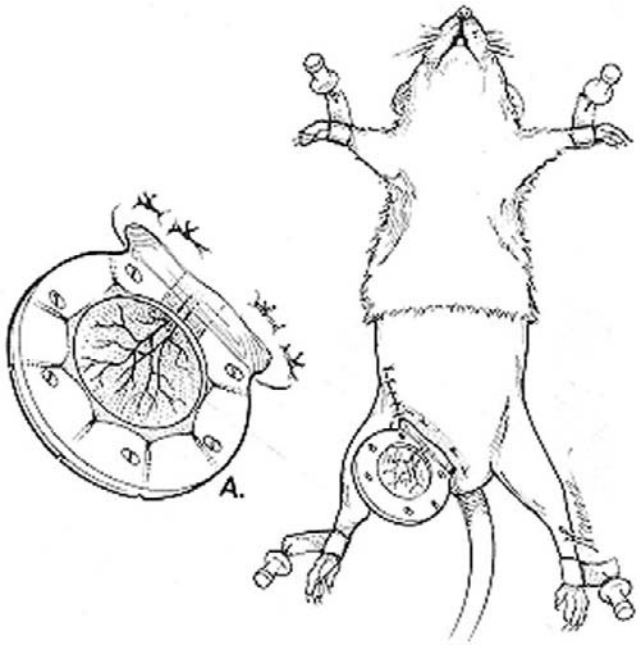

Figure 3 Schematic drawing of the cremaster muscle flap chamber model.

chamber model allowed to perform microcirculatory measurements comparable with standard cremaster muscle island and tube flap model recordings [7].

The Cremaster Muscle Tube Flap Model for Chronic Observation of the Microcirculation

If even longer periods of observation are necessary for the understanding of the microcirculatory mechanisms, the cremaster muscle tube flap is used. With this model the microcirculatory events can be observed for periods up to 14 days.

Technique. The cremaster is dissected as described before. However, after removal of the testis the empty cremaster muscle tube raised on the neurovascular pedicle is preserved (Figure 4). Next a subcutaneous tunnel is created in the anteromedial aspect of the hind limb. The flap is buried in this tunnel, secured distally with a pull-out suture, and kept in the tunnel until the day of microcirculatory measurements. At this time the flap is opened, spread over the top of the Plexigas platform, and set up for the measurements. This tube flap model is well tolerated by the animal, and the muscle viability is not affected by the staged surgical procedure required for monitoring.

This model has been successfully applied in research requiring longer periods of observation [7], such as studies on the long-term effects of flap denervation, evaluation of hemodynamic effects of pharmacological agents, and studies monitoring acute phases of allograft rejection.

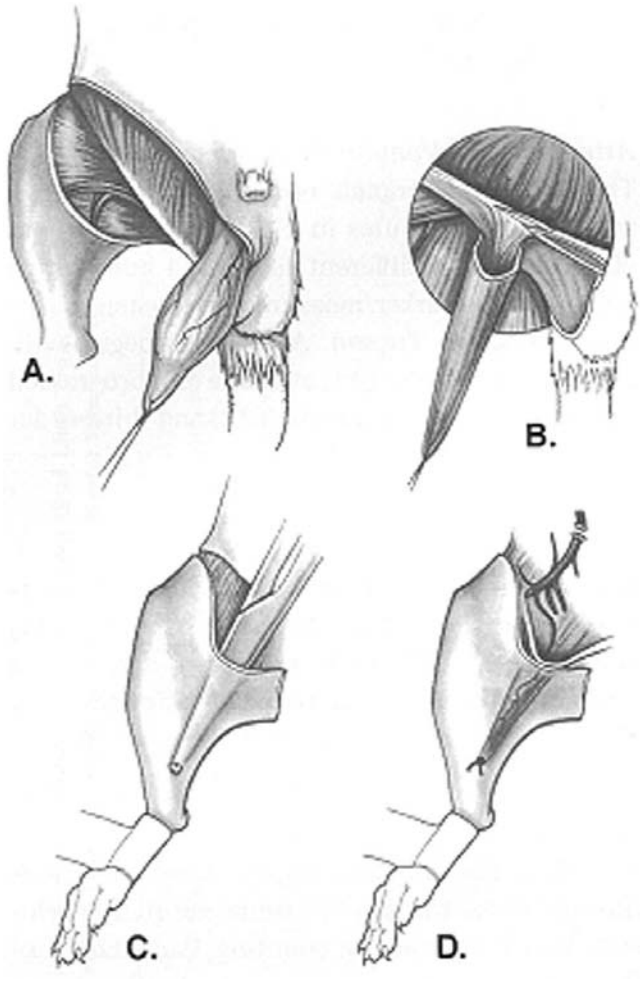

Figure 4 Steps in the hind limb–cremaster transplantation procedure: **(A)** Extraction of the testis from the cremaster muscle, **(B)** dissection of the cremaster tube flap on the neurovascular pedicle, **(C)** preparation of the subcutaneous tunnel for the preservation of the muscle flap for chronic observations, **(D)** insertion of the muscle flap into the tunnel, transection of the vascular pedicle at the iliac level, and limb amputation at the mid-femoral level.

Microcirculatory Responses to Cremaster Muscle Denervation

Since the cremaster muscle flap is an isolated axial pattern flap in which all collateral vessels are transected, it is the ideal model to study the effects of muscle denervation including influence of neurogenic factors on the microcirculatory response. Applying this model it is also possible to test the microvascular response to the topical application of the vasoactive substances. In such scenarios the cremaster muscle flap can be applied as an acute or as a chronic model.

1. *Technique—acute model*. After cremaster muscle flap dissection on the neurovascular pedicle, the denervation procedure is performed by resecting a 1-cm segment of the genitofemoral nerve in the groin area leading to flap sympathectomy. Next, the adventitia of both the iliac and femoral artery and vein are excised circumferentially just above and below the pudic-epigastric pedicle resulting in somatic denervation of the flap. The flap is then prepared for microcirculatory evaluation.
2. *Technique—chronic models*. We have developed chronic models for long-term microcirculatory recordings. The cremaster muscle tube flap could be modified by the two-stage denervation procedure. In the first stage an incision is made in the groin, and the iliac and femoral vessels and genitofemoral nerve are exposed. Next, the standard denervation procedure of 1 cm of nerve segment resection and excision of the femoral artery and vein adventitia is performed. The flap denervation can be carried out from 24 hours up to 14 days. At this point the second-stage procedure of standard surgical dissection of the cremaster muscle flap on the tissue bath is performed and microcirculatory measurements revealing the effects of flap denervation are recorded. As a result of these observations a triphasic sequence was observed, starting with (1) an acute hyperadrenergic phase, followed by (2) a non-adrenergic phase (vasodilatation) and (3) a sensitized phase where increased capillary perfusion and hyperresponsiveness to vasoactive substances was observed. Based on these observations it was evident that microcirculation can be significantly improved by muscle sympathectomy and somatic denervation [8].

A Model of Cremaster Muscle Isograft and Allograft Transplant

After transplantation, two patterns of tissue damage can occur during allograft rejection. One is caused by cell-mediated or antibody-mediated damage. The second is due to the tissue ischemia and surgical trauma causing microvascular destruction [9]. Since these patterns are dependent on the interactions between the allograft endothelium as well as allograft and recipient immune systems, a quantitative assessment of the microvascular events occurring during allograft rejection is crucial. The cremaster muscle flap was introduced to transplantation studies to serve as a "window" for direct microcirculatory measurements of the hemodynamic events occurring due to ischemia/reperfusion injury and the acute phase of allograft rejection following muscle transplantation. The cremaster tube flap can be transplanted alone as a free flap, or it can be incorporated into the donor's limb as a part of a composite tissue graft. This allows a monitoring sequence and timing of cremaster muscle allograft transplant rejection at the microcirculatory level. Further, the advantages of this cremaster flap preparation include the possibility of comparing differences between hemodynamic and cellular responses among the transplant donor and transplant graft recipient and to investigate the changes occurring within the intra- and extravascular compartments.

1. *Technique of the cremaster muscle free flap transplantation model*. The cremaster muscle tube flap is designed based on the iliac and femoral vessels, which are transected above the cremaster vascular pedicle take-off. The dissected cremaster muscle free flap is next transplanted to the recipient animal, and the pedicle is anastomosed to the femoral vessels of the recipient. Next a tunnel is created in the medial border of the hind limb, into which the flap is inserted for long-term observations. The transplanted tube flap allograft is then removed from the limb, opened, and spread on the tissue bath for the microcirculatory observation of allograft acceptance/rejection at the designated times.
2. *Technique of the combined hind limb–cremaster muscle transplantation*. This model allows study of microcirculatory response to composite tissue allografts across the MHC barrier. The rat hind limb is dissected together with the cremaster muscle, which is incorporated as a tube flap into the medial border of the limb. Transplantation from donor to recipient involves the four-step procedure. First, the hind limb of the recipient animal is amputated [10], followed by preporation of the hind limb–cremaster graft of the donor animal and preparation of the cremaster muscle tube flap implantation for chronic observations, as outlined in Figure 4. Next, the iliac vessels are exposed, ligated, and transected. The hind limb is then amputated. The hind limb–cremaster composite tissue graft is transplanted into the designated recipient (iso- or allograft), and the cremaster muscle tube graft is dissected and prepared for microcirculatory measurements.

The cremaster flap has proven to be a reliable tool for monitoring microcirculatory hemodynamics during composite tissue graft rejection. At the microcirculatory level the rejection process after allotransplantation begins as early as 24 hours posttransplant. It is characterized by a decrease of capillary perfusion and marked increase in the activation of adherent and transmigrating leukocytes, proceeding clinical the signs of allograft rejection [9, 10]. These observations were significant and added to our understanding of composite tissue allograft rejection as well as allowing us to distinguish between events occurring as a result of the transplantation trauma and rejection phenomenon.

Cremaster Muscle Model for Tumor Implantation

Since the cremaster muscle flap is a well-vascularized tissue it is applicable to solid tumor implantation. Following implantation, tumor growth and angiogenesis, along with molecular transport within the tumor and the delivery of genetic vectors and anticancer therapeutic agents, can be studied. Also, this model allows direct control of the inflow and outflow of the substances into the cremaster microcirculation, which is important during evaluation of tumor biology and drug testing.

Technique. Through an incision on the anterior surface of the exposed cremaster muscle, the testicle pedicle and spermatic cord are isolated and dissected. The testis is removed from the cremaster pouch and retracted into the abdominal cavity. The tumor cell suspension is then injected directly into the cremaster muscle. The incision is then closed, and the cremaster tube flap is implanted into the medial border of the limb. It is withdrawn from the limb only at the time of microcirculatory measurements. Intraarterial injection of substances of interest is done directly into the pudic-epigastric pedicle after clamping of the iliac and femoral vessels.

To summarize, the cremaster muscle flap model has been proven to be a novel model for cancer research with broad applicability and with specific value for the study of tumor biology and angiogenesis.

Glossary

Blood rheology: The study of the flow and deformation of red blood cells.

Cremaster muscle: Thin (200 microns) skeletal muscle covering testicles. Innervated by the genitofemoral nerve and vascular supply provided by pudic-epigastric vessels. Because of its thin muscle layers, the cremaster may be transilluminated and used for intravital microscopic observations.

Hemodynamics: The study of physical aspects of blood circulation, including cardiac function and peripheral vascular physiology characteristics.

Intravital microscopy observation: Observation performed under magnification of the light microscope upon a living tissue, in this case the cremaster muscle flap observed under 1,800× magnification.

Leukocyte–endothelial interaction: The relation between leukocytes present within the vessels and the vascular endothelium that can be altered in physiological and pathological states.

Microcirculation: Circulation of blood in the most distal part of the circulatory system, within the smallest vessels of the body such as arterioles, venules, and capillaries.

Dr. Siemionow did her orthopedic surgery and hand surgery training in Poznan, Poland, and Helsinki, Finland, respectively. Later she became a Hand and Microsurgery Fellow at the Christine M. Kleinert Institute for Hand and Microsurgery (Louisville, KY).

Currently she is the Director of Plastic Surgery Research, Head Microsurgery Training, Department of Plastic Surgery at The Cleveland Clinic Foundation. She is a full staff member of the Plastic Surgery Department and holds joint appointments with the Department of Orthopedic Surgery and the Transplant Center and with the Department of Immunology, at the Cleveland Clinic Foundation. She has adjunct appointments at Ohio State University and Case Western Reserve University.

Dr. Siemionow has received several awards for her contributions in the fields of hand surgery, microsurgery and transplantation. She is the author of 122 peer-reviewed articles and 319 abstracts.

Andrea Moreira-Gonzalez, M.D., is currently a Research Fellow at the Department of Plastic Surgery at the Cleveland Clinic Foundation. Dr. Gonzalez is a fully trained plastic surgeon that did her general and plastic surgery training in Sao Paulo, Brazil. After she did a Craniofacial and Reconstructive Fellowship at the Institute for Craniofacial and Recoonstructive Surgery in Southfield, Michigan. Dr. Gonzalez received several awards for her research in Reconstructive Plastic Surgery and is the author of 15 peer-reviewed articles and 47 abstracts.

CHAPTER 30

The Hamster Cheek Pouch as a Research Model of Inflammation

Erik Svensjö
Instituto Biofísico Carlos Chagas Filho, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Acute inflammation is characterized by increased microvascular permeability to plasma proteins and leukocyte recruitment into inflammatory sites at postcapillary venules but not in arterioles or capillaries. The hamster cheek pouch as prepared for intravital microscopy has become a versatile model for studies of the very first events (within seconds, minutes, and hours) of inflammation as indicated by instant changes in blood flow (arteriolar constriction or dilation), number of blood-perfused capillaries, increased leukocyte rolling and adhesion, and macromolecular leakage in postcapillary venules following the application of a great variety of inflammatory stimuli. Its value for studying the effects of proinflammatory mediators on plasma exudation or macromolecular leakage as well as leukocyte adhesion in postcapillary venules has been established by a large number of studies.

Morphology

Hamster cheek pouches are bilateral invaginations of the oral mucosa and can be everted from the anesthetized hamster with their blood flow intact. They are therefore well suited for intravital microscopy. The cheek pouch tissue is transparent and the anatomical elements of the microcirculation, arterioles, capillaries and venules can be easily identified (Figure 1). Cheek pouches, as prepared for intravital microscopy, have been used for studies of inflammation, tumor growth, vascular smooth muscle function, blood flow regulation, and leukocyte behavior—rolling and adhesion—at the microcirculatory level. The hamster cheek pouch preparation (HCP) was described for the first time as a "natural window" for microscopic observation and motion picture recording of blood flow, vessel wall caliber, and intravascular behavior of blood cells by Fulton, Jackson, and Lutz in 1946. The early observation that the cheek pouch of an anesthetized hamster can be brought out and applied on a stage for intravital microscopy with minimal interference with their blood flow resulted in its application for physiological studies of arterioles, capillaries, and venules. The cheek pouch can also be studied in situ by introducing a light rod through the mouth into the pouch and applying an acrylic chamber on top of the light rod after a skin incision. It appears that these two methods of preparing the HCP for intravital microscopy give equivalent results. The way to prepare the HCP for physiological studies of the microcirculation was developed and refined by Duling in 1973 using the everted cheek pouch. Ever since dextrans labeled with fluorescein isothiocyanate—FITC dextrans—became available as intravital markers of vascular permeability in 1970, the HCP has been used in numerous studies of inflammation as induced by a large number of different inflammatory mediators or procedures, such as bradykinin, histamine, adenosine diphosphate (ADP), serotonin, prostaglandins, or leukotrienes; by temporary ischemia of the pouch (IR); or by application of live parasites (*Trypanosoma cruzi, Leishmania donovani*) (Table I).

Detailed descriptions of the morphology of the cheek pouch have been given by Priddy and Brodie in 1948 and by Handler and Shepro in 1968. Briefly, the cheek pouches of the golden hamster are invaginations of the oral mucosa, extending beneath the subcutaneous tissue down to the shoulder region, and they can be characterized histologically as skinlike. The length of the distended cheek pouch is approximately 2.5 to 5.5 cm, and the width is about 1 cm. All parts except the distal portion of the pouch have longitudi-

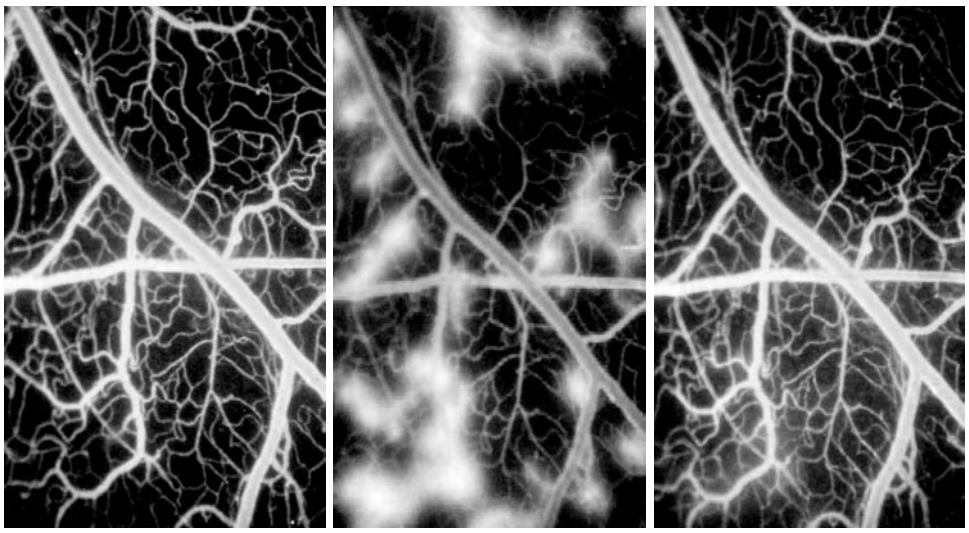

Figure 1 Fluorescent micrograph of the hamster cheek pouch after IV injection of FITC-dextran. Same area before **(A)**, 5 minutes after **(B)**, and 30 minutes after **(C)** topical application of bradykinin (4×10^{-7} M). More than 25 leakage sites at postcapillary venules are shown by extravasation of FITC-dextran at postcapillary venules. (see color insert)

Table I Mediators or Procedures That Have Been Shown to Increase FITC-Dextran Leakage in Postcapillary Venules.

Mediator or procedure	Effective concentration
Histamine, serotonin	10^{-6} M
Bradykinin, substance P	10^{-7} M
ADP, adenosine, inosine	10^{-5} M
Prostaglandins E_1, E_2 and E_{2a}	$<10^{-8}$ M
Leukotrienes C_4, D_4, E_4, B_4	$<10^{-9}$ M
Complement C3a, C5a	$<10^{-9}$ M
Cytokines – IL-1β	1 µg/ml
Platelet activating factor (PAF)	$<10^{-9}$ M
Fibrin-derived peptides	
VEGF (vascular endothelial growth factor)	$<10^{-9}$ M
Polyarginine, polylysine, major basic protein (MaBP)	$<5 \cdot 10^{-9}$ M
oxLDL, apolipoprotein B derived peptides	0, 1 mg/ml
Ischemia/Reperfusion (I/R)	30 min ischemia
ROS (reactive oxygen species)	
Oxidant injury (tertiary-butyl-hydroperoxide, TBOOH)	10^{-4} M
Immune aggregates (ovalbumin [OA] immunized hamsters)	<1 µg/ml of OA
Phorbol ester (PDBu)	10^{-6} M
Smokeless tobacco extract	
Endotoxin	7 µg/ml
Trypsin, cruzipain, gingipain	$>10^{-8}$ M
Live parasites—*Trypanosoma cruzi*, *Leishmania donovani*	10^7/ml

nal muscle fibers. The pouch is provided with a long retractor muscle and a sphincter-like arrangement around its aperture. There are no specific regional lymph nodes, and the nonmuscular part of cheek pouch lacks lymphatic drainage and has been characterized as an immunologically privileged site. Three layers are distinguishable in the pouch membrane. The epithelium is devoid of hair follicles and glands. The pouch is attached to the subcutaneous tissue by loose areolar connective tissue. The cheek pouch vasculature is mainly supplied by branches of the external carotid artery, via three saccular arteries. Blood is also supplied via the arteries of the retractor muscle. Terminal arterioles supply capillaries, which drain into postcapillary venules, which in turn empty into collecting venules. Arteriole-to-arteriole and venule-to-venule anastomoses are often seen, but there are no arteriole-to-venule anastomoses. The arterioles and, to a lesser extent, the venules are surrounded by numerous mast cells that appear to promote the oriented migration of leukocytes from the venules into the extravascular space.

Cheek Pouch Preparation

For microscopic observation, the single layer pouch preparation is performed essentially as described by Duling (1973). Alternatively the pouch may be studied in situ after insertion of a light rod and an acrylic skin chamber. There are no discrepancies reported for results achieved with either of these two procedures. However, the everted cheek pouch offers better optical conditions and a larger area (about 1 cm^2) for observations of the microvasculature. A hamster is anesthetized by intraperitoneal injection of pentobarbital and is then placed on a heating pad controlled by

a rectal thermistor. A tracheal tube is inserted to facilitate breathing and a femoral vein is catheterized for administration of supplemental anesthetic or other intravenous drugs. The experimental setup of the hamster cheek pouch preparation is illustrated in Figure 2. The animal is placed on an acrylic stage in the middle of which there is a well with a circular silicon rubber ring surrounding a transillumination window. The cheek pouch is everted with the aid of a moist cotton stick, the distal nonmuscular part of the pouch is identified and pinned to the silicon ring, and the pouch is dissected under a stereomicroscope at 10× magnification. A central area is selected with no major arterioles or venules and an incision is made in the top layer, which then is moved aside and pinned to the silicon ring. Now the loose areolar connective tissue is exposed and can be removed to have a single-layer preparation with the best optical conditions. During the preparation, and throughout the experiment, the cheek pouch is constantly superfused with a bicarbonate-buffered saline solution that is continuously bubbled with 5 percent CO_2 in N_2 at 37°C, and thus provides a physiological level of oxygen, temperature, and acidity (pH). For studies of vascular permeability changes, an intravascular marker such as fluorescein-labeled albumin can be used. Alternatively, an intravascular marker with a molecular weight similar to that of albumin namely fluorescein-labeled dextran (FITC-dextran), is used in a dose that has minor if any effect on platelet function and blood clot formation. FITC-dextran 70,000 or 150,000 Da is dissolved in normal saline and injected i. v. in a dose of 50 to 100 mg kg^{-1} body weight. Properly mounted and dissected, the cheek pouch is a noninflamed preparation as judged from the presence of vascular tone and absence of sites with FITC-dextran leakage (as seen in Figure 1), and absence of excessive leukocyte rolling and adhesion in postcapillary venules; the preparation can be utilized for intravital microscopy for several hours.

Changes in Vascular Permeability

In a classical electron microscopy study by Majno and Palade (1961), it was shown that postcapillary venules of 20 to 30 µm diameter leaked carbon particles through gaps formed between endothelial cells as a result of histamine stimulation and endothelial cell contraction. Such gaps have been confirmed to exist in the HCP after bradykinin stimulation. Studies combining intravital microscopy with subsequent electron microscopy of the same cheek pouch showed that interendothelial gaps had formed at sites where extravasation of FITC-dextran already had been observed in vivo, as in Figure 1B. The advantage of FITC-dextran as a marker is that it can first be observed in living tissue and then can be traced as dark precipitates after the fixation of the tissue, which demonstrates the pathway through interendothelial gaps taken by macromolecules in inflammation. The gaps are formed as a result of mediator-induced (e.g., bradykinin) contraction of endothelial cells in the postcapillary venules. Supportive evidence for endothelial cell contraction as a mechanism for gap formation can be found in the pharmacological studies of smooth muscle relaxant drugs that maintain the intracellular level of cAMP (adenyl cyclase activators, β_2-adrenoreceptor stimulants) or block its break-

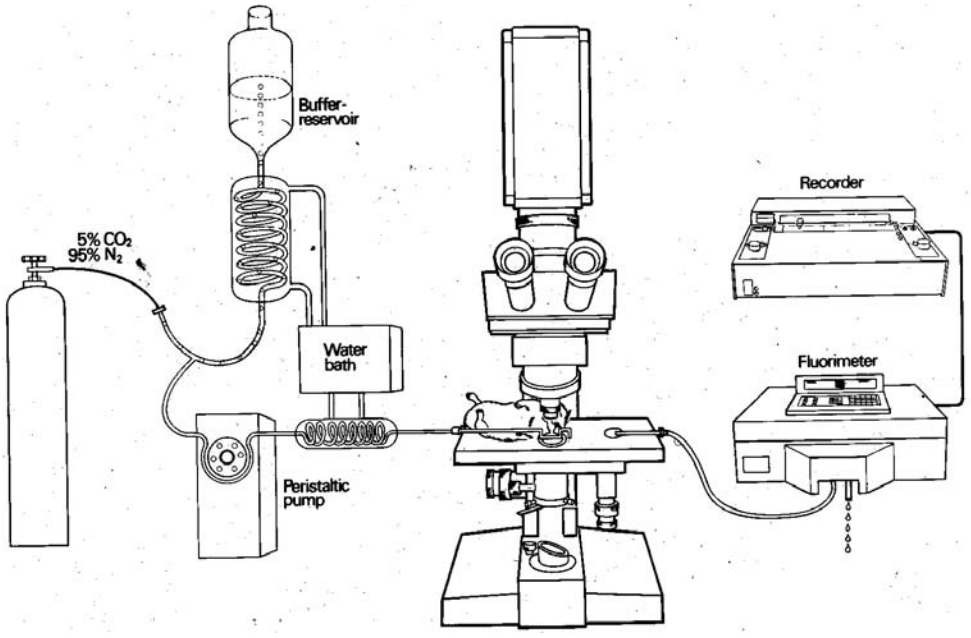

Figure 2 Schematic illustration of the experimental setup for the hamster cheek pouch model. The bicarbonate buffer superfusing the cheek pouch is heated and equilibrated with 5 percent CO_2 and 95 percent N_2. A peristaltic pump keeps buffer flow to microscope stage and fluorimeter constant.

down (phosphodiesterase inhibitors), which counteracts the mediator-induced contraction, the subsequent gap formation, and thus, the macromolecular leakage (Table II).

There has been some controversy in the past on the nature of endothelial gaps, intracellular or intercellular, but the controversy was resolved in a study by McDonald et al. (1999) on the formation of interendothelial gaps and their function as a route for plasma leakage in inflamed rat trachea. Using five different methods to examine normal and inflamed tissue samples, the researchers concluded that most of the openings in leaky venules were intercellular gaps, not transcellular holes, and that the formation and closure of gaps are likely to be energy dependent, while the process of plasma leakage is not, provided there is adequate driving force for extravasation. The cellular mechanisms of gap opening and closure still remain to be elucidated.

The mean diameter of postcapillary venules in the HCP most prone to leak on mediator stimulation varies between 8 and 15 μm, and the interendothelial gaps formed after stimulation with bradykinin vary between 0.08 and 1.4 μm in width.

For studies of macromolecular leakage at postcapillary venules, it is sufficient to use a magnification of 40× to 50× and for measurements of arteriolar diameter and for studies of leukocyte rolling and adhesion a water-immersible lens is recommended with a magnification of 200× to 400×. Illumination with a 50- to 100-W mercury lamp and filtering of the light with proper excitation and emission filters clearly shows the intravascular FITC-dextran and its extravasation after stimulation (see Figure 1). Epi-illumination gives better contrast between fluorescent and nonfluorescent tissue. Inflammatory mediators and drugs that may affect macromolecular leakage can be added to the superfusion buffer before it flows over the cheek pouch. The microvascular permeability increase or macromolecular leakage following the addition of bradykinin to the superfusion buffer is immediate; can be seen as early as at 30 seconds after its application; and reaches a maximum between 2 and 5 minutes after its application. The macromolecular leakage is measured by counting the number of leaking postcapillary venules (leaks) per cm^2 with 2-minute intervals until the maximal value is reached. The maximal number of leaks per cm^2 correlates with the fluorescent light intensity as measured with a photomultiplier on top of the microscope and also with the amount of FITC-dextran eliminated by the superfusing buffer and measured by in fluorimetry. The HCP is cleared

Table II Inhibitors of Mediator-Induced Macromolecular Leakage in the HCP.

Inhibitor	Concentration, M or dose	Mediator or procedure
β_2-adrenoceptor agonist (terbutaline, salbutamol)	10^{-6} M	Histamine, bradykinin, LTB_4, adenosine, phorbol ester, oxidant injury, I/R
Phophodiesterase inhibitors (Rolipram, milrinone)	10^{-5} M	Bradykinin
Theophylline (adenosin receptor agonist)	10^{-5} M	Histamine
Glucocorticoids (budesonide, methylprednisolone, dexamethasone)	10^{-7} M	Histamine, bradykinin, LTB_4, LTC_4, PAF, immune aggregates, oxidant injury, I/R, phorbol ester, endotoxin
Calcium antagonist (verapamil)	10^{-5} M	Histamine, bradykinin
Bradykinin-2-receptor antagonists (HOE 140, NPC 17647)	10^{-5} M	Bradykinin
Triglycylvasopressin, 1-desamino-8D-argininvasopressin	10^{-8} M	Histamine, bradykinin
H_1-receptor antagonist (mepyramine, dimethpyrindene)	$2 \cdot 10^{-6}$ M	Histamine
$5HT_2$-receptor antagonist (ketanserin)	$5 \cdot 10^{-7}$ M	Serotonin, histamine
Staurosporin (protein kinase C inhibitor)	10^{-9} M	Phorbol ester (PDBu)
NOS-inhibitors (L-NA, L-NAME, L-NMMA)	10^{-5} M	Histamine, bradykinin, I/R, PAF, endotoxin
Prostacyclin, iloprost	10^{-10} M	I/R
CuZn-SOD, EC-SOD (superoxid dismutases)	25 mg/kg, i.v.	I/R, oxidant injury
Tocopherol	10^{-5} M 1 mg/kg/day	I/R, oxidant injury (TBOOH)
Ascorbic acid	10^{-5} M	I/R, oxidant injury (TBOOH)
Flavonoids:hydroxylrutoside, diosmin, ruscus extract (Cyclo 3 Fort)	5–80 mg/kg/day	I/R, oxidant injury (TBOOH)
Glibenclamide, gliclazide (sulfonylureas, diabetes drugs)	10^{-8} M	I/R
WEB 2170 (PAF-antagonist)	10^{-5} M	PAF, oxLDL
Ropivacain (local anestetic)	10^{-5} M	LTB_4
Melatonin		I/R
Ketoprofen (COX-inhibitor)	$> 10^{-5}$ M	IL-1β, bradykinin
Nedocromil		Histamine, LTB_4
Lipoxin		LTB_4
Dextran sulfate	1, 75 mg/kg	LTB_4, polylysine

from the extravasated FITC-dextran at 30 minutes after a permeability increase and appears as before the increase (see Figure 1C). A linear dose–response relationship has been shown to exist between the number of leaks and the logarithmic dose of bradykinin, histamine, and several leukotrienes and also between the maximal number of leaks and the amount of FITC-dextran eliminated by the superfusion buffer over the course of 30 minutes.

Another characteristic of the response to certain inflammatory mediators such as bradykinin, histamine, and leukotriene B_4 is that on repeated stimulation with the same submaximal dose at 30-minute intervals, there is apparently no downregulation of receptor function and thus only slight reduction in the macromolecular leakage response over a time period when measured as number of leaks. Therefore, the HCP can be used with the first application of the mediator as a control followed by as many as seven subsequent applications together with different inhibitors. Certain mediators and procedures can make the HCP resistant to a secondary stimulation of the same kind. Thus a secondary application of ischemia/reperfusion (I/R), platelet activating factor (PAF), or parasites to the cheek pouch will result in a response which is 30% or less of the first. There is no complete understanding of the mechanisms behind this state of preconditioning to secondary stimulation, but a detailed study on the subject has been published by Korthuis et al. (2003).

Altogether, these data suggest that the HCP can be very useful in physiological and pharmacological studies on the regulation (inhibition or potentiation) of macromolecular leakage via interendothelial gaps induced by a mediators acting on the endothelial cells in postcapillary venules.

Inhibition of Mediator-Induced Macromolecular Leakage

Pharmacological inhibition of mediator (bradykinin) induced macromolecular leakage in the HCP was first shown with the β_2-adrenoreceptor terbutaline. Since then a variety of drugs have been studied for their potential to inhibit plasma leakage in the HCP as listed in Table II. The listed drugs represent different physiological and pharmacological principles as exemplified by selective receptor blockers (mepyramin, HOE 140, theophylline, ketanserin), calcium antagonists (verapamil), glucocorticoids (budesonide, methylprednisolone, dexamethasone), nitric oxide synthetase (NOS) inhibitors (L-NA, L-NAME, L-NMMA), antioxidants (ascorbic acid, tocopherol, flavonoids), potassium channel blockers (glibenclamide, gliclazid, for treatment of diabetes) and drugs interfering with leukocyte adhesion or activation (antioxidants, prostacyclin, NOS-inhibitors, superoxide dismutase, dextran sulfate).

β_2-Adrenoreceptor stimulants (terbutaline, salbutamol) and phosphodiesterase inhibitors (rolipram, milrinone) will cause arteriolar dilation on application to the HCP. Nevertheless they all inhibit macromolecular leakage in postcapillary venules, thus emphasizing that in spite of increased blood flow and perfusion pressure in the arterioles that should favor plasma leakage from the venules, the effect of the drug localized to receptors on the endothelial cells of the postcapillary venules is the dominant factor in the regulation of plasma leakage in inflammation. Neutrophil-induced changes in vascular permeability are the result of a complex interaction between adhesive proteins expressed on the surface of leukocytes and endothelial cells, selectins, and integrins, which finally results in the firm adhesion of leukocytes in postcapillary venules. It is possible to interfere with the leukocyte–endothelial cell interaction at different steps. Monoclonal antibodies against adhesion glycoproteins have been used to elaborate mechanisms of leukocyte rolling and adhesion. Dextran sulfate, and possibly also heparin, acts by neutralizing charged peptides released from the LTB_4-activated neutrophil, thereby inhibiting macromolecular leakage by 85 percent. Ropivacain, a local anesthetic with anti-inflammatory properties, may reduce the rolling and firm adhesion of LTB_4-stimulated neutrophils and also the macromolecular leakage, see Table II. These effects could be explained by a shedding of selectins on the surface of leukocytes. Studies on neutrophil or leukocyte induced macromolecular leakage illustrate that the final result of inhibitor action is localized to the venular endothelial cells in the postcapillary venules. Antioxidants such as ascorbic acid, tocopherol, flavonoids, and SODs may not exert any constriction or dilation, but they may neutralize products released from adhering and activated neutrophils. Asthma and diabetes are today recognized as inflammatory diseases, and asthma drugs, which have been studied in the HCP (β_2-adrenoreceptor stimulants, theophylline, glucocorticoids, chromoglycate), all have a significant inhibitory effect on histamine-induced macromolecular leakage. The antidiabetic drugs, glibenclamide and gliclazide, may counteract I/R-induced inflammatory effects in the HCP.

Conclusions

Increased macromolecular leakage through widened gaps between contracted endothelial cells of postcapillary venules is an important event in inflammation. It is induced by a direct action on the venular endothelium of mediators released from mast cells or from activated leukocytes. Cell-mediated (polymorphonuclear leukocyte) macromolecular leakage, like that caused by leukotriene B_4 is reversible and can be reproduced at 30-minute intervals but that induced by I/R-, PAF-, or parasite-application may cause a state of preconditioning. The HCP is a practicable model for studies on the very first events of inflammation as indicated by the increased rolling/adhesion of leukocytes and macromolecular leakage in postcapillary venules for several reasons: (1) the effects of inflammatory mediators and anti-inflammatory drugs in the HCP have been confirmed in other animal models; (2) measurement of rolling/adhesion of leukocytes and

macromolecular leakage can be made simultaneously; and (3) monitored superfusion of the HCP facilitates mediator administration and drug treatment with great accuracy.

Permeability, Tone and Hemodynamics

CHAPTER 31

Regulation of Microvascular Permeability

D. O. Bates

Microvascular Research Laboratories, Department of Physiology, Preclinical Veterinary School, University of Bristol, Bristol, United Kingdom

Introduction

The rate at which fluid and solutes cross the vascular wall is determined by the driving forces for exchange (pressure or diffusion gradients), the surface area available for exchange, and the permeability of the vascular wall to fluid or solute. This permeability is regulated by the cells forming the capillary walls—the endothelium—and is dynamic in both time and space.

Microvascular Permeability to Water: Hydraulic Conductivity (L_p)

Although cell membranes are freely permeable to the diffusion of water, they have a high resistance to fluid flow down a hydrostatic pressure gradient. L_p is given by the fluid flow per unit pressure per unit area.

What Is the Site of the Resistance to Fluid Flow?

The main pathway of fluid flow across the walls of continuous capillaries is the intercellular cleft, and in fenestrated endothelium through fenestrae. The conductance is determined the viscosity of the fluid (η), the path length (Δx), and the fourth power of the radius of the pathway (r^4). The cleft of most endothelial cells in the capillary and postcapillary beds is approximately 20 to 30 nm wide throughout its length (see Figure 1) with at least one tight junction. Breaks in the tight junction strand, approximately every 2 to 3 μm and usually 50 to 200 nm long and overlapping junctional strands further into or out of the cleft, give rise to a tortuous pathway for fluid flow through the cleft. The path length is therefore greater than the cleft length, and the radius is smaller than the cleft width, but greater than the space between the tight junction molecules.

How Can L_p Be Measured?

Cell Culture Models

L_p can be measured of endothelial cells in culture. A monolayer grown on polycarbonate filters is pressurized and the flow rate through the monolayer measured. The area of the monolayer and the pressure difference are known, so L_p can be calculated. Two main problems with this technique are the lack of formation of a perfect monolayer and the compression of endothelial cells and the underlying basement membrane onto the filter (sealing). The L_p of monolayers is up to two orders of magnitude greater than in vivo.

Measurement of L_p in Single Vessels in Vivo

L_p can be measured in single arterioles, capillaries, and postcapillary venules using the Landis–Michel technique. A single microvessel in a thin flat tissue such as the mesentery is cannulated and perfused with a solution of known oncotic pressure and containing flow markers (erythrocytes). The vessel is then occluded by a glass rod, and the rate of filtration per unit area of vessel wall per unit pressure (L_p) is determined from the rate of movement of the flow markers, the radius of the vessel, and the length of the vessel.

Measurement of Filtration Capacity in Whole Organs

L_p can be estimated in whole tissues by measuring the gain of weight or volume induced by an increase in fluid filtration after an increase in capillary pressure. The venous

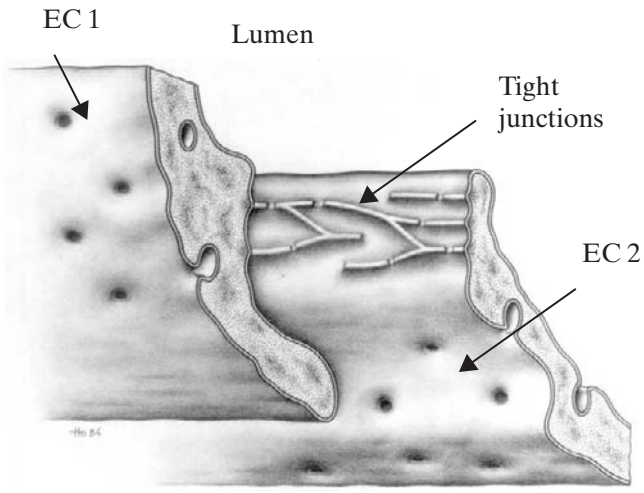

Figure 1 Three-dimensional reconstruction of an endothelial cell cleft from ultrathin serial sections. Endothelial cell 1 (EC1) has been cut away to reveal the tight-junction structure of endothelial cell 2 (EC2) to be visible in the cleft. Tight junction strands run along the cleft and have small breaks in them that allow fluid and solutes through.

pressure of the tissue can be increased, either by cannulating the draining vein or by inflating a cuff. The increase in weight or volume of the tissue per unit pressure is the capillary filtration coefficient (CFC, or K_f), which is the product of the mean L_p and the surface area available for exchange.

Microvascular Permeability to Solutes

Lipophilic versus Hydrophilic Solutes and the Importance of Flow Limitation

The solute permeability (P_s) of the capillary wall is dependent on the oil:water partition coefficient, the diffusion coefficient of the solute, Δx, the radius of the solute relative to the pore, and the pore area. Fat-soluble molecules are therefore very permeable across the capillary wall (P_s for oxygen is $1–10 \times 10^{-3}\,cm\,s^{-1}$). The concentration gradient across the capillary wall can only be maintained by relatively high blood flows. Highly permeable solutes are therefore flow limited rather than diffusion limited. Small hydrophilic molecules are also flow limited, even though their transport is predominantly through extracellular pathways. Larger molecules such as plasma proteins have a P_s that is normally so low that the concentration gradient along the vessel is maintained independently of the rate of flow for most perfused vessels, and is therefore diffusion limited. Intermediate-sized solutes such as glucose move from flow limitation to diffusion limitation as the P_s of the vessel changes.

The Sites of Solute Permeability

In continuous capillaries the location of the barrier to solute movement is in the endothelial cell cleft. There are at least three possible barriers to solute flux—the glycocalyx, the tight junctional strands, and the adherens junctions of the cleft. There is still some support for the concept of transcellular movement of protein and other large solutes through the vesicular system of endothelial cells. Fused vesicle clusters attached to the lumen have been seen to cross the entire width of the cell and fuse with vesicle clusters attached to the abluminal side of the cell, thereby providing a potential route for solute movement.

Measurement of Permeability to Water-Soluble Solutes

Problems Common to Methods of Solute Permeability Measurement

P_s can be determined by measuring the solute flux across the vascular wall and calculating P_s based on known driving forces for solute flux, in a manner analogous to that for L_p. The P_s of a membrane to a particular solute is set by Fick's law—the rate of diffusive flux per unit concentration difference per unit surface area. However, the total solute flux across the vascular wall depends upon diffusive and convective fluxes—that is, the rate of solute movement carried along in the flow of fluid that is also crossing the vessel wall. Furthermore, the concentration gradient across the vessel wall is also set by the balance of the diffusive and convective solute fluxes. The interstitial solute concentration depends upon solute flux relative to water flux. This ratio of diffusive to convective solute flux must be used to calculate the true driving force for diffusive solute movement. It is only possible to use the measurement of solute flux to accurately calculate P_s when all these parameters are known. P_s has been measured in cell culture models, in whole organs, and in single vessels. Most methods for measuring P_s use labeled solutes. These include radiolabeled (e.g., ^{125}I-albumin, ^{57}Cr-EDTA), or fluorescently labeled molecules (e.g., FITC-albumin), or dyes that bind to specific molecules (e.g., Evans blue, which binds albumin). All these methods suffer from two potential problems—dissociation of the marker from the test molecule and alteration of the test molecule by the marker.

1. *Tracer dissociation.* This can lead to a marked overestimation of P_s. For instance, Evans blue has a molecular weight of 960, albumin 66,000. Therefore for every molecule of EB that dissociates, P_s is 69-fold overestimated—if 1 percent of the EB dissociates, then 69 percent of the P_s will be that of EB, not that of albumin. Moreover, free EB is flow limited rather than diffusion limited. Therefore changes in EB transport occur far more easily by changing blood flow. This is also true for FITC and radiolabeled molecules that undergo radiolysis—^{125}I-albumin usually has 0.01 to 2.5 percent dissociated ^{125}I. This can be avoided by the use of tracers that do not readily dissociate, such as TRITC, or by nonnative tracers that are themselves detectable, such as green fluorescent protein or fluorescent dextrans.

2. *Alteration of the test molecule.* The process of labeling molecules may also alter their characteristics. Albumin is denatured when labeled with FITC, resulting in a change of charge and pH, and it has a different P_s than when it is labeled with other fluorescent molecules. Although this may have a small effect on P_s under normal conditions, it may be highly significant in conditions where albumin is endogenously modified (e.g., diabetes).

CELL-CULTURE MODELS

There are numerous problems measuring P_s of endothelial monolayers in cell culture. These include those outlined earlier concerning measurement of L_p. Because P_s of the monolayer is so much higher than in vivo, basement membrane can significantly contribute in vitro. This can be controlled by measuring P_s after removal of endothelial cells. Since cells are grown on a synthetic insert, the path length between the junction and the nearest pore in the membrane can also change. The average endothelial cell surface area and shape can be determined to eliminate this possibility. It is also necessary to ensure that there is not a significant decrease in the solute concentration difference between the endothelial cell and the pore, or the endothelial cell and the lower chamber. Calculation of true P_s (in cms^{-1}) should be carried out rather than solute flux (mgs^{-1}).

MEASUREMENT OF SOLUTE PERMEABILITY IN SINGLE VESSELS

P_s can accurately and effectively be measured in individual microvessels by determining solute flux under known conditions of diffusive and convective driving forces. A vessel is cannulated with a pipette divided by a septum. The two halves are perfused at separate pressures and one side filled with a fluorescent tracer. The perfusate is switched rapidly to the fluorescently labeled one, thereby giving a known concentration difference. The total fluorescence of and around the vessel is measured. With small molecular weight solutes (convective flux being negligible) the rate of increase of fluorescence can be used to calculate solute flux per unit concentration gradient per unit area—P_s. For larger solutes (or for small solutes in very tight vessels such as the blood–brain barrier), solute flux can be measured at a variety of pressures such that convective flux can be measured.

MEASUREMENT OF SOLUTE PERMEABILITY IN WHOLE TISSUES

Permeability–surface area product (*PS*) is usually measured in whole tissues, since it is difficult to measure the surface area. *PS* can be measured using radiolabeled, colorimetric, or fluorescent tracers—bearing in mind the measurement problems discussed earlier. Assuming that the tracers are effectively labeled, do not dissociate, and do not denature the compound, *PS* can be accurately assessed using a double-labeled tracer technique. This involves perfusing animals for increasing amounts of time with a tissue tracer (e.g., ^{125}I-albumin), followed by injection of a second reference tracer (e.g., ^{131}I-albumin) for 1 minute to allow circulation. The animal is then killed, a blood sample is taken, and the tissue is excised and weighed. The lungs are then dried completely and water content determined. The reference tracer (V_r) distribution volume is calculated from the plasma concentration and the reference tracer tissue counts. Tissue distribution volume (V_t) is calculated from the tissue tracer counts and the blood. The albumin distribution volume (V_a) can be calculated from V_r and V_t. V_a will increase over time as solute moves from vascular to tissue so the time experiments are used to calculate initial solute flux. V_a is measured under normal conditions and during increased filtration rate. The relationship between filtration rate and solute flux can be used to calculate the *PS*. A common mistake in this method is to divide rather than subtract the first tracer from the second. This results in the calculation of a meaningless ratio dependent on blood flow rather than *PS*.

Reflection Coefficient (σ)

The reflection coefficient of a membrane to a solute is the osmotic pressure exerted by that solute across the membrane as a fraction of the osmotic pressure across an ideal membrane (it is a function of the mean pore area relative to the mean cross-sectional area of the solute). σ for albumin, for instance, in normal capillaries is close to 1: It exerts almost its full osmotic pressure. An increase in the pore diameter (which would also increase solute P_s) would drastically reduce σ to albumin.

MEASUREMENT OF σ IN SINGLE MICROVESSELS

Reflection coefficient to macromolecules can be measured using the Landis–Michel technique [1]. A single vessel is cannulated and perfused as described for L_p. σ can be calculated as the root of the ratio of the pressure required to balance filtration to that of the colloid osmotic pressure determined across an ideal membrane by a colloid osmometer. σ has been determined in a number of capillary beds using these techniques.

MEASUREMENT OF σ IN WHOLE ORGANS

Under conditions of high filtration rates the interstitial protein concentration, when expressed as a fraction of the plasma protein concentration, approximates to the permitted fraction, or $1 - \sigma$. Thus if filtration rate is raised and interstitial fluid can be sampled, σ can be estimated. One way of doing this is to cannulate a lymphatic draining the tissue and measure the protein concentration under conditions of high filtration rate, after equilibration.

Normal—or Baseline—Vascular Permeability

Hydraulic Conductivity—L_p

L_p of microvascular beds is heterogeneous under normal conditions, and the mechanisms that regulate baseline

permeability are not clear. The number of tight junction strands is greater in vascular beds with lower L_p and P_s (e.g., blood–brain barrier). Some signaling pathways have been shown to be able to increase junctional strand number in endothelial cells in culture and to decrease L_p in vivo. Intracellular cAMP can stimulate the formation of tight junction strands by PKA-mediated phosphorylation of junctional associated proteins. The degree of filling of Ca^{2+} stores in the endothelial cells may regulate baseline L_p, although the link between Ca^{2+} stores and cAMP mediated pathways has not yet been determined. Nitric oxide has been implicated, since inhibition of NO synthase results in a transient increase of baseline L_p. The presence of fenestrations will result in a much greater baseline L_p, as is seen in renal, salivary, and synovial capillary beds, to name a few.

Solute Permeability—P_s

Little is known of the intracellular signaling cascades that regulate normal P_s, but for small solutes this is likely to be the same as that governing L_p. For larger molecular weight solutes, despite many decades of research, it is still not clear what are the contributions to basal P_s of the different signal transduction pathways.

Oncotic Reflection Coefficient—σ

Regulation of reflection coefficient is dependent on the functional pore radius. Diaphragms in fenestrae decrease the pore radius such that fenestrated endothelium has a high σ despite a high L_p. Little is known concerning the signaling pathways that regulate fenestrations, although the isolation of the protein that forms diaphragms across fenestrae of caveolae—PV-1—should mean that regulation of fenestrations will become more clearly understood.

Agonist-Mediated Increased Vascular Permeability

Mediators of Increased Permeability

G-Protein-Coupled Receptor Agonists

Vascular permeability to both water and solutes can be increased by inflammatory mediators released by neurons (e.g., substance P), mast cells (e.g., histamine), and platelets (e.g., ATP). These agonists act through stimulation of seven transmembrane domain G-protein coupled receptors, resulting in phospholipase C-β activation, inositol 1,4,5-trisphosphate production, release of Ca^{2+} from intracellular stores, and subsequent Ca^{2+}-mediated Ca^{2+} entry across the cytoplasm. This Ca^{2+} increase is common to many agonists that increase P_s. It leads to a series of intracellular signaling events, the relative roles of which are still being established. It appears that activation of nitric oxide synthesis, production of NO, and subsequent activation of guanylyl cyclase is critical in many agonist-mediated increases in both L_p and P_s.

Tyrosine Kinase Receptor Agonists

Other factors that increase permeability include growth factors such as VEGF that act through receptor tyrosine kinases and result in activation of phospholipase C-γ, and hence diacylglycerol production and Ca^{2+} entry but in this case, independently of Ca^{2+} stores.

Physical Forces

P_s to small and intermediate-sized solutes, such as K^+ and glucose-sized molecules, can be increased by shear stress. P_s to albumin and L_p are not affected. These increases in permeability are NO dependent and can be abolished by increasing cAMP concentrations. Recent evidence has implicated the activation of NO through a VEGF-R2 mediated signaling pathway possibly involving an integrin-mediated activation of Src.

The Site of Increased Permeability

There are a number of ultrastructural alterations in endothelial cells in vessels in which permeability is increased. These include intercellular gaps (between separate endothelial cells), transcellular gaps (through individual endothelial cells), induction of fenestrations, collections of vesicle-like structures known as vesiculo-vacuolar organelles (VVOs), vacuole formation, and reduction in cleft length and tight junction overlap. Each of these ultrastructural events has been linked to increased permeability stimulated by one or more agonists, but the molecular mechanisms regulating these are not yet clear.

The Cleft

The molecules that contribute to the formation of the cleft—the occludins in the tight junction, and the cadherins in the adherens junctions—can be regulated by anchoring proteins on the cytoplasmic side of the membrane. These proteins, such as ZO-1 and the catenins, are phosphorylated in response to many permeability enhancing agonists. Furthermore, prevention of their phosphorylation can prevent permeability increases in some model systems—particularly in vitro. Although there is some evidence that this may also be true in vivo, the significance of phosphorylation of these proteins is still not clear.

Gaps

Endothelial gaps were for many years thought to be intercellular, indicating a breakdown in the cleft. However, in the vast majority of these studies only single sections have been examined using transmission electron microscopy or scanning electron microscopy. Serial section reconstruction is necessary to prove that a gap is between rather than through the cell. When serial sections have been carried out, both intercellular and transcellular gaps have been shown, and the relative frequency of these appears to alter with the agonist. Some agonists, such as VEGF, result primarily in intracellular gaps, whereas others, such as substance P, appear to create intercellular gaps.

FENESTRATIONS, VACUOLES, AND VESICULOVACUOLAR ORGANELLES

The induction of fenestrations by release of paracrine factors has been shown in response to VEGF, but does not appear to be a widespread mechanisms for inducing increased permeability. The induction of clusters of vesicles (or caveolae), or the formation of large vacuoles that span the cell occurs in response to VEGF and in tumor vessels, presumably formed from a Ca^{2+}-mediated fusion of vesicles to form continuous pathways through the cell. Ferritin tracer experiments show that these caveolae are open to perfusing substances. VVOs, vacuoles, fenestrations, and transcellular gaps may all be part of a single cascade, resulting from Ca^{2+}-mediated activation of vesicle fusion.

Glossary

Hydraulic conductivity (L_p): The convective permeability of the vessel wall to fluid flow. Can be defined as the filtration rate per unit pressure difference per unit area. Dependent on relative viscosity of fluid as it flows through the cleft, the functional pore radius (to the power 4), and the path length.

Oncotic reflection coefficient (σ): The ratio of the osmotic pressure exerted by a molecule across the vascular wall to that exerted by the solute across an ideal semipermeable membrane. Is a function of the solute area relative to the pore area, or the true solute concentration in the pore relative to the free concentration.

Solute flux (J_s): The rate of solute movement across the vessel wall. This is driven by both convection (dependent on filtration rate, reflection coefficient, and plasma solute concentration), and diffusion (dependent on the concentration gradient, the surface area, and the solute permeability).

Solute permeability (P_s): The diffusive permeability to a solute. Can be defined as the diffusive solute flux per unit concentration gradient per unit area for small solutes. Depends on the restricted diffusion coefficient, the equilibrium partition coefficient, the mean pore area, and the path length.

Capsule Biography

Dr. David Bates is a British Heart Foundation Lecturer, University of Bristol Senior Research Fellow, and Director of the Microvascular Research Laboratories in the Department of Physiology at the University of Bristol, United Kingdom. He received his Ph.D. in Physiology from the University of London and postdoctoral training in the Department of Genetics, University of Glasgow, and Human Physiology, University of California at Davis. He was a lecturer in Medicine at the University of Leicester, before moving to Bristol in 1999. His research focuses on the vascular endothelial growth factors and their effects on permeability, angiogenesis, and lymphangiogenesis.

CHAPTER 32

Regulation of Vascular Endothelial Cell Signal Transduction and Phenotype by Mechanical Factors

Konstantin G. Birukov
Department of Medicine, Johns Hopkins University, Baltimore, Maryland.

Vascular endothelial cells play significant roles in regulating vascular functions in health and disease. Mechanical forces such as shear stress and cyclic stretch sequentially activate mechanosensors, intracellular signaling pathways, specific transcription factors, cytoskeletal remodeling, and the expression of genes and proteins and, as result, profoundly modulate endothelial cell functions. This article describes the nature of mechanical forces acting on vascular endothelium in physiological conditions and pathological settings and discusses signaling pathways of mechanotransduction, as well as the effects of physiological and pathological mechanostimulation on gene expression patterns in vascular endothelium.

Mechanical Forces Acting on Vascular Endothelium

Mechanical forces in the form of shear stress imposed by blood flow and mechanical strain resulting from heart propulsions and hydrostatic pressure affect all vasculature in the organism and play an important role in physiological and pathological vascular responses. However, differences in hemodynamics and additional mechanical forces resulting from respiratory cycles form unique mechanical environment experienced by pulmonary vascular endothelial cells (ECs). In systemic circulation, vascular endothelium experience higher hydrostatic pressure and shear rates (15–40 dyn/cm^2), and estimated amplitude of vessel distension caused by heart propulsions ranges within 5 to 10 percent. Pulmonary circulation is characterized by lower hydrostatic pressure and shear stress. Whereas a large body of literature exists on the effects of shear stress in endothelial cells, very little is known about effects of mechanical stretch on pulmonary endothelium. Although the degree of lung cell stretching is not known precisely in critically ill patients submitted to mechanical ventilation, many in vitro studies have used cyclic uniaxial strain in the range of 5 to 30 percent elongation to mimic physiological and pathological reactions of cell stretching, which correlated with vascular stretching caused by mechanical ventilation at high tidal volumes (20–25%). Thus, cyclic strain (or stretch) is more prominent factor in the cells of the alveolar capillaries in the lung, whereas shear forces may have differential effects on various potions of the vascular bed with gradient decline from the arterial endothelium in systemic circulation to the capillaries from systemic and pulmonary vascular beds.

Shear Stress

In large arteries, the mean wall shear stress is typically in the range of 20 to 40 dyn/cm^2 in the regions of uniform geometry and away from branch vessels. Estimated shear rates in the pulmonary artery are 10 to 20 dyn/cm^2. The actual values of shear stress for different segments of human pulmonary vascular tree have not been yet determined; however, calculations using data obtained from animal models suggest that the range of shear stress in lung arterial tree is 0.1 to 4 dyn/cm^2.

The pathological role of disturbed flow in atherogenesis is manifested by the focal distribution of atherosclerotic lesions in the bifurcations and curved regions of the arterial tree where blood flow is disturbed by flow separation, and the rates of shear stress are low and unsteady in these lesion-prone areas. Direct correlation was found between decreased shear rates and turbulent flow with increased local permeability of ECs. Experimental manipulations with flow rates and patterns in situ and in cell culture models suggest increased endothelial permeability and lipid deposition in the areas of reduced or disturbed laminar flow and completely preserved barrier properties of endothelial monolayer in the areas with normal or elevated flow. Although both pulmonary and systemic circulation are constantly exposed to varying levels of shear, lung endothelial cells experience variable flow patterns in vivo under physiological and pathological conditions that are dictated by unique features of the pulmonary circulation. For example, the distribution of blood flow throughout the human pulmonary vasculature is nonuniform and decreases from the base to the apex of the lung. In pathological situations, such as severe hypovolemia or mechanical ventilation at excessive airway pressure, apical pulmonary arterial pressures may fall below alveolar pressures, resulting in capillary collapse and cessation of blood flow. Cessation of pulmonary flow through defined segments is observed after thromboembolism, or in response to hypoxic vasoconstriction, a condition unique to the pulmonary circulation, which may result in capillary collapse. Thus, the differences in systemic and pulmonary flow patterns may dictate different mechanisms of flow-induced regulation of endothelial functions in these systems.

Mechanical Strain

Mechanical strain experienced by endothelial cells from systemic and pulmonary circulation is a superposition of pulsatile and tonic components. Tensile stress is imposed on the vascular wall by hydrostatic pressure counteracted by tonic contraction of vascular smooth muscle cells and elastic components. In addition, cyclic stretch is imposed by heart propulsions. Pulsatile distension of the arterial wall in systemic circulation normally does not exceed 10 percent to 12 percent, whereas various vasomotor reactions may change diameter of smaller caliber "resistance" arteries may reach 60 percent of initial diameter or more and last minutes or hours. Chronically increased blood pressure and vascular transmural stress activates vascular cell proliferation and collagen and fibronectin synthesis, which results in thickening of the vascular wall as a feature of hypertension-induced vascular remodeling. Direct measurements of interstitial/vascular distension in the mechanically ventilated lung are not currently available because of the complexity of local distension patterns in the lung parenchyma further complicated by uneven regional lung distension observed during inflammation and lung injury. However, studies by S. Margulies' group [1] suggest that if lung volume increases from 40 to 100 percent of total lung capacity, alveolar epithelial cell basal surface area increases by 34 to 35 percent. Pathological lung distension observed in ventilator-induced lung injury (VILI) induces alveolar and vascular barrier dysfunction, increased inflammatory cytokine production, macrophage activation, and acute inflammation that may culminate in pulmonary edema or acute respiratory distress syndrome. Several groups including ours have established cell culture models related to in vivo VILI conditions and reproduced in cell culture models cellular responses such as cytokine production and exacerbation of agonist-induced endothelial barrier dysfunction by high-amplitude cyclic stretch observed in the injured lung (Birukov et al., 2003; Dos Santos and Slutsky, 2000; Pugin et al., 1998; Vlahakis et al., 1999) [2–5]. These models are now intensively utilized in studies of pathophysiological mechanotransduction and gene expression, which will be described later.

Mechanosensors and Signal Transduction Pathways

Cell membranes, cell attachment sites, and cytoskeletal network directly experience hemodynamic forces, and most likely serve as primary mechanosensors, as was shown in pioneering work by the groups of P. Davis and J. Shyy (Davies, 1995; Shyy and Chien, 2002) [6, 7]. Cells adhere to neighboring cells and to the extracellular matrix via transmembrane receptors of cadherin (cell-to-cell) and integrin (cell-to-substrate) families. In the cytoplasmic domain, these receptors are coupled to protein complexes, which link receptors with cytoskeleton and also mediate mechanical signal transduction via activation of signaling molecules such as tyrosine (focal adhesion kinase, p60Src) kinases, serine (Erk-1,2, JNK, and p38 MAP kinases) protein kinases, inositol lipid kinases (phospholipase C), and some growth factor receptors (VEGF and PDGF receptors). Activation of mechanoreceptors triggers multiple signal cascades with ion channels (Na^+ channel, K^+ channel, chloride-selective channel) and heterotrimeric G-proteins ($G\alpha q$) being activated within seconds of mechanical stimulation, and protein kinases (protein kinase C, MAP kinases, nonreceptor protein tyrosine kinases) activated within minutes of stimulation. Protein kinase–mediated phosphorylation of specific cytoskeletal and cell contact proteins, other enzymes, and transcription factors induces cytoskeletal remodeling and stimulates gene expression in vascular cells. Figure 1 summarizes major signal pathways and cellular responses induced by shear stress and cyclic stretch.

Although most putative mechanosensors and mechanotransduction pathways are stimulated by both shear stress and stretch, the nature of mechanical forces and amplitude may still differentially affect certain signaling systems. For example, shear stress exposure selectively activates small GTPase Rac, which results in peripheral translocation of actin polymerization proteins and specific cortical actin remodeling, whereas cyclic stretch stimulates small GTPase Rho without affecting Rac and induces cytoskeletal

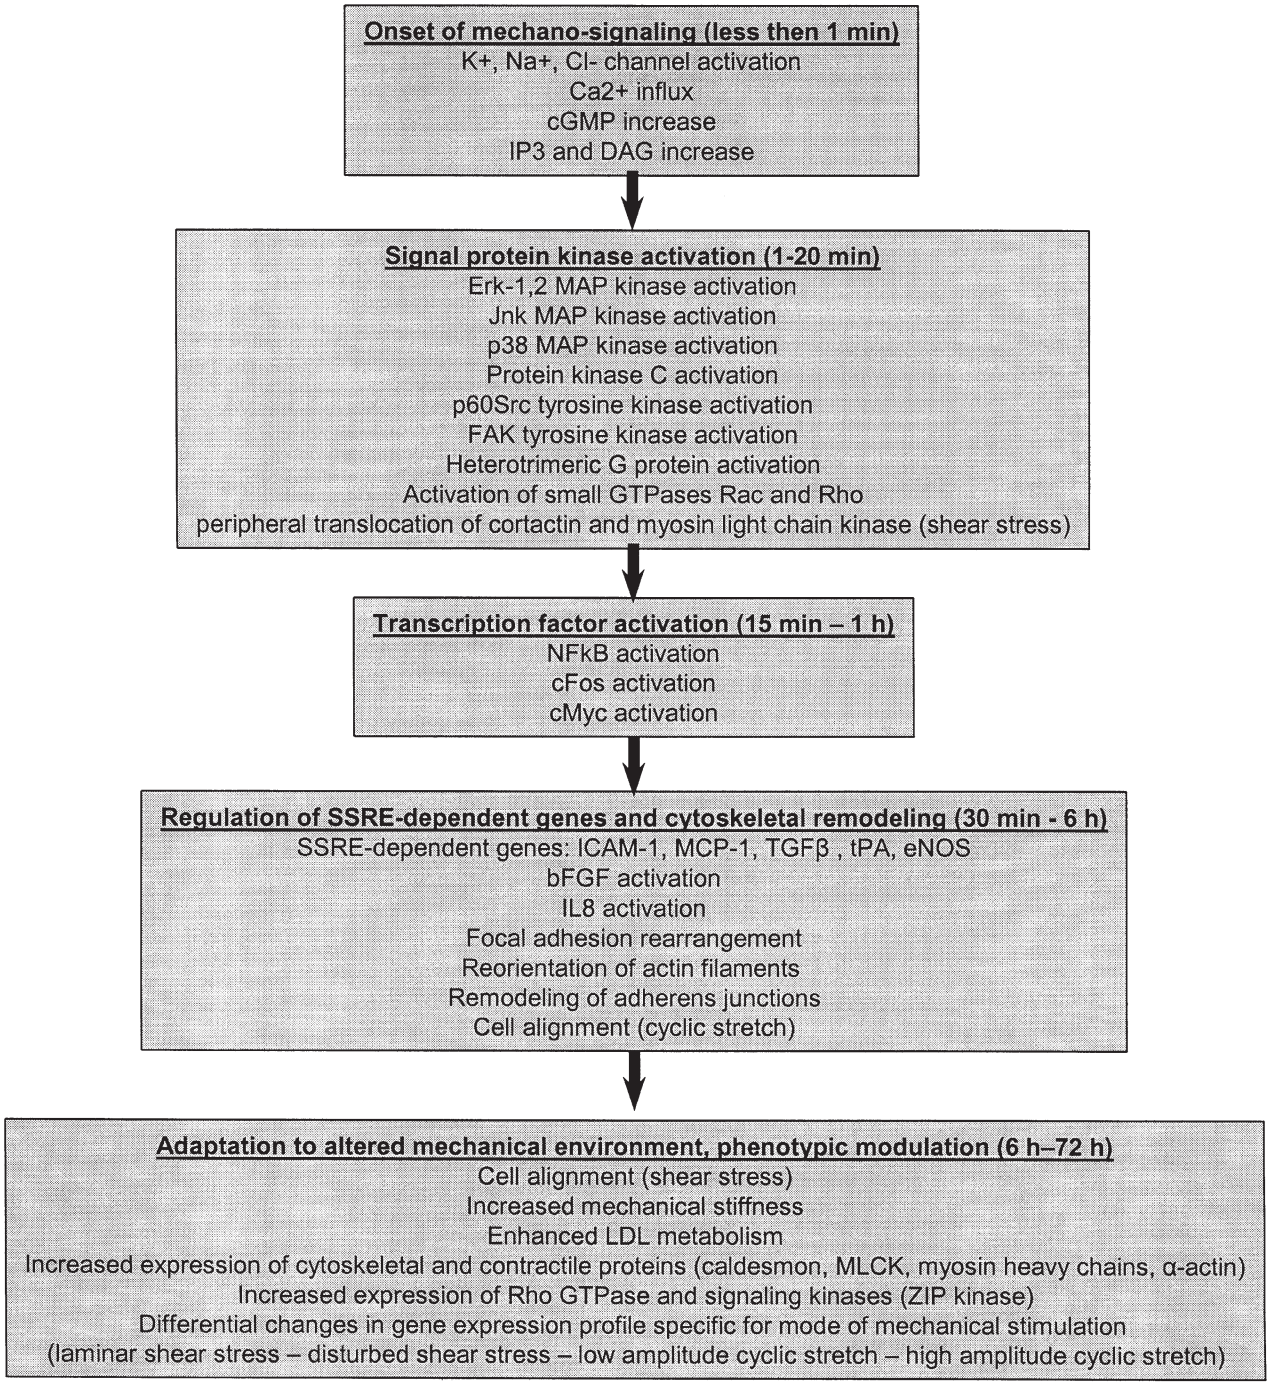

Figure 1 Major signal pathways and cellular responses induced by shear stress and cyclic stretch. Activation of mechanoreceptors triggers multiple signal cascades with ion channels (Na^+ channel, K^+ channel, chloride-selective channel) and heterotrimeric G-proteins (Gαq) being activated within seconds of mechanical stimulation, and protein kinases (protein kinase C, MAP kinases, nonreceptor protein tyrosine kinases) activated within minutes of stimulation. Protein kinase–mediated phosphorylation of specific cytoskeletal and cell contact proteins, other enzymes, and transcription factors induces cytoskeletal remodeling and stimulates gene expression in vascular cells.

remodeling distinct from shear stress. Furthermore, most protein kinases and ion channels involved in mechanochemical signaling exhibit amplitude-dependent activation that may alternatively regulate gene expression described hereafter.

Effect of Mechanical Stimulation on Endothelial Phenotype and Gene Expression Profile

Shear Stress–Regulated Gene Expression

Research on the regulation of endothelial gene expression by flow began more than 10 years ago, when expression of specific proteins and transcription of individual genes was compared between static cultures and cells exposed to laminar or disturbed flow. These studies revealed major groups of shear stress–responsive genes, which include transcription factors, cytokines, growth factors, adhesion molecules, enzymes, and cytoskeletal proteins. Analysis of shear responsive promoters identified to date showed that ability to respond to applied shear stresses can be directly linked to the presence of specific, *cis*-acting sequence elements, termed shear stress responsive elements (SSRE), which were discovered by M. Gimrone's group. Two negative and two positive SSREs within promoter regions of shear stress–regulated genes have been identified so far. In addition, two distinct groups of transcription factors mediate flow-induced induction and suppression of specific gene expression. More recently, endothelial gene regulation by shear stress was documented by several groups using DNA microarray technology [8–11]. These studies compared gene expression profiles in endothelial cells exposed to high-shear steady laminar flow, which represents "atheroprotective" flow conditions, and low-shear, nonsteady, nonunidirectional flow (disturbed flow) that simulates conditions in the atherosclerosis-prone areas of the arterial circulation. As result, thousands of endothelial genes were screened, and more than 100 shear stress–regulated genes including genes with not-yet-known function have been detected. The principal conclusions of these studies were as follows: (1) Acute shear stress transiently activates the expression of genes related to the activation of endothelium; (2) chronic laminar shear stress promotes expression of a subset of endothelial genes that can exert potent antithrombotic, antiadhesive, antiproliferative, and antioxidant effects in endothelial cells; (3) disturbed flow is not simply the absence of laminar flow, but in fact represents a distinct biomechanical stimulus that has profound impact upon the gene expression profile of endothelial cell culture; and (4) under chronic (24 hours) conditions of laminar flow, more genes are suppressed than induced, whereas disturbed flow dramatically induces proatherogenic, proinflammatory genes such as E-selectin, VCAM-1, ICAM1, PECAM-1, thrombospondin, and MCP-1. These findings support the notion about a specific shear stress–mediated EC phenotype that may play an important role in the development of vascular pathologies and responsiveness of the EC monolayer to external chemical and mechanical stimuli.

Cyclic Stretch–Regulated Gene Expression

Similar to flow, mechanical strain is also a potent regulator of gene expression. Phenotypic responses of vascular cells exposed to cyclic stretch in vitro include increased

Table I Selected Genes Differentially Regulated by Low- and High-Amplitude Cyclic Stretch.

	Fold change at 5%	Fold change at 18%
Signal transduction		
Inducible T-cell kinase	—	17.1
Nuclear receptor subfamily 1, group D, member 2	—	3.2
Angiopoietin 2	1.8	2.1
HMG-CoA-synthase	NC	4.0
Proteinase-activated receptor 2	1.4	2.1
Proteinase-activated receptor 1	NC	–1.2
Rho B GTPase	1.87	2.1
Rho C GTPase	NC	1.4
Cell adhesion		
Gap junction protein, alpha 5	—	2.8
Intercellular adhesion molecule 1 (CD54)	NC	2.0
Beta 3 Integrin	1.5	2.1
Beta-catenin	NC	2.1
Cadherin-13	8.5	1.7
Cell–cell signaling		
Placental growth factor, VEGF-related	1.8	2.0
Ephrin A1	1.2	2.1
Ephrin B2	1.7	2.0
Cytoskeleton		
Smooth muscle myosin heavy chain	NC	1.4
Filamin	NC	1.7
Inflammation/remodeling		
Human cyclooxygenase-2	NC	3.0
TGF-β superfamily protein	1.6	2.3
Proteinase-activated receptor 2	1.4	2.1
ZIP-kinase	1.3	1.7

Expression profiling was performed using the Affymetrix GeneChip system. Samples obtained from cells exposed to 5 percent or 18 percent cyclic stretch (48 hours) were hybridized to the Affymetrix HGU95Av2 Array (~12,000 full-length genes). Affymetrix Microarray Suite software was used to determine relative gene expression. GeneSpring and MAPPFinder software was used for microarray data analysis. Results represent fold increase in cDNA signal in cyclic stretch-preconditioned cells over static control. NC, no change; —, signal absent.

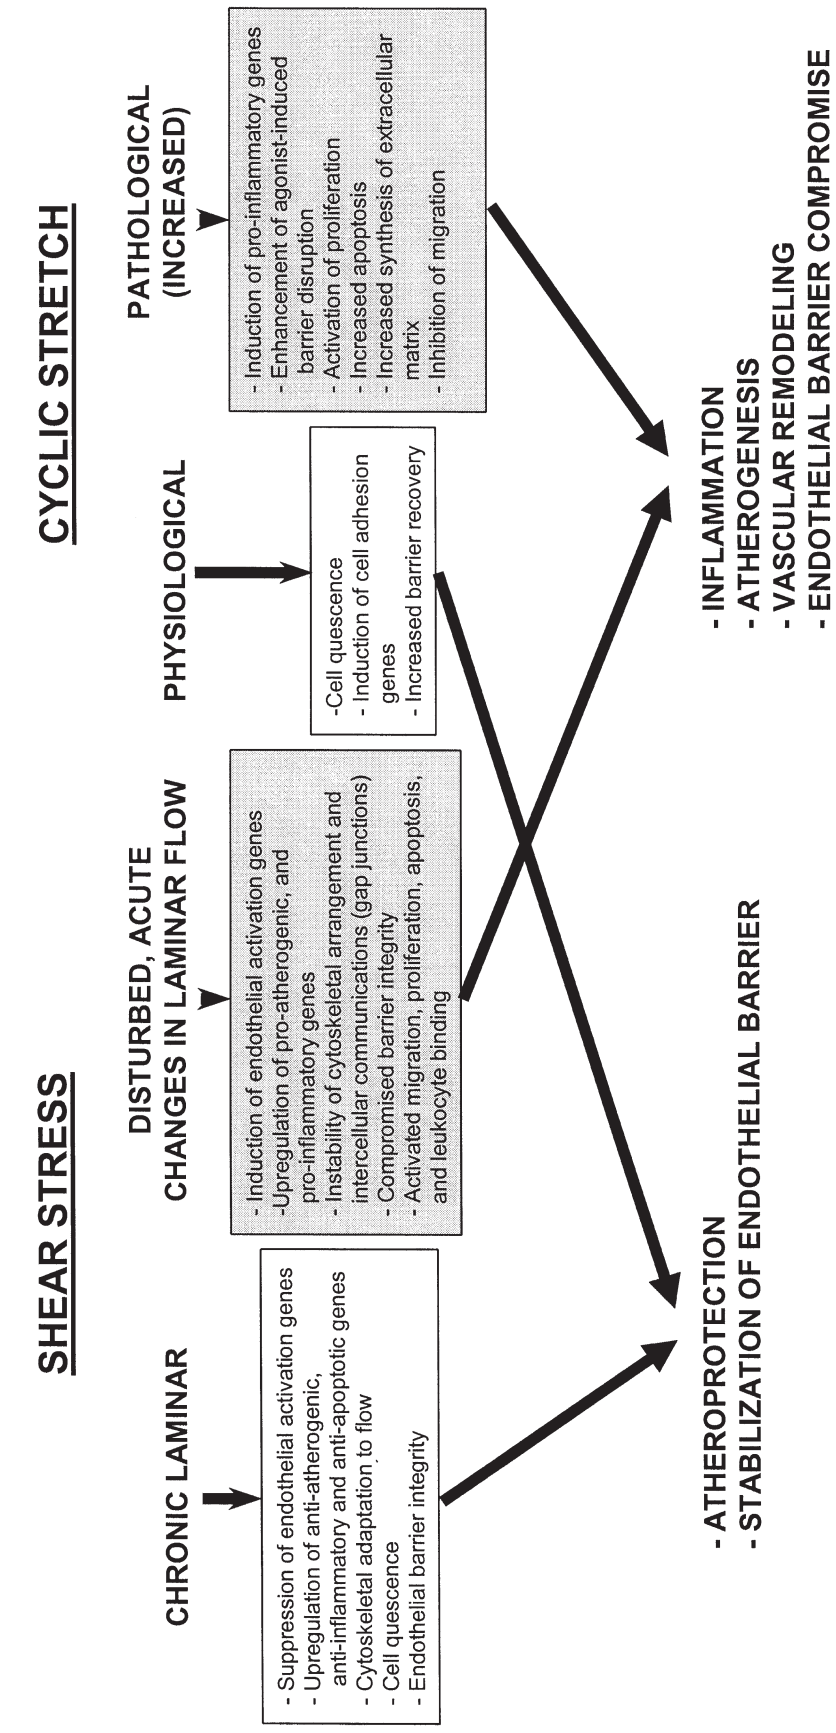

Figure 2 The differential responses of the endothelium to various patterns of shear stress and cyclic stretch. Physiologically relevant laminar shear stress and cyclic stretch promote endothelial cell quiescent state, induce expression of antiatherogenic and anti-inflammatory genes, and promote endothelial barrier integrity and recovery after edemagenic stimuli such as thrombin. In contrast, disturbed flow and pathologically increased amplitudes of cyclic stretch induce endothelial activation, extracellular matrix production, and expression of proinflammatory and apoptotic genes, which may lead to vascular remodeling and propagate endothelial barrier dysfunction, atherogenesis, and inflammatory processes in the vasculature.

expression of contractile and cytoskeletal proteins (myosin light chain kinase, smooth muscle myosin heavy chains, desmin, h-caldesmon) and increased expression of thrombin receptor PAR1 in vascular smooth muscle cells. A number of bioactive proteins regulated by cyclic stretch have been also identified in endothelial cells and macrophages and include IL-8, TGF-beta, VEGF, and monocyte chemotactic protein-1. Analysis of vascular gene expression regulated by mechanical strain reveals differential responses to physiological and pathophysiological (increased) levels of mechanical strain. For example, release of FGF-2, a growth factor involved in cellular repair after injury, is induced in vascular smooth muscle cells stretched at 14 percent and 33 percent elongation, but not at 5 percent elongation. Significant increase in IL-8 production is observed in endothelial cells exposed to cyclic stretch at 15 percent elongation, whereas stretch at 6 percent elongation did not affect IL-8 levels. In pulmonary circulation, pathological overdistension of the lung may induce inflammatory process–triggered mechanical activation of macrophages and epithelial and endothelial cells, which may cause alveolar and endothelial barrier dysfunction and vascular leak and culminate in pulmonary edema. Recently, microarray DNA technologies have been applied to assess time and amplitude dependence of cyclic stretch effects on gene expression profile in human pulmonary endothelial cells [2]. The results showed that cyclic stretch at physiologically relevant and pathological amplitudes (5% and 18% elongation, respectively) induced distinct expression patterns of genes involved in signal transduction, cytoskeletal remodeling, cell adhesion, inflammatory responses, and regulation of endothelial barrier function (Table I).

Concluding Remarks

Shear stress and tensile forces are now well recognized as factors that regulate endothelial signaling, cytoskeletal remodeling, gene expression, and physiological responses. A rapidly growing body of evidence indicates that endothelial cell discriminate between laminar and spatial gradients of shear stress, steady and pulsatile laminar flow, and low- and high-amplitude cyclic stretch. Moreover, the pattern of mechanical stimulation determines whether endothelial cells will develop pro- or anti-inflammatory cell response and also may differentially regulate endothelial barrier properties (Figure 2). Experimental and analytical tools are being developed to assess the stress distribution throughout cell structures that might be involved in mechanotransduction. Further studies will address the role of specific patterns of mechanical forces experienced by endothelium in physiological and pathological conditions (acute injury, inflammation, hypertension, ventilator-induced lung injury) and will identify key cellular targets for drug design and gene therapy.

Glossary

Mechanical strain or stretch: Change in length in relation to initial length.

Shear stress: Force per unit surface area in the direction of flow exerted at the fluid–surface interface.

Stress: Force per unit area.

Capsule Biography

Dr. Konstantin Birukov has been studying the role of mechanical factors in vascular endothelial and smooth muscle cell biology since 1989. His group primarily focuses on mechanochemical regulation of signaling, phenotypic expression and endothelial permeability. His work is supported by grants from the NHLBI and NIH (HL075349, HL076259).

CHAPTER 33

Autacoid Production by Hemodynamic Forces

Ingrid Fleming
Johann Holfgang Goethe-Universität, Frankfurt, Germany

Autacoid Production by Hemodynamic Forces

In all higher organisms the cardiovascular system represents an elaborated transport network, which is essential for the maintenance of vital functions by supplying oxygen and nutrients to tissue and removing by-products of metabolism. In order to adapt to the varying demands of the tissues, the circulatory system has evolved central and local control mechanisms that act in concert to maintain an adequate blood flow. At a given blood pressure, the blood flow to each organ is determined by the peripheral vascular resistance of this organ, which is adjusted by a variety of local mechanisms affecting the tone of the smooth muscle cells in the so-called resistance vessels, that is, small terminal arteries and large and small arterioles. Endothelial cells, situated at the interface between blood and the vessel wall, play a crucial role in controlling vascular tone and homeostasis, particularly in determining the expression of pro- and anti-inflammatory genes. Many of these effects are mediated by the generation and release of endothelium-derived autacoids, which are generally short-lived and locally acting vasoactive compounds. In vivo, endothelial cells are constantly subjected to mechanical stimulation by the viscous drag generated at the luminal surface of endothelial cells by the streaming blood (wall shear stress) and the cyclic strain of the vascular wall, which results from the pulsatile changes in blood pressure. Such stimuli not only determine acute autacoid production but can also affect the expression of autacoid-producing enzymes.

Endothelium-Derived Autacoids

The potential role of endothelial cells in flow-dependent dilation gained considerable interest after the pioneering observation by Furchgott and Zawadzki [1] that the endothelium can actively induce changes in vascular tone by the release of a labile relaxing factor. In fact, an obligatory role of endothelial cells in sensing changes in blood flow signals and transducing them into vasodilator responses was demonstrated in large conduit arteries in situ as well as in arteries in vitro. Furthermore, clinical studies revealed that the flow-dependent dilation, which occurs in different vascular beds in humans, is reduced or even abolished by hypercholesterolemia and arteriosclerosis. Although there are a number of additional endothelium-derived vasodilator and vasoconstrictor autacoids [endothelin-1, prostacyclin (PGI_2), prostaglandin H_2, the superoxide anion (O_2^-), and the endothelium-derived hyperpolarizing factor: EDHF], none of these autacoids play as central a role in the regulation of vascular tone and homeostasis as the free radical nitric oxide (NO).

Nitric Oxide

In endothelial cells NO is generated from the amino acid L-arginine by the endothelial NO synthase (eNOS), which is a constitutively expressed membrane-bound enzyme. Functional eNOS is a homodimer whose activity is determined by its interaction with a group of eNOS-associated proteins that include calmodulin, caveolin-1, and heat shock protein 90 (hsp90), as well as by intracellular levels of Ca^{2+} ($[Ca^{2+}]_i$), and the phosphorylation of several regulatory serine and threonine residues.

Distinct signaling pathways modulate the activity of eNOS in response to agonists and hemodynamic stimulation. Whereas the former is largely a Ca^{2+}-dependent process, the activation of eNOS by fluid shear stress does not require a maintained increase in $[Ca^{2+}]_i$ but is dependent on the activation of the phosphatidylinositol 3-kinase and

the subsequent activation of the serine kinase Akt, which phosphorylates eNOS on Ser^{1177} (Figure 1). This step increases enzyme activity two- to four-fold and thus increases NO production. Provided the stimulus is maintained, Akt remains activated for several hours, as does the production of NO. The NO-dependent relaxation of vascular smooth muscle cells involves the activation of the soluble guanylyl cyclase and the subsequent increase in cyclic GMP levels, which, via the activation of G kinase, elicits a decrease in vascular smooth muscle cell $[Ca^{2+}]_i$.

NO is, however much more than a vasodilator and is generally thought to play a central role in maintaining the endothelium in a noninflammatory phenotype by influencing the activity of several transcription factors and thus attenuating the expression of proinflammatory genes such as the adhesion molecules E-selectin and vascular cell adhesion molecule-1 (VCAM-1). With the progression of vascular disease, NO-dependent vasodilatation becomes impaired, partly as a consequence of the interaction of NO with O_2^- generated by enzymes such as NADPH oxidase, to generate the strong oxidant peroxynitrite ($ONOO^-$) and partly as a consequence of eNOS uncoupling. The latter phenomenon relates to a switch from the production of NO to the generation of O_2^- by eNOS and has been linked to decreased cellular levels of the essential cofactor tetrahydrobiopterin. The consequence of these changes is a decrease in the bioavailability of NO and a reduction in the vasodilator response to agonists such as acetylcholine as well as the activation of redox-sensitive transcription factors (e.g., nuclear factor kappa B [NF-κB]), the activation of which is normally suppressed by NO.

Prostacyclin

Cyclo-oxygenase (COX) is the key enzyme in the synthesis of prostanoids, and two COX isoforms (COX1 and COX-2) have been identified in endothelial cells. Although these enzymes catalyze the same reaction, they have distinct pharmacological profiles and biological roles. COX-1 is constitutively expressed in endothelial cells, whereas COX-2 is expressed in other cell types in response to proinflammatory stimuli. The availability of the COX substrate, arachidonic acid, which is released from membrane phospholipids by phospholipase A_2 (PLA_2), is the rate-limiting step in prostaglandin synthesis, and PGI_2 is the major product of the subsequent COX pathway in all arterial and venous endothelial cells studied so far. As a consequence of the Ca^{2+} sensitivity of PLA_2, the synthesis of PGI_2 by endothelial cells is a Ca^{2+}-dependent process. This codependency on Ca^{2+} means that in many circumstances NO, PGI_2, and EDHF can be generated simultaneously.

The apparent redundancy in the major vasoactive autacoid generating pathways means that the loss of one vasodilator can be compensated for by one of the others. For

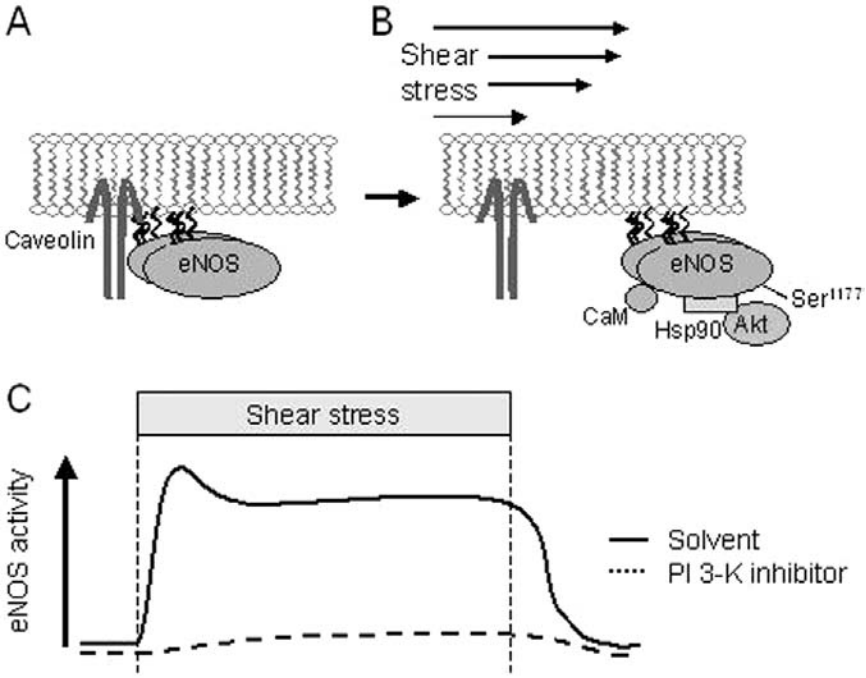

Figure 1 Endothelial cell activation by fluid shear stress increases eNOS phosphorylation and activity. In unstimulated endothelial cells the eNOS dimer is associated with caveolin, which inhibits its activation, which means that NO output is low **(A)**. In response to the application of fluid shear stress, the phosphatidylinositol 3-kinase (PI 3-K) is activated and in turn activates Akt, which associates with the eNOS scaffolding protein hsp90 and phosphorylates eNOS on Ser^{1177} **(B)**. This step elicits the dissociation from caveolin and increases NO production. Shear stress–induced increases in endothelial NO production can be abrogated by preventing the activation of PI 3-K **(C)**. (see color insert)

example, in wild-type mice flow-dependent vasodilatation in gracilis muscle arterioles appears to be mediated by NO. However, in male eNOS$^{-/-}$ mice, flow-induced vasodilatation of these arterioles can be attributed to the generation of PGI_2.

The Endothelium-Derived Hyperpolarizing Factor

In various blood vessels, endothelium-dependent relaxations can be accompanied by the endothelium-dependent hyperpolarization of smooth muscle cells. These endothelium-dependent relaxations and hyperpolarizations can be partially or totally resistant to inhibitors of COX and NO synthases and could be observed without an increase in intracellular levels of cyclic nucleotides in the smooth muscle cells. Therefore the existence of an additional pathway that involves smooth muscle hyperpolarization was suggested and attributed to an endothelium-derived hyperpolarizing factor. The contribution of EDHF-mediated responses as a mechanism for endothelium-dependent relaxation increases as the vessel size decreases, apart from the coronary and renal vascular beds in which EDHF also plays a major role in conduit arteries. Different mechanisms appear to underlie EDHF-mediated responses in different arteries; however, experimental evidence favors three explanations for the EDHF phenomenon (Figure 2):

1. K^+ ions are released from stimulated endothelial cells through Ca^{2+}-activated K^+ (K_{Ca}) channels and subsequently elicit relaxation by activating K^+ channels and/or the Na^+/K^+-ATPase on vascular smooth muscle cells, thus inducing hyperpolarization and decreasing the open probability of voltage-operated Ca^{2+} channels, through which the Ca^{2+} required for contraction enters the cell.
2. An increase in endothelial $[Ca^{2+}]_i$ triggers the activation of a phospholipase A_2 that liberates arachidonic acid from membrane phospholipids. The arachidonic acid is then metabolized by cytochrome P450 epoxygenase(s) to epoxyeicosatrienoic acids (EETs), which either contribute to the hyperpolarization of endothelial cells or are released from endothelial cells to activate K^+_{Ca} channels on underlying vascular smooth muscle cells.
3. Direct transfer of an electrical signal (i.e., endothelial cell hyperpolarization) to vascular smooth muscle cells via myo-endothelial gap junctions. This mechanism appears to be particularly important in the microcirculation.

The majority of the work performed to date that has led to the characterization of EDHF-mediated responses has involved the use of receptor-dependent agonists such as acetylcholine and bradykinin. However, the limited studies that have addressed the response to hemodynamic stimuli suggests that pulsatile stretch is a particularly important stimulus for the generation of EDHF. This phenomenon may be related to the fact that pulsatile stretch elicits much larger and more prolonged increases in $[Ca^{2+}]_i$ in endothelial cells than fluid shear stress does. Indeed, K_{Ca} channel-dependent hyperpolarization is preferentially stimulated by pulsatile flow as opposed to steady flow, and pulsatile stretch/cyclic strain has been reported to increase the generation of EETs by native porcine coronary endothelial cells as well as to increase the expression of the EET-generating cytochrome P450 epoxygenase.

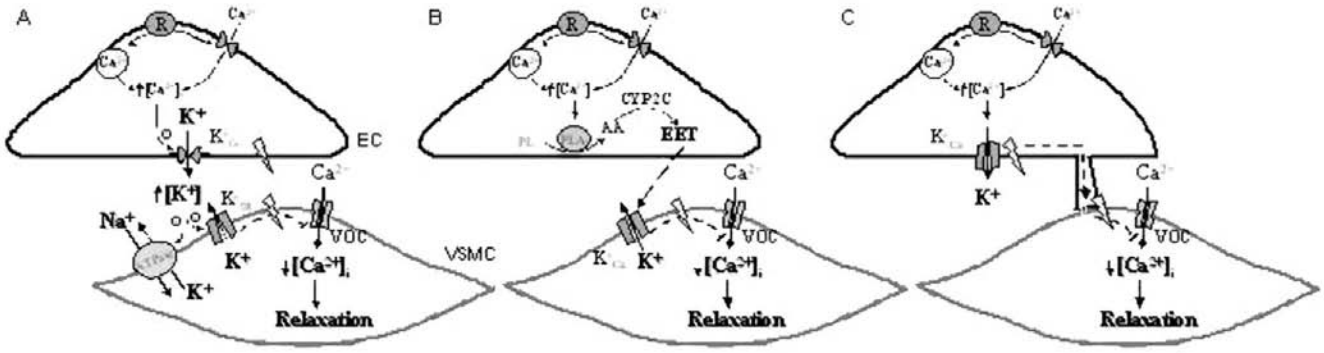

Figure 2 Three models contributing to endothelium-derived hyperpolarizing factor-mediated relaxation. **(A)** The K^+ ion hypothesis. In response to the receptor (R)-dependent activation of endothelial cells (EC), intracellular concentration of Ca^{2+} ($[Ca^{2+}]_i$) increases and activate Ca^{2+}-dependent K^+ (K^+_{Ca}) channels, which results in the efflux of K^+ ions into the subintimal space and endothelial cell hyperpolarization (lightning symbol). The increase in extracellular K^+ activates inwardly rectifying K^+ channels (K^+IR) and/or the Na-K-ATPase which elicit vascular smooth muscle cell (VSMC) hyperpolarization and decrease the open probability of voltage-dependent Ca^{2+} (VOC) channels. As a consequence $[Ca^{2+}]_i$ in the smooth muscle cells decreases and relaxation occurs. **(B)** The cytochrome P450 hypothesis. An increase in $[Ca^{2+}]_i$ activates a phospholipase A_2, which liberates arachidonic acid (AA) from membrane lipids. Arachidonic acid is then metabolized to epoxyeicosatrienoic acids (EETs) by a cytochrome P450 2C (CYP 2C) epoxygenase. EETs then increase the open probability of K^+_{Ca} in the underlying smooth muscle cells to elicit hyperpolarization and relaxation. **(C)** The gap junction hypothesis. Endothelial cell activation as described elicits endothelial cell hyperpolarization by activating K^+_{Ca} channels. This hyperpolarization is, however, transferred to smooth muscle cells via myo-endothelial gap junctions rather than by the release of an endothelium-derived factor. The final steps are the same, that is, inhibition of Ca^{2+} entry into smooth muscle cells and relaxation. (see color insert)

Hemodynamic Forces and the Endothelium

Shear Stress

Blood flow through a vascular segment generates a viscous drag at the luminal surface of endothelial cells (Figure 3), which can be expressed as shear stress (τ) and calculated according to Poiseuille's law:

$$\tau = 4\eta Q/r4\pi$$

(where η = viscosity, Q = blood flow, r = internal vessel radius).

This relation highlights the fact that relatively small decreases in vessel diameter at constant flow can markedly increase shear stress at the endothelial surface. It should be noted, however, that shear stress is calculated under the assumption that the flow profile is parabolic, a situation that is never realized in vivo because of the pulsatile nature of blood flow and the fact that blood vessels are distensible. Branching and bifurcations along the vascular tree together with a gradual decrease in diameter also disfavor the establishment of a stable flow profile.

Pulsatile Stretch/Cyclic Strain

Although it is sometimes assumed that pressure per se is a proper physiological stimulus for the vascular wall, it must be emphasized that the application of pressure in the physiological range (below 1 atm) to a tissue that is essentially incompressible because of its high water content has no direct effect on cell function. Rather, the pressure exerted on a compliant tissue elicits deformation, that is, either distension (stretch) or compression. As a result of pulsatile pressure changes, cells within the vascular wall are subjected to three-dimensional cyclic strain in the radial, longitudinal, and circumferential directions. There are also cell–cell-generated forces that are influenced by hemodynamic stimuli but that cannot be expressed by a simple physical relationship. One example is the isometric contraction in which the development of contractile force within the smooth muscle cell layer counteracts the distending transmural pressure. Under such conditions there is a relative displacement of opposing cell layers within the vascular wall (e.g., smooth muscle cells versus elastic lamina and endothelial cells), despite the fact that no net movement occurs. Although the displacement induced may be subtle, the close physical arrangement of endothelial focal adhesion contacts and the smooth muscle would tend to suggest that the forces developed at the abluminal surface of endothelial cells may be greater than those generated by shear stress on the luminal surface.

In principle, the relative contribution of pulsatile stretch and wall shear stress to the adjustment of local vascular tone is likely to depend on a number of factors including vessel

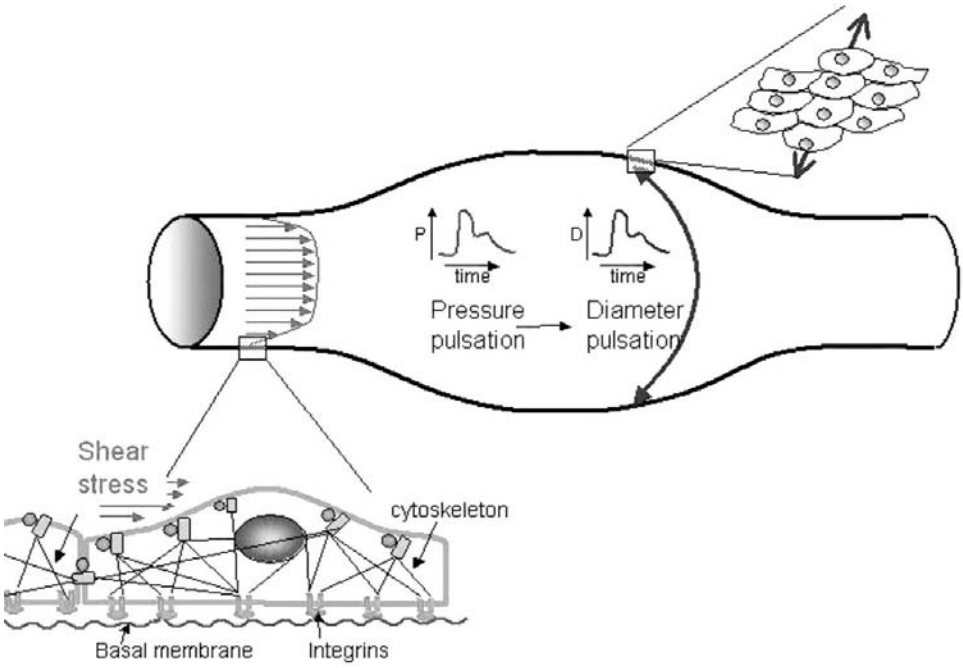

Figure 3 Scheme illustrating the hemodynamic forces affecting endothelial cells. Note that, because of the pulsatile nature of flow, the flow profile is flattened compared to the parabolic flow profile present under steady-state conditions, resulting in a greater shear stress at the endothelial cell surface. The simultaneous pressure (P) pulse distends the vessel diameter (D) and stretches endothelial cells in the range of 1–5% strain. These stimuli result in a redistribution of force across the endothelial cell cytoskeleton and the activation of signaling molecules (including integrins) at the abluminal and luminal cell surfaces as well at sites of cell-cell contact. Adapted from Busse, R., and Fleming, I. (2003). Regulation of endothelium-derived vasoactive autacoid production by hemodynamic forces. *Trends Pharmacol. Sci.* **24**, 24–29, reprinted with permission from Elsevier Science Ltd. (see color insert)

architecture, moment-to-moment changes in smooth muscle activity, and the ability of endothelial and smooth muscle cells to sense hemodynamic stimuli and to produce vasoactive factors. Although it is tempting to break down hemodynamically generated forces into singular physical components such as circumferential stretch/strain and wall shear stress, it must be emphasized that such a procedure is purely theoretical, as changes in pulsatile stretch and shear stress are inextricably linked.

Mechanochemical Coupling

The term mechanochemical coupling describes how endothelial cells translate physical stimuli into intracellular signals and ultimately into changes in autacoid production. Initially, one or more mechanoreceptors were suggested to sense changes in fluid shear stress at the endothelial cell surface; however, the endothelial cell cytoskeleton itself can be regarded as a mechanoreceptor. The cytoskeletal frame of an endothelial cell is composed of actin filaments, intermediate filaments, and microtubules that transverse the cells and end in characteristic adhesion complexes at the luminal cell surface (caveolae), at the abluminal surface (focal adhesion points), or at cell–cell boundaries. Signaling molecules are clustered around and inherent in these sites so that it is conceivable that fluid shear stress acting on the luminal surface of the endothelial cell is transmitted through the entire cell by the cell cytoskeleton to activate signal transduction cascades in specific signaling hot spots.

Other possible mechanisms by which endothelial cells may sense shear stress are through mechanosensitive ion channels and the glycocalyx, a layer of glycoproteins extending into the extracellular space, which may be displaced by shear stress to elicit an intracellular response. Alternatively, flow induces changes in the concentrations of endothelial agonists (e.g., ATP, ADP, and bradykinin) in the unstirred boundary layer at the cell surface, and thus may affect intracellular signaling pathways.

Integration of the Vascular Response (Ascending Dilatation)

The resistance network that controls blood flow to skeletal muscle comprises terminal arterioles, as well as larger arterioles and the small (feeder) arteries from which they derive. In small (terminal) arterioles the products of energy metabolism are effective dilators, but the accumulation of metabolites alone has relatively little effect on vascular resistance. The reason for this is that in order to achieve optimal vascular conductance, both small arterioles and the larger arterioles feeding them must dilate in concert. More than 70 years ago the German physician A. Schretzenmayer provided the first experimental evidence for flow-induced dilation. In the hind legs of anesthetized cats he showed that whenever blood flow to the leg was increased, there was a concomitant increase in the diameter of the feeding femoral artery. It was concluded that this flow-dependent dilator response, which improves conductivity of feeding vessels, was due to a tissue-derived signal transmitted along the vascular tree. Since distal transection did not impede the dilation of conduit arteries in response to flow, it became evident that this dilator response was a locally generated phenomenon of the vascular wall. Further studies led to the concept of an “ascending or conducted dilation” in conduit arteries under conditions of high tissue oxygen demand. This coordinated longitudinal transmission of vasomotor responses is essential for the optimization of vascular conductivity and organ perfusion.

Experimentally, ascending dilatation can be studied in vivo and in vitro by assessing the response to a vasoactive substance at the point of application (local response) as well as at a remote site. This conducted vasodilatation can travel bidirectionally and the amplitude of the conducted vasodilatation is generally smaller than that of the local response. Although there is a gradual decline in the conducted vasodilatation along some arterioles, there is no obvious decay of the conducted response along feed arteries.

Conducted responses have been intensively investigated, but the exact mechanism remains to be clarified. Most researchers agree that NO does not play a major role in this response. Indeed, conducted vasodilatation in response to a number of stimuli is not affected by NOS inhibitors and the response is apparently intact in eNOS-deficient mice. Changes in membrane potential appear to be central to the phenomenon of ascending dilatation, and responses are generally attributed to the propagation of a hyperpolarization along the vascular wall that is linked either to the actions of an EDHF or to the direct transmission of an electrical signal between vascular cells. Over the past few years evidence has accumulated to suggest that homocellular as well as heterocellular gap junctional communication are involved in the phenomenon of conducted dilatation.

At this point, it is necessary to note that not all vessels within one vascular bed respond in the same way in response to an accumulation of vascular metabolites or to mechanical stimuli (transmural pressure and shear stress). Metabolic control exerts a dominant influence on the smallest arterioles (< 20 μm), but is a generally less important stimulus in more upstream vessels. The pressure-induced myogenic response dominates in middle-sized arterioles, whereas its influence wanes upstream in relatively large arterioles (100–200 μm) in which fluid shear stress predominantly governs tone.

Glossary

Ascending dilation: In a contracting skeletal muscle, low PO_2 and vasoactive metabolites elicit a local response and initiate a conducted vasodilatation that “ascends” the vascular tree to induce the simultaneous vasodilatation of the feed arteries as well as branch arteries and thus increase blood flow. This coordinated longitudinal transmission of vasomotor responses is essential to achieve optimal organ perfusion.

Autacoid: From the Greek *autos* [self] and *akos* [remedy]. Endothelium-derived autacoids such as NO, PGI_2, and O_2^- are generally short-lived and locally acting.

Endothelium-derived hyperpolarizing factor: Describes endothelium-dependent relaxation that is not mediated by either nitric oxide or prostacyclin but is temporally correlated with endothelial cell hyperpolarization and followed shortly thereafter by smooth muscle cell hyperpolarization and relaxation.

Myogenic tone: An intrinsic mode of control of activity in which the stretch of the vascular smooth muscle cell membrane results in the activation of stretch-sensitive channels. The result is depolarization and contraction.

Capsule Biography

Ingrid Fleming (although from Northern Ireland) is a Professor of Physiology at the Johann Wolfgang Goethe University in Frankfurt. Her research interests center on signal transduction in vascular cells, in particular on the regulation of nitric oxide synthase activity and the phenomenon of nitric oxide/prostacyclin or endothelium-derived hyperpolarizing factor (EDHF)-mediated vascular relaxation.

CHAPTER 34

Ion Channels and Arteriolar Tone

William F. Jackson
Michigan State University, East Lansing, Michigan

Introduction

Arteriolar tone refers to the degree of contraction of smooth muscle cells that wrap around these microvessels. Smooth muscle contractile activity (i.e., arteriolar tone) determines the diameter of the arteriolar lumen, which, in turn, sets the hydraulic resistance of these microvessels to blood flow. Thus, arteriolar tone importantly contributes to regulation of systemic vascular resistance and blood pressure; the distribution of blood flow to and within the body's tissues and organs; and regulation of solute and water exchange in downstream capillaries and venules. Arteriolar smooth muscle cells integrate a myriad of excitatory and inhibitory stimuli from blood pressure, circulating hormones, neurotransmitters, local metabolites, and endothelium-derived factors to determine arteriolar tone, and hence arteriolar diameter and resistance. Ion channels, proteins that form ion-selective, water-filled pores in the plasma membrane of cells, in both smooth muscle and endothelial cells, play a central role in determining and regulating arteriolar tone. Ion channels provide the major source of intracellular Ca^{2+} that activates contractile proteins in smooth muscle and stimulates the synthesis and release of vasoactive substances from endothelial cells. In addition, ion channels significantly contribute to the determination and regulation of membrane potential. Membrane potential, in turn, modulates Ca^{2+} influx through ion channels, the release of Ca^{2+} from intracellular stores, and cell Ca^{2+} sensitivity. Ion channel–mediated changes in membrane potential also are transmitted along microvessels to modulate arteriolar tone at distant sites. Thus, ion channels participate in all aspects of regulation of arteriolar tone.

Ion Channels Expressed in Arterioles

Vascular smooth muscle and endothelial cells in the wall of arterioles express a large number of ion channels (Table I). These include one or more varieties of voltage-gated Ca^{2+} channels, at least four different classes of K^+ channels, several types of nonselective cation channels and at least two classes of Cl^- channels. All of these channels arise from multigene families that also display splice variation. Table I shows the isoforms of channel proteins that are thought to underlie the ion channels present in arteriolar vascular smooth muscle and endothelium. In addition, blockers or inhibitors of the channels are shown. Please note that with the exception of a few substances, such as the scorpion toxin, iberiotoxin, that selectively blocks large-conductance Ca^{2+}-activated K^+ channels, most of the substances listed show only limited selectivity. For example, all of the inhibitors of Ca^{2+}-activated and swelling-activated Cl^- channels also inhibit voltage-gated Ca^{2+} or nonselective cation channels, such that their use in functional studies is very limited.

Voltage-Gated Ca^{2+} Channels

Voltage-gated Ca^{2+} channels in smooth muscle cells play a major role in the regulation of arteriolar tone. Importantly, they transduce changes in vascular smooth muscle membrane potential (produced by other ion channels and transporters) into changes in Ca^{2+} influx and intracellular Ca^{2+}. Signals that depolarize smooth muscle open voltage-gated Ca^{2+} channels, allowing Ca^{2+} to diffuse into cells down their electrochemical gradients, raising intracellular Ca^{2+}, leading to smooth muscle contraction and increased arteriolar tone. Conversely, hyperpolarization of smooth muscle closes these channels, reducing intracellular Ca^{2+} and leading to decreases in arteriolar tone.

The dominant voltage-gated Ca^{2+} channels expressed in vascular smooth muscle cells are nifedipine-sensitive, L-type Ca^{2+} channels that begin to activate at −50 mV under physiological conditions. Smooth muscle cells in some arterioles also express other types of voltage-gated Ca^{2+} channels. These include T-type channels that are insensitive to

Table I Ion Channels in Arteriolar Smooth Muscle and Endothelial Cells.

Ion channel[a]	VSM[b]	ENDO[c]	Additional subunits	Conductance (pS)	Primary stimuli	Inhibitor(s)[d]
L-type Ca^{2+}	CaV 1.2b	— or ?[e]	β, $\alpha_2\delta$	25	Depolarization (> −50 mV)	Nifedipine, diltiazem, verapamil, $Cd^{2+} > Ni^{2+}$

nifedipine, activate at very negative membrane potentials (−70 mV), and inactivate rapidly, and nifedipine-insensitive, high voltage-activated Ca^{2+} channels (R-type Ca^{2+}) with activation properties similar to those of L-type channels.

The presence of voltage-gated Ca^{2+} channels in endothelial cells remains controversial. Studies of endothelial cells from conduit arteries have uniformly failed to demonstrate their presence. However, a few studies of microvascular endothelial cells have demonstrated the presence of both L-type and T-type voltage-gated Ca^{2+} channel currents. The generality of these findings has not been established and the physiological function of endothelial cell voltage-gated Ca^{2+} channels in the regulation of arteriolar tone is unknown.

K^+ Channels

Arteriolar smooth muscle cells express at least four different classes of K^+ channels in their membranes. These include large conductance, Ca^{2+}-activated K^+ (BK_{Ca}) channels, several types of voltage-gated K^+ (K_V) channels, ATP-sensitive K^+ (K_{ATP}) channels, and inward rectifier K^+ (K_{IR}) channels. All appear to contribute to the regulation of arteriolar tone in the microcirculation. As in other cells in the body, K^+ channels play a major role in determining membrane potential. Opening of K^+ channels causes K^+ ions to diffuse out of cells, down their electrochemical gradients. This loss of positive charge causes membrane hyperpolarization, closure of voltage-gated Ca^{2+} channels, and decreased arteriolar tone. Conversely, closure of open K^+ channels leads to membrane depolarization and opening of voltage-gated Ca^{2+} channels, leading to increased arteriolar tone.

Microvascular endothelial cells also express multiple types of K^+ channels including two types of Ca^{2+}-activated K^+ channels, K_V channels, K_{ATP} channels, and K_{IR} channels. These K^+ channels also significantly contribute to the regulation of membrane potential in endothelial cells that, itself, can act as a signal to regulate arteriolar tone (see later discussion). In addition, membrane potential determines the

electrochemical gradient for Ca^{2+} influx through nonselective cation channels, that contributes to the production of endothelium-derived vasodilators such as NO, prostacyclin, and epoxides of arachidonic which also participate in the regulation of arteriolar tone (see Figure 4). Potassium channels also may allow changes in membrane potential to be conducted, in a nondecremental fashion, along the length of arterioles, further contributing to the regulation of arteriolar tone.

BK_{Ca} CHANNELS

Large-conductance, Ca^{2+}-activated K^+ channels represent one of the most abundant K^+ channels expressed in smooth muscle membranes. These channels open with membrane depolarization and increases in intracellular Ca^{2+} and are modulated by a number of cell signaling pathways. They play a major role in the negative feedback regulation of smooth muscle membrane potential during vasoconstriction (see Figure 2) and participate in the mechanism of action of several vasodilators (see Figure 3). Like many ion channels, BK_{Ca} channels exist in signaling complexes with voltage-gated Ca^{2+} channels, protein kinases (protein kinase A, cGMP-dependent protein kinase, protein kinase C), phosphatases, and other signaling proteins (Figure 1). These macromolecular signaling complexes also appear to be located adjacent to smooth endoplasmic reticulum Ca^{2+}-activated, Ca^{2+}-release channels (ryanodine receptors, RYR) such that focal release of Ca^{2+} from RYR triggered by Ca^{2+} influx through voltage-gated Ca^{2+} channels (i.e., Ca^{2+} sparks) can activate BK_{Ca} channels in smooth muscle. Microvascular endothelial cells likely do not express BK_{Ca} channels in vivo.

sK_{Ca} AND IK_{Ca} CHANNELS

Native endothelial cells in arterioles express two types of Ca^{2+}-activated K^+ channels: small conductance, sK_{Ca} channels, and intermediate conductance, IK_{Ca} channels that are distinct from BK_{Ca} channels. These channels are responsible for agonist-induced hyperpolarization of endothelial cells and thus play an important role in regulation of arteriolar tone. In addition to having much smaller single channel conductances, both channels are insensitive to the highly selective BK_{Ca} channel blocker, iberiotoxin, and are not voltage-gated such that they are easily distinguished from BK_{Ca} channels. Both sK_{Ca} and IK_{Ca} channels require calmodulin to display Ca^{2+}-dependent modulation, unlike BK_{Ca} channels that bind Ca^{2+} directly.

K_V CHANNELS

Arteriolar smooth muscle cells express a number of different K_V channels and there are species and regional differences in the specific gene products that are expressed. As their name implies, K_V channels are activated by membrane depolarization. These channels participate in the regulation of resting membrane potential, the negative feedback regulation of membrane potential during vasoconstriction (Figure 2), and may participate in the mechanism of action of both vasoconstrictors (Figure 2) and vasodilators (Figure 3). As noted in Table I, most K_V channels expressed in arteriolar smooth muscle can be blocked by aminopyridines such as 4-aminopyridine. In addition, KV 1 family members can be selectively inhibited by the triterpene correolide. Agitoxin-2 also blocks KV 1 family channels with the notable exception of KV 1.5 and can be used to distinguish between KV 1.5 and other KV 1.X–mediated responses. Microvascular endothelial cells also may express K_V channels that function in the negative feedback regulation of membrane potential to limit depolarization.

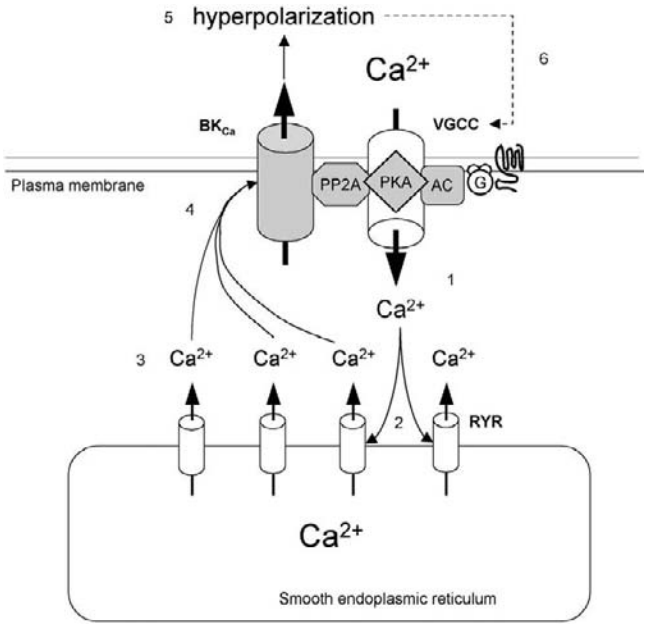

Figure 1 Ion channels form signaling complexes. Simplified schematic diagram of a signaling complex in a smooth muscle cell consisting of voltage-gated Ca^{2+} channels (VGCC), G-protein-coupled receptors, adenyl cyclase (AC), protein kinase A (PKA), protein phosphatase 2A (PP2A), and large-conductance Ca^{2+}-activated K^+ channels (BK_{Ca}). The VGCC and BK_{Ca} channels are functionally coupled to ryanodine receptors (RYR) in the membranes of smooth endoplasmic reticulum (SER) adjacent to the plasma membrane. **1**, Ca^{2+} influx through VGCC increases local Ca^{2+} concentration in the sub-plasmalemmal space. **2**, This local increase in Ca^{2+} triggers Ca^{2+}-induced Ca^{2+} release from the SER through RYR. **3**, This Ca^{2+} release results in a focal increase in subplasmalemmal Ca^{2+} (a Ca^{2+} spark). **4**, The Ca^{2+} spark, along with Ca^{2+} entry through VGCC activates BK_{Ca} channels. **5**, The resultant K^+ efflux hyperpolarizes the membrane. **6**, The hyperpolarization closes VGCC providing negative feedback control of the system.

K_{ATP} CHANNELS

Both arteriolar smooth muscle and endothelial cells express K_{ATP} channels. These channels open when intracellular ATP levels decrease; hence their name. However, they also may be activated by elevated nucleotide diphosphates, reduced intracellular pH, and phosphorylation by protein kinase A (PKA) and cGMP-dependent protein kinase (PKG). In both smooth muscle and endothelial cells, they may act as sensors of the metabolic status of cells, opening during ischemic or hypoxic conditions in response to

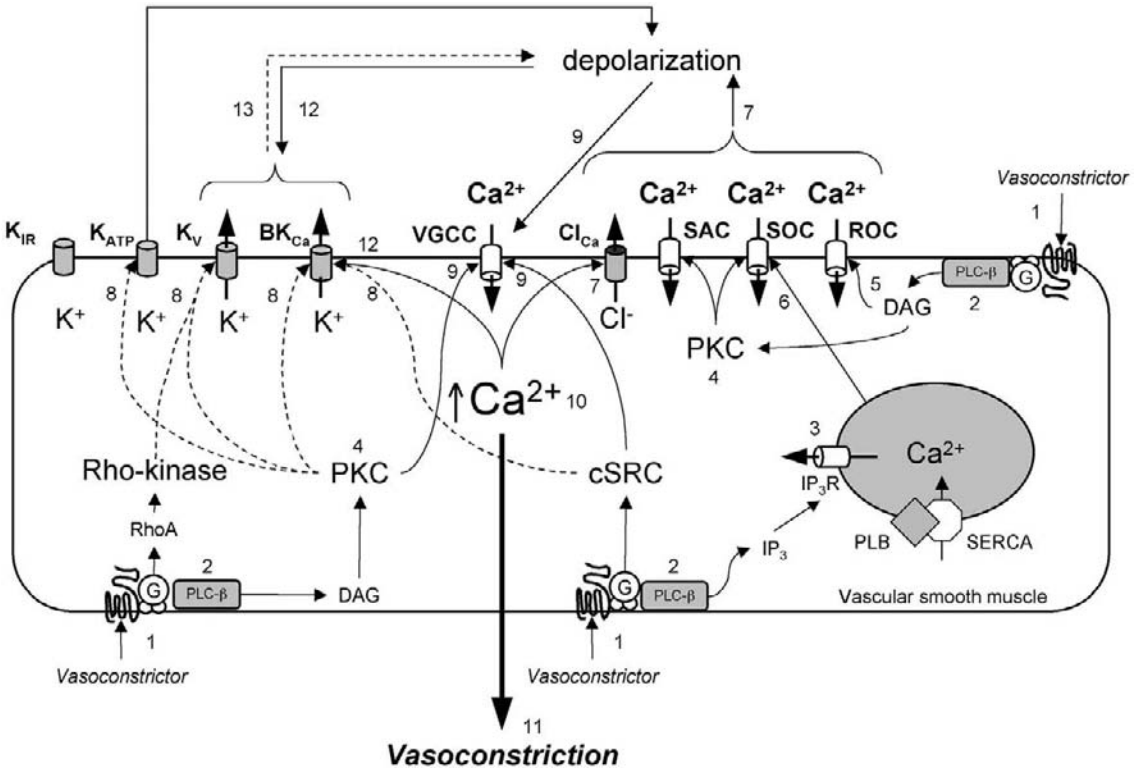

Figure 2 Ion channels and vasoconstriction. Simplified schematic diagram showing the role played by ion channels in contraction of arteriolar smooth muscle cells. Solid lines and arrows indicate stimulatory effects, whereas dashed lines represent inhibitory effects. **1**, Vasoconstrictors such as norepinephrine, angiotensin II, vasopressin or endothelin, bind to G-protein-coupled receptors to activate effector proteins such as phospholipase C-β (PLC-β). **2**, Activated PLC-β then acts on membrane phospholipids to form inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). **3**, IP_3 binds to IP_3 receptors (IP_3R) on the smooth endoplasmic reticulum, releasing stored Ca^{2+}, and raising intracellular Ca^{2+}. **4**, The DAG formed and the presence of increased $[Ca^{2+}]_{in}$ activate protein kinase C, which then phosphorylates a number of ion channels including store-operated channels (SOC), stretch-activated channels (SAC), voltage-gated Ca^{2+} channels (VGCC), ATP-sensitive K^+ channels (K_{ATP}), voltage-gated K^+ channels (K_V), and large-conductance Ca^{2+}-activated K^+ channels (BK_{Ca}). **5**, In addition to activating PKC, DAG also can activate receptor-operated channels (ROC). **6**, The release of Ca^{2+} from intracellular stores, through, or in addition to, activation by PKC, opens SOC channels. **7**, The influx of Ca^{2+} and Na^+ through SAC, SOC, and ROC, along with Cl^- efflux through Ca^{2+}-activated Cl^- channels (Cl_{Ca}), depolarizes the smooth muscle cell membrane. **8**, This depolarization is supported by PKC-dependent closure of K_{ATP} channels, K_V channels, and BK_{Ca} channels, Rho-kinase-dependent inhibition of K_V channels, and downregulation of BK_{Ca} channels by the tyrosine kinase cSRC. **9**, Membrane depolarization along with stimulatory effects of PKC and cSRC on VGCC open these channels and provide a major source of steady-state Ca^{2+} influx. **10 and 11**, The released Ca^{2+}, along with Ca^{2+} influx through SAC, SOC, ROC, and VGCC, raise intracellular Ca^{2+} leading to smooth muscle contraction and vasoconstriction. **12**, The increase in $[Ca^{2+}]_{in}$ along with membrane depolarization activate BK_{Ca} channels, and the depolarization also activates K_V channels. **13**, The resulting efflux of K^+ provides a negative feedback signal that limits membrane depolarization and appears to prevent overactivation of the muscle and vasospasm. Other abbreviations: PLB, phospholamban; SERCA, smooth endoplasmic reticulum Ca^{2+} ATPase.

elevated ADP, reduced ATP, and reduced intracellular pH. Endogenous vasodilators such as adenosine, prostacyclin, epinephrine acting through β-adrenergic receptors, and calcitonin-gene-related peptide (CGRP) open these channels (Figure 3), whereas vasoconstrictors tend to close K_{ATP} channels (Figure 2). In skeletal muscle and coronary arterioles they play an important role in the regulation of smooth muscle resting membrane potential and tone, participate in functional hyperemia, and mediate, in part, hypoxia-induced vasodilation in these tissues.

K_{IR} Channels

Arteriolar smooth muscle and endothelial cells also express K_{IR} channels. These channels open with small, physiological increases in extracellular K^+ concentration (Figure 3) and may participate in functional hyperemia in skeletal muscle, cardiac muscle, and the brain. As implied by their name, K_{IR} channels show strong inward rectification due to intracellular block of the outward current flow through the ion-conductive pore by Mg^{2+} and polyamines at membrane potentials positive to the K^+ equilibrium potential. More importantly, these channels may display an "N"-shaped current–voltage relationship such that between the potassium equilibrium potential and potentials 10 to 20 mV more positive, K_{IR} channels conduct small outward K^+ currents. It is these small outward currents that allow K_{IR} channels to contribute to the regulation of arteriolar tone. Endothelial K_{IR} channels also are stimulated by increased

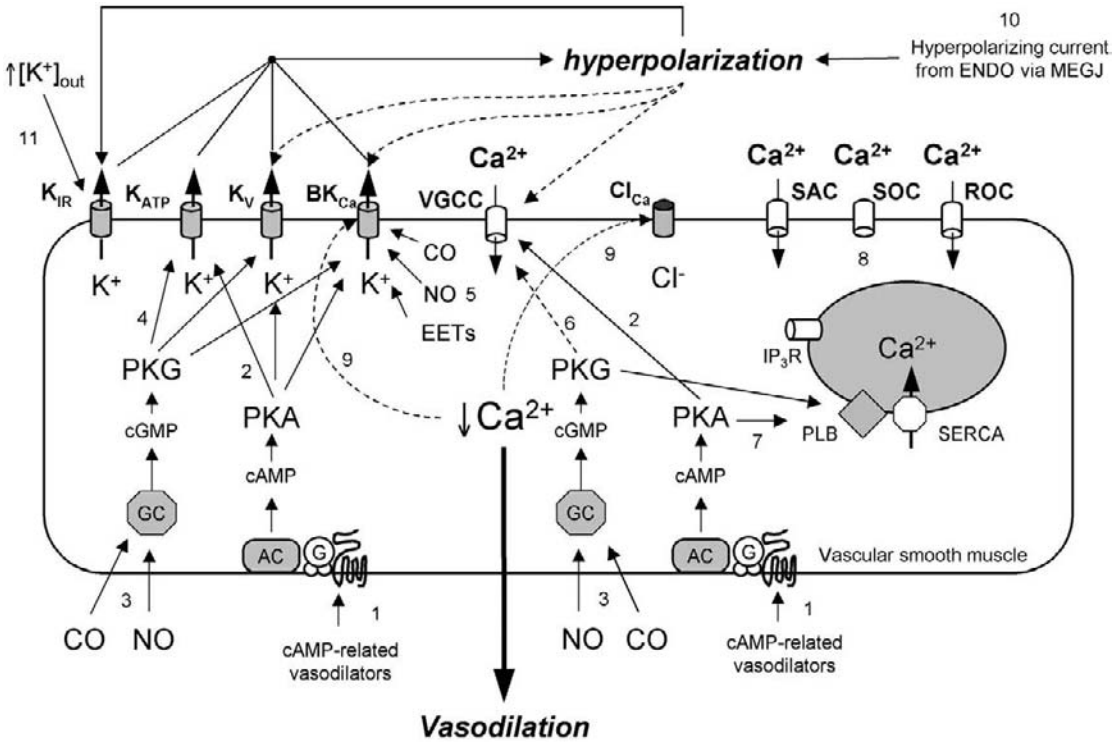

Figure 3 Ion channels and vasodilation. Simplified schematic diagram of the role played by ion channels in the mechanism of action of vasodilators on arteriolar smooth muscle cells. Solid lines and arrows indicate stimulatory effects, whereas dashed lines represent inhibitory effects. **1**, Vasodilators such as adenosine, prostacyclin (PGI_2), epinephrine, and calcitonin-gene-related peptide (CGRP) all bind to G-protein-coupled receptors and activate adenyl cyclase (AC) to form cAMP, which then activates protein kinase A (PKA). **2**, PKA phosphorylates and activates K_{ATP} channels, K_V channels, BK_{Ca} channels, and VGCC. The activation of the K^+ channels tends to hyperpolarize smooth muscle, closing VGCC, reducing Ca^{2+} influx, lowering $[Ca^{2+}]_{in}$, and leading to smooth muscle relaxation and vasodilation. **3**, Vasodilators such as NO, CO, and atrial natriuretic peptide (ANP) stimulate guanylyl cyclase (GC) to form cGMP, which then activates cGMP-dependent protein kinase (PKG). **4**, PKG targets K_{ATP}, K_V, and BK_{Ca} channels, leading to hyperpolarization and, ultimately, vasodilation. **5**, In some instances NO, CO, and epoxides of arachidonic acid may directly activate BK_{Ca} channels. **6**, Phosphorylation of VGCC by PKG is inhibitory and contributes to cGMP-PKG induced vasodilation. **7**, Both PKA and PKG also phosphorylate other proteins such as phospholamban (PLB) and phospholipase C-β (not shown in figure). Phosphorylated PLB disinhibits the smooth endoplasmic reticulum Ca^{2+} ATPase (SERCA) reducing $[Ca^{2+}]_{in}$ and refilling SER Ca^{2+} stores. **8**, This latter effect closes store-operated channels (SOC) as indicated. Phosphorylation of phospholipase C-β reduces production of DAG and IP_3, leading to reduced activity in both stretch-activated channels (SAC) and receptor-operated channels (ROC) contributing to the reduction in $[Ca^{2+}]_{in}$. **9**, The reduced $[Ca^{2+}]_{in}$ also closes Ca^{2+}-activated Cl^- channels, removing another depolarizing current, and tends to close BK_{Ca} channels, limiting their effect. **10**, In some arterioles, smooth muscle cells are electrically coupled to endothelial cells such that hyperpolarization of endothelial cells (ENDO) can also hyperpolarize smooth muscle leading to vasodilation. **11**, Inward-rectifier K^+ channels (K_{IR}) may be recruited during membrane hyperpolarization. These channels are also activated by increases in extracellular K^+ ($[K^+]_{out}$).

shear stress (Figure 4). In both smooth muscle and endothelial cells, K_{IR} channels are probably modulated by protein kinases, although this has not been studied in the microcirculation.

Nonselective Cation Channels

Vascular smooth muscle cells and endothelial cells express a number of nonselective cation channels that likely all arise from the transient receptor potential (TRP) family of ion channels originally described in the photoreceptors of the fruit fly, *Drosophila*. All of the TRPC isoforms expressed in smooth muscle and endothelial cells (see Table I) form nonselective cation channels that conduct Na^+ and Ca^{2+} into cells, and none appear to be voltage-gated. This large family of proteins forms channels that open when intracellular Ca^{2+} stores are depleted (store-operated channels, SOC), open with membrane stretch (stretch-activated channels, SAC), or open upon receptor activation (receptor-operated channels, ROC). They contribute to the regulation of arteriolar tone by providing a regulated pathway for entry of Ca^{2+} into both smooth muscle and endothelial cells. In smooth muscle, Ca^{2+} entry through SOC and ROC contributes to vasoconstrictor-induced increases in arteriolar tone, and Ca^{2+} influx through SAC importantly contributes to pressure-induced changes in arteriolar tone (Figure 2). In endothelial cells, SOC are the source of maintained increases in intracellular Ca^{2+} that contribute to the steady-state production of endothelium-derived autacoids (Figure 4).

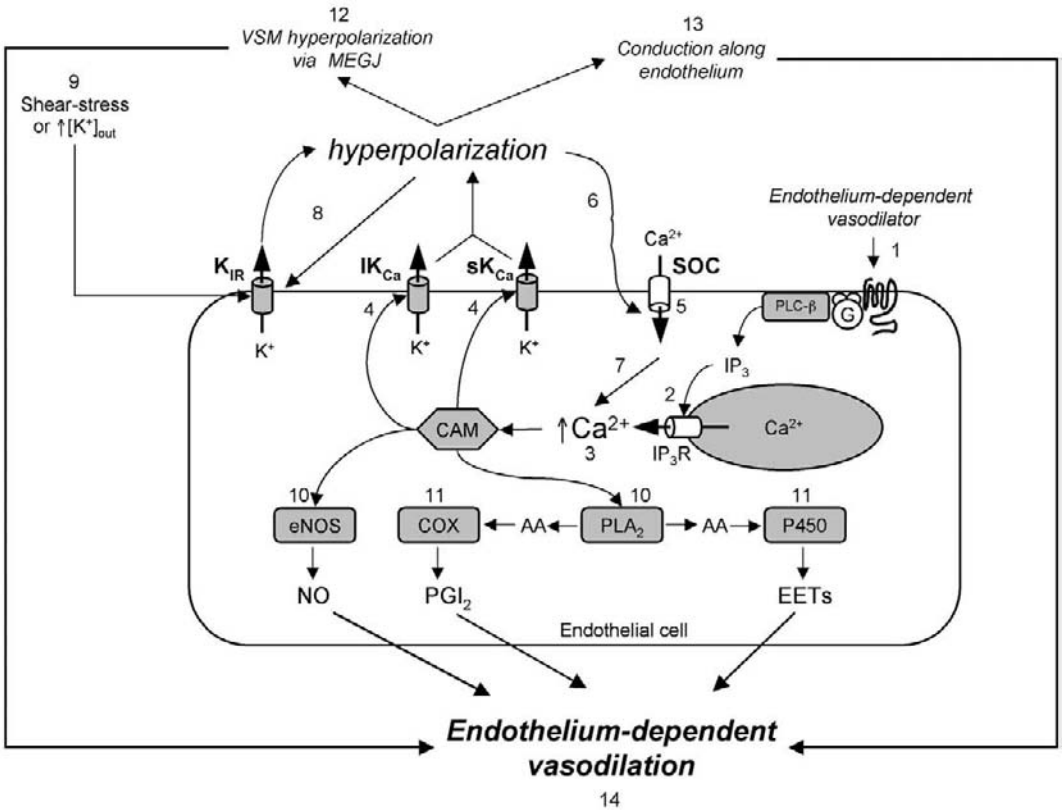

Figure 4 Ion channels and endothelial hyperpolarization. Simplified schematic diagram of the role played by ion channels in the mechanism of action of endothelium-dependent vasodilators, shear-stress and elevated extracellular K^+ (($[K^+]_{out}$). **1**, Endothelium-dependent vasodilators such as acetylcholine, bradykinin, ATP, and histamine bind to G-protein-coupled receptors to activate phospholipase C-β (PLC-β) leading to the formation of inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG, not shown). **2**, IP_3 binds to IP_3-receptors (IP_3R) on the smooth endoplasmic reticulum, releasing stored Ca^{2+}. **3**, This causes a rapid rise in intracellular Ca^{2+}. **4**, The increased $[Ca^{2+}]_{in}$ then binds to calmodulin (CAM) associated with a number of proteins including intermediate (IK_{Ca}) and small (sK_{Ca}) conductance Ca^{2+}-activated K^+ channels, leading to membrane hyperpolarization. **5**, The release of Ca^2 from intracellular stores activates store-operated channels (SOC). **6**, The membrane hyperpolarization caused by opening of IK_{Ca} and sK_{Ca} channels increases the electrochemical gradient for diffusion of Ca^{2+} into the cells through SOC, and amplifies this current. **7**, This amplified Ca^{2+} influx yields a sustained elevation in $[Ca^{2+}]_{in}$. **8**, The hyperpolarization induced by IK_{Ca} and sK_{Ca} channels can activate inward rectifier K^+ channels, augmenting the hyperpolarization. **9**, This effect may be enhanced by increases in shear-stress or elevated $[K^+]_{out}$, both of which activate K_{IR} channels. **10**, The elevated Ca^{2+}, through Ca^{2+}-CAM then activates proteins such as NO-synthase (e-NOS) and phospholipase A_2 (PLA_2). Activation of e-NOS leads to production of NO, while activation of PLA_2 liberates arachidonic acid (AA) from membrane phospholipid stores. **11**, Released arachidonic acid is then rapidly metabolized by cyclooxygenase (COX) to prostacyclin (PGI_2) and other vasodilator prostaglandins, and to epoxides (EETs) by cytochrome P-450 (P450). **12**, In some arterioles, smooth muscle cells (VSM) are electrically coupled to endothelial cells through myoendothelial gap junctions (MEGJ), such that endothelial hyperpolarization, per se, in the absence of another mediator, can lead to vasodilation. **13**, In addition, endothelial cells in arterioles are electrically coupled so that hyperpolarization can be conducted for long distances along the length of arteriolar endothelium. **14**, All of these signals (hyperpolarization, NO, PGI_2, EETs) are integrated by overlying smooth muscle cells to yield vasodilation.

Cl^- Channels

Vascular smooth muscle and endothelial cells also express chloride channels. These include Ca^{2+}-activated Cl^- (Cl_{Ca}) channels and swelling or volume-activated Cl^- (Cl_{SW} channels). The molecular identity of the Cl^- channels expressed in vascular smooth muscle and endothelial cells remains unclear as indicated in Table I. In both smooth muscle and endothelial cells, the intracellular concentration of Cl^- is such that opening of channels conducting these anions leads to diffusion of Cl^- out of the cells, and membrane depolarization. Calcium-activated Cl^- channels are activated by increases in intracellular Ca^{2+}. In smooth muscle, they contribute to vasoconstrictor-induced membrane depolarization (Figure 2). Their function in arteriolar endothelial cells has not been established. In endothelial cells and in smooth muscle cells, Cl_{SW} channels play an important role in the regulation of cell osmolarity and volume and likely participate in the regulation of resting membrane potential. Smooth-muscle Cl_{SW} channels may play a role in pressure (stretch)-induced membrane depolarization and increases in tone.

Membrane Potential and Arteriolar Tone at Rest

Arterioles in the microcirculation at rest display substantial tone largely due to the impact of blood pressure on the smooth muscle. Under these conditions, smooth muscle and endothelial cells have a membrane potential of about –30 mV. This relatively depolarized membrane potential results from the outward flow of K^+ through K^+ channels (a hyperpolarizing current) that is balanced by efflux of Cl^- ions and inward flow of Na^+ and Ca^{2+} ions (all depolarizing currents). There appear to be substantial regional and species differences in the specific ion channels that contribute to resting membrane potential. However, general patterns appear.

In arteriolar smooth muscle cells at rest, membrane potential is determined by K^+ efflux through K_V channels, cation (Na^+ and Ca^{2+}) influx through SOC, and probably Cl^- efflux through Cl_{SW} channels. In skeletal muscle and coronary vascular beds, K_{ATP} channels also contribute to resting membrane potential. In vivo studies suggest that voltage-gated Ca^{2+} channels and BK_{Ca} channels may not be active at rest. The mechanisms responsible for the apparent lack of activity of voltage-gated Ca^{2+} channels at rest in vivo have not been established. However, it is likely that the low resting activity of arteriolar BK_{Ca} channels in vivo reflects the low activity of voltage-gated Ca^{2+} channels, with which the BK_{Ca} channels are functionally coupled (Figure 1), along with a high Ca^{2+} threshold of microvascular BK_{Ca} channels. Inward rectifier K^+ channels do not contribute to resting potential because of the relatively depolarized membrane potential (–30 mV) found in arteriolar smooth muscle cells. Calcium-activated Cl^- channels appear silent at rest due to their high Ca^{2+} threshold.

The ion channels that contribute to resting membrane potential in arteriolar endothelial cells have not been established. However, similar to the overlying smooth muscle cells, K_V channels, Cl_{sw} channels and nonselective cation channels probably contribute to the relatively depolarized membrane potential in endothelial cells in resting arterioles (–30 mV). In addition, blood flow over the endothelium may activate endothelial K_{IR} channels through a shear-stress dependent mechanism, such that these K^+ channels may also contribute to resting membrane potential of arteriolar endothelial cells. Also, because smooth muscle and endothelial cells may be electrically coupled by myoendothelial gap junctions in some arterioles, both smooth muscle and endothelial ion channels may contribute to the membrane potential of the other cell type.

Ion Channels and Vasoconstriction

In general, endogenous vasoconstrictors such as norepinephrine, angiotensin II, vasopressin, and the endothelins tend to activate smooth muscle cation influx through voltage-gated Ca^{2+} and nonselective cation channels, activate Cl^- efflux through Cl_{Ca} channels, and inhibit K^+ efflux through K^+ channels, resulting in membrane depolarization, net Ca^{2+} influx, and an increase in intracellular Ca^{2+} leading to smooth muscle contraction (Figure 2). In addition to the mechanisms outlined in Figure 2, the vasoconstrictor-induced increase in intracellular Ca^{2+} bolsters depolarization by activation of the Ca^{2+}-dependent phosphatase 2B (PP2B, calcineurin), which dephosphorylates K_V and K_{ATP} channels to reduce their activity (not shown in Figure 2). Although the activity of K_V and BK_{Ca} channels is somewhat blunted by the inhibitory mechanisms outlined in Figure 2, the membrane depolarization and, in the case of BK_{Ca} channels, the elevated intracellular Ca^{2+} lead to net activation of both K_V and BK_{Ca} channels. This K^+ channel activity importantly limits the depolarization and provides an effective negative feedback signal so that overstimulation and vasospasm do not occur. Thus, ion channels play a key role in vasoconstriction.

Ion Channels and Vasodilation

Vasodilators tend to have effects on smooth muscle ion channels that oppose those of vasoconstrictors (Figure 3). In general, they reduce Ca^{2+} influx by a number of mechanisms (see Figure 3), leading to a reduction in intracellular Ca^{2+}, smooth muscle relaxation, and vasodilation. The only exceptions to this pattern are vasodilators that act through the cAMP-PKA signaling cascade. Voltage-gated Ca^{2+} channels are phosphorylated by PKA, leading to their activation. Although counter to the general Ca^{2+}-lowering trend induced by most dilators, this increased activity in voltage-gated Ca^{2+} channels may provide local Ca^{2+} to maintain the activity of BK_{Ca} channels (see Figure 1), despite a general lowering of intracellular Ca^{2+} by other means.

In skeletal muscle, cardiac muscle, and the brain, increases in tissue activity lead to release of K^+ ions from the active cells, resulting in elevation of the extracellular concentration of K^+ from 5 mM to between 8 and 20 mM. Such increases in extracellular K^+ can activate smooth muscle K_{IR} channels leading to membrane hyperpolarization and vasodilation (Figure 3). In arterioles where smooth muscle cells are electrically coupled to endothelial cells by myoendothelial gap junctions, endothelial K_{IR} channels may contribute to K^+-induced hyperpolarization and vasodilation through a similar mechanism (Figure 4).

Vasodilators such as acetylcholine, bradykinin, ATP, and histamine lead to relaxation of vascular smooth muscle and decreases in arteriolar tone in intact arterioles by stimulating the release of vasodilator substances from endothelial cells. Ion channels play an important part in this process, as outlined in Figure 4. Calcium-dependent activation of sK_{Ca} and IK_{Ca} channels hyperpolarizes endothelial cells and augments Ca^{2+} influx through SOC, providing a maintained increase in intracellular Ca^{2+} to support endothelial autacoid production. In addition, the endothelial hyperpolarization, per se, may be transmitted through myoendothelial gap junctions to hyperpolarize and relax the overlying smooth

muscle (Figure 4). Shear stress and increases in extracellular K^+ may also hyperpolarize endothelial cells by activation of K_{IR} channels. These channels may also be recruited by membrane hyperpolarization caused by activation of other K^+ channels serving to amplify the initial hyperpolarization. Hyperpolarization-induced activation of K_{IR} channels also may allow conduction of hyperpolarization from endothelial cell to endothelial cell, that are coupled by gap junctions, providing a means to transmit hyperpolarization for long distances along arterioles. Similar to their effects on smooth muscle, vasodilators such as adenosine also may activate K_{ATP} channels on endothelial cells, providing another pathway for endothelial cell hyperpolarization and regulation of arteriolar tone (pathway not shown in Figure 4). Thus, ion channels significantly contribute to the mechanism of action of vasodilators both in smooth muscle and in endothelial cells.

Ion Channels and Disease States

Diseases such as hypertension and diabetes appear to affect ion channel expression or function and contribute to altered arteriolar tone associated with these pathologies. In hypertension there appears to be an upregulation of voltage-gated Ca^{2+} channels, nonselective cation channels, and BK_{Ca} channels, but decreased function of K_V and K_{ATP} channels that likely contribute to altered arteriolar tone and reactivity observed in this disease. Similarly, in diabetes there is a depression of BK_{Ca}, K_V, and K_{ATP} channel function that may contribute to diabetic vascular dysfunction. Conversely, sepsis is associated with a large increase in the activity K_{ATP} channels that may underlie the systemic vasodilation and reduced arteriolar tone associated with this condition. Thus, ion channels participate in both physiological and pathophysiological regulation of arteriolar tone.

Glossary

Depolarization: Refers to cell membrane potential becoming more positive.

Electrochemical gradient: The driving force that determines the direction of net diffusion of ions through ion channels. Its magnitude is determined by the difference between the cell membrane potential (which determines the electrical force on the ion) and the concentration difference for the ion that exists across the membrane (which determines the chemical "force" on the ion). Its magnitude can be calculated as the difference between the membrane potential and the equilibrium potential for a given ion.

Equilibrium potential: Theoretical membrane potential that would be required to exactly oppose diffusion of an ion down a given concentration gradient. It is also referred to as the Nernst potential.

Hyperpolarization: Refers to cell membrane potential becoming more negative.

Myoendothelial gap junctions: Gap junctions between endothelial cells and smooth muscle cells that allow ions and small molecules to diffuse between the two cell types. They allow electrical activity in one cell type to be transmitted to the other cell type.

Capsule Biography

Dr. Jackson is a professor in the Department of Biological Sciences at Western Michigan University and in 1998 won the Distinguished Faculty Scholar Award, Western's highest honor for research accomplishments. His laboratory focuses on ion channel function and expression in arterioles, their modulation by oxygen, and their function in regulation of microvascular blood flow. Dr. Jackson's research is supported by Public Health Service grant HL 32469 from the National Heart, Lung and Blood Institute.

CHAPTER 35

Roles of Nitric Oxide in the Microcirculation

Michelle I. Lin and William C. Sessa
Yale University School of Medicine, Boyer Center for Molecular Medicine, New Haven, Connecticut

Introduction

Nitric oxide (NO), a free radical gas produced by the NO synthase (NOS) family of proteins, is a ubiquitous second messenger in diverse physiological responses in the cardiovascular system including vasodilation, anticoagulation, vascular remodeling and angiogenesis. In vitro and in vivo studies using NOS inhibitors or more recently, using mice deficient in each of the three mammalian isoforms, namely (1) endothelial NOS (eNOS), (2) cytokine-inducible NOS (iNOS), or (3) neuronal NOS (nNOS), have shown definitive roles of NO and its sources in the cardiovascular system. The purpose of this review is to highlight the evidence supporting various functional roles of NO in the microcirculation.

NO and Vasodilation

NO is clearly the major endothelium-dependent vasodilator produced by large blood vessels (Figure 1). In the aorta or carotid arteries of mice deficient in eNOS (eNOS –/– mice), endothelium-dependent vasodilation is eliminated, thus supporting eNOS derived NO as the source of the relaxing factor that led to the Nobel Prize–winning experiments by Furchgott, Murad, and Ignarro awarded in 1998. However, the vasodilatory roles for NO in arterioles and venules appear less unanimous, and the importance of NO as a vasodilatory agent (deciphered by the sensitivity of the response to blockage of NOS) depends on the stimulus (flow, acetylcholine, bradykinin, and so on), the vascular bed studied (coronary, cremaster, gracilis, mesentery), the species (human, rat, mouse, hamster), and more recently, the number of endothelial–smooth muscle interconnections (i.e., myo-endothelial gaps). In eNOS (–/–) mice, the local vasodilatory actions of acetylcholine or flow induced changes in blood flow are not diminished, because of compensation by upregulation of nNOS, endothelium-derived hyperpolarizing factor (EDHF), and vasodilatory prostaglandins [1, 2]. However, the local vasodilatory action of histamine was absent from second order arterioles in eNOS (–/–) mice [3]. These are only a few of the many examples highlighting some of the differential response to NO as aforementioned. Another theory imparting NO as an important factor in microvascular blood flow control is the concept that NO bound to hemoglobin in red blood cells can serve as a stable NO adduct for delivery at sites of resistance. Clearly NO binds to the heme moiety of hemoglobin while a reactive thiol, cysteine β 93, and hemoglobin can undergo allosteric changes in structure initiated by a drop in arteriolar pO_2, and release NO from these sites [4]. Although this principle can be demonstrated in model systems, the physiological role of NO via its release from hemoglobin in regulating blood flow in the microcirculation remains controversial [5]. An alternative, emerging theory of how the endothelium may control microvascular blood flow is through another endothelium-dependent vasodilator, EDHF. In systems where NOS is blocked or absent, EDHF may subserve a role as a key regulator of microvascular blood flow control.

NO and the Homeostasis of the Blood Cell Interaction with the Vessel Wall

Preserving a Nonthrombogenic Surface of the Endothelium

In addition to the role of NO as a vasodilator, NO in the microcirculation can prevent platelets from adhering to the endothelium and can assist with the disaggregation of activated platelets to the endothelium or underlying basement membrane (Figure 1). More recently, this concept was unequivocally demonstrated in mice deficient for eNOS [6, 7]. Bleeding times were decreased in eNOS (–/–) mice and platelet adhesion to venules was increased in response to bacterial lipopolysaccharide (LPS) when a NOS inhibitor was given. Similarly, mice deficient in eNOS, but not iNOS or nNOS, also exhibited increased platelet adhesion. In both instances, eNOS in the endothelium as well as in the platelet per se contributed to the antiplatelet actions of eNOS-derived NO.

Maintaining an Anti-inflammatory State of the Vessel Wall

Inflammation can be described as the physiological response of the microcirculation to injury or infections. Designed to close off or destroy injured tissue, inflammatory response is hallmarked by increases in leukocyte–endothelium interactions. Recently, NO has emerged as a crucial endogenous anti-inflammatory mediator in a number of pathophysiological states including hypercholesterolemia and ischemia-reperfusion injury. More specifically, NO can act by downregulating cytokines, resulting in the downregulation of endothelial cell adhesion molecules (ECAMs). The mechanism of leukocyte recruitment is mediated by these ECAMs such as the selectin family (P- and E-selectin), which are important modulators of leukocyte–endothelium interaction via leukocyte rolling along the endothelium and adhesion to the endothelium. Once the cells begin to roll, they can then firmly attach to the endothelium via integrin interaction with endothelial intercellular adhesion molecules (ICAMs) to promote leukocyte adhesion.

Pharmacological studies have shown that NOS inhibitors could increase leukocyte adhesion, an effect that can be reversed by large amounts of exogenous L-arginine. Similar studies using eNOS (–/–) mice confirmed that upon activation of an inflammatory response, eNOS derived NO is critical for reducing leukocytes adhesion and the extent of tissue injury. Recent data suggest that NO is derived from eNOS and nNOS, but interestingly, iNOS may be an endogenous inhibitor of P-selectin. eNOS and nNOS (–/–)

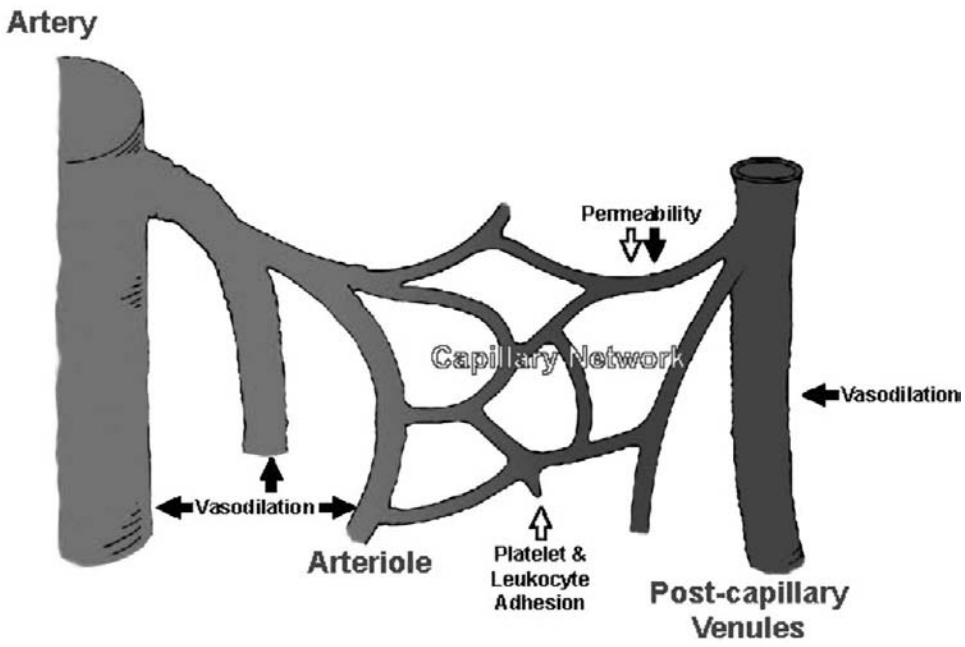

Figure 1 The role of NO in the microcirculation. NO, a gaseous free radical, can exert multiple effects in the microcirculatory bed and is a major player in regulating the cardiovascular system. Studies have shown the vasodilatory effect of NO in large blood vessels as well as in the arterioles and venules. This mainly occurs when NO synthesized by the endothelium diffuses to the surrounding vascular smooth muscle, activating guanylyl cyclase (GC), thereby increasing cytosolic cGMP to produce smooth muscle relaxation. NO can also regulate homeostasis of the blood vessel wall by preventing platelet adhering and disaggregation from the endothelium. Furthermore, NO can negatively regulate leukocyte-endothelium interaction by downregulating cytokines and ECAMs such as P-selectin that are important for leukocyte rolling and adhesion to endothelial cells. Thus, NO serves as an anti-inflammatory mediator in pathological conditions such as hypercholesterolemia or as a cardioprotectant in myocardial ischemia-reperfusion injuries. In addition, NO is a crucial regulator of microvascular permeability. Controversy exists to whether NO promotes or inhibits basal versus stimulated changes in vascular permeability. (see color insert)

mice exhibited increased expression of P-selectin in their mesenteric venules as well as increased leukocyte rolling and adhesion that can be blocked by both the P-selectin neutralizing antibody and a high-affinity P-selectin ligand [8]. This supports previous findings that NOS inhibition by NOS inhibitors caused a significant increase in P-selectin expression in the postcapillary venules. Using another inflammatory model, namely the myocardial ischemia-reperfusion injury, NO was also shown to provide a protective role in the injury cascade leading to inflammation. In particular, other studies by the Lefer group have shown that eNOS-deficient mice exhibited exacerbated reperfusion injury compared to wild-type mice, an effect associated with upregulated P-selectin expression and enhanced infiltration of neutrophils. Recently, transgenic mice overexpressing eNOS in the endothelium have been generated. In accordance with the findings from eNOS (–/–) mice, overexpression of eNOS in these transgenic mice exhibited an ameliorated response to myocardial infarction with a 33 percent reduction in infarct size without changes in systemic hemodynamics or differences in baseline ventricular morphology and function. Taken together, these findings are in agreement with previous observations of the cardioprotective role by NO in the myocardial microcirculation using exogenous NO donors and the exacerbated injury when animals were treated with NOS inhibitor.

Role of NO in Regulating Vascular Permeability

One of the initial events in an acute inflammatory response is increased extravasation of fluid and protein from postcapillary venules at sites of tissue injury. Under physiological conditions, microvascular fluid exchange is primarily determined by blood flow, Starling forces, and the perfused surface area. The perm-selectivity barrier to solute flux is determined by multiple factors including the identity of the endothelium (tissue bed), composition of tight versus adherens junctions, and extracellular matrix.

Using cannulated, venular microvessels in the mesentery, a variety of inflammatory agents such as ATP, ionomycin, bradykinin, histamine, and VEGF stimulated increases in $[Ca^{2+}]_i$ slightly preceding the initial peak in vascular leakage. The delay of the onset of changes in permeability suggests that in addition to the initial increase of $[Ca^{2+}]_i$, calcium-dependent signaling cascades (i.e., eNOS) may contribute to vascular permeability. Furthermore, NOS inhibitors can reduce ATP-induced increases in single vessel permeability, while 8-Br-cGMP, a membrane-permeable cGMP analog, can potentiate ATP driven increases in permeability. These agents, however, did not affect the ATP induced rise in $[Ca^{2+}]_i$, which further suggests that the increase in $[Ca^{2+}]_i$ was necessary for an agonist-induced increase in permeability but not entirely sufficient.

Over the years, studies on the action of NO in regulating vascular permeability have yielded conflicting observations (Figure 1). Early studies using NO donors and NOS inhibitors demonstrated the negative regulatory effect of NO in microvascular permeability. For example, administration of a NOS inhibitor, N^{ω}-nitro-L-arginine-methyl ester (L-NAME), increased transvascular fluid and protein flux, whereas subsequent NO donors such as sodium nitroprusside (SNP) reversed this effect in the intestinal circulation. The increase in permeability was not due to hemodynamic alteration, a phenomenon in which L-NAME has been suggested to play a role. Many other studies using NOS inhibitors or NO donors also demonstrated that NO negatively regulates permeability in response to a host of inflammatory agents including bradykinin, carrageenan, substance P, and mustard oil. In addition, increases in intracellular levels of cGMP by NO donors or activators of guanylate cyclase (sGC) have also been associated with a decrease in endothelial permeability.

On the other hand, the NO-sGC-cGMP pathway can positively regulate microvascular permeability. Upon receptor activation and subsequent stimulation of phospholipase C (PLC), increase in cytosolic calcium can lead to activation of eNOS and NO production. NO activates guanylate cyclase (GC) and increases cGMP production, resulting in protein kinase G (PKG) activation and phosphorylation of proteins that regulate the contractile apparatus or cytoskeleton. In cannulated porcine coronary venules, VEGF and histamine can induce increases in permeability, as measured by the rate of FITC-albumin transfer into the extravascular space in a cGMP-PKG dependent manner. Administration of the NO donor SNP increased permeability similar to that induced by histamine, and this increase can be blocked completely by an inhibitor of guanylate cyclase.

Recent studies have examined the effect of eNOS in modulating vascular permeability using eNOS (–/–) mice or using a synthetic peptide that inhibits eNOS activity. A pivotal study by Jain's laboratory [9] demonstrated that eNOS (–/–) mice, but not iNOS (–/–) mice showed impairment in VEGF-induced increases in permeability, further confirming the importance of eNOS as the predominant NOS isoforms in the regulation of VEGF induced vascular permeability. To further examine the role of eNOS in regulating vascular permeability, our laboratory has generated a synthetic fusion protein containing the eNOS inhibitory domain of caveolin-1 and a cell permeable peptide that facilitates the uptake of cargo proteins/oligonucleotides [10]. This peptide, which we termed cavtratin, can inhibit acetylcholine-induced, endothelium-dependent relaxation, thereby reducing the amount of NO generated block eNOS and not iNOS activity. Furthermore, it can specifically. Administration of this peptide in vivo can block both carrageenan- and mustard oil–induced inflammation and edema formation. Furthermore, this peptide, which did not have an antiangiogenic or cytostatic effect, can selectively block tumor microvascular permeability, leading to decreased tumor progression. Recently, cavtratin has been shown to block PAF-mediated increases in hydraulic conductivity in venules, thus validating the antileak actions of the peptide [11]. Combined with our observations that eNOS (–/–) mice exhibited decreased tumor permeability and progression, these studies may pro-

vide novel insights into development of new antipermeability drugs to target tumor growth.

Conclusions

The discovery of NO has led to the identification of multiple physiological roles for this gaseous second messenger in the microcirculation. We surmise that the local autocrine actions of NO that govern inflammation and vascular permeability in the microcirculation may be as important as its vasodilatory role in conduit vessels. Furthermore, the diverse function of NO may extend beyond the vascular bed. Recent findings using NOS inhibitors and eNOS (–/–) mice revealed an important role of endothelial derived nitric oxide in mediating lymphatic fluid flow in the microlymphatic network (new reference #12). Therefore, future mechanistic studies and the development of novel reagents to faithfully manipulate the NO-sGC-PKG pathway will help dissect the physiological importance of NO in the microcirculation and microlymphatic beds.

Glossary

Endothelium: The innermost layer of cells lining all blood vessels.

Nitric oxide: A free radical gas produced by the enzyme nitric oxide synthase.

Permeability: The leakage of fluid or proteins from the circulation after tissue injury.

Vasodilation: Dilation of a blood vessel to increase blood flow.

Capsule Bibliography

Dr. Sessa is a Professor in the Department of Pharmacology at Yale University and the Director of the Vascular Cell Signaling and Therapeutics Program. His laboratory research focuses on identifying cell biological and molecular pathway that influence the function of blood vessels during vessel remodeling, angiogenesis, and inflammation. His work is funded from the NIH.

Ms. Michelle I. Lin is a Ph.D. student examining how nitric oxide regulates vascular permeability.

CHAPTER 36

Rheology of Blood Flow in the Microcirculation

Herbert H. Lipowsky
Department of Bioengineering, The Pennsylvania State University, University Park, Pennsylvania

Introduction

It is widely acknowledged that the resistance to flow within individual microvessels (R) results from the effective viscosity (η) of blood and geometric factors, where the latter is often referred to as vascular hindrance (z). Under idealized conditions of fluid flow with a constant viscosity (i.e., a Newtonian fluid) and Poiseuille flow (parabolic velocity profile), z is proportional to vessel length (L) and inversely proportional to D^4, yielding the relationship that $R \sim \eta z$. It has been shown that over the broad range of diameters encountered as blood traverses the microvascular network, the principal determinant of resistance in the normal flow state is the relationship that $R/L \sim 1/D^4$ and that substantial departures from this behavior in the low-flow state and pathological conditions arise from the rheological properties of blood [1].

Rheology (from Greek *rheo*, flow) is the study of the flow and deformation of materials. The general aim of rheological studies is to characterize the intrinsic mechanical properties of a fluid or solid in terms of the resistance it offers to deformation under a given load, or shear at a prescribed rate. The viscous properties of blood in large-bore tubes and viscometric instruments have provided a foundation for understanding the rheology of blood in microvessels. With the assumption that blood is a homogenous fluid with an intrinsic viscosity, these devices have revealed that blood viscosity falls as shear rates ($\dot{\gamma}$) rise (shear thinning) from on the order of 0.1 to 1,000 seconds^{-1}, in contrast to the behavior of a Newtonian fluid with constant viscosity. The intrinsic viscous properties of bulk suspensions are typified by a parametric set of curves of viscosity (η) versus shear rate ($\dot{\gamma}$), as illustrated in Figure 1 for cat blood using a cone-plate viscometer. The shaded area represents the general regime of $\dot{\gamma}$ and hematocrit for the microcirculation in the normal flow state. At a given shear rate, blood viscosity rises exponentially with increasing red blood cell (RBC) concentration (hematocrit), to an extent dependent upon prevailing $\dot{\gamma}$. Viscosity of the suspending medium (plasma) has been shown to be invariant, with $\dot{\gamma}$ (Newtonian) and is dependent mainly upon protein content and temperature.

Within the circulation, in large diameter vessels representative of the macrocirculation (i.e., > 100 μm), blood may be treated as a homogeneous continuum with intrinsic properties characterized by an "apparent viscosity." The term apparent viscosity is used since viscosity of a homogenous fluid (e.g., water, molasses) is a material property that may be dependent upon shear rate, is invariant with the size of the vessel through which it flows and is dependent mainly on temperature. In vitro viscometric studies have revealed that apparent viscosity (η) rises as shear rate ($\dot{\gamma}$) is reduced. The decrease in η with increasing $\dot{\gamma}$ depends strongly on levels of hematocrit. A comparison of this "shear thinning" of blood in the presence and absence of aggregating agents suggests that about 75 percent of the decrease is a result of the disruption of red cell aggregates, and 25 percent is due to red cell deformation in response to increased shear stresses. In vivo, the particulate nature of blood affects this relationship. The dominance of noncontinuum effects in the smallest microvessels result in an effective blood viscosity that is strongly dependent upon microvessel diameter.

Microvascular Hematocrit

It is evident that microvascular hematocrit may be the dominant determinant of apparent viscosity in microvessels. Because of the particulate nature of blood, three hematocrits

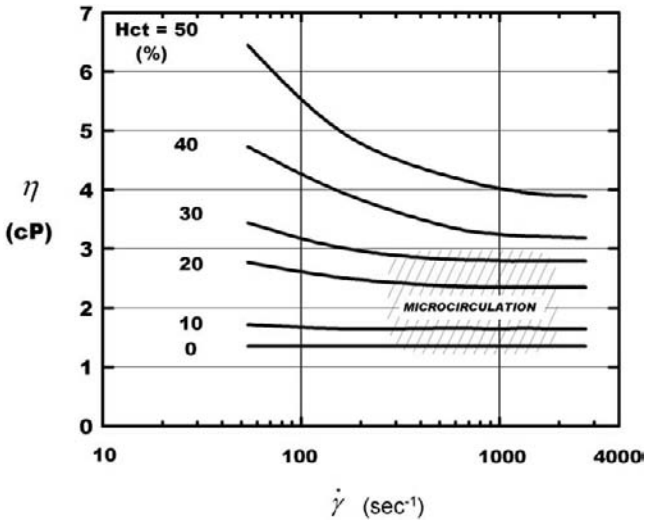

Figure 1 Apparent viscosity (η) versus shear rate ($\dot{\gamma}$) at various levels of hematocrit was obtained in a large scale cone-plate viscometer. The cross-hatching delineates the typical range in microvessel hematocrit, η, and $\dot{\gamma}$ found in the microcirculation in the normal flow state. Redrawn from a study of cat blood by Lipowsky et al. (1980). *Microvasc. Res.* **19**, 297–319.

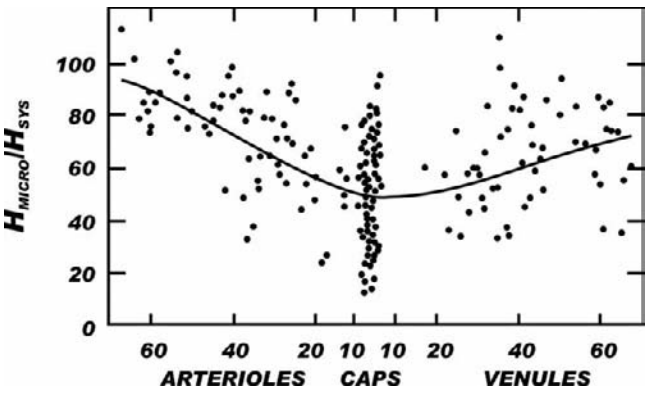

Figure 2 Representative distribution of microvessel hematocrit (H_{MICRO}), normalized with respect to systemic values (H_{SYS}), measured in the cremaster muscle of the rat for microvessels ranging from arterioles to venules of the indicated luminal diameter. H_{MICRO} falls below H_{SYS} because of the Fåhraeus effect and plasma skimming at arteriolar branches. From the data of House and Lipowsky (1987). *Am. J. Physiol.* **252**, H211–H222.

must be considered when describing blood flow in small-bore tubes or microvessels: (1) the feed hematocrit (H_{FEED}), (2) the discharge hematocrit (H_{DISCH}), and (3) the tube or microvessel hematocrit (H_{TUBE} or H_{MICRO}). The feed hematocrit represents the packed cell fraction contained in the suspension that supplies the small blood vessels and is equivalent to the red cell fraction present in large vessels of the macrocirculation, typically larger than 100 μm in diameter. The discharge hematocrit is the volume fraction of red cells found in a hypothetical collection container that receives flow from the exit of a microvessel or small tube. In the absence of any cell screening events at the tube entrance, $H_{FEED} = H_{DISCH}$. The tube or microvessel hematocrit is defined as the packed cell fraction resident within the lumen of the tube at any instant of time and is determined by suddenly stopping the flow and assaying the packed cell fraction of RBCs within the tube. Given that RBCs flow through a tube with an average velocity of V_{RBC}, it has been shown that $V_{RBC}H_{TUBE} = V_{MEAN}H_{DISCH}$, where V_{MEAN} is the mean velocity of blood (cells plus plasma) calculated by dividing the volumetric flow rate (Q) by the cross-sectional area (A) of the tube, that is, $V_{MEAN} = Q/A$. These relationships lead to a hypothetical minimum value for H_{MICRO} if it is assumed that Poiseuille's law governs the flow of blood. That is, for Poiseuille flow with a parabolic velocity profile within the tube, V_{MEAN} is $^1/_2$ the maximum velocity that occurs along the tube center line, V_{CL}. Hence, if all RBCs were infinitesimally small and traveled along the vessel centerline, the lowest value of H_{MICRO} attainable would be $^1/_2$ that of H_{DISCH}. In contrast, the theoretical maximum value of H_{MICRO} that could be attained within a tube is governed by packing considerations for rigid particles of volume equivalent volume to that of red cells. For a rigid spherical particle, the maximum volume fraction would be about 53 percent, whereas for a rigid RBC it would be about 64 percent.

Within the microvasculature, H_{MICRO} has been shown to span a much broader range of values under normal and pathological conditions. Direct measurements of H_{MICRO} reveal that as microvessel diameter falls throughout successive divisions, H_{MICRO} falls to on the order of 25 percent of systemic values (H_{SYS}) as blood approaches microvessels comparable in diameter to the characteristic size of an RBC. The average capillary hematocrit has been found to vary among tissues as a result of different topographical patterns of blood vessels and luminal diameters within a given microvascular division, as illustrated in Figure 2 for the cremaster muscle (rat). Two processes give rise to this fall: the Fåhraeus effect and plasma skimming.

Since the pioneering studies of Robin Fåhraeus (1929; see Ref. [2]) it has been recognized that hematocrit in tubes comparable in size to that of the red cell may be reduced dramatically below the feed hematocrit that supplies a tissue. This behavior has been attributed to rapid changes in the mean velocity of red cells relative to that of plasma, as summarized by Cokelet [3]. As tube diameter is diminished toward the size of a red cell, the velocity of red cells increases relative to the mean velocity of plasma. Hence, to maintain conservation of red cell flux, the tube hematocrit falls and fewer red cells travel through the tube at a faster than normal speed (relative to plasma) to maintain the same red cell volumetric flow. With further reductions in tube diameter to the point where red cells must undergo large deformation to gain entry to the tube, the Fåhraeus effect reverses, as evidenced by increasing H_{TUBE} with diminishing diameter as the motion of RBCs becomes hindered and their sequestration in the tube leads to increases in H_{MICRO} above H_{SYS}.

Direct measurements of H_{MICRO} by cell counting or spectrophotometry within single microvessels have revealed a

heterogeneous distribution of H_{MICRO} within any given division of the network [4] indicative of hematocrit reductions due to other effects. The principal mechanism leading to further reductions in H_{MICRO} is that of skimming off of plasma by daughter branches at bifurcation points within the network, as first observed by Poiseuille [5]. It has been suggested that H_{MICRO} is relatively uniform across the lumen (radial direction) of an arteriole or venule, compared with the heterogeneity associated with successive branchings. However, the presence of a thin annulus of plasma surrounding the core of RBCs within a microvessel facilitates an uneven distribution of RBCs at arteriolar branchings [3]. The proportions of RBCs from the core, and the cell-free plasma layer that is captured by an arteriolar branch at a bifurcation, is dependent upon the relative magnitudes of total volumetric flow from parent to daughter branch at a bifurcation. At the final ramifications of the arteriolar network, red cell entry into capillaries is dependent upon the presence of a sufficient pressure gradient that can sustain red cell deformations at the capillary entrance and hence the capillary branch with the fastest stream (greatest pressure gradient) captures the majority of red cells. In concert with the Fåhraeus effect, plasma skimming contributes to the markedly lower than systemic hematocrits in the capillary network.

Other mechanisms of hematocrit reduction have been implicated as a source of the low capillary hematocrit. It has been suggested that irregularities in the capillary lumen, due to departures from a circular cross-section, introduce substantial errors in computing H_{CAP} that may result in systematically low values. Uncertainties in observing the luminal surface of the capillary endothelium may also introduce significant errors in estimating H_{CAP}. The presence of a thick (~ 0.5 μm) surface layer of carbohydrates and proteins on the surface of the endothelium (the glycocalyx) may also affect estimation of H_{CAP}. Removal of the endothelial surface layer by enzymatic degradation of the glycocalyx (see review by Pries et al. [6]) has resulted in a substantial rise in capillary hematocrit.

The observed low capillary hematocrits have raised critical questions on the role of hematocrit in oxygen transport to tissue. It is generally accepted that the potential for oxygen transport from blood to tissue is related to the concentration of RBCs within the microvasculature. However, the low levels of microvessel hematocrit are inconsistent with the fact that for a given level of oxyhemoglobin, oxygen content is proportional to the product of mean corpuscular hemoglobin concentration and H_{MICRO}. Attempts to account for all of the factors contributing to reduced hematocrit (Fåhraeus effect, plasma skimming, uncertainties in capillary diameter, and so on) have not resolved the disparity between H_{SYS} and H_{CAP}. This situation may have persisted because hematocrit measurements do not consider the flow-weighted flux of red cells within individual microvessels. In contrast, the flow-weighted estimates of red cell fraction obtained using techniques of indicator dilution (with fluorescently labeled RBCs and plasma) have revealed average tissue hematocrits approaching systemic values, which are substantially greater. Nonetheless, the importance of H_{MICRO} rests in that it remains a major determinant of the apparent viscosity of blood in microvessels, and hence of resistance to blood flow.

In addition to the dynamic processes that affect RBC apportionment at branch points, RBC mechanical properties may dramatically affect capillary hematocrit. Pathologically stiff red cells (e.g., in sickle cell disease, the thalassemias, or hereditary spherocytosis) may affect the distribution of cells. Because of cell–cell interactions, less deformable RBCs have a tendency to become trapped within networks with nontube-like vessels, such as the lung, spleen, liver, or bone marrow. The permeability characteristics of the microvessel wall may also affect hematocrit. In the classical study of disruption of the permeability of the small blood vessels leading to complete vascular stasis, as first described by August Krogh [1], the hyperpermeable vessel wall may allow compaction of RBCs to hematocrits approaching 100 percent.

Apparent Viscosity

The bulk viscosity of blood obtained by in vitro viscometry (Figure 1) does not fully address the viscous properties that determine microvessel perfusion for a given pressure gradient. In microvessesls larger than 20 μm in diameter, it has been demonstrated that at low physiological hematocrits, and in the normal flow state, the apparent viscosity (η) varies linearly with H_{MICRO} (see Zweifach and Lipowsky [1]). In vitro studies of blood behavior in small-bore tubes have demonstrated that reductions of H_{MICRO} attendant to diameter reductions result in a decrease in effective viscosity as well, which has been referred to as the Fåhraeus-Linqvist effect [2]. In vivo, increased viscosity occurs with reductions in $\dot{\gamma}$, suggesting that the heterogenous perfusion of the microvasculature in the low flow state may arise in part due to substantial elevations in η. However, in vitro studies with small tubes do not reflect these trends and suggest that additional mechanisms may contribute to shear-dependent resistance increases in small blood vessels [7].

Red Cell Aggregation

The effect of red cell aggregation (RCA) on the resistance of flow in vivo has also been fraught with controversy. Infusing aggregating agents such as high-molecular-weight (500 kDa) dextran into animals results in some studies in systemic effects indicative of increased resistance to flow caused by RCA. However, other studies demonstrate a reduction in regional resistance in isolated tissues, suggestive of reductions in systemic hematocrit attendant to RBC sequestration in other regions. In vitro studies of RCA in vertically positioned small-bore glass tubes have shown that the apparent viscosity of blood decreases with increasing

degrees of RCA. However, in vivo measurements in the low-flow state suggest a dramatic rise in apparent viscosity with reductions in $\dot{\gamma}$. The sequestration of red cell aggregates in regional networks has been shown to dramatically decrease systemic hematocrit, the extent of which is strongly dependent on the strength the aggregating agents.

Two mechanisms have been implicated in aggregate formation: osmotic depletion, which results in hydrostatic pressures that tend to force apposing cells together in the presence of macromolecules, and molecular cross-bridging, whereby solutes cause the binding of one cell to another. Modeling and experimental studies reveal that with weaker aggregating forces, red cells assume the configuration of rouleaux (Figure 3A), which may be disrupted by shearing forces at branch points in the arteriolar network. With stronger aggregating forces, clumps of cells are formed that appear to be more easily trapped at microvascular branch points (Figure 3B).

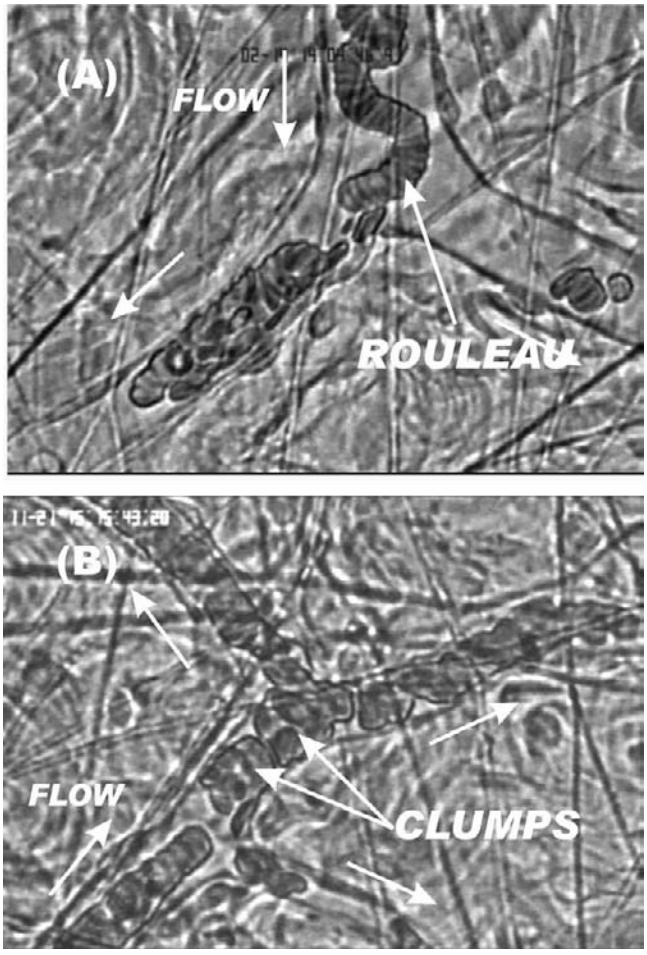

Figure 3 Red cell aggregates at the entrance of precapillary vessels in the low-flow state. Two levels of aggregation are shown, corresponding to **(A)** rouleaux formation in the presence of elevated fibrinogen (0.7 g%) and **(B)** clumping in response to 3 g% high-molecular-weight dextran (500 kDa). The apparently stronger clumps are formed as apposing RBC membranes are linked by dextran cross-bridging with the result that clumps are readily trapped within the entrance to small microvessels. From Pearson and Lipowsky (2004). *Microcirculation* **11**(3), 295–306.

Blood Cell Deformability

Blood cell deformability is a major source of the resistance to flow. Increases in bulk viscosity of RBCs in suspension clearly result from reductions in the ability of RBCs to deform under shear ($\dot{\gamma}$). However, these abnormalities in η are small compared with the dramatic rise in resistance to flow as individual cells enter the true capillaries. In most species, blood cellular elements (erythrocytes and leukocytes) are similar in size or slightly larger than the true capillaries, and they must be deformed by prevailing pressure gradients to gain entry into a capillary. The pressure gradient required to propel RBCs and WBCs into a capillary of a given diameter is strongly dependent on the ratio of cell diameter (D_{CELL}) to capillary diameter (D_{CAP}), that is, D_{CELL}/D_{CAP}. As D_{CELL}/D_{CAP} is reduced, small increases in cell stiffness may inhibit its entry into a capillary. As a result, RBCs and WBCs tend to traverse the microvascular network through pathways of least resistance, with the larger and less deformable WBCs bypassing the smallest diameter capillaries. As shown in Figure 4, plasma, red cells, and leukocytes traverse the capillary network through different pathways that are dictated by their ability to enter a vessel of a given diameter.

Resistance to Blood Flow in Microvessels

The behavior of small blood vessels in response to vasoregulatory stimuli and pathological disturbances affect the rheological state of blood within the microvasculature. The principal determinants of the apparent viscosity (hematocrit and shear rate) are directly influenced by levels of flow and alterations in vascular diameter. These physiological responses are inseparable from the viscous properties of blood. Several shear-dependent mechanisms of vasoregulation (e.g., those mediated by prostacycline and nitric oxide) are strongly dependent on levels of shear stress (τ) which is related to η by Newton's law of friction, $\tau = \eta\dot{\gamma}$. Thus, changes in vascular diameter may affect the apportionment of flow (Q) throughout successive microvascular divisions and the fraction of the overall arteriovenous pressure drop that appears along individual microvessels. These pressure gradients, in turn, dictate flow and wall shear rates within a single vessel. If blood behaves as a Newtonian fluid, and Poiseuille's law governs the relationship between pressure gradient and flow, then wall shear rate would be given by $\dot{\gamma} = 32Q/\pi D^3$. This relationship serves to couple the intrinsic properties of blood to microvessel flow (Q) and diameter (D) via the relationship between η and $\dot{\gamma}$.

The relationship among hemodynamic resistance, flow and viscosity has suggested that an optimal hematocrit may exist that maximizes the delivery of oxygen to tissue. As H_{MICRO} is increased, elevations in η will result in increased resistance and hence reductions in flow. Although RBC content (and hence oxygen carrying capacity) would be increased, the convective flux of oxygen ($\sim Q \times H_{MICRO}$)

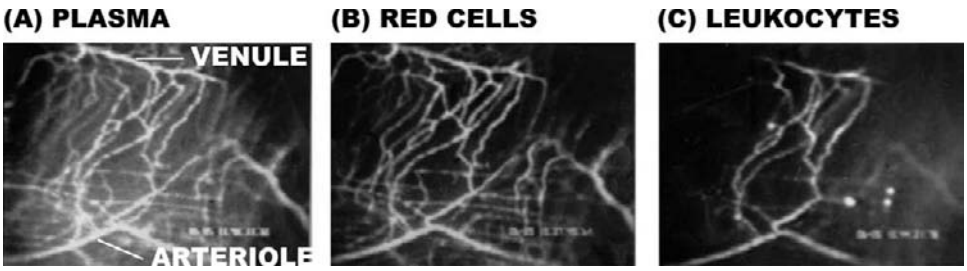

Figure 4 Blood cell deformability is an important determinant of the ability of RBCs and WBCs to pass through the capillary. In many networks the true capillaries are often smaller than the characteristic size of a blood cell. Shown are the pathways of perfusion taken by fluorescently labeled plasma **(A)**, RBCs **(B)**, and WBCs **(C)**. Compared to plasma, the lesser intensity of RBCs in many vessels suggests that many RBCs traverse the network from arteriole to venule through larger diameter pathways. This behavior is much more striking for the larger and stiffer WBC that appears to travel through more centrally situated thoroughfare channels. From Eppihimer and Lipowsky (1994). *Am. J. Physiol.* **267**, H1122–H1134.

may be reduced. Conversely, reductions in H_{MICRO} may decrease resistance (η) and thus increase Q, while diminishing the red cell content (H_{MICRO}). It has been demonstrated that there exists an optimum level of hematocrit that serves to maximize red cell flux through the microvascular network. With changes in H_{MICRO} above or below its optimum value, red cell flux may fall dramatically. Measurements of red cell flux in various organs reveal a paraboloid maximum dependent on H_{MICRO}, with a relationship that is affected by the state of vasodilation or constriction with the arteriolar network.

The long-standing hypothesis that decreased viscosity will enhance oxygen transport by improving flow has recently been challenged by developers of blood substitutes [8]. It has been shown that elevations in blood substitute viscosity serve to elicit a vasodilatory response to increased shear stresses and thus enhance microvascular blood flow. The inverse relationship between resistance to blood flow and the fourth power of vascular diameter (Poiseuille's law; see Sutera and Skalak [5]) serves as a dominant determinant of microvascular perfusion [1].

Interactions of the RBCs and WBCs with the microvessel wall may also affect the resistance to flow. In some pathological disorders, such as sickle-cell disease, RBCs have a tendency to adhere to the microvessel wall, and if levels of flow are low enough, their adhesion may impair perfusion of the network by obstruction of the microvessel lumen. The receptor-mediated adhesion of WBCs to the venular walls of postcapillary venules may also have a dramatic effect on resistance to flow. During the inflammatory process, WBC adhesion may proceed to an extent where it can obliterate the venular lumen. It has been demonstrated that as few as 12 WBCs adhering to the wall of a postcapillary venule per 100 μm of venular length may double the resistance to flow within that vessel. Indirect studies of hindlimb perfusion have suggested that the presence of WBCs within the capillaries may affect the distribution of red cells and thus adversely increase resistance. However, removal of WBCs from the circulation has shown only a 5 percent decrease in resistance at the capillary level. In the low-flow state, the entrapment of WBCs at the entrance to capillaries may also adversely affect resistance to flow and diminish the throughput of flow from arteriole to venule. The extent to which these effects impair microvascular perfusion has been shown to be dependent upon the rate of accumulation of WBCs, the stiffness of the WBC, and the influence of inflammatory mediators that affect WBC deformability.

Although a wealth of in vitro and in vivo rheological studies have served to characterize the intrinsic mechanical properties of blood cell suspensions and blood cellular elements, new mechanisms have come to light that may affect the resistance to flow in microvessels. It has been suggested that low levels of red cell aggregation (as may occur in fibrinogenemia) may enhance the contact of WBCs with postcapillary endothelium and thus promote elevation of leukocyte–endothelium adhesion [9], leading to increased resistance to flow. Studies of the function of the endothelial glycocalyx have suggested that its removal may result in diminished resistance to blood flow [6]. Recent studies have demonstrated that components of the endothelial glycocalyx may be shed during inflammation and ischemia, resulting in diminished resistance due to increases in the vascular lumen, or increased resistance due to elevations in WBC adhesion to venular endothelium [10]. It is clearly evident that in order to understand the rheological determinants of the resistance to flow within the microcirculation proper, greater attention needs to be given to blood interactions with the endothelial cell surface at the molecular level.

Author's Biographical Sketch

Dr. Lipowsky is currently Professor and Head of the Department of Bioengineering at Penn State University. He has been studying the in vivo rheology of blood flow in the microcirculation for the past 30 years and has pioneered several techniques for making rheological measurements in the living animal using techniques of intravital microscopy.

CHAPTER 37

Endothelial Ca^{2+} and Endothelium-Derived Hyperpolarizing Factor (EDHF)-Mediated Vasodilatation

Sean P. Marrelli
Assistant Professor, Department of Anesthesiology, Baylor College of Medicine, Houston, Texas

The Endothelium as a Modulator of Vascular Tone

A single thin layer of endothelial cells comprises the innermost layer of all blood vessels from capillaries to large arteries and veins. One of the more recently discovered functions of the endothelial cell layer is that of a modulator of vascular tone. Endothelial cells are capable of responding to numerous physiological stimuli (such as circulating humoral factors, sheer stress, and so on) by producing vasoactive substances that are then released to the adjacent smooth muscle cells. Two of the most well known endothelium-derived vasoactive substances, prostacyclin (PGI_2) and nitric oxide (NO), are capable of producing vasodilatation upon reaching the smooth muscle. PGI_2 is one of several potential products produced by the cellular metabolism of arachidonic acid. NO is a gaseous factor produced from the conversion of L-arginine to L-citrulline by nitric oxide synthase. NO (or an NO-containing compound) was identified as endothelium-derived relaxing factor (EDRF). The physiological importance of these two vasodilatory factors was recognized by the awarding of the Nobel Prize in Physiology/Medicine in 1982 and 1998 for work leading to the discovery and physiological role for PGI_2 and NO, respectively.

An Additional Mechanism of Vasodilatation, EDHF

In the mid-1980s, it became apparent that endothelium-dependent vasorelaxation could not always be completely accounted for by the actions of PGI_2 and NO. It had been known for some time that isolated arteries could be relaxed (or dilated) by factors such as acetylcholine (ACh), bradykinin (BK), and adenosine diphosphate (ADP). However, whereas the relaxation could be abolished by the removal or damaging of the endothelial layer, the relaxation was not always completely blocked by the combined inhibition of PGI_2 and NO synthesis. It was further noted that the PGI_2/NO-independent relaxation was associated with smooth muscle hyperpolarization. These findings prompted some investigators to conclude that an additional relaxing factor must exist; they termed it endothelium-derived hyperpolarizing factor (EDHF) [1].

Mechanism of EDHF-Mediated Vasodilatation

Although the proposed mechanism of EDHF-mediated vasodilatation is continually evolving, the following represents a general understanding at this time (see Figure 1). (1)

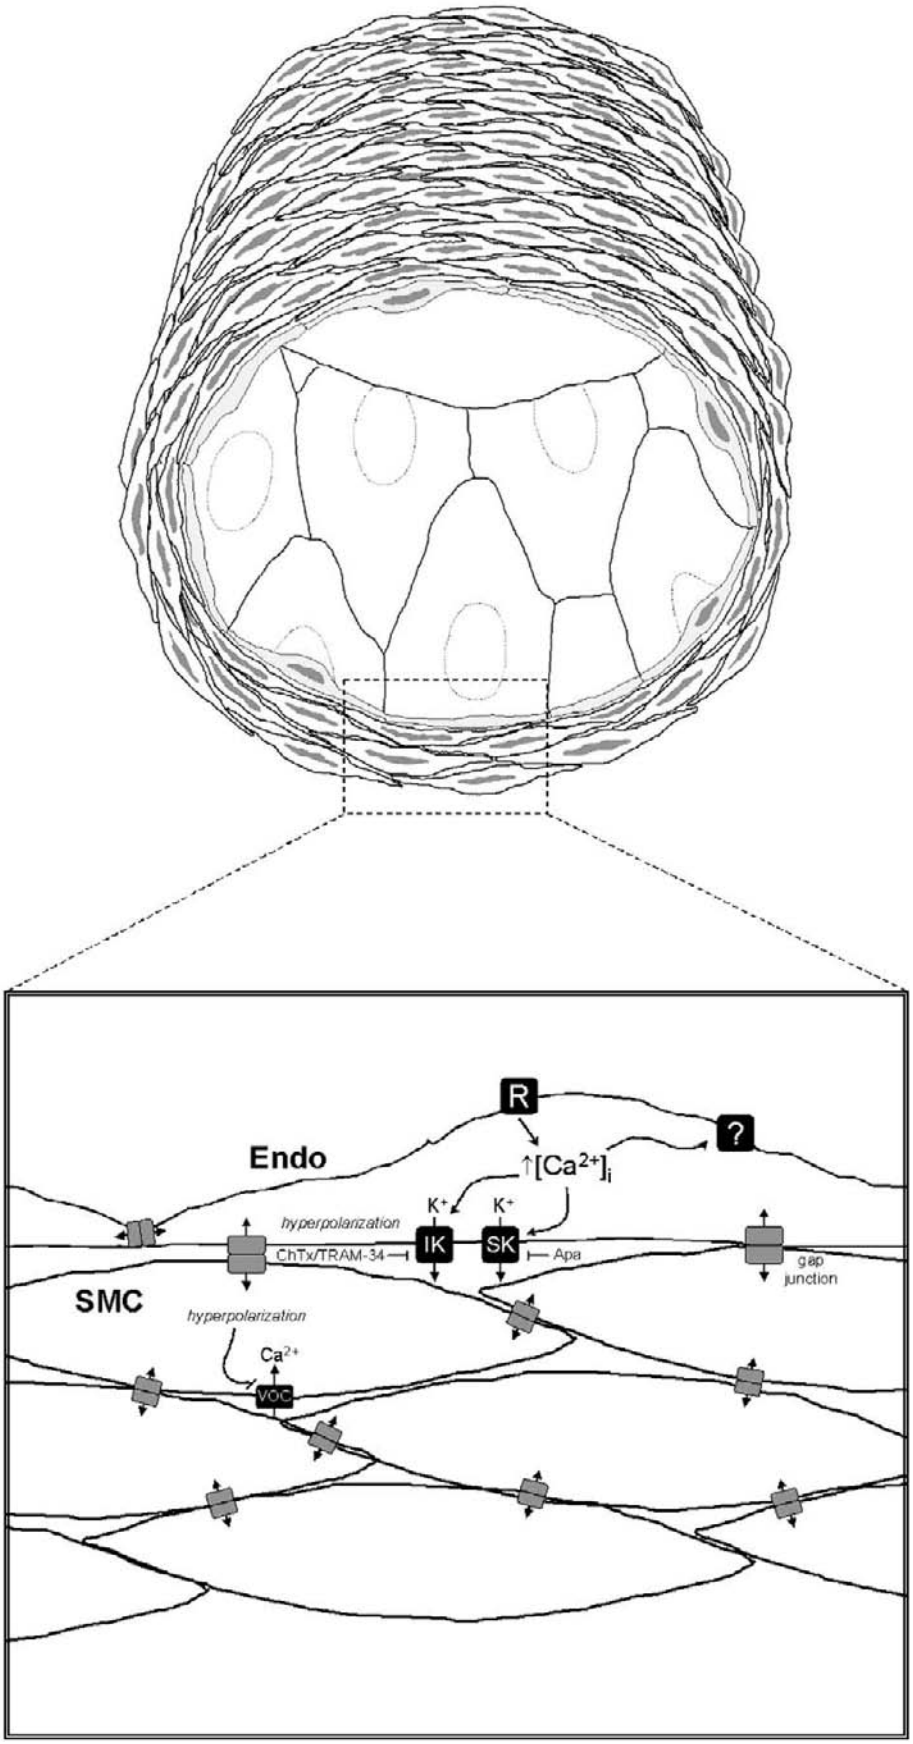

Figure 1 Cartoon depiction of the role of endothelial cytosolic Ca^{2+} ($[Ca^{2+}]_i$) in EDHF-mediated vasodilatation. Abbreviations: Endo, endothelial cell; SMC, smooth muscle cell; R, receptor; IK, intermediate-conductance K_{Ca} channel; SK, small-conductance K_{Ca} channel; VOC, voltage-operated Ca^{2+} channel; ChTx, charybdotoxin; Apa, apamin. Possible Ca^{2+}-sensitive mechanisms that could modulate the EDHF-dependent mechanism are represented by "?."

An agonist binds to its receptor on the endothelium. This binding initiates a cascade of events that leads to an elevation of endothelial cytosolic free calcium ($[Ca^{2+}]_i$). Calcium ionophores, such as A23187, have also been demonstrated to initiate EDHF-mediated dilations by producing an increase in endothelial $[Ca^{2+}]_i$. (2) Elevated endothelial $[Ca^{2+}]_i$ stimulates endothelial calcium-sensitive K channels (K_{Ca}) and promotes hyperpolarization of the endothelium. Elevated endothelial $[Ca^{2+}]_i$ also results in activation of other pathways that may be important modulators of the EDHF-dependent mechanism. (3) The endothelial hyperpolarization then promotes smooth muscle hyperpolarization by a mechanism that is still quite controversial. One of the prevailing ideas is that hyperpolarization is conducted directly via myoendothelial gap junctions, which form electrical couplings between adjacent smooth muscle and endothelial cells. There is pharmacological, electrophysiological, and histological evidence in support of such a mechanism. Another idea is that K^+ ions extruded from basolateral K_{Ca} channels stimulate smooth muscle inwardly rectifying K channels (K_{ir}) and/or Na^+/K^+-ATPase. A small elevation in extracellular K^+ has been shown to stimulate smooth muscle K_{ir} channels and Na^+/K^+-ATPase, and could thus promote smooth muscle hyperpolarization in this way. Although the evidence in support of the latter mechanism is much less prevalent, it could be partly due to the technical difficulties in measuring K^+ in the small intercellular space between endothelial and smooth muscle cells. (4) Smooth muscle hyperpolarization promotes the closure of voltage-operated Ca^{2+} channels (VOC). The smooth muscle VOCs are inactivated at hyperpolarized membrane potentials and thus significantly reduce smooth muscle Ca^{2+} influx. The reduced Ca^{2+} influx combined with Ca^{2+} extrusion and resequestration results in a reduction in smooth muscle $[Ca^{2+}]_i$ and subsequent relaxation or vasodilatation.

Although it was initially believed that EDHF-mediated dilations were the result of a transferable *factor* (similar to NO and PGI_2-mediated responses), recent studies suggest otherwise. Instead, it appears much more likely that EDHF-mediated dilations reflect a *process* by which endothelial hyperpolarization is translated into smooth muscle hyperpolarization (see previous discussion). For this reason, some investigators have begun referring to the mechanism as endothelium-dependent hyperpolarization (EDH). It should be noted that more than one EDHF-dependent mechanism may exist. For instance, the mechanism in coronary and renal arteries may critically involve the cytochrome P450-dependent production of epoxyeicosatrienoic acids (EETs). For the purpose of this article, however, only the former (and seemingly more prevalent) mechanism will be reviewed.

Role of K_{Ca} Channels in EDHF-Mediated Dilation

There are three classes of K_{Ca} channels, large-conductance K_{Ca} (BK_{Ca}), intermediate-conductance K_{Ca} (IK_{Ca}), and small-conductance K_{Ca} (SK_{Ca}), named based on their respective unitary channel conductance [2]. The conductances for BK_{Ca}, IK_{Ca}, and SK_{Ca} channels are 200–250 pS, 20–80 pS, and 2–20 pS, respectively. All of the channels are activated by Ca^{2+}, though the IK_{Ca} and SK_{Ca} channels are activated at much lower Ca^{2+} concentrations than the BK_{Ca} channels (250–500 nM versus 1–10 μM). The channels also differ in that the BK_{Ca} channels are voltage sensitive (activated upon depolarization) whereas the IK_{Ca} and SK_{Ca} channels are voltage insensitive. There are three known isoforms of SK_{Ca} channels, SK1, SK2, and SK3, whereas the IK_{Ca} channel (IK1) does not have any additional known isoforms.

One of the hallmarks of EDHF-dependent responses is the sensitivity to certain K_{Ca} channel inhibitors. For most peripheral arteries, complete inhibition of the response requires combined inhibition of IK_{Ca} (charybdotoxin) and SK_{Ca} channels (apamin) [3, 4]. In the cerebral circulation, complete inhibition appears only to require inhibition of IK_{Ca} channels. Inhibition of the BK_{Ca} channels alone (iberiotoxin) or in combination with SK_{Ca} channels does not affect the EDHF-dependent response.

Because charybdotoxin is a nonspecific blocker (inhibits BK_{Ca}, IK_{Ca}, $K_v1.2$, $K_v1.3$), earlier studies inferred the involvement of IK_{Ca} channels based on sensitivity to charybdotoxin and lack of sensitivity to iberiotoxin (BK_{Ca} selective) or other K_v channel blockers. The recent development and application of apparently IK_{Ca}-specific inhibitors (such as TRAM-34) has provided direct confirmation of the critical involvement of IK_{Ca} channels in EDHF-mediated responses.

Role of Endothelial $[Ca^{2+}]_i$ in EDHF-Mediated Vasodilatation

The critical role for endothelial $[Ca^{2+}]_i$ in EDHF-mediated responses initially gained wide support based on the following evidence: (1) agonists known to produce EDHF-mediated responses produced elevations of endothelial $[Ca^{2+}]_i$ in cultured endothelial cells, (2) Ca^{2+} ionophores (such as A23187) produced endothelium-dependent smooth muscle hyperpolarization, and (3) removal of Ca^{2+} from the bathing medium reduced or eliminated endothelium-dependent smooth muscle hyperpolarization. The evidence supporting the critical involvement of endothelial Ca^{2+} is discussed further hereafter.

Chen and Suzuki were among the first to demonstrate the Ca^{2+}-dependency of EDHF-mediated responses [5]. By measuring rabbit carotid artery smooth muscle membrane potential by sharp electrode, they were able to demonstrate that ACh-mediated smooth muscle hyperpolarization consisted of two components (see Figure 2). When ACh was applied to endothelium-intact arteries in PSS with a standard Ca^{2+} concentration ($[Ca^{2+}]_o$) of 2.5 mM, ACh produced a significant smooth muscle hyperpolarization that was sustained for several minutes (top trace). However, in the pres-

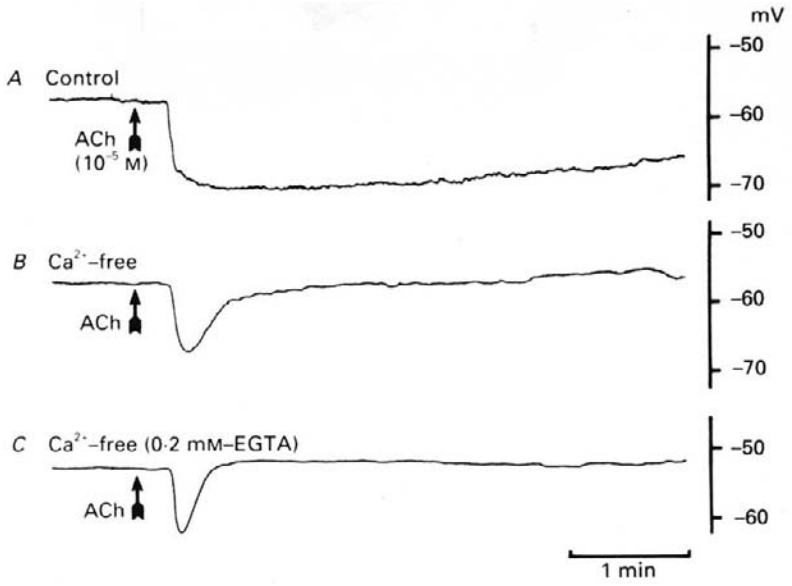

Figure 2 Acetylcholine (ACh)-induced hyperpolarization generated in different $[Ca^{2+}]_o$ solutions. $[Ca^{2+}]_o$ = 2.5 mM **(A)**, 0 mM **(B)**, and 0 mM with 0.2 mM EGTA (**C**). ACh (10^{-5} M) was applied at the arrow in each trace. Reproduced with permission from Chen and Suzuki (1990). *J. Physiol.* **421**, 521–534.

ence of nominally Ca^{2+}-free (no Ca^{2+} added to the PSS) or Ca^{2+}-free/EGTA solution (Ca^{2+} chelator added to remove any residual Ca^{2+}), ACh produced only a transient hyperpolarization (middle and bottom traces). Application of ACh to arteries from which the endothelium was destroyed or remove produced no smooth muscle hyperpolarization. Additionally, application of the Ca^{2+} ionophore, A23187, promoted smooth muscle hyperpolarization that was similarly dependent upon an intact endothelium. Thus, it was concluded that endothelium-dependent hyperpolarization of the smooth muscle consisted of two components, a transient hyperpolarization that utilized intracellular store Ca^{2+} and a sustained hyperpolarization that was dependent on Ca^{2+} influx from the extracellular medium.

Early on in the study of EDHF-mediated responses, it was noted that the involvement of an EDHF-dependent mechanism varied greatly in the vessels studied. For instance, whereas some vessels appeared to utilize EDRF/NO and EDHF-mediated mechanisms, others appeared to utilize only the EDRF/NO-mediated mechanism. It was therefore questioned why EDHF-mediated responses occurred in some vessels but not others. One hypothesis that was put forth by Nagao et al. speculated that the reason was due in part to differences in endothelial $[Ca^{2+}]_i$ attained in a particular artery [6]. The principal evidence for this conclusion was from an experiment in which A23187 was administered to rat mesenteric arteries in the absence or presence of an inhibitor of nitric oxide synthase (NOS). The authors found that A23187 was able to promote vasorelaxation in both conditions; however, it required a higher concentration of A23187 to do so in the presence of the NOS inhibitor. Thus, assuming that the increased concentration of A23187 resulted primarily in an increase in endothelial $[Ca^{2+}]_i$, it appeared that the EDHF-mediated response required a higher endothelial $[Ca^{2+}]_i$ than the EDRF/NO-mediated response. Thus, one possible explanation for the heterogeneity of EDHF-mediated responses was that the ability of the agonists to increase endothelial $[Ca^{2+}]_i$ varied in the different preparations.

A subsequent study by Marrelli investigated a possible Ca^{2+} threshold for EDHF-mediated responses more directly [7]. In that study, Marrelli selectively measured endothelial $[Ca^{2+}]_i$ in response to agonists that have been shown to produce or not produce EDHF-mediated responses in rat cerebral arteries. It was demonstrated that EDRF/NO-mediated dilations were initiated at a threshold of 220 nM Ca^{2+} (resting = 145 nM), whereas EDHF-mediated dilations were not initiated until 340 nM Ca^{2+} (see Figure 3). The threshold for EDHF-mediated dilation was similar for both a receptor-dependent agonist (uridine triphosphate; UTP) or a receptor-independent mechanism to increase endothelial $[Ca^{2+}]_i$ (Br-A23187). Interestingly, the study also demonstrated that a "non-EDHF-dependent" agonist could be made to elicit an EDHF-mediated dilation if the Ca^{2+} response was augmented. For instance, stimulation of endothelial $P2Y_1$ receptors with 2-methylthioadenosine triphosphate (2MeS-ATP) produced maximal dilations through an exclusively EDRF/NO-dependent mechanism. Dilations were completely abolished in the presence of a NOS inhibitor. However, if the baseline endothelial $[Ca^{2+}]_i$ was elevated or primed with a low concentration of UTP or Br-A23187 (though not enough to elicit EDHF-mediated dilation by itself), subsequent addition of 2MeS-ATP resulted in a greater increase in endothelial $[Ca^{2+}]_i$ and an EDHF-mediated dilation. These experiments indicated that EDHF-mediated dilations are not inherently linked to certain

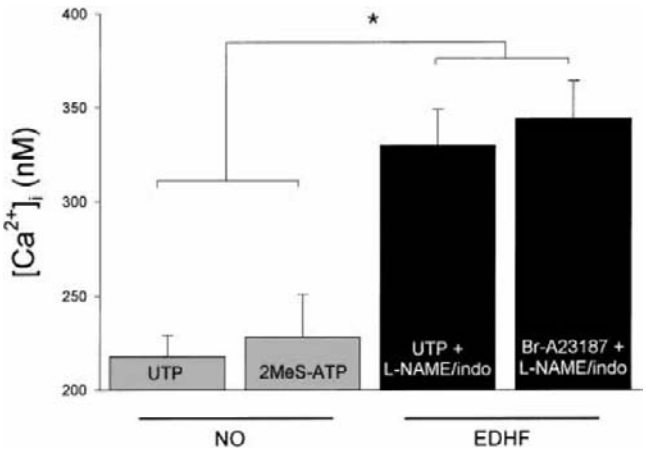

Figure 3 Comparison of the endothelial $[Ca^{2+}]_i$ threshold for nitric oxide (NO)- and EDHF-mediated vasodilatation. Data are presented as the mean SE $[Ca^{2+}]_i$ required to elicit a 15% dilation. In the concentrations used and in the absence of L-NAME (nitric oxide synthase inhibitor), UTP and 2-MeS-ATP produced vasodilatation through the production of NO (gray bars). In the presence of L-NAME plus indomethacin (cyclooxygenase inhibitor), UTP and Br-A23187 produced a dilation through the production of EDHF (black bars). There is a significantly higher threshold for EDHF-mediated vasodilatation compared with that of NO. $*P < 0.05$ between the indicated groups by one-way ANOVA. Reproduced with permission from Marrelli (2001). *Am. J. Physiol. Heart Circ. Physiol.* **281**, H1759–H1766.

receptor systems that either are or are not capable of eliciting EDHF-mediated responses. Rather, the ability of a receptor system to produce an EDHF-mediated response depends more on its potential to increase endothelial $[Ca^{2+}]_i$.

How Does Elevated Endothelial $[Ca^{2+}]_i$ Produce Vasodilatation?

The interpretation of the role of endothelial Ca^{2+} in EDHF-mediated responses has recently undergone significant revision. At one time, it was widely held that elevated endothelial $[Ca^{2+}]_i$ served primarily to activate a putative "EDHF synthase" (or to trigger release of a stored EDHF). More recent studies, however, indicate that the essential role of elevated endothelial $[Ca^{2+}]_i$ may instead be to promote endothelial hyperpolarization via stimulation of endothelial K_{Ca} channels, in particular the IK_{Ca} and SK_{Ca} channels. This idea is further supported by the fact that the endothelial $[Ca^{2+}]_i$ required to initiate EDHF-mediated dilations (340 nM Ca^{2+}) falls right within the range of $[Ca^{2+}]$ reported to activate IK_{Ca} and SK_{Ca} channels (~250–500 nM Ca^{2+}) [2, 7].

The type and location of the K_{Ca} channels involved in EDHF-mediated responses is still being worked out. However, recent data points to involvement of IK_{Ca} channels alone (cerebral arteries) or in combination with SK_{Ca} channels (peripheral arteries) located on the endothelium. Endothelial cells have been demonstrated to possess both IK_{Ca} and SK_{Ca} channels by pharmacological, electrophysiological, and molecular techniques. Native endothelial cells do not appear to express BK_{Ca} channels. Native smooth muscle cells express BK_{Ca} channels as well as certain SK_{Ca} channels, but they may not express IK_{Ca} channels under normal conditions. From these data, it would appear likely that the K_{Ca} channels involved in the EDHF-mediated response are located on the endothelial cells.

Admittedly, activation of K_{Ca} channels is not the only outcome of elevated endothelial $[Ca^{2+}]_i$. One Ca^{2+}-dependent enzyme that has been demonstrated to be involved in the EDHF-mediated response of some arteries is cytosolic phospholipase A2 ($cPLA_2$). The $cPLA_2$ enzyme is a Ca^{2+}-dependent lipase that catalyzes the hydrolysis of the *sn*-2 linkage of diacyl glycerophosphates, releasing fatty acids such as arachidonic acid. Significant activation of $cPLA_2$ has been demonstrated at Ca^{2+} concentrations of 230 to 450 nM, a concentration range that brackets the endothelial $[Ca^{2+}]_i$ concentration for initiating EDHF-mediated responses. One possible explanation of the $cPLA_2$ dependence of EDHF-mediated dilations in some arteries is simply that arachidonic acid or one or more of its numerous metabolites is the EDHF. In coronary arteries in particular, epoxygenase metabolites of arachidonic acid may act as hyperpolarizing factors. However, an alternative explanation is that arachidonic acid or its metabolites *modulate* the EDHF-dependent mechanism—but are not the EDHF themselves. For instance, arachidonic acid has been demonstrated to activate endothelial transient receptor potential cation channels (TRPV4), which are capable of carrying inward Ca^{2+} currents. Thus, one conceivable mechanism could involve $cPLA_2$-dependent release of arachidonic acid, activation of TRPV4 by arachidonic acid, increased Ca^{2+} influx, and subsequent sustained activation of endothelial IK_{Ca} and SK_{Ca} channels. In this hypothetical scenario, the sensitivity of the mechanism to $cPLA_2$ inhibition could vary depending on several tissue-specific variables such as TRPV4 channel prevalence, relative contribution of other Ca^{2+} regulation mechanisms, K_{Ca} channel Ca^{2+} sensitivity, and so on. If one therefore considers that $cPLA_2$ can participate in a modulating role, the degree to which it is able to modulate the EDHF-dependent mechanism could vary considerably between arteries and might thus explain the heterogeneity of effects seen with PLA_2 inhibitors. Although the preceding scenario is still hypothetical, it is intended to emphasize the point that a number of EDHF candidate factors should also be considered as potential modulators of endothelial K_{Ca} channels—and therefore EDHF-mediated vasodilatation.

A Relationship between Endothelial Membrane Potential (V_m) and Endothelial $[Ca^{2+}]_i$?

A number of studies have been performed to evaluate the relationship between endothelial membrane potential (V_m) and endothelial $[Ca^{2+}]_i$. The bulk of these studies have been performed with cultured endothelial cells while only a

handful of studies have evaluated the relationship in endothelium from intact arteries. In cultured endothelial cells, Ca^{2+} influx has been shown to be notably modulated by endothelial V_m. As the endothelial cell becomes more hyperpolarized, the driving force for Ca^{2+} entry is increased and greater Ca^{2+} influx results following agonist stimulation [8]. If this relationship were to hold true for endothelium within intact arteries, then one possible effect of stimulating endothelial K_{Ca} channels (and thus hyperpolarizing the endothelium) would be to promote greater Ca^{2+} influx in response to EDHF-dependent agonists. In this scenario, the effect of K_{Ca} channel blockers on the EDHF-mediated response could be to prevent endothelial $[Ca^{2+}]_i$ from reaching a critical threshold. However, from the few studies that have addressed this issue in intact arteries, the relationship between endothelial V_m and endothelial $[Ca^{2+}]_i$ is uncertain. When high K^+ has been used to nonselectively inhibit all K^+ channels, agonist-mediated increases in endothelial $[Ca^{2+}]_i$ were shown to be either reduced [9, 10] or unaltered [11]. However, when charybdotoxin plus apamin was administered to block the K_{Ca} channels, agonist-mediated increases in endothelial $[Ca^{2+}]_i$ were shown to be undiminished, despite complete inhibition of the EDHF-mediated relaxation/dilation [9, 11] (see Figure 4). These findings support the conclusion that the essential role of endothelial K_{Ca} channels is not to promote or maintain adequate Ca^{2+} entry for EDHF-mediated dilation. Instead, the essential role of the endothelial K_{Ca} channels appears to be to produce endothelial hyperpolarization, entirely downstream of endothelial Ca^{2+}, and thus promote smooth muscle hyperpolarization more directly. This conclusion is supported by a study by Marrelli et al. in which an IK_{Ca} channel agonist (1-EBIO) was administered selectively to the endothelium in intact pressurized cerebral arteries [11]. 1-EBIO produced significant hyperpolarization of the endothelium and vasodilatation despite no change in endothelial $[Ca^{2+}]_i$. Thus, endothelium-dependent hyperpolarization of the smooth muscle can be produced without any elevation of endothelial $[Ca^{2+}]_i$ if endothelial K_{Ca} channels are activated by some other means. Taken as a whole, it appears that the primary role of endothelial Ca^{2+} in the EDHF-dependent mechanism may be that of the principal physiological activator of the IK_{Ca} and SK_{Ca} channels.

Role of Endothelial $[Ca^{2+}]_i$ in EDHF-Mediated Responses in Pathology

An increasing number of studies demonstrate potentiated EDHF-mediated responses following a variety of pathological conditions, including ischemia/reperfusion (I/R), hypercholesterolemia, and congestive heart failure. The mechanism by which this potentiation occurs remains largely unknown. However, in cerebral I/R, the potentiated EDHF-mediated dilations are accompanied by augmented endothelial $[Ca^{2+}]_i$ responses [12]. In this case, for a given agonist concentration, there was a greater increase in endothelial $[Ca^{2+}]_i$ in the I/R endothelium compared with control. It was speculated that the greater Ca^{2+} responses following I/R might have resulted from some dysfunction in endothelial Ca^{2+} handling. It remains to be determined if endothelial Ca^{2+} is similarly altered in other pathological situations in which EDHF-mediated responses are potentiated.

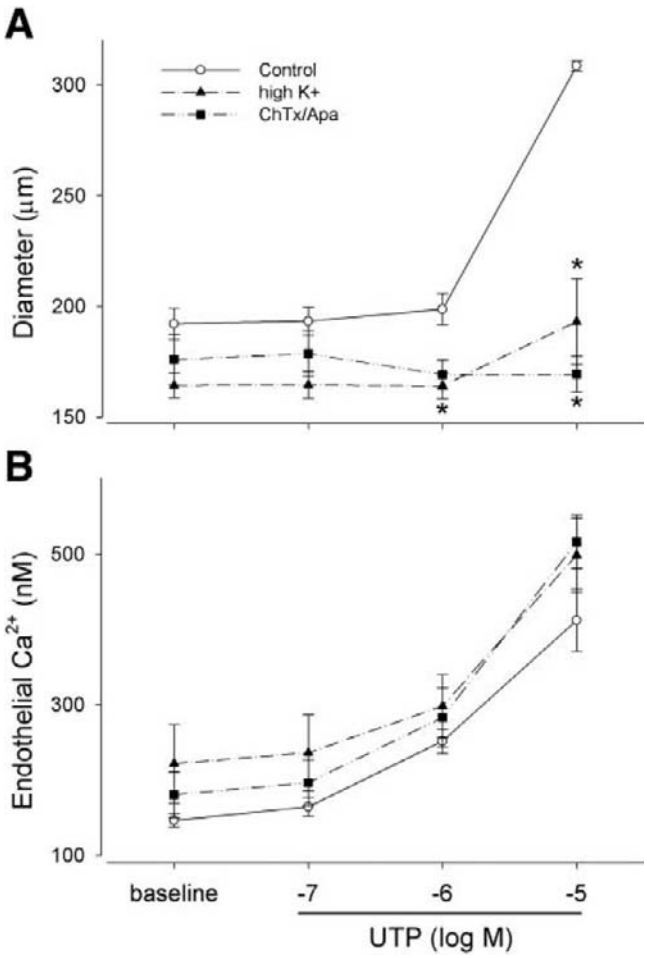

Figure 4 Role of endothelial K^+ channels in endothelial $[Ca^{2+}]_i$ response. Summary of simultaneous measurements of diameter **(A)** and endothelial $[Ca^{2+}]_i$ **(B)** in response to UTP (10^{-7} to 10^{-5} M). All experiments were performed in the presence of L-NAME and indomethacin. Responses to UTP were performed in the presence of L-NAME/indomethacin alone (control), with luminal 60 mM K^+ (high K^+, nonselective K^+ channel inhibitor), and in the presence of charybdotoxin/apamin (ChTx/Apa; combination blocks all K_{Ca} channels). Diameter responses for both high K^+ and ChTx/Apa were significantly different compared with control (two-way repeated-measures ANOVA). *Individual differences ($P < 0.05$, Tukey's test). Reproduced with permission from Marrelli et al. (2003). *Am. J. Physiol. Heart Circ. Physiol.* **285**, H1590–H1599.

Summary of Endothelial $[Ca^{2+}]_i$ in EDHF-Mediated Vasodilatation

EDHF-mediated vasodilatation appears to require the activation of endothelial IK_{Ca} and SK_{Ca} channels in order to

promote smooth muscle hyperpolarization and subsequent vasodilatation. The role of endothelial $[Ca^{2+}]_i$ in this mechanism appears to be as the principal physiological activator of those channels. Therefore, factors that significantly affect the endothelial $[Ca^{2+}]_i$ response should be able to variably modulate IK_{Ca} and SK_{Ca} channel activation, and thus EDHF-mediated vasorelaxation.

Capsule Biography

Dr. Marrelli is an assistant professor in the Department of Anesthesiology at Baylor College of Medicine where he studies endothelial regulation of vascular tone. In particular, Dr. Marrelli's research focuses on the blood vessels of the cerebral circulation and the effects of ischemia/reperfusion (or stroke) on subsequent vascular function.

CHAPTER 38

Role of the Endothelial Cell Cytoskeleton in Microvascular Function

Laura Linz McGillem and Joe G. N. Garcia

Center for Translational Respiratory Medicine, Division of Pulmonary and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland

Introduction

No single cellular organizational element has commanded so much attention in the endothelial cell recently as the group of proteins known as the cytoskeleton. As depicted in Figure 1, the endothelial cytoskeleton is involved in multiple critical endothelial biologic processes including angiogenesis, mechanotransduction, apoptosis, and critical elements of the inflammatory response including leukocyte diapedisis and barrier regulation. The cytoskeleton is composed of three primary elements—actin microfilaments, intermediate filaments, and microtubules. Each will be discussed in the context of microvascular endothelial activation and dysfunction.

Microfilament Cytoskeleton Overview

Endothelial cells (ECs) contain an abundance of the molecular machinery necessary to generate tension via an actomyosin motor—actin and myosin, the key components of the microfilamentous cytoskeleton, represent a major portion of the total endothelial cellular protein content (15–20%). G-actin is a globular monomer that assembles reversibly to form polymerized actin fibers (or F-actin) conferring strength on structural elements regulating cell shape, particularly when accompanied by phosphorylated myosin. F-actin filaments within peripherally distributed cortical bands are essential for maintenance of endothelial integrity and basal barrier function. The actin microfilament cytoskeleton is a dynamic structure that undergoes rearrangement under the control of various actin binding, capping, nucleating, and severing proteins and is focally linked to multiple membrane adhesive proteins such as cadherin molecules, glycocalyx components, functional intercellular proteins of the zona occludens and zona adherens, and focal adhesion complex proteins. More than 80 actin-binding proteins have been identified and are critical participants in cytoskeletal rearrangement and tensile force generation, and serve to provide a high level of fine tuning of cell shape, adhesion, and orchestrated cell migration as well as regulation of endothelial junctional stability [1]. Edemagenic agents, such as thrombin, initiate cytoskeletal rearrangement characterized by the loss of peripheral actin filaments with a concomitant increase in organized F-actin cables that span the cell as "stress fibers" (Figure 2). One actin binding protein, cofilin for example, exerts actin-depolymerizing activity critical to cortical actin rearrangement that is inhibited by Rho GTPase pathway activation during stress fiber formation [1]. In addition, reduction in either expression or activity of the abundant actin-severing protein gelsolin significantly decreases stress fiber–dependent contraction in cultured cells. Another actin-binding protein involved in cellular contraction is the 27-kDa heat shock protein, hsp27, whose actin binding properties are altered by phosphorylation through a p38 MAP kinase-driven pathway. Reduction of hsp27-induced inhibition of actin polymerization alone can produce stress fiber formation.

Manjno and Palade first observed ultrastructurally that lung EC exhibit a rounded morphology producing paracellular gaps during inflammatory edema [2], a finding similarly observed after thrombin or histamine challenge. This dramatic cell shape change was an early implication of direct involvement of endothelial structural components, particularly the dynamic actin-containing microfilament EC cytoskeleton. Focally distributed changes in tension/relaxation can be accomplished by regulation of the level of myosin light chain (MLC) phosphorylation and actin stress fiber formation. Formation of cytoplasmic stress fibers, critical to cellular contraction and increased intracellular tension, occurs via the coordinate activation of the small GTPase Rho and Ca^{2+}/CaM-dependent myosin light chain kinase, which together increase the level of phosphorylated myosin light chains in a spatially distinct manner. The resultant increases in actin stress fiber formation and actomyosin cellular contraction disrupt the barrier-regulatory balance with tethering forces and destabilize cytoskeletal-junctional linkages culminating in increased vascular permeability [1]. Direct inhibition of either MLCK or Rho kinase as well as Ca^{2+}/calmodulin antagonism attenuates thrombin-induced MLC phosphorylation, gap formation, and barrier dysfunction as well as the increased vascular permeability observed in many but not all models of lung edema.

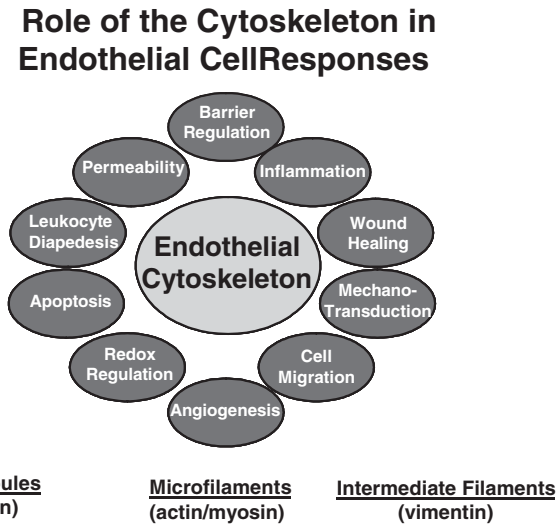

Figure 1 Role of the Cytoskeleton in Endothelial Cell Responses. (see color insert)

Endothelial Cell MLCK Isoform

EC MLCK is an ATP- and Ca^{2+}/calmodulin-dependent enzyme essential for generation of centripetal cellular tension via its ability to enhance actomyosin motor activity [1]. EC MLCK appears to be enriched in microvascular endothelium compared to macrovascular cells, likely a reflection of the diversity of function within that tissue. Gene expression studies have noted that expression of the EC MLCK gene distinguishes micro- from macrovascular endothelium. Myosin light chain kinase (MLCK)-dependent stress fiber formation results in EC contraction and intercellular gap formation with decreased transmonolayer endothelial resistance (TER) and increased fluid and solute translocation [1]. Nonskeletal-muscle MLCK exists as high-molecular-weight (~210 kDa) and low-molecular-weight (130–160 kDa) isoforms that are derived from a single gene. Human ECs express only the high-molecular-weight form (EC MLCK) cloned by our group, with multiple splice variants also detected by RT-PCR. The two most predominantly expressed variants (EC MLCK 1 and 2) differ only by a single exon deletion (encoding AA# 436–505), which results in EC MLCK 2 containing 69 fewer amino acids than EC MLCK 1. This deleted region contains two sites for $p60^{src}$-catalyzed tyrosine phosphorylation (Y^{464},

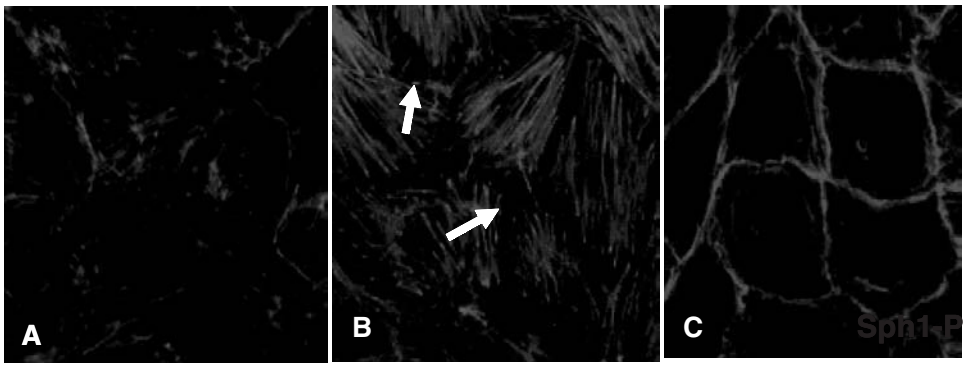

Figure 2 Actin microfilaments distribution is altered by agents that affect vascular endothelial cell permeability. Human lung endothelial cells contain randomly distributed filamentous actin (red) in a stable monolayer (A). Edemagenic agents, such as thrombin, cause cytoskeletal rearrangement resulting in thick actin bundles "stress fibers" which span the cell. Increase intracellular tension and contraction results in formation of intercellular gaps (B, arrows). Platelet derived-phopholipids such as sphingosine 1-phophate are barrier protective and result in an increase in cortical actin at the cell periphery (C). (see color insert)

Y^{471}) that serve to produce differential regulation of EC MLCK splice-variant activity.

The EC MLCK isoform, like the endothelial cytoskeleton in general, is highly multifunctional and serves as an important effector in numerous endothelial processes. In multiple in vitro and in vivo models of EC permeability, increased MLCK activity produces increased MLC phosphorylation within newly formed stress fibers, intracellular tension, cell rounding, paracellular gap formation, and subsequent EC barrier disruption. Inhibition of EC MLCK attenuates or prevents vascular leak produced by ischemia reperfusion, neutrophils, TGFB, thrombin, and mechanical stress as well as neutrophil influx in response to LTB4 or FMLP. More recently, we have described increased MLC phosphorylation in a cortical distribution during EC barrier enhancement [3], suggesting possible spatially-defined MLCK activation that can differentially regulate permeability. EC MLCK has been implicated in TNF-induced endothelial cell apoptosis, mechanotransduction, and calcium signaling.

Rho Family GTPases and the Cytoskeleton

The Rho family of small GTPases are intimately involved in cytoskeletal rearrangement and the distribution and assembly intercellular adherens complexes and focal adhesions. We and others have shown that over expression of constitutively active Rac enhances peripheral actin polymerization in the cortical ring [3]. Rac activation induces lamellipodia formation, membrane ruffling, the formation of cortical actin filaments, and the spreading of ECs, whereas inhibition of Rac GTPase leads to increased monolayer permeability and enhances the thrombin-mediated barrier dysfunction response through a variety of signaling proteins. We recently reported the critical importance of Rac GTPase-dependent cortical actin rearrangement in the augmentation of pulmonary endothelial cell (EC) barrier function by sphingosine 1-phosphate (S1P), HGF, shear stress, simvastatins, and oxidized phospholipids. Ligation of cell surface S1P receptors triggers a complex signaling cascade mediated by intracellular G-proteins that activate Rac GTPase and modulate molecular trafficking to and enzymatic activity at the cell periphery, resulting in peripheral cytoskeletal enhancement and the formation of functional adherens junction complexes.

Furthermore, Rac GTPase is essential for translocation of cortactin, an F-actin binding protein that stimulates actin polymerization and stabilizes the filamentous actin network, an event necessary for the peak barrier enhancing response to S1P in vitro [3]. Conversely, dominant negative Rac prevents the translocation of cortactin and subsequent actin polymerization in the cell periphery, and attenuates barrier enhancement by simvastatin, sphingosine 1-phosphate, and shear stress. Src kinase-mediated phosphorylation of cortactin alters the binding of cortactin, via its SH-3 domain, to MLCK, a molecule potentially important for the organization of filamentous actin in the cortical ring. Finally, Rac inactivates the actin severing protein, cofilin, in the cell periphery through a signaling cascade involving PAK-1 and LIM kinase. Clearly, multiple signaling proteins contribute to modulate dynamic cytoskeletal arrangements, which play a key role in the maintenance or disruption of endothelial barrier integrity.

Microtubule Cytoskeleton Overview

Microtubules (MTs) are cylindrical polymeric 25-nm tubes composed of parallel bundles of 13 linear protofilaments made up of α/β tubulin heterodimers. Uniform orientation of the protofilaments within the tubule conveys polarity to the entire microtubule. Microtubules continually undergo cyclic polymerization and depolymerization, known as dynamic instability. Post-translational modifications of tubulin molecules, such as acetylation and detyrosination, as well as capping of the microtubules' plus ends, are thought to stabilize and mature microtubules. Microtubules have critically important roles in mitosis, cell migration, and intracellular transport of a large number of proteins and organelles via microtubule-associated proteins (MAPs).

Multiple aspects of endothelial cell motility, including migration, morphological changes, and proliferation as well as control of endothelial cell intracellular tension and contractility, involve cross-linking between the MT and actin microfilament networks. Microtubule distribution and dynamic instability regulate the activity of small GTPase-mediated signal transduction cascades that control microfilament network dynamics due in part to nonmotor MAPs known as MT-associated guanine-nucleotide exchange factors (GEFs), a family of proteins that regulate activity of Rho GTPases. Furthermore, MT depolymerization results in activation of Rho, stress fiber formation and apoptosis. Inversely, multiple signaling molecules associate with MT and may regulate MT dynamics including Rac1, proteins upstream of Rac1, and mDia1 [4]. It is clear that microtubule distribution and state of assembly/disassembly has a significant impact on the state of endothelial cell intracellular tension and contractility.

Microtubules and Vascular Barrier Function

Control of vascular endothelial cell barrier function results from a delicate balance between contractile and tethering forces that is significantly regulated by cross-linking of MT and actin cytoskeletal networks. Disruption of the MT network appears to set off a cascade of downstream effects on Rho-dependent mechanisms, including release of MT-bound GEFs and subsequent activation of the small GTPase Rho and Rho kinase, which ultimately results in a significant increase in MLC phosphorylation and subsequent contractile force.

Multiple factors regulate the actomyosin and MT-dependent effect on EC permeability. These include the

barrier-protective effect of the cAMP-dependent protein kinase A (PKA) which likely stabilizes the MT network and retards Rho kinase activation by RhoGEFs [5].

Inflammatory cytokines such as tumor necrosis factor (TNF)-α that are secreted by macrophages and endothelial cells increase EC permeability. Presence of TNF-α also induces destabilization of microtubules. TNF-α induces MLC phosphorylation accompanied by microfilament rearrangement; however, subsequent EC permeability appears to be independent of MLCK and Rho kinase. Microtubule disassembly most likely affects TNF-α induced actin network changes and EC permeability.

Microtubules and Response to Shear Stress

Vascular endothelial cells are exposed to constant physiological shear stress from blood flow. Microtubules contribute to the stability of microvascular cells via intracellular distribution changes concomitant with EC migration and motility. Within the endothelial cell in an intact quiescent monolayer, microtubules are distributed in an extensive array radiating from the centrosome, or MT organizing center (MTOC), which is randomly oriented around the nucleus. Stress on the monolayer, such as wounding or fluid shear, is accompanied by alterations in the MT network distribution such as temporary displacement of the MTOC and realignment of the microtubules [6]. Shear stress also causes EC to undergo morphological changes such as lamellipodia extension and directional migration that appear to require active MT dynamics. Chemical stabilization of MT depolymerization causes a reduction in EC migration, as well as attenuated lamellipodial protrusion in response to flow.

Microtubules and Tube Formation

Angiogenesis is a multistep process including the directed migration of endothelial cells (EC) in response to chemotactic signals. Each of the key steps in angiogenesis (sprouting, branching, lumen formation, and barrier stabilization) involves a major role for the cytoskeleton in regulation of the signaling events, especially via the Rho GTPase pathway. MT are involved in cell motility dynamics during tube and lumen formation as well as maintenance of the 3-D nascent tube postangiogenesis (Figure 3). MT destabilizing drugs that limit tumor growth via inhibition of mitosis in both tumor cells and vascular EC are an important part of antitumor therapy. Interference with MT dynamics by stabilization or depolymerization results in capillary tube collapse due to loss of EC structural integrity. This phenomenon involves the Rho GTPase pathway since inhibitors of Rho activity results in blockage of capillary tube collapse [7].

Intermediate Filament Cytoskeleton Overview

Intermediate filaments (IFs) represent the third major element involved in EC cytoskeletal structure. Despite greater diversity than the highly conserved components of either actin microfilaments or microtubules, IF proteins share a common dimer structure containing two parallel α-helices which combine to form apolar fibrils that associate with an array of IF-binding proteins while connecting to the nuclear envelope, peripheral cell junctions, and other cytoskeletal components. IF proteins are expressed in a highly cell-specific manner. Vimentin is the primary IF protein found in EC and other cells of mesenchymal origin. These data suggest that potential roles for IF in EC cytoskeletal structure, and more specifically barrier function, are likely to be subtle and subject to compensation by biologic redundancy.

IFs were defined on the basis of their 7- to 12-nm filament structure, which distinguished them from microfilament and microtubules. Helical polymers of IF proteins are made up of conserved central rod domains flanked by variable C- and N-terminal domains. In vivo studies of vimentin assembly resulted in characterization of three distinct, progressive structural assembly intermediates (particles, squiggles, and long filaments) that exist in a state of equilibrium between subunits and longer polymers. IF distribution in spread, interphase cells is predominantly arranged in long filaments extending from the nucleus to the cell surface, with particles and squiggles apparent at the extreme periphery of the cell. Evidence shows that the assembly of IFs is a complex process, which most likely is highly regulated by signaling cascades associated with cell motility.

Vimentin IFs are very dynamic structures undergoing constant assembly/disassembly, as well as anterograde and retrograde movements. Microtubule-based movement of IF is thought to be critical for assembly and maintenance of the vimentin IF network [8]. Most likely, the dynamic properties of vimentin IF network in the vascular endothelial cell is important in regulation of cell shape and resistance to hemodynamic stress that accompanies blood flow.

Mechanical Strain, Shear Stress, and Flow

Vascular endothelial cells withstand constant mechanical shear force of blood flow and can adapt in response to acute and chronic changes in hemodynamic forces. These physiological changes in the vascular wall are regulated by the IF cytoskeleton and IF-associated proteins, which not only serve as internal scaffolding for the endothelial cell, but are also linked to the plasma membrane, contacts to adjacent cells and to the basement membrane. Vimentin protein expression is higher in macrovascular endothelial cells lining vessels subjected to the highest hemodynamic strain,

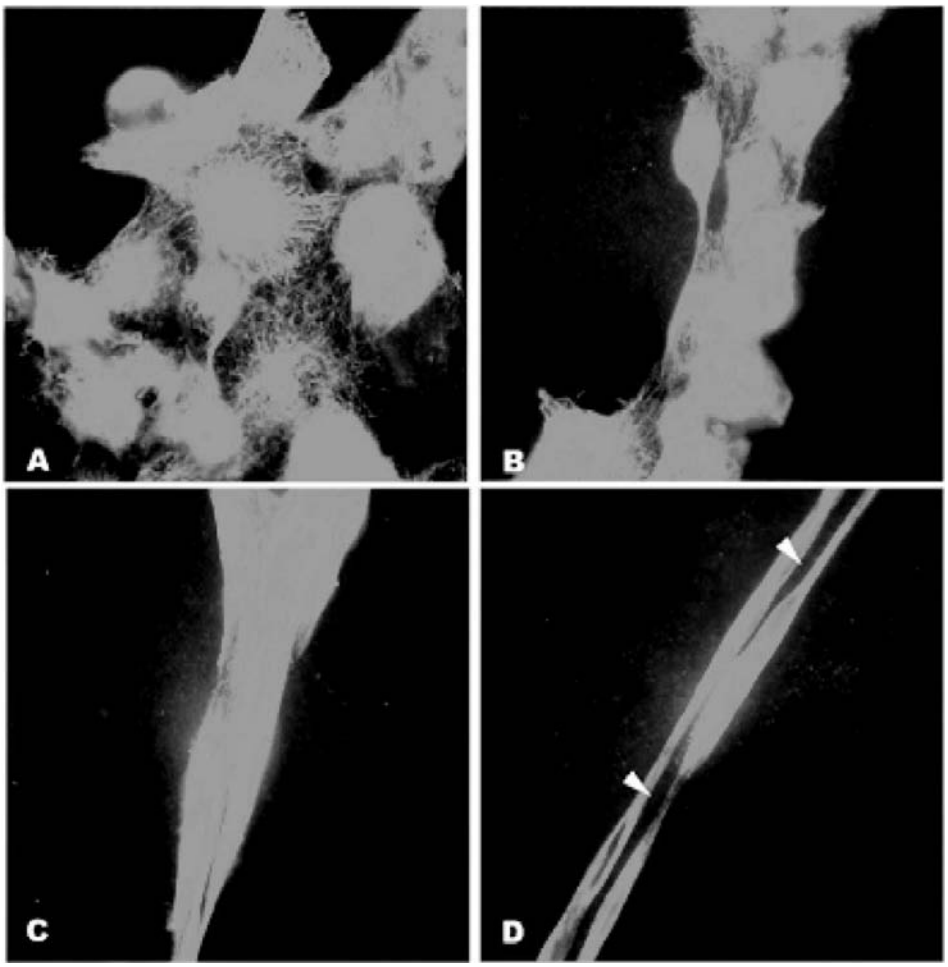

Figure 3 Microtubules are involved in endothelial cell dynamics during capillary-like tube and lumen formation. Human lung microvascular (HLMV) endothelial cells were plated on extracellular matrix (Matrigel, BD Biosciences) and labeled with antibodies specific for tubulin (green). In the early stages of capillary-like tube formation (1–4 hr) HLMV EC are grouped together and display a spread morphology with microtubules arrayed in a radial pattern (A, arrowheads) and begin to migrate into a linear arrangement (B). In the middle stage of tube formation (5–9 hrs), HLMV EC have elongated into capillary-like cords of cells with more elongated microtubule arrays (C). In late capillary-like tube formation (>12 hrs), a lumen is visible (D, arrowheads) between the HLMV EC with compressed linear microtubule distribution. (see color insert)

such as the aorta, compared to EC lining vessels under less shear stress. The physical properties of vimentin IF suggest that they are responsible for resistance to shear strain. Although rigid microfilaments are first to break or fluidize under high strain, vimentin IFs are a more resilient protein polymer with bimodal elastic properties such that vimentin IFs have a higher elasticity under conditions of low strain but become harder and more resistant under higher strains. Presence of a flexible vimentin intermediate filament network is important for maintaining not only the structural integrity of individual cells but also the integrity of the endothelial cell monolayer lining the microvessel. Specifically, vimentin IFs are critical for maintaining the structural integrity of endothelial cells under shear stress, and may also be a conduit for signaling cascades triggered by mechanical force.

Vimentin phosphorylation occurs rapidly in thrombin- or phorbol-stimulated endothelium; however, the role of vimentin in EC structure and resultant barrier function remains unclear. Although vimentin IF disassembly results in dramatic alteration of actin and microtubule filaments in cultured cells, fibroblasts derived from vimentin knockout mice displayed normal actin and microtubule architecture. While the vimentin knockout animals themselves developed normally without gross blood vessel abnormalities, absence of vimentin in walls of mesenteric arteries reduced vessel dilation in response to flow [8]. Downstream responses to flow may be the result of intracellular mechanosignaling events triggered by deformation of the IF cytoskeleton. Adaptation of the EC vimentin IF network occurs in response to changes in flow. Vimentin IF networks display rapid directional displacement within minutes of initial

exposure to unidirectional laminar flow. Over a period of hours, cytoskeletal filaments align themselves in the direction of flow. Primary IF network displacement due to the onset of laminar flow imposes a significantly larger change in the vimentin IF above the nucleus compared with displacement that is occurring in the cytosol closer to the substrate. These observed spatial changes may be a means of distribution of local shear force transmission throughout the cell and therefore convey cell signaling messages via a mechanosignaling pathway.

Intermediate Filaments and Microvascular Endothelial Cell–Cell Junctions

Microvascular permeability and barrier function are dependent on maintenance of tight cell–cell intercellular junctions. Adjacent cells assemble junctions composed of transmembrane proteins linked to cytoplasmic multiprotein plaques that anchor microfilament or IF cytoskeletal networks to the plasma membrane. Microvascular EC junctional adhesive plaques maintain cell morphology, tissue integrity, and a semipermeable barrier and participate in cell signaling pathways. Endothelial cells contain microfilament-associated adherens junctions and tight junctions. Vascular endothelial cadherin (VE-cad) is an important component of the Ca^{2+}-dependent EC adherens junction and, along with other junctional proteins such as desmoplakin and β- and γ-catenin (plakoglobin), link the actin and vimentin intermediate filament networks of adjacent cells.

Inflammatory factors affect vascular permeability by disturbing cell–cell junctions and the vimentin IF network. Histamine decreases EC barrier function, most likely by rapidly increasing phosphorylation of multiple junctional proteins including VE-cadherin and vimentin and inducing a rapid reorganization of the vimentin IF. Biochemical studies reveal that the histamine treatment decreases association between the vimentin cytoskeleton and VE-cadherin, but not actin and VE-cadherin [9]. The IF network may then participate structurally and also appears to be involved in assembly and function of microvascular endothelial cell–substrate and cell–cell attachment that effects endothelial cell function.

Intermediate Filaments and Microvascular Endothelial Cell–Matrix Junctions

Endothelial cell–extracellular matrix adhesion is mediated by focal contacts and vimentin-associated matrix adhesions (VMAs) at the basal cell surface where the cytoskeleton is linked to heterodimeric clusters of α/β integrin proteins. Heterodimeric integrin pairing appears to convey functional diversity. Focal contacts are not only mechanical anchors but also participate in cell–matrix signaling. Along with microfilaments, vimentin IF can also insert into focal contacts composed of α6β4 laminin binding integrins in microvascular endothelial cells. Bone marrow microvascular cells are attached to the basement membrane via αvβ3 integrin-containing vimentin-associated matrix adhesions. Vimentin IFs are likely to have a structural/functional role in EC focal contact organization. Vimentin IFs appear to stabilize and regulate cell–matrix adhesions since VMAs became larger, greater in number, and showed increased association with vimentin IFs in ECs subjected to hemodynamic shear stress or flow. Functionality of IF attachment to focal contacts has been further demonstrated by the reduction of the size of VMAs in ECs with reduced vimentin IFs by means of vimentin-silencing RNA. These vimentin knockdown cells display drastically reduced adhesion under physiological flow rates. Vimentin IFs in endothelial cells both stabilize and regulate the size of FCs, which allows regulation of cell–matrix adhesion and resistance to flow [10].

Summary

The roles of actin microfilaments, microtubules, and intermediate filaments in EC function are becoming increasingly defined and appreciated as increasingly complex. The actin cytoskeleton is intimately involved in numerous endothelial cell biologic processes of critical importance to the function of the organ and the entire organism as well. Historically viewed as separate and distinct cytoskeletal systems, microtubules and actin filaments are now known to interact functionally during dynamic cellular processes. Microtubule disruption induces rapid assembly of actin filaments and focal adhesions, isometric cellular contraction that correlates with the level of MLC phosphorylation, increased permeability across endothelial cell monolayers, and increased transendothelial leukocyte migration, while microtubule stabilization attenuates these effects. The mechanisms involved in these effects are poorly understood but are likely to be mediated through interaction with actin filaments, suggesting significant microfilament–microtubule crosstalk and an intriguing role for the microtubule cytoskeleton in EC barrier regulation. The exact roles of intermediate filaments such as vimentin await further exploration.

Glossary

Cadherin: A cell type specific calcium-dependent transmembrane protein present in adherens junctions.

Cortactin: An actin-bundling protein that is phosphorylated by tyrosine kinase $pp60^{src}$.

Endothelial permeability: Dynamic process that involves alteration and contraction of cytoskeletal structure as well as loosened adhesive junctions to allow intercellular passage of fluid.

MLCK: ATP- and Ca^{2+}/calmodulin-dependent kinase that phosphorylates myosin light chain.

Rac GTPase: Members of large family of signaling proteins, which hydrolyze GTP to GDP and have roles in regulation of motility.

Rho GTPase: Members of large family of signaling proteins which hydrolyze GTP to GDP and are involved in signaling cascades linking extracellular stimuli to dynamic actin cytoskeletal rearrangement including stress fiber formation.

Tubulin: Globular protein that exists as a heterodimer in polar linear polymers that compose microtubules.

Vimentin: Type III intermediate filament protein expressed in cells of mesenchymal origin.

Cell Sci*. 2004. **117**(Pt 2), 133–141. *Intermediate filaments (IFs) are dynamic motile cytoskeletal elements that assemble in three distinct structural forms, but are most frequently observed as an extensive network of IFs extending from the perinuclear region to the endothelial cell surface. Vimentin IFs in each of the structural forms are motile and travel via microtubule-based motors along microtubule tracks (MT) tracks. IF motility speed appears to be based on both the type of IF and the state of assembly. Cross-linking between the MT and IF network appears to be critical to cell function, since disruption of IF motility results in significant pathological conditions in multiple cell types including neurons.*

Capsule Biography

Dr. Joe G. N. Garcia is the Dr. David Marine Professor of Medicine, Director of the Division of Pulmonary and Critical Care Medicine, and Director of the Center for Translational Respiratory Medicine at The Johns Hopkins University School of Medicine in Baltimore, Maryland. One of his primary research interests include the regulation of the pulmonary microvascular endothelial barrier by the endothelial cytoskeleton.

Dr. Laura Linz McGillem is a postdoctoral fellow in the department of Pulmonary and Critical Care Medicine. Her thesis work at Louisiana State University Health Sciences Center included isolation and characterization of a novel nonmuscle myosin from bovine retina. Her interests include endothelial cell physiology, cell–cell adhesions, and the cytoskeleton.

CHAPTER 39

Microvascular Permeability

C. C. Michel
Biomedical Sciences Division, Faculty of Medicine, Imperial College, London

Introduction

Microvascular permeability is a collective phrase to describe the barrier properties of microvascular walls in terms of the ease with which fluid and solute molecules are transported between blood and tissues. The higher the microvascular permeability to a particular solute, the lower the barrier of the microvascular walls to that solute.

Permeability is measured quantitatively in terms of permeability coefficients whose values are determined by the properties of pathways through the endothelium. In many experimental studies, changes in permeability are inferred from changes in solute transport from blood to tissues. When this is done the results should be examined critically, because several factors in addition to permeability may influence blood tissue transport. Only changes in the permeability coefficients yield information that may be interpreted unambiguously in terms of changes in permeability.

Permeability Coefficients

For practical purposes, there are three permeability coefficients. Two of these describe the permeability to a particular solute (the diffusional permeability and the solute reflection coefficients) and the third describes fluid permeability (the hydraulic permeability).

The Solute Diffusional Permeability Coefficient

The solute diffusional permeability, P_d, is defined under conditions where there are no net movements of fluid through microvascular walls. It is the transport of the solute through unit area of microvascular wall divided by the concentration difference of that solute between the fluid inside and that immediately outside the microvessel. P_d has units of velocity ($cm\,sec^{-1}$). Writing the definition of P_d as an equation:

$$P_d = \frac{J_{Sd}/S}{(C_C - C_i)} \quad (1)$$

where J_{Sd} is the net transport of solute from the microvascular blood into the tissues in the absence of net fluid flux through the vessel wall, S is the area of microvascular wall through which transport occurs, C_c is the mean solute concentration inside, and C_i is the mean solute concentration immediately outside the microvessel. The condition that net fluid movements between the blood and the tissue should be zero is especially important when P_d is being estimated for macromolecules. It is of less importance when permeability is high, as it is for small molecules (see later discussion). The number of perfused capillaries in a tissue determines S, and this varies independently of permeability. C_i is often unknown and estimates of P_d are often made under conditions where C_i can be assumed to be approximately zero. C_c is a function of the arterial and venous concentrations and also of microvascular blood flow and of the permeability itself (see later discussion).

P_d is dependent on the lipid solubility, molecular size, and charge of the solute. Lipid-soluble molecules have high permeabilities, as they can pass through cell membranes and so can exchange through the entire area of the microvascular walls. Oxygen, nitrogen, and carbon dioxide have high enough fat solubilities to fall into this category. The P_d values of lipid-soluble molecules may be greater that $0.1\,cm\,sec^{-1}$. Water-soluble molecules are confined to specialized pathways through the endothelium and their values for P_d are nearly always less than $10^{-3}\,cm\,sec^{-1}$. In most tissues (e.g., skin, connective tissues, muscle, nerves) the specialized pathways are located between the endothelial cells and pass through occasional breaks in the junctional strands. In tissues associated with secretory and absorptive epithelia (e.g., intestinal mucosae, kidney, exocrine and endocrine glands) the permeability pathways are fenestrations, disk-like openings (400 to 700 Å in diameter) through thinned areas of endothelium covered with a fine diaphragm with an

overlying layer of glycocalyx (cell coat). In intact microvessels, values for P_d of water-soluble molecules fall more rapidly than their values for diffusion coefficient as molecular size increases (see Figure 1A).

Solute Reflection Coefficient

Solutes are also transported through microvascular walls by fluid filtration and reabsorption. This *convective* component of solute transport is proportional to net fluid flow and to the solute reflection coefficient, σ. If net fluid filtration from plasma to tissues is J_V and the mean plasma concentration of the solute inside the microvessel is C_c, the convective component of transport, J_{Sc}, is

$$J_{Sc} = J_V C_c (1 - \sigma) \tag{2}$$

The reflection coefficient is therefore the fraction of solute that is reflected or rejected at microvascular walls during ultrafiltration and $(1 - \sigma)$ is the fraction of the solute molecules that is transported. The reflection coefficient also determines the effective osmotic pressure that the solution of a particular solute can exert across a particular

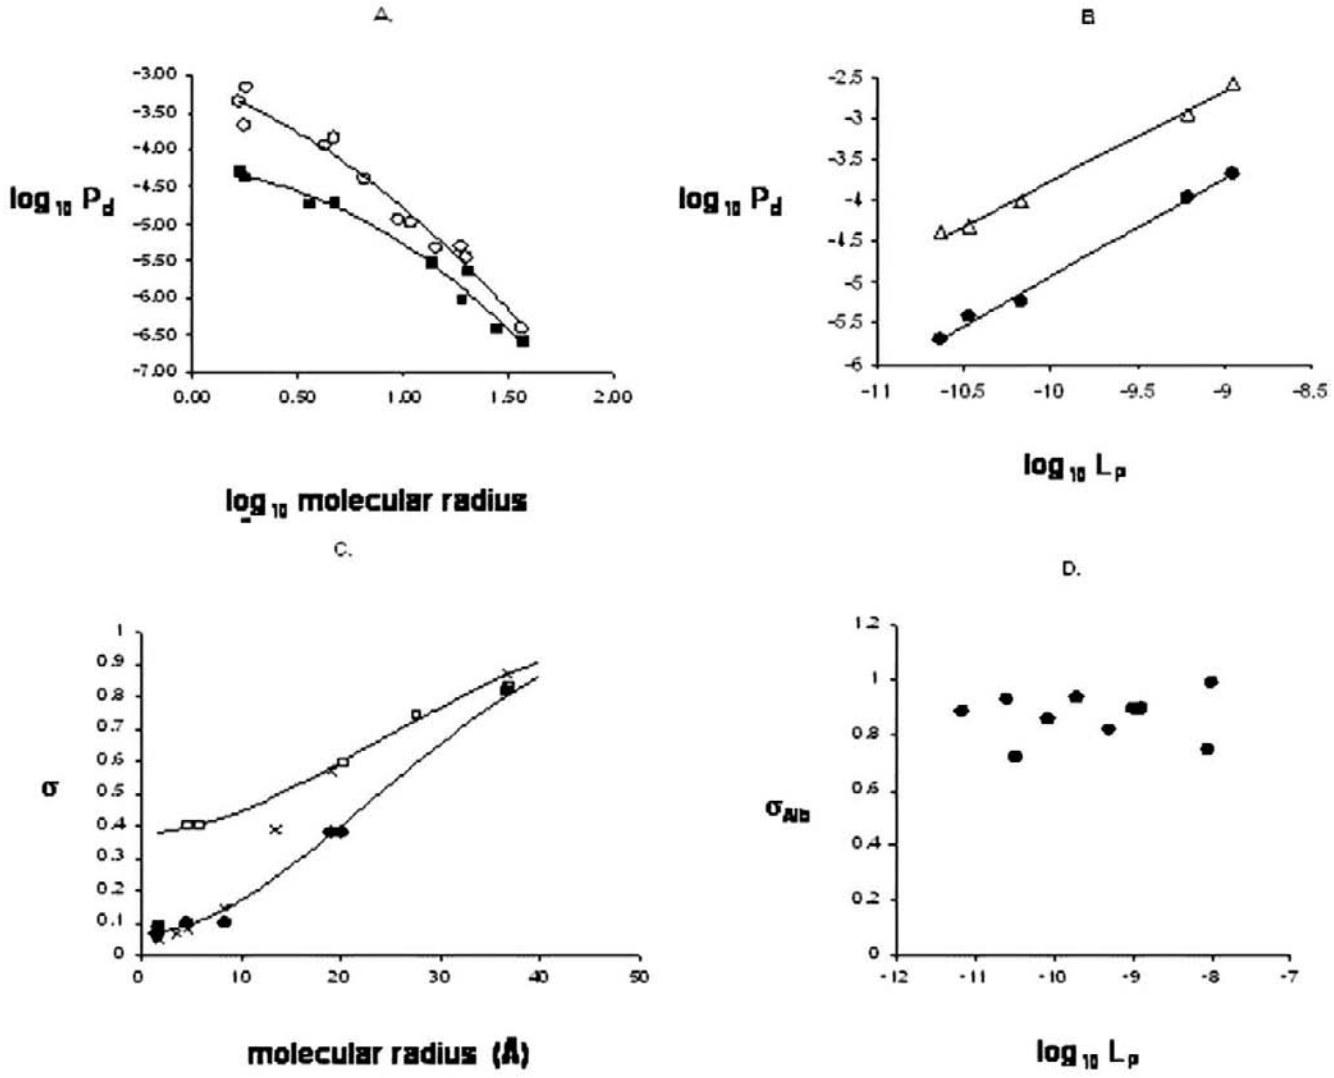

Figure 1 Microvascular permeability to fluid and hydrophilic molecules. **(A)** Diffusional permeability (P_d) to solutes of varying molecular radii in mesenteric capillaries (open circles) and muscle capillaries (closed squares). Data are plotted as $\log_{10}$ values to cover the range of P_d. Note how P_d for the the two capillary types differ by > 10-fold for the smallest molecules but converge as log radius approaches 1.6 (~40 Å). **(B)** Log P_d to NaCl (open triangles) and inulin (closed circles) plotted against log L_P. The slopes of the relations do not differ significantly from direct proportionality. [Modified from Michel and Curry (1999). *Physiol. Rev*. **79**, 703–761.] **(C)** Reflection coefficient (σ) for hydrophilic molecules for capillaries of cat skeletal muscle (open squares), rat limb capillaries (crosses), and frog mesentery (solid circles) plotted against molecular radius. The high values of σ to the smallest molecules differ in cat muscle capillaries suggest a large aquaporin pathway in these vessels [data of Wolf and Watson (1989). *Am. J. Physiol*. **256**, H282–H290]. (**D**) Reflection coefficient to serum albumin (σ_{Alb}) against $\log_{10} L_P$ for capillaries of different tissues. The lowest values of L_P are for skeletal muscle and the highest are for glomerular capillaries [based on Michel, C. C. (1988). *J. Physiol*. **404**, 1–29].

membrane. Thus the osmotic pressure of a 5-mM solution of glucose may be 127 cm H_2O in an osmometer fitted with a membrane impermeable to glucose molecules in agreement with van't Hoff's law. A 5-mM difference in glucose concentration across the walls of a mesenteric capillary, however, exerts an effective osmotic pressure less than one tenth of this. This is because 90 percent of the glucose molecules pass relatively freely through capillary walls and only 10 percent are reflected, that is, σ for glucose is just less than 0.1. This leads to an alternative definition of σ in terms of the total (or van't Hoff) osmotic pressure and the effective osmotic pressure that a solution of a particular solute exerts across a particular membrane, that is,

$$\sigma = \frac{\text{Effective osmotic pressure}}{\text{Theoretical osmotic pressure}} \quad (3)$$

Strictly speaking, σ defined in Eq. (3) is the osmotic reflection of the solute (σ_d) and that defined in Eq. (2) is the solvent drag reflection coefficient (σ_f). The values of σ_d and σ_f are identical for solutions where the relations between concentration and osmotic pressure are linear. Small differences are present for σ_f and σ_d of macromolecules where osmotic pressure rises as a second order power function of concentration. For all solutes at all membranes, σ has a maximum value of 1.0 when the membrane is completely impermeable to solute but permeable to solvent. For water-soluble molecules of biological solutions, σ has a minimum value of zero. Because σ describes a fraction or a ratio, it has no units.

Hydraulic Permeability

The hydraulic permeability, L_P, is also referred to as the hydraulic conductivity, hydraulic conductance, water permeability, and filtration coefficient. It is defined as the net fluid flow through unit area of microvascular wall per unit difference in pressure between the lumen of the vessel and its abluminal surface. Thus if net fluid filtration or reabsorption, J_V, occurs between blood and tissue through an area of capillary wall, S, then:

$$L_P = \frac{J_V / S}{(\Delta P - \sigma \cdot \Delta \Pi)} \quad (4)$$

where ΔP and $\sigma\Delta\Pi$ are the differences in hydrostatic pressure and effective osmotic pressure, respectively, between the inside and outside of the microvessel. The hydraulic permeability has units of velocity per unit pressure difference, such as $\text{cm sec}^{-1}\,\text{cm H}_2\text{O}^{-1}$. In microvessels with fenestrated endothelia, water passes through the fenestrations with water-soluble molecules. Similarly, in vessels with nonfenestrated endothelia, water shares the pathways between the cells with hydrophilic solutes, but here there is an additional (water only) pathway through cell membranes via aquaporin channels. In most nonfenestrated vessels the water-only pathways contribute 10 percent or less to L_P, though there is evidence in some skeletal muscle capillaries their contribution may be as high as 40 percent.

Permeability Coefficients of Microvessels in Different Tissues and Their Interpretation

Permeability coefficients have been measured in single microvessels mainly in mesentery but also in other tissues including skeletal muscle, brain, lung, and kidney. Estimates of microvascular permeability have also been made for capillary beds in different organs and tissues. Because many millions of capillaries may contribute to net transport here, values are obtained for the products P_dS and L_PS. The value of S, the area of microvascular wall, may be estimated from the histology of the tissue assuming that the number of perfused vessels per unit volume is same in the tissue prepared for histology and in that where the permeability measurements were made. (For methods of permeability measurement, see article in this volume on "Regulation of Vascular Permeability" by D. O. Bates.)

There is reasonably good agreement between estimates of P_d and L_P obtained from whole tissues and organs and for single vessels in the same tissue. There is, however, great variation between the mean values of L_P and P_d to the smaller hydrophilic solutes in different microvascular beds. In vessels with fenestrated endothelium, L_P and P_d for low-molecular-weight water-soluble solutes vary directly with the number of fenestrations per unit area of endothelium. Values for the L_p of fenestrated vessels are different in different tissues. Thus in the fenestrated ascending vasa recta in the renal medulla, L_p may exceed $10^{-5}\,\text{cm sec}^{-1}\,\text{cm H}_2\text{O}^{-1}$, whereas in fenestrated vessels of the intestinal mucosa, L_p is in the range of $10^{-6}\,\text{cm sec}^{-1}\,\text{cm H}_2\text{O}^{-1}$, reflecting the lower density of the endothelial fenestrations on the intestinal capillaries. The L_P of vessels with continuous nonfenestrated endothelium varies between 10^{-6} and $10^{-9}\,\text{cm sec}^{-1}\,\text{cm H}_2\text{O}^{-1}$, depending on the tissue of origin, and similar variations are seen in P_d. Here, the ultrastructural basis of variable permeability is less obvious. Although electron micrographs of muscle capillaries and mesenteric capillaries look similar, both types of vessel appearing as tubes of flattened endothelial cells lacking fenestrations and joined by junctions of similar ultrastructure, L_P values for mesenteric capillaries are 20 to 50 times greater than L_P for muscle microvessels. Similar differences are seen for values of P_d to NaCl in mesenteric and muscle microvessels (see Figure 1A). The differences in permeability reflect different frequencies of breaks in the strands of tight junctions that join adjacent cells. At present, detailed ultrastructure of the intercellular junctions is known only for heart muscle and mesenteric capillaries. The sieving properties of these two types of vessel, however, are very similar and in both vessel types, P_d falls rapidly as solute molecular radius approaches 40 Å.

Although microvascular L_P and P_d for small water-soluble molecules vary greatly from one tissue to another, L_P bears a constant relation to P_d for a given solute (e.g., inulin). Figure 1B shows that variations in P_d to NaCl and inulin in different tissues are directly proportional to varia-

tions in L_P. This is strong evidence that the permeability pathways for small hydrophilic solutes are principally those used for fluid exchange.

By contrast, σ to macromolecules is very similar in all normal microvessels. The value for serum albumin is between 0.85 and 0.99 in nearly all microvascular beds (see Figure 1D). Such values are essential for normal fluid balance (see later discussion). This is indicative of a common structure in all microvascular walls that is responsible for molecular sieving. At present, the favored candidate for this structure is the luminal glycocalyx of the endothelial cells, and this hypothesis has been boosted by several recent reports.

A fall in σ and a rise in L_P is characteristic of the increase in permeability seen in acute inflammation.

While σ for macromolecules approaches unity as molecular radius approaches 40 to 50 Å, finite permeabilities have been measured for all naturally occurring macromolecules. These lie in the range of 10^{-9} to 10^{-8} cm sec^{-1}. Whereas smaller hydrophilic molecules pass through channels in microvascular walls that have a limiting size of 40 to 50 Å (molecular radius), macromolecular permeability involves different pathways. There is evidence for two mechanisms: transcytosis by endothelial caveolae that act as shuttles across the cell; or convection through a minute number of large pores (radius ~250 Å) consisting of transcellular channels formed by fusion of caveolae or by occasional open intercellular junctions.

Permeability and Exchange of Fluid and Solute between Blood and Tissues under Physiological Conditions

Fluid Exchange

Fluid transport is determined by the differences in hydrostatic and the effective osmotic pressures across microvascular walls. This is Starling's principle and when written as an equation it is:

$$J_V = L_P S\left(\Delta P - \sum_n \sigma_n \cdot \Delta\Pi_n\right) \quad (5)$$

where J_V is net fluid transport (filtration) from blood to tissue, S is surface area of microvascular wall through which filtration is occurring, ΔP is the mean hydrostatic pressure difference across the walls of the exchange vessels, and $\Sigma_n \sigma_n \Delta\Pi_n$ is the summation of the effective osmotic pressures set up across the exchange vessel walls by all the solutes present in the plasma. Note that when fluid is being reabsorbed into the blood, J_V has a negative sign, indicating that the tissues are losing fluid.

Starling, in 1896, first appreciated that the effective osmotic pressure difference was determined by macromolecules. He pointed out that while these solutes make a small contribution to the total osmotic pressure of the plasma, they represent the only solutes that are normally present at different concentrations in the plasma and in the interstitial fluids. For all other solutes, $\Delta\Pi$ is zero across most microvascular walls. Furthermore, we now know that unlike the other solutes of the plasma, the macromolecules normally exert more than 85 percent of their full osmotic pressure ($\sigma > 0.85$).

Microvascular walls are slightly but measurably permeable to all the macromolecules that contribute to the effective osmotic pressure term. This means that the difference in macromolecular concentration between the plasma and the tissue fluid (and hence the effective osmotic pressure term) is itself a function of the permeability and the fluid filtration rate. In most tissues, the concentration difference depends on fluid entering the tissue spaces faster than macromolecules, diluting the pericapillary macromolecules to concentrations well below those of the plasma. Drainage of tissue fluid by the lymph at the same rate as it is being formed by microvascular ultrafiltration keeps the interstitial fluid volume constant. Net fluid uptake from the tissues into the plasma (reabsorption) accelerates the equilibration of macromolecules across microvascular walls, diminishing their effective osmotic pressure. Thus fluid reabsorption can occur for only limited periods in most tissues before the effective osmotic pressure difference across the microvessel walls is reduced to less than the hydrostatic pressure difference. Reabsorption then ceases and a low level of filtration develops. One important consequence of this is that the popular textbook diagram illustrating Starling's principle of microvascular fluid balance, where fluid is filtered from the arterial end of a capillary and is reabsorbed at the venous end, bears little relation to reality.

Continuous reabsorption of fluid does occur in tissues such as the intestinal mucosa and the kidney. Here the interstitial concentration of macromolecules is kept low by the continuous secretion of protein-free fluid into the interstitium by the adjacent epithelial cells. For a full discussion of microvascular fluid exchange, the reader should consult the references by Levick (1991) or Michel (1997), listed at the end of this chapter.

Solute Exchange

Convection and Diffusion

The transport of solute through microvascular walls is the sum of transport of the solute by diffusion and by convection. This addition is slightly complicated for when solute and fluid are being carried in the same channels through microvascular walls; convection of solute in the same direction as diffusion reduces the concentration gradient at the entry to the channels so that the mean gradient is no longer the difference in concentration across the wall divided by wall thickness. Convection in the opposite direction to diffusion increases the gradient. This effect of convection on the diffusion gradient is expressed in terms of the ratio of the velocity of solute transport by convection to its velocity by diffusion through the membrane. This ratio is the Péclet number, *Pe*, and here it is defined as:

$$Pe = \frac{J_V(1-\sigma)}{P_d S} \tag{6}$$

Using *Pe* to modify the expression for the diffusional component, the total solute transport by diffusion and convection from micro-vessel to tissues becomes (see Curry 1984):

$$J_S = P_d S(C_C - C_i)\frac{Pe}{e^{Pe}-1} + J_V(1-\sigma)C_c \tag{7}$$

where $(C_C - C_i)$ is the mean concentration difference across the walls of the exchange vessels. Taylor, Renkin, and their colleagues have used expressions of the general form of Eq. (7) to analyze macromolecular transport between the plasma and lymph.

MEAN CONCENTRATION IN THE EXCHANGE VESSELS

In many microvascular beds, small highly diffusible molecules have very low Péclet numbers and convective solute transport is negligible. Under these conditions, J_S may be described by the simple diffusion expression

$$J_S = P_d S(C_C - C_i) \tag{8}$$

C_C, the mean concentration in the microvessels, lies between the arterial concentration, C_a, and the venous concentration, C_V, by an amount that is determined by the blood flow, *F*, and the permeability–surface area product, P_dS. Writing this as an equation we find

$$C_c = C_i + (F/P_d S)(C_a - C_v) \tag{9}$$

When C_i is constant, Renkin showed that C_c falls exponentially between C_a and C_v. For the special case of $C_i = 0$, C_v is related to C_a by the expression

$$C_v = C_a e^{-P_d S/F} \tag{10}$$

Various forms of Eqs. (9) and (10) have been used to develop methods for measuring permeability to small molecules. Because microvascular permeability to macromolecules is usually low, their concentrations fall negligibly between entry and exit of exchange vessels and for these solutes, C_C approximates to C_a. This approximation may not be valid when permeability is increased.

CLEARANCE AND EXTRACTION

Renkin also pioneered the use of Eq. (10) for examining how *F* and P_dS influence blood–tissue exchange. At the same time he clarified the terms solute clearance and solute extraction showing how they would vary with blood flow and solute permeability.

The clearance of a solute from the blood into the tissues supplied by a microcirculation is the net rate of solute transport divided by its arterial concentration, that is, J_S/C_a. Clearance from the tissues to blood is J_S/C_i. Renkin argued that blood–tissue clearance could be thought of being the product of blood flow and extraction where the extraction was the arteriovenous concentration difference divided by either C_a (for clearance blood to tissue) or C_i for clearance between tissues and blood. Using Eq. (10), he argued that

$$Clearance = F(1 - e^{-P_d S/F}) \tag{11}$$

where the extraction is $(1 - e^{-P_d S/F}) = (C_a - C_v)/C_a$. From this it follows that when P_dS is large compared with *F*, clearance is determined largely by blood flow, but when *F* exceeds P_dS, clearance approximates more and more closely to P_dS as *F* increases. These predictions are consistent with experiments where the blood and tissue clearances of diffusible solutes have been investigated over a wide range of blood flows.

The permeability of microvascular walls to macromolecules under normal conditions is very low compared with *F*. The unidirectional clearance of macromolecules from blood to tissue does not, however, yield a value of P_dS. From Eq. (7), unidirectional clearance (i.e., clearance when C_i is close to zero) is

$$Clearance = \frac{J_S}{C_a} = \frac{J_V(1-\sigma_f)}{(1-e^{-Pe})} \tag{12}$$

Only when J_V is small relative to P_dS does clearance approximate to P_dS.

Clearance is sometimes used as a measure of microvascular permeability, but Eqs. (11) and (12) show that this is valid for small molecules only when blood flow is large relative to P_dS and for large molecules only when filtration rate is small relative to P_dS. Furthermore, it is important to remember that P_dS is not permeability but the product of permeability and surface area. This means that when looking for changes in permeability, P_d and *S* have to be separated before a change in permeability can be inferred from a change in P_dS.

Glossary

Clearance of a solute from blood to tissues: The net transport of solute per unit time (flux) divided by the arterial (inflowing) concentration. Clearance of a solute from tissues to blood is the net flux divided by the tissue concentration. Clearance is also the product of extraction and blood flow.

Extraction, E, of a solute from blood into tissues: The difference between the arterial and venous blood (or plasma) concentrations divided by the arterial concentration. Extraction of a solute from tissues to blood (when the arterial concentration is zero) is the venous concentration of that solute divided by the tissue concentration.

Hydraulic permeability, L_p: Net fluid flow per unit area of microvascular wall divided by the difference in hydrostatic pressure across the wall. It is determined by both the frequency and the dimensions of the channels that transmit fluid through the wall.

Solute diffusional permeability, P_d: Net transport per unit time of a specific solute through unit area of microvascular wall divided by the concentration difference of that solute across the wall. For hydrophilic solutes, P_d is determined by both the number of channels per unit area of wall and the molecular radius of the solute relative to the dimensions of the channels.

Solute reflection coefficient, σ: Has two definitions. It is either the fraction of molecules of a specific solute that are reflected at (i.e., not carried through) the microvascular wall during ultrafiltration of fluid through the wall, or it is the ratio of the effective osmotic pressure that a given concentration difference of the solute exerts across the microvascular wall to the osmotic pressure that the same concentration difference would exert across a membrane that was impermeable to the solute but permeable to water. For hydrophilic molecules, it is determined by the size of the channels to solute and to water and is independent of the frequency of channels.

Capsule Biography

C. Charles Michel is Emeritus Professor of Physiology and Senior Research Investigator at Imperial College, London. His main research interest for over 30 years has been microvascular permeability and microvascular exchange and his contributions have been recognized by various awards including the Malpighi Medal of the European Society for Microcirculation (!984), the Annual Prize Lecture of The Physiological Society (1987), and his election to Honorary Membership of the American Physiological Society (1993), The Physiological Society (2001), and the British Society for Microcirculation (2001).

CHAPTER 40

TNF-α-Induced Pulmonary Endothelial Permeability: The Role of the Microtubule Cytoskeleton

Irina Petrache, Anna A. Birukova, and Alexander D. Verin
The Johns Hopkins University

The endothelial cell cytoskeleton was long believed to merely constitute a scaffolding cellular structure. Recent research highlights an active role of cytoskeletal structures in the cellular metabolism, as well as in its response to external stresses. In this chapter we show how the endothelial cell microtubule cytoskeleton participates in endothelial barrier dysfunction induced by a proinflammatory cytokine, tumor necrosis factor-α.

Endothelial Barrier Function

The main role of the pulmonary vascular tree is in respiration: the uptake of oxygen and the elimination of carbon dioxide. At the alveolar level, blood vessels are lined only by endothelial cells that come in close proximity with epithelial cells, on the luminal side of the airways. The endothelial cells lining the vessels are in contact with each other, making the vascular wall a tight barrier. Any breach in the endothelial cells barrier results in leakage of fluid from the lumen of the vessels into the interstitial tissue and/or alveolar lumen, severely impairing gas exchange. Disruption of the vascular barrier is a prominent feature of acute lung injury syndrome and results in pulmonary edema formation and subsequent respiratory dysfunction or failure. The endothelial barrier integrity is the result of a balance between the tethering and contractile forces acting on endothelial cells, which are critically dependent upon cytoskeletal components, including the actin-based microfilaments, intermediate filaments, and microtubules [1]. Endothelial cell activation by inflammatory stimuli is often accompanied by enhanced cellular contraction and formation of intercellular gaps, major events leading to increased vascular permeability and pulmonary interstitial edema.

Tumor Necrosis Factor-α

Tumor necrosis factor-α (TNF-α) is a major proinflammatory cytokine secreted in increased amounts by macrophages and endothelial cells in situations linked pulmonary edema formation, such as pneumonia, sepsis, systemic inflammation and injury. TNF-α has been implicated in endothelial cell activation, endothelial cell death by apoptosis, and increased vascular permeability. The mechanisms by which TNF-α triggers endothelial barrier disruption include contraction of the intracellular actin microfilaments and formation of inter-cellular gaps that parallel in time the development of trans-endothelial permeability [2]. The rearrangement of the actin-based cytoskeleton is the result of actin–myosin movement, which, as in muscle cells, follows the phosphorylation of the myosin light chains. TNF-α induces significant actin microfilaments contraction via myosin light chain phosphorylation, a reaction catalyzed by both myosin light chain kinase (MLCK) and Rho kinase. However, inhibition of either enzyme does not prevent TNF-α-induced endothelial barrier dysfunction [2], suggesting that MLCK-independent microfilament changes and/or other cytoskeletal structures, such as intermediate filaments, microtubules, and adherens junctions, may be involved.

Microtubules

Microtubules are highly dynamic cytoskeletal polymers that reside in all eukaryotes and are essential for a wide variety of processes, including intracellular signal transduction, vesicular and organelle transport, development and maintenance of cell shape and cell locomotion, and regulation of cell division. The individual microtubule is formed by a linear association of protofilaments, which are composed of tubulin heterodimers α and β assembled in "head to tail" structure. Thus, each microtubule itself has a polarity, and the two ends have structural and kinetic differences. The "plus end" is characterized by a much more extensive duration of growing and shortening than the opposite "minus end"; thus the processes of polymerization and depolymerization of microtubules occur preferentially at the plus end. Microtubules form a lattice network of rigid hollow rods and undergo continual assembly and disassembly by the reversible addition and loss of tubulin dimers at the ends of microtubules. The linkage between the microtubule network and the contractile cytoskeleton has not been fully explored. However, an active crosstalk between microtubules and actin is required to control microtubule dynamics. This interplay has a key role in determining the cell polarity and regulation of migration. The microtubule–actin interaction is essential in regulation of endothelial integrity and wound repair [3–5]. The microtubule cytoskeleton is emerging as an important modulator of TNF-α-induced pulmonary endothelial permeability (Figure 1). A role for microtubule dynamics in permeability has been also demonstrated for other agents known to cause endothelial barrier damage such as nocodazole and hydrogen peroxide. The mechanisms by which TNF-α induces changes in the microtubule cytoskeleton are only beginning to be elucidated. TNF-α treatment induces microtubule destabilization and a decrease in the acetylated tubulin [6]. Microtubule stabilization by taxol or epothilone B inhibits actin rearrangement, vascular endothelial (VE)-cadherin redistribution, and

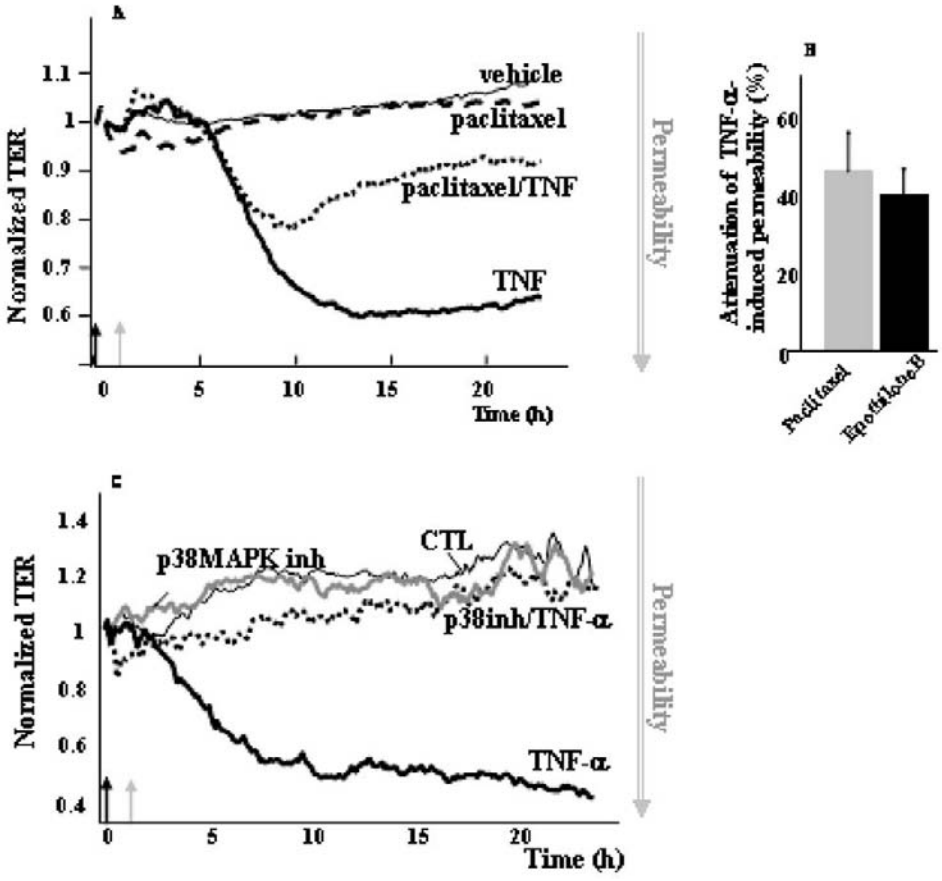

Figure 1 The effects of microtubule stabilization and p38 MAPK inhibition on TNF-α-induced endothelial permeability. (**A**, **C**) Representative tracings of normalized electrical resistance measured across endothelial cell monolayers (TER). Endothelial cells were exposed to vehicle (control) and TNF-α [20 ng/ml], where the gray arrow on the abscissa indicates the time of challenge. TNF-α induced TER reduction was evident at 4 hours with a maximal effect at 10 hours of exposure. **(A)** Microtubule stabilization by paclitaxel (black arrow) significantly inhibits TNF-α-induced decreases in resistance. **(C)** P38 MAPK inhibition by SB203580 inhibits TNF-α induced permeability. **(B)** Bar graph demonstrating the effect of the microtubule-stabilizing agents paclitaxel end epothilone B on the maximal TNF-α-induced decrease in TER. No significant difference was noted between the two agents ($p = 0.44$). (see color insert)

intercellular gap formation in response to TNF-α [6], suggesting first important crosstalk among the microtubule cytoskeleton, the actin microfilaments, and the zonula adherens proteins and second, that microtubules are opposing cellular contraction. This effect has been confirmed by the finding that microtubule disassembly leads to instant Rho kinase activation and cell contraction, potentially triggered by the release of Rho activating factors bound to microtubules ([7] and unpublished data).

The Role of the Mitogen Activated Protein Kinase (MAPK) Pathway

(a) The mechanisms by which TNF-α triggers microtubule network disassembly, followed by actin cytoskeleton rearrangement and intercellular junction changes, include the activation of the MAPK pathways. The MAPK pathways are important intracellular signaling pathways that are activated by TNF-α-induced ligation of the TNF receptors, TNFR1 (p55) and to a lesser extent TNFR2 (p75). Each component of the MAPK pathways is differentially recruited by specific stimuli resulting in kinase-specific signaling and regulation of cell growth, differentiation, and apoptosis. There are three main MAPK signaling pathways, the p42/p44 MAPK, the (Jun activated) JNK MAPK, and the p38 MAPK.

(b) The p38 MAPK is a stress-activated MAPK family that consists of four isoforms: p38-α, p38-β, p38-γ, and p38-δ. P38-α and β, isoforms inhibitable by cytokine-suppressive anti-inflammatory drugs, appear to be critical mediators of TNF-α-induced microtubule disassembly, actin microfilament rearrangement, and endothelial permeability. How p38 MAPK regulates microtubule dynamics in not well understood, but may involve direct phosphorylation of microtubule-associated proteins. Potential candidates are *tau*, a substrate for p38-γ, which when phosphorylated has decreased ability to promote microtubule assembly [8], and stathmin, a substrate for p38-δ, which can regulate the dynamics of microtubules [9]. In addition, p38 MAPK inactivates kinesin, an ATPase that mediates plus end–directed transport of organelles along microtubules.

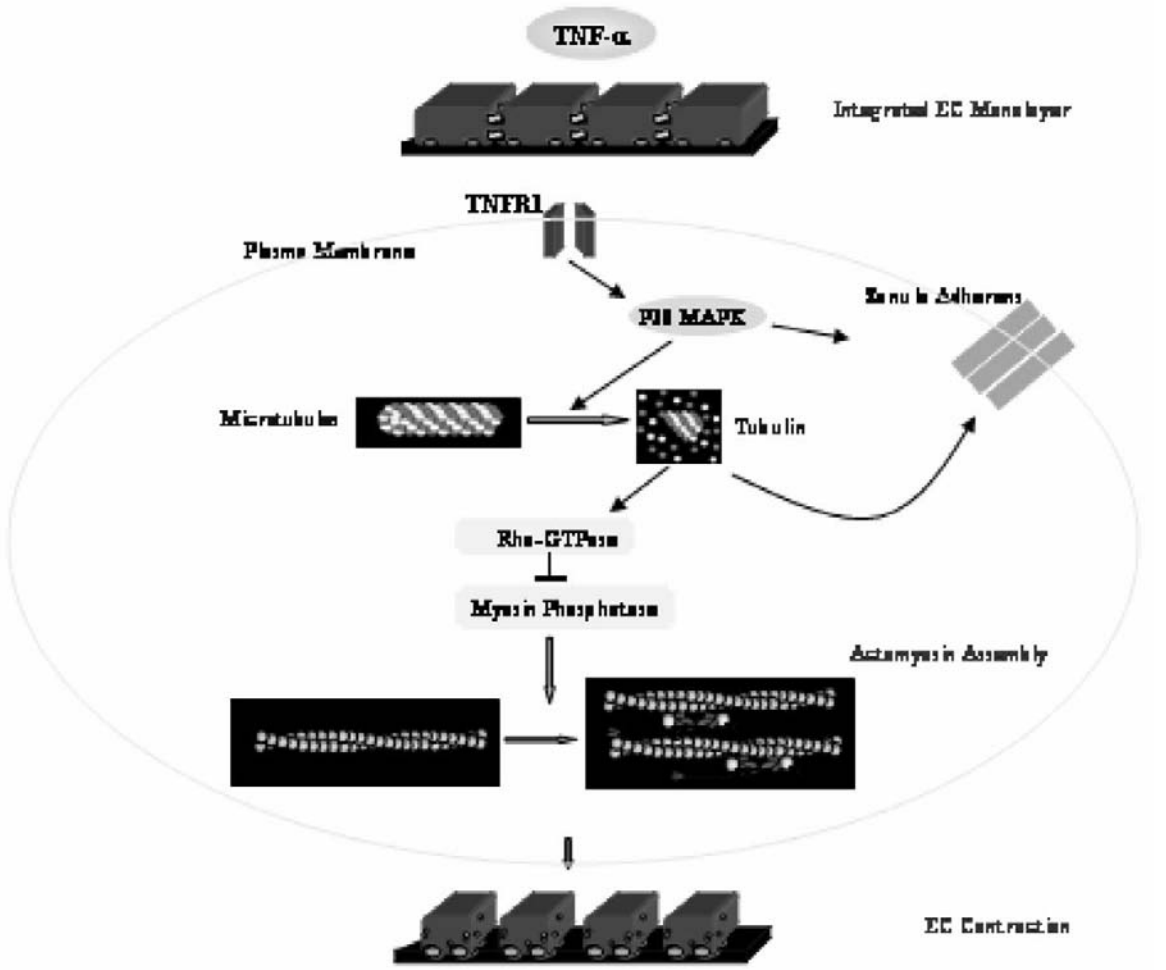

Figure 2 Schematic representation of putative pathways of TNF-α-triggered endothelial cell permeability. TNF-α acts via p38 MAPK to trigger microtubule disassembly and subsequent actin microfilament rearrangement and cell–cell contact disruption. Additionally, the p38 MAPK engages microtubule-independent cytoskeletal mechanisms of barrier dysfunction. (see color insert)

(c) The effects of p38 MAPK activation may encompass multiple cellular pathways, in addition to the microtubule cytoskeleton (Figure 2). The actin cytoskeleton function is regulated by p38 MAPK via direct activation of MAPK-activated protein kinase-2 (MAPKAP kinase-2), which in turn phosphorylates and activates an actin-binding protein, heat shock protein-27 (HSP-27). Nonphosphorylated HSP-27 normally exists in high-molecular-weight multimers that serve as chaperones. Serine phosphorylation of HSP-27 results in the dissociation of HSP-27 into monomers and dimers with redistribution of HSP-27 to the actin cytoskeleton and subsequent actin reorganization into stress fibers.

This brief review of endothelial cytoskeletal pathways engaged by TNF-α and their crosstalk with signaling pathways that regulate vital endothelial cell responses highlights the complex regulation of pulmonary vascular permeability. Elucidation of the complex orchestration of the endothelial barrier function will lead to potential therapies for the pulmonary edema seen in acute lung injury syndromes.

Glossary

Microtubules: Components of the intracellular cytoskeleton. They are organized intro a network that spans the cytoplasm and connects with other cytoskeletal structures. The dynamic function of the microtubule regulates the position and function of other intracellular proteins and organelles.

Mitogen activated protein kinases (MAPK): Important intracellular serine–threonine kinases. These enzymes are organized into signaling pathways that are activated by specific stimuli and lead to the downstream activation of specific cellular responses, such as gene transcription and cellular apoptosis.

TNF-α: A cytokine secreted by cells in increased concentrations in situations of stress, injury, and inflammation. It acts on cells by ligating specific receptors, which then trigger intracellular proinflammatory responses.

Capsule biography

Dr. I. Petrache has been an assistant professor in the Pulmonary and Critical Care Division at the Johns Hopkins University School of Medicine since 2000. During her fellowship training at Johns Hopkins, she focused on studies of endothelial cell permeability induced by TNF-α. Her work is supported by grants from the NHLBI and NIH.

Dr. A. Birukova was recently appointed a Research Associate in the same Division. Her research interests include molecular mechanisms of microtubule-mediated endothelial cell barrier regulation. Her work is supported by Scientist Development grant from American Heart Association.

Dr. A. Verin is currently an associate professor in the Pulmonary and Critical Care Division at the Johns Hopkins University. His primary research interest includes involvement of cytoskeletal components (particularly microtubules) in the regulation of endothelial permeability. His work is supported by grants from the NHLBI and NIH.

CHAPTER 41

Vasoactive Signals and Pericyte Function in the Retina

Donald G. Puro
University of Michigan

Although constituting the largest portion of the circulatory system and the sites of greatest resistance, capillaries traditionally have been thought to play only a passive role in the regulation of blood flow. However, evidence is accumulating that blood flow can be actively controlled at the capillary level in at least in some vascular beds. Experimental support for the concept that capillaries actively regulate local perfusion is based chiefly on studies of the retinal vasculature.

Role of Pericytes in Blood Flow Regulation

The microcirculation of the retina is anatomically and physiologically specialized to distribute oxygen and nutrients to areas of metabolic need within a tissue that must be translucent.

Specialized Features of the Retinal Vasculature

One adaptation that minimizes interference with light passing through the retina is the low density of capillaries. In the retina, the intercapillary distance is at least 50 μm, which is less dense than in other tissues. Although the relatively paucity of retinal capillaries is a successful compromise between visual function and nutritive needs, a consequence is that there little functional reserve. As a result, a tight link between local perfusion and neuronal metabolism is essential in the retina.

Having blood flow controlled exclusively by local conditions facilitates efficiency in the distribution of oxygen and nutrients within the retina. Local control is ensured by the absence of autonomic innervation, which limits extrinsic oversight by the central nervous system. Also, the presence of an endothelial barrier restricts the effects of circulating vasoactive molecules. In addition, the lack of precapillary smooth muscle sphincters, which control local perfusion in most other tissues, suggests that retinal blood may be regulated within capillaries, rather than exclusively at precapillary sites.

Pericytes as Regulators of Capillary Perfusion

Candidates for regulating retinal blood flow at the capillary level are the pericytes. As in nearly all vascular beds, these abluminally located cells envelop the capillaries and postcapillary venules of the retina. Suggestive of the particular importance of pericytes in the retinal microcirculation, the density of these cells is greatest in the retina. Their expression of molecules such as α-smooth muscle actin supports the hypothesis that pericytes are contractile elements of the microvasculature. By contracting or relaxing, pericytes may adjust lumen size and thereby control capillary perfusion. However, even though vasoconstriction is observed in isolated retinal microvessels at sites adjacent to contracting pericytes, it remains to be definitively demonstrated that these cells regulate capillary blood flow in vivo.

Regulation of Pericyte Contractility

Assay Systems

Knowledge of the regulation of pericyte contractility is based on several experimental assay systems.

CULTURED RETINAL PERICYTES

Many studies testing the effects of vasoactive molecules use cells grown on a silicone surface. The laboratories of

D'Amore and Shepro pioneered in developing this assay system for retinal pericytes. Contraction of these cells is detected by the induction of wrinkles in the underlying silicone. An advantage of using a culture system is that only pericytes are present. Thus, indirect effects mediated by other types of cells are excluded. However, one disadvantage is that pericytes are likely to change during long-term culture. Certainly the exquisite morphology of in vivo pericytes is lost, as the cells quickly become rather nondescript flat cells in vitro; molecular and physiological changes may also occur. Furthermore, the tens of minutes that are often required for the induction of wrinkles in the silicone preclude assessment of pericyte responses within shorter time periods that may be more physiologically relevant.

Isolated Retinal Microvessels

More recently, Puro and his associates have used differential interference optics and time-lapse photography to detect pericyte contraction and relaxation in microvessels freshly isolated from the rat retina. Pericytes in the isolated microvessels retain their morphology and maintain a close association with the underlying endothelial tube. Because retinal pericytes are coupled via gap junctions to dozens of neighboring vascular cells, the ability to study pericytes that are an integral component of a multicellular functional unit can reveal a more complete picture of how the retinal microvasculature responds to vasoactive signals. Another advantage is the ability to detect pericyte contraction or relaxation, as well as microvascular constriction or dilation, within seconds after the onset of exposure to vasoactive substances. However, a caution is that findings based on studies of isolated microvascular complexes must ultimately be confirmed in vivo.

Retinal Capillaries in Situ

Funk and his colleagues have shown that it is feasible to monitor the effects of various vasoactive chemicals on the diameters of capillaries in isolated rat retinas. This in situ assay system should be useful, although a direct assessment of pericyte contraction or relaxation in situ has yet to be reported. A deficiency in both the in situ system and the use of isolated microvessels is that the vascular lumens are not perfused during an experiment. As a result, the role of shear stress and other intraluminal forces in determining the microvascular response to vasoactive molecules cannot be assessed. A challenging goal is to visualize in vivo the changes in pericyte shape, lumen diameter, and blood flow induced by vasoactive signals.

Contractile Responses to Vasoactive Molecules

Putative vasoactive molecules, which are known to affect the contractile tone of retinal pericytes, originate from a number of sources (Figure 1). Sites include the underlying endothelial cells that form the capillary tube, the glia that ensheathe the pericyte/endothelial complex, and the neurons that release vasoactive neurotransmitters. In addition, a breakdown of the blood–retinal barrier exposes pericytes to molecules from the vascular system.

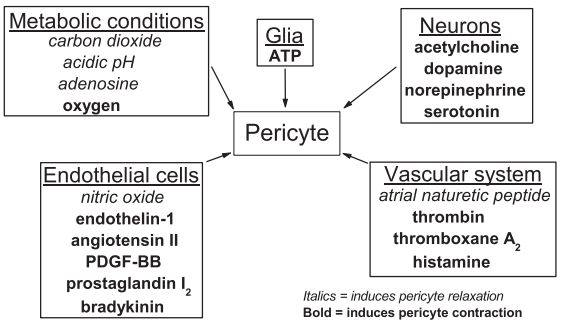

Figure 1 Schematic diagram of the likely sources of the vasoactive signals that are known to regulate the contractility of retinal pericytes. PDGF-BB, platelet-derived growth factor-BB.

Effects of Vasoactive Signals on Pericyte Physiology

The study of the mechanisms by which vasoactive molecules regulate pericyte contractility is in its infancy. Because ion channels are likely to be important in mediating the responses of pericytes to vasoactive signals, several laboratories have used electrophysiological methods to begin the task of determining the effect of these molecules on the ionic currents of pericytes. Also, because calcium regulates the contractile apparatus of pericytes, the effects of vasoactive molecules on the intracellular concentration of this divalent cation are of importance. However, at present, only a minority of the molecules known to alter pericyte contractility have been evaluated for effects on ion channel function and intracellular calcium levels.

Regulation of Ion Channels

Five molecules that induce retinal pericytes to contract have been analyzed for their effects on ion channel activity. These putative vasoactive signals include (1) acetylcholine, which activates muscarinic receptors to elicit pericyte contraction; (2) ATP acting via $P2X_7$ and $P2Y_4$ receptors; (3) endothelin-1, whose contractile effect is via ET_A receptors; (4) platelet-derived growth factor-BB (PDGF-BB), which is the ligand for PGDF-β receptors; and (5) angiotensin II, for which the subclass of receptor mediating the contractile response of retinal pericytes remains to be determined.

For each of these putative vasoconstrictors, a depolarization of pericytes is caused by the opening of calcium-activated chloride channels (Cl_{Ca}) and also, except for acetylcholine, the activation of calcium-permeable nonspecific cation (NSC) channels. In addition, an inhibition of ATP-sensitive potassium (K_{ATP}) channels, as has been demonstrated for endothelin-1, provides an additional mechanism by which vasoactive molecules can cause depolarization. With a decrease in the membrane potential,

there is an opening of the L-type voltage-gated calcium channels (VGCCs), which are expressed by retinal pericytes (Figure 2).

Only two vasodilators have been tested for their effects on the ion channel activity of retinal pericytes. Adenosine, acting at A_1 and A_{2a} receptors, activates K_{ATP} channels. In contrast, nitric oxide (NO) does not affect K_{ATP} channels, but causes pericyte relaxation by a mechanism involving the cGMP-mediated inhibition of VGCCs.

Regulation of Intracellular Calcium

There are two general mechanisms by which putative vasoconstrictors cause the intracellular concentration of calcium to increase in retinal pericytes (Figure 2). One is an influx of this divalent cation via calcium-permeable NSC channels and VGCCs. Another is the release of intracellular stores of calcium. These pathways for increasing cytoplasmic calcium are interrelated. For example, the release of calcium stores is associated with the activation of the Cl_{Ca} channels in retinal microvessels. In addition, it is likely that an influx of calcium triggers the release of stored calcium.

Both influx and release appear to contribute to the increase in pericyte calcium observed during exposure to the five tested vasoconstrictors, that is, acetylcholine, ATP, angiotensin II, endothelin-1, and platelet-derived growth factor BB. At present, the effects on pericyte calcium levels of the vasodilators adenosine and NO are not known. Future experimental study is needed to clarify the relative functional roles in pericytes of the NSC channels and the VGCCs. Also, the relative importance of calcium influx versus calcium release in regulating pericyte contractility is not well understood.

Regulation of Microvascular Gap Junctions

In the retinal microvasculature, pericytes are coupled by gap junctions to dozens of their neighboring vascular cells. Recently, Puro and colleagues discovered that molecules such as endothelin-1, angiotensin II, and extracellular ATP potently and reversibly close these gap-junction pathways. Thus, vasoactive signals not only affect individual microvascular cells, but also regulate the effective size of the multicellular functional units that play a role in the control capillary blood flow. The regulation of intercellular communication within the pericyte-containing microvasculature may be an important, previously unappreciated mechanism by which local perfusion is dynamically affected by vasoactive molecules. Finally, the effects of putative vasoactive signals on the calcium sensitivity of the pericyte contractile apparatus remain to be determined.

Pericyte Pathobiology

Diabetes

The microvessels of the retina are particularly vulnerable to damage induced by diabetes. An early histological sign of diabetic retinopathy is the loss of pericytes. Currently, the mechanisms causing this sight-threatening complication remain uncertain.

PURINOCEPTORS

Recently, Sugiyama and his colleagues proposed that vasoactive molecules, such as extracellular ATP, can become vasotoxic in the diabetic retina. They found that activation of $P2X_7$ purinoceptors not only plays a role in transducing the contractile response of pericytes to ATP, but also can induce the formation of lethal transmembrane pores. Although high agonist doses are required to open $P2X_7$ pores in nondiabetic retinal microvessels, normally nonlethal concentrations trigger apoptosis in diabetic capillaries. Thus, a diabetes-induced increase in the vulnerability of retinal microvessels to the lethal effect of $P2X_7$ receptor activation may be a previously unrecognized mechanism by which diabetic retinopathy progresses.

ENDOTHELIN-1

Because epidemiological studies indicate that hyperglycemia is a key factor associated with the development of

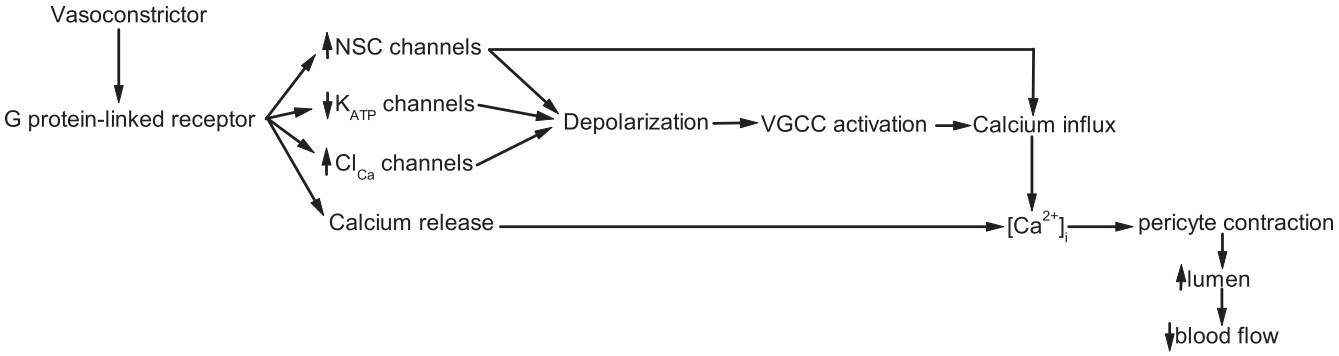

Figure 2 Schematic diagram of putative pathways by which vasoactive signals induce pericyte contraction and thereby decrease blood flow. Not shown are possible interactions between calcium release and calcium influx, that is, calcium induced calcium release and store-operated calcium channels. NSC, calcium-permeable nonspecific cation channels; K_{ATP}, ATP-sensitive potassium channels; Cl_{Ca}, calcium-activated chloride channels; VGCC, voltage-gated calcium channels; $[Ca^{2+}]_i$, intracellular calcium concentration.

diabetic retinopathy, the effect of glucose on pericyte responses to vasoactive molecules is of interest. Using cultured bovine pericytes, investigators have found that the contractile response of these cells to endothelin-1 is attenuated when the culture medium contains a high concentration of glucose. Experiments by McGinty and her coworkers indicate that a glycation-induced decrease in the function of L-type VGCC accounts for a reduction in the endothelin-induced influx of calcium and consequently the diminished contractile response of pericytes to this vasoactive molecule. An alteration in the vasoconstrictive effect of endothelin-1 may contribute to the dysfunction of autoregulatory mechanisms observed in the retinal circulation well before the onset of pericyte death and clinical signs of diabetic retinopathy.

Microvascular Gap Junctions

Soon after the onset of experimental diabetes, the intercellular communication system linking pericytes with their neighboring microvascular cells is disrupted by a mechanism involving the upregulation of protein kinase C. This closure of gap junction pathways disrupts the multicellular organization of the retinal microvasculature and may compromise mechanisms to match local blood flow to the needs of neurons. Not only could the loss of cell-to-cell communication adversely affect neuronal function, but it may metabolically isolate pericytes and contribute to their demise early in the course of diabetic retinopathy.

Blood–Retinal Barrier Breakdown

In many retinal disorders, including diabetic retinopathy, the blood–retinal barrier is compromised. At sites where this barrier is defective, serum-derived molecules leak from the blood vessels into the retina. Because pericytes are located on the abluminal surface of the vascular endothelium, they are among the first cells to be exposed to molecules leaking from the circulatory system. As a result, the responses of pericytes to blood-derived molecules may determine how the retina functions when the vascular endothelial barrier is leaky.

In one of the first studies to establish that pericytes are contractile, Kelley and coinvestigators demonstrated that serum causes these cells to contract. More recently, Sakagami and coworkers showed that exposure of isolated pericyte-containing microvessels to serum activates calcium-permeable NSC and Cl_{Ca} channels. Associated with the opening of these channels, pericytes depolarize, contract, and cause the adjacent lumens to constrict.

Serum-induced contraction of pericytes may be a successful adaptive response to a breakdown of the blood–retinal barrier. For example, contraction of leaky microvessels would shunt blood away from areas with a defective vascular endothelium. On the other hand, extensive shunting of blood may cause ischemic damage, contribute to the demise of pericytes, and facilitate the progression of diabetic retinopathy.

Ischemia

Under physiological conditions, PDGF-BB activates NSC and Cl_{Ca} channels. With the opening of these channels retinal pericytes depolarize and contract (Figure 2). However, during a prolonged inhibition of ATP synthesis, some pericytes hyperpolarize and relax in response to PDGF-BB. This PDGF-induced increase in membrane potential is due to the activation of K_{ATP} channels, which close when the intracellular ATP concentration falls to an extremely low level. The capability of a vasoactive signal to elicit vasoconstriction when energy supplies are ample and vasodilation under ischemic conditions provides an efficient mechanism to link the function of the microcirculation to the local metabolic needs. Future studies may reveal other dual-action signals that play a role in the regulation of the retinal microcirculation.

Glossary

ATP-sensitive potassium (K_{ATP}) channels: Potassium-selective ion channels that are inhibited by intracellular ATP ($[ATP]_i$). By causing a decrease in $[ATP]_i$, ischemia activates these channels, which cause pericytes to hyperpolarize. Although activated as $[ATP]_i$ falls from millimolar concentrations, K_{ATP} channels require ~10 μM ATP to remain open. As a result, as $[ATP]_i$ declines below 10 μM, these channels again close.

Nonspecific cation (NSC) channels: Ion channels that are permeable to sodium and potassium and, in some cases, calcium. Opening these channels causes pericytes to depolarize. Membrane hyperpolarization increases the influx of calcium through calcium-permeable NSC channels.

$P2X_7$ purinoceptors: A member of the family of receptor-operated channels activated by extracellular ATP. Unlike nearly all other types of ion channels, the sustained activation of $P2X_7$ purinoceptors is associated with the formation of transmembrane pores, which can cause cell death.

Pericytes: Cells located on the outer walls of capillaries and postcapillary venules. Thought to play a role in regulating blood flow, maintaining vessel structure, and inhibiting endothelial proliferation. The loss of these cells is an early histological sign of diabetic retinopathy.

Voltage-gated calcium channels: Ion channels that are selectively permeable to calcium and activated by membrane depolarization.

CHAPTER 42

Regulation of Microvascular Hydraulic Conductivity

Rolando E. Rumbaut and Virginia H. Huxley
[1]*Baylor College of Medicine, Houston, Texas*
[2]*University of Missouri–Columbia, Columbia, Missouri*

Introduction

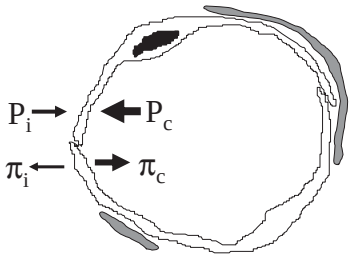
Transport of water and hydrophilic solutes across microvascular walls (capillaries and postcapillary venules) is an essential mechanism for delivery of nutrients to tissues. The ease of water movement across microvessel walls is described by the coefficient hydraulic conductivity (L_p). L_p reflects net volume flux ($cm^3 sec^{-1}$) per unit surface area (cm^2) per unit pressure (cmH_2O). L_p was assumed previously to be a fixed property of microvessels; however, it is now evident that L_p may be regulated actively under both physiologic and pathologic conditions. In this chapter, we review current aspects of regulation of L_p, common methods for assessing this coefficient in vivo, and implications of alterations in L_p. We will limit our scope to data derived from in vivo models; techniques for in vitro assessment of L_p of cultured endothelial cell monolayers are exemplified by the work of Tarbell and colleagues [1].

Forces Regulating Transvascular Water Movement

Movement of water across microvascular walls is dependent upon pressures acting upon both sides of the microvessel. Starling first described this principle in 1896, by proposing that plasma was retained in the circulation by the osmotic pressure exerted by plasma proteins (oncotic, or colloid osmotic pressure), which opposes the outward hydrostatic pressure. In addition, the hydrostatic and oncotic pressures of the extravascular compartment (interstitium) affect net water movement, which is governed by the difference between hydrostatic and oncotic pressure gradients (intravascular minus extravascular). This balance, referred to as "Starling equilibrium," is illustrated in Figure 1. The modern form of the Starling equation for fluid filtration is also shown in Figure 1. It includes hydraulic conductivity (L_p), defined in the introduction, and a second coefficient, the osmotic reflection coefficient (σ, a dimensionless coefficient ranging from 0 to 1), an index of the selectivity of the microvascular barrier to an osmotically active solute. In the majority of the circulation, small solutes such as NaCl have σ approaching 0, whereas in vivo measures of σ to albumin under physiologic conditions typically range between 0.8 (heart) and 0.99 (skeletal muscle). Based on this equation, positive values of J_v denote filtration, whereas negative values denote water reabsorption into the microvessels.

Pathways for Volume Flux across Microvascular Walls

In microvessels with continuous endothelium, the majority of transvascular J_v is presumed to occur via the interendothelial cell junctions. Numerous mathematical models have been proposed to describe the geometry of these pathways, including cylindrical pores, rectangular slits, and a fiber matrix model [2]. Each of these models alone is unable to fully account for in vivo measures of volume and hydrophilic solute flux across microvessels. Of these models, the fiber matrix model appears to describe many of the transport coefficients measurable in vivo. The fiber matrix model is consistent with experiments involving disruption of the endothelial surface layer (glycocalyx). For example, perfusion of microvessels with cationized ferritin demonstrates a layer up to 100 nm thick on the endothelial cell surface. Exposure of microvessels to an enzyme, pronase, results in reduction of the thickness of this surface layer and a significant increase in microvessel L_p. Similarly,



$$J_v = L_p S [(P_c - P_i) - \sigma (\pi_c - \pi_i)]$$

J_v: volume flux
L_p: hydraulic conductivity
S: surface area
P_c: capillary hydrostatic pressure
P_i: interstitial hydrostatic pressure
π_c: capillary oncotic pressure
π_i: interstitial oncotic pressure
σ: reflection coefficient

Figure 1 Pressures responsible for fluid movement across a capillary, and modern form of the Starling equation for fluid filtration. See text for details.

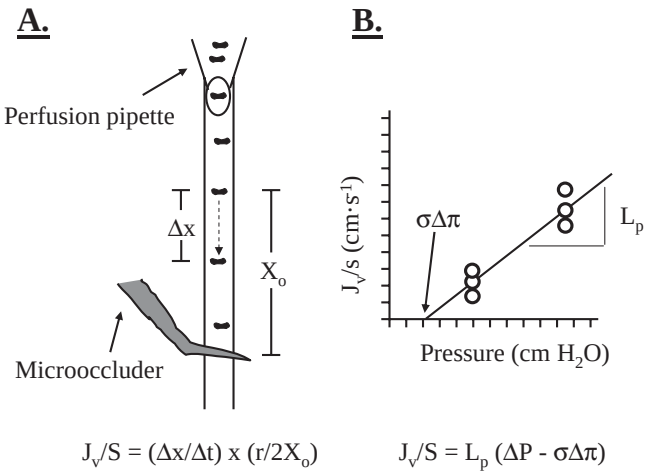


Figure 2 Landis–Michel technique for measurement of hydraulic conductivity (L_p) in individually perfused microvessels. **(A)** Relative placement of microinstruments and calculation of fluid filtration rate per unit surface area (J_v/S) based on vessel radius and erythrocyte location and velocity. **(B)** Calculation of L_p based on measures of J_v/S at different hydrostatic pressures.

microvessel perfusion with a solution devoid of proteins reduces the thickness of the surface layer and induces a significant increase in L_p (known as the "protein effect"). These studies support the notion that the glycocalyx (which may be modeled as a fiber matrix) contributes significantly to the microvascular barrier to volume flux. Based on recent electron microscopic observations suggesting the presence of a thick endothelial surface layer (200 to 500 nm), elaborate models of a fiber matrix overlying interendothelial cell clefts with junctional strand gaps have been proposed [3]. Although these models describe many in vivo measures of transvascular volume and solute flux, their validity remains to be confirmed.

Assessment of Transvascular Water Movement in Vivo

Single Perfused Microvessels

Eugene Landis first reported measures of L_p of individual microvessels in the early 20th century [4]. By occluding capillaries of the frog mesentery, he described that on occasions erythrocytes moved toward the micro-occluder and on other occasions they moved away from the occlusion site. Cells moving toward the occluder were interpreted as representing fluid filtration, whereas those moving away denoted reabsorption. He calculated the rate of filtration or reabsorption per unit surface area (J_v/S) based on the erythrocyte velocity. By correlating J_v/S to capillary pressure (P_C) measured with a micropipette, he determined a linear relation between P_C and J_v/S. The slope of that relation is the L_p, and the x pressure axis intercept in Landis' experiments approximated the oncotic pressure of frog plasma. Those experiments provided evidence in vivo of Starling's hypothesis for fluid filtration. The Landis technique to assess L_p, modified by Michel and colleagues [5], is illustrated in Figure 2A. A microvessel is perfused with a micropipette connected to a water manometer, to measure microvascular hydrostatic pressure, containing marker erythrocytes in a physiological salt solution of predetermined composition. Downstream from the site of cannulation, a micro-occluder is used to stop flow intermittently in the vessel. Assuming cylindrical geometry, and negligible interstitial hydrostatic pressure (P_i), L_p is the slope of the measures of fluid filtration at the set of hydrostatic pressures (see Figure 2B). This technique allows for paired measures of L_p in individual microvessels under control conditions and following exposure to a variety of experimental conditions in the luminal, abluminal, or both surfaces of the microvessel. Further, given that the oncotic pressure is known, the intercept on the pressure axis can be used to determine σ for the specific vessel and colloid (Figure 2B). Much of our current understanding of physiologic and pathologic regulation of hydraulic permeability is based on experiments using the Landis–Michel technique to measure L_p.

Whole Organs

Experimental evidence of fluid filtration consistent with Starling's hypothesis was described in whole organ preparations in the mid-20th century [6] when hind limbs from cats and dogs were isolated, perfused, and the weight of the hind limb recorded continuously. Using this technique, fluid filtration was determined from the rate of gain of limb weight, and fluid reabsorption from the rate of loss of limb weight. The arterial and venous hydrostatic pressures were adjusted experimentally, and values that resulted in neither filtration

nor reabsorption were established, resulting in an "isogravimetric state." The hydrostatic pressures required for the isogravimetric state varied according to the oncotic pressure of the perfusate solution, as predicted by the Starling equation. The relationship between filtration rate and "capillary" pressure (calculated from the arterial and venous hydrostatic pressures) was linear, with the slope equal to the filtration coefficient (K_f). K_f is the product of L_p and surface area, the latter coefficient being unknown in whole-organ experiments but measurable in single-perfused microvessels (assuming cylindrical geometry).

Regulation of Hydraulic Conductivity

Control Conditions

Figure 3 shows the distribution of control values of L_p determined in individual microvessels of the frog ($n = 1111$) and rat mesentery ($n = 89$) in our laboratories. Median L_p for frog capillaries is 3.3 and for rat venules is 1.8 ($\times 10^{-7}$ cm sec^{-1} cmH_2O). Several features are noteworthy. First, the shapes of the distribution are similar despite being derived from different vessel types (capillaries and postcapillary venules) from two phylogenetically distinct species. Second, the broad spread of the distribution under physiologic conditions precludes describing J_v by a single value. Third, the distributions in each case do not fit a normal distribution; they are normalized by a fourth root transformation [7]. Of interest, a similar frequency distribution was noted by Pappenheimer's group of K_f values in the feline hind limb [8]. The authors speculated that if the pathways responsible for fluid filtration were "pores" with a circular cross-section, a normal distribution of pore radii would result in a skewed distribution of filtration coefficient, varying according to the fourth power of the pore radius. However, ultrastructural evidence of cylindrical pores as a pathway for volume flux is lacking.

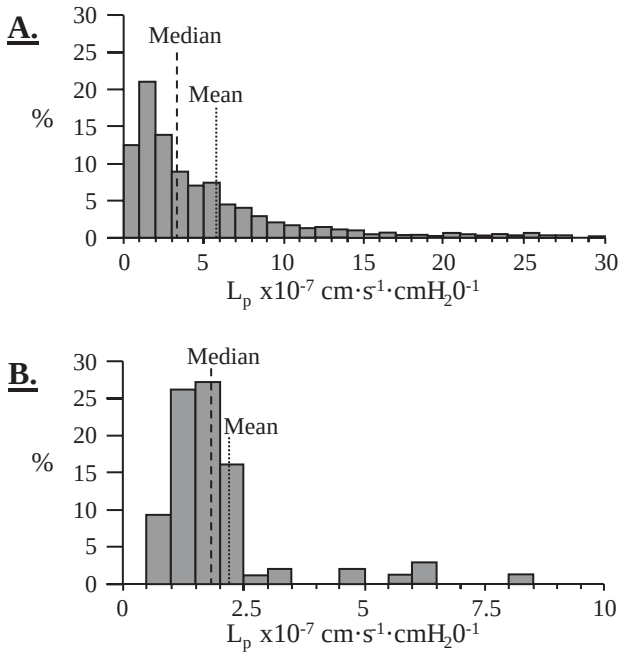

Figure 3 Frequency distribution of L_p of single perfused frog mesenteric capillaries (**A**, $n = 1111$) and rat mesenteric venules (**B**, $n = 89$). Note nonnormal distribution of values with similar shape in both cases.

Control L_p values in frog mesenteric capillaries demonstrate a gradient of values across the capillary network. Capillaries near arterioles (arteriolar capillaries) typically have the lowest values, followed by midstream capillaries (true capillaries) and then capillaries near postcapillary venules (venular capillaries). This phenomenon is illustrated by our median L_p values (in units of 10^{-7} cm sec^{-1} cmH_2O) in the frog mesentery of arteriolar capillaries ($L_p = 1.8$, $n = 192$), true capillaries ($L_p = 2.9$, $n = 580$), and venular capillaries ($L_p = 5.1$, $n = 339$). Since hydrostatic pressure across the capillary network has a decreasing gradient, the gradient of L_p values may attenuate variations in net volume flux across the capillary network. Despite this, the relative L_p and hydrostatic pressure gradients across the network tend to favor filtration across true and venular capillaries.

Active Changes in Hydraulic Conductivity

In Landis' initial experiments, he reported that frog mesenteric capillary L_p increased in response to a variety of insults including ischemia, hypoxia, and increased acidity. More recent work has shown acute increases in microvascular L_p with less injurious stimuli. For example, agonists that increase intracellular levels of cyclic guanosine monophosphate (cGMP) such as atrial natriuretic peptide (ANP), sodium nitroprusside, and 8-bromo-cGMP induce reversible, dose-dependent increases in capillary L_p. The endothelial cell structures responsible for these reversible changes in L_p remain to be determined, though in the case of ANP, the change in permeability is independent of the "protein effect" [9]. These data suggest that the microvascular barrier for volume flux may be regulated independently by different mechanisms. Other agents shown to increase L_p include histamine, bradykinin, serotonin, vascular endothelial growth factor (VEGF), adenosine triphosphate and calcium ionophores (see Ref. [2]). Many of these agents enhance intracellular endothelial calcium; temporal correlations between changes in endothelial calcium and microvascular L_p have been described [10]. In addition to increases in L_p, several agents have been reported to decrease microvascular L_p, including nitric oxide synthase inhibitors [11] as well as agents that increase endothelial cell cyclic adenosine monophosphate or activate adenylyl cyclase (rolipram, isoproterenol, forskolin; [12]). These studies demonstrate that microvascular volume flux may be subject to regulation by a variety of physiologic as well as pathologic stimuli. Under physiologic conditions, changes in L_p may influence the rate of delivery of water and nutrients to tissues. Pathologic increases in permeability, or hyperpermeability, would favor enhanced fluid filtration and may lead to tissue swelling, or edema. Of interest, on occasion a single inflammatory

mediator may result in different changes in permeability in different portions of the microvasculature. For example, the inflammatory agonist bradykinin induced changes in L_p with distinct temporal and spatial variations in frog capillaries [13]. Thus, in addition to the heterogeneous control values of L_p across the network described earlier, the changes in L_p in response to the same agonist may vary across the microvascular network.

Summary

Delivery of water and hydrophilic nutrients to tissues may be regulated at the level of the microvasculature, primarily in capillaries and postcapillary venules. Hydraulic conductivity (L_p) is a coefficient that reflects the ease of passage of water across microvascular walls. Data derived from single-perfused microvessels demonstrate that control values of L_p have a broad distribution, with evidence of spatial differences within microvascular networks. Further, L_p is not a fixed coefficient of individual microvessels, but instead is subject to active regulation by both physiologic and pathologic stimuli. The cellular molecular basis for active changes in the endothelial pathways that regulate microvascular L_p is an area of ongoing research.

Glossary

Microvascular hydraulic conductivity (L_p): The ease of passage of water across microvascular walls, reflecting net volume flux ($cm^3\,sec^{-1}$) per unit surface area (cm^2) per unit pressure (cmH_2O).

Protein effect: An effect of plasma proteins that reduces L_p, presumably at the level of the endothelial surface layer. Removal of proteins from microvessel consistently induces significant elevations in L_p.

Reflection coefficient (σ): An index of the selectivity of the microvascular barrier to an osmotically active solute; it is a dimensionless coefficient, theoretically ranging from 0 to 1.

CHAPTER 43

The Role of Gap Junctions in the Regulation of Arteriolar Tone

N. M. Rummery and C. E. Hill
John Curtin School of Medical Research, Australian National University, Canberra, Australia

Gap junctions are low-resistance channels which connect adjacent cells in almost all mammalian tissues, including blood vessels, allowing the direct transfer of electrical current and molecules of < 1 kDa in molecular weight. Because of their small size, many important metabolites and signaling molecules elicited by receptor activation, such as calcium, inositol trisphosphate, or cyclic AMP, would be expected to pass through gap junctions from one cell to another. Since arteriolar tone relies on the balance of vasoconstrictor and vasodilator pathways, which involve such signaling molecules or the opening of ion channels in the cell membrane and subsequent changes in membrane voltage, it is expected that gap junctions will play a pivotal role in coordinating this process.

Structure and Regulation of Gap Junctions

Structure of Gap Junctional Channels

Gap junctions comprise a family of membrane proteins known as connexins (Cxs). Six individual Cx proteins oligomerize in the plasma membrane of one cell to form a connexon or hemichannel. A complete gap junctional channel linking adjacent cells results from the docking of two connexons, one from each of the two opposing cells (Figure 1). To date, 20 different types of mammalian Cx proteins, commonly named after their molecular weight in kilodaltons (kDa), have been identified. All of these Cxs have the same basic molecular structure, consisting of four α-helical membrane-spanning domains, two extracellular loops, and three cytoplasmic regions including one intracellular loop. Gap junctional channels may be either homo- or heteromeric in nature, depending on whether a single or multiple types of Cxs are present in each connexon (Figure 1). Gap junctions can also be homo- or heterotypic depending on the Cx content of the two connexons (Figure 1).

Gap junctional channels demonstrate unique electrical and biochemical properties depending on the constituent Cx isotypes. In turn, the distinct functional properties of each Cx protein arise from specific amino acid sequences found in the intracellular loop and carboxy terminus. The formation of heterotypic and heteromeric channels, which express a mixture of more than one Cx, has been shown to confer channel properties that are distinctly different from those of homotypic channels formed from each of the individual Cxs. For example, the ability to permit the passage of particular second messengers has been shown to vary with the Cx composition of gap junctions. Thus, it is important to determine the specific Cx composition of the gap junctional channels formed in any particular artery or arteriole, since this is likely to have a significant impact on vascular function.

Regulation of Gap Junctions

The function of gap junctions can be regulated by factors that act in either the short or long term. Short-term regulation is predominantly concerned with rapid and reversible changes in channel conductance resulting from alterations in the opening probability of the channels or alterations in channel turnover. On the other hand, long-term regulation of gap junctions involves alterations in gene expression at the mRNA and protein levels. In blood vessels, changes in Cx expression have been observed at branch points where blood flow is disturbed and shear stress turbulent. Such forces may also be expected to be encountered within the branching of resistance networks.

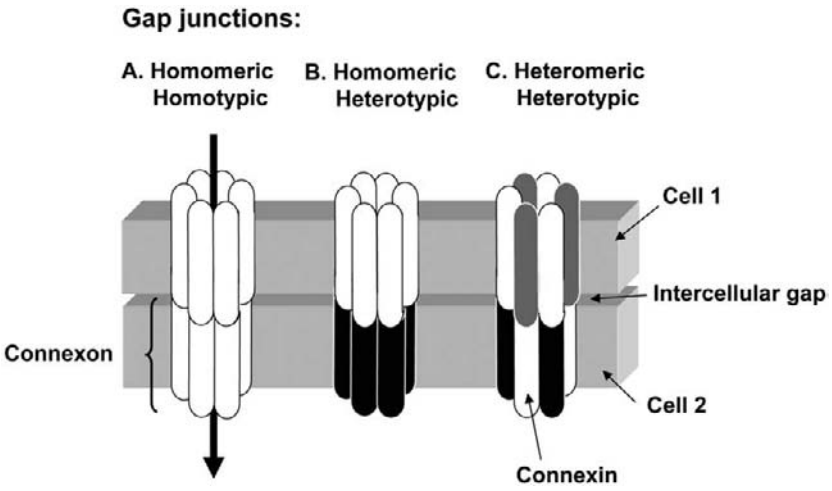

Figure 1 Structure of gap junctional channels. Gap junctions comprise two connexons, each of six Cx proteins, which may be of the same or different types, in adjacent cells.

Conductance of gap junctional channels can be modulated by a number of different factors, such as phosphorylation, changes in intracellular Ca^{2+} concentration and pH. The result of the phosphorylation of Cx proteins on conductance appears to depend on the component Cx isotypes and presumably relates to the number and location of specific phosphorylation sites, both of which vary among the different Cx proteins. Since many important vasoactive stimuli activate intracellular pathways resulting in increases in intracellular calcium or in the activation of protein kinases, it is likely that these stimuli will also modulate gap-junctional communication. Thus, cellular communication within the vascular wall may be dynamically controlled by increased or decreased channel open probability and gating, as well as Cx synthesis, assembly, trafficking, and degradation.

Expression of Gap Junctions in Vascular Tissue

The vascular wall is composed of a single inner layer of endothelial cells surrounded by layers of smooth muscle cells called the media (Figure 2). Both the endothelial and smooth muscle cells are spindle shaped but they are arranged with their longitudinal axes at right angles, the endothelial cells along the vessel axis and the smooth muscle cells transversely around the vessel (Figure 2). Large conduit arteries, such as the thoracic aorta, have many layers of smooth muscle cells that are interspersed with layers of elastic tissue to provide rigidity for the pressures experienced in these vessels. The so-called muscular arteries lack these elastic laminae, but still show considerable variation in the number of smooth muscle cell layers within the media. In the microcirculation, the number of smooth muscle cell layers is reduced to one or two.

At the ultrastructural level, gap junctions have been identified by their pentalaminar structure in which the proximity

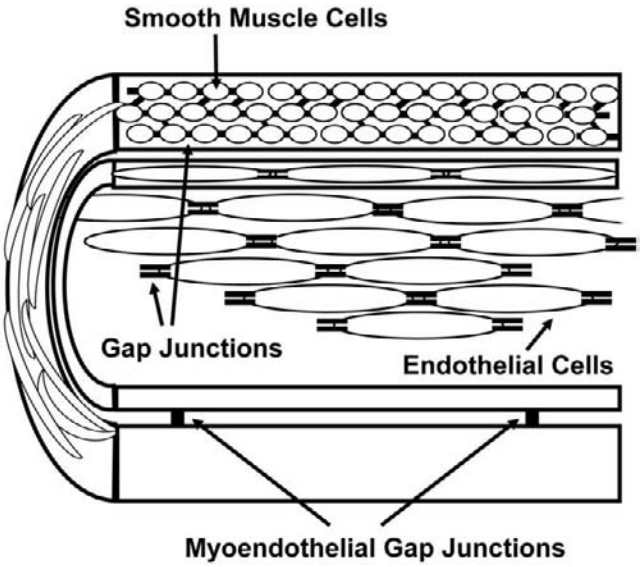

Figure 2 Anatomical structure of the arterial wall. Endothelial and smooth muscle cells are arranged at right angles to each other with adjacent cells being coupled by gap junctions.

of the outer membrane leaflets of the two opposing cells is seen as a single dark line (Figure 3A). In some cases, a 2-nm gap can be seen at this point. Such gap junctions have been commonly identified between adjacent endothelial cells and, more occasionally, between adjacent smooth muscle cells as well as between the two cell layers.

Within vascular tissue, four Cxs have been identified using subtype selective antibodies against Cxs 37, 40, 43, and 45. Cxs 37, 40, and 43 have been detected in the vascular endothelium of most vessels, whereas the situation in the smooth muscle appears to be more variable (Figure 3B). At least some of this variability may be due to heterogeneity in Cx expression among different animal species, as well as to variation within and between different vascular beds. Given

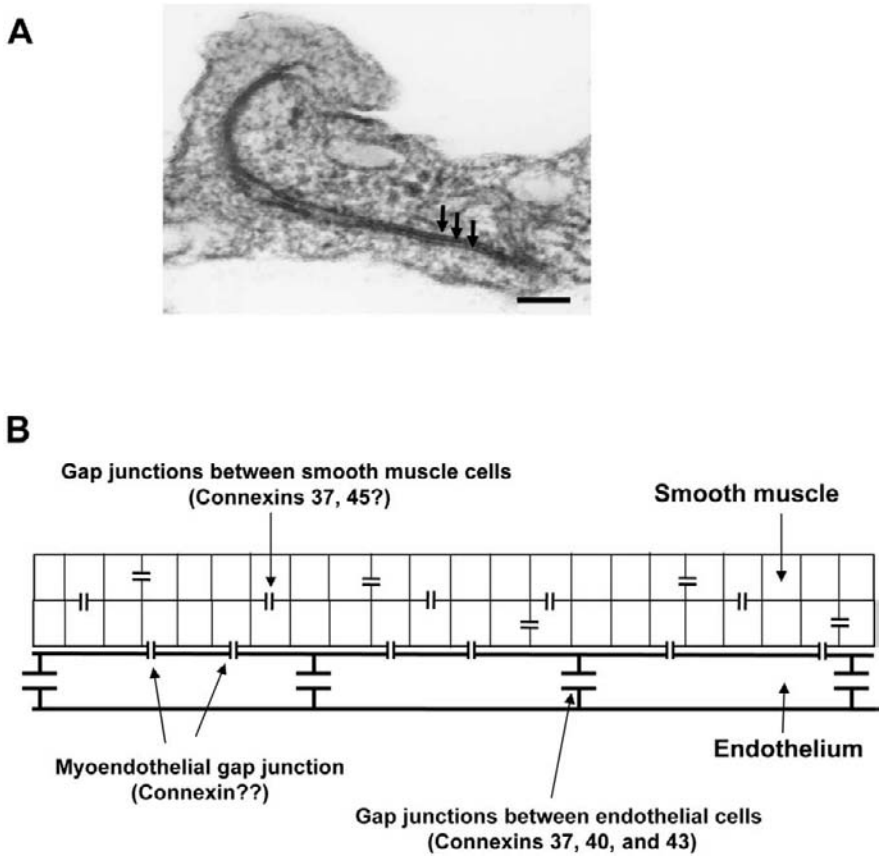

Figure 3 Gap junctions in the arterial wall. **(A)** Pentalaminar structure (arrows) of a gap junction connecting two endothelial cells of the rat basilar artery (kindly supplied by Dr. Shaun Sandow). that different Cx isotypes may form channels with unique electrical and biochemical properties, the heterogeneity in Cx expression among different vessels may contribute to heterogeneity in vascular responses.

Gap Junctions in the Endothelium

In the vascular endothelium, Cxs 37, 40, and 43 have been commonly found in both large and small arteries. At the ultrastructural level, large areas of intact pentalaminar gap junctions, up to and sometimes larger than 1 μm in length, are readily found in vessels of all sizes, confirming the view that endothelial cells are well coupled throughout the vasculature (Figure 3A). At the light microscope level, using immunohistochemistry and subtype selective antibodies, gap junctions appear as puncta that delineate the cell borders of endothelial cells (Figure 4A,B).

In the endothelium of many large vessels, Cxs 37, 40, and 43 have been described to be colocalized in the same gap junctional plaque, suggesting an ability to form heteromeric gap junctional channels. Although some variation in the relative expression of the three Cxs has been observed among different arteries, Cx40 appears to be the most highly expressed, whereas the expression of Cx43 may be the most variable in large vessels. Indeed, Cx43 appears to be specifically associated with areas where flow is turbulent, for example, at arterial branch points. Expression of Cxs is also subject to variation between species and in disease, development, and aging.

In the small vessels of the microvasculature, as in the larger muscular arteries, expression of all three Cxs has been reported in the endothelium (Figure 3B). Once again, variability exists in the relative expression within and between vascular beds and in the same vessel in different species, although Cx40 still appears to be the most highly expressed of the endothelial Cxs, whereas Cx37 expression may be more variable in these smaller vessels. Thus, Cx37 was consistently found along with Cxs40 and 43 in the endothelium of mesenteric resistance arteries, but was absent from the arterioles of the rat mesentery.

Gap Junctions in the Media

For many years Cx43 was considered to be the Cx linking smooth muscle cells. This view largely arose through investigations involving large elastic arteries such as the aorta, where Cx43 expression is indeed robust and abundant, and through the use of smooth muscle cell lines derived from the aorta. Comparative studies of Cx43 expression in a range of vessels including large and small

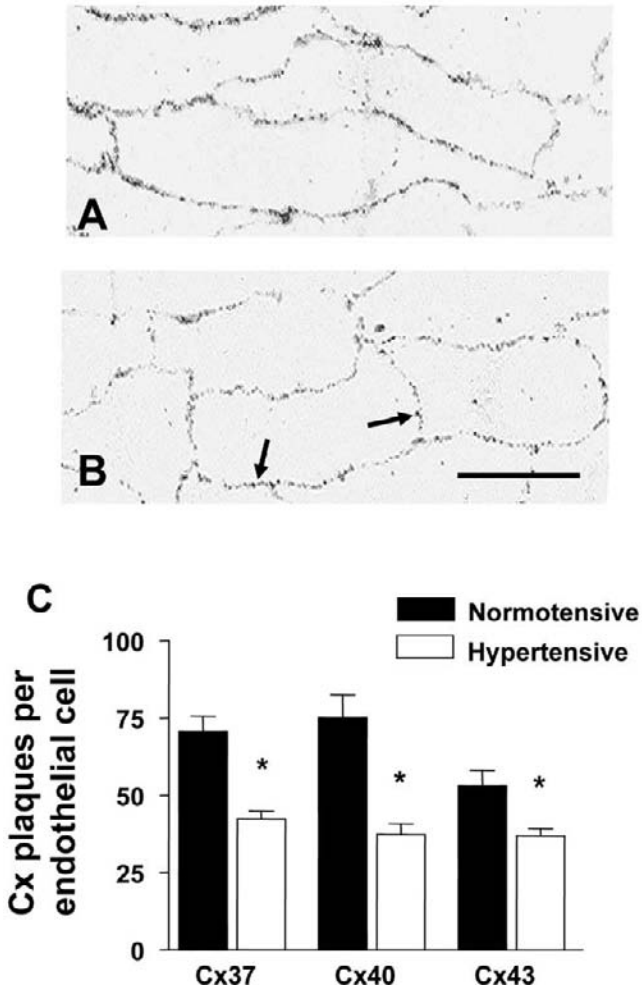

Figure 4 Changes in Cx expression in endothelial cells in hypertension. Punctate Cx40 expression (arrows) in caudal artery of normotensive **(A)** and spontaneously hypertensive rats **(B)**. Calibration bar 20 μm. **(C)** Expression of Cxs37, 40, and 43 per endothelial cell is reduced in hypertension (*$P < 0.05$). [Rummery et al. (2002). *J. Hypertens.* **20**, 247–253; permission granted from Lippincott, Williams & Wilkins.]

muscular arteries, however, demonstrated that expression of Cx43 was absent from the muscle layers of the latter vessels and that, even in the large conduit vessels, the expression of Cx43 decreased with distance from the heart.

The development of Cx45 knockout mice provided the first anatomical evidence that this Cx may play a role in the media of murine arteries. Subsequently Cx45 was detected in the media of the thoracic aorta and caudal arteries of rats and in smaller cerebral vessels. Interestingly, expression of Cx45 was reported to be inversely correlated with that of Cx43 in the aorta, and the suggestion was made that these two Cxs may be associated with different states of cell activity and differentiation. Although reports of Cxs37 and 40 expression in the media of large arteries also exist in the literature, these have not always been confirmed and may have arisen through the use of incompletely characterized Cx antibodies or may constitute further examples of variation in expression across animal species.

In muscular arteries, both large and small, there are few reports of the expression of Cx43. In general, Cx40 is also rarely described in the media of these vessels, although it is convincingly expressed in the renin-secreting smooth muscle cells of the juxtaglomerular apparatus. More recently, a role for Cxs37 and 45 has been identified in the media of a number of muscular arteries of rodents, including small microcirculatory cerebral vessels.

The intensity and extent of the Cx staining within the media of muscular arteries and arterioles suggest that the incidence of gap-junctional channels may be less than that observed in the endothelium or in the media of conduit vessels. At the ultrastructural level, pentalaminar gap junctions between smooth muscle cells are rarely observed and, where described, are much smaller (~100 nm) than those in the endothelium. Dyes, such as Lucifer yellow, that readily pass between endothelial cells do not pass between smooth muscle cells in arterioles of the microcirculation, again suggesting major differences between the coupling within the two cell layers. Interestingly, in larger muscular arteries such as the caudal artery, Lucifer yellow passes between smooth muscle cells in a radial but not a longitudinal direction, and nerve-evoked responses elicited in adventitial smooth muscle cells can be recorded in luminal smooth muscle cells. Taken together, these data suggest that coupling within the media of arteries and arterioles may be significantly less than that within the endothelium and may often be more effective in the radial compared with the longitudinal direction.

Myoendothelial Gap Junctions

Unlike homocellular coupling within the blood vessel wall, less is known regarding the nature of heterocellular coupling via myoendothelial gap junctions (MEGJs) between the endothelial and smooth muscle cell layers, and the Cxs comprising these junctions remain unidentified. Several studies have confirmed electrophysiologically that MEGJs exist in the microcirculation through the transfer of current pulses, dyes, and calcium from one cellular layer to the other. However, few structural reports of MEGJs existed in the literature until serial section electron microscopy was employed to elucidate their incidence. These latter studies have revealed that MEGJs are very small (~100 nm) and that in general the incidence of MEGJs increases as vessel size decreases. Thus, MEGJs might be expected to play an important role in the function of the microcirculation and in the control of vascular resistance.

Involvement of Gap Junctions in Responses Affecting Arteriolar Tone

The maintenance of arteriolar tone is achieved through a balance between vasoconstriction and vasodilation. Alterations to this balance have been implicated in disease states such as hypertension and atherosclerosis.

Vasoconstrictor Responses

THE MYOGENIC RESPONSE

The myogenic response refers to the nerve- and endothelium-independent vasoconstriction in response to increased transmural pressure and vasodilation in response to reduced pressure. This autoregulatory response is considered to be a major determinant of vascular tone and to reduce downstream damage to microcirculatory elements from significant and sudden changes in systemic pressure. The myogenic response is more prominent in smaller vessels, but is also differentially effective among vascular beds. It is now well established that the myogenic response is initiated by depolarization of vascular smooth muscle cells and an increase in intracellular calcium concentration via the opening of voltage-dependent calcium channels. The involvement of gap junctions in this response is suggested from the attenuation of myogenic tone by putative inhibitors of gap junctions. Gap-junctional coupling among the smooth muscle cells would be expected to facilitate the spread of the depolarizing current to coordinate constriction, particularly if the pressure stimulus was insufficient to activate all the intramural muscle cells—for example, those more distant from the lumen. Thus, it may be predicted that gap junctions would be less important in the myogenic response of arterioles.

VASOMOTION

Rhythmical contractions, or vasomotion have been demonstrated in many different vascular beds, including microcirculatory vessels of the systemic and cerebral circulations both *in vivo* and *in vitro*. Vasomotion has been suggested to be important for the maintenance of vascular resistance and blood flow. The common underlying mechanism involves release of intracellular calcium, which initiates a depolarization of the cell membrane and subsequent oscillation in membrane voltage due to sequential opening and closing of calcium and potassium channels. Gap-junctional coupling has been suggested to be critical to coordinate these oscillations between adjacent smooth muscle cells, and putative gap-junction inhibitors have been shown to prevent vasomotion in a number of vascular beds.

Vasodilatory Responses

The endothelium plays an important role in the control of vascular tone through the release of several mediators that act on the underlying smooth muscle to cause a relaxation. These factors, which are released in response to hemodynamic forces such as shear stress, include nitric oxide (NO), prostaglandins, and endothelium-derived hyperpolarizing factor (EDHF). NO and prostaglandins are both released from the endothelial cells and diffuse to the smooth muscle cells, where they activate intracellular pathways. Although it is possible that in large vessels gap junctions within the media might be involved in the spread of vasodilatory responses, this is unlikely to be so critical in the microcirculation where the media is made up of only one or two cell layers.

As its name suggests, EDHF produces a hyperpolarization of the endothelium, followed by hyperpolarization and relaxation of the smooth muscle due to a reduced calcium influx through voltage-dependent calcium channels. The precise identity of EDHF is controversial, with chemical factors, which can diffuse from the endothelium to the smooth muscle, as well as simple electrical coupling of the two cell layers via MEGJs being proposed as the likely candidates.

In general, the importance of NO and EDHF are inversely related. Thus, NO is more important in large arteries with multiple layers of smooth muscle, whereas EDHF has been found to be more important in smaller vessels with fewer smooth muscle cell layers. EDHF would therefore be seen to play a significant role in the microcirculation. Correlation of the incidence of MEGJs and the importance of EDHF as a vasodilatory factor has led to the suggestion that EDHF activity could be more simply explained by heterocellular coupling via MEGJs. Data from a number of laboratories, using putative gap-junctional uncouplers to inhibit EDHF activity and serial section electron microscopy to quantify MEGJs, have provided convincing support for this hypothesis in a variety of vessels, including the mesenteric microcirculation. Other studies have indicated that the myogenic response is antagonized by EDHF, since they share a common target of calcium-dependent potassium channels, whose activity will reduce membrane potential and decrease the activity of the voltage-dependent calcium channels.

Conducted Vascular Responses

An important function of the microcirculation is to regulate tissue perfusion by conducting vasodilatory responses from capillaries and small arterioles to upstream feed vessels to coordinate tissue blood flow to metabolic demands. Conducted vasoconstriction has also been reported in microvessels, and in the kidney this may be important for the operation of the tubuloglomerular feedback mechanism.

Conduction of vasomotor responses has been shown to rely on the electrotonic spread of current through gap-junctional channels within the vascular wall. Selective disruption of the continuity of one or the other of the two cellular layers has confirmed that the endothelium is the principal site for conduction of vasodilation, although in some vessels vasodilatory responses can be conducted in the smooth muscle if the endothelial pathway is impaired. On the other hand, vasoconstrictor responses are conducted in the smooth muscle and not in the endothelium in some vessels, whereas in others these responses are not conducted along the vessel at all. These data are in line with the immunohistochemical results suggesting that coupling between smooth muscle cells along the length of arteries may be less effective than coupling within the endothelium.

Acetylcholine evokes a conducted vasodilation that appears to be mediated by EDHF, whereas NO,

prostaglandins, and EDHF are all thought to modulate vasodilation at the local site of drug application. MEGJs are therefore considered to play an important role at the distal site in order for the hyperpolarization to be transferred to the smooth muscle and effect a relaxation through the inactivation of voltage-dependent calcium channels. The reduced conduction of endothelium-dependent vasodilatory responses in the skeletal microcirculation of mice lacking Cx40 further highlights the importance of endothelial gap junctions in these responses.

Conclusions

The preceding discussion has indicated that gap junctions play an important role in microvascular functions that can affect arteriolar tone and, in turn, systemic pressure and effective tissue perfusion. Since these functions are often compromised during vascular disease, such as hypertension, diabetes, and atherosclerosis, it may be expected that changes in expression of particular Cxs will accompany these states. Indeed, mice lacking Cx40 are hypertensive, while changes in expression of Cxs have been reported in the endothelium of large arteries in hypertensive animals (Figure 4). Increases in Cx43 have also been described early in the formation of atherosclerotic lesions, suggesting that upregulation of Cx43 may be required for the initial smooth muscle cell proliferation, while inflammatory mediators appear to modulate Cx expression and compromise conduction of microvascular responses.

Taken together, these data point to gap junctions as potential therapeutic targets for the treatment of cardiovascular diseases. More precise data regarding the control of gap-junctional function in intact tissues, the distribution of particular Cx isoforms in different parts of the microcirculation, and changes during disease will shed further light on the feasibility of this proposal.

Glossary

Conduction: Propagation of physiological responses to distal sites within the vasculature.

Cxs: Protein components of gap-junctional channels.

Endothelium-derived hyperpolarizing factor (EDHF): Putative factor producing endothelial hyperpolarization and relaxation of smooth muscle.

Gap junction: Intercellular channel connecting the cytoplasm of adjacent cells, allowing the transfer of electrical current and small ions.

Myoendothelial gap junction: Gap junction connecting endothelial and smooth muscle cells.

Myogenic response: Nerve- and endothelium-independent vasoconstriction in response to increased transmural pressure and vasodilation in response to reduced blood pressure.

Vasomotion: Rhythmical contractions of a blood vessel.

Capsule Biography

Dr Nicole Rummery completed her Ph.D. on the expression of vascular Cxs in arteries from normotensive and hypertensive rats under the supervision of Professor Caryl Hill, who heads the Blood Vessel laboratory at the John Curtin School of Medical Research. Research in the laboratory is focused on the involvement of gap junctions in vascular function, particularly the role played in vasomotion and in the mechanism of action of EDHF. Work is supported by the National Health & Medical Research Council and the National Heart Foundation of Australia.

CHAPTER 44

Vascular Control Mechanisms in Skeletal Muscle

Ingrid H. Sarelius
University of Rochester, Rochester, New York

In skeletal muscle, blood flow is very tightly coupled to metabolism. That is, as the metabolic rate of the muscle tissue changes (for example, during exercise) blood flow through the tissue changes proportionately as a result of changes in tone (i.e., the relative dilation) of the arterioles. In resting muscle, arterioles are partially constricted; generally this constriction is measured at 40 to 60 percent in arterioles of resting muscle. Thus there is considerable capacity in most skeletal muscle beds to change the resistance to flow through the tissue, or through some regions with respect to others. Studies such as those of Folkow and Halicka in the late 1960s established that the metabolically related increase in blood flow was greater in oxidative versus glycolytic muscles; this response differential can occur between different regions in a single muscle where the metabolism is different. These kinds of studies, especially when undertaken in isolated muscles, established that there must be direct coupling between arteriolar responses and metabolic rate, and a great deal of effort, over many decades, has identified roles for a variety of metabolically related products in vascular control. These include, for example, changed PO_2, purines (especially adenosine), K^+, H^+, lactate, and many others. Duling's group, in the 1970s, showed, using direct electrically induced contraction of individual skeletal muscle fibers, that arterioles can indeed be directly and locally coupled to a metabolic stimulus: Interestingly, it is only recently that new advances have been made in identifying mechanisms underlying this response (see Section IV). The goal of this chapter is to summarize what is known about the mechanisms underlying principally the local control of skeletal muscle arteriolar tone. Where appropriate, contributions to these local responses by integrating signals (such as those from neural inputs, or from flow) will be discussed, and important gaps in our knowledge will be identified.

Not all arterioles respond similarly to the same stimuli, and an important aspect of understanding the control of these vessels is to identify how different inputs differentially affect different parts of the microcirculation, and how this is integrated into a coordinated vascular response subserving changes in muscle blood flow. Topics that will be covered in this chapter therefore include the organization of skeletal muscle microvasculature with particular reference to the responses of different parts of the arteriolar tree; mechanisms of communication among the cells of the arteriolar wall; local metabolic response mechanisms; and control of arteriolar function via capillaries and venules.

I. Microvascular Network Organization in Skeletal Muscle

As in many other organ systems, skeletal muscle microcirculation consists of, in series, a divergently branching arteriolar network, a system of branching capillaries (the principal exchange bed for respiratory gases and nutrients), and a converging venular system. Until the early 1980s, most people viewed skeletal muscle microcirculation as a simple branching hierarchy, with each branch level being in series with those proximal and distal to it, and with all elements at any specified branch level being functionally equivalent and arranged in parallel with each other. During the 1980s and subsequently, rekindled interest in understanding the organization of skeletal muscle microcirculation, particularly arterioles and capillaries, has led to a better understanding of the organization of this system.

First, it became clear that like many other organs, skeletal muscle has prominent arcading arteriolar systems. These

arteriolar arcades presumably serve to equalize the driving pressure for flow through subsequent branches across wide regions of the tissue; each arcade gives rise to several smaller arterioles that each branch two or three times and then give rise to capillaries. In general, the arcading arterioles are larger (greater than about 80 to 100 μm in diameter) than the terminally branching arteriolar systems. These larger vessels are also the arterioles that are most likely to be "paired" with collecting venules: The functional consequences of this anatomical arrangement for arteriolar control will be discussed later.

Second, the terminally branching arteriolar trees (diameter usually less than about 65 μm, down to approximately 10 μm) are not paired anatomically with venules and are the controllers of capillary perfusion (see Section VI). Capillaries arise from the distal ramifications of these arteriolar trees. They are arranged in groups (variously called networks, units, or modules), and capillary recruitment occurs when these groups of capillaries are perfused as a result of dilation of the small arterioles from which they arise.

II. The Cells of the Arteriolar Wall

All but the very largest arterioles consist of a single layer of smooth muscle cells (SMCs) wrapped circumferentially around the vessel, which is lined by a single layer of endothelial cells (ECs) oriented axially along the vessel. In addition to these major cell types, the adventitial (abluminal) aspect of the arteriole supports perivascular nerves, pericytes, fibroblasts, and a substantial extracellular matrix. All of these elements have the capacity to contribute to arteriolar control; the role of neural inputs, both central and perivascular, is best documented, but it is also now established that signals generated by the extracellular matrix can influence arteriolar tone through integrin coupling to Ca^{2+} channels, although how this might contribute to control of skeletal muscle arterioles is not known. Similarly, the contribution of pericytes (or other cell types located in close apposition to the arteriolar wall) to responses of arterioles in skeletal muscle remains largely undefined. The arteriolar wall is exposed to inputs from both the vessel lumen and the tissue space. It is established that ECs respond to mechanical inputs, of which the most prominent is flow, but other luminal stimuli have been identified. For example, red blood cells, in addition to their role in oxygen delivery, have been postulated to act as modifiers and/or sources of ATP and NO. On the abluminal side of the arteriole, skeletal muscle myocytes are a primary source of vasoactive agents, but additionally, the arteriole can respond to external mechanical stimuli, such as compression of microvessels induced by muscle contraction, and will be of course be influenced by neural inputs. Overall, these arterioles are exquisitely responsive to a very wide range of inputs; redundancy of control mechanisms clearly confers survival advantages on this important system but requires that the microcirculatory network also have the capacity to integrate all this information to produce appropriately coordinated responses. Thus, an important emerging issue is that of identifying the mechanisms by which many inputs are integrated locally, and perhaps of even more significance, how they are integrated over the length of individual arteriolar segments, and across the microvascular network.

III. Differential Responses of Large versus Small Arterioles

Skeletal muscle arterioles, like those of other organs, display myogenic tone, that is, in response to the transmural (distending) pressure exerted on the wall by the blood, the SMCs increase their degree of constriction. How this is manifest at any level of the microcirculation depends on the transmural wall stress, which is a function of both the pressure and the vessel radius. Thus the myogenic effect should be less in smaller vessels; despite this, smaller arterioles typically have higher tone those located more proximally. This reflects longitudinal differences in the ability of arterioles to respond to other regulatory mechanisms (local, neural). Differential sensitivities of larger versus smaller arterioles to a variety of stimuli is an important way in which integration of responses is achieved in the arteriolar microcirculation. In skeletal muscle microcirculation, perivascular nerves and varicosities are found in association with arterioles of all sizes, but arteriolar sensitivity to adrenergic inputs is not uniform across the network. Both α_1 and α_2 adrenergic receptors have been identified on large arterioles, while α_2 receptors appear to predominate on smaller arterioles. Furthermore, most studies suggest that larger vessels (sometimes classified as first- and second-order vessels, in contrast to the smaller third- through fifth-order vessels) are more susceptible to neural inputs than are smaller arterioles; third- through fifth-order arterioles are in turn more responsive to metabolic stimuli than are larger arterioles. In like manner, oxygen sensitivity appears to predominate in smaller arterioles, while flow-dependent responses are more prominent in first- and second-order vessels. Notwithstanding these gradations in response characteristics as one moves distally through the network toward smaller arterioles, most arterioles do exhibit some degree of responsiveness to all these inputs. An important unanswered issue is to identify which of these differences are an acute reflection of the local conditions, and which reflect phenotypic differences in response capability.

IV. Metabolic Regulation of Arteriolar Tone

A. Oxygen

Oxygen has consistently been implicated in regulation of arteriolar tone, and although involvement of changes in P_{O_2} in regulation of skeletal muscle function is intuitively compelling, no obvious "oxygen sensor" has been identified

despite decades of searching. Thus it has seemed unlikely that oxygen has a direct effect on the arteriolar wall. However, recent work has revisited this issue, and although the signaling mechanisms are still not clarified, it is clear that at least in some arterioles, including those in skeletal muscle, oxygen can directly affect the cells of the arteriolar wall via a cytochrome P450–dependent pathway, and also possibly by mitigation of adrenergic vasoconstrictor tone at a step in the SMC signaling cascade that is distal to an increase in Ca^{2+}. There is compelling evidence that K_{ATP} channels are implicated in local metabolic responses, but this does not appear to be via a direct effect of oxygen on the function of these channels in SMCs.

Most investigators have concluded that oxygen modulates local arteriolar responses indirectly—that is, as muscle metabolism changes, local PO_2 will also change, as will the balance of metabolites released from the contracting muscle. It is thus easy to conceptualize a control system in which some or all such products feed back on the arteriole to produce changes in force development by the SMCs. Using this logic, a variety of possible mediators have been identified. The challenge is to demonstrate directly what role any such agents play on the cellular mechanisms regulating tone in the blood vessel wall.

B. Adenosine

By reason of its release from contracting muscle fibers during decreased P_{O_2}, adenosine (ADO) has long been implicated in metabolic control. There is evidence from direct observations of small arterioles that ADO is indeed involved in the local metabolic response. However, it accounts for only a fraction of the dilation in response to near-maximal muscle contraction and appears to have a greater effect in smaller arterioles. This might explain why studies of whole organs or in intact animals have not invariably implicated this purine in metabolic dilation. It is widely assumed that ADO acts on smooth muscle, and it is established that SMCs in skeletal muscle arterioles display both P_1 and P_2 purinergic receptors; however, purinergic receptors are also found on ECs, and recent work suggests that local metabolic responses in small arterioles may be coupled through P_1 receptors on ECs. Purines are known to increase EC Ca^{2+}, and this increase in EC Ca^{2+} has also been implicated in mediation of metabolic vasodilation in small arterioles. In some circulations (e.g., coronary) ADO acts via K_{ATP} channels, but in skeletal muscle arterioles this does not appear to be the case.

C. Ions, Particularly K^+

Many ions have vasoactive properties and have been identified as possible mediators of metabolic vasodilation. These include potassium, hydrogen, and overall osmolarity, as well as charged moieties such as lactate, all of which have been detected in venous blood during changes in muscle metabolism. Of these, raised extracellular $[K^+]$ has received the most attention, and it is established that small increases in $[K^+]$ of the order of 5 to 10 mM can lead to vasodilation in a variety of arterioles, including those from skeletal muscle. The mechanism(s) by which this dilation is brought about are still unclear: Evidence supporting a role for K_{IR} channels and for Na^+/K^+ ATPase activation has been published, but more definitive work in this area is needed.

D. Other Molecules Contributing to Functional Hyperemia

There is considerable evidence implicating nitric oxide (NO) as a signaling intermediate—local arteriolar dilation to muscle contraction can be significantly attenuated in the presence of blockers such as L-NAME. Several different actions of NO have been identified. It appears to support vascular dilation directly, possibly via a K_{ATP} channel-dependent signaling pathway. Studies in NOS-deficient mouse models suggest that at least part of the NO is derived from nNOS located in skeletal muscle fibers; contributions from eNOS have also been identified, but there is a lot still to be learned about the mechanisms underlying this response. In many systems, NO release from ECs has been implicated in flow-dependent responses, and it is possible that this stimulus also contributes to NO release during blood flow changes associated with changes in muscle metabolism. NO also attenuates sympathetic vasoconstricion in an action known as "sympatholysis": Again, this mechanism is not fully understood, but this aspect of the contribution of NO to vasodilation also appears likely to involve K_{ATP} channels. Whether they are located on SMCs, ECs, or the skeletal muscle fibers remains to be determined.

It has also been shown that the arteriolar dilation to muscle contraction is partially blocked by indomethacin, implicating prostaglandins in the regulation of this function. As both NO and prostaglandins have been implicated in flow-dependent responses in skeletal muscle, a challenge will be to sort out which aspects of this pathway are primary versus secondary as a consequence of local changes in the prevailing flow that are themselves a consequence of local changes in arteriolar tone. Recent work has shown, not surprisingly, that multiple local vasoactive pathways can be activated simultaneously upon contraction of skeletal muscle, and at least some of these are independent of any local hemodynamic changes.

V. Integration of Metabolic Response Pathways

A. Myoendothelial Communication

In addition to considerations about which control mechanisms for arteriolar responses reside on SMCs versus ECs, it has become apparent that these two cell types can be closely coupled, thus enabling the arteriolar wall to act as a syncytium. In small arterioles there are gap junctions between adjacent ECs and between adjacent SMCs; in

addition the two cell types are connected by myoendothelial gap junctions. This arrangement allows signals to spread axially along the vessel, and also to be communicated directly between ECs and SMCs. Local paracrine signaling from ECs to SMCs is, of course, well established (NO, EDHF), but it is now clear that intracellular transfer of signaling intermediates can also occur from SMCs to ECs. It has recently been shown that the increased SMC Ca^{2+} that occurs when arterioles constrict can be transferred to ECs, raising Ca^{2+} in these cells and contributing to NO release, which in turn ameliorates the original vasoconstriction. How this response pattern contributes to in situ arteriolar responses is not yet clear, but it indicates that vessels in their native environment can respond in an even more closely integrated way than previously thought.

B. Axially Propagated Responses

In the past two decades, a great deal of work, much of it in skeletal muscle arterioles, has established that in these vessels, responses can be propagated axially over considerable distances (millimeters) from their point of local origin. Most of this work has focused on understanding the mechanisms underlying dilations and constrictions conducted axially as a result of local stimulation by acetylcholine and phenylephrine, respectively. These agents induce hyper- and hypopolarizations, respectively, that are transmitted axially along the vessel in a manner that appears to be dependent largely (although not necessarily entirely) on gap-junction communication. Although the principal pathway for this transmission appears to be ECs, signals can also be transmitted via a SMC pathway, and an important task will be to identify what control mechanisms determine whether transmission is via ECs or SMCs or both cell types. Not all local vasomotor events result in a propagated signal; for example, it has been shown that contraction of skeletal muscle fibers causes a local dilation that involves ADO, NO, and a separate, K_{ATP} channel–dependent pathway, but that the NO-dependent component of this response is not propagated axially, whereas the ADO and K_{ATP} channel–dependent components are. Similarly, locally applied purines induce a mixed response, constriction followed by dilation, but only the dilator component is propagated axially. Not all of these responses appear to depend entirely on gap-junctionally mediated transmission, but what other signaling pathways are involved is not known at this time. Initial work suggests that the remote response to purines is dependent on increased EC Ca^{2+} at the remote site, but how this relates to the signaling cascade is entirely unknown. Despite the fact that there is much to be learned about the mechanisms underlying these communicated responses, their potential contribution to integration of skeletal muscle responses is clear. If only local dilations were produced in muscles in response to contraction of individual motor units, then at submaximal motor unit recruitment one might expect arterioles to exhibit a series of randomly located local dilations that would not support changes in flow through the vessel: Conduction of these dilations along the arteriolar wall allows the vessel to respond as a coordinated entity, thus facilitating decreased resistance to flow across the vessel (and network region) as a whole.

C. Flow-Dependent Dilations

Skeletal muscle arterioles are sensitive to flow, and, interestingly, larger rather than smaller vessels are more responsive to this stimulus (compared to the conducted responses discussed earlier, which appear to be most prominent in smaller arterioles). It has also been shown that ascending flow-dependent dilations can be propagated proximally to encompass the inflow vessels to the tissue, thus enabling flow to be increased to the entire tissue. Thus the picture that is emerging is one in which small arterioles, by reason of their electrical and/or local paracrine coupling, are able to exhibit responses that are conducted beyond their region of origin to enable the vessel to respond as a coordinated whole, while larger arterioles, being flow sensitive, exhibit an ascending dilatory behavior that subserves increased flow into the tissue under conditions of increased metabolism.

VI. Control of Capillary Recruitment

Capillaries, having no smooth muscle, are not generally thought to actively participate in blood flow control. However, in a series of studies in the 1980s and 1990s, Tyml and others showed that capillaries in skeletal muscle are capable of responding to vasoactive stimuli such as norepinephrine by producing vasoconstriction elsewhere in the network and hence decreasing capillary flow. The implication was that these signals were axially propagated along the vessel wall. In the 1990s, Sarelius and coworkers showed that capillaries could sense contraction of underlying skeletal muscle fibers and send a dilator signal to upstream arterioles, thus increasing flow through the "active" capillary network. They showed that this signal was specific to capillaries associated with actively contracting muscle fibers. This mechanisms explains how capillary recruitment can be matched closely with metabolic requirements, despite the fact that the controllers of these vessels are located upstream of the capillaries that they control, and often remote from the contracting fibers.

VII. Venular–Arteriolar Communication

As noted in Section I, larger arterioles are located anatomically in a "pair" with larger collecting venules. This raises the possibility that control mechanisms may be coupled from these outflow venules to their neighboring arterioles—an attractive idea that conceptualizes how changes in venous outflow due to changes in metabolism could be coupled back locally within the tissue to change inflow capacity. The idea that venous P_{O_2} may be sensed in this

way by inflow arterioles has been raised repeatedly for many decades. In recent years, veno-arteriolar coupling of responses to metabolites such as adenosine has been clearly demonstrated, indicating that this means of communication within the muscle has the capacity to modify inflow to the tissue in a way that, at least conceptually, should serve to match blood flow to metabolism more closely.

VIII. Summary

Blood flow control in skeletal muscle achieves very close coupling between flow and the metabolism of the tissue. Integration of control is achieved by several means. There are differences in response capacity to many stimuli between large and small arterioles. Communication of signals among the cells of the arteriolar wall, both axially and between SMCs and ECs, enables the vessel and network to respond as a coordinated whole. Ascending flow-dependent dilation has also been identified as a mechanism supporting rapid modulation of the inflow to the tissue. Cellular signaling mechanisms underlying these responses are still being worked out: In addition to roles for such metabolically related substances as oxygen and adenosine, contributions from NO, and one or more EDHFs, have been identified. A role for K_{ATP} channels is strongly indicated, but where in the signaling cascade these channels contribute to the response is not clear.

Glossary

Arcading arteriolar system: Arterioles that form a continuous loop from which smaller arterioles branch, in contrast to a bifurcating arteriolar system, in which an arteriole diverges into two smaller branches.

Gap-junction communication: Transfer of signals between the cytosols of two adjacent cells via a channel in their membranes.

NOS: Nitric oxide synthase, the enzyme responsible for production of nitric oxide. (eNOS is an isoform found in endothelial cells; nNOS, an isoform found in skeletal muscle.)

Transmural wall stress: The (normalized) tension in the vessel wall that resists the pressure exerted by the blood in the vessel lumen.

Capsule Biography

Dr. Sarelius is a Professor of Pharmacology and Physiology and of Biomedical Engineering at the University of Rochester. Her laboratory focuses on cell communication in the arteriolar wall, and on signaling between blood cells (primarily leukocytes) and the microvessel wall. Her work is supported by grants from the National Institutes of Health.

CHAPTER 45

Protein Kinases and Microvascular Permeability

Mack H. Wu and Sarah Y. Yuan
University of California School of Medicine, Sacramento, CA

Blood–tissue exchange occurs in the downstream segments of microvasculature, namely capillary and postcapillary venules. The wall of these exchange microvessels consists of a sheet of cells, endothelial cells, which connect to each other with closely opposed intercellular junctions. This endothelial sheet is tethered to a network of extracellular matrices in the basement membrane, forming a barrier structure that controls the transvascular movement of blood components. The permeability of microvascular endothelium is maintained by an equilibrium between the contractile force generated at the endothelial cytoskeleton and the adhesive forces produced at endothelial cell–cell junctions and cell–matrix focal contacts (Figure 1). A dynamic interaction among these structural elements controls the opening and closing of the paracellular pathways for fluid and cells to move across the vessel wall and thus serves as a fundamental mechanism in the physiological and pathological regulation of blood–tissue exchange.

Aberrations of microvascular barrier function lead to an abnormal extravasation of blood components, resulting in tissue edema and dysfunction. This cellular process is involved in inflammation, ischemia-reperfusion injury, trauma, sepsis, diabetes, and atherosclerosis. Under such disease conditions, many inflammatory mediators are released, and most of them possess a potent permeability-increasing effect. These mediators, including histamine, bradykinin, platelet activating factor, growth factors, glycation products, cytokines, reactive oxygen species, and activated leukocytes, can interact with the microvascular endothelium and activate an array of intracellular second messengers, which in turn catalyze a series of biochemical reactions at the endothelial cytoskeleton and cell–cell and cell–matrix adhesive structures (Figure 2). Ultimately, endothelial cells contract or undergo conformational changes, resulting in endothelial hyperpermeability and microvascular barrier dysfunction.

Protein kinases, classified as serine/threonine kinases or tyrosine kinases based on their substrate specificity, constitute an important category of intracellular second messengers that mediate the structural and functional changes occurring in the endothelium under physiological conditions as well as during inflammatory stimulation. Several groups of protein kinases have been characterized and their involvement in the cellular response to inflammation or injury has been documented. The following discussion focuses on the protein kinases that are frequently implicated in the modulation of microvascular permeability.

Myosin Light-Chain Kinase (MLCK)

Actin and myosin are the major contractile components in the cytoskeleton. The cross-bridge movement between actin and myosin provides a mechanical basis for not only the maintenance of centripetal tension but also the development of contractile force in cells during physical or chemical stimulation. In vascular endothelial cells, the interaction between actin and myosin is mainly governed by the phosphorylation status of the regulatory myosin light chain (MLC). Two major mechanisms control the activity of MLC. On one hand, myosin light-chain kinase directly phosphorylates MLC at Thr-18 and/or Ser-19, resulting in MLC activation and actin–myosin binding. On the other hand, myosin-associated protein phosphatase dephosphorylates MLC and thus counteracts the MLCK effect, leading to cell relaxation. Certain types of agonists and cells can

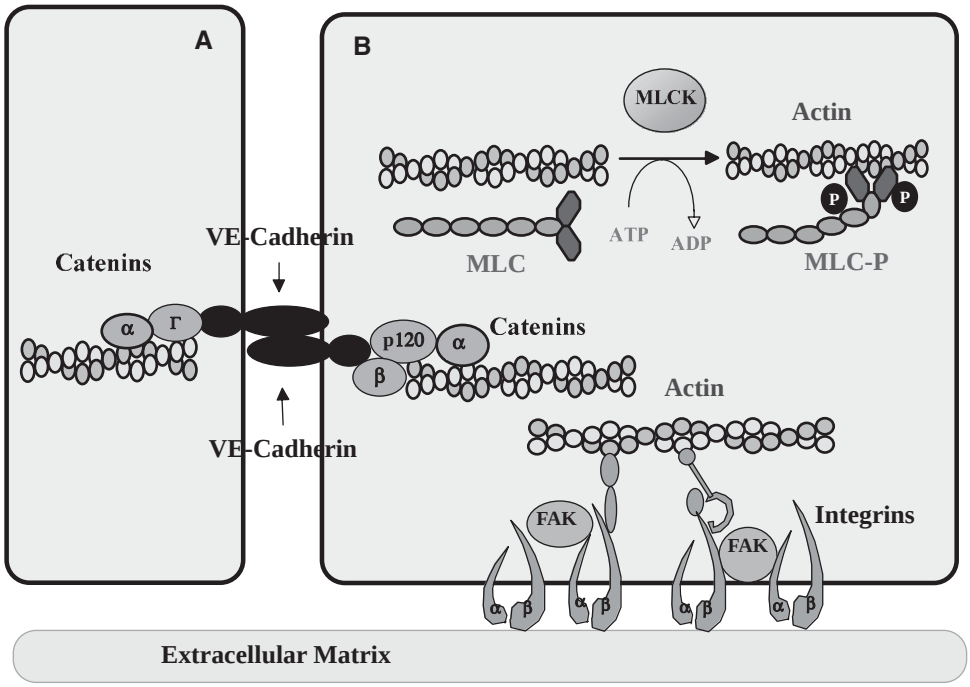

Figure 1 A schematic diagram of microvascular endothelial barrier structure. The barrier is formed by a layer of endothelial cells that connect to each other (e.g., cell A to cell B) through the junctional adhesive molecule VE-cadherin, which binds to another VE-cadherin in the junction and connects to actin cytoskeleton via a family of catenins (αβγ, and p120). This endothelial lining is tethered to the extracellular matrix through the binding of transendothelial receptor integrins (composed of α and β subunits) and a family of cytoskeleton-linking proteins including focal adhesion kinase (FAK). The integrity of this barrier structure is maintained by VE-cadherin-mediated cell–cell adhesions and focal adhesion-supported cell–matrix attachment, whereas myosin light chain kinase (MLCK)-catalyzed myosin light chain (MLC) phosphorylation promotes cross-bridge movement between actin and myosin leading to cell contraction. A dynamic interaction among these structural elements controls the opening and closing of the paracellular pathways for fluid, proteins, and cells to move across the endothelium.

activate the contractile process by increasing MLCK activity through calcium/calmodulin signaling or by directly phosphorylating MLCK. Other agents are able to stimulate actomyosin contraction by inhibiting MLC phosphatase activity. In particular, a family of Rho-like small GTPases and their downstream effector, Rho kinase, have been implicated in the regulation of MLC phosphorylation through inhibition of MLC phosphatase.

The functional importance of the contractile mechanism in controlling microvascular permeability has been subject to extensive investigation. Recent studies provide strong evidence for a link between MLC phosphorylation and stress fiber formation or tension development in the endothelial cells. A causal role of MLCK in the endothelial hyperpermeability response to inflammatory mediators has been established through experiments in cultured endothelial monolayers as well as in intact isolated venules, where administration of pharmacological agents or transference of synthetic peptides that specifically block MLCK function can prevent the increase in permeability caused by thrombin, histamine, cytokines, oxygen radicals, and activated neutrophils. Furthermore, inhibition of MLCK or knockout of endothelial MLCK genes has proven to effectively attenuate microvascular leakage under clinically relevant conditions such as severe burns and sepsis. These findings confirm that endothelial MLCK plays a critical role in mediating microvascular barrier dysfunction during inflammation and injury.

Protein Kinase C (PKC)

Protein kinase C represents a family of at least 10 serine/threonine kinases (α, β1, β2, γ, δ, ε, ν, θ, μ, ξ, and λ). These isozymes show distinct expression patterns and are responsible for diverse cellular responses. Most of them can be activated by phorbol esters and diacylglycerol (DAG), as experimentally indicated by membrane translocation and increased phosphorylating activities. PKC activity is negatively regulated by serine/threonine protein phosphatases.

Functionally, despite its perhaps minor effect on the basal barrier property of the endothelium, PKC has been frequently referred to as a key mediator of microvascular hyperpermeability under stimulated conditions. Direct activation of PKC with DAG or phorbol esters increases the flux of fluid and macromolecules across the microvascular endothelium, whereas PKC inhibitors reduce the increases

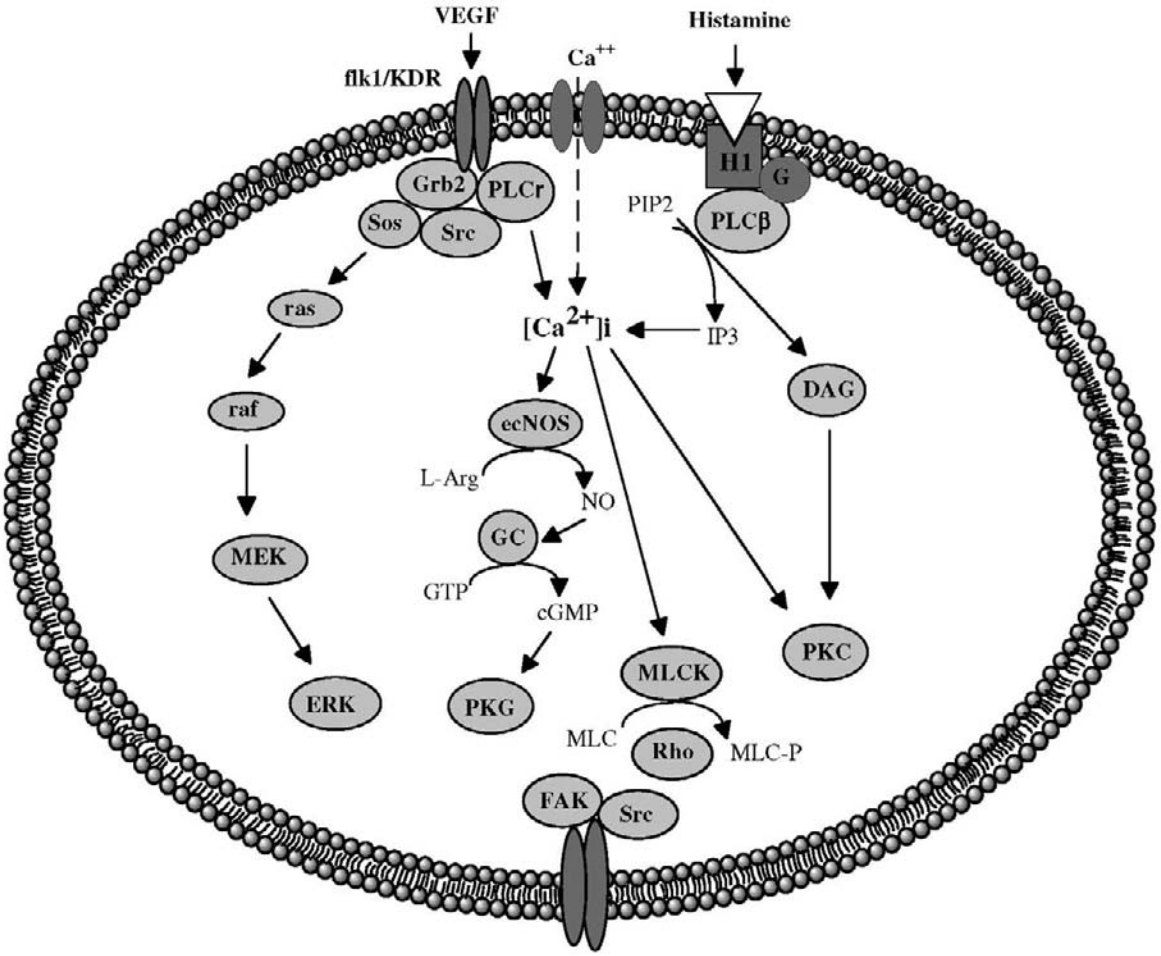

Figure 2 A model for the signal transduction of agonist-induced microvascular hyperpermeability. Histamine and vascular endothelial growth factor (VEGF) are used to represent permeability-increasing agonists. Histamine binding to its receptor (H) activates phospholipase C beta (PLCβ) via a G protein (G), catalyzing the production from inositol bisphosphate (PIP_2) to inositol trisphosphate (IP_3) and diacylglycerol (DAG). DAG directly activates protein kinase C. In parallel, IP_3 stimulates an internal release of Ca^{2+} followed by an influx of extracellular Ca^{2+}, leading to upregulation of nitric oxide synthase (ecNOS) and nitric oxide (NO) production from its precursor L-arginine (L-Arg). Nitric oxide stimulates guanylate cyclase (GC) to produce cGMP, a potent activator of cGMP-dependent protein kinase (PKG). The elevated intracellular calcium also stimulates PKC and myosin light-chain kinase (MLCK); the latter phosphorylates myosin light chain (MLC-P). The hyperpermeability effect of VEGF is triggered by its tyrosine kinase receptor flk1/KDR and mediated through two major signaling pathways. On one hand, activated phospholipase C gamma (PLCγ) elevates the intracellular calcium and subsequently activates the PKG, PKC, and MLCK cascades. On the other hand, KDR receptor occupancy results in the recruitment of several adaptor proteins, such as Grb2, Sos, and Src, which further produces the ras-raf-MEK-ERK cascade. In addition, the nonreceptor tyrosine kinases FAK and Src as well as the Rho-family of GTPases are also involved in the endothelial response to inflammatory stimulation. All of these protein kinases—PKG, PKC, MLCK, MAPK, and tyrosine kinases—may directly or indirectly target the endothelial barrier structure to cause an opening of the paracellular pathway for transendothelial flux of fluid and macromolecules. (see color insert)

in endothelial permeability caused by thrombin, bradykinin, platelet activating factor, hydrogen peroxide, VEGF, or neutrophils. Importantly, clinical and experimental evidence is accumulating that PKC activation and subsequent microvascular barrier dysfunction may underlie the initiation and progress of circulatory disorders associated with diabetes, atherosclerosis, and ischemia-reperfusion injury.

Recent advances in molecular technologies enable direct targeting of particular PKC isoforms by selective inhibitors, synthetic peptides, or antisense oligonucleotides. Experiments employing these approaches reveal the relative importance of PKCα, PKCβ, PKCδ, and PKCμ (also known as PKD) in the regulation of microvascular permeability. Some studies demonstrate that endothelial hyperpermeability resulting from hyperglycemia, ischemia, and angiogenesis or inflammatory stimulation is a PKCα-dependent event. In contrast, others suggest that PKCβ overexpression in endothelial cells potentiates agonist-induced transendothelial flux of macromolecules, whereas pharmacological or antisense inhibitors of PKCβ diminish the increase in endothelial permeability caused by phorbol esters or oxygen radicals. Oral administration of LY333531 or LY290181, selective pharmacological antagonists of PKCβ, prevents microvascular leakage in the retina and kidney of diabetic

animals. More recently, evidence is emerging that PKCδ and PKD may be required for the microvascular permeability response to phorbol ester and diacylglycerol, typical exogenous and endogenous activators of PKC, respectively.

How PKC alters endothelial barrier function remains an interesting question. Both the cytoskeleton and cell–cell junctions are potential targets of this potent kinase. More specifically, it has been reported that PKC activates the endothelial contractile apparatus by inducing MLC phosphorylation and actin polymerization. Recent experiments suggest that the endothelial contractile response can be triggered by a PKC-dependent activation of the Rho pathway. Furthermore, disassembly of endothelial adherens junctions has been linked to PKC activation. In addition to its direct effect on the cytoskeletal and junctional structures, PKC may indirectly alter the endothelial barrier function through crosstalk with other intracellular signaling molecules. In this regard, the nitric oxide (NO) pathway has been increasingly recognized as a potential downstream target of PKC. An in vivo experiment in the hamster cheek pouch demonstrates that phorbol ester–induced macromolecular transport in the microcirculation is reduced when NO synthesis is blocked. This is further supported by evidence of enhanced nitric oxide synthase (NOS) phosphorylation and NO production in microvessels or endothelial cells exposed to PKC activators. A comparative analysis of the permeability response to PKC activators in isolated venules before and after NOS inhibition indicates that the barrier loosening effect of PKC is mediated, at least in part, through the endothelial production of NO.

Cytosolic calcium is an important cofactor required for the regulation of PKC function. Within this context, PKCα and PKCβ are the predominant isozymes that are dependent on calcium for activation. Many permeability-increasing agonists are able to stimulate the release of calcium from intracellular stores followed by influx from extracellular space. This process, in addition to directly activating PKC, can upregulate the activity of other enzymes and second messengers in endothelial cells, such as MLCK and NO, which more likely serve as intracellular signals secondary to the PKC pathway in the transduction of endothelial permeability response. Currently, studies are ongoing to define the precise role of cytosolic calcium in the complex interactions among multiple protein kinases in microvascular endothelial cells upon inflammatory stimulation.

cAMP- and cGMP-Dependent Protein Kinases (PKA and PKG)

In general, an increase in the intracellular level of cAMP promotes endothelial barrier integrity, and the effect is most likely mediated through PKA. Studies have been carried out in cultured cells, perfused microvessels, and intact tissues in which application of PKA activators, such as β-adrenergic agonists or cAMP analogs, reduces endothelial permeability and prevents microvascular leakage during inflammation and ischemia-reperfusion injury. Recently, an endogenous PKA competitor, PKI, has been identified in vascular endothelial cells and is being used for selective inhibition of PKA. Infection of human dermal microvascular endothelial cells with adenovirus containing PKI gene results in overexpression of PKI and abrogates the cAMP-mediated protection against increased endothelial permeability.

The barrier protection effect of PKA may be related to its ability to stabilize endothelial cytoskeletal and adhesive structures. There are reports that PKA causes dephosphorylation of MLC, dissociation of F-actin from myosin, stabilization of cytoskeletal filaments, and strengthening of cell–matrix adhesions. Moreover, PKA is well known for inhibiting leukocyte adhesion and platelet aggregation. This effect may play an indirect role in preventing the endothelial barrier from being damaged by activated leukocytes or platelets and their metabolites. Finally, it is possible that the PKA pathway functions through interactions with other signaling molecules such as PKG.

In contrast to the general consensus on the barrier-tightening effect of PKA, there is considerable controversy as to whether the cGMP-PKG cascade acts as a barrier protector or a permeability-increasing factor. Most in vitro experiments using cultured endothelial cells derived from large vessels or nonexchange microvessels show that an elevation of intracellular cGMP by NO donors or guanylate cyclase activators is associated with a decrease in endothelial permeability. On the other hand, in vivo observation and in vitro studies using microvascular endothelial cells report a PKG-dependent increase of microvascular permeability in response to a variety of agonists, including NO donors, histamine, bradykinin, tumor necrosis factor, platelet activating factor, and VEGF. These apparently contradictory findings may result from variations in cell types and experimental conditions. With regard to experimental models, cultured cells may not fully mimic the in vivo state of microcirculation. For example, it has been reported that PKG expression is dramatically reduced in cultured endothelial cells during serial passage. Whether the cells are exposed to a physiological range of shear stress and a normal calcium environment also affects the expression and activity of the kinase. Recent experiments in intact perfused microvessels show that selective inhibition of NOS, guanylate cyclase, or PKG suppresses venular hyperpermeability caused by shear stress, histamine-type agonists, and VEGF. It has been postulated that certain types of physical and chemical stimuli increase microvascular permeability by activating the NO-cGMP-PKG signaling cascade. Such a mechanism may account for the direct effect of the stimuli on microvascular endothelium where leukocytes and platelets are absent.

It seems that PKA and PKG form a pair of yin-and-yang-like functional antagonists in controlling microvascular permeability. Protein kinase A may play a dominant role in the maintenance of basal barrier property and counteract the

effect of PKG in response to inflammation. The interaction between the two protein kinases can occur at several levels: competing for a common target at the cytoskeleton or junctions, counteracting to modulate leukocyte and platelet function, or feedback regulating through phosphodiesterases (PDE). Three forms of PDE, namely, cGMP-stimulated PDE II and IV and cGMP-inhibited PDE III, have been shown to affect PKA-associated alteration in endothelial permeability.

Mitogen-Activated Protein Kinases (MAPKs)

Mitogen-activated protein kinases are involved in multiple cascades of serine/threonine and tyrosine phosphorylating reactions that mediate diverse cellular responses to growth factors, physical stress, and cytokines. The most studied MAPKs in mammalian cells are extracellular signal-related kinases (ERK 1/2), c-jun N-terminal kinases (JNK), and p38 proteins. Although ERK 1/2 is mainly known for its role in cell growth and p38 MAPK plays a major role in cellular responses to stress and injury, both have been implicated in the regulation of vascular endothelial permeability. A typical case is seen in endothelial cells or intact microvasculature subjected to VEGF stimulation: Inhibition of ERK 1/2 with the ERK kinase inhibitor PD98059 or inhibition of p38 with SB203580 blocks VEGF-induced increases in permeability. In addition to the growth factor, many inflammatory agonists, including histamine, thrombin, hydrogen peroxide, and intracellular calcium elevating agents, are able to phosphorylate ERK 1/2. In parallel, the same types of substances have been found to induce endothelial cytoskeletal contraction and junctional barrier failure through a p38-related mechanism. Clearly, activation of either the ERK 1/2 or the p38 pathway can cause changes in endothelial barrier function; however, their relative contribution may vary depending on the form of stimulation, type of vessels, and duration of observations.

Nonreceptor Protein Tyrosine Kinases (PTKs)

Phosphorylation of proteins on serine/threonine residues is often initiated by or coupled with tyrosine phosphorylation. In fact, tyrosine phosphorylation has so far been considered the primary or even the exclusive indicator of signal transduction in multicellular organisms. Enhanced PTK activity has been implicated in not only cancer and proliferative diseases, but also in inflammatory disorders. Inhibition of PTKs effectively blocks the increase in endothelial permeability induced by a wide spectrum of inflammatory mediators, whereas upregulation of tyrosine phosphorylation with tyrosine phosphatase inhibitors exerts opposite effects.

Protein tyrosine kinases can be categorized into receptor tyrosine kinases, such as the VEGF receptor KDR, and nonreceptor tyrosine kinases, such as Src kinases and focal adhesion kinase (FAK). The Src family, containing c-Src, Lyn, Fyn, Lck, Hck, Fgr, Blk, and Yes, exerts potent phosphorylating and transforming effects through interaction with the SH2 and SH3 domains of effector proteins. The activity of Src is upregulated by phosphorylation at Tyr-416 (located in the catalytic domain) and negatively regulated by phosphorylation at Tyr-527 (near the carboxyl terminus). It has been documented that the Src signaling is required in multiple cellular processes, such as cell contraction and migration, angiogenesis, and vascular leakage. Blockage of Src activity or Src deficiency reduces cerebral edema associated with stroke in animal models. Recent experiments show that Src mediates vascular endothelial permeability responses to tumor necrosis factor and reactive oxygen metabolites. In addition, specific blockage of Src activity by pharmacological agents or Src-inhibiting peptides abolishes the increase in albumin permeability caused by C5a-activated neutrophils in isolated venules as well as in cultured venular endothelial monolayers. Further biochemical analysis confirms that activated neutrophils stimulate Src phosphorylation at Tyr-416 and decrease phosphorylation at Tyr-527, two events that are known to upregulate Src activity.

Several pathways may be activated through Src signaling. For example, MAPK has been identified as a downstream effector of Src. More importantly, Src may directly alter endothelial barrier structure by phosphorylating contractile proteins and adhesion proteins. Supporting this is biochemical evidence of coimmunoprecipitation and immunocolocalization between Src and the cytoskeletal and junctional components. Myosin light chain kinase, β-catenin, and FAK have been identified as potential Src substrates. Therefore, it is highly possible that Src activation serves as a common signal in coordinating cytoskeletal contraction, junctional disorganization, and focal adhesion redistribution in response to multiple protein kinase cascades that are triggered by inflammatory mediators.

Another nonreceptor tyrosine kinase known to modulate endothelial barrier structure and function is FAK. Focal adhesions are referred to as transmembrane structures that anchor the cells to extracellular matrices in the basement membrane. Major components of the focal structure include a family of transmembrane receptors, namely integrins, and their associated intracellular proteins, such as talin, α-actinin, and paxillin, which link the cytoskeleton to integrins. Not only does this structure support the physical attachment of endothelial lining to the basement membrane, it also serves as a transducer in mediating cellular response to physical stress or chemical stimuli. Because of the lack of catalytic activity in integrin receptors, such signaling reactions are transduced via a network of integrin-associated proteins located in focal adhesions. Of these proteins, FAK is a major protein kinase capable of catalyzing various downstream signaling cascades leading to a dynamic regulation of focal adhesion morphology and distribution. The

activity of FAK is mainly regulated through tyrosine phosphorylation, preferentially by the Src-family tyrosine kinases. FAK-mediated focal adhesion assembly and reorganization play a critical role in cell contraction and migration during stimulation by integrins or nonintegrin factors including shear stress, growth factors, and permeability-increasing agents such as thrombin, platelet activating factors, phorbol esters, and even leukocyte adhesion molecules. Recent evidence is accumulating in support of the functional importance of FAK to the microvascular barrier effect. For example, there are reports that protein tyrosine kinase blockades abolish FAK phosphorylation-coupled endothelial barrier dysfunction. Downregulation of FAK expression using antisense approaches modulates agonist-induced increases in endothelial monolayer permeability. More importantly, inhibition of FAK activity through direct delivery of FAK-related nonkinase (FRNK), an endogenously expressed FAK competitive inhibitor, into intact isolated venules significantly attenuates the hyperpermeability response to VEGF or activated leukocytes.

Several pathways may be considered for potentially underlying the effect of FAK on endothelial barrier function. On one hand, FAK-signaled focal adhesion disassembly and redistribution may reduce cell–matrix adhesion forces, leading to rounding of the endothelial cell and widening of interendothelial channels. This is consistent with an emerging view that FAK activation leads to disassembly, rather than assembly, of focal adhesion complexes. On the other hand, activated FAK may directly participate in the development of contractile force in the endothelial cells resulting in intercellular gap formation. In support of this notion, FAK phosphorylation has been linked to actin polymerization and stress fiber formation in endothelial cells treated with VEGF. Alternatively, FAK could indirectly affect endothelial barrier function by coordinating secondary intracellular signaling molecules, including the Src family of tyrosine kinases and the Rho family of GTPases. In this regard, FAK may function as a scaffolding protein that recruits and activates Src, Rho, and other focal adhesion-associated proteins, which in turn cause changes in the cytoskeleton or intercellular junctions, leading to endothelial hyperpermeability.

Summary

Endothelial barrier integrity is maintained by adhesive interactions occurring at the cell–cell and cell–matrix contacts via junctional proteins and focal adhesion complexes that are anchored to the cytoskeleton. Under physiological conditions, cyclic AMP and PKA counteract with the NO-PKG pathway to protect the basal barrier function. Upon stimulation by physical stress, growth factors, or inflammatory agents, endothelial cells undergo a series of intracellular signaling reactions involving activation of PKC, PKG, MAPKs, and PTKs. These protein kinases further trigger biochemical and conformational changes in the barrier structure and ultimately lead to an opening of the paracellular pathway. In particular, MLCK activation and subsequent MLC phosphorylation in endothelial cells directly result in cell contraction and shape changes. The PTK-mediated phosphorylation of junctional proteins causes disorganization of adherens junctions or dissociation of VE-cadherin–catenin complex from its cytoskeletal anchor, leading to loose or opened intercellular junctions. Additionally, FAK phosphorylation-coupled focal adhesion assembly and redistribution provide an anchorage support for the conformational changes occurring in the cells and at the cell junctions. The Src-family tyrosine kinases may serve as a common signal that coordinates these molecular events to facilitate the paracellular transport of macromolecules. The critical roles of protein kinases in the endothelial hyperpermeability response implicate the therapeutic significance of protein kinase inhibitors in the prevention and treatment of diseases and injuries that are associated with microvascular barrier dysfunction.

CHAPTER 46

Vesiculo-vacuolar Organelles Are Permeability Structures in the Endothelium of Normal and Tumor Microvessels

Ann M. Dvorak and Dian Feng
Beth Israel Deaconess Medical Center, Boston, Massachusetts, and Harvard Medical School

Introduction

The microcirculation functions to provide rapid exchange of nutrients and waste products between blood and tissues. Large molecules, such as plasma proteins, exit most capillaries at low rates and by two routes: (1) vesicular transport via the shuttling of 50- to 70-nm cytoplasmic vesicles present in endothelial cells (or by interconnected vesicles that form transendothelial cell channels), and (2) interendothelial cell gaps.

We identified a new endothelial cell organelle, which we termed the vesiculo-vacuolar organelle (VVO) (Figure 1) [1]. This organelle provides the major route of extravasation of macromolecules at sites of augmented vascular permeability induced by vascular permeability factor/vascular endothelial growth factor (VPF/VEGF), a tumor-derived cytokine, in venules associated with experimental tumors [1, 2]. We also reported extensive VVOs in venular endothelium in an animal model of allergic inflammatory eye disease, characterized by histamine secretion from augmented mast cell expression. Further studies used multiple ultrastructural methods to determine (1) the substructure and contents of VVOs, (2) the formation of VVOs, (3) the mechanism of upregulated function of VVOs, and (4) whether tumor cytokines and mediators of inflammation with permeabilizing properties could recapitulate in normal vessels the upregulated VVO function of tumor vessels [3].

VVOs Are the Major Site of Hyperpermeability of Tumor Blood Vessels

Tumor microvessels are typically fourfold to tenfold more permeable to circulating macromolecules than comparable normal vessels. We injected several different macromolecular tracers intravenously into mice or guinea pigs bearing solid or ascites tumors and followed the extravasation of these tracers from tumor and normal vessels over time by light and electron microscopy [1, 2]. These studies led to the identification of VVOs in the endothelium of tumor microvessels. The vesicles and vacuoles of individual VVOs extend across endothelial cells, interconnecting with each other and with the luminal, abluminal, and often the lateral plasma membranes by stomata that may be open or that are guarded by thin diaphragms. These stomata and their closing diaphragms likely provide the structural basis for regulation of tracer passage across the microvascular endothelium.

VVOs were found to provide a transcytotic pathway by which soluble macromolecular tracers extravasated from leaky tumor blood vessels. Within seconds of intravenous

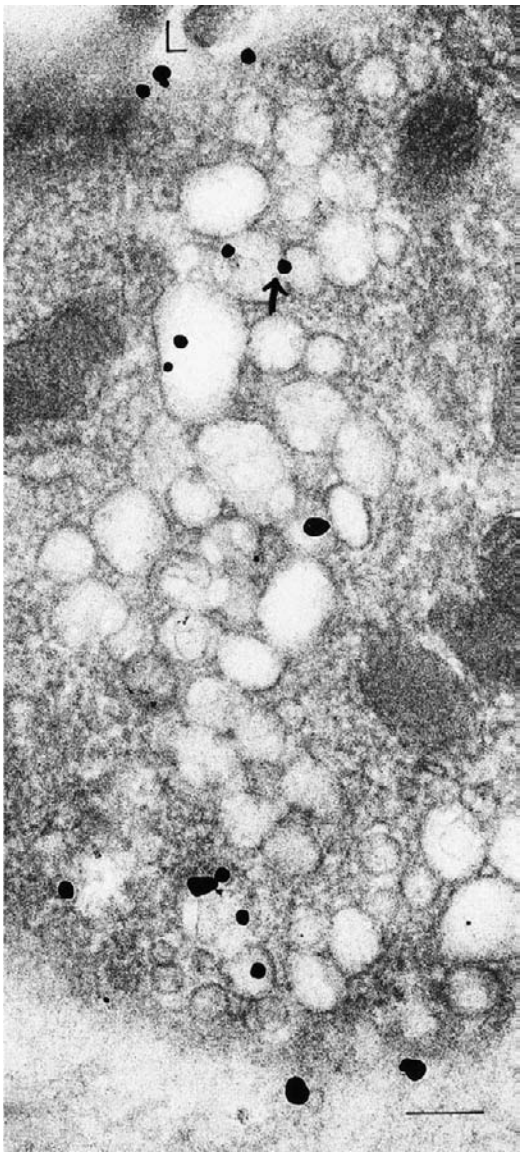

Figure 1 Platelet endothelial cell adhesion molecule (PECAM, CD31) localization to a VVO and plasma membranes (luminal and abluminal) of a mouse skin venule. In this thickened portion of venular endothelium the characteristic VVO stretches from the luminal to the abluminal surfaces of this endothelial cell. Localization is with an immunonanogold method. Particles are associated with stomata and their diaphragms (arrow), which typify the ultrastructural anatomy of VVOs. L, Lumen. Bar = 170 nm.

injection into tumor-bearing mice, macromolecular tracers were found in VVO vesicles that opened to the vascular lumen. Initially, tracers were found in VVO vesicles that opened to the vascular lumen, but VVO vesicles and vacuoles were rapidly labeled at all levels of endothelial cell cytoplasm. Vesicles that opened to the endothelial cell ablumen spilled both tracers into the underlying basal lamina. Ferritin ($d \sim 11$ nm) was not found to exit tumor vessels through interendothelial cell junctions at any time interval up to 1 hour. The small protein tracer HRP ($d \sim 5$ nm) did exit tumor vessels through normally apposed interendothelial junctions, but only after a delay of at least 5 minutes, at a time when extensive HRP extravasation had already taken place through VVOs.

Subsequent study revealed that morphologically similar VVOs were present, and with equal frequency, in the venular endothelium supplying skin and many other tissues in normal animals as well as remote from tumor sites in tumor-bearing animals. However, normal venules extravasated only very small amounts of macromolecules and their VVOs were minimally labeled with ferritin and HRP.

Vessels supplying some tumors were fenestrated and prominent collections of ferritin were also found in and beneath individual fenestrae, suggesting that these structures had provided a second pathway for tracer extravasation [1]. In contrast, some vessels supplying other tumors were not fenestrated, and tracer extravasated exclusively by the transcellular VVO route.

VVO Structure

Clusters of VVOs are deployed at intervals in the cytoplasm of endothelial cells. They are often concentrated near lateral borders of endothelial cells, that is, parajunctionally, and provide a direct link between the vascular lumen and ablumen. Approximately 12 percent of VVOs extend from luminal to the abluminal plasma membranes when viewed in single, random 80-nm electron microscopic sections, and in serial sections, this value approaches 100 percent [3]. The individual vesicles and vacuoles comprising VVOs are bounded by membranes and interconnect with each other and with the endothelial cell plasma membranes by means of stomata that are closed by thin diaphragms. The stomatal diaphragms measure less in diameter than the diameter of individual VVO vesicles and vacuoles. The presence of tracers within adjoined vesicles–vacuoles, as well as within the stomata connecting them, provides prima facie evidence that such vesicles and vacuoles are in open communication with each other. However, in some cases, the stomata joining individual vesicles and vacuoles were closed by a diaphragm, and passage of macromolecular tracers was restricted such that one vesicle or vacuole contained tracer whereas the other did not. It would seem, therefore, that the diaphragms that separate individual stomata serve to restrict the passage of cargo and may be opened and closed individually.

VVO structure cannot be fully appreciated by electron microscopy of standard 70- to 100-nm sections. In serial 12- to 14-nm ultrathin sections for electron microscopy and computer-assisted three-dimensional reconstructions, a network of interconnecting vesicles and vacuoles was revealed and established that VVOs provide a continuous, often serpentine pathway across venular endothelium, extending to both the lumen and ablumen at multiple sites [3]. Subsequent studies have revealed that the VVOs of adjacent

endothelial cells also open to the interendothelial cleft, and in some instances, VVOs from adjacent endothelial cells connect across the intercellular cleft between adjacent endothelial cells, raising the possibility that plasma may extravasate by a VVO pathway that extends across overlapping endothelial cells.

The large size and complexity of VVOs suggest that they are sessile structures and that their component vesicles and vacuoles do not shuttle back and forth across endothelial cell cytoplasm. In evaluation of ultrathin (12- to 14-nm-thick) serial sections, only 9 of 1,395 (0.65%) uncoated vesicles were found to be single entities, free and unattached in the cytoplasm, that is, > 99 percent were attached to other vesicles and vacuoles as parts of VVOs [3].

VVO Function

The venules of normal tissues permit only minimal extravasation of circulating macromolecules; consistent with this finding, the VVOs of normal tissues, although structurally similar to those of tumor vessels, differ functionally from tumor endothelial cell VVOs in that they permit only minimal entry and passage of macromolecular tracers. To account for the functional differences between the VVOs of tumor vessels and those of normal venules, we postulated that VVO function was regulated by vasoactive mediators that in some way opened the stomata that connected individual VVO vesicles and vacuoles with each other and with the venular lumen and ablumen. We also postulated that one such mediator, VPF/VEGF, was likely responsible for opening these stomata in hyperpermeable tumor vessels, thereby accounting for the relatively free passage of macromolecular tracers through tumor vessel VVOs. Consistent with this hypothesis, the tumors we studied synthesize and secrete large amounts of VPF/VEGF. Moreover, tumor cell-secreted VPF/VEGF was found to localize on the surface of tumor microvascular endothelial cells as well as in association with the VVO vesicles and vacuoles in their cytoplasm [3].

In addition, another such mediator, histamine, could act similarly in opening stomata in hyperpermeable vessels in allergic inflammation. In fact, using a new enzyme-affinity-gold postembedding method to detect histamine, we localized histamine, which is secreted from mast cells in the allergic eye disease mouse model, to VVOs in involved vessels.

If VVO function is regulated by VPF/VEGF or other vasoactive mediators, then these mediators would be expected to increase the microvascular permeability of normal venules by opening VVO stomata to the passage of macromolecules. In fact, this proved to be the case. Injection of small amounts of VPF/VEGF, histamine, or serotonin into the normal flank or scrotal skin of guinea pigs, rats, and mice greatly increased the permeability of local venules [3]. Electron microscopy demonstrated that the circulating tracer (anionic ferritin) exited such venules primarily by way of VVOs, just as in tumor microvessels. Rapidly after intradermal injection of these mediators, and continuing for some minutes thereafter, increasing amounts of circulating ferritin entered VVO vesicles contiguous with the venular lumen and proceeded across the endothelium through a succession of interconnecting VVO vesicles and vacuoles to reach the vascular ablumen and underlying basal lamina, that is, tracers followed the same pathway across normal dermal venule endothelial cells as in leaky tumor microvessels. Most stomata connecting adjacent VVO vesicles and vacuoles to one another and to the luminal and abluminal plasma membranes were functionally open in that the passage of ferritin was not restricted. However, diaphragms closed some stomata to the passage of ferritin since ferritin molecules accumulated in immediately proximal vesicles or vacuoles. Thus, stomatal diaphragms were able to serve as barriers that limited the further transcellular passage of macromolecular tracers. Endothelial cell junctions remained intact, and ferritin was never observed in them. Together, these data establish VVOs as the major pathway by which soluble plasma proteins exit nontumor venules in response to several mediators that increase venular hyperpermeability.

VPF/VEGF induces its biological effects by binding to two tyrosine kinase receptors, VEGFR-1 (fms-like tyrosine kinase receptor or Flt) and VEGFR-2 (fetal liver kinase 1 or Flk-1 in rodents; kinase insert domain-containing receptor or KDR in man), which are selectively expressed in vascular endothelium and are both strikingly upregulated in tumors, wounds, and inflammation in which VPF/VEGF is overexpressed. We used ultrastructural preembedding immunoperoxidase and immunonanogold methods to localize VEGFR-2 (flk-1/KDR) in vascular endothelium in model systems in which VPF/VEGF is highly expressed: (1) glomerular and peritubular capillaries of normal mouse kidney; (2) microvessels supplying a well-characterized mouse mammary carcinoma; and (3) new vessels induced by an adenoviral vector, engineered to overexpress VPF/VEGF (adeno-vpf/vegf) [4]. Microvascular endothelial cells were positive for VEGFR-2 in all three models and, in the latter two, could be localized to the luminal and abluminal surfaces and to the membranes of cytoplasmic VVOs. The stomatal diaphragms of some VVOs and caveolae were VEGFR-2-positive, best seen with the peroxidase reporter when the entire vesicle membrane was not stained. Localization of VPF/VEGFR-2 to VVO membranes, to the luminal and abluminal plasma membranes of vascular endothelium, but not to the lateral plasma membranes at interendothelial cell junctions is consistent with the mechanisms that we have proposed for the increased microvascular permeability that is induced by VPF/VEGF and other vasoactive mediators [4].

Stomatal diaphragms are likely the structures that regulate VVO permeability. Support for this concept is based on the strategic localization of VEGFR-2 on this diaphragm

which closes stomata in VVOs and of VPF/VEGF bound to VVOs in endothelia present in animal tumor models [4].

VVO Formation

Given the similarities between caveolae and VVO vesicles and vacuoles, it is possible that VVOs might form from the linking together of individual caveolae. It is also possible that the larger vesicles and vacuoles of VVOs might form from the fusion of two or more caveola-sized vesicles. We did ultrastructural preembedding immunoperoxidase to localize caveolin in VVOs in vitro and in vivo [5] to investigate the first possibility. These studies showed, both in vivo and in vitro and as in caveolae, that endothelial cell VVOs were caveolin-positive, lending support for formation of caveolin-positive VVO clusters from the joining of individual caveolin-positive caveolae. We used an ultrastructural morphometric approach [3] to investigate the second possibility. For example, a fusion mechanism has been proposed in the generation of several types of cytoplasmic secretory granules in which small progranules of unit size fuse with each other in varying combinations to form larger mature granules whose volumes represent multiples of the volume of the unit progranule [6]. By analogy, the volume of the various VVO vesicles and vacuoles would not be expected to fall on a continuum but instead would represent multiples of the volume of the smaller unit vesicle. Measurements of the volumes of vesicles and vacuoles comprising VVOs revealed a heterogeneous distribution, where the volumes of individual vesicles and vacuoles were not continuous but exhibited a periodic modal distribution [3]. The most frequently occurring vesicle–vacuole had a unit volume of ~0.00015 μm^3; this value corresponds to a spheroid of diameter ~60 nm, that is, the size of typical capillary caveolae. Vacuoles corresponding to the fusion of as many as 10 unit vesicles were detected. The data, therefore, are consistent with the hypothesis that larger VVO vesicles and vacuoles arise from the fusion of different numbers of caveola-sized unit vesicles.

We also have investigated the substructural localization of other proteins of importance to vesicular trafficking and fusion, generally. One such protein, vesicle-associated membrane protein (VAMP), is localized to the cytoplasmic side of caveolar and VVO membranes [3]. The presence of this vesicle-SNARE protein in these locations lends support to the proposed construction of VVOs from fused caveolae.

VVO Fate

Once formed, VVOs are sessile, multichambered structures occupying vast expanses of venular cytoplasm. They restrict the passage of macromolecules from the blood vascular spaces at their narrow points in stomata that are closed by thin diaphragms. These diaphragms are opened, making VVOs porous—a process that is rapidly induced by exposure to well-known permeabilizing molecules, such as VPF/VEGF, histamine, and serotonin.

We envision at least three possible fates for VVOs in venular endothelium: (1) opened, leaky VVOs could close, thereby returning vessels to their prior nonleaky state; (2) opened, enlarged stomata in permeabilized VVOs could open further, allowing retention of opened vesicles and vacuoles in their fused state to form large transcellular holes through which circulating endogenous and exogenous particulates could freely enter the extravascular space [3]; or (3) VVOs could serve as an extensive intracellular store of membranes that, in certain circumstances, could rapidly and greatly expand the endothelial plasma membrane. This expansion could be instrumental in the rapid formation of large vessels (“mother” vessels) in VPF/VEGF angiogenesis models [4] and in the enhanced endothelial surface process and migration sac formation that accompanies endothelial thinning and loss of VVOs at points of neutrophil transmigration in an animal model of acute inflammation [3].

Presently, there are no data to confirm the first possibility, but long-term studies of VVO architecture following transient permeability events are in progress. Considerable data have accrued in support of the second proposed fate of VVOs [3]. In studies of VPF/VEGF and other vasoactive mediators in combination with soluble macromolecular tracers, we encountered relatively few openings across venular endothelium. In such experiments, ferritin and HRP extravasated across venular endothelium primarily by way of VVOs. However, when we used colloidal carbon (d ~ 50 nm) as a tracer, a particulate that is, for the most part, too large to enter or pass through the narrow necks of stomata in VVOs, we observed a substantial (threefold to thirtyfold) increase in endothelial cell openings [3], suggesting that, in response to vasoactive mediators, holes may develop from a rearrangement of VVO vesicles and vacuoles to form larger membrane-lined vacuolar structures and, eventually, channels of sufficient size to allow the passage of particulate tracers as large as erythrocytes.

The third possible fate of VVOs as a membrane store for rapidly expanding endothelial plasma membrane has gained some support from studies of transendothelial cell neutrophil migration in acute inflammation [3]. Here, we noted that VVOs became less numerous in thinned endothelium through which neutrophils were traveling, and that a markedly expanded endothelial cell luminal membrane covered many extended endothelial cell cytoplasmic processes and provided additional membrane to form migration sacs that enclosed migrating neutrophils. By analogy, the markedly and rapidly enlarged “mother” vessels in tumor and VPF/VEGF-induced angiogenesis models lend support to the third possibility, since VVOs were not a conspicuous component of the cytoplasm of the enlarged mother vessels and the formation of mother vessels occurred rapidly in an angiogenesis model. VVOs may provide membrane for the rapid formation of these vessels in angiogenesis.

Thus, the fate of VVOs includes at least three possibilities—to recover in place by reforming diaphragms between their components or to persist by remaining in place without reclosure of stomata (e.g., in acute and chronic inflammation); to expand further to form large transcellular holes (to facilitate transcellular trafficking in inflammation); or to provide rapid expansion of endothelial plasma membranes by externalizing their membrane in acute inflammatory and angiogenesis models.

Summary

A newly defined endothelial cell permeability structure, termed the vesiculo-vacuolar organelle (VVO), has been identified in the endothelia of normal venules, in the microvasculature that accompanies tumors, and in venules associated with allergic inflammation. This organelle provides the major route of macromolecular extravasation at sites of increased vascular permeability induced by vascular permeability factor/vascular endothelial growth factor (VPF/VEGF), serotonin, and histamine in animal models. Continuity of these large sessile structures between the vascular lumen and extracellular space has been demonstrated in kinetic studies with ultrastructural electron-dense tracers and by ultrathin serial sections. Ultrastructural enzyme-affinity cytochemical and immunocytochemical studies have identified histamine and VPF/VEGF bound to VVOs in vivo in animal models where these mediators of permeability are released from mast cells and tumor cells, respectively. The high-affinity receptor for VPF/VEGF, VEGFR-2, and platelet endothelial cell adhesion molecule (PECAM-1, CD31) were localized to VVOs and their substructural components by pre-embedding ultrastructural immunonanogold and immunoperoxidase techniques. Similar methods were used to localize caveolin and vesicle-associated membrane protein (VAMP) to VVOs and caveolae, indicating a possible commonality of formation and function of VVOs to caveolae.

Glossary

Caveola: A small, flask-shaped substructural organelle attached to the plasma membranes of endothelial cells. It is distinguished by suborganellar anatomic structures including stomata, knobs, diaphragms, and necks and functions in transendothelial cell transport of macromolecules, either by motion of vesicles through endothelial cells or by fusion of vesicles to form short, transendothelial cell channels.

Enzyme-affinity-gold electron microscopy: A specialized ultrastructural technique developed to identify subcellular sites of specific enzyme substrates by binding of gold–enzyme complexes to sample substrates. An example is the localization of the substrate histamine, by the specific enzyme diamine-oxidase-gold probe.

Vesiculo-vacuolar organelle: A newly identified endothelial cell structure that connects all plasma membrane domains of endothelial cells and provides an anatomical route of transendothelial cell passage of macromolecules. They are particularly prominent in thick venular endothelium, and their functions are upregulated by potent permeability mediators. This organelle is composed of fused small, caveola-sized vesicles and larger vacuoles that display suborganellar anatomic structures including stomata, knobs, diaphragms, and necks.

Capsule Biography

Dr. Dvorak, a pathologist, heads the electron microscopy unit in the Department of Pathology at Beth Israel Deaconess Medical Center, a major teaching hospital at Harvard Medical School in Boston, MA. Her laboratory primarily focuses on the cell biology of endothelial cells, mast cells, basophils, and eosinophils in health and disease. Her work is supported by grants from the NIH.

CHAPTER 47

The Multistep Cascade of Leukocyte Extravasation

[1,2]Britta Engelhardt and [1]Dietmar Vestweber

[1]*Max Planck Institute for Molecular Biomedicine*

[2]*Theodor Kocher Institute, Bern, Switzerland*

Introduction

Leukocyte extravasation from the blood into tissues plays a key role in innate and adaptive immunity and in inflammation. In order to understand the task of extravasation of a leukocyte traveling in the blood stream, Paul Kubes [1] recently suggested that we picture ourselves plunged into the water of a "roaring river," in order to imagine the high shear forces white cells are exposed to in the mainstream of the blood. In either scenario stopping and exiting the flow becomes an incredibly daunting task. Whereas we might struggle by various means using our hands and feet to exit the river, in the case of the white cell, a well-coordinated and extremely efficient sequence of leukocyte endothelial interactions has evolved allowing the leukocyte to marginate from the main bloodstream, to slow down and to "hold on" (adhere) to the endothelial vascular wall, and eventually to extravasate. Here, we will summarize the sequence of molecular steps known to govern leukocyte extravasation across the vascular wall to date.

The Multistep Paradigm

In order to ensure immunosurveillance of the body the recruitment of leukocytes from the blood into the different tissues needs to be a well controlled process directing the extravasation of the appropriate cell at the proper location at the right time. The multistep paradigm for leukocyte extravasation [2] has proven to be a valid framework for understanding the sequence of dynamic interactions between the circulating leukocyte and the endothelial cell during this process. The multistep paradigm postulates that an initial transient contact of the circulating leukocyte with the vascular endothelium, generally mediated by adhesion molecules of the selectin family and their respective carbohydrate ligands, slows down the leukocyte in the bloodstream. After an initial capture the leukocyte rolls along the vascular wall with greatly reduced velocity. The rolling leukocyte can now "sense" chemotactic factors from the family of chemokines presented on the endothelial surface. Chemokines bind to their respective serpentine receptors on the leukocyte surface. These receptors deliver a G protein–mediated pertussis toxin–sensitive signal into the cell resulting in the functional activation of adhesion molecules of the integrin family present on the leukocyte surface. Activation of integrins leads to an increase in their affinity and/or avidity. Only "activated" integrins are able to mediate the firm adhesion of leukocytes to the vascular endothelium by binding to their endothelial ligands from the immunoglobulin (Ig) superfamily of adhesion receptors. This ultimately leads to leukocyte diapedesis, through endothelial cell contacts involving molecules of the endothelial adherens and tight junctions [3]. Some reports even suggest that leukocytes extravasate by transcytosis through endothelial cells. Successful recruitment of circulating leukocytes into the tissue depends thus on the productive leukocyte/endothelial interaction during each of these sequential steps.

Capture and Rolling: Selectins and Selectin Ligands

Extravasation of leukocytes takes place in postcapillary venules. The process known as capture or tethering hereby represents the very initial contact of a white cell with the endothelium. The transiently captured leukocyte might

begin to roll along the endothelial surface. Rolling velocities are between 5 and 40 μm/sec and thus below that of freely flowing cells within the same postcapillary venules where mean blood flow velocities range from 1,000 to 4,000 μm/sec (Figure 1).

Capture and rolling are usually mediated by the selectin family of adhesion molecules, which has only three members. Selectins recognize via their N-terminal lectin domain fucosylated and sialylated glycoprotein ligands. Leukocyte (L)-selectin is constitutively expressed on all granulocytes and monocytes and most lymphocytes. Platelet (P)-selectin is stored in α-granules of platelets and in Weibel-Palade bodies of endothelial cells and translocated to the cell surface within minutes upon their activation during inflammation. Endothelial (E)-selectin is not constitutively expressed but induced on endothelial cells by inflammatory stimuli.

As post-translational modifications rather than the protein itself are recognized by the selectins, there are many candidate ligands for selectins. P-selectin glycoprotein ligand 1 (PSGL-1) has been most extensively characterized at the cellular, molecular, and functional level. PSGL-1 is constitutively expressed on all lymphocytes, monocytes, eosinophils, and neutrophils. It is the major ligand for P-selectin but can also bind to E-selectin. L-selectin glycoprotein ligands have been identified in high endothelial venules

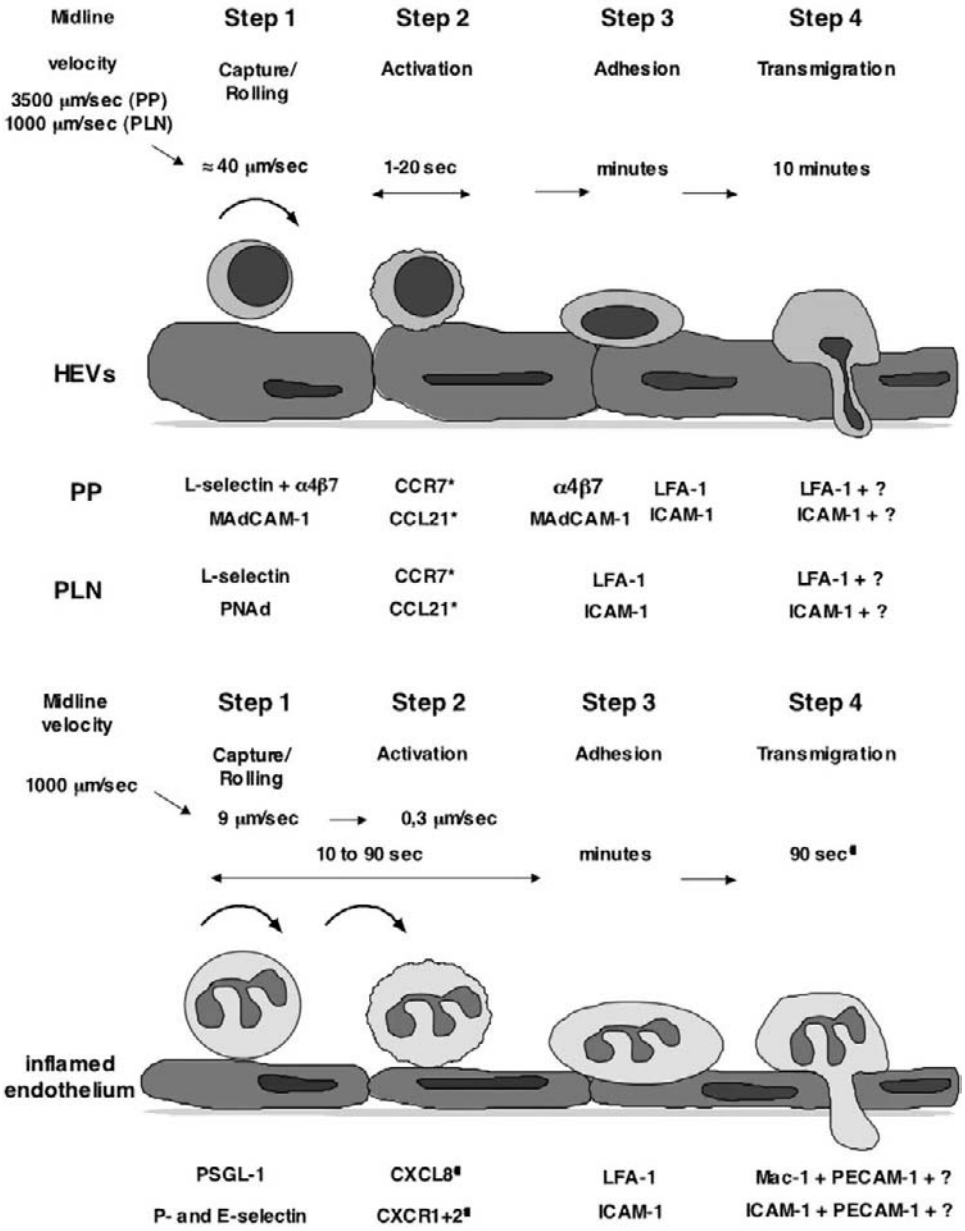

Figure 1 The multistep model of leukocyte endothelial interaction. **Top**: Lymphocyte/HEVs interactions in Peyer's patches (PP) or peripheral lymph nodes (PLN). **Bottom**: Neutrophil interaction with inflamed endothelium. *, Only T cells, unknown for B cells; #, only demonstrated in vitro. The velocities of free-flowing (noninteracting) cells and rolling leukocytes as well as other time estimates are derived from intravital microscopic observations published from the laboratories of Ulrich von Andrian, Eugene Butcher, and Klaus Ley. (see color insert)

(HEVs) of secondary lymphoid organs and are collectively known as the peripheral node addressins (PNAd) and recognized by the monoclonal antibody MECA-79. L-selectin mediates the rolling of naive lymphocytes on PNAd in HEVs of peripheral lymph nodes. Mice lacking L-selectin have very small peripheral lymph nodes due to the failure of their lymphocytes to roll on HEVs at this site. Evidence for the importance of selectins for effective neutrophil recruitment into inflamed tissues is derived from mice lacking either selectins or selectin ligands and from patients suffering from leukocyte adhesion deficiency II (LADII). These patients fail to incorporate fucose into selectin ligands and thus lack functional selectin ligands. Interestingly, the defect does not affect a biosynthetic enzyme. The defective gene in LAD II is a GDP fucose transporter in the Golgi membrane that provides the fucosyltransferases with their substrate [4]. As a consequence of this defect, leukocytes lacking selectin ligands cannot be captured to endothelium and patients suffer from bacterial infections.

Besides the adhesion receptor family of selectins and their ligands, on lymphocytes, α4-integrins have been shown to support capture and rolling. α4-integrin mediated rolling is rather slow and was measured to be around 10 μm/sec. α4β1 (VLA-4) mediated capture of T lymphoblast on its vascular ligand VCAM-1 is required for successful recruitment of activated T cells into the central nervous system [5], whereas α4β7 (LPAM-1) mediated capture and rolling via MAdCAM-1 on HEVs in mucosal associated lymphatic tissue is required for the recruitment of α4β7-integrin^{positive} gut homing lymphocytes to these sites. One key to the participation of α4-integrins in capture and rolling of lymphocytes is their localization on the microvillous processes on the surface of circulating cells, which they share with L-selectin.

Activation: Chemokines and Chemokine Receptors

In order to stop a rolling leukocyte, further signals are required. This is illustrated by in vivo observations that both neutrophils and lymphocytes can use L-selectin to roll in HEVs of peripheral lymph nodes; however, only lymphocytes have the ability to stop [6]. This points to the necessity of selective signals that specifically trigger adhesion of lymphocytes but not of neutrophils in HEVs.

Chemokines have been recognized to trigger adhesion of leukocytes to the endothelium under shear. Chemokines are a family of about 50 low-molecular-weight chemotactic cytokines (8 to 14 kDa) that can bind to and signal through seven transmembrane spanning G-protein coupled receptors expressed on leukocytes but also on other cell types. Chemokines share sequence homologies and are divided into four groups (CC, CXC, CX_3C, and C) based on the orientation of conserved cysteines in their amino termini [7]. The chemokine receptors are grouped accordingly into four receptor families (CCR, CXCR, CX_3CR, and CR). Chemokine receptors preferentially signal via $G_{\alpha i}$-proteins, which can be blocked by pertussis toxin. The expression of chemokine receptors varies greatly among different leukocyte subsets and can change upon lymphocyte activation. Furthermore, chemokines are differentially expressed in different tissues. Many chemokines have been shown to bind to the surface of endothelial cells. This is due to the fact that most chemokines have highly charged amino acid residues that can mediate binding to heparan sulfate and other glycosaminoglycans (GAGs).

In order to examine the ability of chemokines to induce adhesion in the context of the multistep recruitment cascade, many investigators have employed in vitro flow chamber assays that mimic blood flow. Using these assay systems, chemokines have been demonstrated to trigger arrest of rolling lymphocytes on purified ligands or on endothelial cells under shear and have therefore been called "arrest chemokines" [8]. The chemokine CCL21 (SLC) was shown to trigger the arrest of T lymphocytes rolling on purified L-selectin ligands on ICAM-1. CCL21 is constitutively expressed on HEVs in peripheral lymph nodes. As only T lymphocytes but not neutrophils possess CCR7, the receptor for CCL21, it becomes plausible that only lymphocytes but not neutrophils can be arrested in HEVs in vivo. The importance of the CCL21/CCR7 chemokine/chemokine receptor interaction for successful T-cell homing to peripheral lymph nodes is exemplified by the lack of T cells within peripheral lymph nodes of CCR7-deficient mice or in mice that, because of a spontaneous mutation, lack expression of CCL21. Other chemokines have been characterized triggering the arrest of monocytes on inflamed endothelium [8]. Thus the chemokine/ chemokine receptor system has a great impact in the specificity of leukocyte extravasation at the level of cell arrest.

Firm Adhesion: Integrins and Ig Superfamily Members

Leukocyte integrins form a family of noncovalently linked αβ-heterodimeric transmembrane proteins and are normally expressed on circulating leukocytes in a relatively inactive state. Upon chemokine receptor engagement, integrins become functionally activated within seconds, triggering leukocyte arrest on the endothelium. With the exception of the fact that a pertussis toxin–sensitive G-protein signal is delivered into the cell by the chemokine receptors, the downstream signals leading to integrin activation, commonly referred to as "inside-out-signaling," are as yet unknown. "Functional activation" of integrins on the leukocyte surface is achieved by an affinity increase through conformational changes, an avidity increase by integrin clustering, or a combination of both effects [9].

Each class of leukocytes displays a particular pattern of integrins that can change in a signal- and time-dependent fashion. For example resting human T lymphocytes express β1-, β2-, and β7-integrins on their surface, whereas neutrophils express mostly β2-integrins, and to a lesser degree also β1- and β3-integrins. All leukocytes, however, express at least one member of the β2-integrin family, which is

restricted to the leukocyte lineage and therefore referred to as the leukocyte integrins. The β2-integrins are a family of four receptors, namely LFA-1 (αLβ2; CD11a/CD18), Mac-1 (αMβ2; CD11b/CD18), p150,95 (αxβ2; CD11c/CD18), and αDβ2 (CD11d/CD18). Especially LFA-1 and Mac-1 are involved in leukocyte extravasation by mediating adhesion to intercellular adhesion molecule-1 (ICAM-1) and ICAM-2 on endothelial cells, whereas αDβ2-integrin was shown to bind to vascular cell adhesion molecule 1 (VCAM-1).

Involvement of LFA-1 in lymphocyte homing to peripheral lymph nodes was first demonstrated by Alf Hamann (in 1988) by antibody inhibition studies and was more recently confirmed by intravital microscopy, where it could be demonstrated that LFA-1 mediates the activation-dependent adhesion of lymphocytes on HEVs at this site [6].

The importance of β2-integrins in leukocyte recruitment is exemplified by an inherited autosomal recessive disease in man, called leukocyte adhesion deficiency-I (LAD-I). LAD-I is the result of mutations in the β2 integrin subunit inhibiting cell surface expression and/or function of all β2-integrins. Patients suffer from recurring soft-tissue infections, impaired wound healing, and gingivitis. The CD18 "knockout" mouse has similar problems to human LAD-I patients. The disorder is primarily considered a failure of neutrophil function, extravasation of which relies most heavily on β2-integrins, because they lack significant levels of other integrins.

Monocytes and lymphocytes can use other integrins, such as the α4-integrins, when the β2-integrins are missing. There are two α4-integrins, VLA-4 (α4β1; CD49d/CD29) and α4β7-integrin. α4β7 is the lymphocyte receptor for mucosal addressin cell adhesion molecule -1 (MAdCAM-1). MAdCAM-1 is expressed on postcapillary venules in the lamina propria of the gut, and on HEVs of the intestine associated lymphoid tissues, especially the Peyer's patches and the mesenteric lymph nodes, thus directing trafficking of gut homing lymphocytes expressing its lymphocyte receptor α4β7 το τηεσε σιτεσ. MAdCAM-1 is also found to be upregulated above constitutive levels in the intestinal lamina propria of patients suffering from ulcerative colitis or Crohn's disease and contributes to the maintenance of these chronic inflammatory diseases. Constitutive expression of VCAM-1 on endothelial cells is low or absent with the exception of the central nervous system, where constitutive VCAM-1 is involved in mediating the firm adhesion of α4-integrin positive T lymphoblasts in postcapillary venules [5].

Transendothelial Migration

Firm adhesion of the leukocyte to the endothelial surface is a prerequisite for diapedesis. The β2-integrins LFA-1 and Mac-1 and their endothelial ligand ICAM-1 have been implied to be involved in transendothelial migration (TEM) of T lymphocytes. In fact, endothelial cells lacking both ICAM-1 and ICAM-2 no longer support TEM of T cells in vitro. The apparent dual role of ICAM-1 in mediating firm adhesion and TEM can be assigned to different parts of the molecule. Whereas the extracellular domain of endothelial ICAM-1 suffices to mediate T-cell adhesion, the cytoplasmic domain is required to mediate TEM of T cells, probably by inducing Rho-signaling within the endothelial cells. Activation of Rho leads to cytoskeletal rearrangements within the endothelium, which are necessary to allow the passage of leukocytes across the endothelial cell wall. The actin cytoskeleton within the endothelium is anchored at cell–matrix interaction sites but also in cell-to-cell contacts forming adherens and tight junctions. Migrating leukocytes have been found to induce a delocalization of the vascular endothelial (VE)-cadherin from the endothelial adherens junctions by a yet unidentified mechanism, which potentially disrupts the endothelial adherens junction in a defined region and allows the leukocyte to exit via the opened gap. On the other hand, direct manipulation of adherens junctions causing molecular disorganization and an increase in vascular permeability shows no influence on TEM of leukocytes in vitro, demonstrating that TEM of leukocytes is not directly correlated to changes in endothelial permeability. Besides VE-cadherin other molecules were found to be concentrated at the lateral borders of endothelial cells and have been implicated in the process of transendothelial migration of leukocytes. These include the Ig-superfamily members platelet endothelial cell adhesion molecule 1 (PECAM-1) and the junctional adhesion molecules (JAMs: JAM-A, JAM-B, and JAM-C) and probably a unique molecule CD99. All of these molecules are potentially capable of homophilic interactions, which are thought to be involved in the establishment of the endothelial cell-to-cell contacts. PECAM-1, CD99, JAM-A, and JAM-C have also been demonstrated to be expressed on leukocytes. Therefore leukocyte extravasation through the endothelial cell junctions is often pictured as a zipper-like model, where the leukocyte on its passage transiently replaces the homophilic molecular interactions usually occurring in between the endothelial cells. This concept is supported by the findings that antibodies blocking homophilic interactions of PECAM-1 arrest leukocytes at the apical surface of endothelial cells. On the other hand, PECAM-1 deficient mice do not reveal any major defect in leukocyte extravasation, indicating that a requirement of PECAM-1 is not obligatory for TEM. Additionally, antibody inhibition studies have implied the JAMs to be involved in leukocyte extravasation. Interestingly, all members of the JAM family are able to bind to either β2– or β1–integrins on activated leukocytes, further supporting their possible involvement in leukocyte endothelial interactions.

Observations arguing for an alternative transcellular route for extravasating leukocytes through endothelial cells may suggest that their might be more than one molecular mechanism or route for leukocytes to move through the endothelial cell barrier. A number of very well performed studies documented leukocyte extravasation by sparing endothelial cell-to-cell contacts, suggesting that leukocytes

traverse the endothelial cell proper [10]. In fact, Gowans and colleagues, who discovered the postcapillary venules within the lymphoid organs as the exit sites of circulating lymphocytes in the early 1960s [11] were even convinced that the specialized endothelial cells in HEVs engulf lymphocytes by mechanisms resembling phagocytosis, thus allowing their passage from the bloodstream to the lymphoid tissue. Thus, although certain stimuli may trigger a transcytotic pathway of leukocyte TEM, based on the current experimental evidence the general belief is that leukocytes traverse the endothelium through small gaps at intercellular junctions. The orchestration of molecular signals exchanged between the leukocyte and the endothelium during this process remains to be determined.

Outlook

Since the multistep cascade of leukocyte recruitment was put forward [2], we have come a long way in our understanding of the traffic signals involved in leukocyte recruitment from the blood into tissue. However, although many of the players involved have been characterized, we still lack detailed mechanistic insights into their orchestrated function. How can chemokines trigger integrin activation and leukocyte arrest in seconds? Where and how do leukocytes penetrate the vascular wall without increasing vascular permeability? How are shear forces involved in leukocyte adhesion and TEM? Filling in the gaps in our understanding of the multistep cascade of leukocyte/endothelial interaction in the near future promises exciting new insights into this well-regulated process, which directs the trafficking of the correct cells at the right time to the right place in order to fight infections and disease.

Capsule Biography

After heading a research group at the Max-Planck Institute in Münster, Germany, Dr. Engelhardt became director of the Theodor Kocher Institute at the University of Bern, Switzerland, in November 2003. Her research focuses on leukocyte trafficking into the central nervous system.

Dr. Vestweber became head of the Institute of Cell Biology at the University of Münster in 1994 and in 2001 became the founding director of the new Max-Planck-Institute for Molecular Biomedicine in Münster. His work focuses on the extravasation of leukocytes into inflamed and lymphoid tissue.

Vascular Endothelial Cadherin and Neutrophil Transmigration

Bastien Hermant, Marianne Weidenhaupt, Stéphanie Heyraud, and Danielle Gulino-Debrac

Laboratoire d'Ingénierie des Macromolécules, Institut de Biologie Structurale Jean-Pierre Ebel, Grenoble, F-38027 and UMR-CNRS-CEA-UJF 5075, France

This review focuses on the major proteins involved in the various stages of the transmigration of leukocytes across the endothelium and on the molecular mechanisms underlying this process.

Introduction

He Endothelium

The endothelium is a monolayer of cells covering the inside of the entire vascular tree. It is also a semipermeable barrier that, by modulating its intercellular junctions, allows the transmigration of various blood constituents (Figure 1). Morphologically, three types of organelles constitute endothelial cell junctions. At the apical side of the cells, tight junctions seal the cells. Gap junctions, which are sometimes intercalated with tight junctions, allow the exchange of ions and small molecules between adjacent cells. Adherens junctions, located at a more basal position, mediate the physical contacts between cells and are anchored in the actin cytoskeleton.

The endothelium is also the point of entry of circulating leukocytes into inflamed tissue. The mechanism of leukocyte entrance into tissues is a complex, multistep event involving leukocyte adhesion to the endothelium and subsequent migration across the blood vessel wall [1]. Whereas the early steps leading to leukocyte adhesion are well understood, it is still unclear how leukocytes actually crawl through the endothelial wall. A recent study suggested that leukocytes could pass across the body of endothelial cells using a transcellular route, but it is generally accepted that most leukocyte transendothelial migration occurs via paracellular rather than transcellular routes.

Neutrophils

Leukocytes are circulating blood cells involved in defending the body against infective organisms and foreign substances. During normal immunosurveillance, leukocytes circulate in search of foreign antigens. Injury or infections cause inflammatory responses that lead to the recruitment of granulocytes, monocytes, and T cells to the sites of inflammation. Responding to the signals induced by infections or tissue damages, sentinel cells stationed in the tissues, mast cells and macrophages, release histamine, eicosanoids, and chemokines, which cause vasodilatation of blood vessels and consequently a decrease of the blood flow. This facilitates the capture of leukocytes on the surface of the endothelium. In parallel, inflammatory cytokines such as TNFα stimulate the endothelium to express adhesion receptors on its apical surface with which leukocytes can interact.

Following transmigration into the tissue, leukocytes undergo directed migration through a concentration gradient of chemotactic cytokines to the site of inflammation. According to their type and their specialized function, leukocytes release different inflammatory cytokines that, in turn, activate other white blood cells and enhance leukocyte recruitment to the inflammatory site.

Neutrophils form the primary defense against bacterial infections. Similarly to the other cells of the immune

*Current address: European Molecalar Biology Laboratory (EMBL), Grenoble, France

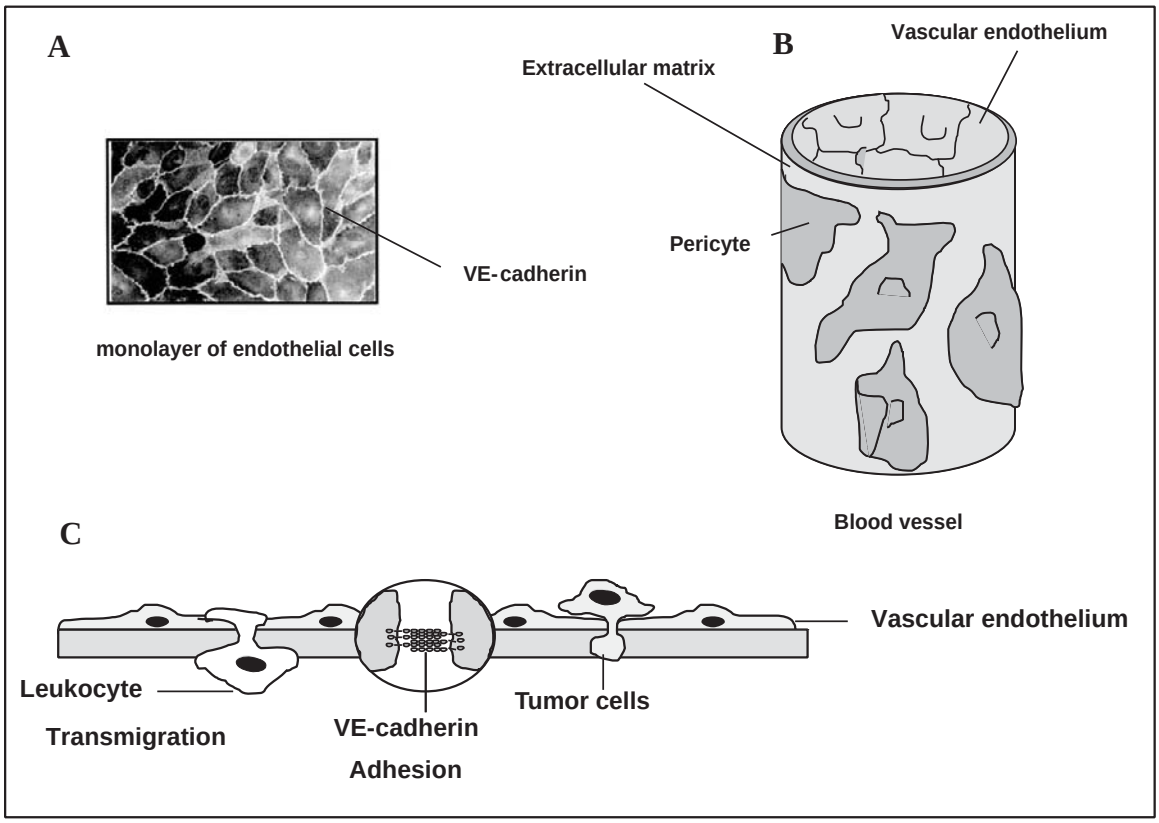

Figure 1 VE-cadherin is involved in the maintenance and restoration of the endothelium integrity. The endothelium is made up of a monolayer of endothelial cells **(A)** that separates blood components from underlying tissues **(B)**. VE-cadherin is expressed at the lateral junctions between endothelial cells **(C)**. Different types of leukocytes and tumor cells transmigrate at the intercellular junctions where VE-cadherin is expressed **(C)**.

system, they are produced in the bone marrow and circulate in the bloodstream. However, they can move out of blood vessels into infected tissue where they attack the foreign substances mainly through phagocytosis which allows them to "eat" other cells and foreign substances. Both the transmigration of neutrophils across the endothelium and the intracellular degradation of antigens are at least in part mediated by proteases, of which there are four classes: serine proteases, metalloproteases (MMPs), thiol proteases, and aspartate proteases. The first two classes play a critical role in the degradation of extracellular components, whereas the two others are involved in the intracellular degradation of antigens. Serine proteases, characterized by the presence of a catalytic triad made of histidine, aspartic acid, and serine, are packed into the azurophil granules of neutrophils. They include elastase, cathepsin G, proteinase 3, and Cap37, the last being enzymatically inactive. Upon stimulation of neutrophils by proinflammatory mediators, the content of the azurophil granules is translocated toward the external membrane of neutrophils. These surface-bound proteases are catalytically active and remarkably resistant to naturally occurring protease inhibitors [2].

Markers Expressed at Endothelial Cell–Cell Junctions

In addition to proteins that are encountered at interepithelial cell contacts, such as JAMs and CD99, the endothelial junctions express specific marker proteins such as PECAM-1 and VE-cadherin (vascular endothelial cadherin, also known as cadherin 5). All these adhesive receptors, being localized at the endothelial cell–cell junctions, are on the path of leukocyte emigration.

Platelet Endothelial Cell Adhesion Molecule-1 (PECAM-1)

PECAM-1 is a transmembrane glycoprotein of the immunoglobulin gene superfamily expressed at the surface of monocytes, neutrophils, and naive T lymphocytes and also concentrated at endothelial cell–cell junctions. It possesses an extracellular region consisting of six Ig-like domains and a cytoplasmic tail exhibiting a variable size due to differential splicing [3] (Figure 2).

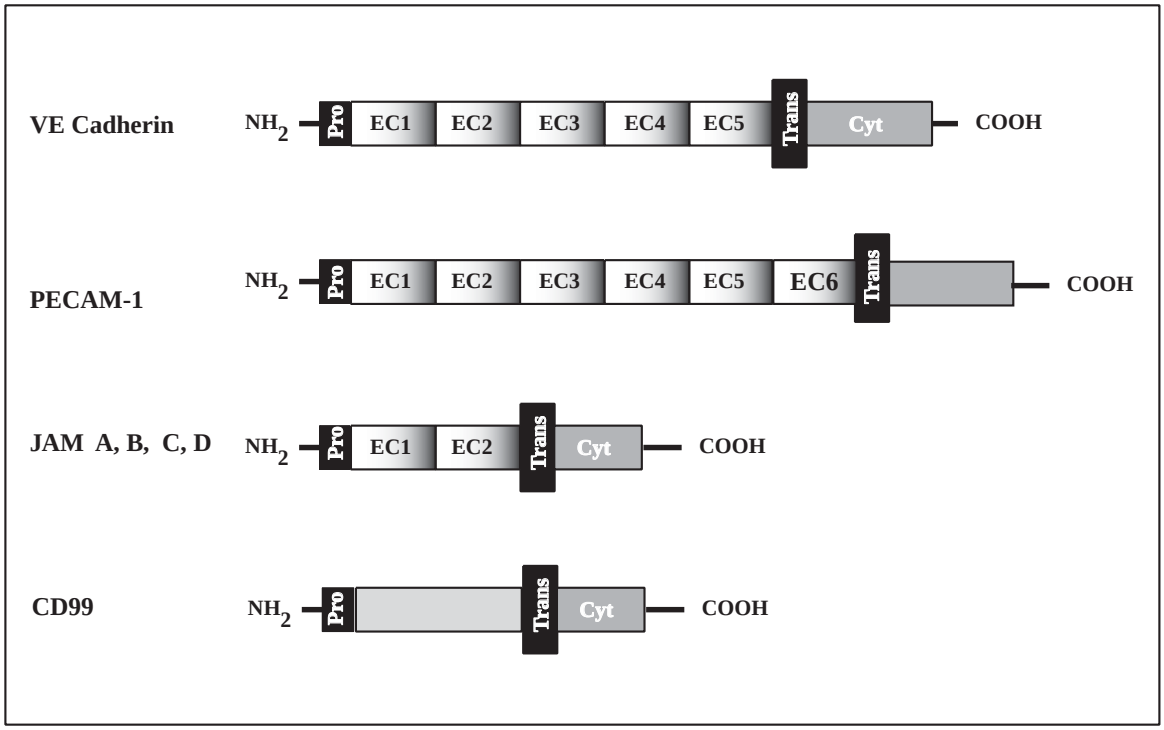

Figure 2 Schematic structures of the adhesion receptors expressed at endothelial cell–cell junctions. VE-cadherin belongs to the cadherin superfamily and PECAM-1 and JAM A, B, C, D to the immunoglobulin family, whereas CD99 is a unique molecule. ECi: Ig domains. Pro and Trans correspond to the propeptide and the transmembrane domain of each molecule. Cyt designates their cytoplasmic parts.

The extracellular domain of PECAM-1 binds very weakly to PECAM-1-expressing cells because of its low affinity for its cellular target. Once expressed at the surface of liposomes, however, PECAM-1 is able to promote the association of these vesicles. It can be deduced that PECAM-1 is able to interact homophilically when it is highly concentrated at the surface of the membrane. To define the immunoglobulin domains responsible for mediating homophilic binding, several chimeric proteins with one, two, three, four, or five Ig domains deleted were elaborated. Using an adhesion assay, these studies establish that the two N-terminal Ig domains EC1 and EC2 of PECAM-1 (Figure 2) are both necessary and sufficient to mediate homophilic interactions, but maximal stable binding requires all six extracellular Ig domains of PECAM-1. These homophilic interactions occur at the junctions between endothelial cells and may be involved in the diapedesis of leukocytes by creating heterotypic links between leukocytes and endothelial PECAM-1 molecules. However, PECAM-1-deficient mice suffer from only limited effects on the transendothelial migration of leukocytes. This probably results from an existing redundancy between adhesion molecules involved in leukocyte transmigration.

Similarly to other adhesive receptors of the immunoglobulin superfamily, PECAM-1 is also able to establish heterophilic interactions with integrins, particularly with $\alpha V\beta 3$ expressed at endothelial cell–cell junctions (Figure 4).

Cadherins

Endothelial cells express both N-cadherin and VE-cadherin at their surface. Despite similar expression levels, only VE-cadherin is expressed at cell–cell junctions, whereas N-cadherin is spread over the cell membrane. In fact, whereas VE-cadherin mediates homotypic interactions resulting in endothelial cell–cell attachment, N-cadherin seems to essentially participate in the anchorage of other N-cadherin-expressing cells, such as pericytes, to the endothelium. These N-cadherin-mediated interactions may allow the formation of the cellular multilayer structure required for the elaboration of shear stress–resistant vessels. This review will focus mainly on VE-cadherin as this is the major cadherin molecule of endothelial cell junctions.

VE-cadherin belongs to the superfamily of cadherins which are Ca^{2+}-dependent cell–cell adhesion receptors. Cadherin molecules consist of five extracellular modules designated as EC1 to EC5, a single transmembrane domain, and a cytoplasmic tail (Figure 2). The major property of cadherins is to mediate, via their extracellular parts, homophilic interactions. This means that cadherin X selectively interacts with cadherin X. Based on these homophilic interactions, cells expressing identical cadherins interact together by means of homotypic interactions. In contrast, cells expressing various cadherins segregate into like groups when mixed. To generate strong cell–cell adhesion,

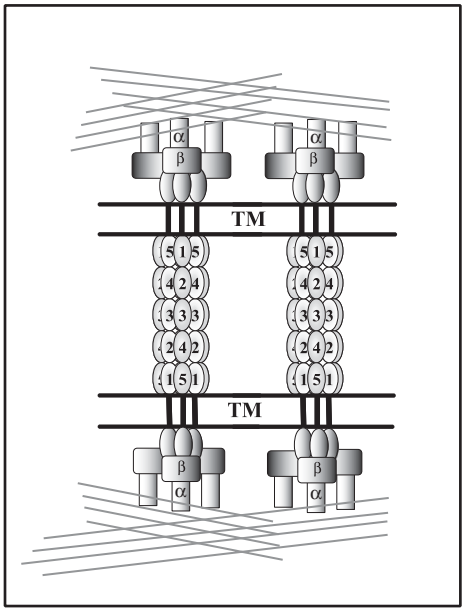

Figure 3 VE-cadherin and its intracellular partners elaborate the adherens junctions between endothelial cells. VE-cadherin molecules elaborate homophilic interactions that are able to link neighboring endothelial cells. Their extracellular domains self-associate to form a hexameric structure at the endothelium surface while their cytoplasmic tails bind proteins such as β catenin. VE-cadherin is anchored to the actin cytoskeleton (—) by the fixation of α catenin on VE-cadherin-bound β catenin.

homophilic and homotypic interactions between the cadherin ectodomains must be strengthened by intracellular interactions involving the cytoplasmic tails of cadherins. This domain exhibits two highly conserved regions: the first one, located at the C terminus of the cytoplasmic domain, binds β-catenin. The second one, close to the membrane, interacts with another catenin protein named p120. The anchorage of cadherins to the actin cytoskeleton is indispensable for the development of strong cell–cell adhesion. This connection is mediated by α-catenin, which interacts on one hand with cadherin–bound β-catenin and on the other with the actin cytoskeleton (Figure 3).

We demonstrated that VE-cadherin participates in the maintenance and restoration of the endothelium integrity. Moreover, we also proved that VE-cadherin elaborated hexameric probably antiparallel structures absolutely required for the elaboration of stable endothelial adherens junctions [4] (Figure 3).

The existence of an unknown cadherin at the surface of T cells was discovered in 1996. Similarly to classical cadherins, this new cadherin is able to bind α, β, and γ catenins and may interact with VE-cadherin, thus facilitating the homing of T cells.

CD99

CD99 is a 32-kDa glycoprotein, discovered in 1988 and expressed at the surface of all human T cells and many other hematopoietic cell types such as platelets, neutrophils, and red blood cells. It is also found at the lateral borders of confluent monolayers of human endothelial cells similarly to PECAM-1 and VE-cadherin. CD99 shares no structural homology with any known family of proteins.

Recent studies established that CD99 is involved in the control of the transport of newly synthesized MHC class I molecules to the plasma membrane in B lymphocytes, suggesting that it may be associated with the post-Golgi trafficking machinery.

In T cells, CD99 exists under two different isoforms, 32 kDa and 28 kDa, respectively, generated by alternative splicing. The 32-kDa form corresponds to the full-length protein, whereas the 28-kDa form exhibits a deletion within its cytoplasmic domain. These two CD99 forms can elaborate homophilic associations, leading to the formation of homodimers and heterodimers. Recently, it was established that the heterodimeric form, created via the formation of a covalent disulfide bridge between the cysteines 155, is able to induce T-cell apoptosis. It can be deduced that the elaboration of these dimers modulates the fate of T cells via the transduction of a proapoptotic signal.

Analysis of the cytoplasmic tail of CD99 reveals a lysine triplet (K151K152K153) that may function as a putative binding site for ezrin/radixin/moesin. These proteins are known to link surface proteins, such as E selectin and ICAM-2, to the actin cytoskeleton.

Junctional Adhesion Molecules (JAMs)

JAMs form a new Ig-like superfamily of adhesion receptors whose first member, called JAM A, was only discovered in 1998. Since that time, three other members have been described as JAM B, C, and D [5]. (JAM D is also named as JAM 4 in the literature.) They contain two extracellular immunoglobulin-like domains, a transmembrane domain and a relatively short cytoplasmic tail (Figure 2). Although all JAMs localize at endothelial cell–cell junctions and more precisely at tight junctions, they display different cellular distributions. Thus, the expression of JAM B is restricted to some endothelial subpopulations including high endothelial venules or lymphatic cells, whereas JAM A is expressed in platelets and in endothelial and epithelial cells. Following their transfection into CHO or MDCK cells, JAM A and B molecules are specifically enriched at cell–cell contact sites at the level of tight junctions, suggesting that they are capable of promoting cell–cell adhesion. In vitro studies indicate that the extracellular part of JAM-A self-associates as a dimer and this homodimerization seems to be required for its adhesive function and the organization of the junctional endothelial structure.

JAMs are also able to mediate heterophilic interactions. For instance, although JAM C is unable to interact with JAM A, it binds firmly to JAM B. Moreover, JAMs can interact with some integrins generally expressed at the surface of leukocytes. Thus, whereas JAM-A is a ligand of the β2 integrin LFA-1, JAM-B is the counterreceptor for the leukocyte β1 integrin α4β1, and JAM C interacts with the

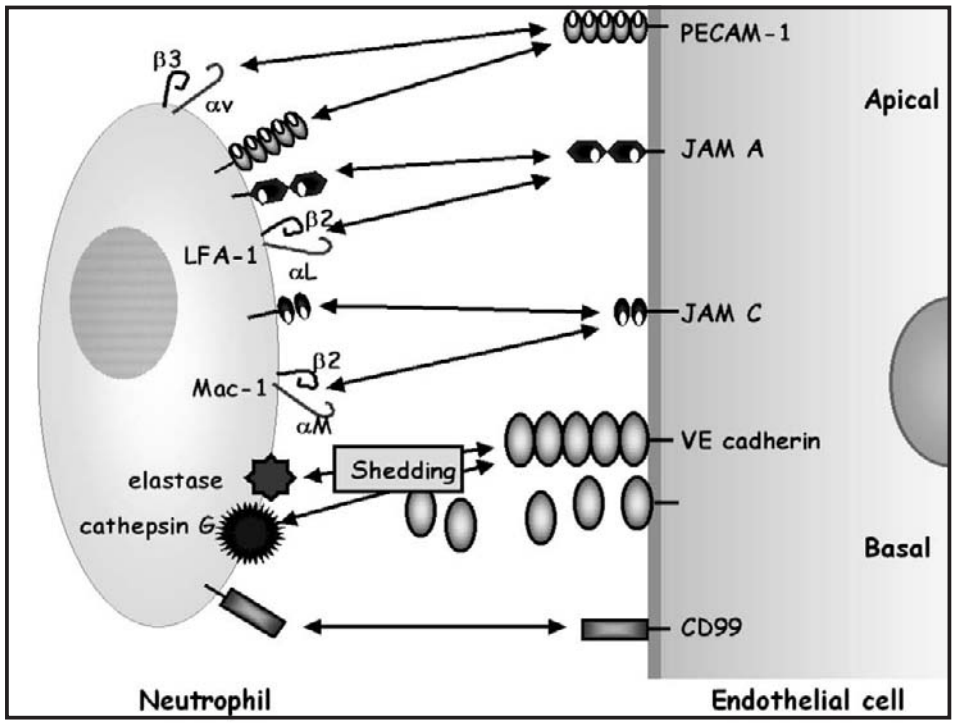

Figure 4 Adhesive interactions between endothelial cells and transmigrating neutrophils. The transmigration process involves several adhesive receptor pairs. By means of homophilic and heterophilic interactions, neutrophils progress through the endothelial junctions. The first transmigration step implicates homophilic and heterophilic PECAM-1 interactions. These homophilic interactions are elaborated between PECAM-1 molecules expressed at the surface of both endothelial cells and neutrophils, whereas the heterophilic ones involve the leukocyte integrin αVβ3. These PECAM-1 interactions are relayed by homophilic CD99-mediated interactions. Several interactions mediated by different JAMs receptors also participate in the transmigration, but their time course is still not known. When migrating neutrophils reach the adherens junctions where VE-cadherin is expressed, elastase and cathepsin G bound to the neutrophil cell surface can cleave its extracellular domain, thus opening their way through the adherens junctions.

β2 integrin Mac-1. These interactions significantly expend the repertoire of contacts between endothelial cells and leukocytes.

Mechanism of Leukocyte Diapedesis

The mechanism of leukocyte entrance into tissues requires, first, leukocyte adhesion to the endothelium and, subsequently, migration across the blood-vessel wall.

Leukocyte Adhesion

The leukocyte adhesion cascade is a sequence of adhesion and activation events that precede the extravasation of leukocytes. This multistep event is mediated by the engagement of adhesion receptors on leukocytes and their counter-receptors on endothelial cells. First, leukocytes escape from the bloodstream by capture or tethering to the endothelium. Indeed, during inflammation, endothelial cells are activated by signals emanating from inflammatory mediators such as TNFα, nitric oxide, and complement factors. Within minutes of stimulation, P- and E-selectins are expressed at the surface of endothelial cells and interact with their primary ligand PSGL-1 (P-selectin glycoprotein ligand-1), constitutively found on all leukocytes. This allows the capture of leukocytes on the surface of endothelial cells and permits neutrophil celerity to be slowed. Following a rolling phase, neutrophils are arrested on the endothelial cell surface. This adhesion step is mostly mediated by interactions involving β2-integrins on the leukocyte surface and immunoglobulins such as ICAM-1 and VCAM-1 on the endothelium. Subsequently, neutrophils migrate on the endothelial surface by amoeboid movement toward the borders of endothelial cells where transmigration occurs.

For more details on the coordinated interplay between the adhesion and signaling proteins involved in the process of firm adhesion of leukocytes on the endothelium, the reader is referred to an excellent recent review [6].

Leukocyte Transmigration

The multiple steps implicated in the transmigration process require the formation and destruction of homophilic and heterotypic interactions between receptors expressed at

the surface of leukocytes and endothelial cells. To investigate the role of each adhesion receptor described earlier, attempts were made to block transendothelial migration of leukocytes using specific antibodies.

Role of PECAM-1 and CD99

Pretreating monocytes or neutrophils with antibodies specific for PECAM-1 inhibited their emigration across endothelial cell monolayers in in vitro assays. Reciprocally, blockage of endothelial cell PECAM-1 results in an effective inhibition of leukocyte transmigration. It was also found that PECAM-1 is required for in vivo leukocyte recruitment, because antibodies against PECAM-1 were able to block the accumulation of neutrophils in the peritoneal cavity in a rat model system. This means that homophilic interactions of PECAM-1 on leukocytes with PECAM-1 on endothelial junctions are involved in transmigration. In fact, PECAM-1 is constitutively recycled along the endothelial cell borders. During the transendothelial migration process, recycling is targeted to the part of the junction across which monocytes are squeezing. Indeed, anti-PECAM-1 antibodies block the recruitment of PECAM-1 to the zones of leukocyte migration and thereby the leukocyte transmigration process.

The role of CD99 in leukocyte transendothelial migration was more recently established by a similar method using anti-CD99 antibodies. Thus, whereas anti-CD99 antibodies have no effect on monocyte adhesion, they are able to block their transmigration significantly. Inhibition of either leukocyte or endothelial cell CD99 blocked leukocyte transmigration with equal efficiency, suggesting that homophilic interactions between CD99 expressed on both monocytes and endothelial cells are required for transmigration [7]. This effect is more drastic than the inhibition induced by anti-PECAM-1 antibodies. Simultaneous use of anti-PECAM-1 and anti-CD99 antibodies completely blocks the ability of monocytes to transmigrate. This additive effect suggests that PECAM-1 and CD99 possess distinct roles in the transmigration process. In fact, leukocytes arrested by anti-PECAM-1 antibodies adhere to the apical surface of the endothelium, whereas those arrested by anti-CD99 antibodies are trapped inside the endothelial cell–cell junctions. This indicates that PECAM-1 and CD99 are differentially located along the interendothelial junction and are sequentially involved in the transmigration process. PECAM-1-mediated homotypic interactions are probably relayed by CD99-mediated ones during leukocyte migration. To date, it is difficult to ascertain whether such a sequential process can be extended to the other leukocyte subfamilies, the surface expression of CD99 of the various types of leukocytes being only partially known.

Role of JAMs

Concerning the role of JAMs on the transendothelial migration of leukocytes, several antibodies directed against JAM A were described to have the capability to inhibit the transmigration of monocytes, T cells, and neutrophils in vitro and in vivo. Thus, in a model of meningitis in mice, it was demonstrated that the addition of anti-JAM A antibodies strongly reduced monocyte and neutrophil infiltration into the cerebrospinal fluid and brain parenchyma. Moreover, anti-JAM B or a soluble fragment of JAM B were also able to block chemokine-induced lymphocyte transmigration.

In fact, JAM A plays a critical role in the diapedesis of leukocytes. After stimulation of endothelial cells with both TNFα and IFNγ, JAM-A is redistributed from the junctions to the endothelial surface. Subsequently, it becomes available to interact with the activated form of the β2-integrin LFA-1 (β2αL), thus contributing to the adhesion of leukocytes on the activated endothelium. At this stage, homophilic interactions involving JAM A expressed both on leukocytes and on endothelial cells are not crucial to firm adhesion of leukocytes. This is particularly true for monocytes and neutrophils that express very low amounts of JAM A at their surfaces. The interaction of JAM A with LFA-1 contributes first to the chemokine-triggered adhesion and second to the transmigration of memory T cells, neutrophils, and lymphocytes.

The binding of endothelial JAM A to LFA-1 on leukocytes may disrupt junctional homophilic JAM A interactions, thereby unlocking interendothelial junctions. Complementary data are needed to understand the interplay between the homophilic and heterophilic JAM A–mediated interactions occurring during leukocyte transmigration.

Moreover, according to the subpopulation of leukocytes, the transmigration step involving the JAM family implicates different couples of adhesion receptors. For example, JAM B expressed at the surface of high endothelial venules interacts with JAM C of T cells and NK and dendritic cells. This molecular pair seems to play a critical role in the trafficking of T, NK, and dendritic cells into and out of high endothelial venules.

Role of VE-Cadherin

In contrast to antibodies specific for PECAM-1, JAMs, or CD99, antibodies directed against the extracellular domain of VE-cadherin increase the recruitment of leukocytes to the infection sites. In fact, the anti-VE-cadherin antibodies have the ability to disrupt the VE-cadherin homophilic interactions. This results in the formation of gaps between endothelial cells through which leukocytes can easily squeeze. In physiological conditions, alterations of VE-cadherin-mediated adhesion also occur at endothelial junctions during leukocyte transmigration. Indeed, immunofluorescence experiments reveal that VE-cadherin and α-, β-, and γ- catenins disappear from cell-to-cell contacts following adhesion of neutrophils to endothelial monolayers. This effect appears only where neutrophils firmly adhere while VE-cadherin-based complexes remain intact in areas devoid of adherent neutrophils. By contrast, PECAM-1 distribution remains unaffected.

The mechanism leading to the formation of gaps at cell–cell junctions during leukocyte transmigration is still controversial. To cast some light on this mechanism, move-

ments of VE-cadherin occurring during leukocyte transmigration were observed using real-time microscopy. Thus, transmigration of fluorescently labeled leukocytes was followed in real time by two-color fluorescence microscopy using HUVECs expressing endogenous VE-cadherin and a VE-cadherin protein fused with its C-terminal part to Green Fluorescent Protein (VE Cad-GFP) [8]. This study showed that transmigration occurs both through preexisting gaps and through de novo gap formation. Gap widening accommodates to the size of the transmigrating leukocyte, allowing a narrow contact between the endothelial cell and the leukocyte. The widening of the gaps seems to be accompanied by a clustering of the VE Cad-GFP molecules on the edge of the forming clefts. After transmigration, the displaced molecules diffuse back to reconstitute the junctions. This leads to a rapid resealing of the junctions within 5 minutes after leukocyte transmigration. These results were confirmed by a real-time study following the differential movements of VE-cadherin in living endothelial cells during transmigration of neutrophils with anti-VE-cadherin antibodies that do not interfere with transendothelial migration. The lateral movement of VE-cadherin was hypothesized to be a consequence of its decoupling from the cytoskeleton, probably initiated by an intracellular signal due to leukocyte adhesion to the endothelium. In both of the studies, only the movement of the cytoplasmic tail of VE-cadherin was followed in real time. It is not known whether the extracellular domain of VE-cadherin remains intact during the lateral movement.

Real-time fluorescent imaging shows that neutrophils only move laterally underneath the vascular endothelium instead of deeply into the vascular tissue. Thus, the question as to how neutrophils go across the endothelium before penetrating into the surrounding tissues remains unanswered. The curtain effect that moves VE-cadherin is necessary but not sufficient to completely support leukocyte transmigration.

The event initiating the lateral movement of VE-cadherin may correspond to the cleavage of this adhesive receptor by proteases expressed at the surface of transmigrating neutrophils. This hypothesis is based on the fact that elastase, at the surface of transmigrating neutrophils, mainly localizes to the migration front [9]. Thus, after the adhesion to the endothelial cell surface, elastase is expressed on the apical face of neutrophils, avoiding contact between proteases and the endothelial cell surface. When neutrophils reach endothelial cell–cell junctions, elastase moves from the apical face to the basal face where it comes in close proximity with junctional components. An in vivo study suggested that elastase may contribute to lung neutrophil accumulation and microvascular injury during intestinal ischemia-reperfusion (IR). Moreover, following IR, elastase and VE-cadherin fragments were found in the bronchoalveolar fluid.

Despite results obtained in vitro and in vivo, the participation of proteases in the transmigration of leukocytes is still controversial. Indeed, a study published in 2002 suggested that elastase and MMP9 are not essential for neutrophil transmigration. This assumption is based on the use of neutrophils depleted in both elastase and MMP9 that show no defect in their transmigration capacity. These results contradict our own study as we assessed that VE-cadherin is cleaved following adhesion of neutrophils to endothelial cell monolayers [10]. Using specific inhibitors of neutrophil proteases, we were able to identify elastase and cathepsin G bound to the neutrophil surface as the major proteases involved in the cleavage of VE-cadherin. Furthermore, inhibition of both membrane-bound proteases inhibited neutrophil transmigration in in vitro assays. In vivo, the surface-bound elastase and cathepsin G may cleave VE-cadherin on very restricted areas close to the sites of neutrophil adhesion. On the endothelium, the redundancy between these two proteases can explain why neutrophils still transmigrate across endothelial monolayers in the presence of specific inhibitors of elastase and also why neutrophils from elastase-deficient mice show no defect in transendothelial migration. Indeed, cathepsin G can replace elastase, thus allowing the neutrophil transmigration to occur despite elastase inhibition or deficiency.

The involvement of a paracrine mechanism in neutrophil-mediated alteration of the endothelial barrier function was suggested by Gautam and coworkers. Upon neutrophil adhesion to the endothelium, leukocyte β2-integrin signaling triggered the release of the neutrophil CAP37, a serine protease without catalytic activity that induced a cytoskeletal rearrangement and the formation of gaps in the endothelium in vitro. Alteration of the endothelium may result from the interaction between CAP37 on the surface of neutrophils and proteoglycans present at the endothelial cell surface. This interaction could stimulate endothelial cell contraction by a yet unidentified mechanism.

Conclusions

During the past 5 years, it has been established that new receptors such as JAMs and their integrin counterreceptors play major roles in leukocyte transmigration. Also, the fate of VE-cadherin during leukocyte transmigration is now better understood. In particular, it has been shown that membrane-bound neutrophil elastase and cathepsin G facilitate neutrophil transmigration by cleaving the extracellular part of VE-cadherin.

These adhesive receptors are definitely more than just a molecular glue, because it is suspected that they mediate intracellular signaling. Thus, some data from our laboratory suggest the existence of VE-cadherin-mediated signaling pathways triggered by the destabilization of cadherin junctions. This pathway leads eventually to the restoration of endothelium integrity by a neosynthesis of VE-cadherin molecules. The molecules involved in this pathway remain to be determined. Nevertheless, several elements suggest that β-catenin and possibly the Wnt signaling pathway might play a role in the restoration of endothelium integrity.

A better understanding of the sequential events occurring during transendothelial migration of leukocytes may lead to the discovery of new classes of target molecules for the design of novel drugs that are able to interfere with the transmigration process. Such drugs could have major applications in several important human illnesses such as polyarthritis or cancer.

Glossary

Endothelium: Monolayer of endothelial cells that line the inside of vascular tree.

Neutrophils: A subtype of white cells.

Transmigration: Cellular process allowing white cells to migrate across the endothelial barrier.

VE cadherin: Ca++-dependent adhesive receptor exclusively expressed in endothelium.

Capsule Biography

Dr. Gulino-Debrac is a senior scientist from the Centre National de la Recherche Scientifique (CNRS). Since 1996 she has been in charge of a group working on VE-cadherin in Institut de Biologie Structurale Jean-Pierre Ebel (Grenoble, France). Her work is supported by grants from the CNRS, the Commissariat à l'Energie Atomique (CEA), and the Ligue contre le Cancer.

CHAPTER 49

Vascular Gap Junctions

[1]Michael Koval and [2]Jahar Bhattacharya

[2]Lung Biology Laboratory, College of Physicians and Surgeons, St. Luke's-Roosevelt Hospital Center, Columbia University, New York, New York

Introduction

Gap junctions are intercellular channels that allow diffusion of small solutes and ions between adjoining cells. This intercellular exchange enables intercellular communication of specific signals and metabolic products that promote coordination of multicellular function. In blood vessels, gap junctions have been implicated in such diverse functions as regulation of vascular tone, transendothelial cell migration, and the pathogenesis of atherosclerosis. Here we focus on some essential principles of gap junctional function in the vascular bed.

Connexins

Gap junction channels are composed of proteins in the connexin family. There are almost two dozen mammalian connexins. "Cx" followed by a number, for example, Cx43, denotes each connexin. The number predicts molecular mass, although this prediction may not always be accurate. A gap junction channel consists of two hexameric hemichannels, one in each cell. For some connexins, e.g., Cx32, hemichannels are formed in the endoplasmic reticulum (ER), while for others, such as Cx43 and Cx46, the hemichannels are assembled in the Golgi apparatus [1]. Regulated trafficking of connexin hemichannels to the plasma membrane enables modulation of channel number at the intercellular interface.

The major vascular connexins are Cx37, Cx40, and Cx43, which are expressed differing extents depending on tissue type and location [2]. These connexins, when expressed by the same cell, have been shown to form heteromeric (mixed) gap junction channels including Cx40:Cx43, Cx37:Cx43, and Cx37:Cx40 channels.

The ability of connexins to intermix defines permeability and gating characteristics of the gap junction channel. Connexins also have multiple conductance states. The interpretation of cell–cell coupling by gap junctions requires consideration of both the extent of compatibility between connexin subtypes and the physical–chemical properties of the probe being used. A good approach is to obtain electrophysiological quantifications of net ionic flux across gap junctions simultaneously with those of fluorescent dye transfer. This dual approach normalizes channel permeability against channel surface area. Using this approach, Burt et al. found that communication through heteromeric Cx40:Cx43 channels increased with an increase in the amount of Cx43 relative to Cx40 [3]. Other examples of heteromeric gap junction channels with unique permeability characteristics include the following connexin pairings: Cx37:Cx43, Cx40:Cx43, and Cx43:Cx45. Given that different classes of vascular cells express different ratios of these connexins, this suggests that intercellular communication is regulated through differential connexin expression.

Gap Junctional Regulation

Increasing evidence indicates that proteins that associate with connexins may also regulate channel function. For example, the association of zonulae occludens-1 with both connexins and tight junction proteins suggests that crosstalk may exist between gap and tight junctions. Gap junctions are also modulated by the cystic fibrosis transmembrane conductance regulator, which may also be a part of the junctional complex, and by wnt-1, suggesting a link with

β-catenin and cadherins in gap junctional regulation [4]. However, the functional implications of these interactions are not well understood.

Connexin-specific gating mechanisms modify gap junctional communication. Acidic intracellular pH gates channels formed with Cx43 and Cx46, although not all connexins—for example, Cx37—are pH sensitive. Differential phosphorylation of connexins is another potential mechanism for gap junctional gating. Kinases implicated in this regulation include protein kinase C, which inhibits Cx43 assembly and thereby decreases Cx43-mediated gap junctional communication. A similar inhibitory effect on Cx43 gap junctions is attributed to MAP kinases and src kinases. These considerations indicate that connexin expression alone does not control the level of gap junctional communication; instead, crosstalk between connexins and other signaling pathways also needs to be considered.

Vascular Connexin Expression

Connexin expression is sensitive to cell state and varies with cell and vessel type. Connexin protein expression in situ is typically defined by immunohistochemical localization or by immunoblot. However, cross-reactivity between antibodies, particularly cross-reactivity of anti-Cx40 antibodies to Cx43, is a potential concern when considering analysis of connexin expression in the vasculature.

Gap junctions are more prominent in large than small vessels. Interendothelial and inter–smooth muscle junctions are homologous, whereas endothelial–smooth muscle junctions are heterologous. Cx37 and Cx40 are uniformly expressed by vascular endothelial cells in situ. However, endothelial expression of Cx37 and Cx43 is greater in large than in small vessels. Endothelial Cx43 expression might be species-specific, since the expression is pronounced in rat and bovine aortic endothelium, but less prominent in mouse aortic endothelium. Also, Cx43 expression is higher in areas with turbulent flow, such as at vessel branch points.

Cx43 is the most prominent connexin expressed by vascular smooth muscle. Low levels of Cx37 expressed by resting vascular smooth muscle may be upregulated during new vessel growth. Other connexins expressed by vascular smooth muscle include Cx45, which is limited to specific vascular beds such as cerebral vessels and ascending aorta of rat, and the recently identified Cx31.9.

Heteromer formation is likely to be important for formation of functional myo-endothelial gap junctions since endothelial Cx37 : Cx40 hemichannels are linked to vascular smooth muscle hemichannels containing mainly Cx43 to form well-coupled heterotypic gap junctions. In the absence of Cx37, homomeric Cx40 hemichannels expressed by endothelium and Cx43 hemichannels expressed by vascular smooth muscle would form poorly conducting heterotypic gap junction channels.

Knockout models indicate that the coordinated expression of connexin subtypes is complex in the vascular bed. In one study, endothelial cell–cell coupling was maintained in Cx40-deficient mice by compensatory upregulation of endothelial Cx37, but not Cx43 [5]. However, Cx37 deficiency had little effect on Cx40 or Cx43 expression or on cell coupling. Although Cx37 or Cx40 deficiency alone has little effect on vessel morphology, mice doubly deficient in Cx37 and Cx40 die soon after birth and show abnormally dilated blood vessels, particularly in skin and testis [6]. Vessels in Cx37 –/– Cx40 –/– mice also have permeability defects and localized hemorrhages, suggesting a role for endothelial gap junctions in regulating vessel barrier function. Cx43 deficiency does not affect global vascular development, although coronary artery development is partially defective [7]. Although Cx45 expression in the vascular bed is limited, it plays a critical, yet undetermined, role in vessel development during embryogenesis since Cx45-deficient mice have defective vascular branching and do not develop smooth muscle in large vessels.

Connexins and Vascular Tone

Gap junctions contribute to regulation of vascular tone. Thus, pharmacologic agents and connexin mimetic peptides, which inhibit gap junctional communication, also inhibit vasodilation. In fact, the well-documented phenomenon of conducted vasodilatation in conduit arteries is explained by longitudinal NO conduction along the vascular wall through gap junctions. Further, connexin-mimetic peptides inhibit the transmission of endothelial hyperpolarization to underlying smooth muscle cells, consistent with a role for heterologous endothelial–vascular smooth muscle communicating junctions in so-called endothelium-derived hyperpolarizing factor (EDHF)-induced vasodilation [8]. EDHF-type vessel relaxation mediated by gap-junctional communication is more prominent for small than large vessels. This is consistent with the finding that functional gap-junctional communication is present in small vessels as indicated by the presence of Ca^{2+} waves that propagate between endothelial cells [9].

Consistent with the prominent expression of Cx40 by endothelial cells, endothelial electrical conduction, vasodilation, and smooth muscle activation are defective in Cx40-deficient mice. These mice also have increased blood pressure, indicating a predominant role for Cx40, rather than Cx43, in establishing gap junctional connections between vascular smooth muscle and endothelium [10].

The neonatal lethal phenotype of Cx43-deficient mice has hampered the understanding of Cx43 in vascular function. To address this, Liao et al. [11] used *cre* expression driven by the Tie 2 promoter to preferentially excise the Cx43 gene from endothelial cells. These mice develop normally and their endothelial cells express two other connexins, Cx37 and Cx40, but they have abnormally low blood pressure and a lowered heart rate. Lowered blood pressure was due to increased plasma NO production, which was most likely due to increased eNOS activity. However,

since endothelial NO production is linked to gap-junctional coupling between vascular smooth muscle and endothelial cells, this indicates that Cx43 depletion actually enhanced coupling between these cells, perhaps through enhanced formation of homomeric Cx40 gap junction channels.

Vascular Connexins in Pathologic Conditions

Vascular endothelium has the capacity to form gap junctions with circulating cells such as neutrophils expressing Cx43 and macrophages expressing Cx37. Such interactions may be significant in the development of inflammation, particularly since inflammation increases Cx43 expression in endothelial cells and leukocytes [12]. In contrast, myoendothelial cell–cell communication is downregulated in inflammation. The gap-junctional role in inflammation is also indicated in that gap junction inhibitors promote vascular leak and transvascular cell migration [13], suggesting that gap junctions help maintain vascular barrier function. Tumor cell extravasation might also be regulated by gap-junctional communication, since melanoma cells expressing high levels of Cx26 are able to communicate with vascular endothelium and are more metastatic than cells that lack connexin expression. Interestingly, since Cx26 is believed to be incompatible with Cx37, Cx40, and Cx43, the melanoma cell–endothelial interaction may be attributable to a novel mode of gap-junctional communication, or to an unknown endothelial connexin that pairs with Cx26.

Gap-junctional communication between foam cells and the vascular wall is also likely to promote atherosclerotic plaque formation [14]. Consistent with a role for Cx43 in plaque formation, Cx43 +/– deficient mice that are deficient for LDL receptor expression show significantly less endothelial Cx43 expression and fewer atherosclerotic plaques than mice expressing normal levels of Cx43. Cx43 upregulation in response to disturbed flow during plaque formation or in response to vessel injury may exacerbate this effect. Whether other connexins are involved in plaque formation remains to be determined; however, there are some hints that Cx37 may also play such a role. One possibility is that while some gap-junctional communication is important for transvascular cell migration, excessive cell–cell coupling can be inhibitory, which, in turn, could stabilize a foam cell precursor at sites of plaque formation.

Conclusion

In summary, vascular connexins are central to the structural and functional organization of the vascular bed. Functionally, they are overwhelmingly important for normal vascular development and in the regulation of vascular tone. The formation of gap-junctional channels is a complex process that is subject to plasticity and depends upon cell type and connexin subtype specificity. However, several questions remain. For instance, more needs to be understood with respect to the role of vascular connexins in pathological states. This role may be extensive and highly facilitatory to disease progression, especially in the vascular involvement in inflammation, in atherosclerotic plaque formation, and in abnormalities of blood coagulation. The emerging role of gap junctions in the consideration of vascular pathobiology promises to be fertile ground for future research.

Glossary

Connexin: Channel-forming transmembrane protein subunit. A complete gap junction channel consists of six connexins in one cell pairing with six connexins in an adjacent cell that allow direct transfer of small cytoplasmic molecules from one cell to an adjacent cell.

Gap junction: Originally defined by electron microscopy as a class of cell–cell contact sites with a uniform ~16-nm "gap" between the cells as opposed to tight junctions that show no gap. Gap junctions consist of an array of connexin-based channels that mediate cell–cell communication.

Heteromeric: A gap junction channel composed of two or more different types of connexins completely intermixed.

Heterotypic: Head-to-head interaction between one type of connexin in one cell and a different type of connexin in an adjacent cell.

Homomeric: A gap junction channel composed of a single type of connexin.

Capsule Biography

Dr. Koval's laboratory studies the molecular mechanisms of membrane protein assembly and roles for intercellular communication in regulating pulmonary function. His work on gap junctions started more than a decade ago and is supported by grants from the NIH and American Heart Association.

Dr. Bhattacharya's laboratory investigates intercellular connectivity and coordination in proinflammatory signaling in microvessels. Using lung inflammation as a model, the Bhattacharya group has developed optical imaging methods to quantify signaling mechanisms in cells in situ.

CHAPTER 50

Adhesion Molecules and the Recruitment of Leukocytes in Postcapillary Venules

Klaus Ley

Cardiovascular Research Center and Departments of Biomedical Engineering, Molecular Physiology and Biological Physics, University of Virginia, Charlottesville, Virginia

Postcapillary Venules

Postcapillary venules start where two capillaries meet and discharge their blood into a microvessel of peculiar morphology that rapidly increases its diameter as more capillaries enter. At the beginning, postcapillary venules have a diameter of less than 10 μm, and further downstream, postcapillary venules can be as large as 80 μm. Wall shear rate, the rate of change in velocity near the wall, and wall shear stress, the force exerted per unit area of venule parallel to the vessel axis, are lower in postcapillary venules than in precapillary arterioles, and this contributes to, but does not entirely account for, preferential leukocyte adhesion in these vessels [1]. Recently, the presence of a significant endothelial glycocalyx surface layer has been discovered [2], which is up to 0.5 μm thick and effectively reduces shear stress on the endothelial surface to zero [3]. The shear forces experienced by adherent or rolling leukocytes can be calculated from the cell geometry and an interfacial shear stress present at the interface between glycocalyx and lumen. This interfacial shear stress is, on average, five times higher than the Newtonian wall shear stress estimated for a homogenous fluid and no glycocalyx [3a].

Leukocytes

In human blood, most leukocytes are neutrophils, with a smaller fraction of lymphocytes, monocytes, eosinophils, and basophils. In mouse blood, lymphocytes are more abundant than neutrophils. The lymphocyte compartment contains B cells, various types of T cells, natural killer cells, and others. Blood lymphocytes comprise hundreds of phenotypes distinguishable by flow cytometry.

Under most conditions, leukocyte interactions with postcapillary venules are dominated by neutrophils. Typically, more than 90 percent of all rolling and adherent cells are neutrophils, with the balance monocytes and eosinophils. Lymphocytes rarely roll or adhere in postcapillary venules of nonlymphatic tissues, but roll vigorously in high endothelial venules of lymph nodes and other secondary lymphatic organs. Therefore, reports of leukocyte rolling and adhesion observed by intravital microscopy in nonlymphatic organs almost always refer to neutrophils, although this is not always specifically mentioned. Recently, mice have become available in which certain leukocyte subsets express green fluorescent protein (GFP), so that specific intravital microscopic studies become possible for neutrophils, monocytes, and certain T cells.

Adhesion Molecules

Leukocyte adhesion molecules are defined as transmembrane receptor–ligand pairs that transmit mechanical force. Adhesion molecules are required for leukocyte capture or initial tethering, rolling, firm adhesion, and transendothelial migration (Figure 1). All known adhesion molecules relevant for leukocyte adhesion are type I single-spanning transmembrane molecules (N terminus outside the cell), some are homo- or heterodimers. Although it is formally possible that type II or multispanning or GPI-linked molecules could be involved in leukocyte adhesion, there is no evidence that these molecules actually mediate leukocyte rolling or adhesion under in vivo conditions. Notably, a chemokine–chemokine receptor interaction, a variant of fibroblast growth factor receptor, a GPI-anchored receptor, and a secreted molecule have all been proposed to serve as leukocyte adhesion molecules, but none of these proposed interactions have been substantiated in vivo.

Selectins

The selectins are a class of three C-type (calcium-binding) lectins that are expressed on leukocytes (L-selectin), inflamed endothelial cells (E-selectin), and activated platelets and endothelial cells (P-selectin) [4]. They share a common genomic organization and protein structure with an N-terminal lectin domain followed by an epidermal growth factor (EGF) domain, a number (two to nine) of consensus repeats, a transmembrane domain, and a cytoplasmic domain that is homologous among selectins from different species, but unique to each type of selectin [4]. Selectins bind glycosylated selectin ligands (see later discussion) with high to intermediate affinities (nanomolar range) and high on-rates and off-rates. This unique combination of properties enables selectins to mediate capture between cells in the flowing blood and the endothelium, and rolling through formation and breakage of reversible bonds. All three selectins are important in inflammation. In addition, L-selectin mediates rolling of (naive) lymphocytes in high endothelial

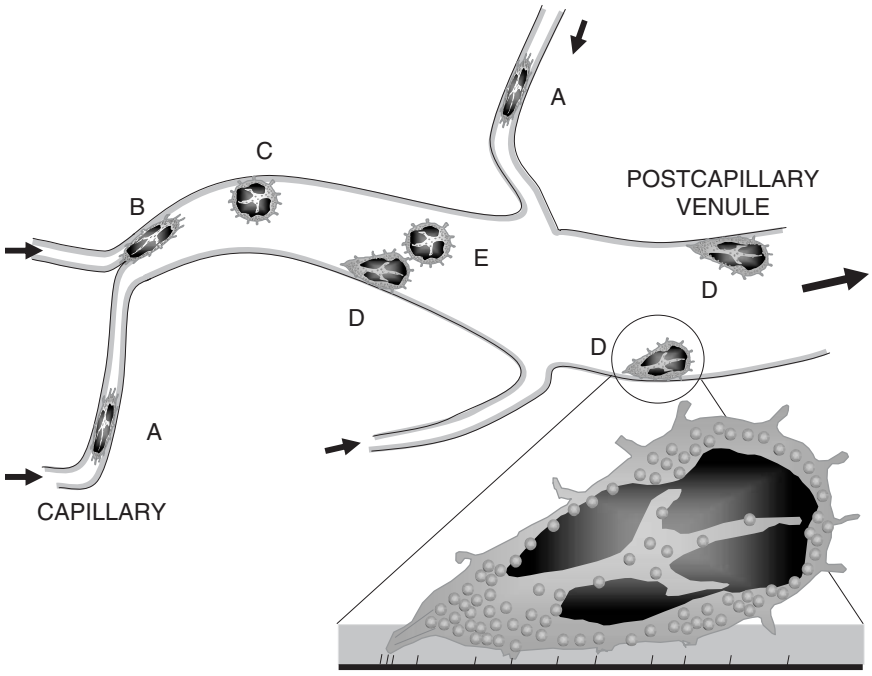

Figure 1 Neutrophils interacting with the endothelium lined with a 500-nm glycocalyx (blue) in a postcapillary venule. In capillaries, neutrophils are deformed into a near-cylindrical shape (A) and deform the endothelial glycocalyx. Almost all leukocyte rolling is initiated at the beginning of postcapillary venules, where leukocytes are in close physical contact with the endothelial surface (B). Noninteracting deformed leukocytes eventually recover their spherical shape (C), but rolling leukocytes, especially neutrophils, acquire a characteristic teardrop shape that reflects the effect of adhesive forces balanced by shear forces on the cytoskeleton (D). Rolling or adherent cells can nucleate L-selectin-PSGL-1-dependent secondary capture or tethering events (E). A close-up of a rolling neutrophil (bottom right) shows the endothelial glycocalyx (grey 500 nm) with endothelial adhesion molecules (E-selectin, 30 nm, and P-selectin, 40 nm). The black hairlike lines represent the length of a P-selectin-PSGL-1 pair (100 nm) completely buried in the glycocalyx. Rolling leukocytes probably continuously deform the glycocalyx as they roll while selectin (and integrin) bonds are formed at the leading edge (right) and broken at the trailing edge (left). Arrows indicate direction of blood flow. (see color insert)

venules of secondary lymphatic organs, P-selectin mediates platelet interactions with leukocytes and endothelial cells, and E-selectin mediates homing of certain lymphocytes to the skin. L-selectin is constitutively expressed on all neutrophils, monocytes, eosinophils, and most lymphocytes. P-selectin is stored in Weibel-Palade bodies of endothelial cells and platelet alpha granules and released upon stimulation by secretagogues. E-selectin is transcriptionally regulated through nuclear factor kappaB (NFκB)-dependent pathways. It is suspected that all three selectins and other adhesion molecules also serve signaling functions. Leukocyte activation upon ligation of L-selectin has been demonstrated, as has endothelial cell remodeling secondary to E-selectin engagement. There is little evidence for signaling through P-selectin, but engagement of endothelial or platelet P-selectin appears to result in activation of the bound cells via selectin ligands.

Selectin Ligands

Many selectin ligands have been proposed, but only P-selectin glycoprotein ligand-1 (PSGL-1) has been fully characterized and confirmed to be relevant in vitro and in vivo. PSGL-1 is a homodimer with functional groups near the N terminus, including three (in mouse, two) sulfated tyrosine residues and a critical threonine decorated with an O-linked carbohydrate chain terminating in the tetrasaccharide sialyl Lewis^x (sLex). sLex biosynthesis requires fucosyl transferase VII and a sialyl transferase (ST), possibly ST3GalIV, and is most likely directly involved in selectin binding. The critical O-linked side chain is located on a core2 structure so that core2 *N*-acetylglucosaminyl transferase is required for biosynthesis of fully functional PSGL-1. PSGL-1 functions much better as a dimer than as a monomer, possibly because P-selectin is also present as a dimer on the cell surface. Cocrystals between PSGL-1 and P-selectin show that both the tyrosine sulfate and the carbohydrate interact with the lectin domain simultaneously.

Although PSGL-1 was initially discovered as a P-selectin ligand, it was later shown to also bind L-selectin and E-selectin. PSGL-1 knockout mice have a significant defect in P-selectin mediated rolling, a complete absence of transient leukocyte–leukocyte interactions known as secondary tethering, and a moderate defect in E-selectin-dependent rolling. This suggests that PSGL-1 may be the only relevant L-selectin ligand on leukocytes, although other L-selectin ligands have been postulated. PSGL-1 is clearly the major P-selectin ligand, accounting for 80 to 90 percent of P-selectin mediated rolling. PSGL-1 appears to mediate leukocyte capture on E-selectin, but is not the E-selectin ligand responsible for the characteristic slow rolling.

Other proposed selectin ligands include mouse GlyCAM-1, which mediates L-selectin-dependent leukocyte rolling when coated on a solid substrate, but is normally secreted from high endothelial venules in secondary lymphatic organs, and in milk. No ortholog of GlyCAM-1 has been found in humans so far. The GlyCAM-1 knockout mouse showed no evidence of defective lymphocyte homing. E-selectin glycoprotein ligand-1 (ESL-1) was shown to bind E-selectin with high affinity, but most ESL-1 is present in the Golgi system and not accessible from the cell surface. CD24 is a GPI-linked glycoprotein that can function as a P-selectin ligand and can mediate rolling of cancer cells on P-selectin, but a function in leukocyte adhesion or rolling was not demonstrated. Other molecules on neutrophils including the integrin Mac-1 express sLex, but the function of these molecules as selectin ligands in leukocyte recruitment remains unclear. A number of other putative L-selectin ligands have been characterized in high endothelial venules, but it is unclear which of these molecules are physiologically relevant.

Integrins

Integrins are heterodimeric transmembrane molecules expressed by almost all cells except erythrocytes. Most if not all integrins exist in two conformations, active (ligand-binding) and inactive. In some integrins, dramatic changes in molecular shape have been demonstrated upon activation [5], but some of these changes may be secondary to isolation conditions. Although these and other results are suggestive of a conformational change, the exact nature of integrin activation remains an area of ongoing investigation. In addition to conformational activation, integrins cluster into groups upon cell activation, leading to a change in avidity of interaction with clustered ligands that may be present on interacting cells.

Integrins are classified by their (smaller) β chain. For leukocyte adhesion, β_1, β_2, β_3, and β_7 integrins are relevant. β_1 integrins are expressed on the surface of most cells including endothelial and smooth muscle cells. On memory lymphocytes, several β_1 integrins are expressed, with an increased expression after cell activation. $\alpha_4\beta_1$ integrin (VLA-4) is also expressed on monocytes and appears to be important in monocyte rolling, adhesion, and recruitment. $\alpha_4\beta_7$ is involved in lymphocyte homing to gut-associated tissues β_2 integrins are almost leukocyte-specific, the only exception being glial cells. All leukocytes express LFA-1 ($\alpha_L\beta_2$). Monocytes, neutrophils, and some effector lymphocytes also express Mac-1 ($\alpha_M\beta_2$). Dendritic cells express $\alpha_x\beta_2$, and some lymphocytes express $\alpha_d\beta_2$. Whereas LFA-1 serves important functions in leukocyte adhesion (see later discussion) and in forming the immunological synapse, Mac-1 is mostly engaged in phagocytic functions of macrophages and other phagocytes. The functions of $\alpha_x\beta_2$ and $\alpha_d\beta_2$ in leukocyte adhesion are unknown.

Immunoglobulins

Most cellular integrin ligands are immunoglobulins. Intercellular adhesion molecule-1 (ICAM-1) is a five-domain immunoglobulin-like molecule expressed on

endothelial cells, most lymphocytes, and most other cells after exposure to proinflammatory cytokines such as interleukin-1 (IL-1) or tumor necrosis factor-α (TNFα). ICAM-1 binds LFA-1 and Mac-1 through its first and third immunoglobulin domain, respectively. ICAM-2 contains two immunoglobulin domains and is expressed on resting endothelial cells and platelets. It also binds LFA-1 and Mac-1. Vascular cell adhesion molecule-1 (VCAM-1) is the main endothelial ligand for VLA-4 and is also expressed on inflamed smooth and cardiac muscle cells.

Another class of immunoglobulins is engaged in homophilic interactions. Platelet-endothelial adhesion molecule-1 (PECAM-1) is a six-domain immunoglobulin expressed by endothelial cells, where it localizes to interendothelial borders, and on platelets and most leukocytes. Antibodies to PECAM-1 inhibit monocyte and leukocyte transendothelial migration, but PECAM-1 knockout mice show a clear defect in transendothelial migration only on some backgrounds. The junctional adhesion molecule (JAM) family encompasses three members, JAM1, JAM2, and JAM3, that also localize to interendothelial borders and regulate endothelial monolayer permeability. In addition, JAM1 interacts with LFA-1, JAM2 (also called JAM-3) with Mac-1, and JAM3 (also called JAM-2) with VLA-4. The JAMs are likely involved in regulating transendothelial migration.

Physiology of Leukocyte–Endothelial Interactions

In postcapillary venules, leukocytes, endothelial cells, shear forces, and adhesion molecules interact to allow leukocyte recruitment to sites of inflammation and lymphocyte recruitment to secondary lymphatic organs. The physiological processes discussed next have been observed in many model tissues and probably apply to skeletal muscle, cardiac muscle, skin, and lymph nodes, but not to the liver, spleen, or lung. In these latter organs the physiology of leukocyte recruitment is not well understood.

Capture or Tethering

Leukocyte adhesion is initiated by leukocyte–endothelial, leukocyte–platelet, and leukocyte–leukocyte contact. Direct capture of leukocytes by endothelial cells is rarely observed, probably because the endothelial cells are covered by a thick glycocalyx layer (500 nm) that dwarfs the adhesion molecules, the longest of which (P-selectin) extends a mere 40 nm from the endothelial plasma membrane. In postcapillary venules, most leukocyte–endothelial interactions are initiated at the point where leukocytes enter the venules from capillaries. Since capillary diameters are smaller than leukocyte diameters in most organs, leukocytes must deform to pass, and in the process squeeze down the endothelial surface layer, which brings them in close contact with the endothelial adhesion molecules. Once engaged, these adhesion molecules support stable rolling, during which the endothelial surface layer is probably continuously flattened. The layer appears to recover after the leukocyte has passed. Most primary leukocyte capture or tethering is mediated by P-selectin on the endothelial cell and PSGL-1 on the leukocyte.

Capture in other parts of postcapillary venules is rare. The few interactions initiated along the venule and not at its beginning involve leukocytes attaching to already adherent or rolling leukocytes in a process called secondary capture or tethering. This process requires L-selectin on the flowing leukocytes and PSGL-1 (and possibly other molecules) on the adherent leukocytes. Sometimes, adherent or rolling leukocytes may leave behind fragments in the form of tethers or cytoplasts, which can nucleate more leukocyte rolling through an L-selectin-dependent process similar to secondary tethering. Endothelial E-selectin does not support much tethering, but its limited tethering function appears to require PSGL-1. Integrins and immunoglobulins have no known role in capture, but LFA-1 stabilizes adhesion events initiated by selectins in plate-and-cone model systems.

Rolling

Under mild inflammatory conditions, P-selectin is rapidly expressed on the surface of endothelial cells and supports stable neutrophil rolling at a characteristic velocity of 20 to 50 μm/sec. During rolling, molecular bonds form and break continuously, and the cell is rolled forward by the torque resulting from the blood flow until the next available bond is pulled taut. In ideal rolling, cells remain in continuous contact with the postcapillary endothelium without ever breaking free, but occasional hops and skips with reattachment are also observed. The velocity of neutrophil, but not lymphocyte, rolling is regulated by proteolytic cleavage of L-selectin from the leukocyte surface.

Lymphocyte rolling in high endothelial venules of the inguinal lymph node, Peyer's patches, and probably other lymphatic organs is achieved by transient L-selectin binding to sulfated and glycosylated endothelial ligands. Although early studies identified GlyCAM-1 and CD34 as potential L-selectin ligands, later studies in gene-targeted mice did not confirm this. Potential L-selectin ligands relevant for rolling include podocalyxin and an incompletely defined molecule called sgp200. In mesenteric lymph nodes, interaction of $\alpha_4\beta_7$ integrin on lymphocytes with MAdCAM-1 on endothelial cells also contributes to rolling.

When inflammatory conditions persist, for example, in the presence of TNFα, E-selectin is also expressed on endothelial cells. E-selectin supports rolling at a markedly reduced velocity of about 5 μm/sec by binding through an unknown leukocyte ligand distinct from PSGL-1. This ligand requires sialylation by sialyl transferase 3-Gal-IV for full functionality. E-selectin engagement may also serve to activate rolling neutrophils.

During severe inflammation induced by TNFα or other cytokines, the leukocyte integrins participate in the rolling process, presumably by engaging in transient bonds with

ligands on endothelial cells [6]. Specifically, Mac-1 has been shown to engage ICAM-1 during rolling, LFA-1 engages an unknown ligand other than ICAM-1 or ICAM-2 [6a]. There is a strong synergy between E-selectin and β_2 integrins in leukocyte rolling [6] so that in the absence of both almost no rolling occurs, and leukocyte recruitment is severely compromised.

Arrest

Rolling leukocytes must arrest to become firmly adherent. Interestingly, this arrest mechanism is fundamentally different for neutrophils and lymphocytes [7]. Lymphocyte arrest was studied in postcapillary venules of Peyer's patches and lymph nodes. It requires activation by the chemokine CCL21 (SLC) through the G-protein-coupled receptor CCR7. In flow chamber systems, CXCL12 (SDF-1) interacting with its receptor CXCR4 has also been shown to mediate arrest of lymphocytes and monocytes. In large blood vessels such as the carotid artery, monocyte arrest is mediated by CXCL1 (Gro-α) binding to its receptor CXCR2 and by CCL5 (RANTES) binding to CCR1,3,5 or a combination thereof.

For neutrophils, the arrest situation is much less clear. Although the textbook paradigm proposes activation through chemokines, and there are plenty of chemokines immobilized on inflamed endothelial cells and at least two relevant chemokine receptors, CXCR1 and 2 (only CXCR2 in mice) expressed on resting neutrophils. Recently, CXCR2 was identified as a ventrophil arrest chemokine receptor in postcapillary venules [8]. Neutrophils roll for a long time (1 to 3 minutes) and distance (several hundred micrometers), apparently scanning the endothelial surface for activating signals, before they arrest. This is in contrast to lymphocyte, which arrest within less than a second of activation [9]. The difference may be found in other activating signals that neutrophils, but not lymphocytes, may receive while rolling. Most prominently, such signals have been shown to emerge from engagement by E-selectin, P-selectin, and L-selectin.

Transendothelial Migration

Transendothelial migration proceeds through interendothelial clefts and through the body of endothelial cells (transcellular). The molecular requirements for each pathway are likely different. β_2 integrins such as LFA-1 and Mac-1 have long been known to be required for transendothelial migration. Recent evidence suggests that they bind junctional adhesion molecules. Certainly, transendothelial migration requires an active participation by endothelial cells, because it can be blocked by chelating intracellular free calcium or by blocking other signaling pathways. Transendothelial migration appears to involve retraction of vascular endothelial (VE)-cadherin. Another candidate molecule possibly involved in transendothelial migration is PECAM-1. Antibody blockade blocks transmigration, possibly by endothelial signaling, and PECAM-1-deficient mice have a significant defect in transendothelial migration.

Migration in the Tissue

Transmigrated neutrophils (and possibly other leukocytes, although this has not been investigated) acquire a different phenotype after transmigration. They express $\alpha_4\beta_1$, $\alpha_2\beta_1$, $\alpha_6\beta_1$, and other β_1 integrins on their surfaces that enable them to engage extravascular matrix components. For migration, $\alpha_2\beta_1$ appears to be most important.

Unresolved Questions

Postcapillary venules are formidable machines for leukocyte recruitment. More than 90 percent of all neutrophils in capillaries begin rolling in postcapillary venules, and more than 90 percent of rolling leukocytes (neutrophils) arrest successfully in cytokine-activated venules. Yet, the overall extraction efficiency during inflammation is less than 50 percent, suggesting that some arresting neutrophils may detach again, or that transmigration may be inefficient. This process is not understood at the quantitative level. The role of the endothelial surface glycocalyx is just beginning to be explored. Rolling, arrest, and transmigration of many lymphocyte subsets including activated Th1 and Th2 CD4 helper cells, CD8 cytotoxic cells, natural killer cells, γd T cells, and NKT cells have not been studied in vivo. Very little is known about eosinophil and basophil recruitment and the resolution of inflammation, a process that likely also involves cell interactions in postcapillary venules. Finally, the mechanisms mentioned previously are valid for some tissues, but not the lungs, liver, spleen, kidney, or brain. Suitable intravital microscopy systems and other models need to be developed to address these issues.

Capsule Biography

Dr. Ley has headed the Cardiovascular Research Center at the University of Virginia since 2001 and was the winner of the 1986 Abbott Microcirculation Award and the 2001 Curt A. Wiederhielm Award of the Microcirculatory Society. His laboratory primarily focuses on inflammatory processes in the microcirculation, in atherosclerosis and inflammatory bowel disease. His work is supported by grants from the NIH.

CHAPTER 51

Cell Adhesion Molecules: Structure, Function, Organization, and Role in Leukocyte Trafficking through the Lung

[1]Lina H.K. Lim and [2]Bruce S. Bochner

[1]Department of Physiology, National University of Singapore, Singapore
[2]Department of Medicine, Division of Allergy and Clinical Immunology, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Introduction

The endothelial cells (ECs) lining the walls of blood vessels in the microcirculation have a number of important functions. These include contributions to tissue structure and growth, and mediation of leukocyte recruitment from the circulation into the tissue, either for homeostasis or during inflammation. ECs can express many structures on their luminal surfaces including adhesion molecules (AMs) that are key players in leukocyte infiltration from the circulation to the tissue. This chapter will focus on the description of AMs and their ligands that mediate leukocyte-EC circulating interactions, relating to cell recruitment. Further, it will address tissue-specific expression of AMs and their related functions, particularly in the lung and pulmonary circulation [1].

General Dynamic Events Leading to Leukocyte Migration

Leukocyte recruitment from the blood into tissue sites of inflammation involves initial contact with the vascular endothelium under shear flow. Leukocytes in the circulation generally passage harmlessly through in the center stream of the vessel, where the velocity is greatest. Diffusive forces caused by the microcirculatory network (increasing diameters from the capillary to the venule) allow smaller, faster erythrocytes to pass the more slowly moving leukocytes, driving them toward the vascular wall. This encourages leukocyte–endothelial interactions, resulting in rolling, where leukocytes move more slowly than flowing erythrocytes. Under these conditions, leukocyte rolling velocities on postcapillary venules are reduced to approximately 10 μm/sec. Leukocytes can then overcome shear forces and attach to the endothelium through a sequence of adhesive events, mediated by specific AMs present on both the leukocyte and the endothelium. Subsequently, transmigration across the EC can occur, followed by further migration through the basement membrane and into the surrounding interstitium (Figure 1).

Leukocytes generally do not interact with the endothelium on the arteriolar wall, but adhere and migrate at the site of the postcapillary venule. The diffusive forces and shear rates created through the microvascular network can partly explain this typical location of leukocyte extravasation. However, arteriolar and venular ECs exposed to the same shear rates in vitro demonstrated dramatically different leukocyte–EC interactions and adhesion properties, indicating that shear forces alone are not enough to sustain leukocyte trafficking. Venular ECs are specialized in supporting

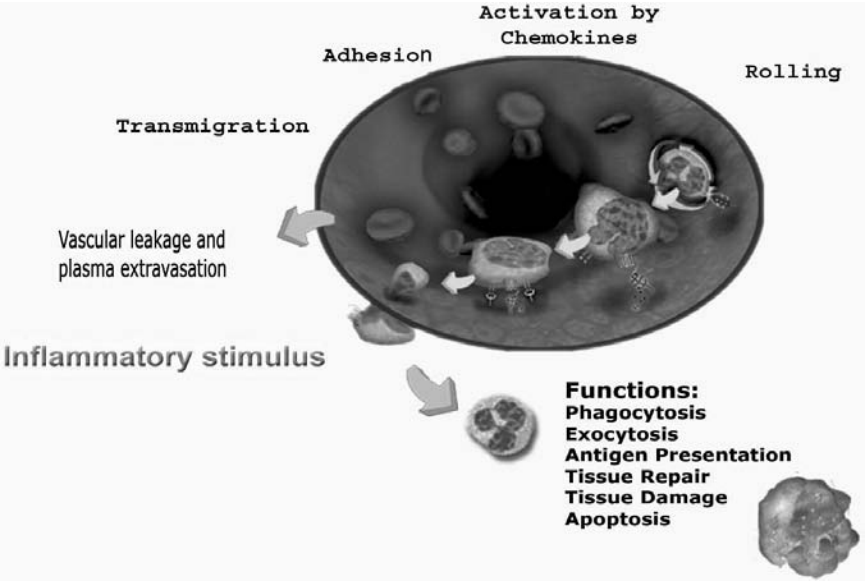

Figure 1 General mechanisms involved in leukocyte trafficking in the microcirculation. Shown is a schematic representation of the multistep paradigm of leukocyte recruitment. Leukocytes undergo rolling and activation by EC-displayed chemokines, followed by adhesion onto and transmigration across the endothelium to perform their extravascular functions. Illustration by A. K. Khaw. (see color insert)

leukocyte adhesion, distinctly different from the arteriolar ECs, because of particular AMs (e.g., E-selectin) located exclusively on the venular endothelium. In addition, lymphocytes exit the circulation and enter lymph nodes through specialized high endothelial venules that express their own unique, specific AMs for lymphocyte homing.

Techniques Used to Observe Leukocyte Trafficking

Many indirect and endpoint experimental systems have been used to study inflammation and leukocyte infiltration, such as lavages and histology. However, these do not serve to determine the sequences and events leading to leukocyte extravasation. Consequently, a state-of-the-art in vivo technique, known as intravital microscopy, was established to this end, and provides direct visual observation of living circulation in vivo (e.g., in mice, rats, guinea pigs, hamsters, bats and cats). Here, all the events of leukocyte trafficking, that is, rolling, adhesion, and transmigration through the vascular endothelium, can be visualized in real time. Furthermore, the development of in vitro rolling assays, exerting physiologically relevant shear forces on leukocytes over a layer of ECs, allows intricate dissection of the molecules and mediators involved in endothelial activation and leukocyte recruitment. Further, the relative importance of all the AMs involved in leukocyte recruitment has been demonstrated using blocking reagents (e.g., antibodies and small molecule antagonists), gene targeting, or knockout animals. However, because of compensatory mechanisms, overlapping functions and regulatory processes, data from knockout (double or triple) animals need to be more carefully examined.

Endothelial AMs Involved in Leukocyte Trafficking

The AMs found on vascular ECs, with their corresponding ligands on the leukocyte, are usually distinguished by their contribution to rolling or firm adhesion (see Figure 2) [2]. The selectins (E-selectin, P-selectin) on the EC, and L-selectin on the leukocyte, are involved in initial tethering and rolling, while members of the immunoglobulin (Ig) superfamily of AMs, such as intercellular adhesion molecule-1 (ICAM-1) and cadherins, are mainly involved in adhesion and migration, respectively. However, it is possible that under certain circumstances, ICAMs and integrins can mediate rolling. The time course and magnitude of EC AM expression coordinates the recruitment of leukocytes to sites of inflammation. Thus, the rapid recruitment of rolling leukocytes results from L-selectin activation on leukocytes and rapid mobilization of preformed P-selectin to the EC surface. Leukocyte adhesion can also be fast because of the activation of β_2-integrins on rolling leukocytes, which can interact with constitutively expressed ICAM-1, leading to firm adhesion and subsequent migration (see Figure 1). However, tissue-specific adhesion characteristics are apparent, such as in the liver sinusoidal microcirculation and the lung pulmonary circulation, where selectins are not required for leukocyte recruitment.

Rolling

Rolling is a transitory process that occurs in both noninflamed and inflamed vessels. As a result, many leukocytes "patrolling" the microvasculature will come into brief

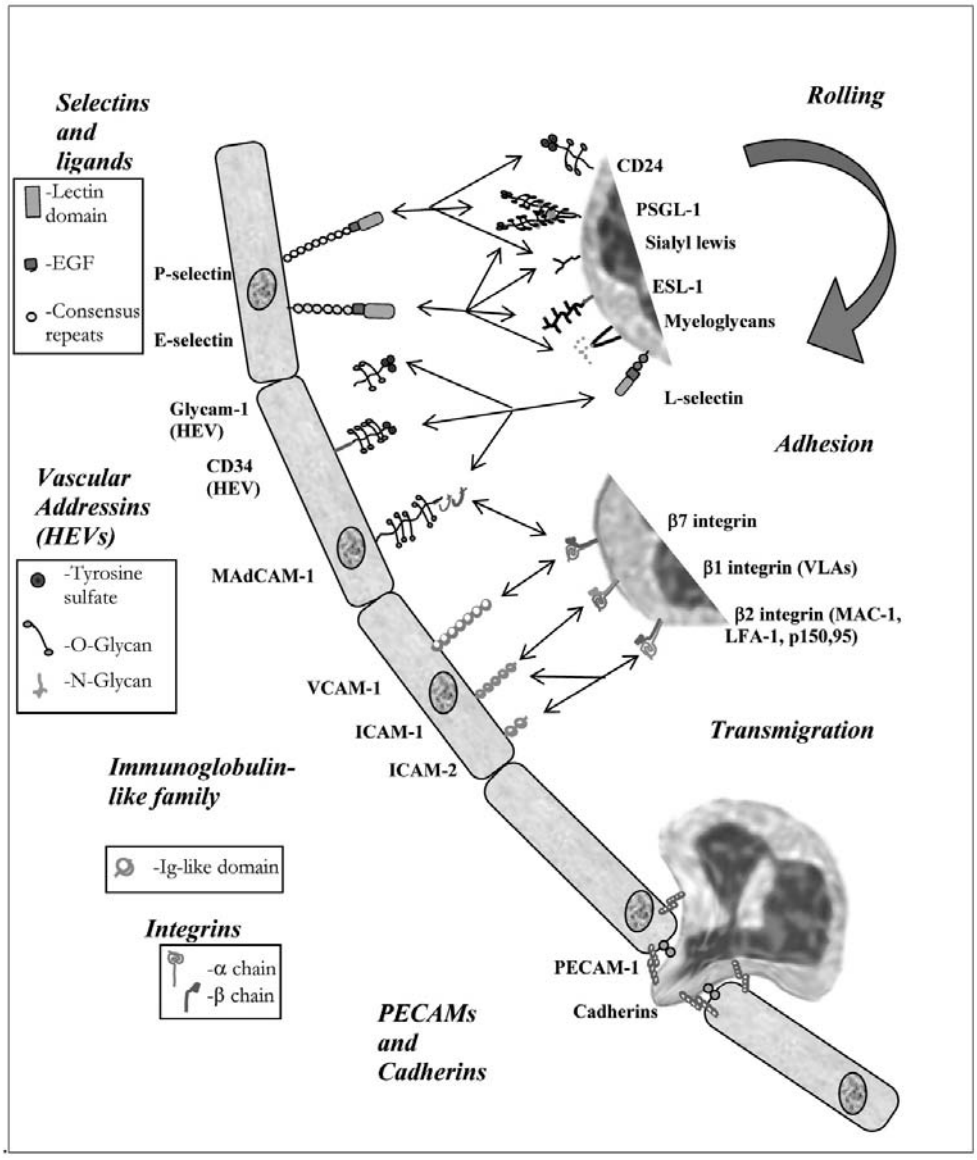

Figure 2 Endothelial cell adhesion molecules and counterligands on leukocytes involved in cell trafficking. Activated EC express selectins that can bind to their carbohydrate receptors to allow leukocyte rolling under physiologic shear forces. Addressins expressed on high endothelial venules (HEVs) in lymph node vessels are expressed for lymphocyte homing; their peripheral vascular counterparts are less well defined. If activation occurs, leukocytes adhere to the endothelium via Ig-like superfamily proteins and integrins. Transendothelial migration is regulated by PECAM-1, cadherins, and other structures. (see color insert)

contact with the endothelium. Sometimes, rolling leukocytes interact with other attached leukocytes in a process known as tethering. Approximately 80 percent of these cells will gently roll and detach from the endothelium and rejoin the circulation, while the remainder will roll more slowly and may adhere and flatten onto the endothelium. The first response to inflammatory stimuli that can be observed using intravital microscopy is an increase in the number of rolling cells, with a concurrent reduction in leukocyte velocity. Leukocytes will integrate chemokine and other signals on the EC surface while rolling along the endothelium until they reach a critical level of activation, resulting in firm adhesion.

SELECTINS AND THEIR LIGANDS

The selectins are C-type lectins characterized by the presence of an N-terminal calcium-dependent carbohydrate recognition domain [3]. They are single-chain membrane glycoproteins that recognize counter-ligands usually containing sialylated and fucosylated carbohydrate residues, such as sialyl lewis x (Figure 2). There are three selectin AMs important in mediating initial tethering and rolling. Two selectins (E-selectin and P-selectin) are found on ECs, and one, L-selectin, is found on leukocytes.

L-selectin (Leukocyte-selectin) is involved mainly in the tethering of leukocytes to the endothelial surface, and proteolytic loss of expression of L-selectin, especially on granu-

locytes, occurs in conjunction with the activation of other AMs such as integrins. This soluble L-selectin can be detected in the serum and can competitively bind to endothelial ligands, blocking the interactions with leukocyte-bound L-selectin. The interaction of L-selectin with the EC is short-lived and usually with one of several ligands, such as CD34, mucosal addressins (e.g., MAdCAM-1), or vascular addressins.

P-selectin (platelet-selectin), originally named granule-external membrane protein, is a 140-kDa glycoprotein constitutively expressed in α-granules of platelets and the Weibel-Palade bodies of ECs. P-selectin is thought to be the predominant AM responsible for the rolling phase of the leukocyte adhesion cascade. Stimulation of ECs with inflammatory mediators such as histamine and thrombin results in translocation and expression of P-selectin on the cell surface within minutes. Reactive oxygen species (ROS), sulfidopeptide leukotrienes, and complement products can also induce fast mobilization of P-selectin onto the EC surface. P-selectin surface expression is transient and is recycled by reinternalization. P-selectin expression can also be transcriptionally regulated by cytokines such as interleukin-4 (IL-4) and IL-13. Thus, it is possible that P-selectin is important in Th2-mediated inflammatory diseases. In contrast, tumor necrosis factor (TNF), IL-1, and lipopolysaccharide (LPS), which induce other AMs on ECs, do not induce P-selectin gene transcription or expression. Like all the selectins, P-selectin binds to sialyl lewis x molecules but more specifically binds to P-selectin glycoprotein ligand-1 (*PSGL-1*), a homodimeric structure and member of the sialomucin family of AMs found on all circulating leukocytes. P-selectin can also bind to CD24 and other ligands. The interactions between P-selectin and PSGL-1 cause leukocyte–EC contacts and rolling along the venular endothelium. The P-selectin–EC associations are longer than the L-selectin–EC interactions and result in slower leukocyte rolling velocities. The signal transduction pathways that follow P-selectin binding to its ligand involve the activation of mitogen-activated kinases, Src kinases, and increases in intracellular calcium. All these pathways can lead to other downstream events such as integrin activation, shape change, and further ROS production.

E-selectin (endothelial-selectin) expression is protein synthesis dependent, occurring on the cell surface approximately 4 hours after activation with TNF, IL-1, or LPS. Eosinophils and neutrophils bind equally well to P-selectin, whereas eosinophils form fewer primary tethers to E-selectin. E-selectin has similar, possibly redundant functions to P-selectin, but more importantly, may be important in converting rollers to adherent cells, as E-selectin mediates even slower rolling than P-selectin. The off-rate of E-selectin is similar to that of P-selectin; thus, it is likely that E-selectin or its ligand is more highly expressed than P-selectin and PSGL-1. In addition, because its peak expression is around 4 hours, E-selectin could functionally support rolling when P-selectin expression is reduced or when P-selectin is internalized. E-selectin is capable of binding to PSGL-1 and other sialic acid–containing glycoproteins, but the primary E-selectin ligands in humans are glycolipid structures termed myeloglycans. In mice, the identified ligand of E-selectin is a glycoprotein known as E-selectin ligand-1 (ESL–1).

Studies in knockout animals have revealed the importance of L-selectin and P-selectin in the initial induction of rolling, while all selectins can support stable rolling. However, in E-selectin and P-selectin double-deficient mice, L-selectin can sufficiently produce rolling that results in activation and adhesion, suggesting that overlap and redundancy occur in selectin function. Interestingly, E-selectin and β_2 integrin AMs (together with ICAMs) cooperate to control the time that a leukocyte takes to roll and firmly adhere. Further, these double-deficient mice exhibit signs of early lethality. This suggests that E-selectin operates "downstream" from P-selectin, more toward the firm adhesion step of the cascade.

In summary, selectins are either constitutively expressed, or inducible with inflammatory mediator or cytokine exposure. These AMs all play roles in early stages of extravasation involving tethering and rolling, with varying degrees of attachment. This allows temporary interaction of patrolling leukocytes in the circulation with vascular ECs, allowing them to react to stimuli (e.g., chemokines) presented on the EC surface. This, in turn, causes leukocyte activation and subsequent extravasation.

ADDRESSINS

In secondary lymphoid tissues (such as lymph nodes and Peyer's patches), the entry site for naive T and B lymphocytes is known as the High Endothelial Venule (HEV), because of its cuboidal shape. The ECs of HEV express specific AMs that allow lymphocyte homing into the lymphoid tissue, while other cells, such as granulocytes, may enter the HEV but do not stop. Murine HEVs selectively bind to an antibody, MECA-79, that recognizes a carbohydrate epitope not found on ECs of postcapillary venules or large vessels in the spleen or thymus. These carbohydrate epitopes bind to L-selectin, are partly responsible for the tissue-specific trafficking of lymphocytes, and are called vascular addressins [4, 5]. The peripheral node addressins (PNAds) include GlyCAM-1 (glycosylation-dependent cell AM), CD34, podocalyxin, and Sgp200, whereas mucosal or mesenteric addressin is thought to be MAdCAM-1 (Mucosal Addressin cell AM-1). The adhesion molecules are important in the homing of lymphocytes and dendritic cells to lymphoid tissues for antigen presentation.

Firm Adhesion

Firm adhesion of leukocytes on the vascular endothelium occurs after the activation of leukocyte AMs by chemokines and other stimuli presented on the EC surface. All firmly adherent leukocytes are exclusively recruited from the rolling pool. The AMs involved in firm adhesion are mainly the members of the Ig superfamily of AMs and their integrin ligands.

IG SUPERFAMILY OF AMS

This is a wide family of AMs, consisting of Ig-like domains characterized by intrachain disulfide bonds. Together with their ligand counterparts, they play major roles in leukocyte adhesion and the regulation of firm adhesion. Members include ICAM (intercellular AM)-1, -2, and -3 and VCAM-1 (vascular cell AM-1).

ICAM-1 is found constitutively at low levels on the EC surface, but is upregulated upon exposure to inflammatory cytokines (e.g., TNF, IFN-γ, and IL-1) with peak expression after about 24 hours. Of note, treatment of ECs with IFN-γ selectively increases the expression of ICAM-1, with no effect on other AMs. ICAM-1 contains five Ig-like extracellular domains, where the first Ig-like domain (on the amino-terminal end) is the recognition site for fibrinogen, an extracellular matrix protein, and the integrin lymphocyte associated function antigen (LFA-1 or CD11a/CD18). The third Ig-like domain recognizes another integrin, macrophage antigen-1 (Mac-1 or CD11b/CD18). Mac-1, found on granulocytes and monocytes, binds ICAM-1 with high affinity. As described, LFA-1 can also bind to ICAM-1, but with lower affinity than Mac-1. ICAM-1 has another interesting function, in that it is the exploited receptor of most strains of rhinovirus and the malarial parasite. The ligation of ICAM-1 can cause structural changes in junctional EC cytoskeleton proteins without causing EC injury or retraction. These structural proteins have been shown to dissociate within minutes of leukocyte–EC adhesion. This could be linked to subsequent events in transmigration.

ICAM-2 is a truncated form of ICAM-1, with only two Ig-like domains. LFA-1 binds to ICAM-2 with higher affinity than to ICAM-1. ICAM-2 is highly and constitutively expressed on ECs, without further expression after stimulation. It is found preferentially at endothelial borders, and thus could be important in transmigration. *ICAM-3* is found on resting leukocytes, but can be induced in ECs. It contains five Ig-like extracellular domains, similar to ICAM-1, and binds to LFA-1 and $\alpha d\beta_2$, another β_2 integrin found on most leukocytes.

VCAM-1 is found at very low levels, if at all, on nonactivated ECs, but is upregulated substantially after long-term exposure to cytokines. It is expressed on the surface of IL-1 and TNF activated EC, and similar to the ICAMs, binds to integrins. However, it binds to a different class of integrins with β_1 and β_7 subunits. The most common ligand for the binding of VCAM-1 is very late antigen-4 (VLA-4, CD49d/CD29), found on eosinophils, basophils, mast cells, lymphocytes, and monocytes, but not neutrophils. VLA-4-VCAM-1 binding has been shown to mediate leukocyte rolling and adhesion. In particular, VCAM-1 ligation is essential for eosinophil and monocyte migration, and exposure of ECs to the Th2 dependent cytokines IL-4 and IL-13 (and TNF and IL-1 synergistically) selectively increases VCAM-1 expression, indicating the potential importance of VCAM-1 in Th2-mediated diseases such as allergy and asthma.

In summary, the Ig superfamily of adhesion molecules and integrins plays an extremely important role in the adhesion step of the recruitment cascade. ICAM-1 is important in adhesion of essentially all leukocytes, while VCAM-1 is the Ig-like adhesion molecule involved in adhesion of all leukocytes except neutrophils.

Transmigration

The final step of cell recruitment involves transmigration between adjacent ECs at tricellular junctions, a pause in the wall, and subsequent penetration through the basement membrane. During the adhesion phase, a disruption of EC-cadherin complexes occurs, inducing a loss of lateral junction localization, leading to migration between ECs [6]. *PECAM-1* (platelet endothelial cell adhesion molecule-1, CD31) is another member of the Ig super family and is vitally important in the transmigration step of neutrophil recruitment. It has six Ig-like domains as well as immunoreceptor tyrosine-based inhibitory motifs. PECAM-1 is in especially high density at the gap junction area of ECs, but is evenly distributed on platelets and leukocytes. Because of its concentration at the intercellular junctions of the vascular endothelium, it is thought to be a crucial AM to guide adherent cells to the migration site. PECAM-1 mediates endothelial transmigration through binding to itself (homophilic) or to other ligands (glycosaminoglycans such as CD44). PECAM-1 is also involved in the migration through the basement membrane and subendothelial matrix. PECAM-1 is critical for neutrophil (but not eosinophil) transendothelial migration, and the first Ig-like domain is important for this step. Cells treated with anti-PECAM-1 antibodies, or PECAM-IgG constructs comprising domain 1, arrest on ECs but do not transmigrate. Furthermore, the 6th Ig-like domain is thought to be important in the migration across the basement membrane. In this case, as there is no PECAM-1 expressed in the basement membrane, PECAM-1 is thought to bind to an as yet unidentified structure in the basal lamina. It may be possible that PECAM-1 is more involved in migration across the basement membrane, as leukocytes from PECAM-1–deficient mice do migrate through ECs but are delayed in their migration across the basement membrane. Altogether the process of leukocyte recruitment from the circulation into the tissue involves many AMs on the leukocyte as well as the EC. Thus, the process requires a step-by-step activation and deactivation (or deadhesion) of each and every constituent for successful leukocyte extravasation.

Tissue-Specific Expression of AMs in the Lung Microvasculature

The aforementioned sequence of events and mechanisms leading to the transmigration of leukocytes out of the circulation has been shown to occur in vitro and in vivo in tissues

such as the mesentery. However, several recent studies have shown differences in leukocyte trafficking characteristics in the pulmonary circulation when compared to the systemic circulation [1]. The location of leukocyte extravasation and the requirements for AM expression have also proven to be different, possibly because of the unique structural features of the lung microcirculation [7]. This suggests that tissue-specific leukocyte trafficking and differential expression of AMs exist in the lung, and thus, the mechanisms of leukocyte trafficking must not be thought of as a generalized set of occurrences. We have recently developed a rat model of intravital microscopy in the airway circulation or tracheal microcirculation [8] and demonstrated that leukocyte recruitment in the circulation of the trachea is similar to the systemic circulation. Other intravital microscopy techniques to study microvessel behavior and leukocyte trafficking in the pulmonary circulation have been created. One utilized an implanted window in the thoracic wall of rabbits and dogs. In addition, transplantation of neonatal lung into skin folds of nude mice has been used to examine leukocyte recruitment in revascularized lung tissues [9].

Margination and Migration in the Pulmonary Circulation

In the systemic circulation of the airways and other tissues, migration occurs in postcapillary venules, following the typical sequence of leukocyte trafficking described previously. However, several distinct characteristics are seen in the pulmonary circulation. For example, leukocytes marginate and transmigrate in alveolar capillaries, rather than the normal site of migration, the postcapillary venule. Many leukocyte–EC interactions take place in the pulmonary capillary bed via a process known as sequestration. Here, the network consists of capillary segments that connect several alveolar walls and generally contain many more leukocytes compared to other tissue vascular beds. In fact, the concentration of leukocytes (neutrophils or polymorphonuclear [PMN] cells in this case) in pulmonary capillary blood is 35 to 100 times more than that of systemic vessels. This could be an active process, or simply due to small capillary diameters (2 to 5 μm). Leukocytes are approximately 8 μm in diameter, so they would need to deform to squeeze through such small vessels, taking more time to travel through this microcirculation. Although selectin-mediated rolling occurs in pulmonary postcapillary venules, most migrated neutrophils (97%) are found in the capillary network, where rolling does not occur, as the leukocyte arrests without rolling because of the size of the capillaries. Similarly, leukocytes transmigrate out of the capillary network in the lung, because of their slow transit and interaction with the capillary EC, possibly independent of PECAM-1.

Selectins

Due to the small diameters of pulmonary capillaries, arrest and migration in the pulmonary circulation can occur without rolling. P-selectin is expressed on pulmonary venular and arteriolar EC, but not capillary EC in rabbits, whereas in the rat, P-selectin is completely nonexpressed. Thus, it can be proposed that in this case, selectins are not required for leukocyte trafficking in the pulmonary circulation. Further, from experiments using E-selectin and P-selectin-deficient mice, pulmonary migration to *Streptococcus pneumoniae*, a Gram-positive bacterium (see next section), was increased, indicating that selectin expression actually suppresses leukocyte migration out of the pulmonary circulation. This contrasts with other, allergen-driven cell recruitment models, where selectin deficiency or blockade reduces T cell and eosinophil recruitment. The depletion of L-selectin from neutrophils does not affect the rate and response of sequestration in the lung induced by complement fragments. This suggests that selectins may not be required for migration to Gram-positive bacteria. However, selectin-mediated processes are involved in migration to Gram-negative bacteria or endotoxin (*Escherichia coli*, LPS), where selectin deficiency protects against endotoxin-induced septicemia, lung injury, and death.

During acute lung injury, blockage of all selectins can result in approximately 40 percent inhibition of leukocyte infiltration and vascular permeability. High tidal volume ventilation activates lung microvessels in a P-selectin-dependent process. Furthermore, E-selectin is upregulated in lungs of fatal acute respiratory distress patients infected with Gram-negative bacteria. Thus the role of selectins in acute respiratory distress and acute lung injury appears somewhat variable depending on the inflammatory condition.

Ig Superfamily and Integrin Ligands

ICAM-1 is expressed at constitutively high levels on pulmonary capillary and venular ECs, and at low levels on ECs in the systemic circulation [10]. This could be one reason why activated leukocytes (with increased expression of activated β2 integrins) are sequestered in the lungs. However, pulmonary migration of granulocytes can occur independently of β2 integrins depending on the inflammatory stimuli. Using neutralizing antibodies to CD18, leukocyte migration from activation by Gram-negative bacteria (*Pseudomonas aeruginosa* and *E. coli*), IL-1, LPS, and phorbol esters can induce CD18-dependent lung migration pathways, involving ICAM-1, while Gram-positive bacteria (*S. pneumoniae*) and complement products induce CD18-independent pulmonary recruitment. Accordingly, ICAM-1 expression (as high as it is on pulmonary ECs) is further upregulated by Gram-negative bacteria and LPS, but not by Gram-positive bacteria in these animal models. Interestingly, expression of CD18 and L-selectin in neutrophils exposed to *E. coli* was altered only after migration and not while in the circulation. In contrast, in response to *S. pneumoniae*, CD18 and L-selectin levels were increased and reduced, respectively, before migration, indicating their involvement. In these cases, the expression and requirement for CD18 before and during migration is inversely corre-

lated and the limiting factor could be the increased expression of ICAM-1. In patient samples of sepsis-induced lung injury, ICAM-1 as well as VCAM-1 expression is highly upregulated. Hydrochloric acid instillation into the trachea, an animal model of gastric acid inspiration, causes lung injury and endothelial activation. It does not require CD18 for leukocyte accumulation, but subsequent lung injury and injury to other organs is CD18 dependent. It is possible that VCAM-1 or other AMs can be involved in Gram-positive bacterial infections. The mechanism underlying CD18-independent leukocyte recruitment in the pulmonary circulation is still unknown.

Migration in the Systemic Bronchial Circulation

Leukocyte trafficking and endothelial migration in the systemic circulation of the lungs is not well studied. Only 1 percent of the cardiac output is directed to the airway circulation to supply the central airways and bronchi. These vessels form a plexus network around the airways, supplied by the bronchial artery, sending branches into the muscle and submucosa. It remains unknown whether leukocyte infiltration close to the bronchi is occurring from the bronchial circulation or the pulmonary circulation. It seems unlikely that tissue-infiltrating leukocytes such as eosinophils found in and around the bronchi in airway conditions such as asthma exit through the pulmonary circulation. Thus, it is important to know the recruitment properties of this circulation. As mentioned previously, we have developed a model of intravital microscopy in the upper airways to address this issue [8]. Although this model uses the tracheal circulation, the function and regulation of tracheal muscle and tissue mirror the smaller airways. Leukocyte–endothelial rolling and adhesion induced by Gram-negative bacterial LPS and the leukocyte-activating bacterial peptide fMLP (formyl-methionyl-leucyl-phenylalanine) occurred in postcapillary venules, with parameters similar to that of the systemic circulation. Furthermore, using the same model, high-pressure mechanical ventilation induced EC activation and leukocyte recruitment in tracheal microvessels, which was sensitive to selectin blockage. In a lung transplant model [9], where intravital microscopy was done in revascularized vessels of the lung, TNF-induced leukocyte rolling and adhesion occurred in the venules and arterioles, and this, too, was dependent on selectins. It was interesting that no arrest or sequestration was seen in the capillaries. However, rolling leukocytes in the postcapillary venules were elongated, perhaps because of shape change from traversing through the capillary network. It is possible that because these are newly revascularized vessels, it may be a model of angiogenesis rather than pulmonary circulation per se. In any case, this indicates that selectins are likely important in the recruitment of leukocytes in the airways. Similarly, other studies have observed that lymphocyte homing to the bronchial endothelium is P-selectin-PSGL-1 mediated, and VCAM-1, E-selectin, and CD18 independent. Furthermore, strong expression of P-selectin and ICAM-1 was found on bronchial ECs, with low or negligible expression of E-selectin.

Summary

This review has described the general mechanisms involved in leukocyte recruitment, focusing on the important roles of AMs. Recruitment characteristics in the lung microcirculation have been outlined. The inflammatory stimuli and disease condition may play a role in the site and regulation of leukocyte recruitment and EC activation in the lungs. Various conditions that affect the central conducting airways may induce recruitment in the systemic airway circulation, while the pulmonary network may be more important in other more acute lung injuries from invading organisms, septicemia, or chemicals. The mechanisms of leukocyte recruitment in this circulation are not well elucidated, but it appears that the bronchial microvasculature is similar to other systemic microcirculation. This suggests CD18-dependent recruitment, with selectin-mediated rolling and transmigration across ECs in bronchial/tracheal vessels. This also indicates that the events leading to leukocyte infiltration from the bronchial systemic circulation may differ from those in the more well-studied pulmonary circulation. It is here where cells are sequestered without rolling, and CD18-independent migration occurs. It can be suggested that in the lung, two different endothelial phenotypes may exist, depending on the structure and function of the circulation they support, i.e., gaseous exchange or blood supply, for the pulmonary and airway circulation, respectively. Future studies should elucidate the differences between these two circulations in the same functioning organ, enhancing the understanding of the pathophysiology of lung disorders, and possibly validating novel targets to treat diseases that primarily affect the lungs.

Glossary

Adhesion molecule: A cell surface glycoprotein or glycolipid that functions in the interaction between cells or between cells and the extracellular matrix. Adhesion molecules are found on virtually all cell types.

Alveoli: The air sacs in the lungs where oxygen and carbon dioxide are exchanged between blood and inhaled air.

Bacterial endotoxin (LPS): A component of Gram-negative bacterial cell wall released from bacteria. Once released, it stimulates many inflammatory reactions.

Capillaries: The smallest of vessels, with the thinnest walls, where gas exchange takes place between the blood and the surrounding tissues.

Endothelial cells: These exist as a monolayer of cells lining the insides of blood vessels. They act together (endothelium) to form a selective barrier that regulates movement of cells, proteins, and fluids from the circulation to the tissue. They are also important in blood vessel growth, tissue repair, and coagulation.

Gram-negative bacteria: Bacteria characterized by two outer membranes that fail to stain with Gram's stain. Organisms include *E. coli*, *Salmonella*, and cholera.

Gram-positive bacteria: Bacteria characterized by two outer membranes that do stain with Gram's stain. Organisms include *Staphylococcus*, *Streptococcus*, and *Pneumococcus*.

Intravital microscopy: A technique used in live animals to directly observe the microcirculation of tissues in real time using video microscopy.

Leukocytes: Also known as white blood cells, these migratory cells function in immune surveillance and host defense.

Nude mice: Mice lacking thymus development and T-lymphocytes.

Polymorphonuclear cells (PMNs): Also called granulocytes, these are leukocytes with a characteristic multilobed nucleus and cytoplasmic granules. They can be classified as neutrophils, eosinophils, and basophils. Neutrophils are the most abundant circulating leukocyte important in responses to bacterial infections, whereas eosinophils and basophils are more rare in the circulation and important in allergic and parasitic diseases.

Pulmonary circulation: This is the circulation carrying blood from the heart to the lungs and back for oxygen and carbon dioxide exchange.

Systemic circulation: This is the circulation carrying blood from the heart to the whole body for oxygen consumption and back to the heart and lungs for reoxygenation.

Transgenic (or knockout) mice: These are mice with specific mutations (or deletions) and altered genetics used for study of specific gene function.

Lymphocyte recirculation and the localized recruitment of antigen-specific T cells to sites of inflammation are critical to the surveillance and effector functions of the immune system. A tightly regulated series of molecular interactions with the microvascular endothelium (extravasation) allows T lymphocytes to continuously recirculate from the bloodstream into lymphoid and nonlymphoid tissue scanning for their cognate antigen. During these frequent encounters the endothelium itself has the opportunity to display antigen to transiting T lymphocytes with the potential to modify their functions.

Regulation of T-Cell Trafficking by the Endothelium

The Multistep Paradigm of Lymphocyte Extravasation

Lymphocyte extravasation is initiated by transient interactions with the blood vessels through adhesion receptors including selectins and their ligands, members of the integrin superfamily, and the vascular hyaluronan-binding CD44. By virtue of these interactions T cells tether the vascular wall where they are exposed to chemokines (chemotactic cytokines), bound to the endothelial cell (EC) surface by glycosaminoglycans (GAGS). Chemokines trigger pertussis toxin–sensitive G-protein coupled receptors on the T cells. This "activation" event leads to conformational changes in the T-cell integrin adhesion molecules (including members of the β2 and β1 family of integrins, such as LFA-1 and VLA-4) that increase their affinity for their ligands. Chemokines also induce changes in the T cell shape (from round and villous to polarized), which create an ideal surface of interaction between T cells and ECs. As a consequence T cells flatten over and firmly adhere to the endothelium. Additional molecular interactions involving adhesion molecules (including integrins and junction adhesion molecules) and chemokines guide the migration of the adherent lymphocyte through the endothelial junctions (transendothelial migration or diapedesis). Some EC molecules such as CD31 appear to optimize the efficiency of this last step of the migratory process. A summary of the T cell–EC interactions leading to T-cell extravasation is provided in Figure 1. Together with intrinsic properties of the T cells (such as the high expression of certain adhesion molecules, as observed in memory T cells), signals mediated by these relatively well-characterized ligand–receptor interactions are likely to determine whether a T cell that is engaging in adhesive interactions with EC will eventually migrate into the underlying tissue.

T Lymphocyte Phenotype and Function is Modified By Transendothelial Migration

Once T cells have crossed the endothelial barrier, they remain localized for a variable length of time between the endothelial layer and the basal membrane and eventually enter the tissue. Tissue infiltration is a slow and complex process, which involves T-cell interactions with the basal membrane and the extracellular matrix and migration induced by tissue-derived chemokines. Thus, once a T cell has crossed the endothelial barrier and is committed to migration, it undergoes a genetic reprogramming leading to functional changes including induction of matrix metalloproteinase (MMP) expression, and responsiveness to tissue-derived chemoattractants that enable them to invade the

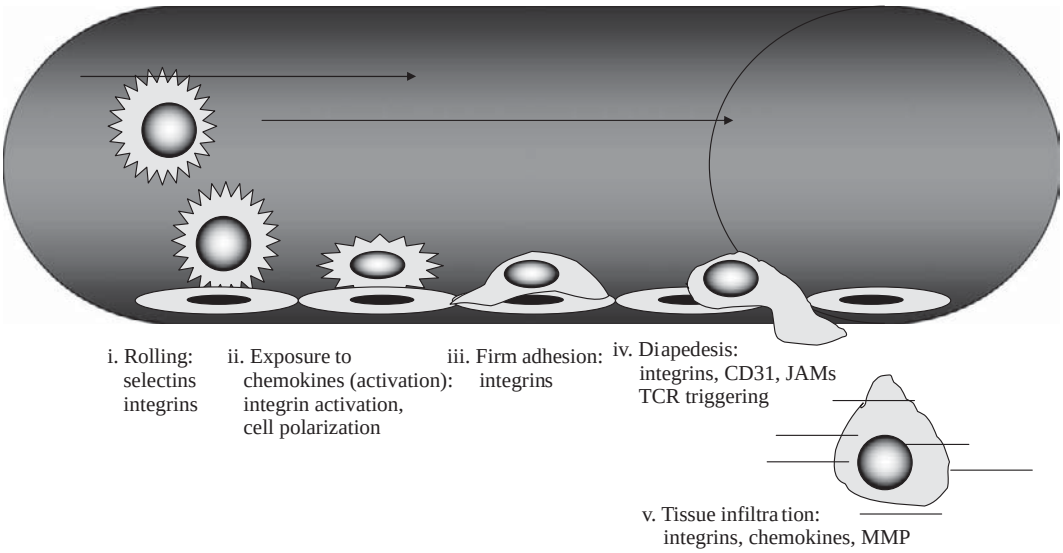

Figure 1 The multistep paradigm of lymphocyte extravasation. T cells are first engaged in selectin-mediated transient interactions with the endothelium. In this way, they become exposed to endothelium-bound chemokines. This induces increased affinity of T-cell integrin for their endothelial ligands and causes T-cell polarization (i.e., change of shape and redistribution of surface molecules). T cells thus firmly adhere to the endothelium and eventually migrate through the endothelial cell junctions. Once in the tissue, T lymphocytes respond to stimuli that lead them to the site of inflammation. (see color insert)

tissue and reach the inflammatory site. It is likely that the endothelium itself delivers the necessary signals to transiting T cells, which favor T-cell motility and further infiltration of the underlying tissue. In this context, upregulation of certain molecules (including at the transcriptional level), such as CD86 and CD69, has been observed in T cells following noncognate interactions with the EC. These changes are likely to help further activation of the T cells once they have reached their antigenic sites within the tissue. In line with these studies, we have observed that T-cell transendothelial migration is accompanied by activation of the transcription factor AP-1, without induction of NF-κB. This genetic reprogramming correlates with the upregulation of certain adhesion (LFA-1, VLA-4), activation (CD69), and costimulatory (CD86) receptors and with increased T-cell motility and antigen responsiveness to tissue invasiveness. These effects were dependent on $\alpha_L\beta_2$ integrin/CD54 interactions during adhesion to the endothelium.

Thus, T-cell extravasation is accompanied by phenotypic and functional changes induced by the interactions with the EC, which favor tissue infiltration by T cells and their further activation once they reach the antigenic site. The nature of the endothelium-derived signals that induces "proinvasive" genetic reprogramming in T lymphocytes and the molecular changes required for tissue invasion by T cells remain poorly characterized.

Recirculation of Memory and Naive T Cells and Tissue-Specific Homing

The ability of T lymphocytes to reach antigenic tissue is regulated at different levels. Naive T cells recirculate through secondary lymphoid organs (spleen, lymph nodes, and Peyer's patches) through the expression of L-selectin (CD62L) and the chemokine receptor CCR7. Expression of their ligand is restricted to the microvasculature of secondary lymphoid organs. Following antigen encounter and activation in the lymphoid tissues, changes are induced in the array of surface-expressed adhesion receptors, which allow effector memory T-cell access into nonlymphoid tissue. These changes include loss of CD62L and CCR7 expression and upregulation of other adhesion (LFA-1) and chemokine (CXCR4, CCR5) receptors. It has recently been described that a subset of memory T cells (central memory T cells) retain expression of the chemokine receptor CCR7 and the ability to traffic through secondary lymphoid organs. Finally, a third subset of memory T lymphocytes differentiates following priming in the lymph nodes, namely the follicular homing T cells, which specialize in delivering help to B cells. These cells are retained in the lymphoid tissue characterized by the expression of the chemokine receptor CXCR5, which mediates their recruitment in the B cell areas of the lymph node.

Memory and effector T cells generally display selective tropism for specific peripheral tissue such as the skin or the gut (tissue-specific homing). This is mediated by the use of different combinations of adhesion and chemokine receptors (molecular "area code") at distinct anatomical sites that facilitate the T lymphocyte return to that site. For example, high-level expression of $\alpha4\beta7$ integrin, whose ligand mucosal addressin cell adhesion molecule (MAdCAM)-1 is expressed on postcapillary venules in the intestinal lamina propria, targets one population of memory T cells to this site. In addition, a subset of these intestinal $\alpha4\beta7$hi cells also expresses CCR9, the specific receptor for the

chemokine CCL25, or thymus-expressed chemokine (TECK), which is produced by small intestinal epithelium. In contrast, memory and effector cell recruitment to inflamed skin requires expression of lymphocyte surface ligands for vascular selectins, such as the E-selectin ligand cutaneous lymphocyte antigen (CLA) in humans and P-selectin ligand in mice. In addition, skin-homing T cells express CCR4, the specific receptor for the chemokine CCL17, or thymus and activation-regulated chemokine (TARC), expressed by keratinocytes. T cells acquire these receptors during priming in the lymphoid tissue. The genetic reprogramming leading to the acquisition of a molecular area code is determined by the local lymphoid organ microenvironment.

Immunogenicity of the Microvascular Endothelium

The properties of endothelial cells as antigen-presenting cells are likely to be important during local inflammatory responses and following transplantation of vascularized tissues, where EC are the first alloantigen-bearing target encountered by transiting host T cells. Endothelial cells constitutively express major histocompatibility complex (MHC) class I molecules, which enables them to present antigen to $CD8^+$ (cytotoxic) T lymphocytes. In addition, vascular EC often acquire the potential to present antigen to $CD4^+$ (helper) T cells, since MHC class II molecule expression on small vessels is a common finding in a variety of inflammatory conditions and human capillary ECs have been shown to express MHC class II molecules in heart, kidney, and liver. Triggering of the T-cell antigen receptor (TCR) by the endothelium is likely to occur during the sustained adhesive interactions leading to T-cell extravasation. The functional consequences of antigen presentation by the endothelium, particularly its ability to initiate T-cell responses, are still controversial. A key point in these issues is that ECs (at least in the human system) do not express the B7 family of costimulatory molecules that, when triggered in conjunction with the antigen receptor, allow autocrine production of the T cell growth factor inteleukin-2 and cell division. Other costimulatory molecules that have been found to be expressed by endothelial cells, such as inducible T-cell costimulator-ligand (ICOS-L), are unable to induce IL-2 gene transcription, although they can support the production of other cytokines, such as IL-4. Finally, negative regulators of T-cell activation, such as programmed death-ligand 1 (PD-L1) and PD-L2, have been identified on ECs.

$CD4^+$ (Helper) T Cells

The conclusions from some studies on the functional effect of cognate recognition of the endothelium by $CD4^+$ T cells are to date controversial. Some groups have reported that EC can support mitogen-induced T-cell proliferation, antigen-specific T-cell proliferation, and primary alloresponses. These authors hypothesized that during antigen presentation by ECs, costimulation can be provided by surface molecules other than B7, such as LFA-3. Other groups, including ourselves, have failed to detect alloproliferation of human and mouse $CD4^+$ T lymphocytes induced by either resting or cytokine-treated endothelium. Possible explanations for these discrepancies include a contamination with bone-marrow-derived antigen presenting cells (such as dendritic cells) of either the EC or the T-cell preparations.

An interesting observation that arose from these studies is that, unlike what has been observed with other costimulation-deficient parenchymal cells, memory T cells were not rendered hyporesponsive by cognate recognition of B7-negative endothelium. It is possible that the availability of accessory molecules displayed on the EC surface and coengaged during cognate recognition might modulate the signal delivered through TCR engagement. Thus antigen presentation in the absence of costimulation, but in the presence of strong cell–cell adhesion, mediated by the large array of accessory molecules displayed on the EC surface, might fall below the threshold required for T-cell activation but above that leading to T-cell silencing.

$CD8^+$ (Effector) T Cells

The few studies that have investigated the effects of cognate recognition of EC by $CD8^+$ T cells have focused on the development of proliferative responses, and, as for $CD4^+$ T cells, contradictory results have been reported. Some studies have concluded that EC can induce human and murine $CD8^+$ T lymphocyte differentiation, although with a low efficiency compared with conventional antigen-presenting cells (APC), and with impaired ability to secrete γ-IFN. In contrast, other investigations suggested that human ECs are unable to stimulate a functional response by freshly purified $CD8^+$ T cells.

In Vivo Studies

Similarly to all the in vitro studies described, the few studies analyzing antigen presentation by EC in vivo have led to conflicting conclusions. A caveat that must be borne in mind is that the microvascular endothelium has different phenotypic characteristics in different species. For example, murine EC express the costimulatory molecule CD80 but not CD40, whereas human ECs are totally B7-negative but express functional CD40. A recent study has suggested that EC allorecognition by adoptively transferred $CD8^+$ T cells in the absence of $CD4^+$-mediated T cell help and professional hematopoietic antigen-presenting cells leads to heart allograft rejection in MHC class I recipients. However it has clearly been shown that secondary lymphoid organs are required for transplant rejection, implying that antigen presentation by graft-resident dendritic cells migrated in the host lymphoid tissue is required for alloreactive T cells to be activated. The reason for these discrepancies remains unresolved.

A possible compromise of these opposite views is the recent definition of EC as "semiprofessional" APC, due to their ability to enhance T-cell responsiveness and cytokine production without eliciting full T-cell activation. Given that ECs might display tissue-specific as well as foreign peptides, full competence as APC would be potentially dangerous in terms of self-tolerance, and induction of nonresponsiveness following cognate recognition of ECs would be likewise undesirable for virus-specific T cells entering an infected tissue. Thus the neutral effects on subsequent T-cell behavior, described earlier, could be advantageous to overall immunoregulation. Of course the primary immunological function of EC is to regulate lymphocyte trafficking. Recent developments in vascular immunology suggest that antigen presentation by EC might induce a different activation response, inducing T-cell transendothelial migration.

TCR-Dependent T-Cell Trafficking

The possibility that Ag location might in some way mediate specific T-cell localization and tissue retention has been suggested by some studies looking at the migration of autoantigen-specific T cells in experimental models of inflammation. The participation of TCR-derived signals in the regulation of T-cell migration was suggested long ago by the observation that TCR triggering can induce integrin activation and immobilize migrating T cells. A role for TCR-triggering by the endothelium (during extravasation) in the regulation of T cell trafficking has also emerged from in vitro studies showing that antigen display by the endothelium leads to the recruitment of specific human and murine $CD4^+$ and $CD8^+$ T cells into the tissue. A recent study has provided the first in vivo evidence that insulin-specific $CD8^+$ T cells require antigen presentation by pancreatic microvascular endothelium to gain access to pancreatic islets [1]. These data have been confirmed by our observation that TCR-triggering by the endothelium induces T cell diapedesis without affecting adhesion [2]. The mechanism whereby cognate recognition promotes transmigration has yet to be fully defined, and it is likely to involve TCR-mediated activation of signaling pathways that control adhesion molecule activation and cytoskeletal rearrangements. In this context, recent studies have established a role for adapter proteins such as Vav, ADAP (FYB), and SKAP-55 in the activation of integrins following TCR triggering. Downstream events in these pathways are likely to involve Ras/Rho family GTPases, including Ras, Rho, Rac, and Cdc42.

Although it is clear that the majority of T-cell recruitment into tissues is regulated by noncognate mechanisms, antigen display by the endothelium can enhance the specificity and efficiency of lymphocyte recruitment into and retention at antigenic sites of inflammation, thus minimizing collateral damage caused by excessive antigen-nonspecific inflammatory cells. A summary of the functional effect of T cell–EC interactions discussed here is provided in Figure 2.

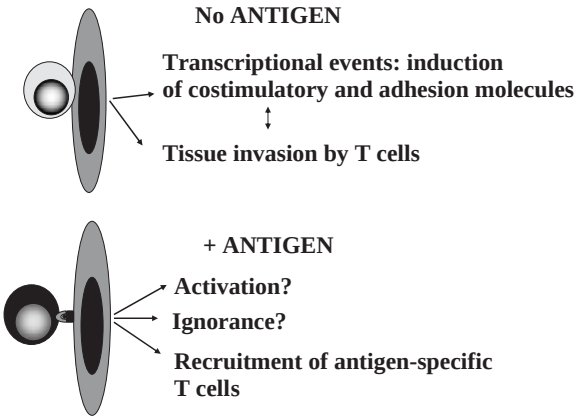

Figure 2 Functional consequences of T cell–endothelial cell interactions. Sustained interactions with the endothelium during extravasation induce a genetic reprogramming in T lymphocytes leading to upregulation of adhesion and costimulatory molecules. As a consequence, T cells become more tissue-invasive and hyperreactive to antigenic stimuli. The effects of antigen presentation by the endothelium to transiting T cells during extravasation are less clear; however, this event appears to favor the extravasation of antigen-specific T lymphocytes. (see color insert)

Introduction

The formation of the microvasculature is a complex process requiring proper cell–cell and cell–extracellular matrix (ECM) communication events. A vascular basement membrane rich in many ECM proteins surrounds all blood vessels and regulates multiple vascular cell functions. Endothelial cells and pericytes, and indeed most eukaryotic cells, recognize ECM ligands primarily via members of the integrin family of proteins [1]. Integrins are heterodimeric cell surface receptors consisting of noncovalently associated α and β subunits. Most integrins recognize multiple ECM ligands, and many ECM proteins can bind to more than one integrin receptor. In vertebrates there are 26 integrin genes, 18 encoding α subunits and 8 encoding β subunits, yielding 24 distinct integrin heterodimers (Figure 1). At least five integrins (α1β1, α2β1, α5β1, αvβ3, and αvβ5) are expressed at some point on endothelial cells or pericytes [2]. Here we summarize pertinent data linking integrins and their ECM ligands to various microvascular events.

Microvascular Integrins and Their Extracellular Matrix Ligands

α5β1 Integrin

Various genetic data support the notion that the integrin α5β1 and its ECM ligand, fibronectin (FN), are absolutely essential for normal blood vessel function. Mouse embryos harboring an ablated α5 gene die by embryonic day (E) 10.5, displaying severe embryonic and extraembryonic vascular defects, as well as posterior trunk and somitic abnormalities. Additionally, α5-null embryonic stem (ES) cells injected into syngeneic mice form teratocarcinomas with reduced size and a poorly developed vasculature. Also, embryoid bodies derived from α5-null ES cells display delayed vascular differentiation and organization. In concordance with the α5 genetic data, deletion of the FN gene leads to embryonic lethality associated with severe vascular defects, and similar angiogenic abnormalities are observed in FN-null embryoid bodies [2].

Other experimental models also support a necessary role for α5β1 and FN in angiogenesis. For example, protein expression of α5β1 and FN is upregulated on angiogenic tumor blood vessels. Likewise, in the chick chorioallantoic membrane (CAM) assay, angiogenic growth factors upregulate α5β1 expression. In both systems anti-α5β1 or anti-FN function-blocking antibodies or peptide antagonists perturb neovascularization [3].

α1β1 and α2β1 Integrins

The collagen-binding integrins α1β1 and α2β1 are both upregulated on angiogenic blood vessels following vascular endothelial growth factor (VEGF) stimulation (reviewed in Ref. [2]). Function-blocking anti-α1 and -α2 antibodies inhibit angiogenesis in vivo using Matrigel plugs or transplanted tumor models. Interestingly, α1-null mice are viable and fertile, yet are less susceptible to tumor growth. This resistance correlates with increased levels of circulating matrix metalloproteinase (MMP) activity involving MMP-2, MMP-7, and MMP-9. Elevated proteolysis in α1-null mice leads to the conversion of plasminogen to angiostatin, a potent inhibitor of endothelial cell neovascularization. Mice harboring a deletion of the α2 gene are viable and fertile and do not display any gross vascular abnormalities. Obviously, analysis of mice null for both α1β1 and α2β1

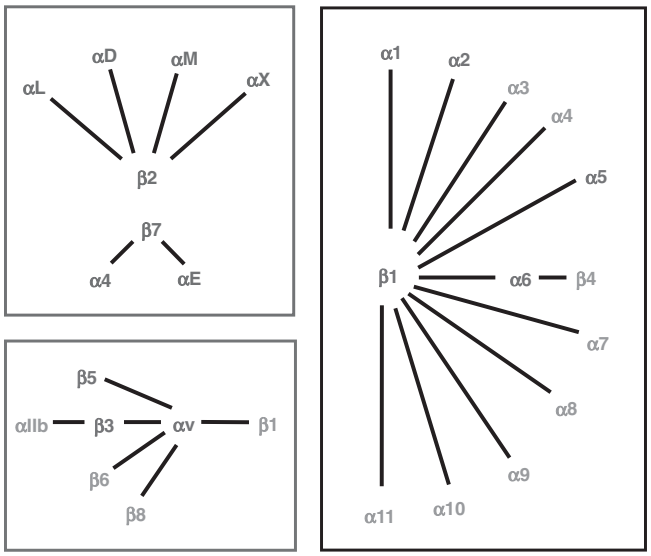

Figure 1 The integrin family of ECM receptors. The 26 integrin α and β subunits, separated into three groups, are shown. Lines connecting subunits indicate the 24 known heterodimeric pairs. The leukocyte-specific integrins are shown in blue. Integrins with proposed roles in various microvascular functions are highlighted in red. (see color insert)

expression should be useful in understanding the exact functions of these integrins during physiological and pathological angiogenesis.

β1 Integrins

The β1 integrin subunit can pair with at least 12 α subunits (Figure 1). Various β1-containing integrins are expressed in virtually all vertebrate cells and are involved in most aspects of development. Not surprisingly, β1 genetic ablation leads to very early (E7.5) embryonic lethality, prior to the onset of vascular development. Analyses of β1-null ES cells, embryoid bodies, and teratocarcinomas reveal an essential role for β1 integrins in blood vessel formation. Whereas β1 integrins are dispensable for endothelial cell differentiation, they are required for VEGF-induced endothelial cell proliferation and blood vessel elaboration.

As mentioned previously, integrins α1β1 and α2β1 are also important for microvascular formation. It is likely that some of the defects observed in the absence of β1 integrin can be explained by loss of α1β1 and α2β1 function. However, ES cells or embryoid bodies null for β1 integrin, α5 integrin, or fibronectin display many strikingly similar defects. Thus, many of the β1-null defects can be explained by loss of integrin α5β1. Again, these data emphasize that fibronectin and its primary receptor, α5β1 integrin, play essential roles in the regulation of vascular development [4].

αv Integrins

The αv integrin subunit can pair with β1, β3, β5, β6, and β8, yielding five distinct integrin heterodimers (Figure 1). An extensive body of published data exists concerning αvβ3 and αvβ5 during various types of physiological and pathological angiogenesis. Various angiogenic growth factors or cytokines upregulate αvβ3 or αvβ5 protein expression on cultured endothelial cells or on vessels using the CAM assay. Likewise, many angiogenic blood vessels display increased levels of αvβ3 or αvβ5. Function-blocking antibodies or peptide antagonists inhibit this integrin-mediated neovascularization in these various systems, ultimately leading to endothelial cell death. Along these lines, αvβ3 has been intensely pursued as a potential anti-angiogenic target, and αvβ3 antagonists are currently being tested in human clinical trials.

Surprisingly, ablation of the β3 and/or β5 genes does not lead to angiogenic abnormalities. Mice null for both αvβ3 and/or αvβ5 are viable and fertile, and developmental vasculogenesis and angiogenesis proceed normally in these mutants. Physiological angiogenesis occurs normally in β3-null or mice null for both β3 and β5. No experimental differences are observed using hypoxia-induced retinal angiogenesis or growth factor–mediated corneal neovascularization models. Interestingly, tumor growth and neovascularization are actually enhanced in β3-/- or β3/β5-null mice [5]. Thus, it is difficult to infer the significance of αvβ3 and αvβ5 in neovascularization based on the antibody and peptide inhibition results versus the genetic ablation data.

One could argue that, in mice lacking β3 and/or β5 gene expression, other αv-associated integrins are compensating for normal αvβ3 and/or αvβ5 functions. As mentioned earlier, αv can indeed pair with five different β subunits. However, mice null for the αv gene, and thus lacking the expression of all five αv integrins, do not display general vascular defects. Approximately 70 percent of αv-nulls survive to E10.0, having developed a normal vasculature, but die by E10.5 because of placental defects. The remaining αv-null embryos that survive the mid-gestation crisis subsequently develop to term with a largely normal vasculature. However, they do develop cerebral hemorrhage and a cleft palate, and they die shortly after birth. The hemorrhage is not due to endothelial or pericyte defects, but rather involves defective associations between cerebral vessels and central nervous system glia [6]. Interestingly, the cerebral hemorrhage in the αv-nulls is specifically due to the loss of integrin αvβ8; mice null for the β8 gene display phenotypes that are essentially identical to those seen in the αv-nulls [2].

Interpreting the Conflicting Data

It is difficult to reconcile the conflicting experimental data regarding the necessity of αvβ3 function during pathological, and especially tumor, neovascularization. It is important to note that the antagonism of an existing integrin function is certainly quite different from ablation of the integrin gene product. Thus, one should exercise caution when interpreting data using such different experimental approaches. However, there are cases where genetic ablation

of integrin expression and acute inhibition of integrin function lead to quite similar results. For example, various data using β3 antagonists implicate αvβ3 as important for bone reabsorption. This function is also revealed after ablation of the β3 gene. Antibody or peptide inhibition of the platelet integrin αIIbβ3 leads to defective platelet aggregation. Mutations in the human β3 gene also lead to abnormal platelet aggregation and the bleeding disorder Glanzmann thrombasthenia. β3-null mice develop abnormalities that are very similar to this human disease. Similarly, genetic ablation of the α5 gene, as well as acute inhibition of α5 function, both clearly show that this integrin is important for neovascularization.

Accumulating data support the concept of cross-talk pathways existing among different integrins. Inhibition of one integrin signaling cascade can in turn affect other integrin-mediated signaling events. Thus, antagonists that perturb αvβ3 function may be affecting other integrins involved in neovascularization, possibly including α5β1 and/or α1β1. Another likely possibility, discussed in more detail later, is that in some cases a given integrin can be pro- or antiangiogenic. For example, growing evidence suggests that αvβ3 is a negative regulator of pathological angiogenesis. Ablation of the β3 gene would remove this negative regulation, leading to enhanced neovascularization. This is indeed the result during pathological angiogenesis in the β3-null mouse model. In any case, it is likely that the acute inhibitors of angiogenesis are affecting microvascular events in a far more complicated manner than originally expected, and more extensive reviews discussing these possibilities have recently been published [5, 7].

Cross Talk between Vascular Integrins and Receptor Tyrosine Kinases

Integrin–ECM adhesion regulates many intracellular signaling events, affecting cellular responses such as migration, differentiation, and proliferation. Initiation of integrin-ECM adhesion occurs via two primary mechanisms, generally termed *outside-in* and *inside*-out signaling. Inside-out signaling involves the modulation of integrin–ECM affinity via signaling events originating within the cell. Outside-in signaling results from direct integrin-ECM binding, leading to the activation of downstream signaling cascades. Whereas integrin activation can occur via a variety of stimuli, growth factors and their cognate receptor tyrosine kinases (RTKs) are established synergistic signaling partners [8]. Importantly, cross talk between integrin and RTK pathways is necessary for microvascular development and maintenance [9].

Generally, signaling cross talk between vascular integrins and RTKs positively regulates each other's function. For example, the integrin αvβ3 can physically interact with Flk-1, the VEGF-A receptor tyrosine kinase. αvβ3-Flk1 association augments VEGF-A-induced Flk-1 phosphorylation and enhances endothelial cell migration on vitronectin, an αvβ3 ligand. A similar physical link between αvβ3 and the PDGFR-β has been reported. αvβ3 interaction with both Flk-1 and PDGFR-β occurs via the αvβ3 extracellular domain and is independent of growth factor stimulation.

Growth factor regulation of integrin signaling also occurs at the transcriptional level. VEGF treatment of endothelial cells stimulates the transcription of multiple integrin subunits including αv, β3, β5, α1, and α2. In other cases, growth factor stimulation of integrin expression can be quite specific. For example, basic fibroblast growth factor (bFGF)-induced angiogenesis leads to the specific upregulation of endothelial αvβ5 integrin.

The Role of the ECM in Regulating Vascular Integrin Functions

The *angiogenic switch* model [10] posits that a delicate balance exists between pro- and antiangiogenic factors. Changes in the levels of such factors regulate whether a blood vessel remains in a quiescent state, or becomes activated and angiogenic. Many ECM proteins within the vascular basement membrane, acting via integrins, are major regulators of the angiogenic switch. An emerging theme is that the exact function of a given ECM protein, as well as the integrin receptor(s) it binds, can be greatly affected by proteolytic events [11]. Several examples of how such endogenous "cryptic" fragments affect microvascular function are described next.

Type IV collagen, a major component of the vascular basement membrane, is normally a ligand for the integrins α1β1 and α2β1. MMP9 cleavage of collagen IV yields the potent angiogenesis inhibitor *tumstatin*. In vitro tumstatin induces apoptosis of endothelial cells by inhibiting the protein translation machinery. Likewise in vivo, tumstatin is a potent inhibitor of tumor neovascularization. Tumstatin's antiangiogenic effects are mediated by binding to the αvβ3 integrin.

Proteolysis of the C-terminal NC1 domain of collagens XV or XVIII generates the antiangiogenic factor endostatin. Murine *endostatin* inhibits VEGF- or bFGF-induced endothelial cell proliferation and migration in vitro, and also represses pathological angiogenesis in some transplantable tumor models. Endostatin is reportedly a ligand for both α5β1 and αvβ3. Intact collagen XV and XVIII do not bind to these integrins. Importantly, while the exact molecular mechanisms by which endostatin exerts its antiangiogenic effects remain unknown, it is clear that they are different from those regulated by tumstatin and do not require αvβ3.

Proteolysis of many other ECM proteins also generates antiangiogenic fragments, although the mechanistic details of how they exert these effects remain unclear. For example, when proteolytically cleaved, thrombospondin-1 "cryptic fragments" bind to the scavenger receptor CD36 and serve as potent repressors of angiogenesis [12]. Similarly, degra-

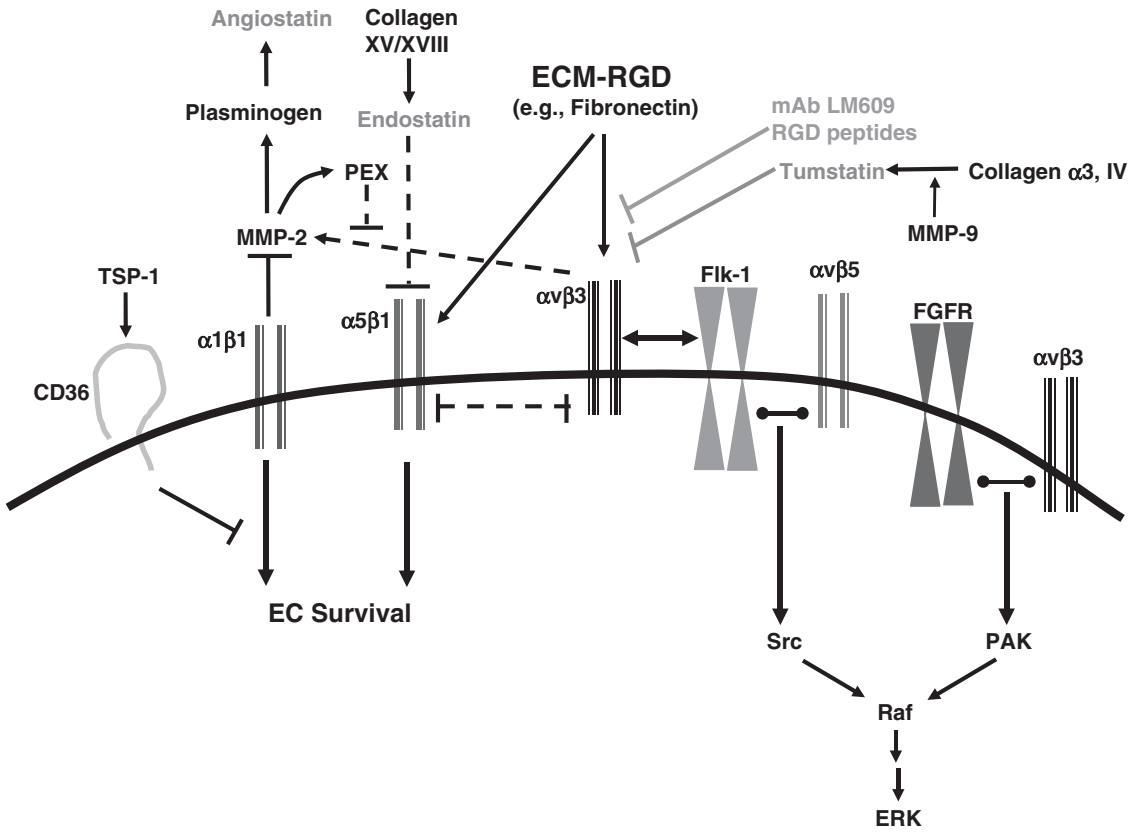

Figure 2 Integrin signaling cascades during angiogenesis. Various integrins, extracellular matrix proteins, and receptor tyrosine kinases with roles in endothelial cell function are shown. Pink lettering indicates endogenous inhibitors of integrin-mediated angiogenesis. Orange lettering indicates blocking antibodies or peptide antagonists that inhibit integrin function. Lines with double-headed arrows indicate direct physical connections between proteins. Double-headed ball-ended lines denote signaling cross-talk between receptors. (see color insert)

dation of the proangiogenic factor fibronectin generates the angiogenesis inhibitor anastelin.

Conclusion

Integrins and their various ECM ligands play essential roles in virtually every aspect of physiological and pathological microvasculature formation. This is controlled largely through integrin-mediated signal transduction and involves extensive cross talk with other signaling cascades, including those involving growth factor receptor tyrosine kinases (Figure 2). Additionally, ECM proteolysis regulates integrin functions, in many cases switching integrin regulation of neovascularization from a positive to a negative state. These various data highlight microvascular integrins and their ECM ligands as attractive candidates for therapeutic intervention to selectively enhance or repress various forms of physiological or pathological neovascularization.

Glossary

Cell Adhesion: The process by which cells adhere to each other and to components of the extracellular environment. Precise regulation of cell adhesion is necessary for normal developmental and physiologic maintenance. Abnormal regulation of cell adhesion events can lead to various disease states, including cancer.

Extracellular matrix: A complex mixture of secreted macromolecules that comprise the noncellular material of all tissues. Besides providing structural support, the extracellular matrix is biologically active and influences a host of dynamic cellular responses.

Integrin: Heterodimeric cell surface molecules composed of α and β subunits. Integrins serve as the cell's primary adhesion receptors for extracellular matrix ligands and play important roles in regulating cellular functions, ranging from differentiation to proliferation and migration.

Capsule Biography

Dr. Joseph McCarty was a postdoctoral researcher in the Center for Cancer Research at MIT. He is currently an Assistant Professor in the Department of Cancer Biology at the University of Texas MD Anderson Cancer Center. His research focuses on the development and maturation of the brain vasculature.

Dr. Richard Hynes was a Daniel K. Ludwig Professor of Biology at MIT and an Investigator of the Howard Hughes Medical Institute. His research interests concern the role of cell adhesion in physiology and pathology.

CHAPTER 54

Platelet Phospholipids Tighten the Vascular Endothelial Barrier

Fred L. Minnear

Department of Physiology and Pharmacology, Robert C. Byrd Health Sciences Center, West Virginia University, Morgantown, West Virginia

Platelets are key to the physiological processes of thrombosis and hemostasis and are repositories for biologically active mediators that influence many cellular functions such as aggregation, adhesion, growth, and mitogenesis as well as matrix formation and fibrinolysis. Platelets (or thrombocytes) also support the vascular endothelium, maintaining the semipermeable barrier to the passage of water and protein. Recently, two platelet phospholipids, lysophosphatidic acid (LPA) and sphingosine 1-phosphate (S1P), have been demonstrated to have a myriad of biological activities including cell proliferation, migration, survival, mitogenesis, and chemotaxis as well as matrix assembly, tumor cell invasion, and angiogenesis. LPA and S1P also enhance the barrier function of the vascular endothelium. This review will focus on the interaction of platelets and the vascular endothelium in promoting endothelial barrier function and will identify possible signaling pathways and cellular targets activated by LPA and S1P.

Platelets Support the Endothelial Barrier

Thrombocytopenia in patients is often characterized by petechial hemorrhages due to capillary leakage. Thrombocytopenic animals demonstrate gross purpura and alterations in the microvasculature as evidenced by gaps between endothelial cells and leakage of radioactive tracers into the surrounding tissues. The vascular endothelia are thinner and have open pores and membranous diaphragms. Evidence of a dysfunctional endothelial barrier and tissue edema due to thrombocytopenia have been observed in many experimental models such as the frog hindlimb, the thyroid lobe of dogs, the ear of postirradiated rabbits, the thoracic duct lymph of dogs, the coronary microvasculature of rats, and the lungs of sheep. Sheep chronically depleted of platelets with an anti-platelet antibody develop petechial hemorrhages, an increase in the transendothelial clearance of protein in the lungs, and pulmonary edema at a left atrial pressure of 20 mmHg.

Transfusion with platelet-rich plasma reverses these abnormalities. When comparing an isolated, thyroid lobe of a dog perfused with platelet-poor plasma and its counterpart lobe perfused with platelet-rich plasma, the lobe with platelet-poor plasma had gross purpura, endothelial gaps, and increased leakage of protein into the tissue. Transfused platelets labeled with radiosulfate rapidly interact with the vascular endothelium of thrombocytopenic animals and incorporate the label within the endothelium. Interestingly, a common finding is that the number of platelets required to reverse hemorrhage or capillary leakage is much less than that required to correct bleeding times. Thus, platelets in some way nurture the microcirculation.

Three theories have been proposed to explain this endothelial barrier-supporting function of platelets. The first and obvious explanation is that platelets physically block pores or gaps in the vessel wall. The second theory is that platelet components promote endothelial cell growth. The third, and most studied, theory is that platelets continually release a novel humoral factor that decreases endothelial permeability.

The measurement of diffusive permeability across confluent, endothelial cell monolayers developed in the 1980s provided a novel methodology to directly test these three theories. Initial studies addressed the first theory that

platelets simply act as plugs between leaky endothelial cells. Washed human platelets, but not paraformaldehyde-fixed platelets, both of which attached sparingly to endothelial cells, reduce the flux of ^{125}I-labeled albumin across endothelial cell monolayers. Subsequently, a number of studies demonstrated that the permeability-decreasing activity of platelets resides in a soluble factor as platelet-conditioned medium (PCM) consistently decreases albumin permeability across endothelial cell monolayers derived from bovine aorta and bovine and human pulmonary arteries and microvessels. Thus, platelets decrease endothelial permeability via the release of a soluble factor and not by plugging of endothelial pores or gaps.

Accepting the notion that this activity of platelets resides in a soluble factor, investigators focused on a number of familiar platelet components such as serotonin, norepinephrine, and cyclooxygenase metabolites. Proven antagonists or inhibitors of these metabolites did not prevent the decrease in albumin permeability induced by platelets, platelet lysate, or PCM. At the time, norepinephrine (predominately a β_1-adrenergic agonist) was an intriguing possibility because it was known that β-agonists decrease endothelial permeability. This activity of β-agonists, however, favors the β_2-subtype, the predominant receptor subtype on vascular endothelial cells.

When my laboratory entered this area of research, adenosine was proposed to be the active platelet factor. We [1] ruled out adenosine as the likely candidate by the following experimental findings. PCM contains micromolar concentrations of AMP, ADP, and ATP, but adenosine is below detectable levels as measured by high-performance liquid chromatography. Although adenosine directly decreases endothelial permeability, inactivation of adenosine with adenosine deaminase, which metabolizes adenosine to inactive inosine, does not block the activity of PCM. Furthermore, the adenosine-receptor antagonist BW-A1433U83 does not block the decrease in endothelial permeability induced by platelets or PCM. A fraction of PCM smaller than 3 kDa that contains micromolar concentrations of AMP and ADP has no activity, whereas a fraction larger than 3 kDa that contains much reduced levels of AMP and ADP significantly reduces permeability. Thus, adenosine and adenine nucleotides are not the primary factors responsible for the platelet activity; instead the activity resides in a fraction of PCM larger than 3 kDa.

As early as 1956, a protein fraction extracted from platelets was reported to reduce capillary permeability in the rat hind limb. Haselton and Alexander [2] and Patil and others [1] demonstrated 35 years later that the active platelet factor is heat-stable, trypsin-sensitive, and >3 kDa. Some of these findings point to a protein as the active factor. An obvious difficulty with this notion is how platelets could replenish the store of a protein continuously released into the plasma, considering platelets have a limited ability to synthesize proteins. This criticism prompted us to consider viable alternatives. There were also conflicting pieces of data in the literature. The fact that the active factor is sensitive to trypsin and, in addition, is precipitated in saturated ammonium sulfate implicates a large charged protein, yet the activity is heat stable.

Still assuming that the permeability-decreasing activity of PCM is associated with a protein fraction, Patil et al. [1] performed anion- and cation-exchange chromatography to increase the specific activity of a protein fraction. These experiments provided evidence that the activity resides with a negatively charged protein such as albumin because the active fraction binds to and requires a high salt concentration to elute the activity from an anionic exchange column. Applying PCM to a calibrated Sephacryl S-200 gel filtration column yields three major protein fractions with activity present only in the fraction with an elution volume of albumin. Activity also resides with the albumin immunoprecipate following removal of albumin from the PCM with an anti-albumin antibody. It was at this time that Alexander and coworkers [3] provided convincing evidence that the active factor is a phospholipid. Their findings pointed to lysophosphatidic acid (1-acyl-2-hydroxyl-3 phosphoglyceride, LPA).

That LPA might be the active factor was somewhat of a surprise because LPA had been reported to increase the permeability of endothelial cell monolayers derived from brain capillaries. However, the findings of Alexander and coworkers [3] are compelling. Activity is present in the methanol extract of PCM and is eliminated by enzymatic treatment with phospholipase B, which cleaves at the *sn*-1,2 positions, and with alkaline phosphatase, which cleaves at the phosphomonoester bond. Phospholipase A_2, which cleaves at the *sn*-2 position where a hydroxyl group but no lipid is present in a phospholipid, has no effect. Using a similar protocol, Minnear et al. [4] extracted lipids with methanol from albumin fractions obtained from PCM either by immunoprecipitation with an anti-albumin antibody or by passing the PCM through a Blue-Sepharose column. Successive extractions with methanol yield activity in the methanol extract and loss of activity in the extracted albumin fraction.

Lysophosphatidic Acid (LPA)

LPA was originally reported to be a growth factor released from activated platelets and other injured cells. LPA and thrombin, another mitogen and well-known permeability-increasing agent in vitro, initiate similar cellular responses and signaling pathways such as mobilization of intracellular calcium, stimulation of phospholipase C and protein kinase C, formation of actin stress fibers, and contraction of fibroblasts. These known actions of LPA would link this phospholipid to an increase in endothelial permeability, as has been observed in endothelial cells from brain microvessels and human umbilical veins. In contrast, LPA decreases endothelial permeability in bovine endothelial cells from the lung and aorta. Thus, the effects of LPA on vascular permeability may be organ, tissue, or species specific.

Sphingosine 1-Phosphate (S1P)

S1P came to prominence a few years after LPA and was found to mimic many of the biologic activities of LPA. A seminal study from the laboratory of Garcia [5] demonstrated that S1P decreases endothelial permeability across cell monolayers derived from bovine and human pulmonary arteries and human umbilical vein. In a number of cell types, S1P appears biologically to be much more potent than LPA. For example, S1P is more active than LPA in human umbilical vein endothelial cells with regard to the intracellular mobilization of calcium, cytoskeletal reorganization, and cell migration. In our hands, S1P increases the barrier function of endothelial cell monolayers derived from pulmonary arteries to an approximately twentyfold greater extent than does LPA.

S1P and LPA are the leading candidates for the soluble factor released from platelets that maintains the barrier function of the vascular endothelium. The plasma concentrations of S1P and LPA are 0.2 μM and negligible, respectively, and the serum concentrations are 0.5 to 1.0 and 10 μM, respectively. Both S1P and LPA are present in platelets and to a lesser extent in other cells such as leukocytes, fibroblasts, erythrocytes, and adipocytes and are released upon activation during blood coagulation, inflammation, tissue injury, and neoplasia. Platelets have the potential to synthesize and store S1P because platelets have an abundance of sphingosine kinase, which converts sphingosine to S1P, and relatively no lipases to degrade S1P. S1P and LPA bind to albumin on which they retain biological activity and are protected against hydrolysis by serum phospholipases. Cellular responses of S1P and LPA have been grouped into two categories: (1) growth-related activities such as proliferation, differentiation, and suppression of apoptosis; and (2) cytoskeletal functions such as shape change, aggregation, adhesion, chemotaxis, contraction, and secretion. Micromolar concentrations are required for growth-related functions and nanomolar concentrations stimulate cytoskeletal responses.

Although S1P has been proposed to be the major factor in PCM that imparts the barrier-enhancing property, no one has detected S1P in active conditioned medium. We attempted to identify the lipids in two batches of PCM and in the albumin immunoprecipitate from one of the batches of PCM by using electrospray mass spectrometry (Table I); all three samples were equally potent in enhancing endothelial electrical resistance. A number of lipids were identified, and there were 10 unknown lipids. Lipid profiles were almost identical between PCM and the methanol extract of the albumin immunoprecipitate, indicating the importance of albumin as a lipid-carrier. Interestingly, LPA was detected as a small peak of palmitoyl (16:0)-LPA only in one batch of conditioned medium. Palmitoyl-LPA, stearoyl-LPA, and arachidonoyl-LPA are the major molecular species of LPA produced from thrombin-stimulated platelets. Surprisingly, S1P was not present in any of the three samples tested.

Regulation of Vascular Endothelial Permeability and Proposed Cellular Targets

A working hypothesis for the regulation of endothelial permeability, which was popular in the 1990s, states that signaling pathways that balance competing adhesive and contractile forces control the paracellular flux of macromolecules. Endothelial cell–cell and cell–matrix contacts tether endothelial cells to each other and to the extracellular matrix, respectively, and act against centripetal tension generated by actin–myosin motors. Thus, agents that enhance barrier function would do so by decreasing isometric tension; and the opposite would occur for barrier-decreasing agents. This hypothesis is supported by studies that have demonstrated that cAMP-enhancing agents increase barrier activity in association with decreases in myosin light-chain phosphorylation. The additional measurement of cellular isometric tension, however, provides a different conclusion in that cAMP-enhancing agents promote barrier function independently of cellular tension. In our hands, S1P and LPA increase endothelial barrier activity in association with increases in myosin light-chain phosphorylation and cellular isometric tension. S1P increases isometric cellar tension to a slightly lesser extent than can be induced by thrombin, which decreases endothelial barrier function. Thus, changes

in cellular tension are not solely responsible for changes in barrier function as both S1P and cAMP increase barrier activity yet have opposite effects on myosin light-chain phosphorylation and cellular isometric tension.

cAMP-enhancing agents and S1P affect cellular targets that initiate cell spreading and alter the adherens junction proteins, cell-specific cadherins and catenins that mechanically hold cells together. An increase in intracellular cAMP causes the remodeling of actin filaments to the cell periphery and a concomitant loss of actin stress fibers. Spreading of adjacent cells resulting in closer apposition or overlap would increase the pathway for diffusive permeability. The simple act of cell spreading would counteract the cell retraction/contraction induced by barrier-loosening agents such as thrombin. S1P profoundly affects the actin cytoskeleton, inducing both stress fibers and an increase in peripheral actin within minutes. Whether this remodeling of actin influences cell spreading remains to be determined. Alternatively, changes in cortical actin may facilitate the stabilization of the adherens junction, and cAMP-enhancing agents and S1P may function by stabilizing junctions. An increase in intracellular cAMP has been shown to maintain within 10 minutes the transvascular flux of ^{3}H inulin, transepithelial resistance, and the peripheral localization of E-cadherin and ZO-1 in the presence of low calcium in epithelial cells and to increase by 2 hours the peripheral localization of E-cadherin in brain microvascular endothelial cells. S1P has been shown to increase within 1 hour the localization of the adherens junction proteins, VE-cadherin and the catenins, α, β, and γ, at the cell periphery and to increase the amount of VE-cadherin in the actin-associated cell fraction in human umbilical vein endothelial cells. These observations by Lee from the research laboratory of Hla [6] have led to the conclusion that S1P induces the formation of adherens junctions. Therefore, S1P and cAMP-enhancing agents may function to tighten the endothelial barrier at the level of the actin cytoskeleton and/or the adherens junction.

Cell-Signaling Pathways

Although much effort has been generated to identify the active platelet factor, there is a paucity of information concerning the cellular mechanism by which the active factor functions to decrease endothelial permeability. Two signaling pathways have been studied in depth with regard to endothelial permeability. It is well known that the cAMP/protein kinase A pathway prevents and reverses an increase in vascular permeability induced by a variety of mediators, diseases, and syndromes. The effect of the cGMP/protein kinase G pathway on endothelial permeability is controversial and may be cell, tissue, and/or organ specific. Considering the overwhelming list of publications involving the above two signaling pathways, Gainor and coworkers [7] asked whether one of these two pathways is responsible for the permeability-decreasing activity of PCM. Two approaches were taken, using a desensitization protocol with three different cAMP/protein kinase A-enhancing agents and using inhibitors of protein kinases A and G. The cAMP-enhancing agents isoproterenol, forskolin, and 8-bromo-cAMP were incubated individually with endothelial cell monolayers as two separate challenges that were 45 minutes apart. Cells respond to the first challenge of each of these agents with an increase in electrical resistance. Following the second challenge with each agent, electrical resistance does not increase, indicative of desensitization. In contrast, desensitization is not observed when PCM is administered as the second challenge. Pharmacological inhibition of protein kinase A with KT-5720 blocks the increased endothelial electrical resistance induced by 8-bromo-cAMP but has no effect on the activity of PCM, LPA, or S1P. Similar findings are obtained upon inhibition of protein kinase G with KT-5823. The conclusion is that PCM, LPA, and S1P tighten the endothelial barrier via a cellular mechanism independent of protein kinases A and G.

Since cAMP/protein kinase A and G are not involved in the platelet activity, the next logical approach was to turn to the proposed signaling pathways elicited by LPA. LPA as well as S1P activate endothelial differentiation gene (Edg now LPA or S1P) receptors with nanomolar affinities. LPA and S1P bind to a number of Edg receptors, most notably Edg 2 (LPA 1) and Edg 4 (LPA 2) and Edg 1 (S1P 1), Edg 3 (S1P 3), and Edg 5 (S1P 2), respectively. In neurites and fibroblasts, LPA initiates signaling via activation of the G proteins, G_i, G_q, and $G_{12/13}$. The mitogenic response induced by LPA in NIH 3T3 fibroblasts is pertussis toxin sensitive, indicating involvement of the G_i protein, and also includes Ras and mitogen-activated protein kinase. LPA also profoundly influences the actin cytoskeleton via activation of $G_{12/13}$, Rho, and Rho kinase. Rho signaling has been shown to increase actin stress fibers. LPA as well as thrombin reorganizes the cortical actin and causes cell rounding of N1E-115 mouse neuroblastoma cells via a signaling pathway independent of calcium mobilization, activation of protein kinase C, or altered levels of intracellular cAMP. Inactivation of Rho by C3 exoenzyme or *Clostridium difficile* toxin B and subsequent disruption of actin causes an increase in endothelial and epithelial permeability. These observations indicate that novel pathways independent of cAMP/protein kinase A exist that influence mitogenesis, cell shape, cell motility, and endothelial permeability, and that the G_i and $G_{12/13}$ signaling pathways are prime signaling candidates.

Based upon the foregoing literature, initial studies with PCM, LPA, and S1P focused on the G_i signaling pathway because the pathway is well known, it can be manipulated with selective pharmacological inhibitors, and the G_q signaling pathway has been implicated in increasing endothelial permeability. Endothelial cell monolayers were treated first with genistein to generally inhibit tyrosine kinases because there are a number of proteins in the G_i signaling pathway that require tyrosine phosphorylation. Genistein prevents the increase in endothelial electrical resistance induced by PCM and S1P. Next, the Edg-1 receptor was

depleted with antisense oligonucleotide methodology and the G_i protein was inhibited with pertussis toxin. Edg 1 couples primarily with G_i and Edg 3 and Edg 5 with G_q and $G_{12/13}$. Endothelial cells appear to express Edg 1 more abundantly than Edg 3, and Edg 5 is undetectable in human umbilical veins. Depletion of Edg-1 and Edg-3 receptors inhibits the activity of S1P, and pertussis toxin inhibits the activities of both LPA and S1P. Interestingly, pertussis toxin delayed by 10 to 15 minutes the characteristic, rapid rise in endothelial electrical resistance induced by PCM. These different findings with pertussis toxin would suggest that there are other active components in PCM, other than LPA and S1P. Also, pertussis toxin does not prevent the increase in endothelial electrical resistance induced by isoproterenol, providing additional evidence that S1P- and cAMP-enhancing agents function via different cellular targets.

Phosphatidylinositol 3-kinase (PI-3 kinase) is a downstream effector of G_i in many cells and has been linked to other cellular responses induced by LPA and S1P. Inhibition of PI-3 kinase with two mechanistically different inhibitors, wortmannin and LY-294002, also causes a delay of 10 to 15 minutes in the initial, rapid rise in endothelial electrical resistance induced by PCM, LPA, and S1P. Because inhibitors of PI-3 kinase only delay the increase in electrical resistance, other G proteins and signaling pathways could be involved. One possible explanation is that the active platelet factor initiates a fast signaling pathway dependent on PI-3 kinase and a slower-acting pathway independent of this kinase. Another very plausible explanation is that the rapid signaling pathway elicited by S1P requires the interaction of the lipid by-products of PI-3 kinase with pleckstrin homology domains of the signaling proteins. In other words, activation of PI-3 kinase positions the essential signaling proteins in a complex that facilitates a rapid response. Inactivation of PI-3 kinase somewhat uncouples the signaling proteins and temporally delays the signaling process. Taken together these results indicate that PCM, LPA, and S1P rapidly increase endothelial electrical resistance via a novel signaling pathway involving tyrosine kinases, the G_i protein, and PI-3 kinase.

Since inhibitors of G_i and PI-3 kinase significantly modify the permeability-decreasing activity of PCM, LPA, and S1P, the next logical step was to determine if the downstream extracellular signal-regulated kinase (ERK) was involved. PCM and LPA rapidly and transiently increase ERK phosphorylation, indicative of an increase in ERK activity. Inhibition of MEK, the upstream kinase of ERK, with U-0126 blocks the increase in ERK phosphorylation but has no effect on the activity of PCM. Therefore, platelets do not function via ERK to increase endothelial electrical resistance.

Rac and Rho

The function and localization of both Rac1 and Rho in the cell have recently attracted the attention of those investigators studying the barrier function of the endothelium and epithelium. Kaibuchi and coworkers [8] have put forth an intriguing hypothesis that activation of Rac1 and/or Cdc42 strengthens the adherens junction of epithelial cells. Their findings support the notion that active Rac1 and Cdc42 can sequester IQGAP1, a proposed negative regulator of the junction, away from the junction allowing for strong cell–cell adhesion. The opposite occurs when Rac1 activity is decreased in Madin-Darby canine kidney II cells treated with a phorbol ester or hepatocyte growth factor, the latter inducing cell scattering. Now IQGAP1 is associated with β-catenin and not Rac1 at the cell periphery, and there is a loss of α-catenin from cell–cell borders. Expression of a constitutively active Rac1 blocks this disappearance of α-catenin. The binding site on β-catenin for IQGAP1 (amino-terminal 1–183 amino acids) contains the α-catenin binding domain (120–151 amino acids). α-Catenin is the key intermediary that links VE-cadherin and β-catenin to the actin cytoskeleton to form a strong cell–cell adhesion. The presence of IQGAP1 disrupts this linear linkage and results in weak adhesion between cells. Thus, IQGAP1 may contribute to the dynamic nature of the adherens junction.

S1P induces the translocation of Rac1 and its guanine nucleotide exchange factor Tiam1 to the cell periphery in human umbilical vein endothelial cells but does not alter the spacial movement of Rho. However, inhibition of Rac1 or Rho reduces the immunolocalization of VE-cadherin and β-catenin at sites of cell–cell adhesion. Experiments with antisense oligonucleotides, have suggested that Rac1 and Rho function via Edg 1 and Edg 3, respectively. Recruitment of actin to epithelial junctions is dependent on Rac1 activation. The involvement of Rac1 and Rho in the integrity of the adherens junction of endothelial cells, however, is controversial. Inhibition of Rho kinase with Y-27632 has been reported to attenuate the increase in endothelial electrical resistance induced by S1P.

S1P increases the activity of Rac1, and this activation is sensitive to pertussis toxin. Rac1 activity is determined with an affinity precipitation assay using glutathione-*S*-transferase fused to the Rac1/Cdc42 binding domain of p^{21}activated kinase (PAK). Treatment of endothelial cell monolayers with S1P results in an increase in active Rac1 by 10 minutes. Thus, S1P-induced increases in Rac1 activity and endothelial electrical resistance occur within the same time frame and both responses are sensitive to pertussis toxin, indicating the involvement of the G_i protein. As stated earlier, S1P remodels actin within minutes into stress fibers and an increased peripheral actin. Rac1 induces the formation of cortical actin at the leading edge of lamellipodia, and Rho forms stress fibers. Formation of actin stress fibers by S1P is abolished with C3 exoenzyme, an inhibitor of Rho, and with Y-27632, the Rho kinase inhibitor. A dominant-negative Rac1 inhibits both the changes in stress fibers and cortical actin.

Wojciak-Stothard and coworkers in the laboratory of Ridley [9] reported that inhibition of Rho with C3 exoenzyme or adenoviral expression of a dominant-negative Rho

and inhibition of Rho kinase with Y-27632 prevent the increase in endothelial permeability and the decrease in transendothelial electrical resistance induced by thrombin and histamine. These inhibitors also prevent the disassembly of the adherens junctions induced by these inflammatory agents. Surprisingly, adenoviral expression of either a dominant-active or a dominant-negative Rac1 increases the permeability of unstimulated monolayers of human umbilical vein endothelial cells. Faced with the same data induced by either activation or inhibition of Rac1, the authors concluded that the activity of Rac1 must be tightly regulated to maintain the integrity of the adherens junction between endothelial cells. According to the hypothesis of Kaibuchi, both Rac1 and Cdc42 can enhance the barrier function of epithelial cells. Therefore, Rac1 and Cdc42 may be redundant proteins with regard to the regulation of the endothelial barrier.

Beyond Rac1, one study by Garcia and coworkers [5] has looked at the downstream kinase PAK, and cofilin, an actin-severing protein inactivated by LIM kinase. A Rac1-bound PAK phosphorylates LIM kinase causing the subsequent inactivation of cofilin. Both PAK and cofilin translocate to the cell periphery after treatment with S1P. Expression of a dominant-negative PAK-1 or wild-type cofilin reduces the increase in cortical actin. The latter also blunts the increase in endothelial electrical resistance induced by S1P. These authors concluded that a thickened, cortical actin plays a prominent role in the enhanced endothelial barrier activity of S1P. Therefore, inactivation of cofilin via Rac1 to PAK signaling is key to this activity of S1P.

Conclusions and Future Studies

S1P induces cell migration, but as emphasized in this review, S1P also promotes the barrier function of the vascular endothelium. S1P activates both Rac1 and Rho, and both small GTPases have been implicated in the physiological processes of cell migration and endothelial barrier function (see Figure 1). At least for Rac1, this apparent discrepancy may depend on whether Rac1 is localized at cell–cell junctions and involved in barrier function or at the leading edge of a wounded cell and promoting cell migration. To complicate our understanding, these two GTPases have also been associated with processes that loosen the endothelial barrier. Therefore, the current take-home message is that the integrity of the adherens junction, at least in endothelial

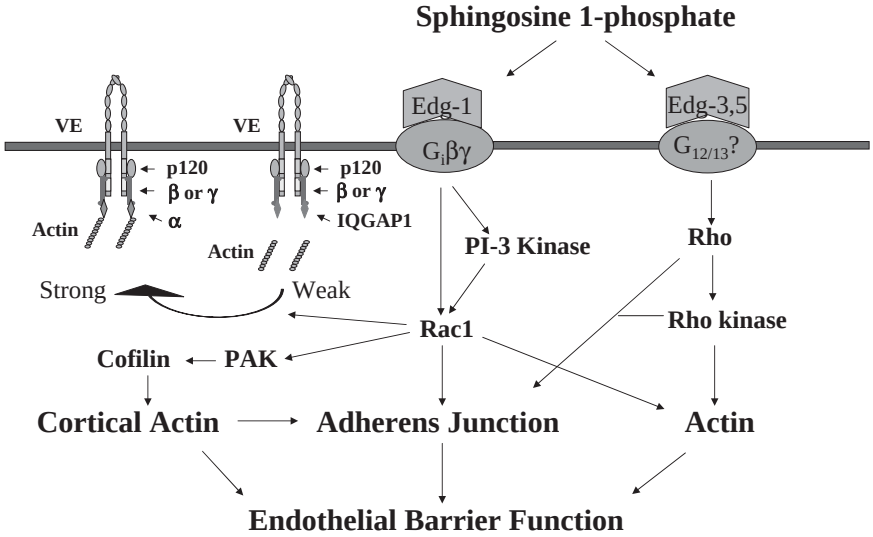

Figure 1 Proposed cellular targets and signaling pathways by which sphingosine 1-phosphate (S1P) tightens the endothelial barrier. S1P binds to endothelial differentiation gene receptors (Edg). Edg 1 couples primarily with G_i and Edg 3 and Edg 5 with G_q and $G_{12/13}$. S1P activates Rac1, and many of the physiological outcomes of S1P and Rac1 are linked to G_i. Down-regulation of Edg 1 or Edg 3 or inhibition of G_i prevents the S1P-induced enhancement of the endothelial barrier. In epithelial cells, Rac1 sequesters IQGAP1 and removes this proposed negative regulator from adherens junction proteins. The resultant linkage to the actin cytoskeleton facilitates the integrity of the adherens junction, although this sequence of events has not been described in endothelial cells. S1P and active Rac1 also remodel the actin cytoskeleton as evidenced by a thickened, cortical actin and stress fibers. Active Rac1 appears to affect cortical actin via activation of PAK and the subsequent inactivation of cofilin. The formation of actin stress fibers involves Rho and Rho kinase, and inhibition of Rho kinase also prevents the barrier-enhancing property of S1P. The linkage of Rho with $G_{12/13}$ and Edg 3 and Edg 5 requires demonstration. To complicate matters, both Rac1 and Rho have also been associated with loosening of the endothelial barrier. Thus, subtle changes in the activation of Rac1 and Rho may profoundly influence endothelial barrier function. VE, vascular endothelial cadherin; p120, p120-catenin; α, α-catenin; β, β-catenin; γ, γ-catenin or plakoglobin; p^{21}-activated kinase. (see color insert)

cells, may be influenced by subtle changes in the Rho family of GTPases, Rho, Rac1, and Cdc42. The cellular targets that regulate endothelial barrier function, whether adherens junction proteins or the actin cytoskeleton located at adhesions between cells and cell to substratum, need to be elucidated and require further study.

Glossary

Barrier function: The semipermeable nature of the endothelium to the passage of water and protein. Includes the movement of water and protein by diffusion and by convection (or bulk flow of water).

Permeability: The process whereby water or proteins diffuses from a higher concentration in the blood through the junctions between endothelial cells to a lower concentration in the tissue.

Rac and Rho: Members of the Rho family of small GTPases that function as intracellular signaling molecules.

Thrombocytopenia: Platelet count in the blood of 50,000/μL or less. Normal platelet count is 150,000 to 300,000 cells per microliter of blood.

Capsule Biography

Dr. Minnear is Professor of Physiology and Pharmacology, Assistant Dean of Graduate Studies, and Director of the M.D./Ph.D. Scholars Program at West Virginia University School of Medicine. His research focuses on regulation of the vascular endothelial barrier to the passage of water and protein with emphasis on the adherens junction and the actin cytoskeleton. His work is supported by grants from the National Heart, Lung and Blood Institute and the American Heart Association.

CHAPTER 55

Role of Gap Junctions in Capillary-Arteriolar Communication

Karel Tyml
University of Western Ontario, London, Canada

Introduction

Gap junctions, found in nearly all mammalian cells, are intercellular channels that permit a direct passage of ions and small molecules (up to 1 kDa molecular mass) between the cytosols of adjacent cells. Gap junctional communication between the cells of vascular wall has been proposed to coordinate microvascular function, including participation in the local control of blood flow.

Conceptually, the local control serves to match the local tissue blood flow to the tissue's metabolic demand. Vasoactive metabolites generated within the tissue during periods of demand are envisioned to reach upstream arterioles to cause adjustment of arteriolar diameter and blood flow to meet this demand. However, for tissues where the distance between the site of demand and upstream arterioles is large (e.g., distances along skeletal muscle fibers can be of the order of 1 mm), it is not clear how metabolic signals reach these arterioles. Since simple diffusion of metabolites across these distances may be too slow in relation to the speed of observed vasomotor responses, a new mechanism of matching the arteriolar response to the local demand has been proposed [1]. This mechanism is hypothesized to involve metabolically induced electrical signals that spread along the capillary endothelium to the arteriole via gap junctions (i.e., capillary–arteriolar communication). The present chapter discusses the available evidence regarding this mechanism and examines how the pathological condition of systemic inflammation could affect this communication.

Gap Junctions in the Microvasculature

Gap junctions (GJ) are formed by a family of integral membrane proteins termed connexins (Cx). Vascular endothelial cells express three connexin family members Cx37, Cx40, and Cx43. In each gap junction, six connexins oligomerize to form a connexon hemichannel at one cell membrane; this connexon docks with a connexon from another cell's membrane to establish an intercellular channel. At the arteriolar level, the presence of gap junctions between endothelial cells, between smooth muscle cells, and between endothelial and smooth muscle cells has been established structurally (i.e., by electron microscopy, immunohistochemistry), and functionally (i.e., by dye coupling and electrical coupling). In mammalian capillaries, gap junctions have been detected by electron microscopy and immunohistochemistry (Cx37 and Cx40 appear to dominate here; [2]).

Direct intercellular communication via gap junctions can be regulated by numerous mechanisms (e.g., gating, connexin protein expression, rates of connexin insertion and removal from the cell membrane) and can be affected by a number of intracellular signaling pathways. At the "macroscopic" level, communication has been shown to be modulated by changes in cytosolic pH and calcium, and by changes in trans-GJ and transmembrane voltages. Thus, capillary–arteriolar communication and, consequently, the local blood flow control, could be modulated acutely (e.g., via altered GJ gating) and chronically (via altered connexin

expression) during disease processes whose targets include gap junctions.

Evidence for Capillary–Arteriolar Communication

In Vivo Work

The majority of experimental evidence for communication along the capillary is indirect. Using amphibian and mammalian skeletal muscle preparations, our laboratory has shown that micropipette application of a minute amount of various vasoactive agents (norepinephrine, phenylephrine, acetylcholine, bradykinin, adenosine analog NECA, KCl) on capillaries 300 to 500 μm away from the feeding arteriole causes constriction/dilation of this arteriole and ensuing reduction/increase in blood flow in capillaries fed by this arteriole (Figure 1). Simple diffusion failed to explain these responses since interventions that do not alter the diffusional process [e.g., treatment of the capillary midpoint with GJ uncoupler, injury at this midpoint (Figure 1), or systemic application of GJ uncoupler] inhibited these responses. These experiments suggested that the capillary itself could sense vasoactive agents and that it could provide a communication feedback path between the site of locally produced/applied agents and the arteriole. Further, stimulation of two capillaries fed by the same arteriole yielded additive/subtractive responses at the arteriolar level, suggesting that the capillary bed could function as a dispersed sensor within the tissue that is able to integrate metabolic signals within this tissue into an "overall" response at the arteriolar level [5].

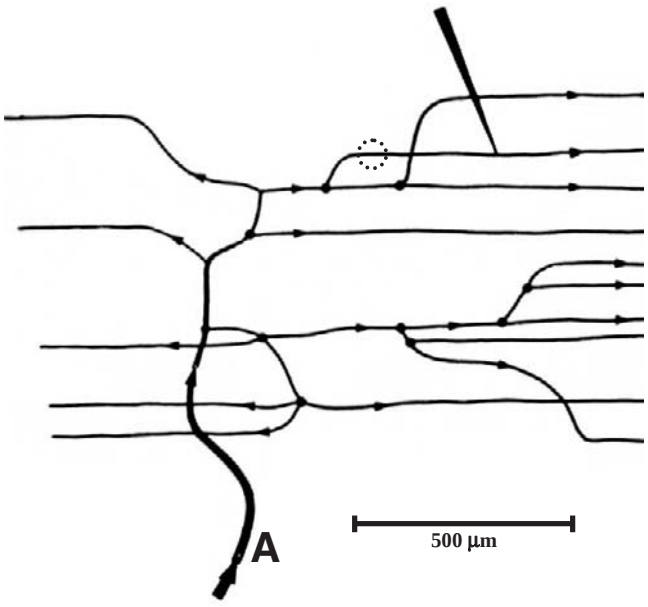

Figure 1 Schematic diagram of experimental arrangement for distal stimulation of capillaries. In this diagram, capillaries are oriented horizontally, run in parallel to each other, and are fed by arteriole "A." Arrows indicate direction of blood flow while dots represent physical junction between microvessels. During the experiment, a minute amount of vasoactive agent is placed on capillary by means of a glass micropipette, 300 to 500 μm away from the arteriole. Responses are measured in terms of changes in arteriolar diameter or changes in red blood cell flow in the stimulated capillary (or any capillary supplied by the terminal end of the arteriole). Local damage of the stimulated capillary at midpoint (i.e., indicated by dotted circle), or pretreatment of the midpoint by gap junction uncoupler, inhibits the arteriolar/blood flow response to the distal capillary stimulus [3, 4]. (Adapted from Ref. [3].)

Although the capillary sensing/communication phenomenon characterized by the above observations gave rise to a new concept of local blood flow control, the physiological significance of this phenomenon is not clear. To this end, two laboratories provided data relevant to this issue. First, Berg and coworkers [6] reported that, in hamster cremaster muscle, locally induced contraction of muscle bundle unit supplied by capillary bed via a single terminal arteriole caused conducted dilation along this arteriole. A local application of a GJ uncoupler on this arteriole prevented this dilation. Since mechanical tugging of the muscle unit did not result in conducted dilation, it was speculated that the capillary bed was involved in the transmission of contraction-induced vasoactive metabolite(s) to the arteriole. Thus, capillary–arteriolar communication could be involved in matching of the dilation-mediated increase in blood flow to the contraction-induced metabolic demand. Second, Collins and coworkers [7] reported that intravenular application of ATP (1 μM) via micropipette caused an upstream arteriolar dilation. ATP at this concentration has been reported to be released from red blood cells in response to low pH and hypoxia in venous blood. In order to explain the upstream dilation, these workers proposed that ATP stimulated endothelial P_{2Y} and P_{2U} receptors in venules to initiate conducted vascular response across the capillary bed to the arteriole. Thus, capillary endothelium could participate in communication of oxygen sensing signals between the venular and arteriolar ends of the microvasculature.

Unlike in capillaries, conduction of local agonist-induced responses is well characterized for the arteriole. Using recording electrodes inserted into the arteriolar wall at the local site of agonist application and at an upstream site, agonist-induced hyper/depolarizations are seen to spread electrotonically along the arteriolar endothelium. Since the capillary endothelium forms a continuous layer with the arteriolar endothelium, the mechanism of capillary sensing/communication has been assumed to be of a similar nature, that is, involving an electrotonic spread of locally induced hyper/depolarizations. Because of technical difficulties, however, direct electrical recordings from the capillary endothelium have not yet been carried out to confirm this mechanism. To date, an indirect approach has been used instead. Using a voltage-sensitive dye loaded into the capillary endothelium, hyperpolarization and depolarization of endothelial cells were observed after local application of agonists [8]. Employing this method, local depolarization initiated at the upstream arteriole site conducted to a downstream capillary site, demonstrating that electrotonic communication can occur along the capillary endothelium [9].

Another group has used a calcium-sensitive dye in venular capillaries of perfused lung. Spontaneous calcium waves were seen to spread along the capillary wall [10]. That this spread was inhibited by a GJ uncoupler indicated that capillary endothelial cells could communicate via gap junctions in vivo.

In Vitro Work

There is considerable in vitro evidence that microvascular endothelial cells (i.e., the major component of the capillary wall) can communicate electrically via gap junctions. When a single endothelial cell grown in a culture dish is connected to a patch-clamp electrode, its measured input electrical conductance is much smaller than that obtained for a confluent cell monolayer (i.e., indicating substantial intercellular coupling within the monolayer). Alternatively, when a cell in a monolayer is injected with brief pulses of electrical current, rapid electrotonic spread of these pulses through the monolayer is seen (i.e., pulse amplitude decreases with distance along the monolayer). Cultured microvascular endothelial cells have been shown to hyper/depolarize in response to application of vasoactive agents. (Note: with increased cell passaging, the responsiveness to many agents disappears, most likely due to the loss of expression of the appropriate receptors.) We have shown that this hyper/depolarization also communicated along the monolayer, but with a substantial spatial decay (only 20 to 30% of the local membrane potential change was seen at 300 μm distance) [11].

Recently, our laboratory has employed an alternative in vitro model to study endothelial cell-to-cell communication. Instead of monolayers, microvascular endothelial cells (origin: rat skeletal muscle) were grown in Matrigel matrix as "capillary-like" structures (i.e., 300 to 500 μm long with about four cells per 100 μm). A local, agonist-induced hyper/depolarization communicated electrotonically along these structures with a much smaller decay (i.e., 70% of the local response at 300 μm) than in monolayers. Thus, communication along these structures better mimicked the one-dimensional communication along in vivo microvessels than the two-dimensional communication seen in monolayers [11]. In both models, GJ uncouplers inhibited communication. Since, in general, all three vascular connexins have been found in cultured endothelial cells, the available functional and structural evidence indicates that endothelial cells in vitro have the fundamental ability to respond to a variety of vasoactive stimuli and to communicate this response (e.g., hyper/depolarization) rapidly along the microvascular endothelium, including the capillary endothelium.

Communication along the Microvasculature during Sepsis

Sepsis is a systemic inflammatory response to a local infectious insult. The release of lipopolysaccharide (LPS) (or comparable bacterial product) into the bloodstream initiates activation of immune cells and subsequent release of inflammatory cytokines that precipitate a number of circulatory disorders. These include decreased systemic vascular resistance, reduced responsiveness to vasoconstrictors and vasodilators at the microvascular level, impaired oxygen utilization, and maldistribution of flow within the capillary bed. Since sepsis can affect endothelial function (e.g., biosynthesis of nitric oxide, permeability), it is possible that sepsis could also affect the capillary–arteriolar communication and, consequently, the feedback pathway of the local blood flow control.

Using the micropipette application approach (Figure 1) in septic rat skeletal muscle (i.e., 24-hour cecal ligation and perforation model of sepsis), we found that sepsis attenuated the arteriolar response to vasodilators applied distally on capillaries. Since this attenuation was more pronounced than the attenuation seen after application of vasodilators directly on the arteriole, we concluded that the capillary sensing/communication was affected by sepsis [12].

Because of the technical limitations of our *in vivo* model, we used our *in vitro* models of communication to tease out the effect of sepsis on capillary sensing and/or communication. Based on the "capillary-like" structure model, LPS (an initiating factor in sepsis) was found to attenuate electrotonic communication along "capillary" length but not alter the local agonist-induced hyper/depolarization [13]. Thus, capillary communication, rather than capillary sensing, was more likely to be affected by sepsis in vivo. Attenuated communication along the "capillary" could occur via reduced GJ conductance between adjacent endothelial cells or via increased transmembrane conductance (i.e., conductance across cell membrane to extracellular space) of these cells. Based on our endothelial cell monolayer model, LPS was found to reduce GJ conductance, but not alter the transmembrane conductance. Further, this reduction was found to be reversible, protein tyrosine kinase dependent, but protein synthesis and mitogen-activated protein kinase independent [14]. Our subsequent study pinpointed Cx43 as the likely GJ protein to be responsible for the reduced GJ conductance. LPS caused phosphorylation of Cx43 tyrosine residue(s), an event that is generally associated with GJ closure and reduced coupling. Altered tyrosine kinase and phosphatase activities modulated in parallel both LPS-induced phosphorylation of Cx43 and reduction in GJ conductance. Thus these studies provided evidence that at least one agent of sepsis (i.e., LPS) could affect the capillary–arteriolar communication via reduced gap junctional coupling of endothelial cells [15].

Summary

Although GJ-mediated intercellular communication between cells of the vascular wall has, in general, been recognized to play a key role in the coordination of vascular function, the role of GJ in capillary endothelial cells has not

yet been completely clarified. Available indirect in vivo evidence implicates capillary GJ participation in capillary–arteriolar communication and the feedback pathway of local blood flow control. Microvascular endothelial cells grown in vitro retain their ability to respond to vasoactive stimuli and to communicate these responses via gap junctions. Thus, concerted research efforts should be undertaken to provide the necessary direct in vivo evidence to firmly establish participation of capillary GJs in local blood flow control under normal and pathophysiological conditions.

Glossary

Capillary: The smallest blood vessel (~5 μm in diameter in mammalian tissues) lacking continuous muscular layer.

Electrotonic spread: Passive spread of electrical current (e.g., carried by the ions of the cell cytosol) whose amplitude decays with distance.

Gap junction: Intercellular channel directly connecting the cytosols of two adjacent cells.

Sepsis: Systemic inflammatory response to local infection.

Capsule Bibliography

K. Tyml is a professor at the Department of Medical Biophysics, University of Western Ontario. His research interests include local microvascular blood flow control, arteriolar reactivity, and the role of capillaries and vascular cell-to-cell communication in this control. Recently, he has examined the pathophysiological effects of skeletal muscle disuse, and sepsis, and the protective effect of vitamin C, on this local control.

PART II

Organ Microvascular Adaptations

SECTION A

Cardiology

CHAPTER 56

Cardiac Microvasculature

William C. Aird

Department of Medicine, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts

Introduction

The goal of this chapter is to review the structural and functional properties of the cardiac microcirculation. The primary focus will be the endothelial lining of the microvessels. The endothelium may be viewed as a subsystem of the blood vessel wall. The blood vessel, in turn, may be considered a subsystem of the cardiovasculature. In serving as a frame of reference, the endothelium readily lends itself to a consideration of other cellular and noncellular components of the cardiac microvasculature.

Structural Topology

The coronary circulation, like all vascular beds, has a treelike or fractal structure. Two major arteries arise from the aorta, the left main coronary artery (which divides into the left anterior descending and the circumflex arteries) and the right coronary artery. These large vessels lie on the epicardial surface of the heart and function as distribution or conduit vessels, providing rapid mass transport of blood to the myocardium. Once the large arteries penetrate the myocardium, they branch into resistant vessels or arterioles. The small arteries and arterioles (75 to 200 μm in diameter) are the primary sites of coronary vascular resistance, and thus the principal regulators of coronary blood flow. These arterioles give rise to a densely packed capillary network, which runs parallel to sheets of cardiomyocytes. Capillaries serve as exchange vessels, transferring oxygen and nutrients to the underling tissue. The mean intercapillary distance is 17 μm at rest, thus providing a mean maximal diffusion distance of 8.5 μm. There are approximately 2,500 cardiomyocytes and 2,500 capillaries per mm^2. In rodents, the capillary–cardiomyocyte ratio ranges between 0.91 and 1.12. At rest only a third of the capillaries are perfused at any one time. During exercise, coronary vasodilation results in increased flow and capillary recruitment. Blood drains from the capillaries into postcapillary venules, cardiac veins, and ultimately the coronary sinus and right atrium. The microcirculation consists of vessels smaller than 300 μm in diameter, and includes small arteries, arterioles, capillaries, and postcapillary venules. The endocardium, which represents the endothelial lining of the atria and ventricles and heart valves (endocardium), is a developmentally and phenotypically distinct vascular bed and is not discussed in this chapter.

Regulation of Coronary Flow

The heart provides bulk flow of blood to the various tissues of the body, contracting approximately $2^1/_2$ billion times during the lifetime of a human. Compared with other organs, the heart has high basal oxygen consumption (8 to 10 mL O_2/min/100 g) and a large A-VO_2 difference (10 to 13 mL/100 mL). The resistance arterioles (and to a far lesser extent the large coronary arteries) are responsible for mediating vasomotor tone and blood flow. Coronary flow is closely matched to metabolic demands and myocardial oxygen consumption. The precise mechanisms that couple oxygen demand with blood flow remain unknown. Several factors appear to be important, including metabolic changes (termed *metabolic dilation*), flow characteristics, and fluctuations in intramural pressure. Each of these factors is differentially regulated in space and time. For example, metabolic-mediated changes in arteriole diameter and blood flow depend, at least in part, on the initial diameter of the vessel and location within the myocardial wall. The arterial system in the human heart is interconnected by collateral vessels that can enlarge and rescue ischemic areas of myocardium.

The Endothelium as an Input–Output Device

Much of endothelial cell biology can be understood—at least conceptually—by considering each and every endothelial cell in the body as an adaptive input–output device (Figure 1). The input arises from the extracellular milieu and may include biochemical or biomechanical signals. The output is manifested as the cellular phenotype and includes a number of structural and functional properties. Some of these properties are expressed at the level of individual cells or cell culture (e.g., protein, mRNA, proliferation, apoptosis, migration, and permeability), whereas other properties are expressed at higher levels of organization—for example the blood vessel (e.g., leukocyte trafficking, vasomotor tone, fibrin deposition) or organism (e.g., redistribution of blood flow, vascular bed-specific phenotypes). Each endothelial cell may have unique intrinsic properties, the so-called set point. Differences in set point are brought about by environmentally induced epigenetic changes in the "hard wiring" of the cell (see later discussion). Differences in signal input and set point conspire to generate phenotypic differences in space and time—a phenomenon known as endothelial cell heterogeneity or vascular diversity.

If one accepts the analogy of each endothelial cell representing its own input–output device, it is not a stretch to consider the endothelium as a circuit board—one that is hard wired (to some extent) to meet the demands of the tissue, and one that is highly vulnerable to short-circuiting as a mechanism of vasculopathic disease. There are important caveats to this model. First, the input–output device is not a black box, but rather a multiorganelle cell with highly complex nonlinear signaling networks. Second, the system displays properties of emergence. In other words, while the individual capillary endothelial cell follows simple local rules and at any point in time and space has a definable

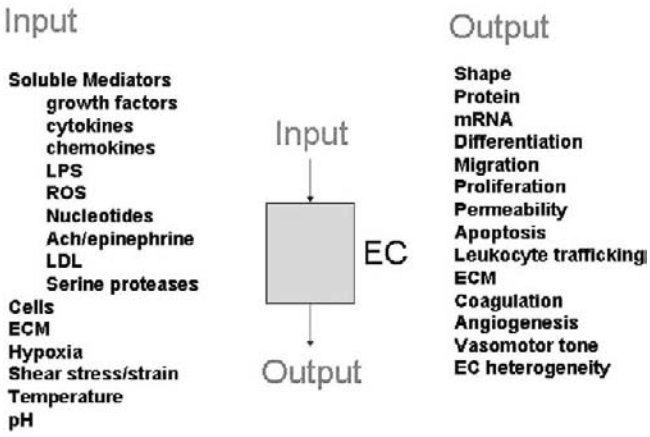

Figure 1 The endothelial cell as an input–output device. Input arises from the extracellular environment and includes a combination of biomechanical and biochemical signals (*left*). The output, or cellular phenotype (*right*), may be expressed at the level of single endothelial cells or at higher levels of organization (e.g., blood vessel, organ, or whole organism). The device itself—depicted here as a "black box"—contains a highly complex array of signal transduction pathways that couple input with output. (see color insert)

(albeit nonlinear) input–output relationship, the properties of the single cell do not predict for behavior of the whole capillary, heart or organism. An important challenge in vascular biology—whatever the vascular bed of interest—is to learn how to integrate the results of studies at the reductionist and holistic ends of the biomedical spectrum to understand the role for the endothelium in health and disease.

Applying the Input–Output Analogy to Cardiac Microvasculature in Health

The notion that the endothelium represents a series of input–output devices is helpful when considering the vasculature or endothelium during development and in the postnatal period. A consideration of cardiac development is beyond the scope of this chapter. The following section will focus on the adult cardiac endothelium.

Conduit and Resistance Vessels

The endothelium of the coronary and resistance vessels has presumably evolved to optimize the transport blood (oxygen and nutrients) to the myocardium. Compared with capillaries or veins, the arterial/arteriolar endothelium is exposed to higher oxygen concentration and shear stress. Like other segments of the cardiac vasculature, the arterial endothelium also experiences forces generated by contraction of the heart. On the abluminal side the endothelium receives signals from extracellular matrix and vascular smooth muscle cells. Based on studies of the heart and other organs, the arterial endothelium differs from its capillary and venous counterparts in morphology, gene and protein expression profiles, and cellular function. As one example, endothelial cells lining the resistance vessels express the highest amounts of endothelial nitric oxide synthase (eNOS), a pattern that is consistent with the established role of nitric oxide (NO) in regulating coronary vascular tone.

The tight coupling of myocardial oxygen consumption and coronary flow may be attributed, in part, to cross talk between cardiomyocytes and resistance vessels. Indeed, it has been proposed that coronary blood flow involves a dynamic, metabolically regulated balance in the production of cardiomyocyte-derived vasodilators (e.g., adenosine, NO, prostacyclin, and bradykinin) and vasoconstricting molecules (e.g., angiotensin II). Whether these and/or other cardiomyocyte-derived factors directly engage vascular smooth muscle cells or communicate indirectly via the endothelium is not known.

Capillaries

Whereas the endothelial lining of arteries and arterioles has evolved to optimize conduit function, the capillary endothelium is adapted to meet the unique and high meta-

bolic needs of the myocardium. If one considers the arteries and arterioles as analogous to train tracks, the capillaries represent the train station—the site where circulating molecules and cells leave and enter the blood. As an input–output device, the endothelium senses numerous mechanical forces, including pressure generated during the cardiac cycle. With each heart contraction, the pressure may result in reduced diameter and flow, particularly in the intramural and subendocardial vessels. The capillary endothelial cell is exposed to multiple biochemical stimuli arising from the blood and abluminal surface (Figure 2). The cardiomyocyte secretes many factors that potentially act in paracrine pathways to maintain or modulate endothelial cell phenotype, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and platelet-derived growth factor (PDGF). VEGF may play a role not only in new blood vessel formation, but also in maintaining survival and adaptive function of the endothelium. On the output side, capillary endothelial cells express a unique pattern of genes and proteins. Moreover, these cells secrete myriad factors that interact with underlying cardiomyocytes, thus contributing to a bidirectional communication between the two cell types. For example, endothelial cells in the myocardium produce NO, endothelin, angiotensin, and prostacyclin, each of which may influence cardiac metabolism and growth, contractile function and conduction. At a functional level, the endothelium participates in the local balance of hemostasis, leukocyte trafficking, and survival/apoptosis. Endothelial cells (together with pericytes) play a critical role in mediating new blood vessel formation. Angiogenesis depends on the sprouting of preexisting capillaries or postcapillary venules, whereas collateral growth (variably termed arteriogenesis) arises from an outward remodeling of preexisting arterioles or small arteries. Angiogenesis normally results in blood vessels of capillary diameter (5 to 8 μm), while arteriogenesis gives rise initially to 10 to 20 μm resistance arterioles and ultimately to conductance arteries. The formation or remodeling of blood vessels depends on the concerted activity of soluble factors released by cardiomyocytes (e.g., VEGF and bFGF), endothelium (e.g., NO), and monocytes (e.g., urokinase-type plasminogen activator, metalloproteinases). Interestingly, there is increasing evidence for the role of endothelial progenitor cells in postnatal blood vessel formation (vasculogenesis) in the setting of cardiac ischemia. The elucidation of the molecular control of angiogenesis, arteriogenesis, and vasculogenesis represents an important foundation for novel cardiovascular therapies.

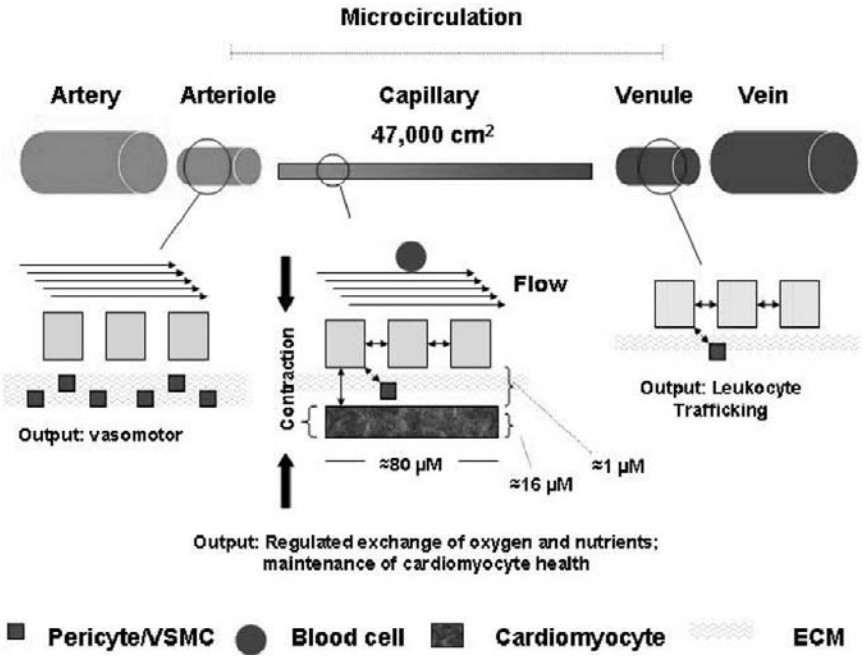

Figure 2 Schematic of cardiac endothelium in health. The endothelium of the artery and arteriole is exposed to comparatively high shear stress and communicates with neighboring smooth muscle cells in the blood vessel wall. In addition to maintaining blood fluidity and barrier function, the endothelial lining of the arteries and arterioles contributes to the control of vasomotor tone. The cross-sectional area of the capillaries is far greater than that of the arteries and veins, thus reducing shear stress at the level of the endothelium and facilitating exchange of oxygen and nutrients with underlying tissue. Multiple input signals arise from the luminal surface (shown is blood flow) and abluminal surface (shown is communication with pericytes and cardiomyocyte, extracellular matrix [ECM], and contractile force). The capillary endothelium plays a critical role in maintaining the viability and function of the myocardium. The endothelium lining the postcapillary venules is the primary site for leukocyte trafficking. (see color insert)

Endothelial cells from the capillaries of the heart (as well as those in the arteries, arterioles, venules, and veins) may possess a distinct "set point," defined as epigenetically programmed switches in phenotype. According to this hypothesis, certain properties of the capillary cells are irreversibly "locked in" by site-specific environmental factors—either during development or in the postnatal period. Although there is compelling evidence that endothelial cells from the epicardial arteries and the endocardium are derived from different subpopulations of precursor cells, little is known about the embryonic origin of capillary endothelial cells. The observation that capillary endothelial cells undergo phenotypic drift in tissue culture, and that this effect is partially reversed by coculture with cardiomyocytes, suggests that at least certain vascular bed–specific properties of these cells are reversibly regulated by the microenvironment. It is important to note that the retention of certain vascular bed–specific properties in vitro does not provide evidence for "genetic predetermination"—after all, each and every cell in the human body has an identical genome. Rather, such findings point to the influence of an epigenetic process at some point during the life of that cell. The distinction between endothelial cell phenotypes dependent on signal input and those that are governed by set point has important therapeutic implications. For example, diabetes is associated with phenotypic changes in microvascular endothelium. Are these changes reversible with correction of the metabolic disease? Or are certain phenotypes irreversibly and indelibly imprinted on the endothelium through modification of the genome? If the latter is correct, then the reversal of endothelial cell "dysfunction" associated with diabetes will be considerably more challenging.

As a result of differences in input signal and set point, the properties of the endothelium differ between different segments of the vasculature within the heart, and even between neighboring endothelial cells within the same vessel. For example, von Willebrand factor (vWF) is expressed at higher levels within the veins of the heart, compared with the arteries or capillaries. eNOS expression is highest in the endocardial and coronary artery endothelium. As a final example, the receptor-type protein tyrosine phosphatase μ is expressed predominantly on the arterial side of the cardiac vasculature.

Venules

Venules and veins function as conduit vessels to deliver deoxygenated blood to the right atrium. Postcapillary venules are the primary site for leukocyte–endothelial interactions and transmigration of leukocytes into the subendothelial space. The propensity for trafficking to occur in postcapillary venules may be explained by the low flow state and/or differential expression of cell adhesion molecules.

Applying the Input–Output Analogy to Cardiac Microvasculature in Disease

Endothelial cell activation is a term that was originally coined to describe the increased adhesiveness of cultured endothelial cells that had been pretreated with cytokines. The term today may be more broadly defined as the phenotypic response of the endothelium to an inflammatory stimulus, usually consisting of some combination of procoagulant and proadhesive properties and loss of barrier function. The term endothelial cell dysfunction was—and to some extent continues to be—used to describe reduced vasodilator reserve in conduit vessels and microvascular resistance vessels in the heart, as observed in atherosclerosis, transplantation, and heart failure. However, the term may be more broadly applied to states in which the endothelial phenotype—whether or not it meets the definition of activation—poses a net liability to the host. Thus, whereas endothelial cell activation describes a definable phenotype of the endothelium, endothelial cell dysfunction describes the cost of the phenotype to the organism.

Endothelial cell dysfunction may arise from any number of changes in the extracellular environment and may in turn contribute to progression in pathophysiology (Figure 3). For example, local differences in blood flow (hemodynamics) may conspire with coronary risk factors to modulate endothelial cell phenotype in the coronary arteries as a prelude to atherosclerosis. Takayasu's arteritis is a necrotizing vasculitis that may be associated with aneurismal dilation of the coronary arteries. Recent studies point to a possible role for endothelial-derived metalloproteinases in this syndrome. Many of the risk factors for conduit vessel disease have also been shown to affect microvascular endothelium, including diabetes and hypertension. Microangiopathic hemolytic anemia, as exemplified by thrombotic thrombocytopenic purpura (TTP), may be complicated by widespread occlusion of small arteries in the heart and recurrent cycles of ischemia–reperfusion. TTP is associated with increased apoptosis of endothelial cells in affected organs. The phenotype of cardiac microvascular endothelial cells has been shown to change in patients with heart failure. Patients with dilated cardiomyopathy have reduced VEGF expression and capillary density. Ischemia–reperfusion injury of the heart is associated with increased ROS generation, decreased NO bioactivity, generation of cytokines and chemokines, complement activation, increased expression of cell adhesion molecules, trafficking of neutrophils and monocytes, mast cell activation, increased permeability, and changes in the ECM. Patients with cardiac syndrome X have reduced coronary microvascular dilatory responses and increased coronary resistance. Sepsis, which is associated with systemic activation of inflammatory and coagulation cascades, may result in abnormalities in systolic and diastolic function. The mechanism does not appear to be related to reduced coronary flow, but rather to the effect of soluble mediators (e.g., input signals) on cardiac endothelium and cardiomyocytes.

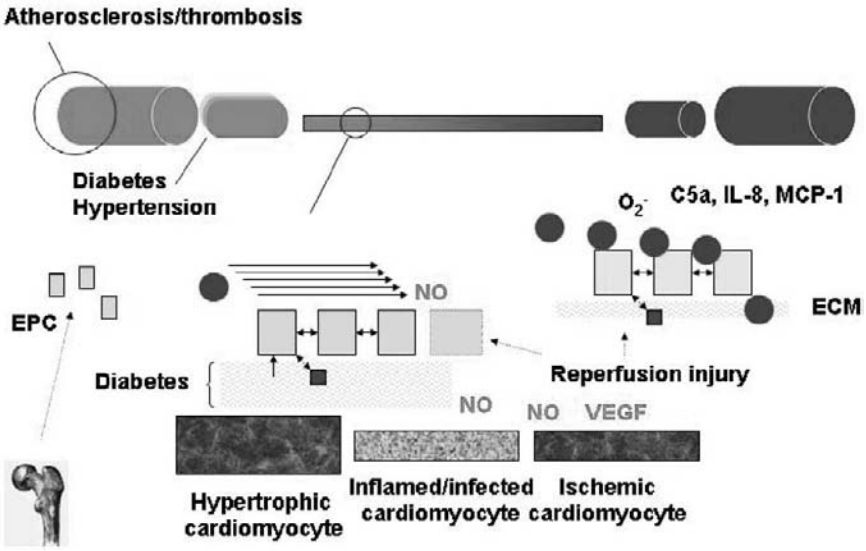

Figure 3 Schematic of cardiac endothelium in disease. The endothelium is both affected by and contributes to cardiac pathophysiology. Atherosclerosis affects the large coronary arteries. Diabetes and hypertension affect large- and small-vessel endothelium. Abnormalities in cardiomyocyte function (e.g., hypertrophic cardiomyopathy, myocarditis, and ischemia) may result in altered paracrine signaling in the endothelium and secondary endothelial cell activation and/or dysfunction. Shown is cardiomyocyte production of nitric oxide (NO) and VEGF. Ischemia/reperfusion results in the exposure of the endothelium to myriad signals, including free oxygen radicals (O_2^-), complement, and cytokines [e.g., interleukin (IL)-8 and monocyte chemoattractant protein (MCP)-1]. Cardiac ischemia may result in increased mobilization and/or uptake of circulating endothelial precursor cells (EPCs) in the cardiac vasculature. (see color insert)

As a final example of microvascular disorders, endothelial dysfunction plays a critical role in mediating cardiac allograft vasculopathy following heart transplantation.

Conclusions

Endothelium and blood vessels carry out certain common core functions: Arteries and arterioles transport blood (oxygen and nutrients); capillaries regulate the exchange of oxygen, and other blood constituents to the underlying tissue; and veins drain the organs of carbon dioxide and metabolic by-products. Different vascular beds employ different strategies to accomplish these tasks. Moreover, each vascular bed—particularly at the level of the capillary—is tightly coupled to the local tissue environment. In the case of the heart, coronary blood flow is highly coupled to the metabolic needs of the cardiomyocytes and is protected by multiple "backup" systems, including the presence of collateral vessels. The microvascular endothelium of myocardial capillaries is exposed to a spatially and temporally regulated input of heart-specific signals—including those that arise from the cardiomyocyte and the hemodynamic forces associated with the cardiac cycle. The dynamic and malleable nature of the endothelium renders these cells vulnerable to pathophysiological changes in the composition of the extracellular milieu. The altered signal input may be transduced by the endothelial cell in ways that perpetuate or accentuate the underlying pathophysiology. Important goals for the future will be to understand how the endothelium contributes to cardiac microvascular disease, and how its privileged location and communication network within the local microenvironment can be exploited for therapeutic purposes.

Glossary

Endothelial cell activation: The phenotypic response of the endothelium to an inflammatory stimulus, usually consisting of some combination of procoagulant and proadhesive properties, and/or alteration in permeability. The criteria for activation depend on the location within the vascular tree.

Endothelial cell dysfunction: An endothelial cell phenotype that represents a net liability to the host. Common examples include coronary artery disease (local dysfunction) and sepsis (systemic dysfunction).

Input–output device: A device that senses the environment and responds in a way that is usually adaptive (function) or nonadaptive (dysfunction). Each endothelial cell behaves like an input–output device, coupling changes in the extracellular milieu (input) to alterations in phenotype (output) via nonlinear networks of intracellular signaling pathways.

Central Nervous System and Eye

CHAPTER 57

The Vasculature of Choroid

Imran A. Bhutto and Gerard A. Lutty
Wilmer Ophthalmological Institute, Johns Hopkins Hospital, Baltimore, Maryland

The choroidal microvasculature lies immediately under or posterior to the retina. Although the gross choroidal anatomy is well known, little information is available on the arrangement of arterioles and venules and their relationship to the choriocapillaris. This chapter will focus on mammalian choroids because avian choroids are uniquely different.

Gross Anatomy

The choroid is considered to be the ocular homolog of the pia arachnoid in brain. It is a long, thin, vascular, and pigmented tissue, which forms the posterior portion of the uveal tract (the iris, ciliary body, and choroid). Because of its great vascularity, the choroid has some of the properties of erectile tissue. Its capillaries form a very unusual pattern, being arranged in a single layer restricted to the inner portion of the choroid; this arrangement enables the capillary layer to provide nutrition for the outer retina (Figure 1). The choroidal stroma contains a considerable number of pigmented melanocytes, which are distributed through all areas of the choroid, although they are more sparse in the innermost layers. The pigment in the melanocytes gives the choroid its characteristic dusky brown color. The choroid has an extensive nerve supply, and many ganglion cells can be found in the stroma and suprachoroidea. The choroid is easily detached from the sensory retina and from the sclera (the collagenous coat of the eye), but it is firmly bound to the optic nerve, because its connective tissue is continuous with that of the optic nerve.

Internally, the choroid is so closely attached to the retina that the retinal pigment epithelium adheres more to Bruch's membrane than to the retinal photoreceptors. Bruch's membrane is the anatomical border between retina and choroid (Figure 1). The area around the choriocapillaris has little or no pigment (Figure 1). Externally the pigmented suprachoroidal connective tissue lamellae are closely bound to those of the lamina fusca of the sclera, the border of choroid and sclera.

The thickness of the choroid is difficult to determine because it diminishes after enucleation or fixation; it has been estimated to be approximately 0.1 mm anteriorly and 0.22 mm posteriorly, with greatest thickness under the macula. The choroidal vasculature in primates is composed of the choriocapillaris (an internal or anterior layer), medium-sized vessels (Sattler's layer), and large arteries measuring 40 to 90 μm, large veins measuring 20 to 100 μm (Haller's layer), nerves, and lymphatics (Figure 2).

The Choroidal Vasculature and Associated Structures

Arteries

There are three main arterial sources of blood to the choroid. The long posterior ciliary arteries (LPCA, temporal, and nasal) follow long, oblique intrascleral courses and, therefore, are easily affected by scleritis. The LPCAs travel in the potential suprachoroidal space and send branches from the ora serrata region posteriorly to supply the choroid as far posterior as the anatomical equator. A ciliary nerve accompanies each LPCA. The second arterial source is the short posterior ciliary arteries (SPCA, 15 to 20 in number) that supply the choroid from equator to optic nerve. The distribution of their entry is perifoveal, peripapillary, or in a compromise pattern, the papillomacular oval. The arteries surround the optic nerve (the circle of Zinn), penetrating and then branching peripherally in a wheel-shaped arrangement. The radial areas supplied by the arteries are separated by watersheds and are triangular, with the apices directed toward the fovea. A watershed zone in choroid is an area that normally fills slowly with blood. Hayreh [1], one of the pio-

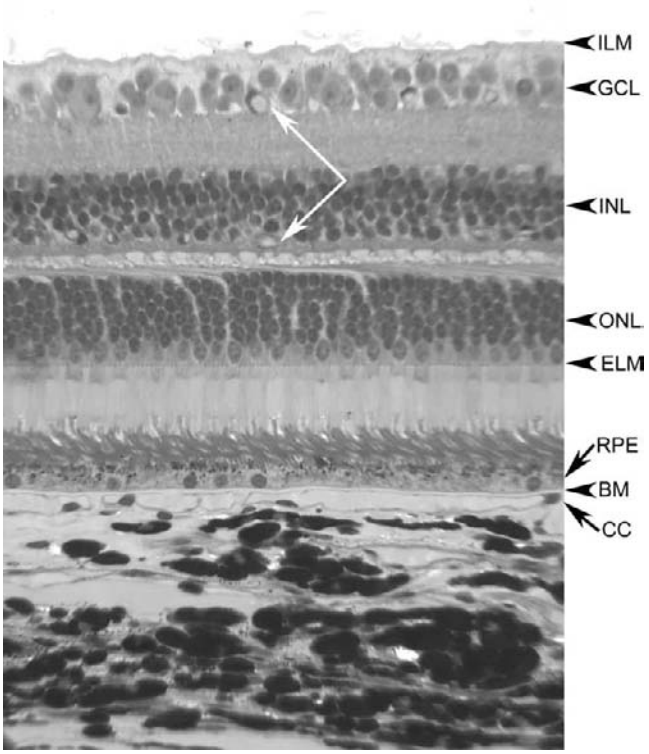

Figure 1 Section from the eye of a rhesus monkey showing retina from the internal limiting membrane (ILM) at the interface of retina and vitreous to the retinal pigment epithelial cells (RPE). Retinal blood vessels (white arrows) are in the ganglion cell layer (GCL) of inner retina, and also a secondary or deep plexus is associated with the inner nuclear layer; their inner and outer segments are below the external limiting membrane (ELM). The nuclei of the photoreceptors are in the outer nuclear layer (ONL). Below Bruch's membrane (BM) is the choroid with choriocapillaris (CC), immediately posterior to Bruch's membrane and large choroidal vessels posterior in the densely pigmented outer choroid. (see color insert)

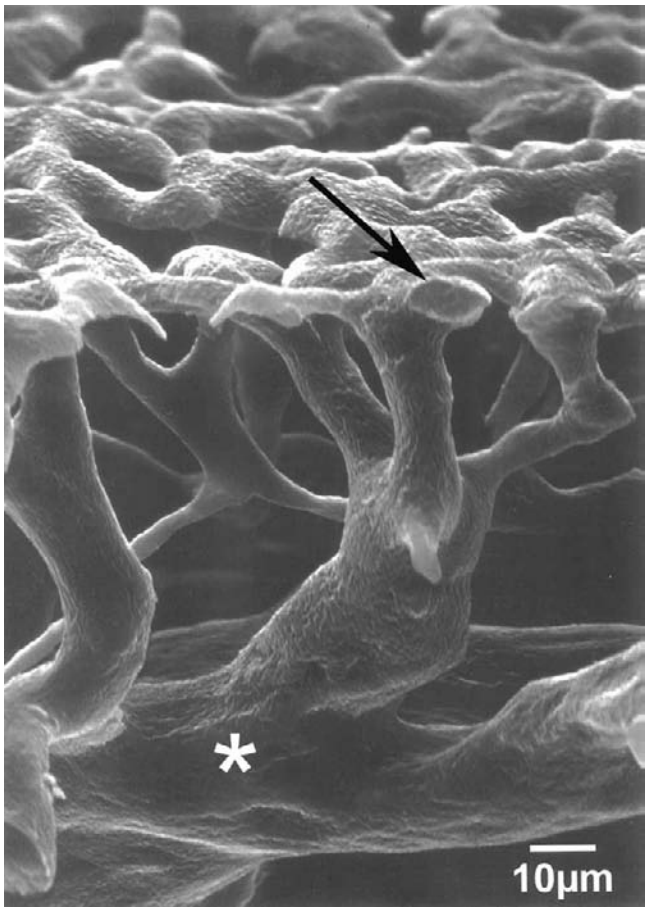

Figure 2 A vascular cast of the choroidal vasculature of a dog. The oval-shaped choriocapillaris (arrow) are at the top with draining venules below connecting to a large vein (asterisk). This section of the cast is the area of the tapedum lucidum, so the venules are more elongated to traverse the tapedum than they would be in a primate.

neers in the study of the choroidal vasculature, has done extensive in vivo experimental studies on choroidal circulation and its watershed zones in human. He has shown that the choroidal vascular bed is a strictly segmental and end-arterial system and has watershed zones situated between the various PCAs, the short PCAs, the choroidal arteries, the arterioles, and the vortex veins. The nature of the choroidal vasculature and the existence of watershed zones in the choroid are of great clinical importance and play a significant role in the production of various ischemic lesions in the choroid. The final arterial source of blood is the anterior ciliary arteries, which send recurrent branches posteriorly to supply the choroid at 3 o'clock and 9 o'clock soon after they pierce the anterior sclera. The arteries of all three vessel systems rapidly extend internally via arterioles to supply blood to the choriocapillaris. Mast cells are intimately associated with most choroidal arteries.

Choroidal Veins (Vortex Veins)

The main venous drainage of the choroid occurs through four to six vortex veins that drain into superior and inferior ophthalmic veins. Postcapillary venules are closely arranged in the macular region. In this area, the venous portion predominates over the arterial one. The meshwork of the venous plexus becomes less dense with increasing distance from the macula. In the extramacular region, the vessels are straighter, losing the tortuousity that is characteristic of the macular region. Vessels of larger lumen form the subcapillaris plexus and eventually flow into the vortex veins. Venous drainage is segmentally organized into quadrants, with watersheds oriented horizontally through the disc and fovea and vertically through the papillomacular region. The macula is centered over both arterial and venous watersheds, which may either predispose it to relative ischemia or prevent ischemia through multiple submacular blood supplies.

Choriocapillaris

The choriocapillaris, located solely in the internal portion of the choroid, appears as a nonhomogenous network of large (20 to 50 μm) capillaries (Figure 2). This monolayer vascular network, flattened in the anterior–posterior aspect,

changes from a dense, honeycomb-like, nonlobular structure in the peripapillary area to a lobule-like pattern in submacular areas and most of the posterior pole and equatorial areas (Figure 3). In the peripheral area, choriocapillaries form more elongated, palmlike or fanlike vascular networks, and finally form arcades that terminate at the ora serrata [2]. The network of choriocapillaris is supplied by feeding arterioles derived from the short posterior ciliary arteries and drained by the collecting venules (Figure 2). These arterioles and venules form the medium-sized vessels of the choroid occupying the choroidal stroma (Sattler's layer). The majority of these vessels in the peripapillary and submacular areas form a 90-degree angle with the posterior aspect of the choriocapillaris (Figure 2). The choriocapillaris lobules measure 0.6 to 1.0 mm (Figure 3).

There is controversy over the idea that "lobules" exist and subdivide the choroid into many functional islands. One hypotheses suggests that the choriocapillaris is a single, continuous capillary vascular layer; although lobules were anatomically separated, they were functionally interconnected. The other hypothesis proposed by Hayreh [1] has advocated the presence of noncommunicating lobules. On the basis of fluorescein angiography findings he described a mosaic of lobules, each one containing an arteriole in the middle and a venule at its periphery.

There is disagreement as well about the location of arterioles and venules in the lobule. Shimizu and Ujiie [3] confirmed the central location of the artery and the peripheral location of the venule. On the contrary, McLeod and Lutty [2], who performed histologic studies of the choriocapillaris stained with alkaline phosphatase reaction product, described a lobular organization of the choroid with arterioles and venules located peripherally and centrally, respectively, in most lobules.

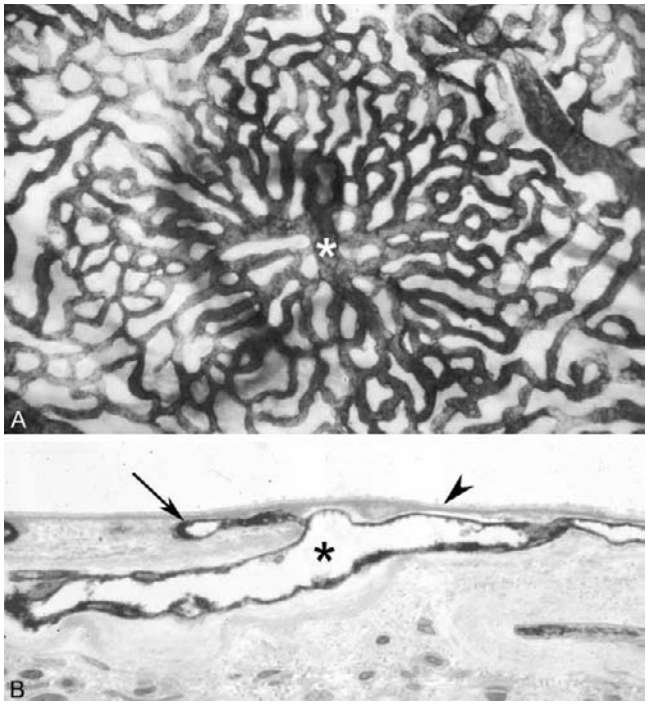

Figure 3 **(A)** Alkaline phosphatase incubated normal human choroid after bleaching. In this area of choroid near the macula, the lobular organization of the choriocapillaris is apparent. There is a draining venule (asterisk) in the center of this lobule. **(B)** Section through the center of the lobule shown in (A) shows blue APase activity in choriocapillaris lumens (arrow) and in the draining venuole (asterisk). The internal limiting membrane (arrowhead) is PAS positive. RPE cells have been removed from Bruch's membrane in processing. (Blue APase reaction product, PAS, and hematoxylin stain.) (see color insert)

Bruch's Membrane (Lamina Vitrea)

Bruch's membrane is a thin noncellular lamina separating the choriocapillaris from the retinal pigment epithelium (RPE). Ultrastructurally, it is composed of the basement membrane of the retinal pigment epithelium (inner basal lamina; 0.3 µm thick); inner collagenous zone (1.5 µm thick); elastic fibers; outer collagenous zone (0.7 µm thick); and basement membrane of the choriocapillaris (0.14 µm thick). Bruch's membrane is eosinophilic and PAS-positive. Mallory and other connective tissue stains show its collagen, and elastic tissue stains show that the membrane contains a well-developed layer of elastic tissue. The inner collagenous layer is thick and may degenerate and split with age. The elastic layer distribution is much more diffuse posteriorly. The basal lamina of the choriocapillaris is incomplete in that it is limited to the actual capillaries and absent at the intercapillary septa.

Retinal Pigment Epithelial (RPE) Cells

RPE cells form the outer blood retinal barrier (BRB). RPE cells measure 16 µm in height and 10 to 60 µm in diameter; they feature apical zonulae occludens (the outer BRB). The RPE nucleus is basal, and its pigment is apical and therefore distant from the choriocapillaris (Figure 1). Inner choroidal vessels (choriocapillaris and medium-sized vessels) are sandwiched between apical RPE pigment of neuroepithelial origin and outer choroidal pigment of neural crest origin.

Visualization of the Choroidal Vasculature

In vivo visualization of the choroid in humans is difficult because of pigmentation of the RPE and choroidal melanocytes. Angiography can be accomplished with sodium fluorescein in lightly pigmented or albino eyes, but not in darkly pigmented fundi as observed in humans of African descent. Angiography with indocyanine green dye, which absorbs and fluoresces in the infrared, has provided the best tool to view the choroidal vasculature in any pigmented fundus. ICG angiography clearly shows blood flow in large choroidal blood vessels, but only high-speed ICG

angiography with pulsed laser light source provides enough resolution to study the choriocapillaris [4].

McLeod and Lutty developed an alkaline phosphatase technique to study histologically the human, cat, and dog choroidal vasculature postmortem [2]. By incubating the excised choroid for alkaline phosphatase histochemical activity and then bleaching the choroid, the choroidal vasculature can be studied at high resolution. The choroid can then be flat-embedded in glycol methacrylate and viewed in dual perspective: choroidal vessel pattern in the flat perspective; vessels of interest sectioned and viewed in cross section as well (Figure 3). Only viable choroidal vessels have alkaline phosphatase activity, so sites of vascular dropout can be studied in detail.

The corrosion cast technique is also an excellent method for studying the three dimensional properties of the choroidal vasculature postmortem [3]. A polymer is injected into the vasculature and allowed to polymerize, and then the tissue is digested away from the polymer. After coating the cast with gold palladium, the vasculature can be viewed in three dimensions with scanning electron microscopy (Figure 2).

Physiology

The choroid lacks autoregulation, that is, it lacks metabolic regulation. We have found that when neonatal dogs are exposed to 100 percent oxygen for 4 days the choroidal vasculature does not constrict. In cat the P_{O_2} in choroid is normally around 70 mmHg, whereas in hyperoxia it increases to 250 mmHg [5]. As a consequence, systemic hypoxia and elevated intraocular pressure lead to decreases in choroidal P_{O_2}. The choroidal vasculature supplies oxygen to outer retina while retinal vasculature supplies oxygen to inner retina. From the measurements and modeling of Linsenmeier's lab [5], the photoreceptors live at the edge. The retina consumes more oxygen per gram of tissue than many other tissues, including brain, barely receiving enough oxygen for maintenance of its normal metabolic function. All of the oxygen for photoreceptor metabolism is supplied by the choroidal vasculature in light conditions and 90 percent of the oxygen consumed by photoreceptors in the dark [5]. As a consequence, choroidal nonperfusion is extremely detrimental to photoreceptor function and viability and retinal detachment from choroid also results in photoreceptor death.

Blood flow rate in cat choroid is said to be at least 10 times higher than retinal blood flow as measured by radioactive microspheres [6]. High blood flow was thought necessary to provide enough oxygen to the retina. However, our recent study using fluorescently labeled erythrocytes demonstrates that, at least in rat, the RBC velocity in choriocapillaris is actually four times slower than in retinal capillaries. The difference in these two values may be due to species differences, but it is more likely due to techniques where the former values are based on blood flow in all choroidal vessels whereas, the RBC velocities where measured directly in capillaries.

Cell Biology

It has been found that rat choriocapillaris had 50 percent fewer pericytes than retinal capillaries. Also, unlike retinal capillaries, pericyte loss does not occur in rat experimental diabetes. Choriocapillaris is unique in that only the retinal side of the capillary has fenestrae, making transport of nutrients to RPE and photoreceptors and removing waste from photoreceptor disk shedding and RPE digestion of these disks more efficient. The same sidedness is observed in the location of VEGF receptors. It has been reported that both VEGF receptor-1 (FLT-1) and VEGF receptor 2 (FLK-1 or KDR) are found on endothelial cells on the retinal side of the choriocapillaris. Perhaps this is related to the basal production of VEGF by RPE. RPE was actually one of the first cells shown to produce VEGF and upregulate production during hypoxia. Perhaps the release of VEGF on the retinal side encourages maintenance of fenestrae on the retinal side of the choriocapillaris.

Pathology

Age-Related Macular Degeneration

The choroidal vasculature is at the heart of age-related macular degeneration. There are many forms of AMD, but the two major types are exudative or wet and nonexudative or dry AMD. In nonexudative AMD eyes, there are macular drusen and sharply defined focal areas of RPE atrophy, which are associated with varying degrees of loss of the choriocapillaris. Drusen is a form of deposit on Bruch's membrane, which is believed to be incompletely digested material from the RPE that cannot traverse Bruch's membrane for removal by the choriocapillaris. One hypothesis states that the deposit of the debris on Bruch's membrane is a result of choriocapillaris insufficiency. Alternatively, debris may accumulate on Bruch's membrane and choriocapillaris atrophy results since it is not needed any more. Drusen appear as refractile structures when viewing the ocular fundus, and the ophthalmologist refers to them as hard drusen when they are sharply demarcated and highly refractile. We have found that hard drusen are present almost always over intercapillary septa and not over choriocapillaris lumens, suggesting that this material accumulates on Bruch's membrane where transport is least likely.

There is considerable controversy over the role of the choroidal vasculature in AMD. Our recent study on geographic atrophy, a form of dry AMD, demonstrated that the RPE cells degenerated first and then the choriocapillaris atrophied. Interestingly, even in areas with complete RPE atrophy, some choriocapillaris segments remained viable (alkaline phosphatase positive) but severely constricted [7].

Exudative AMD is characterized by fluid and hemorrhage beneath the RPE or sensory retina due to choroidal neovascularization (CNV). In exudative AMD, we have observed areas with choriocapillaris atrophy in advance of the growing choroidal neovascularization. Every example of CNV in our study had surviving RPE associated with it. It is tempting to speculate that choriocapillaris loss results in ischemic RPE, and the RPE cells in turn produce angiogenic factors such as vascular endothelial cell growth factor, which stimulated growth of CNV. CNV grows through Bruch's membrane and spreads under the retinal pigment epithelium in most cases (Figure 4).

Whether choriocapillaris is responsible in part for AMD and which forms it initiates remains to be determined. However, there can be no question that there is a dynamic symbiosis between choriocapillaris and RPE and this synergy is disrupted in AMD.

Systemic Diseases

HYPERTENSION

Stenosis, focal narrowing, and occlusion of choroidal arteries accompanied by hypertrophy of smooth muscle cells, endothelial cell proliferation, and reduplication of basement membrane occurs frequently in benign hypertension. These findings led to the assumption that arterial occlusion may precede rarefaction of the choriocapillaris. Long-standing hypertension leads to severe arteriosclerosis, with marked thickening and hyalinization of choroidal arterioles, irregular thickened basement membrane, and reduction in caliber of the lumen. In addition, necrosis and fibrinoid deposition occurs in the choroidal vessel wall. Based on morphologic study of vascular casts on spontaneously hypertensive rats, the early changes in the choroidal vasculature were a decrease in number of draining venules, especially in the peripapillary choroid. As the systolic blood pressure increased progressively, the choroidal vessels were often sparse and tortuous. Some of the venules showed localized aneurismal dilatation and irregular calibers. In long-term hypertension, severe tortuosity, caliber irregularity, and generalized narrowing of the choroidal arteries; considerably decreased number of the draining venules converging from all directions into the vortex veins; narrow ampullae of the vortex veins; and elongated and engorged choriocapillaris were the most extensive morphological changes in the choroid [8].

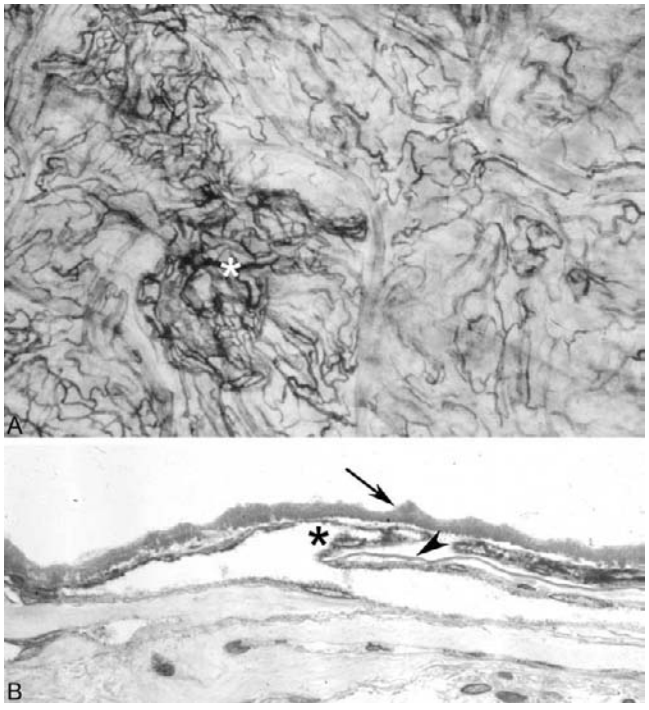

Figure 4 **(A)** Alkaline phosphatase incubated choroid from a diabetic subject. Choroidal neovascularization (CNV) is apparent (asterisk) adjacent to an area with severe choriocapillaris dropout (lack of viable, APase-positive capillary lumens). The yellow areas are drusen. **(B)** Section through the CNV formation in (A) shows that the new blood vessels (asterisk) are between a basal laminar deposit (arrow), which is characteristically positive for PAS, and Bruch's membrane (arrowhead). The origin of the new vessels appears to be choriocapillaris. (Blue APase reaction product, PAS, and hematoxylin stain.) (see color insert)

DIABETIC CHOROIDOPATHY

In both hypertensive and diabetic choroids, we have observed intrachoroidal neovascularization lying deep in choroids near the interface with sclera. These structures, which we termed intrachoroidal microangiopathy or ICMA, were the only sites where we found microaneurysms in human choroids. They were present in 20 percent of the diabetic choroids we have analyzed.

Using the alkaline phosphatase flat-embedding technique, we have observed a fivefold greater loss in choroidal capillaries in diabetic subjects compared to older nondiabetic subjects. This capillary dropout is a hallmark of diabetic retinopathy but had never been quantified in diabetic choroid before [9]. The cause of the choriocapillaris loss may be related to neutrophil-initiated occlusions in choriocapillaris. We documented a twofold greater number of PMNs in diabetic choriocapillaris, compared to normal subjects, and there was a significant increase in PMNs in areas of diabetic choroid with capillary loss as compared to normal-appearing areas of choriocapillaris. The retention of PMNs may be due to increased expression of both ICAM-1 and P-selectin in diabetic choroid. ICAM-1 is constitutively made in normal choriocapillaris, but levels were increased in diabetic choriocapillaris and immunoreactivity was also observed in other choroidal vessels. P-selectin, responsible for leukocyte rolling, was also observed in diabetic choriocapillaris and platelet aggregates in choroid, whereas in normal subjects it was confined to postcapillary venules [10].

Summary

The choroidal vasculature lies between sclera and retina and supplies the majority of nutrients to the outer retina. It

is necessary for normal visual function because it removes waste from photoreceptor disk shedding and supplies 90 to 100 percent of the oxygen photoreceptors require. Dysfunction of the choroidal vasculature occurs in systemic diseases such as diabetes and hypertension and in AMD.

Glossary

Age-related macular degeneration (AMD): Degeneration of choriocapillaris, photoreceptors, and retinal pigment epithelium in macula.

Choriocapillaris: Capillary system of choroid.

Fenestrations: Apertures in the walls of choroidal capillaries that exclude molecules by size.

Acknowledgments

The authors acknowledge and are very grateful to D. Scott McLeod, Wilmer Ophthalmological Institute, who created the figures, critically evaluated this chapter, and provided many of the insights on the choroidal circulation that are mentioned herein. They also thank Stephen Wajer, Johns Hopkins Applied Physics Lab, Laurel, MD, who provided the image of the vascular cast.

Capsule Biography

Dr. Imran Bhutto was awarded an M.D. degree from Sind University, Pakistan and a Ph.D. in Ophthalmology from the University of Nagasaki, Japan, and was a Research Associate in Department of Ophthalmology, University of Nagasaki, Japan, from 1996 to 2001. He was the winner of the Medical Research Award of University of Nagasaki School of Medicine in 2000. His research work primarily focused on ocular blood vessels and systemic diseases, and he has recently become a Research Fellow with Dr. Gerard Lutty at the Wilmer Ophthalmological Institute, Johns Hopkins Hospital, Baltimore, Maryland.

Dr. Gerard A. Lutty was awarded a masters of science degree from Catholic University of America, Washington, DC, and a Ph.D. from the Johns Hopkins School of Medicine Biochemistry, Cellular and Molecular Biology. The Wilmer Ophthalmological Institute is the Department of Ophthalmology but it seemed redundant to say that. He is the recipient of an American Heart Association Established Investigator and a Research to Prevent Blindness Lew Wasserman Merit Award. His research focuses on development of the retinal and choroidal vasculatures and how they change in disease states like diabetes, sickle cell disease, retinopathy of prematurity and age-related macular degeneration. He is an Professor at the Wilmer Ophthalmological Institute, Johns Hopkins Hospital, Baltimore, Maryland.

CHAPTER 58

The Role of the Cytoskeleton in Barrier Function of the Microvasculature

Steven M. Dudek and James H. Finigan
Johns Hopkins University School of Medicine, Baltimore, Maryland

Introduction

The endothelium functions as a semipermeable barrier between circulating vascular contents and the interstitium of the surrounding tissues, and maintenance of this barrier is essential for optimal organ function. For example, the lung is particularly sensitive to perturbations of barrier function because of the enormous surface area of the pulmonary vasculature. Disruption of the pulmonary endothelial lining leads to alveolar flooding during inflammatory conditions such as adult respiratory distress syndrome (ARDS) and sepsis and contributes significantly to the morbidity of these clinical syndromes. As a result, a comprehensive understanding of the regulatory mechanisms involved in endothelial permeability has important clinical implications. Current evidence supports an integral role for the endothelial cytoskeleton in dynamic modulation of vascular barrier function, with recent work highlighting the contribution of the microvasculature to this process. In this chapter, we will focus on the pulmonary vasculature as a model system to outline the cytoskeletal mechanisms that regulate endothelial permeability. Our discussion will begin with a general overview of regulatory mechanisms inherent to endothelial cells (ECs) throughout the vascular bed, and then we will proceed to highlight the permeability properties unique to the microvessel circulation.

Overview of the Cytoskeleton

The cellular cytoskeleton consists of three primary structural elements—actin microfilaments, intermediate filaments, and microtubules (for detailed discussion, see Chapter 38, "Role of the Endothelial Cell Cytoskeleton in Microvascular Function"). The actin cytoskeleton is a dynamic structure that undergoes rearrangement under the control of various actin binding, capping, nucleating, and severing proteins that are intimately involved in regulating the cell shape, motility, and contractile status of cells. Early studies revealed the primary role of actin filaments in EC permeability as demonstrated by the observations that cytochalasin D, which disrupts the actin cytoskeleton, increases EC permeability, while phallacidin, an actin stabilizer, prevents barrier disruption by various agonists. Providing a structural framework to the cell, the actin microfilament system is focally linked to multiple membrane adhesive proteins that connect it to cell–cell (adherens junctions, tight junctions) and cell–matrix (focal adhesion) junctions that anchor the endothelium. In addition, actin filaments, through interaction with myosin, are critical to EC tensile force generation necessary for cell shape changes and barrier regulation (as discussed in detail later).

The functional roles of microtubule and intermediate filament cytoskeletal components in EC barrier regulation are less well defined. Microtubules, polymers of α and β-tubulin forming a lattice network of rigid hollow rods spanning the cell that undergo frequent assembly and disassembly, interact functionally with actin filaments during dynamic cellular processes. Microtubule disruption with agents such as nocodazole or vinblastine induces rapid rearrangement of actin filaments and focal adhesions, cellular contraction, and increased permeability across EC monolayers, while microtubule stabilization with paclitaxel attenuates these effects. These results suggest that actin

microfilament–microtubule crosstalk plays an important, but still poorly defined, role in EC barrier regulation.

Although the third major element involved in EC cytoskeletal structure, intermediate filaments (IFs), exhibit greater diversity than the highly conserved components of actin microfilaments or microtubules, IF proteins share a common dimer structure containing two parallel α-helices that associate with IF-binding proteins that in turn connect to the nuclear envelope, peripheral cell junctions, and other cytoskeletal components. Vimentin, the primary IF protein found in EC and other cells of mesenchymal origin, does not appear to have an essential function in EC barrier regulation. Fibroblasts derived from vimentin knockout mice have normal actin and microtubule architecture, while the animals themselves develop normally without any obvious phenotypic abnormalities, suggesting that functional roles for IF in EC barrier function are subject to compensation by biologic redundancy.

Regulation of Permeability by the Endothelial Cell Cytoskeleton

Because the actin microfilament system is well studied and known to be essential for EC barrier regulation, we will explore its functional role in greater detail in this section. The current paradigm of EC barrier regulation suggests that a balance exists between barrier-disrupting cellular contractile forces and barrier-protective cell–cell and cell–matrix tethering forces. As outlined in Figure 1, both competing forces in this model are intimately linked to the actin-based EC cytoskeleton by a variety of actin-binding proteins that are critical both to tensile force generation and to linkage of the actin cytoskeleton to adhesive membrane components. Although less structured than in skeletal or smooth muscle cells, ECs contain similar molecular machinery for generation of tension via an actomyosin motor (actin and myosin represent more than 15% of total EC protein). Focally distributed changes in tension within EC are accomplished by regulation of the level of myosin light chain (MLC) phosphorylation, which promotes actomyosin interaction, and subsequent actin stress fiber formation. There is a good association between the development of transcellular actin stress fibers, increased MLC phosphorylation, enhanced tension development, paracellular gap formation, and increased EC permeability. A key regulator of this EC contractile apparatus in this process is the Ca^{2+}/calmodulin (CaM)-dependent enzyme myosin light chain kinase (MLCK).

Balancing these EC contractile forces are cell–cell and cell–matrix contacts that provide tethering forces essential for mechanical stability and barrier maintenance (Figure 1). Adherens junctions are the primary cell–cell contacts along the EC monolayer and are composed of cadherins bound together in a homotypic and Ca^{2+}-dependent fashion to link adjacent ECs. Cadherins interact through their cytoplasmic tails with the catenin family of intracellular proteins, which provide anchorage directly to the actin cytoskeleton. The primary cadherin in human EC adherens junctions, vascular endothelial (VE)-cadherin, is critical to EC barrier integrity since infusion of VE-cadherin blocking antibody increases lung vascular permeability in cultured ECs and mice. Focal adhesions provide the primary tethering sites of ECs to the underlying extracellular matrix through transmembrane integrin receptors connected to the actin cytoskeleton via multiprotein focal adhesion plaques. These linkages are also essential for EC barrier integrity as blocking antibodies to β_1 integrin alter EC attachment and permeability. Unliganded integrins are not associated with the cytoskeleton, but binding to the ECM induces the attachment of integrins to intracellular actin fibers and stimulates tyrosine phosphorylation of multiple proteins and Ca^{2+} influx. Moreover, intracellular signaling pathways that regulate cytoskeletal rearrangement can also modulate cell–matrix contacts. For example, inhibition of the small GTPase Rho dissociates stress fibers from focal adhesions, decreases phosphotyrosine content of focal adhesion proteins, and enhances EC barrier function. Thus, the tethering forces of both focal adhesion and adherens junction complexes are essential components of EC barrier integrity.

Barrier Disruption

Activation of the contractile apparatus is a critical step in many models of agonist-induced EC barrier dysfunction. For example, one well-characterized model utilizes the central coagulation regulatory protein, thrombin, to induce significant pulmonary vascular leakage. The observation that microthrombi occur in the pulmonary microvasculature of patients with acute lung injury suggests this model has biologic relevance to EC barrier regulation in human disease. Thrombin induces a profound increase in EC permeability through rapid actin cytoskeletal rearrangement and force generation dependent on actomyosin interaction catalyzed by the phosphorylation of regulatory MLC by MLCK. Direct activation of MLCK is sufficient to produce EC contraction and barrier disruption, whereas MLCK inhibition abolishes barrier dysfunction in rat lung models of ischemia–reperfusion injury and ventilator-induced lung permeability. Tyrosine phosphorylation status appears to play an important role in regulation of EC permeability since tyrosine phosphorylation of EC MLCK evokes significant increases in MLCK activity, EC contraction, and subsequent EC barrier dysfunction.

The small GTPase Rho also plays an important role in regulation of the EC contractile apparatus in several models of agonist-induced EC barrier dysfunction. Linking extracellular stimuli to dynamic actin cytoskeletal rearrangement, Rho activation induces increased MLC phosphorylation, actomyosin interaction, stress fiber formation, and subsequent EC barrier dysfunction. The relative contributions of the EC MLCK and Rho pathways in regulating EC permeability are not completely understood since inhibition of either MLCK or Rho activation attenuates

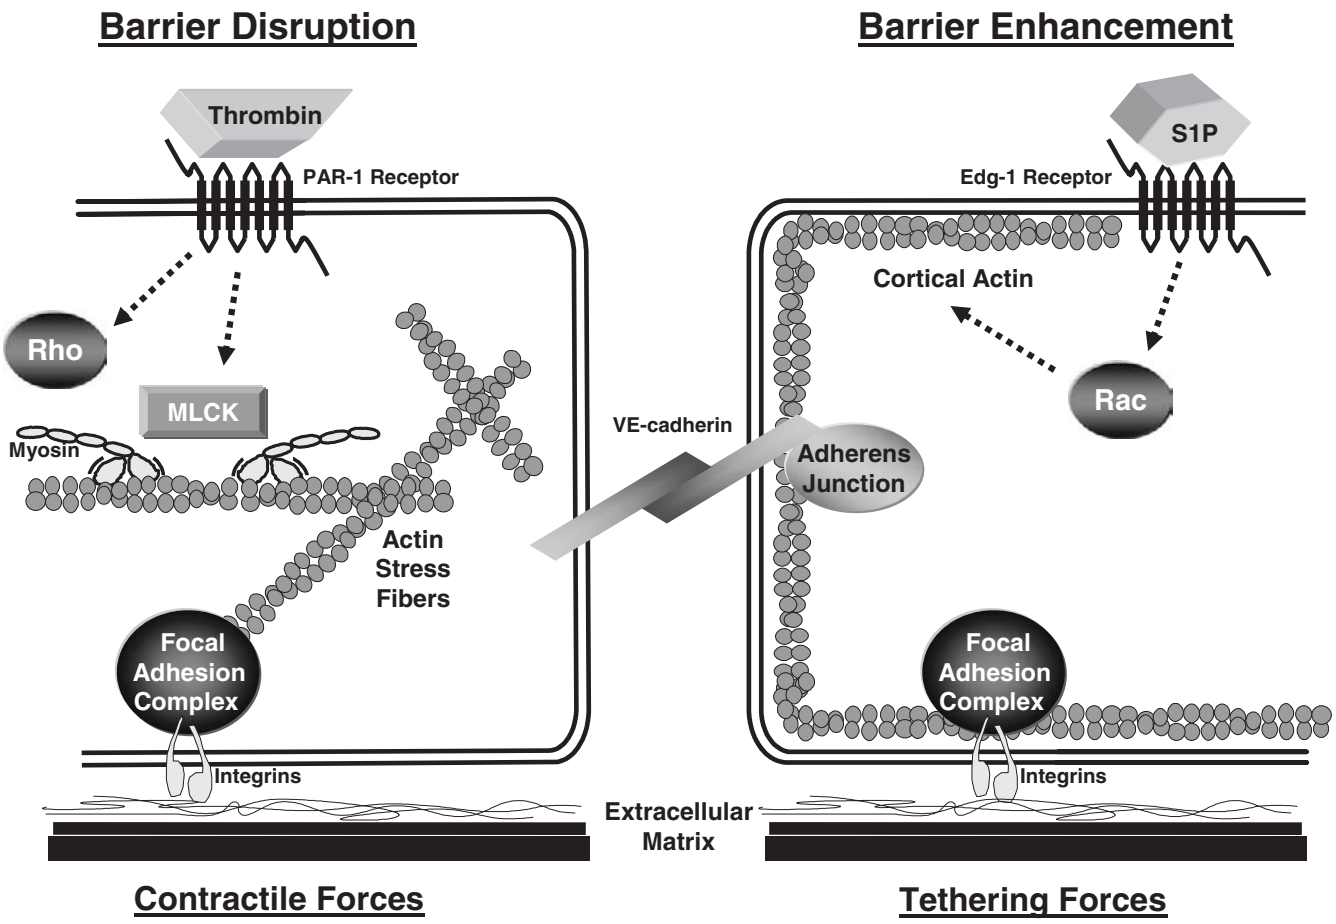

Figure 1 Actomyosin contractile elements compete with cellular tethering forces to regulate EC permeability. The left-hand cell illustrates cytoskeletal changes associated with agonist-induced EC barrier disruption. Thrombin binding to its PAR-1 receptor leads to Rho and MLCK activation along actin stress fibers, actomyosin interaction, contraction, and increased permeability. Conversely, the right-hand cell shows the barrier-enhancing cytoskeletal changes produced by sphingosine 1-phosphate (S1P), which strengthens the cortical actin ring through Edg receptor binding and subsequent downstream Rac activation, cortical actin formation, and adherens junction and focal adhesion rearrangement to decrease permeability. Vascular barrier integrity is dependent upon a balance of these two competing forces.

thrombin-induced EC barrier dysfunction. Recent studies suggest that Rho and MLCK may differentially regulate MLC phosphorylation according to spatial localization within ECs.

Barrier Enhancement

Cytoskeletal rearrangements are also essential for production of EC barrier enhancement by various agonists, such as the platelet-derived phospholipid sphingosine 1-phosphate (S1P), which dramatically reduces pulmonary vascular permeability. S1P binds to G-protein coupled Edg receptors on EC to initiate a series of cytoskeletal protein rearrangements that decreases EC permeability (Figure 1). Activation of the small GTPase Rac results in formation of a prominent cortical actin ring that accompanies S1P-induced EC barrier enhancement. In addition to inducing this cortical actin cytoskeletal rearrangement, S1P alters cell–cell and cell–matrix contacts to reduce EC permeability. S1P dramatically increases localization and interaction of VE-cadherin and catenin proteins at EC cell–cell junctions (adherens junctions). Moreover, while the barrier disrupting agent thrombin rearranges cell–matrix contacts so that focal adhesion proteins assemble at the ends of massive actin stress fibers to anchor cell contraction that pulls ECs apart, S1P induces differential focal adhesion protein rearrangement that associates with cortical actin ring formation that enhances EC barrier function.

Ongoing studies of these contrasting models of EC barrier disruption and enhancement continue to provide insights into potential targets for therapeutic modulation of vascular permeability. This recent work has described additional agonists with impressive EC barrier-enhancing properties. For example, hepatocyte growth factor (HGF) significantly increases pulmonary EC barrier function through enhanced cortical cytoskeleton linkage to cell–cell tethering junctions. Although HGF-induced barrier enhancement requires actin rearrangement and rapidly activates Rac in a manner similar to S1P, the mechanistic pathways are not identical since HGF requires PI-3′-kinase

activity whereas S1P does not. Thus, multiple signaling pathways exist for promotion of EC barrier function. The 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitor and cholesterol lowering agent, simvastatin, induces actin cytoskeletal cortical rearrangement and gene expression alterations over time that protect pulmonary EC barrier integrity from thrombin disruption without affecting basal permeability. In addition, the importance of mechanical forces in regulation of EC permeability is being increasingly recognized. The application of physiologic levels of shear stress to cultured pulmonary EC results in enhanced cortical actin and other cytoskeletal rearrangements that promote barrier function. Conversely, stretch forces similar to those produced during mechanical ventilation make pulmonary EC more sensitive to the barrier disrupting effects of thrombin.

Differential Regulation of Permeability in the Microvasculature

Having described the general mechanisms through which the cytoskeleton regulates endothelial permeability, we will now outline specific characteristics intrinsic to microvascular barrier function. Although the endothelium was initially regarded as relatively homogeneous throughout the vasculature, important phenotypic and functional differences are now appreciated at various sites along the vascular tree. These differences account for the tremendous physiologic variability observed in vascular function along various EC segments in different organ systems. Studies of endothelial heterogeneity typically divide ECs into two primary groups, macrovascular cells from large conduit vessels and microvascular cells from small arterioles, venules, and capillaries.

Isolation and culture of the microvasculature pose a particular challenge, in large part because it is not possible to cannulate the microvasculature. Isolation of microvascular ECs requires physical dissociation of ECs via homogenizing, mincing, or cutting the tissue into 3- to 5-mm^3 pieces before incubation with proteolytic enzymes to release the microvascular ECs. However, these techniques often yield other cell types in addition to microvascular ECs (most frequently fibroblasts); therefore, purification is a key step in the isolation of microvascular ECs. Visual identification of cells based on morphologic characteristics followed by manual separation techniques was an early method of purification but is labor intensive and time consuming. Microvascular ECs can also be removed with specially coated glass beads that specifically adhere to ECs when added to the culture and then are removed using a magnet. Other techniques include fluorescence activated cell sorting (FACS) and gradient centrifugation to separate cells differentially by weight. Regardless of the technique employed, the possibility that other cell types are present in microvascular EC cultures needs to be considered when evaluating experimental results.

Multiple factors contribute to the differential barrier properties of microvascular and macrovascular EC (Figure 2), including cell-specific attributes such as surface protein expression, cell morphology, and permeability. Morphologic differences include a fourfold larger surface area for microvascular ECs relative to pulmonary artery ECs, while electron microscopy reveals tighter intercellular connections, fewer visible gaps, and increased focal adhesion sites in microvascular cells compared to macrovascular ECs. In addition, microvessel ECs contain a more abundant array of intercellular junctional complexes. All of these microvascular EC characteristics combine to decrease basal permeability in these cells relative to large conduit ECs. Specifically, cultured microvascular ECs have tenfold higher barrier integrity than macrovascular ECs as measured by electrical resistance across monolayers. Even within each of these broad categories of macro- and microvascular ECs, significant variability is present. EC morphologic appearance, cell surface glycoproteins, cell–cell interactions, and protein and mRNA expression are all highly variable throughout the vasculature. The functional importance of this variability remains a highly active area of research.

Studies comparing the responses of various EC phenotypes to specific agonists have provided insight into differential barrier function along the vasculature. In general, microvascular ECs are more resistant to agonist-induced lung permeability. Cultured bovine and sheep pulmonary artery ECs have been shown to be more sensitive than microvascular ECs to barrier disruption by agents such as endotoxin or TNFα. However, this relative resistance of microvascular ECs is not universal to every model of agonist-induced permeability since thrombin produces more dramatic barrier disruption in microvascular ECs compared to pulmonary artery ECs. The mechanisms underlying this differential EC barrier regulation remain poorly understood, but it appears that Ca^{2+}-dependent signaling events play a role. For example, macrovascular ECs are more sensitive to barrier disruption induced by store-operated Ca^{2+} entry, whereas microvascular ECs have increased levels of intracellular cAMP, a determinant of focal adhesion complex formation that contributes to barrier integrity. Differential adherens junction protein expression may also account for some of the variability in EC barrier function along the vascular tree. Microvascular ECs express significantly more VE-cadherin protein than macrovascular cells, an observation that appears to have functional importance for cell–cell integrity since the infusion of anti-VE-cadherin antibodies causes increased permeability primarily in alveolar capillaries. Finally, variability in the extracellular environment likely plays an important role in differential EC barrier function. Mechanical forces such as shear stress and cyclic stretch significantly affect EC cytoskeletal organization in ways that alter permeability (as discussed earlier) and are differentially distributed along the vasculature. For example, understanding the effects of shear stress on pulmonary EC barrier integrity must take into account regional differences in blood flow that affect the amount of shear applied

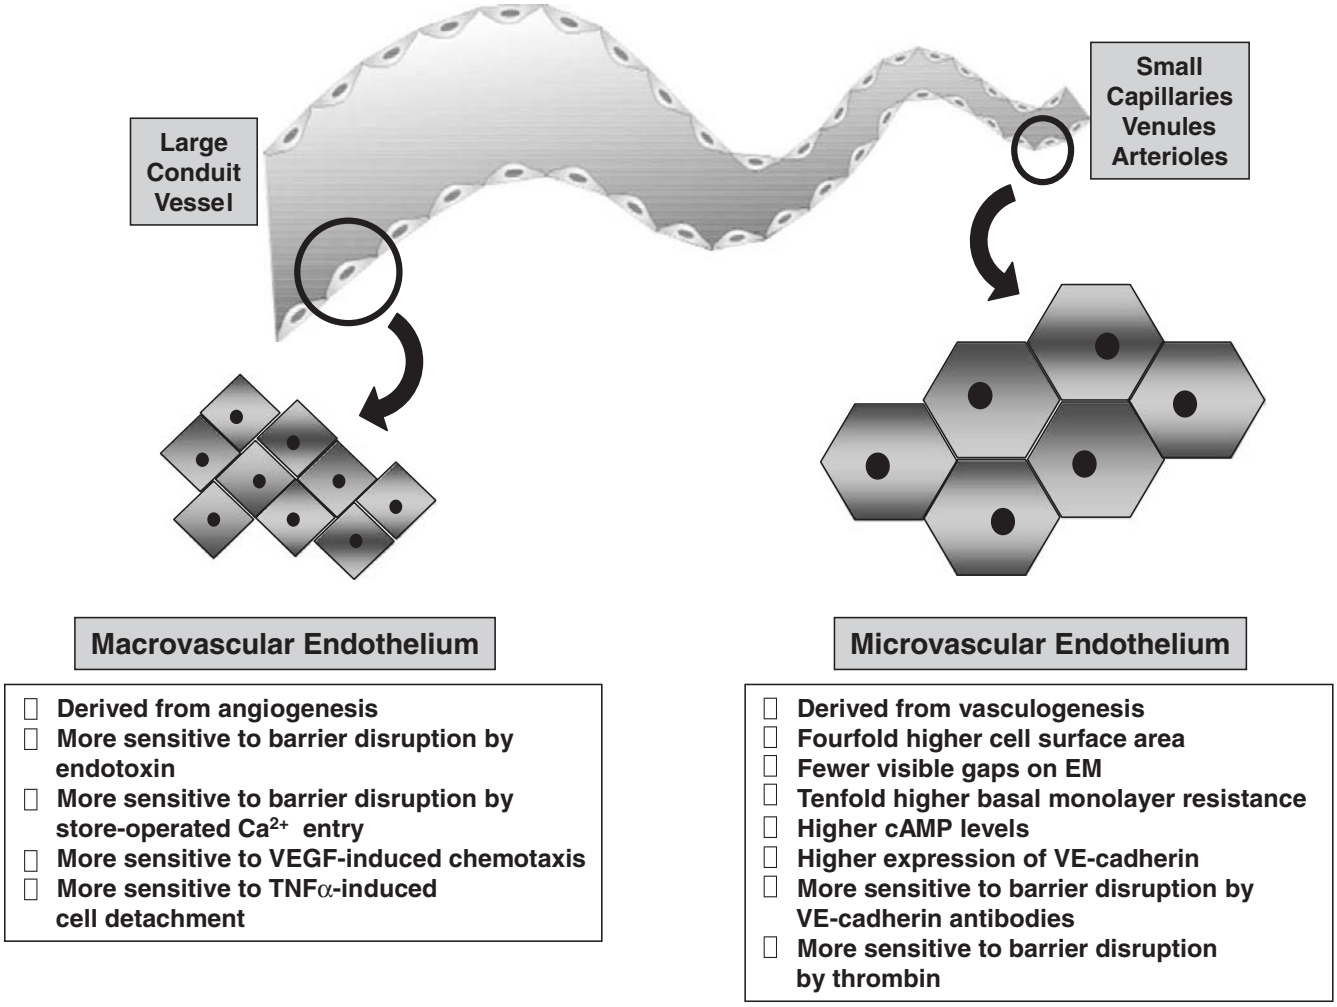

Figure 2 Differential barrier properties of endothelial phenotypes. The diagram shows the cross section of a blood vessel extending from the proximal large arteries to the small microvessels. Listed beneath each broad category of endothelium are specific characteristics related to differences in barrier function between these vascular areas.

to macrovascular ECs relative to microvessel ECs. The contribution of these mechanical forces to differential EC permeability is still incompletely understood.

Glossary

Cytoskeleton: Framework of structural proteins necessary for cell shape and movement. The three primary components are actin microfilaments, microtubules, and intermediate filaments.

Myosin light chain kinase (MLCK): A Ca^{2+}/calmodulin, ATP-dependent enzyme that phosphorylates myosin light chains on serine-19 and threonine-18, which results in increased actomyosin interaction. MLCK activity is a necessary step in many models of vascular permeability.

Sphingosine 1-phosphate (S1P): A biologically active phospholipid generated by hydrolysis of membrane lipids, S1P is produced in significant quantities by circulating platelets and has potent EC barrier-enhancing and chemotactic properties.

Thrombin: A central regulatory molecule in the coagulation cascade, thrombin produces potent EC barrier disruption through stimulation of actomyosin interaction, stress fiber formation, contraction, and intercellular gap formation.

Capsule Biography

Dr. Dudek is a faculty member of the Division of Pulmonary and Critical Care Medicine of the Johns Hopkins School of Medicine. His research focuses on the cytoskeletal regulation of pulmonary vascular permeability in acute lung injury syndromes and is supported by grants from the NIH.

Dr. Finigan is a research fellow performing similar studies in the Division of Pulmonary and Critical Care Medicine of the Johns Hopkins School of Medicine.

CHAPTER 59

Microcirculation of the Brain

Frank M. Faraci and Donald D. Heistad

Departments of Internal Medicine and Pharmacology, Cardiovascular Center, University of Iowa Carver College of Medicine and VA Medical Center, Iowa City, Iowa

The microcirculation of the brain is unique with respect to both its complexity and its heterogeneity. Beginning more than a century ago, studies by Ehrlich and others led to the development of the concept of the blood–brain barrier (BBB). Later work established that cerebral blood vessels have an endothelial structure that is unique and a critically important component of the cerebral circulation. Thus, this present chapter will focus on basic characteristics of the cerebral microcirculation with an emphasis on endothelium. An overview of the role of endothelium under normal conditions will be presented, as well as examples of mechanisms that contribute to microvascular dysfunction in disease states.

Endothelium and the Blood–Brain Barrier

In most regions of brain, tight junctions are present between adjacent endothelial cells. These cells, which constitute the blood–brain barrier (BBB), do not express/possess fenestrations, contain few pinocytotic vesicles, and exhibit very high transendothelial electrical resistance. These unique features are due in very large part to induction of BBB properties by astrocytes. Once induced during later embryological development, the BBB plays many important functions including protecting the brain from fluctuations in changes in concentrations of ions, neurotransmitters, and other substances that could affect neuronal and/or glial function. The genomic and proteomic expression patterns that account for these unique characteristics are only beginning to be defined. Recent studies have begun to explain at the molecular level how permeability of the BBB is regulated. For example, studies in gene-targeted mice have shown that deficiency in claudin-5 (a major cell adhesion protein expressed within endothelium and at tight junctions) increases permeability of the BBB to small molecules.

In addition to the presence of tight junctions between cells, the BBB exhibits other unique permeability characteristics. While the BBB is very selective in relation to substances are allowed to pass from blood to brain, it also expresses a host of transporters for key substances such as glucose and some amino acids.

Many studies have examined the pathophysiology of changes in permeability of the BBB. This work has identified veins and venules as major sites of disruption of the barrier, and found that many conditions (including ischemia with reperfusion, acute hypertension, proinflammatory stimuli, subarachnoid hemorrhage, and meningitis) disrupt the BBB. Although several mechanisms may by involved, a common mediator of this disruption in disease states may be reactive oxygen or reactive nitrogen species (see later discussion).

In contrast to most regions of the brain, some sites within the central nervous system do not have tight junctions between endothelial cells. These sites include the choroid plexus, which is the major site of formation of cerebrospinal fluid (CSF), and the circumventricular organs. Resting levels of blood flow and microvascular permeability within these regions are very high compared to regions expressing the BBB. Regulation of blood flow is also unique in these structures. For example, humoral stimuli such as circulating angiotensin II and vasopressin have marked effects on blood flow to choroid plexus and production of cerebrospinal fluid but little effect on blood flow to other regions of the brain.

The cerebral microcirculation is also unique in that resistance of large arteries appears to be greater in the cerebral circulation than in other vascular beds. Large arteries contribute importantly to total cerebral vascular resistance and are major determinants of local microvascular pressure (arteriolar pressure), which is lower than in other vascular beds.

Endothelium and Vascular Tone

In addition to its fundamental role in controlling vascular permeability, endothelium is also a major regulator of vascular tone. The primary mechanism by which endothelium regulates tone of underlying vascular muscle under normal conditions is by release of endothelium-derived relaxing factor(s) (EDRFs). These factors include nitric oxide (NO), endothelium-derived hyperpolarizing factor(s)(EDHFs), and prostacyclin (Figure 1).

Under normal conditions, most studies indicate that nitric oxide is the predominant EDRF in the cerebral circulation. In both pial (vessels on the surface of the brain) and parenchymal arterioles, many lines of evidence illustrate that nitric oxide from endothelium influences basal tone and mediates the majority of the response to acetylcholine (the classic endothelium-dependent agonist), other receptor-mediated agonists, and increased shear stress (Figure 1). Once it diffuses to vascular muscle, nitric oxide produces relaxation predominantly via activation of soluble guanylate cyclase and increased production of cGMP (Figure 1). This mechanism of endothelium-dependent relaxation may differ from that seen in select peripheral microvascular beds where some studies have suggested that EDHF is the major EDRF in microvessels.

The cerebral microcirculation is unusual in that responses to bradykinin, another endothelium-dependent agonist, are mediated by reactive oxygen species (ROS) in normal cerebral arterioles. It is not entirely clear which reactive oxygen species specifically mediates this response, but hydrogen peroxide may be responsible for bradykinin-mediated vasodilatation (Figure 1).

In addition to modulation of microvascular function, nitric oxide and reactive oxygen species may affect microvascular structure. For example, preliminary findings indicate that genetic deficiency in superoxide dismutase-1 (SOD-1), the CuZn isoform of SOD, produces increases in superoxide and hypertrophy of cerebral arterioles. Increases in cross-sectional area of the vessel wall (hypertrophy) may have functional consequences because hypertrophy of vascular muscle can impair maximal vasodilator capacity.

Although nitric oxide is the primary mediator of microvascular responses to many endothelium-dependent stimuli, EDHF may mediate a major portion of the response of cerebral microvessels to other endothelium-dependent stimuli including selected purines (Figure 1). To date, there has been no convincing evidence that EDHF or reactive oxygen species influence resting tone of cerebral arterioles under normal conditions.

In summary, endothelium-derived nitric oxide influences resting microvascular tone and is a major EDRF in brain. For selected stimuli, however, reactive oxygen species and EDHF can also be important EDRFs in the cerebral circulation.

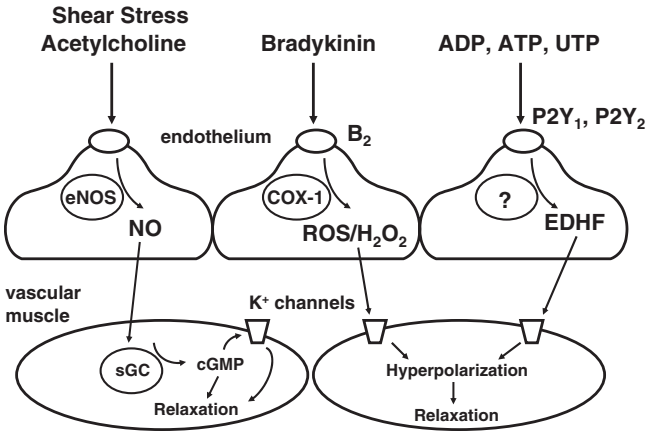

Figure 1 Schematic representation of major mechanisms of endothelium-dependent relaxation of vascular muscle in cerebral microvessels. Nitric oxide (NO) is produced by the endothelial isoform of NO-synthase (eNOS) in response to activation of the M_5 subtype of muscarinic receptor and other endothelium-dependent stimuli. NO diffuses to vascular muscle, where it activates soluble guanylate cyclase (sGC), causing increased production of cyclic GMP (cGMP), activation of cGMP-dependent protein kinase I, and relaxation. In contrast, bradykinin (via activation of the B_2 subtype of receptor) activates cyclooxygenase-1 (COX-1), resulting in production of reactive oxygen species (ROS) including hydrogen peroxide (H_2O_2). H_2O_2 activates potassium channels (K^+ channels) in vascular muscle, producing membrane hyperpolarization and relaxation. In response to some purines (ATP, UTP, ADP), endothelium can produce EDHF through an unknown pathway. By definition, EDHF produces relaxation of vascular muscle by activation of potassium channels and membrane hyperpolarization. In some vessels, cGMP can also activate potassium channels.

Potassium Channels

In blood vessels, there is a close relationship between membrane potential and intracellular calcium, and between membrane potential and vascular diameter. Thus even small changes in membrane potential of vascular muscle produce significant changes in vascular tone. Opening or closure of potassium channels has important effects on membrane potential and thus vascular tone.

Studies utilizing pharmacological approaches, and more recently genetically altered mice, suggest that potassium channels play a major role in mediating microvascular dilatation in response to diverse stimuli. These stimuli include elevations in concentrations of extracellular potassium ion, receptor-mediated agonists (including calcitonin gene-related peptide, prostacyclin, and adenosine), second messengers (cAMP and cGMP), EDRFs, reactive oxygen species (hydrogen peroxide and superoxide anion), chemical stimuli (hypoxia, hypercapnia, acidosis), and calcium sparks.

Endothelium-Derived Contracting Factor

Endothelium has the potential to produce and release a diverse group of contracting factors, named endothelium-derived contracting factors (EDCFs). These factors include endothelin, products of cyclooxygenase activity, and reac-

tive oxygen species. In normal vessels, production of EDCFs appears to be absent or minimal. However, EDCFs may be important mediators of vascular dysfunction in disease states. For example, a cyclooxygenase-derived EDCF produces contraction by activation of PGH_2-thromboxane A_2 receptors in cerebral arterioles of spontaneously hypertensive rat and in a rat model of type I diabetes. In these arterioles, indomethacin or inhibition of prostaglandin H_2/thromboxane A_2 receptors restores endothelial function to normal, suggesting that endothelial dysfunction is mediated by a cyclooxygenase-derived EDCF.

Reactive Oxygen and Nitrogen Species

Nitric oxide and superoxide anion react very efficiently and inactivate each other as they form peroxynitrite. Thus, the bioactivity of nitric oxide depends, in part, on its interaction with superoxide. Increased levels of superoxide impair relaxation of cerebral arteries in response to endothelium-dependent stimuli. Kontos and Wei were the first to provide evidence that superoxide inactivates nitric oxide (EDRF) in vivo.

In addition to reducing bioavailability of nitric oxide, the reaction of nitric oxide with superoxide forms peroxynitrite, a potent oxidant that has the potential to produce endothelial dysfunction through a variety of mechanisms (Figure 2). These mechanisms include nitrosylation and reduction in function of prostacyclin synthase and the mitochondrial isoform of superoxide dismutase, oxidation of tetrahydrobiopterin (a critical cofactor for normal function of NO-synthase), and activation of poly (ADP-ribose) synthetase (PARS).

Superoxide may mediate impairment of endothelial function in the cerebral microcirculation in response to angiotensin II, β-amyloid peptide, or amyloid precursor protein (APP), alcohol, nicotine, and homocysteine, as well as in models of acute hypertension, traumatic brain injury, and ischemia. Endothelium, smooth muscle, and adventitia all have the potential to produce superoxide. There are multiple sources of superoxide, including NAD(P)H oxidase, xanthine oxidase, cyclooxygenase, mitochondria, and NO-synthases, as well as autooxidation of substances such as hemoglobin, tetrahydrobiopterin, and β-amyloid. Thus, inactivation of nitric oxide by superoxide contributes to impaired endothelial and nitric oxide–mediated dilatation of cerebral blood vessels under several pathophysiological conditions.

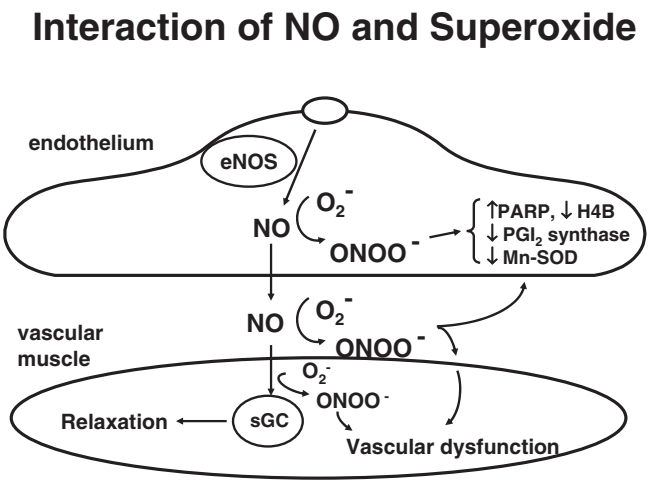

Figure 2 Schematic representation of the interaction of nitric oxide (NO) and superoxide (O_2^-). NO is produced by eNOS and can diffuse to vascular muscle and activate soluble guanylate cyclase (sGC) resulting in vasorelaxation. NO can also rapidly react with superoxide to form peroxynitrite ($ONOO^-$). This interaction can occur in different cell type and subcellular compartments—wherever superoxide is produced. Superoxide can be formed within blood vessels by several sources including NAD(P)H oxidase, cyclooxygenase, xanthine oxidase, and mitochondria. Once formed, $ONOO^-$ can produce vascular dysfunction through a variety of potential mechanisms (see text).

Angiotensin II

It has been known for many years that the renin–angiotensin system contributes importantly to some forms of hypertension. Recent work suggests that activation of this system may contribute to vascular disease under other pathophysiological conditions, including atherosclerosis and diabetes. Angiotensin II has many effects on vascular cells. In aorta, for example, angiotensin II produces oxidative stress, activates components of the inflammatory cascade, and produces endothelial dysfunction.

In the cerebral microcirculation, angiotensin II produces superoxide-mediated endothelial dysfunction and impairs local increases in blood flow in response to somatosensory activation. In stroke-prone spontaneously hypertensive rats (SHRSP) that have endothelial dysfunction, local inhibition of angiotensin-converting enzyme restores endothelial function toward normal, suggesting that endogenous angiotensin II may be a mediator of vascular dysfunction. Using transgenic mice that overexpress both human renin and human angiotensinogen, we have provided evidence that the renin–angiotensin system is an important determinant of microvascular "remodeling" during chronic hypertension.

Capsule Biography

Dr. Faraci is Professor of Internal Medicine and Pharmacology at the University of Iowa College of Medicine. His research deals with the biology of the carotid artery and cerebral circulation with a focus on defining mechanisms that produce vascular dysfunction in disease states. He is an Established Investigator of the American Heart Association and has received the Lamport Award from the American Physiological Society. He is Assistant Editor for Stroke, and Associate Editor for Arteriosclerosis, Thrombosis and Vascular Biology, serves on numerous editorial boards, and is the lead investigator on the Cerebral Vascular Biology Program at the University of Iowa.

Dr. Heistad is Zahn Professor in the Departments of Internal Medicine and Pharmacology at the University of Iowa and staff physician at the VA Medical Center. A major focus of Dr. Heistad's laboratory is physiology and pathophysiology of cerebral blood vessels. He has received the Wiggers Award from the American Physiological Society, the Landis Award from the Microcirculatory Society, and the Research Achievement Award from the American Heart Association. He is Editor-in-Chief of *Arteriosclerosis, Thrombosis, and Vascular Biology*. His work is supported by grants from the NIH and VA.

Model Systems for Studying Blood–Brain Barrier Function

K. L. Hallene, G. Dini, and D. Janigro
The Cleveland Clinic Foundation, Cleveland, Ohio

The blood–brain barrier (BBB) has been described in detail over the years, both physiologically and morphologically [1]. At the cellular level, the BBB is composed of glia and microvascular endothelial cells (ECs). The latter are characterized by the presence of tight junctions, lack of fenestrations, and minimal pinocytotic vesicles. ECs, together with astrocytes, form a selectively permeable barrier protecting the brain from systemic influences, while still providing pathways of transport for nourishment to neurons in the parenchyma. Today, it is generally accepted that movement of ions and molecules across the BBB is restricted due to endothelial cell tight junctions. However, under certain conditions, some toxins may actually increase BBB permeability, allowing entry of potentially noxious substances into the brain. It is therefore recognized that the blood–brain barrier plays a crucial role in the determination of neurotoxicity and its prevention by specific transport mechanisms [2].

Because of the anatomical and topographic obstacles associated with the direct investigation of BBB in vivo, its structure and physiological properties are often inferred from studies of isolated microvessels and primary cultures of brain microvascular endothelial cells. This is true for both the normal and disease states.

Experimental observations first made over a century ago showed that the central nervous system (CNS) is not stained by intravascular water-soluble dyes, providing the first demonstration of the existence of a barrier to the passage of polar compounds from the blood to the brain. Pioneering studies of the BBB were performed in vivo using intracarotid injection single-pass techniques. Further characterization of the BBB at the cellular level more recently has led to the development of in vitro experimental approaches. Isolated brain microvasculature preparations, as well as tissue culture systems using brain endothelial cells, have proven to be a promising methodology to define the characteristics of the brain capillary endothelium at the molecular and cellular level. The purpose of this review is to describe the virtues and pitfalls of cell culture-based models of the BBB.

Monodimensional Models of the Blood–Brain Barrier: Endothelial Cells

The most commonly used model to study the blood–brain barrier in vitro stems from a rather simplified view of the BBB and consists of the so-called "Transwell system," where cells are grown on porous membranes and immersed in growth media (Figure 1). A variety of cells have been successfully grown under these conditions, including, but not limited to, endothelial and epithelial cells from rodents, primates, or human origin. The most attractive features of this model are its simplicity and the ability to perform several experiments at the same time. Many Transwells can be simultaneously loaded with cells or cell lines, and experiments can therefore be rapidly performed, minimizing the cost and need for an experimenter's skills. However, the major pitfalls of this system are that cells are grown in the absence of physiological stimuli, such as perivascular glia, shear stress, or interaction with blood cells present in the cerebral circulation under normal conditions, develop an abnormal permeability across the EC layer. Another limitation of this system is that cells are grown in the presence of serum, on both the luminal and abluminal sides. Conversely, in vivo, only the luminal side is exposed to serum proteins and the abluminal part is exposed to glial influences or cere-

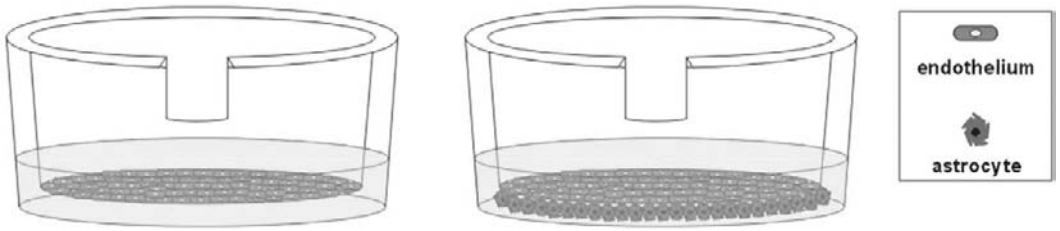

Figure 1 Schematic representation of the Transwell system. Either monodimensional endothelial cultures (*left*) or bidimensional endothelial-astrocyte coculture can be established (*right*). (see color insert)

Table I Advantages and Disadvantages of Each Model Used to Study the BBB in Vitro.

	Monodimensional (Transwell)	Bidimensional (coculture)	Tridimensional (DIV-BBB)
Pros	Ease of use Ideal for Michaelis-Menten kinetics of transport due to fixed volumes in each compartment Can do several experiments at same time Minimal skills Cost efficient	Coculture allows induction of BBB properties Molecule flux across is lower than monodimensional Cost efficient	Artificial capillaries connected by gas-permeable tubing allows source of growth medium, exchange of O_2+CO_2, exposure to flow Induction of BBB properties High TEER Low permeability to sucrose Stereoselective transport Can mimic intravenous/intra-abdominal delivery versus administration by mouth Long term studies possible Presence of drug extrusion mechanisms
Cons	Lacks physiological flow High permeability to sucrose Low TEER Exposure to serum on both sides (luminal + abluminal)	Lacks physiological flow High permeability to sucrose Low TEER (to a lesser extent)	Linear kinetic studies more difficult, because of flow Cost Skills Number of cells to be loaded/used

brospinal fluid. In conclusion, monodimensional cultures based on endothelial cells lack true physiological "barrier function." However, Galla and his colleagues have shown that with the addition of hydrocortisone to serum, the barrier function greatly improves [3]. The physiopathological significance of these findings is unclear, but the modification provided by these investigators greatly improved the usefulness of these models.

Bidimensional Models of the Blood–Brain Barrier: Co-culture of Endothelial Cells and Glia

Bidimensional models of the BBB have been created through the addition of glia to the Transwell system with various levels of success (Figure 1). In doing so, investigators were able to mimic at least one of the fundamental aspects of the BBB, that is, glial–endothelial interactions. It has been well known for some time that glial cells exert a yet unknown influence on their neighboring endothelial counterparts. The nature and significance of this interaction is poorly understood, but it is clear however, that at least in vitro these cells do interact and that glial cells induce BBB properties in endothelial cells. Interestingly, the efficacy of glia to induce BBB properties in endothelial cells is not limited to cerebral endothelial cells since investigators were able to induce BBB properties in nonbrain endothelial cells as well [4].

The main advantage of the bidimensional model, compared to monodimensional, is the attempt to closely mimic the in vivo situation. Thus, the addition of glial cells has led to a decrease in transendothelial leakage. However, this model may also experience some "nonphysiological leak" as well, thus making it more difficult to predict or estimate permeation across the BBB of pharmacological agents or other molecules. Other than those already stated, there are no obvious pitfalls, besides that a source of glial cells is essential, which slightly increases the required skills of the investigator/scientist (Table I).

Tridimensional Dynamic Models of the Blood–Brain Barrier (Flow-Based)

Both short- and long-term changes occur in cerebral arterioles in response to intraluminal flow [5]. Endothelial cells in vivo are continuously exposed to shear stress generated by blood flow. A new in vitro model of the BBB has recently been developed and is characterized by a tridimensional, pronectin-coated hollow fiber structure that enables coculturing of ECs with glia (Figure 2) [6]. In the hollow-fiber apparatus, ECs are seeded intraluminally and are exposed to

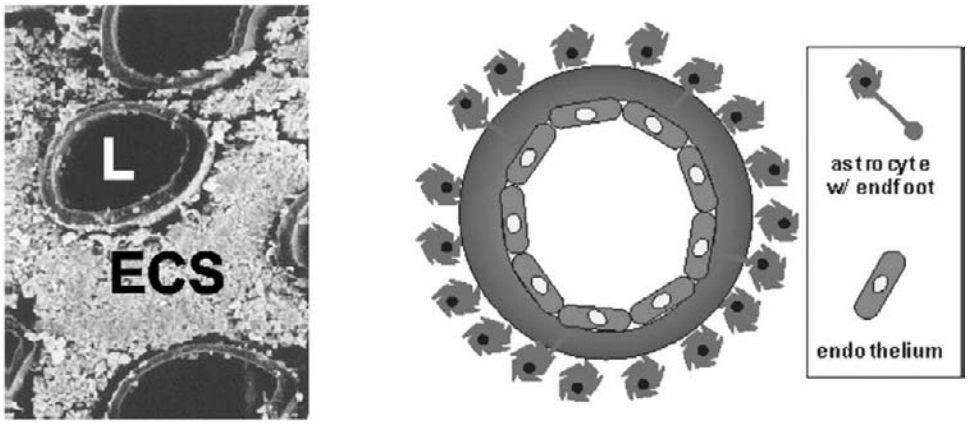

Figure 2 Tridimensional in vitro model of the BBB: Endothelial cells are seeded intraluminally in a pronectin-coated hollow fiber, while astrocytes are cultured extraluminally. *Left panel*: Hollow fiber section (L, lumen; ECS, extracellular space); *right panel*: schematic representation. (see color insert)

flow. Under these conditions, endothelial cells develop a morphology that closely resembles the endothelial phenotype in situ, demonstrating that endothelial cells that are grown under flow conditions develop a greater differentiation than conventional culture. We reported the induction of BBB properties in endothelial cells grown in hollow fibers in the presence of extraluminally seeded glia; this induction of a BBB-specific phenotype included low permeability to intraluminal potassium, negligible extravasation of proteins, and the expression of a BBB-specific glucose transporter. In addition, coculturing of EC with glia affected the overall morphology of these cells and induced the expression of BBB-specific ion channels [6, 7].

The model system used for these studies resulted from a modification of a traditional cell culture system normally used for expansion of hybridoma cells, and the general design of the hollow-fiber apparatus was derived from attempts toward the development of a "cell factory." Cell culture on hollow fibers has been extensively exploited for mass production of rare cell types, antibody production, and modeling of organlike structures such as the blood–brain barrier. Ott et al. [8] used a hollow fiber cell culture apparatus for studies of flow-mediated effects on endothelial cell growth, while Stanness and her colleagues [4] further developed this system by performing permutations of intra- and extraluminal cell growth to study the effects of glia on endothelial cells.

The dynamic in vitro BBB model (DIV-BBB) is constituted by a plastic support containing a variable number of artificial capillaries (approximately 300 μm cross diameter with a lumen of approximately 75 μm). These capillaries bear 0.5-μm transcapillary pores that allow free diffusion of solutes from the extraluminal compartment to the intraluminal space and vice versa. The capillaries are intraluminally perfused at various shear stress rates by pulsatile flow (Figure 3). It was shown that induction of BBB-like characteristics occurs following prolonged coculture of glia and bovine

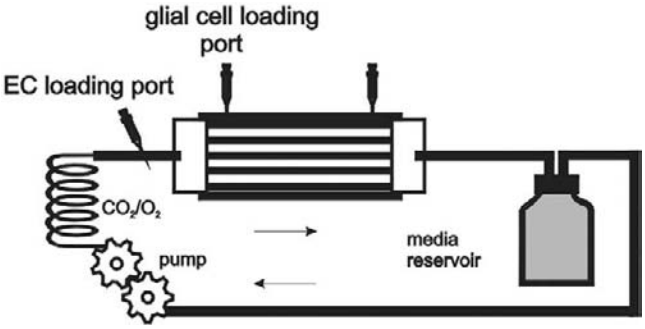

Figure 3 Schematic representation of the tridimensional dynamic in vitro model (DIV-BBB); cells are injected into the system through the loading ports and the flow is maintained by a pump. (see color insert)

aortic endothelial cells and that glia can induce the expression of BBB-specific ion channel proteins in non-BBB endothelial cells [6]. Interestingly, genetically altered astrocytes lacking intermediate filaments were not capable of these induction properties [9].

Several improvements in model design have allowed for better understanding and study of the central nervous system and neurological diseases. This model in particular has several advantages compared to mono- or bidimensional models, such as closely mimicking the conditions of pre- and postcapillary vessels in vivo, and allowing for experimental manipulations and reutilization of the device. In this model, high transendothelial electrical resistance (TEER), low permeability to sucrose, and stereoselective transport also prevail. It is also possible to perform long-term studies (months), and the presence of drug extrusion mechanisms allows for meaningful drug permeation studies. However, there are obvious limitations to this model, including, but not limited to, lack of blood cells, no intraluminal pressure changes, and a lack of neuronal influences. Some of these issues have been addressed recently by Krizanac-Bengez and co-workers [10].

Table II Advantages and Disadvantages of Cell Lines versus Primary Human Cultures.

	Cell lines	Primary human cultures
Pros	Cost effective Easy to use Readily available	Variety of etiologies available Not manipulated Don't divide uncontrollably
Cons	Some conditions/diseases may be unable to be mimicked by these cells May become hyperproliferative or "immortalized"	Obtaining human specimens Skills Number of cells isolated

Cell Lines versus Primary Cultures

Once the "ideal model of the blood–brain barrier" has been designed, one must decide what kind of cells to use for a particular experiment. There are no definitive rules, but one must keep in mind that some conditions are only present in a particular species, as, for example, in the case of humans. However, experiments with dynamic modeling have shown that one of the initiating factors in endothelial cell differentiation consists of cell cycle arrest induced by flow [11]. It is therefore imperative, whatever cells one may decide to use, that these cells themselves be capable of being distracted from the cell cycle by environmental cues.

In fact, if cell lines are to be used, one has to carefully assess their tendency to become either hyperproliferative or immortalized since both conditions will make their differentiation into a mature endothelial phenotype either hard or impossible (Table II). Obviously, cell lines offer numerous advantages, including cost-effectiveness and ease of use. However, with the advent of stem cell research, and our increasing understanding of how blood cells differentiate into endothelial cells, one can envision a future where differentiating factors will be used to induce blood–brain barrier properties in omnipotent stem cells.

Many factors must be taken into consideration if the desire exists to use primary human cultures (Table II). The availability and ease of obtaining human specimens to isolate cells can be a challenging obstacle, unless experiments are performed in proximity to a hospital or similar environment where specimens are readily available. The numbers of cells to be isolated are crucial to running a successful experiment and therefore increase the techniques and time required of the scientist. Although these pitfalls seem major, the benefits of using primary human cultures far outweigh the costs. The main advantages in using primary human cultures are that these cells are not manipulated, allowing the study of the actual disease and its progress. Also, cells can be manipulated as needed for any given experiment. Obtaining human specimens provides a variety of etiologies that otherwise may not be available in cell lines or commercial products. Under normal conditions, primary cells also tend not to divide excessively or take on an "immortal" phenotype, as often occurs in cell lines.

In Vitro Models of the Human Blood–Brain Barrier

The main goals of in vitro studies of the blood–brain barrier are to reproduce as many aspects of the physiology and biology of the BBB in vivo as possible and to understand human disease. Therefore, it is imperative to stress the need for human cell-based models since several pathological conditions cannot be reproduced in cell-line-derived or rodent-based BBB models.

The current understanding of brain pathophysiology has led to the hypothesis that numerous diseases of the CNS are associated with failure of BBB structural integrity or function, as an altered BBB permeability may be observed in several diseases—epilepsy, ischemia, trauma, etc.

Extravasation of plasma proteins with BBB dysfunction can occur through any number of different transcellular or paracellular routes, including altered tight junctions, disruption of EC membranes, or formation of transendothelial channels. These pathways, however, are not mutually exclusive. Regardless of whether BBB disruption or consequences of the disease(s) themselves are the main factors leading to dysfunction or changes in structural integrity, the understanding of the mechanisms of the BBB is limited. This is perhaps due to the lack of comprehensive BBB models.

Conclusions

This chapter has described several properties of BBB models along with the advantages and disadvantages of each apparatus or technique. In the future, new and improved models may be invented and contribute to a better understanding of the etiology of both chronic and acute neurodegenerative brain disorders and disease. In conclusion, an individual cannot clearly define the ideal blood–brain barrier model, since in vivo approaches have obvious pitfalls, and in vitro models are pliable, yet different from in vivo conditions. Given that the ideal model does not exist, caution and skill should be exercised to mimic as closely as possible the specific condition that is to be studied. For example, the use of newborn human cells is a poor model of Alzheimer dementia.

Glossary

Blood–brain barrier (BBB): A membrane characterized by tight junctions, presence of glia, lack of fenestrations, and minimal pinocytotic vesicles separating the brain tissue from circulating blood and possible harmful substances.

Cell culture: A technique for growing cells outside of the organism in nutrient medium under laboratory conditions.

In vitro: In an artificial environment outside the organism.

In vivo: In an environment inside the organism.

Stem cell: A cell that has the ability to divide (self-replicate) for indefinite periods, often throughout the life of the organism. Under appropriate conditions, stem cells can give rise (differentiate) into many different cell types that compose the organism.

CHAPTER 61

Adrenomedullin and Blood–Brain Barrier Function

Béla Kis
Wake Forest University, Winston-Salem, North Carolina

Adrenomedullin (AM), a recently discovered vasodilator peptide, was originally isolated from human pheochromocytoma, and the initial reports suggested that the adrenal medulla, ventricle, kidney, and lung have the highest levels of AM expression. However, since the discovery that the AM gene expression is twentyfold to fortyfold higher in endothelial cells than even in the adrenal medulla, this peptide has been regarded as an important secretory product of vascular endothelium, together with nitric oxide, endothelin-1, and other vasoactive metabolites. Recent data from our laboratory indicate that adrenomedullin, as an endothelium-derived autocrine/paracrine hormone, plays an important role in the regulation of specific barrier properties of brain endothelial cells. In this chapter, we describe current knowledge about the possible role of AM in blood–brain barrier (BBB) functions.

AM, a Vasoactive Hormone

AM is a multifunctional peptide, which is present ubiquitously in the body. The normal plasma concentration of AM is in the range of 1 to 15 pmol/L, and AM is derived mostly from endothelial cells. Its plasma half life is about 20 minutes. It is degraded initially by metalloproteases followed by an aminopeptidase. The lungs are the main clearance site of AM in humans.

AM molecule shows some homology with calcitonin gene-related peptide (CGRP) and amylin, suggesting that AM belongs to the CGRP superfamily. AM consists of 52 amino acid residues in humans and 50 amino acid residues in rats. It has two characteristic structures, a ring structure formed by an intermolecular disulfide bridge and a C-terminal amide structure, which are essential for the receptor binding and the biological activity of AM.

The biological actions of AM are mediated via two specific adrenomedullin receptors, and at higher concentrations AM also can cross-react with the CGRP type 1 (CGRP1) receptor. Although the pharmacology of these receptors is distinct, the main component of both is the calcitonin-receptor-like receptor (CRLR). Whether CRLR functions as an AM or CGRP receptor is dependent on the presence of one of the three receptor activity modifying proteins (RAMP). When CRLR combines with RAMP1 it defines the CGRP1 receptor, whereas the combination of CRLR with either RAMP2 or 3 forms the AM receptors.

CRLR is a member of the type II G-protein coupled receptor family, and like other members of this receptor family it signals via Gs and adenylate cyclase activation. Increased intracellular cyclic adenosine 3′,5′-monophosphate (cAMP) level is the usual result of AM challenge. Intracellular calcium concentrations appear to be unaffected by AM in many different cell types expressing endogenous AM receptors, except endothelial cells where AM can also increase intracellular calcium concentration. When injected intravenously, AM acts predominantly in organs in which the AM gene is highly expressed. These observations suggest a local autocrine and/or paracrine role for AM.

AM has been shown to have a wide range of physiological effects. It is implicated in the regulation of fluid/electrolyte homeostasis, insulin secretion, and glucose metabolism. AM has an important role in pregnancy and fetal growth, inhibits apoptosis, and regulates cell proliferation.

The major role of AM is in the paracrine control of vascular function, supported by the high levels of AM secreted

by endothelial cells and vascular smooth muscle cells. AM is a powerful hypotensive peptide. Its vasodilator effects are mediated in part by an elevation of cytoplasmic cAMP leading to relaxation of vascular smooth muscle cells. In addition, AM acts on endothelial cells; it stimulates nitric oxide production via calcium-dependent activation of endothelial nitric oxide synthase, which also contributes to vasodilatation. AM regulates vascular smooth muscle cell proliferation, inhibits endothelial apoptosis, promotes angiogenesis, and regulates blood coagulation and fibrinolysis. Transgenic overexpressing and knockout models further emphasize that AM is crucial to vascular morphogenesis and function.

Numerous studies defining the circulating AM plasma concentration in different clinical settings showed an elevated AM plasma concentration in a variety of pathological conditions including essential hypertension, chronic heart failure, acute myocardial infarction, pulmonary hypertension, chronic renal failure, diabetes, hyperthyroidism, hyperparathyroidism, sepsis, schizophrenia, autism, bipolar affective disorders, surgical interventions, or during normal pregnancy. Because such a broad range of conditions are associated with elevated AM levels, it seems likely that increases in AM are not causative of disease but rather are compensatory to these pathological events. The results from transgenic mice overexpressing AM gene support the idea of a protective role for AM.

Role of AM in the Microcirculation

Endothelial cells have been shown to contain an elaborate microfilament system allowing active actin- and myosin-based cell contraction. In peripheral endothelium, activation of cell contraction and disturbance of junctional organization subsequently result in the induction of interendothelial gaps followed by enhanced paracellular endothelial permeability. An increased intracellular cAMP level in endothelial cells has been known to decrease the basal permeability properties of the barrier and attenuate the increase in permeability when the endothelial cells are exposed to inflammatory agents. AM, as an autocrine/paracrine hormone, is a potent stimulator of cAMP elevation in endothelial cells. AM can stabilize the barrier function of endothelial cells by a cAMP-dependent relaxation of the microfilament system, thereby preventing endothelial cell contraction and paracellular fluid flux.

Results on transgenic mice show the importance of AM in the regulation of microcirculation. Mice overexpressing AM in their vasculature have turned out to be resistant to lipopolysaccharide-induced shock. On the other hand, AM knockout homozygous mice die at mid-gestation with extreme hydrops fetalis and cardiovascular abnormalities including severe hemorrhages and pericardial effusions. These suggest a general role for AM as an endothelium-derived autocrine hormone in the regulation of endothelial permeability.

AM Production in the Cerebral Microcirculation

Cerebral endothelial cells (CECs) are the most important anatomical and functional constituents of the cerebral microcirculation. The finding of high AM production in peripheral endothelial cells made it probable that CECs could be an important source of AM in the cerebral microcirculation. However, the first report did not support this hypothesis, because Sugo et al. [1] found very low AM production by cultured bovine CECs, which was only a few percent of the AM production of rat aortic endothelial cells. Later this observation was supported by Ladoux and Frelin [2], who described weak AM mRNA expression in clones of rat CECs. It should be mentioned, however, that CECs were passaged a large number of times (10 to 20 passages) in both studies, which is known to deteriorate the original phenotype of the primary cells.

In contrast to these experiments we have recently found unexpectedly high AM production in primary cultures of rat CECs both at the peptide and at the mRNA levels [3]. Rat CECs had about one magnitude higher AM production than was published for other primary cells. Thus, available data indicate that rat CECs have the highest rates of AM synthesis and secretion among the cells studied.

The high AM production of rat CECs was further induced by astrocyte-derived factors; significantly elevated AM production was detected in the culture medium of primary rat CECs cocultured with astrocytes or cultured in astrocyte-conditioned medium. These results suggest that the in vivo AM production may be even higher than that detected in vitro. AM production by rat CECs, however, could not be induced by cytokines, bacterial lipopolysaccharide, and thrombin, which are the most powerful inducers of AM release in peripheral endothelial cells. Our studies also revealed that AM is secreted primarily but not exclusively at the luminal (blood) side of CEC monolayers. Contrary to AM, endothelin-1, a vasoconstrictor peptide, is secreted mostly toward the abluminal (brain) side of bovine CECs.

In addition to CECs, other cellular elements of the cerebral vessels can produce AM, that is, vascular smooth muscle cells, pericytes, or even astrocytes and neurons. All of these cells, however, are on the brain side of the BBB; therefore AM production by both these cells and the choroid plexus seems more likely to contribute to the AM level of the cerebrospinal fluid. AM concentration in the cerebrospinal fluid is comparable to or lower than that in plasma, and an independent regulation of AM level in these two compartments was suggested.

In vivo an approximately 50 percent higher AM concentration was found in the jugular vein than that in the carotid artery, and similarly about a 50 percent higher AM concentration was detected in the venous plasma effluxed from the brain than that from peripheral organs [3]. Previously no significant difference was observed between AM levels in the venous blood from different organs.

These observations strongly support the in vitro findings that the cerebral circulation has an exceptionally high AM

concentration due to the significantly elevated basal AM secretion by brain endothelial cells that is induced by astrocyte-derived factors.

AM Receptors in the Cerebral Microcirculation

The fact that AM behaves as a local autocrine and/or paracrine hormone raises the possibility that AM released by CECs acts primarily on AM receptors present in the cerebral endothelium itself and on neighboring cells. The expression of CRLR, RAMP-1, -2, -3, was characterized on isolated rat cerebral microvessels [4], in rat CECs and cerebral pericytes [3], and in rat astrocytes [2]. In cultured rat CECs and pericytes RAMP-2 showed the highest expression, followed by RAMP-3 and RAMP-1, and exogenous AM increased the intracellular cAMP concentration suggesting the existence of functional AM receptors on these cells [3]. Although astrocyte-derived factors increased the AM production of rat CECs, they did not change the expression of AM receptor components in rat CECs. Oliver et al. [5] reported the same expression pattern of RAMPs in human cerebral vasculature.

Role of AM in Blood–Brain Barrier Functions

Among the endothelial cells of different tissues, the endothelium of the brain is very specific. Although cerebral endothelial cells (CECs) share many common properties of the peripheral endothelium, they have a unique morphological and functional feature, the formation of the BBB. The BBB contributes to the stability of the brain parenchymal microenvironment by strictly controlling the traffic of molecules and cells between the blood and the central nervous system. The BBB has specific, epithelial cell-like morphological characteristics and physical barrier properties, such as tight intercellular junctions, the absence of intercellular clefts, low rate of pinocytosis, many mitochondria, continuous basement membrane, or high transendothelial electrical resistance. Specific, polarized, highly discriminatory membrane transport systems, such as glucose transporter-1, nucleoside transport system, or large neutral amino acid transporter, operate to supply the brain. Efflux transporters, such as P-glycoprotein or members of multidrug-resistance protein family (MRP-1, -3, -4, -5, -6), can eliminate toxic substances from endothelial compartments and brain. The BBB phenotype of CECs is induced by the astroglial environment. Although the effect of neurons on the induction of some specific CEC properties have been described, the effect of astroglia on CECs in vitro has been more extensively studied.

The involvement of cAMP in the regulation of BBB functions has long been known; for example, cAMP elevates transendothelial electrical resistance and decreases paracellular permeability, reduces the rate of fluid-phase endocytosis, and increases P-glycoprotein function. It has been proved that AM has cAMP-like effects on specific BBB functions in vitro [6]. Exogenous AM increased transendothelial electrical resistance and reduced endothelial permeability for the low-molecular-weight sodium fluorescein, which suggests a tightening of intercellular junctions. AM also decreased endothelial fluid-phase endocytosis, a type of nonspecific endothelial transport, although it did not change the transendothelial albumin permeability. AM activated the P-glycoprotein efflux pump, while it did not change the activity of MRP-1 efflux transporter in cultures of rat CECs. Treatment with either the AM receptor antagonist $AM_{22–52}$ or the AM antisense oligonucleotide decreased the basal intracellular cAMP level in rat CECs. Michibata et al. [7] have reported that neutralization of endogenous AM by monoclonal antibodies reduced the basal cAMP production in bovine aortic endothelial cells. In primary rat CECs antisense treatment significantly reduced the AM production and decreased transendothelial electrical resistance [6]. It is remarkable that the basal intracellular cAMP concentration is the highest in rat CECs followed by GP8-immortalized rat CECs and human umbilical vein endothelial cells, which corresponds to the AM production of these cells. These observations suggest that AM, as an autocrine mediator, plays an important role in the maintenance of basal intraendothelial cAMP levels, and AM appears to be an autocrine inducer of BBB functions of CECs via the activation of adenylate cyclase enzyme. Moreover, astrocyte-derived factors increased the AM production by primary rat CECs, suggesting that AM is involved in the astrocytic regulation of the BBB phenotype. Therefore, AM can be a physiological link between astrocyte-derived factors, cAMP, and the induction and maintenance of the BBB properties by rat CECs (Figure 1).

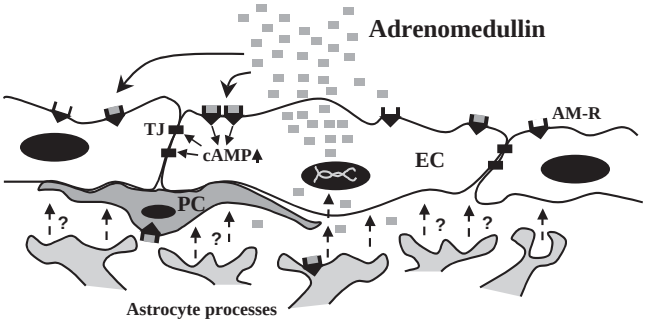

Figure 1 Adrenomedullin and the BBB. Adrenomedullin production in cerebral endothelial cells is stimulated by unknown astrocyte-derived factors. The synthesized adrenomedullin is secreted mostly at the luminal surface of the cerebral endothelial cells into the blood, but also at the abluminal surface. The released peptide acts as an autocrine/paracrine hormone and stimulates cAMP production in the cells. The elevated intracellular cAMP will improve the barrier functions of the cerebral endothelial cells. EC, cerebral endothelial cell; PC, pericytes, TJ, tight interendothelial junction; AM-R, adrenomedullin receptor.

Summary

AM seems to be an important hormone in the cerebral circulation. The concentration of AM is approximately 50 percent higher here than in other regional circulations because of the astrocyte-induced elevated AM production of CECs. AM causes vasodilation in the cerebral circulation and may be important in the maintenance of the resting cerebral blood flow and protective against ischemic brain injury. Recent data from our laboratory indicate that AM, as an endothelium-derived autocrine/paracrine hormone, plays an important role in the regulation of specific BBB properties. AM can be one of the physiological links between astrocyte-derived factors, cAMP, and the induction and maintenance of the BBB. Moreover, the role of AM in the differentiation and proliferation of peripheral endothelial cells and in angiogenesis suggests a more complex function for AM in the cerebral circulation and in the development of the BBB.

Glossary

Gs: A G protein that stimulates adenylate cyclase, leading to increased intracellular cAMP level.

P-Glycoprotein: A 170-kDa integral plasma membrane glycoprotein that functions as an adenosine triphosphate–dependent efflux pump, causing multidrug resistance.

Pheochromocytoma: Hormone-producing (mostly catecholamine) neoplasm of the adrenal medulla.

Capsule Biography

Béla Kis earned his M.D. in 1994 and his Ph.D. in 1998 at Albert Szent-Györgyi Medical University, Szeged, Hungary. He spent 2 years as postdoctoral research fellow at the University of Occupational and Environmental Health, Kitakyushu, Japan, where most of his adrenomedullin-related work was accomplished. Now he is a postdoctoral research fellow at Wake Forest University, Winston-Salem, North Carolina. His research interest is vasoactive mediators and blood–brain barrier function as well as neuronal preconditioning.

CHAPTER 62

Cerebral Microvascular Blood Oxygenation and Neuronal Activity

Ute Lindauer
Experimental Neurology, Charité, Berlin, Germany

Introduction: Definition of the Subject

A tight temporal and spatial relationship exists among neuronal activity, metabolism, and blood flow in the brain. Changes in neuronal activity induce localized changes in metabolism and regional cerebral blood flow (rCBF), a phenomenon termed *neurometabolic and neurovascular coupling*. Consequently, consumption and delivery of oxygen and glucose, the metabolic substrates that fuel the brain, change at the same time. Different temporal and spatial kinetics of oxygen consumption and blood flow lead to complex changes in regional cerebral blood oxygenation. This chapter presents a detailed description of the dynamic changes of blood flow and blood oxygenation during functional activation and relates these to our current knowledge on activation-induced changes of oxygen metabolism in the brain.

Cerebral Blood Oxygen Tension and Hemoglobin Oxygen Saturation at Rest

The brain is a highly oxidative organ. It consumes approximately 20 percent of the body's oxygen and 25 percent of the body's glucose supply. Compared to its small fraction of total body weight (only 2%), a disproportionately large percentage of oxygen and glucose is consumed in the brain. The supply of oxygen to the brain depends on the vasculature, and the brain receives approximately 15 percent of the cardiac output. By reversibly binding oxygen to hemoglobin located in erythrocytes, oxygen transport capacity within the vasculature is significantly increased compared to the amount of oxygen physically dissolved in plasma. Blood oxygen tension (P_{O_2}), hemoglobin oxygen saturation (S_{O_2}), and blood flow of brain microvessels on the one hand, and tissue oxygen tension on the other hand are the basic parameters determining oxygen delivery to tissue. Under resting conditions, a tight but nonlinear relationship exists for brain interstitial oxygen tension and regional cerebral blood flow. The difference in oxygen partial pressure between capillary blood and the tissue determines the PO_2 gradient and, hence, the oxygen flux from microvasculature to nerve and glial cells.

In systemic arterial blood, P_{O_2} values of 80 to 90 mmHg result in an oxygen saturation of hemoglobin of 95 percent. Studies in barbiturate-anesthetized rats have shown that following brain passage P_{O_2} values are reduced to approximately 40 mmHg, leading to an oxygen saturation of hemoglobin of around 60 percent within the blood taken from the sagittal sinus, the venous outflow system of the brain. Blood oxygen tension decreases significantly from pial arteries to intracerebral arterioles, resulting in a comparably low P_{O_2} of approximately 60 mmHg in precapillary resistance vessels. Blood oxygen saturation within the capillary bed drops from approximately 80 percent (P_{O_2} 60 mmHg) to 60 percent (P_{O_2} 40 mmHg), and the major part of oxygen supply to brain tissue occurs within capillaries.

However, P_{O_2} on the venous side of the capillary tree further decreases in small venules. Surprisingly, oxygen saturation of approximately 55 percent in postcapillary venules is significantly lower than in the blood of larger intracerebral veins and the superior sagittal sinus [1]. This higher P_{O_2} in larger venules and veins compared to postcapillary venules can be explained by the well-known fact that arterial O_2 is lost to countercurrent venous exchange before reaching the tissue. In general it can be concluded that the bulk of oxygen delivery to brain tissue occurs at the level of the microcirculation, and not only capillaries but also small arterioles and venules significantly contribute to oxygen supply to brain tissue during normoxia.

Microvascular oxygenation strongly depends on erythrocyte flux within the vasculature. Whereas all capillaries in the brain are perfused by plasma, erythrocyte perfusion under resting conditions is characterized by a pronounced heterogeneity, suggesting that many capillaries are not maximally used. Rapid fluctuations and spatial heterogeneity of density and velocity of red blood cells occur within the capillary network. During global stimulation of cerebral blood flow following systemic hypercapnia, mean blood cell flux and velocity increase, capillary perfusion with red blood cells becomes more homogenous, and the number of poorly blood-cell perfused capillaries decreases. In addition there is evidence for a dilation of capillaries. "Capillary recruitment" within brain microcirculation exists only in the sense of a dynamic adjustment of red blood cell perfusion in continuously plasma-perfused capillaries, but not as opening or closing of capillaries [2].

Cerebral Microvascular Blood Flow Changes during Functional Activation

During increased neuronal activity, vasodilation occurs in the active brain areas. The concept of neurovascular coupling has already been postulated in the 19th century by Roy and Sherrington (for reference see [3]). From their observations Roy and Sherrington postulated that "unknown signals" during increased activity of neurons in the brain induce regional vasodilation and increase of blood flow. Despite extensive research these signals are still not fully understood. In addition, relevant aspects of the different temporal and spatial kinetics of cellular energy metabolism and oxygen consumption leading to the observed complex changes in regional cerebral blood oxygenation have remained enigmatic. Nevertheless, the vascular changes based on the phenomenon of neurometabolic and neurovascular coupling are widely utilized under experimental and clinical conditions by modern techniques providing noninvasive functional brain imaging, where they serve as surrogate markers for neural activity.

The regional CBF is spatially as well as temporally coupled to brain activity. Studies on neurovascular coupling are therefore mainly focused on changes within the cerebral microcirculation.

When neurons are further activated from resting state activity, within the first 1 to 2 seconds regional CBF increases. It reaches a peak response after 3 to 5 seconds, followed by a plateau somewhat lower than the peak response during ongoing neuronal activity, as shown for the cortical blood flow response during somatosensory stimulation of the whisker system in rats [4]. When stimulation stops, CBF returns to baseline within several seconds, and a transient small undershoot can irregularly be detected. A typical example of microvascular blood flow changes due to functional activation by 60 seconds (**A**) or 4 seconds (**B**) of whisker hair deflection in the anesthetized rat is provided in Figure 1.

Changes of red blood cell flow within single capillaries can be investigated by two-photon laser scanning imaging,

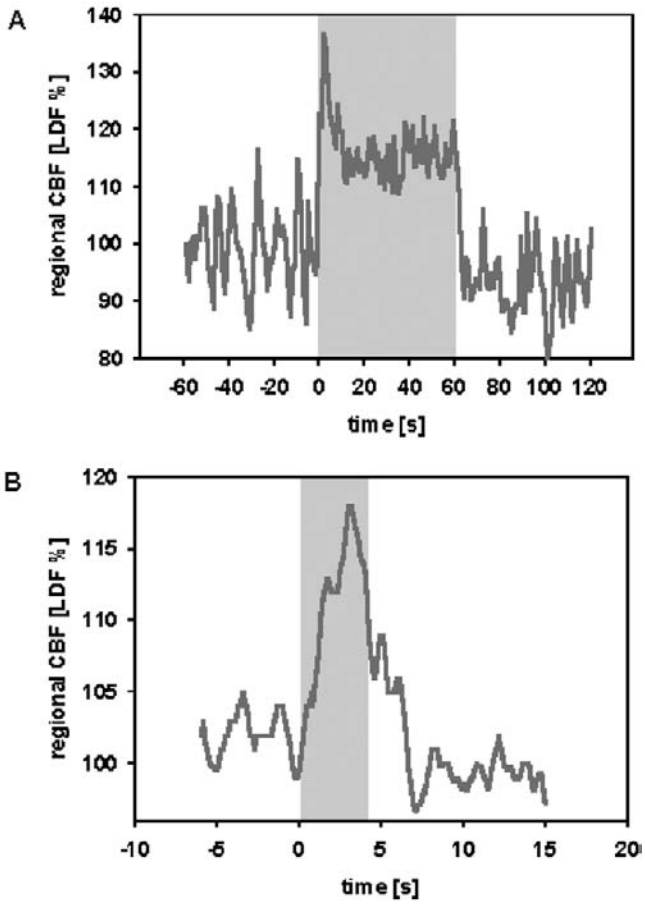

Figure 1 Typical example of microvascular blood flow changes due to functional activation by 60 seconds **(A)** or 4 seconds **(B)** of whisker hair deflection (3 Hz) in the anesthetized rat. Regional cerebral blood flow is measured by laser Doppler flowmetry (LDF); percentage changes from baseline flow at rest (100%) are presented. The stimulation period is indicated by the gray bar within each figure. The regional cerebral blood flow change is temporally tightly coupled to the somatosensory stimulation. Note that during prolonged stimulation (A) the peak blood flow increase is followed by a plateau response slightly lower than the peak response immediately after stimulation onset. No plateau response occurs when short stimulations are performed (B). (see color insert)

providing higher spatial resolution. In olfactory bulb glomeruli of anesthetized rats, it has been shown that during short periods of odor-evoked neuronal activation, a transient and reproducible increase in red blood cell flow in capillaries within the odor specific glomerulus occurs. This increase is largely caused by an increase in red blood cell velocity and only partially accompanied by an increase in linear density of red blood cells. Vascular responses occur as early as 1 to 2 seconds after the neuronal response within the glomerulus. In the olfactory bulb, the arteriolar network penetrating into glomeruli from the surface does not exhibit any precise organization that could provide an arteriolar-based regulation of the glomerulus-specific vascular responses to odors. These findings provide first functional evidence for the hypothesis of a local capillary regulation of microcirculatory blood flow within activated brain areas [5].

Cerebral Microvascular Blood Oxygenation Changes during Increased Neuronal Activity

Cerebral Microvascular Blood Oxygenation Changes Induced by the Regional Cerebral Blood Flow Response during Increased Neuronal Activity

Changes of hemoglobin oxygenation during neuronal activity can be investigated by methods measuring reflection changes followed by spectroscopic analysis of light received from the cortex illuminated with light in the visible wavelength range in experimental animals or in the near-infrared wavelength range in humans. The principle features of changes in oxy- and deoxyhemoglobin during increased brain activity is comparable in animals and humans. Counterintuitively, the stimulation-induced changes in oxy- and deoxyhemoglobin result in regional hyperoxygenation of the blood and, hence, an increase in hemoglobin oxygen saturation. Oxyhemoglobin concentration starts to increase within the first 1 to 2 seconds of stimulation onset and reaches its maximum 2 to 3 seconds later followed by a plateau during ongoing activity. When stimulation stops, oxyhemoglobin concentration returns to baseline within several seconds followed by a transient small undershoot. Deoxyhemoglobin concentration starts to decrease approximately 2 to 3 seconds after stimulation onset and peaks 2 to 3 seconds later. At the end of stimulation deoxyhemoglobin also returns to baseline followed by a transient overshoot. Beside an increase in hemoglobin oxygenation during functional activation, a significant increase in partial molecular oxygen pressure within the microcirculation can be detected. The time course of microvascular P_{O_2} changes exactly match that of oxyhemoglobin during increased neuronal activity [3, 6]. With neuronal activation the fractional change in regional CBF leading to blood hyperoxygenation is approximately twice as large as the fractional change in oxygen metabolism, and both are coupled through a linear relationship that does not depend on stimulus type. It can be suggested that oxygen delivery from brain microcirculation to tissue is limited at rest. Therefore a larger increase in CBF is required to support the smaller increase of oxygen metabolism, because the oxygen extraction fraction is significantly dropping with increased red blood cell velocity [7]. A typical example of microvascular blood oxygenation (**A**) and hemoglobin oxygen saturation (**B**) changes due to functional activation by whisker hair deflection in the anesthetized rat is provided in Figure 2.

Early Cerebral Microvascular Blood Oxygenation Changes during Increased Neuronal Activity

Despite intense research efforts a number of unresolved issues exist regarding functional activation-induced changes in oxygen consumption and delivery. Most investigators agree on the principal features of blood oxygenation changes more than 2 seconds after stimulation onset. However, early oxygenation changes, preceding the rCBF

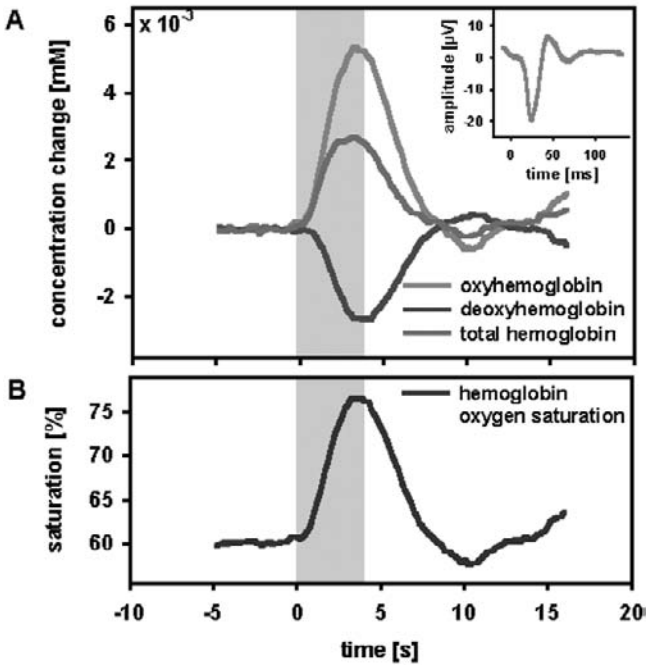

Figure 2 Typical example of microvascular blood oxygenation **(A)** and hemoglobin oxygen saturation **(B)** changes due to functional activation by 4 seconds of whisker hair deflection (3 Hz) in the anesthetized rat. Regional cerebral oxygenation changes are measured by microfiber spectroscopy (wavelength range 510 to 805 nm, wavelength-dependent differential pathlength corrected analysis, estimated hemoglobin concentration 20 µM, mean saturation 60 percent as determined for microcirculatory areas). Total hemoglobin and hemoglobin oxygen saturation changes are calculated from measured oxy- and deoxyhemoglobin changes. Neuronal activity was recorded as somatosensory evoked potentials (SEP). The SEP (average of 4 seconds of 3-Hz stimulation) responsible for the hyperoxygenation response is provided in the small inset in part A of the figure. During functional activation, oxyhemoglobin increases and deoxyhemoglobin decreases, leading to microvascular hyperoxygenation and an increase in hemoglobin saturation. The blood oxygenation changes are temporally tightly coupled to the somatosensory stimulation. (see color insert)

response leading to hyperoxygenation, are controversial. The existence of an early hemoglobin deoxygenation within the first seconds after stimulation onset seems highly elusive. The phenomenon of an early deoxyhemoglobin increase has been termed *initial dip*, since it is detected as a decrease in the magnetic resonance imaging signal induced by an increase of deoxyhemoglobin, which has—in contrast to oxyhemoglobin—paramagnetic properties and can be used as an endogenous paramagnetic contrast agent. Whereas some studies have shown an early increase in deoxyhemoglobin preceding the onset of the CBF response [8, 9], other studies argue against the occurrence of an early loss of hemoglobin oxygenation and decrease in microvascular P_{O_2} that precede the rise in CBF [3, 10]. From further studies in cats and rats it can be concluded that the detection of an early dip mainly depends on the hemodynamic properties. Strong evidence exists for a correlation of the occurrence of an early increase of deoxyhemoglobin and the temporal onset of the regional CBF response, which very much parallels the oxyhemoglobin increase. Hypothetically, a lower baseline CBF and thus lower mean transit time of red blood cells through the cerebral microvasculature may favor a condition in which oxygen delivery lags oxygen extraction. In addition, a correlation of an early deoxyhemoglobin increase and the systemic arterial pCO_2 may exist in humans as well as in animal experiments. The obvious variability of occurrence, amplitude, and rise time of the dip in experiments in cats and monkeys may also depend on the anesthetic and on the depth of anesthesia. Consequently, the early dip has a low overall contrast-to-noise ratio. Its occurrence seems to be highly susceptible to subtle changes of basal physiological condition, and it may thus not be detectable under physiological conditions. In principle, the existence of an early increase in deoxyhemoglobin at the onset of functional activation would suggest that early metabolic changes in the brain during increased neuronal activity are oxidative. An early desaturation of hemoglobin might support the hypothesis of oxygen tension–related mechanisms within the tissue triggering yet unknown signals to the vasculature to induce vasodilation. However, it is still unresolved whether increases in regional CBF and oxygen consumption are dynamically coupled following neural activation or occur in parallel and independent from each other.

Spatial Resolution of Cerebral Microvascular Blood Flow and Blood Oxygenation Changes during Neuronal Activation

During increased neuronal activity, early changes of regional CBF are more localized than later changes at time points when increased blood flow reaches the area of the draining veins. Deoxyhemoglobin concentration is larger in the venous compartment. Therefore, imaging techniques based on deoxyhemoglobin changes during the phase of hyperoxygenation are more affected by the draining vein effect than techniques using early oxyhemoglobin or regional CBF changes for brain mapping. However, as long as the mechanisms and mediators of neurovascular coupling are not known in detail, the question remains whether the area of increased blood flow exactly matches neuronally active areas of the brain or whether cerebral blood flow is controlled on a more coarse spatial scale.

Cerebral Microvascular Blood Oxygenation Changes during Increased Inhibition or Cortical Deactivation

As previously described, noninvasive functional imaging of the activated brain relies on the elevation of glucose and oxygen metabolism, blood flow, and oxygenation due to increased neuronal activity, leading to, for example, an increase of the blood oxygenation level-dependent (BOLD) MRI signal. Traditionally, functional activation is equated with increased excitatory synaptic activity, accompanied by an increase in energy metabolism and CBF and blood hyperoxygenation. On the other hand, reduced activity can be caused either by a decrease in excitatory input to the region of interest (deactivation) or by active synaptic inhibition within the region of interest. Active inhibition is based on the excitation of γ-aminobutyric acid (GABA)-releasing interneurons followed by the interaction of GABA, the main inhibitory neurotransmitter in the brain, with its target receptors. Whereas deactivation is accompanied by a decrease in energy metabolism and glucose consumption within the deactivated area, inhibition by activation of inhibitory interneurons is suppose to be associated with an increase in energy consumption. In line with these considerations, hypermetabolic areas can be defined as areas where excitatory as well as inhibitory neurons are activated. On the other hand, hypometabolic regions are regions with inactivation of both excitatory and inhibitory neurons.

Consequently, different patterns of cerebral microvascular blood oxygenation changes can be expected during active inhibition compared to deactivation. Until now no convincing data have been shown regarding the characteristics of cerebral microvascular blood flow and oxygenation changes during purely or predominantly inhibitory GABAergic neuronal activity. However, during deactivation of the visual cortex it was demonstrated that, compared to classical activation, inverse changes for the microvascular oxygenation parameters occur. A decrease in cortical neuronal activity is accompanied by a decrease in regional blood flow, a decrease in the concentration of oxyhemoglobin, and an increase in the concentration of deoxyhemoglobin. In addition, a decrease in BOLD MRI signal can be detected [6]. This finding implies that the transition from “deactivation” to “rest” to “activation” is a continuous equilibrium of cerebral microvascular blood flow and oxygenation.

Summary

Within the brain, the regional CBF is spatially as well as temporally coupled to neuronal activity. Increased neuronal activity is accompanied by an increase in CBF, whereas during deactivation CBF is reduced. After more than a century of research, we still do not fully understand the physiological meaning of the regional CBF response to changes in cerebral activity: Vascular coupling may provide a constant glucose and oxygen supply to the activated brain tissue—on the other hand, removal of tissue metabolites as lactate may be the driving force for vasodilation. In addition, it remains unclear which signals initiate the very early blood flow response, and which factors or mechanisms mediate the sustained increase in CBF during increased neuronal activity. The CBF response to functional activation or deactivation of brain tissue induces characteristic changes in hemoglobin oxygenation, leading to microvascular hyper- or hypooxygenation, respectively. Stimulation-induced metabolic and vascular responses are utilized to visualize human or animal brain at work and to map brain activity. Neurometabolic and neurovascular coupling thus form the physiological basis for modern functional brain imaging techniques such as functional MRI, near infrared spectroscopy, and optical imaging spectroscopy. Therefore we still need to better understand the physiology of neurometabolic and neurovascular coupling to fully exploit the potential of modern functional brain imaging.

Glossary

Capillary recruitment: Opening or closing of capillaries as a mechanism regulating microvascular blood flow according to demand.

Functional brain imaging: Investigation of stimulation-induced active brain areas by utilizing changes of metabolic or vascular parameters.

Initial dip: Early increase of the concentration of deoxyhemoglobin as evidence for early desaturation of hemoglobin and oxidative tissue metabolism at the onset of functional activation.

Neurovascular coupling: Tight temporal and spatial relationship between regional cerebral blood flow and neuronal activity.

Capsule Biography

Dr. Lindauer is heading the research group on cerebrovascular regulation within the Department of Experimental Neurology at Charité Hospital in Berlin, Germany. Her research mainly focuses on the investigation of mediators and mechanisms of neurovascular coupling as the basis for functional brain imaging.

CHAPTER 63

The Retina Microvasculature

Ming Lu and Anthony P. Adamis
Eyetech Research Center, Woburn, Massachusetts
Foundation of the American Academy of Ophthalmology

Anatomy

Retinal Circulation

Microangiopathies of the retina, including diabetic retinopathy and retinal vessel occlusive diseases, are the leading cause of visual loss. The central retinal artery and its branches perfuse the inner retina extending to the inner portion of the inner nuclear layer. The outer retina is perfused by the choriocapillaris, a capillary system of the choroidal arteries that branch from the ciliary arteries. Both the central retinal artery and the ciliary artery are derived from the ophthalmic artery branch of the internal carotid artery. The larger retinal vessels lie in the innermost portion of the retina near the inner limiting membrane. Astrocytes constrain the retinal vessels to the retina. The retinal blood vessels usually do not extend deeper than the middle limiting membrane, formed by a zone of desmosome-like attachments in the region of the synaptic bodies of the photoreceptor cells. In 30 percent of eyes, a cilioretinal artery also supplies part of the inner retina, with contributions to some portions of the macular circulation in approximately 15 percent of eyes. The venous blood of the retina is drained by the central retinal vein into the cavernous sinus. The interposed capillary bed links precapillary arterioles and postcapillary venules (Figure 1), except in the peripheral retina and the perifoveal area where large anastomotic capillary communications connect the terminal arterioles and venules. The fovea thus contains a capillary-free zone of 400 to 600 μm in diameter. The extreme retinal periphery measuring approximately 1.5 mm in width is avascular.

Retinal Capillary

The retinal capillary plexus is arranged in a two-layer pattern. The superficial layer resides in the nerve fiber and ganglion cell layer and the deeper one in the inner portion of the inner nuclear layer. The peripapillary area contains an additional capillary network in the superficial portion of the nerve fiber layer, called the radial peripapillary capillaries. The inner blood–retinal barrier is retained with tight junctions between capillary endothelial cells, whereas the outer barrier is formed by the apical zonulae occludentes of the retinal pigment epithelium (RPE). The endothelial cells are oriented along the axis of the capillary, with cytoplasmic extensions encircling the lumen. A basement membrane covers the outer surface of the endothelium. There is an interrupted layer of pericytes (mural cells) in the basement membrane, with a ratio of 1 : 1 to the number of endothelial cells. Pericytes regulate microvascular growth and function. Interaction with glial cells including astrocytes is required for the endothelial cells to develop tight junctions and to maintain the inner blood–retinal barrier. The retinal capillaries do not leak fluorescein, glucose, amino acids, or small ions, but are highly permeable to water and lipid-soluble substances such as O_2 and CO_2. Metabolic substrates are transported through the endothelial cells through specific channels, pinocytosis, and other carrier-mediated transport systems. Diabetes, hypertension, and surgical trauma compromise the inner blood–retinal barrier.

Retinal Arterioles

When compared to the same size arteries of other organs in humans, retinal arteries lack an internal elastic lamina and contain gradually decreased layers of smooth muscle cells from the optic disk to the periphery. Retinal arteriolar precapillary annuli are also absent. Where arterioles and venules cross, they share a common basement membrane. Venous occlusive disorders commonly occur at an arteriovenous (AV) crossing.

Innervation

In contrast to the choroidal vessels, the retinal vasculature lacks sympathetic fibers. The retinal blood flow

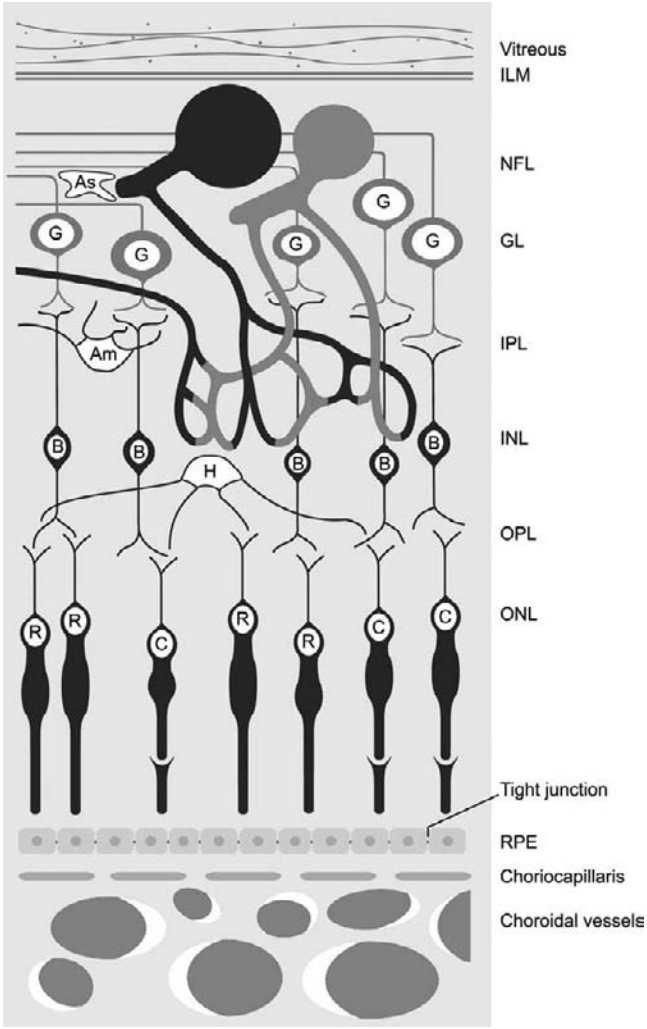

Figure 1 Schematic representation of the retinal and choroidal circulations. The photoreceptor layer is avascular, receiving oxygen from choriocapillaris by diffusion. is autoregulated through modifications of vascular resistance.

Physiology

Blood Flow

Eighty-five percent of the total blood supply to the eye is distributed to the choroid and only 4 percent to the retina. The remaining is distributed to the ciliary body and the iris. The human retinal blood flow has been calculated to be between 35 and 80 μL/min. The oxygen extraction for the retinal blood is about 38 percent. In contrast, the oxygen extraction from the uveal blood is very low, with the arteriovenous difference for the choroidal blood about 3 percent. Choroidal blood flow is extremely high, probably because of the large caliber of the vascular lumen. The choroidal blood flow near the fovea and around the optic nerve head is much higher than the blood flow in the periphery of the eye. Despite the low oxygen extraction rate, about 60 percent of oxygen and 75 percent of glucose are delivered by the choroidal circulation. The high volume of choroidal blood flow may contribute to the removal of heat generated during visual transduction, to the removal of fluid from the outer retina, and to meeting the metabolic needs of the retina. Proteins and other substances of high molecular weight can enter the interstitial space through the fenestration of the choroidal capillaries. Retinal binding protein, vitamin A, and many other micronutrients and ions become available to the RPE for transport to the outer layers of the retina. Both active and passive transport mechanisms facilitate the movement of selected nutrients and waste products across the outer blood–retinal barrier. During aging, lipoprotein accumulates in Bruch's membrane from rod outer segment degradation, which may obstruct the movement of water and waste products across the RPE.

Regulation of Blood Flow

The retinal blood flow is determined by the perfusion pressure and the diameter of the retinal capillaries. Local myogenic responses, metabolic factors, and endothelium-derived substances influence the vascular resistance. The retinal blood flow is autoregulated through modifications of the vascular resistance, that is, changes of the contractile state of the retinal arterioles. Because of the lack of precapillary sphincter in retinal arterioles, metabolic and myogenic stimuli are the major modifiers of the retinal arteriolar diameter. The retinal blood flow is maintained relatively constant despite moderate variations in perfusion pressure, up to 41 percent of baseline values of systemic blood pressure or during an increase of intraocular pressure up to 30 mmHg. As a result, the inner retina tissue partial pressure of O_2 (P_{O_2}) is maintained at constant values during moderate reductions of the perfusion pressure. In contrast, there is no autoregulation in the choroidal vasculature. Choroidal blood flow changes little during sudden increments in blood pressure, as an increased sympathetic activity and consequent vasoconstriction of the choroidal vessels maintain a constant choroidal blood flow. The parasympathetic system seems to play little role in the regulation of the choroidal blood flow. Loss of sympathetic innervation may cause accumulation of fluid in the retina and retinal edema. This is important in diseases such as diabetes and hypertension, in which autonomic control is altered. The choroidal vessels contain α-adrenergic vasoconstrictor receptors but no β-adrenergic vasodilator receptors.

Mechanical stretch and increases in the transmural pressure stimulate the endothelial cells to release contracting

factors. The factors released by the retinal metabolism also optimize retinal blood flow according to metabolic needs. These factors include P_{O_2}, the tissue partial pressure of CO_2 (P_{CO_2}), nitric oxide (NO), prostaglandins (PGs, including PGE_2, PGF_2, PGH_2, and fo forth), and lactate, released either in the blood or in the surrounding retinal arteriole glial or neuronal tissue. Hyperoxia induces vasoconstriction, whereas hypoxia induces vasodilatation of retinal arterioles. The P_{O_2} values measured in the inner retina up to half of its thickness remained stable during hypoxia. In contrast, the P_{O_2} measured near the choroid and in the outer retina decreased in a linear manner according to the variations of systemic P_{O_2}. High oxygen delivery by the choroidal circulation is thus necessary for photoreceptors to function properly. Systemic hypoxia induces an increase in the retinal lactate release, which dilates the arteriolar wall. A rise in P_{CO_2} induces an increase in blood flow.

The endothelium influences the vascular tone by releasing either endothelium-derived relaxing factors, such as NO and PGE_2 and PGF_2, or contracting factors, such as endothelin-1, thromboxane A_2, and PGH_2. These molecules induce relaxation or contraction of vascular smooth muscle cells and capillary pericytes, thus affecting the diameters of arterioles and capillaries. NO released by endothelial cells acts on the vascular smooth muscle cells and accounts for the biologic properties of the endothelium-derived relaxing factor. There is a gradient and a continuous production of NO by the retinal tissue. The effect of endothelin on a vascular bed is difficult to predict, because apart from causing vasoconstriction, it can also release the vasodilators prostacyclin and NO. PGE_2 and PGF_2 are the predominant PGs produced by the retina and choroid, and they induces vasodilatation of the retinal arterioles.

Retinal Oxygen Distribution

The retina has a high rate of oxygen consumption and metabolism for visual transduction. The PO_2 is heterogeneously distributed close to the vitreoretinal interface. O_2 diffusion from the retinal arterioles affects the juxtaarteriolar preretinal and inner retinal layer's P_{O_2}, which is higher than that of the intervascular areas due to oxygen consumption by retinal cells. In contrast, the preretinal and inner retinal (30% depth) P_{O_2} far beyond the retinal vessels remains constant in all retinal areas. The intraretinal P_{O_2} gradually decreases from both the retinal surface and the choroid toward the midretina, with the minimal value at 50 percent of retinal depth. The P_{O_2} near RPE is significantly higher than it is at the inner limiting membrane level, due to much higher O_2 delivery by the choroidal circulation than by the retinal circulation.

Pathophysiology

Retinal Ischemia

Occlusion of retinal arterioles leads to an acute decrease of the inner retinal P_{O_2} and subsequent injury to the inner retinal cells. Systemic hyperoxia but pure O_2 increases inner retina P_{O_2}. This is due to the vasoconstrictive effect of 100 percent O_2. The ischemic retina may require other metabolites in addition to O_2 to resume normal function. In chronic retinal ischemia such as diabetic retinopathy and retinal vein occlusion, modifications of the retinal vascular bed lead to the formation of ischemic areas. The ischemic areas produce vasoproliferative factors such as vascular endothelial growth factor (VEGF), stimulating new vessel formation. The new vessel is leaky because of the scarce intercellular junctions between the endothelial cells. Clinical trials are under way to test the use of intravitreal or subtenon steroids, as well as oral and local anti-VEGF agents, in preventing retinal neovascularization due to ischemia.

Dr Adamis is cofounder and Chief Scientific Officer of Eyetech Pharmaceuticals. His research is focused on the mechanisms of diabetic retinopathy and age-related macular degeneration.

CHAPTER 64

Nitric Oxide and Blood–Brain Barrier Function

William G. Mayhan
Department of Physiology and Biophysics, University of Nebraska Medical Center, Omaha, Nebraska

The endothelium of cerebral blood vessels forms the interface between the blood and brain tissue (blood–brain barrier), and is the main physical barrier that minimizes the entry of blood constituents into brain tissue. This restriction by the blood–brain barrier arises by the presence of tight junctions (zonulae occludens) between adjacent endothelial cells and a relative paucity of pinocytotic vesicles within endothelium of cerebral arterioles, capillaries, and venules. Physical, chemical, and metabolic stimuli can alter the permeability characteristics of cerebral endothelium. For example, acute increases in arterial blood pressure beyond the autoregulatory capacity of cerebral blood vessels, application of hyperosmolar solutions, cerebral hypoxia, cerebral ischemia–reperfusion, synthesis/release of inflammatory mediators during brain injury, and/or activation of blood-borne elements can dramatically alter the permeability characteristics of the blood–brain barrier. However, the precise cellular mechanisms that account for maintaining the basal integrity of the blood–brain barrier and stimulus-induced increases in permeability of the blood–brain barrier remain poorly defined. Recent evidence suggests that the synthesis/release of nitric oxide may play a role in the regulation of permeability of the blood–brain barrier. Thus, this review will focus on studies that have implicated an important role for nitric oxide in the integrity of the blood–brain barrier during physiologic and pathophysiologic conditions.

Concept of a Blood–Brain Barrier

Before a discussion of the role of nitric oxide in the permeability characteristics of the blood–brain barrier, it is important to understand the evolution of our understanding of the blood–brain barrier. More than a century ago Ehrlich found that intravascular injection of dye distributed relatively equally throughout the most tissues of the body, with the exception of the brain. From these studies, Ehrlich concluded that the brain had a lower affinity for the dye than peripheral tissues. However, studies by Goldmann found that dye injected into the circulation stained all tissues except that of brain and spinal cord. Further, when the dye was injected into the cerebrospinal fluid, it stained the brain but did not enter the peripheral circulation. Thus, these discoveries led to the concept that the central nervous system must be separated from the peripheral circulation by some type of barrier, that is, the blood–brain barrier. However, the identity of the ultrastructure of this barrier remained unknown for nearly 50 years.

Since astrocytes were shown to encapsulate cerebral capillaries, it was initially thought that astrocytes composed the blood–brain barrier. With the arrival of the electron microscope, it became clear that structures within cerebral blood vessels, and not astrocytes, constituted the blood–brain barrier. These structures consist of tight junctions between adjacent endothelial cells (i.e., zonulae occludens). In addition, endothelial cells of cerebral vessels are devoid of fenestrations and transendothelial channels and have a paucity of pinocytotic vesicles. Because of its morphology, it was initially thought that the blood–brain barrier was a very static and rigid structure separating the brain from the peripheral environment. However, this view of the blood–brain barrier has evolved over the years, and it is now known that the blood–brain barrier is a dynamic and multifaceted structure that contains important transport pathways and complex enzyme systems that participate in the regulation of the brain's microenvironment.

Nitric Oxide Synthases

Nitric oxide is generated from the metabolism of L-arginine by nitric oxide synthase (NOS). Functionally, NOS can be separated into constitutive and inducible isoforms. The constitutive isoforms of NOS [endothelial NOS (eNOS) and neuronal NOS (nNOS)] appear to be active under basal conditions and can be stimulated by receptor-mediated increases in intracellular calcium. These isoforms of NOS (eNOS and nNOS) produce small quantities of nitric oxide for relatively short periods of time. In addition to the constitutive isoforms of NOS, an inducible isoform of NOS (iNOS) was first identified in macrophages. Unlike that found for the constitutive isoforms of NOS, iNOS is calcium-independent, and when stimulated can produce large, unregulated quantities of nitric oxide for relatively long periods of time.

Many cell types contained within the brain may be responsible for the synthesis/release of nitric oxide under physiologic and pathophysiologic conditions. It appears that a small portion of parenchymal neurons stain for NADPH diaphorase (a marker for nNOS), and thus may be capable of releasing nitric oxide during the activation of nNOS. Since these neurons may be adjacent to cerebral blood vessels, nitric oxide produced during activation of these neurons may influence vascular tone and the transport of molecules across the blood–brain barrier (Figure 1). Endothelium contained within cerebral blood vessels have been shown to express eNOS, and in some instances iNOS. In vivo and in vitro studies of cerebral blood vessels have shown that nitric oxide released by cerebral endothelium contributes to basal tone, agonist-induced changes in diameter of cerebral blood vessels and in reactivity of cerebral blood vessels in response to physiologic stimuli. Thus, the synthesis/release of nitric oxide by activation of eNOS is important in the control of diameter of cerebral blood vessels, and could conceivably be important in the regulation of permeability of the blood–brain barrier (Figure 1). Glial cells (astrocytes, microglia, and oligodendrocytes) are the predominant cell types in the brain and have been shown to release nitric oxide by activation of iNOS. Astrocytes, for example, not only appear to express a constitutive form of NOS in response to a number of vasoactive agonists including neurotransmitters, but also are capable of the synthesis/release of nitric oxide from iNOS in response to lipopolysaccharide and a number of other important cytokines (Figure 1).

Thus, it is conceivable that the synthesis/release of nitric oxide by these cells contained within the brain could have a major impact on the basal integrity of the blood–brain barrier and on increases in permeability of the blood–brain barrier during brain trauma. Unfortunately, very few studies have examined the role of these cellular elements and the various isoforms of NOS on the regulation of permeability of the blood–brain barrier.

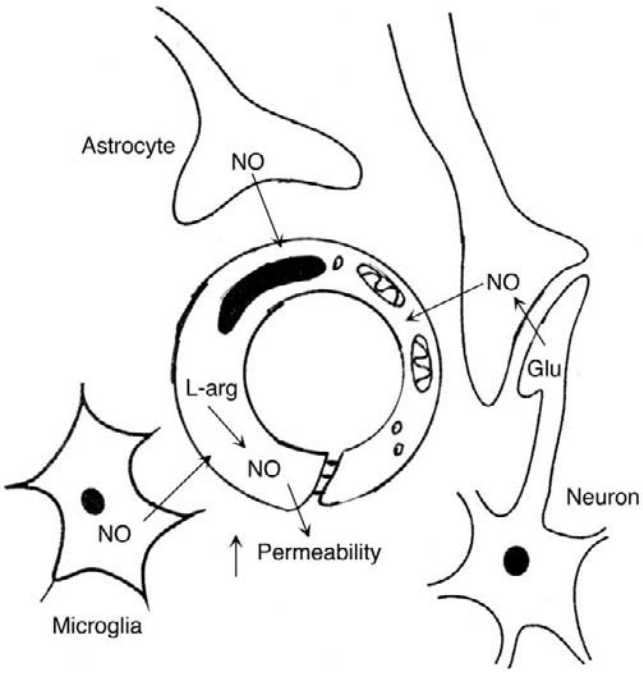

Figure 1 Schematic showing possible sources of nitric oxide (NO) in the brain. NO can be synthesized/released by cerebral endothelium, neurons, astrocytes, and microglia. Activation of glutamate receptors on neurons and stimulation of astrocytes and microglia can stimulate nNOS and/or iNOS, causing local production of NO that could diffuse to cerebral endothelium and influence the permeability of the blood–brain barrier via activation of a number of cellular pathways. Endothelial generated NO from L-arginine (L-arg) in response to inflammatory mediators also may stimulate a number of cellular pathways to influence the permeability of the blood–brain barrier.

Role of Nitric Oxide in Basal Integrity of the Blood–Brain Barrier

Although it is clear that the endothelium, by the synthesis/release of nitric oxide, plays a critical role in basal tone of peripheral and cerebral blood vessels, the role of nitric oxide in maintaining the integrity of the endothelial barrier in peripheral and cerebral vessels remains controversial. A few investigators have suggested that inhibition of NOS (using L-NMMA or L-NAME) increases basal levels of permeability in the peripheral circulation and potentiates agonist-induced increases in peripheral vascular permeability. In contrast, a majority of studies including studies from our laboratory have suggested that inhibition of nitric oxide synthesis using L-NMMA and L-NAME does not influence or decreases basal levels of peripheral microvascular permeability, and inhibits increases in venular permeability of the peripheral microcirculation in response to mechanical stimuli and/or inflammatory mediators. The precise reasons for discrepancies between studies regarding a role for nitric oxide in peripheral microvascular permeability remain elusive, but may relate to regional differences in responses of the microcirculation.

Since many cell types of the central nervous system are capable of the synthesis/release of nitric oxide from the var-

ious isoforms of NOS it is conceivable that nitric oxide may play a critical role in maintaining the integrity of the blood–brain barrier under physiologic conditions. Unfortunately, no studies have systematically examined the precise role of the various isoforms of nitric oxide on basal integrity of the blood–brain barrier, and studies that have attempted to examine the potential role of nitric oxide, in general, in basal permeability of the blood–brain barrier have reported conflicting results. Studies from our laboratory found that L-NMMA (a nonspecific inhibitor of NOS) and aminoguanidine (a specific inhibitor of iNOS) did not alter the basal transport of molecules across the blood–brain barrier. In addition, others have not reported any differences in the basal permeability characteristics of the blood–brain barrier between wild-type and nNOS knockout mice. In contrast, others have reported that inhibition of NOS with L-NAME produced an increase in permeability of the blood–brain barrier. However, treatment with L-NAME also produced a significant increase in blood pressure, and the contribution of changes in blood pressure to an increase in the permeability of the blood–brain barrier was not examined. Thus, although the basal synthesis/release of nitric oxide may play a critical role in basal tone of cerebral blood vessels, the role of nitric oxide in maintaining the integrity of the blood–brain barrier during physiologic conditions remains uncertain. Future studies, using a variety of specific inhibitors of NOS and genetically altered models, will be required in order to precisely determine the role of the various isoforms of nitric oxide in basal integrity of the blood–brain barrier.

Role of Nitric Oxide in Stimuli-Induced Changes in the Blood–Brain Barrier

As discussed for the role of nitric oxide in maintaining the basal integrity of the peripheral circulation, the role of nitric oxide in stimuli-induced changes in peripheral microvascular permeability is also controversial. Some have suggested that the generation of nitric oxide inhibits, whereas an increasing number of studies now suggest that the synthesis/release of nitric oxide accounts for increases in permeability of peripheral blood vessels in response to a variety of stimuli. Although the role of nitric oxide in permeability of the peripheral circulation is becoming increasingly clear, the precise role and cellular mechanisms by which nitric oxide may alter the permeability of the blood–brain barrier in response to various stimuli remains uncertain. The following discussion focuses on studies that have begun to implicate a role for nitric oxide in permeability of the blood–brain barrier under several conditions, that is, stimulation with inflammatory mediators, cerebral hypoxia, cerebral ischemia, and bacterial infections.

Inflammatory Mediators/Cytokines

Before a precise role for nitric oxide in stimuli-induced changes in permeability of the blood–brain barrier could be advanced, it was important to determine whether nitric oxide could directly alter the permeability of the blood–brain barrier. Several lines of evidence suggest that nitric oxide can influence the permeability of the blood–brain barrier. Initial studies found that application of a nitric oxide donor, sodium nitroprusside, could reduce electrical resistance across cultured brain endothelium. In addition, application of nitric oxide increased paracellular permeability of isolated cerebral endothelium. Further, studies from our laboratory have shown that application of donors of nitric oxide (Sin-1 and SNAP) to the cerebral microcirculation produced an increase in permeability of the blood–brain barrier. Thus, it appears that nitric oxide has the ability to produce an increase in the permeability of the blood–brain barrier.

Over the past several years, it has become apparent that many cerebrovascular diseases have an inflammatory component. Since nitric oxide has been shown to contribute to changes in peripheral vascular permeability in response to inflammatory mediators, a number of studies have begun to examine the contribution of nitric oxide to changes in permeability of the blood–brain barrier during stimulation with inflammatory mediators/cytokines. Unfortunately, few studies have examined the precise role of the various isoforms of nitric oxide in this process. For example, it has been difficult to examine the precise role of eNOS in the permeability of the blood–brain barrier since there are no specific inhibitors of eNOS. Thus, most studies that have attempted to implicate a role of eNOS in stimuli-induced changes in permeability of the blood–brain barrier have used a rationale similar to that used for studies of cerebrovascular reactivity, that is, the use of nonspecific inhibitors of NOS (L-NAME, L-NMMA, and L-NNA). Using this experimental regimen, we and others have suggested that the synthesis/release of nitric oxide, presumably via activation of eNOS, contributes to increases in permeability of the blood–brain barrier, primarily in cerebral venules and veins, in response to several important inflammatory mediators (i.e., histamine, bradykinin) that may be released during brain trauma and during acute arterial hypertension.

Cytokines are a group of polypeptides that are involved in the activation of the immune system and in the inflammatory response. Cytokines are classified into several categories including interleukins, tumor necrosis factors, chemokines, interferons, growth factors, and neurotrophins. Cytokines are synthesized/released by many cell types within the brain (microglia, astrocytes, endothelial cells, macrophages, and T-cells) and may play a crucial role in the development of inflammation in the brain during cerebrovascular diseases. For example, there is an increase in the levels of interleukins and tumor necrosis factor in the cerebrospinal fluid of human subjects following acute stroke, subarachnoid hemorrhage, cerebral ischemia, or traumatic brain injury. In addition, neurological diseases such as Alzheimer's disease, Parkinson's disease, multiple sclerosis, and AIDS-related dementia also appear to have an inflammatory component in their pathology that may be

related to the synthesis/release of cytokines. Thus, although a number of studies have shown that cytokines can produce dramatic changes in the permeability of the blood–brain barrier, only recently has the role of nitric oxide in this process been acknowledged. However, the precise role of nitric oxide, the contribution of the various cellular sources of nitric oxide, and potential mechanisms by which nitric oxide can alter the permeability of the blood–brain barrier during pathophysiologic conditions remain unknown.

Cerebral Hypoxia

A number of metabolic changes to the brain can influence reactivity of cerebral blood vessels, regulation of cerebral blood flow, and perhaps the permeability of the blood–brain barrier. Hypoxia produces dramatic increases in the diameter of cerebral blood vessels that appears to be related, in part, to the synthesis/release of nitric oxide, presumably via the activation of nNOS. However, the effects of hypoxia on the blood–brain barrier are controversial. Some investigators have shown that hypoxia produces an increase in permeability of the blood–brain barrier that can be inhibited by exogenous generation of nitric oxide. In contrast, others have shown that hypoxia-induced changes in permeability of the blood–brain barrier can be markedly reduced by inhibition of eNOS or iNOS. Further, others have shown that hypoxia-induced alterations in permeability of the blood–brain barrier are related to changes in the expression of tight-junctional proteins between adjacent endothelial cells. Thus, future studies will be required to precisely examine the role of nitric oxide, the cellular source of nitric oxide, and the influence of nitric oxide on pathways that account for changes in permeability of the blood–brain barrier during hypoxia.

Cerebral Ischemia

Cerebral ischemia has dramatic effects on the nitric oxide biosynthetic pathway. NOS-dependent reactivity of cerebral arteries is impaired following cerebral ischemia/reperfusion via a mechanism that appears to be related to the inactivation of nitric oxide by oxygen radicals. In addition, studies have shown that nitric oxide concentration in the ischemic area increases within several minutes during cerebral ischemia. This increase in nitric oxide production appears to involve activation of eNOS and nNOS during the onset of ischemia, and iNOS during the progression of cerebral ischemia. Although there is little debate regarding the effects of cerebral ischemia on reactivity of cerebral blood vessels and the production of nitric oxide, there is considerable debate regarding the role nitric oxide plays in the mechanisms of ischemic brain injury. Early studies that examined the effects of nonspecific inhibition of nitric oxide on ischemic brain damage found contradictory results, that is, enhanced, reduced, or no change in cerebral ischemic damage. Since these early studies, the use of more specific inhibitors of NOS has yielded more consistent results. Selective inhibition of nNOS has been shown to reduce cerebral ischemic damage, including cerebral edema. Similarly, the use of specific inhibitors of iNOS has been shown to reduce postischemic infarct size following cerebral ischemia. Further, the use of NOS-deficient mice has strengthened the position that eNOS activity might be protective (due to the effects of eNOS on cerebrovascular hemodynamics), while nNOS and iNOS activity may be detrimental to the ischemic brain. Thus, an understanding of the precise roles for the various isoforms of NOS in ischemia-induced damage to the brain, including an increase in permeability of the blood–brain barrier, may lead to new therapeutic approaches for the treatment of many cerebrovascular disorders, including stroke.

Bacterial Infection

Bacterial meningitis remains a life-threatening illness with high morbidity and mortality rate in infants, children, and adults. A characteristic feature of bacterial meningitis, which appears to contribute to the adverse neurological outcome, is an inflammatory response to endotoxins that produces disruption of the blood–brain barrier. Investigators have examined the pathology of meningitis by examining the effects of lipopolysaccharide on the permeability of the blood–brain barrier. Lipopolysaccharide is a major constituent of the outer membrane of Gram-negative bacteria and plays a pivotal role in initiating inflammation of the brain. Treatment of the cerebral circulation with lipopolysaccharide produces an increase in the permeability of the blood–brain barrier. Further, treatment of the cerebral microcirculation with aminoguanidine, to inhibit iNOS, inhibited lipopolysaccharide-induced increases in permeability of the blood–brain barrier. Thus, it appears that the synthesis/release of nitric oxide plays a critical role in changes in permeability of the blood–brain barrier during bacterial infections.

Cellular Mechanisms for the Effects of Nitric Oxide on the Blood–Brain Barrier

There are several potential mechanisms by which nitric oxide could contribute to changes in permeability of the blood–brain barrier (Figure 2). It appears that changes in permeability of the blood–brain barrier during stimulation with inflammatory mediators, for example, may involve the activation of the cGMP pathway by nitric oxide. Activation of this pathway may, in turn, activate a cascade of cellular pathways, including protein kinase G, protein kinase C, and/or mitogen activated protein kinase (MAPK). In addition, it is possible that the synthesis/release of nitric oxide may stimulate the contraction of endothelial cytoskeletal proteins to produce contraction of adjacent endothelial cells,

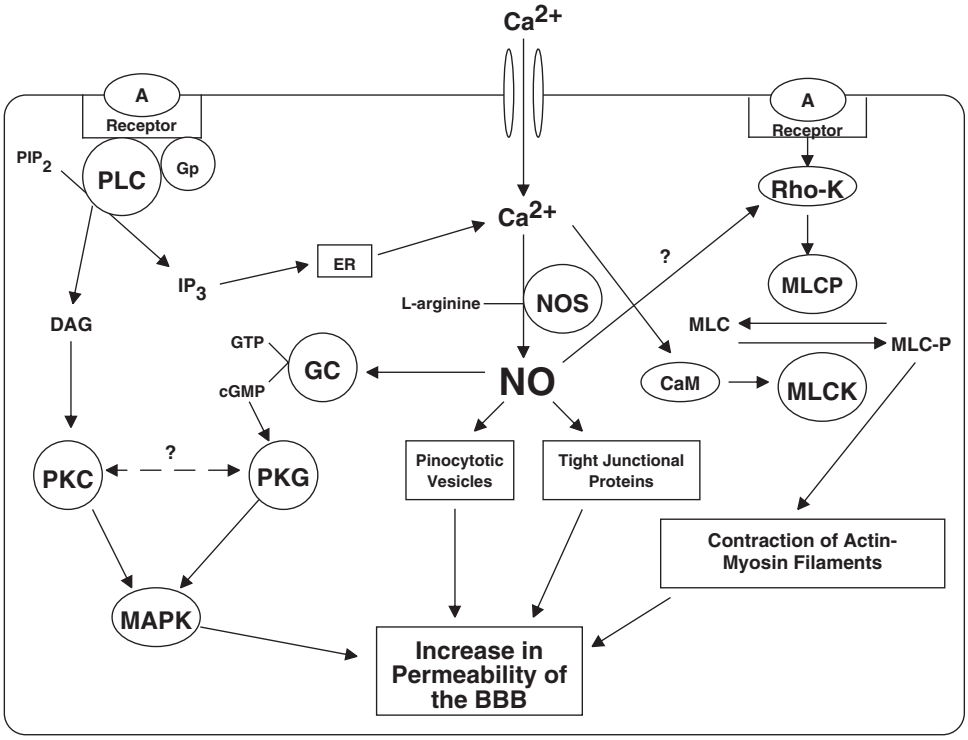

Figure 2 Schematic representation of potential pathways by which nitric oxide (NO) may influence the permeability of the blood–brain barrier. It appears that an agonist (A) binding to a receptor may activate phospholipase C (PLC) via a G protein (Gp) to catalyze the production of inositol trisphosphate (IP_3) and diacylglycerol (DAG) from inositol bisphosphate (PIP_2). IP_3 stimulates the release of calcium from the endoplasmic reticulum (ER) and also increases the influx of extracellular calcium, leading to activation of nitric oxide synthase (NOS) to produce NO from L-arginine. NO appears to stimulate guanylate cyclase (GC) to produce cyclic GMP (cGMP), a potent activator of protein kinase G (PKG). PKG may directly increase the permeability of the blood–brain barrier, may interact with protein kinase C (PKC), and/or may stimulate mitogen activated protein kinase (MAPK) to produce an increase in permeability of the blood–brain barrier. In parallel, DAG may stimulate PKC, may interact with PKG, and/or may stimulate MAPK to produce an increase in permeability of the blood–brain barrier. In addition to this pathway, NO may have direct effects on the formation of pinocytotic vesicles within endothelial cells and/or on tight junctional proteins to produce a pathway for the movement of molecules from the vasculature into brain tissue. Further, changes in permeability of the blood–brain barrier may be related to the effects of NO on endothelial cytoskeletal components. Thus, an increase in intracellular calcium via a Ca-calmodulin interaction (CaM) activates myosin light chain kinase (MLCK) to phosphorylate myosin light chain (MLC), leading to an increase in actinomyosin interaction, and subsequent endothelial cell contraction to increase permeability of the blood–brain barrier. It is also possible that an agonist and/or NO may stimulate myosin light chain phosphorylation (MLC-P) through Rho kinase (Rho-K) pathway inhibition of myosin light chain phosphatase (MLCP) activity resulting in contraction of actinomyosin filaments and an increase in permeability of the blood–brain barrier.

and thus provide a pathway for the movement of molecules and/or influence the formation of pinocytotic vesicles within cerebral endothelium (Figure 2). Further, it is possible that that nitric oxide does not directly produce an increase in vascular permeability, but plays an obligatory role in macromolecular transport, as has been shown for peripheral blood vessels. Future directions to determine the precise role of nitric oxide and mechanisms by which nitric oxide produces changes in permeability of the blood–brain barrier in response to various stimuli, including inflammatory mediators and mechanical and metabolic stimuli, will certainly advance our understanding of this process and will contribute to new therapeutic approaches for the treatment of inflammatory cerebrovascular diseases.

Summary and Conclusions

Although a significant number of studies have clearly demonstrated an important role for nitric oxide in the regulation of diameter of cerebral blood vessels, there is an overall lack of information regarding the potential role of nitric oxide in permeability of the blood–brain barrier. Future studies must continue to focus on identifying the contribution of the nitric oxide biosynthetic pathway to the permeability of the blood–brain barrier. In addition, while many cellular second-messenger systems have been implicated in contributing to the effects of nitric oxide on peripheral microvascular permeability, the role of these pathways in changes in permeability of the blood–brain barrier under

physiologic and pathophysiologic conditions remains unknown. Thus, future studies directed at identifying the precise cellular role of nitric oxide in the permeability of the cerebral microcirculation will be critical. The complementary use of in vitro and in vivo models using innovative pharmacological approaches and unique genetic models will certainly advance our understanding of the role of nitric oxide in basal integrity and pathophysiologically induced changes in permeability of the blood–brain barrier. The answers provided by these unique studies will provide insights into new therapeutic approaches for the treatment of many neurological and cerebrovascular diseases that produce an increase in the permeability of the blood–brain barrier.

Glossary

Blood-brain barrier: An anatomical and physiological barrier. It is formed by complex interendothelial cell tight junctions that form a continuous sealing. The barrier serves to protect the brain from agents in the blood, but also controls the influx and efflux of numerous substances to maintain proper homeostasis in the brain.

Cerebrovascular disease: Disease processes that involve blood vessels of the brain.

Inflammation: A condition in which tissues react to an injury. Inflammation is marked by vasodilation, leukocyte infiltration, redness, heat and pain.

Nitric oxide: A free radical gas derived from a guanidino nitrogen of L-arginine. Nitric oxide is a major secretory product of many cell types and is a pluripotent biological mediator.

Permeability: A process by which substances penetrate or pass across or through a cell membrane.

Introduction

The brain is highly enriched in fatty acids such as docosahexaenoic acid (DHA) and arachidonic acid. These fatty acids are major constituents of the phospholipid bilayer of the cell membrane, and modulate the tight junction permeability and occludin protein expression in brain capillary endothelial cells (ECs). This review summarizes the main findings of the in vitro approach in blood–brain barrier (BBB) research, describes the unique tight-junction features of the brain endothelium, and provides a short overview on how these BBB characteristics can be induced by the fatty acids in cerebral ECs.

Overview: Tight Junction and Fatty Acids

Brain capillary ECs lining the cerebral microvasculature form the BBB. The BBB is a complex of tight junctions between brain ECs. This barrier between the blood and the central nervous system (CNS) is relatively impermeable to ions, many amino acids, small peptides, and proteins. The maintenance of such an efficient barrier between the blood and brain compartments is essential for normal brain function. The barrier formed by the tight junctions has the important function of protecting the brain from fluctuations in the composition of the plasma. Accordingly, disruption of the BBB can be a relatively major part of the pathology following cerebral ischemia. Physiological and morphological studies have indicated that the relationship between the transepithelial electrical resistance (TER) and intramembrane particle strand number is logarithmic. In fact, the TER across the BBB in vivo is believed to be $1{,}000\,\Omega\cdot cm^2$. In freeze-fracture electron micrographs, tight junctions appear as a set of continuous, anastomosing intramembrane particle strands in the cytoplasmic face with complementary grooves in the extracellular face. Various tight junction–associated proteins have been identified, including zonula occludens (ZO)-1, ZO-2, ZO-3, cingulin, 7H6 antigen, occluding, and claudin. It has been shown that ZO-1 binds to occludin in vitro and is colocalized with F-actin in cultured cells. In particular, occludin and claudin-5 are integral membrane

proteins localized within tight junction strands that have been shown to serve as functional components of the tight junction of vascular ECs. Therefore, both occludin and claudin-5 contribute to the electrical barrier function of tight junctions and possibly to the formation of aqueous pores within tight junction strands in brain ECs. These proteins together with the actin cytoskeleton are major determinants of tight-junction structure and also play a role in the regulation of tight junctions. Tight-junction formation appears to be regulated in part by signal transduction pathways involving G proteins, release of intracellular Ca^{2+}, and activation of protein kinase C. Fatty acids are the major constituents of the phospholipid bilayer of the epithelial cell membrane and reportedly modulate the permeability of the epithelial cells. Various reports have demonstrated the effects of fatty acids on tight junction permeability and occludin protein expression in an umbilical vein endothelial cell line. It has also been demonstrated that exposure to fatty acids significantly increased TER in ECs derived from the brain. On the other hand, the absorption-enhancing effects of the sodium salts of two medium-chain fatty acids have been studied in monolayers of intestinal epithelial cell lines derived from colonic carcinoma. Medium fatty acids induced a rapid increase in epithelial permeability in the intestinal cell lines. These reports suggest that the fatty acids contribute to the regulation of tight junctions in ECs. Essential fatty acids are structural components of all tissues and are indispensable for cell membrane synthesis. Brain, retinal, and other neural tissues are particularly rich in long-chain polyunsaturated fatty acids (PUFAs). These fatty acids serve as specific precursors for eicosanoids, which regulate numerous cell and organ functions. It is generally accepted that PUFAs are essential for growth and development, and their crucial role in the development of the CNS has been the subject of many studies. The important role of fatty acids, including PUFAs, for tight junction assembly in brain capillary ECs is well established. Furthermore, tight junction formation appears to be regulated in part by the release of PUFA from astrocytes in vivo.

Metabolism and Supply of Polyunsaturated Fatty Acids to Brain Capillary Endothelial Cells

The brain is highly enriched in the long-chain PUFAs such as DHA (22:6ω-3) and arachidonic acid (20:4ω-6). In particular, DHA is the most abundant ω-3 fatty acid in the brain. These PUFAs can be synthesized from fatty acid precursors linoleic acid (18:2ω-6) and linolenic acid (LA,18:3ω-3) through a process of fatty-acid chain elongation and desaturation. By contrast to the PUFAs, their respective precursors, linoleic acids and LA, are present at only low levels in the brain. The liver is a major site where shorter-chain dietary PUFA is converted to arachidonic acid and DHA, although some retinal and cerebral cells, such as retinal pigment epithelial cells and astrocytes, have the ability to produce DHA. Moreover, low levels of DHA and several of its ω-3 PUFA precursors normally are present in the plasma, and all of these substrates can be utilized in the brain. The brain capillary endothelial cells are thought to take up PUFA precursors and target them preferentially into the brain, performing some elongation and desaturation in the process. In rats, after incubation of cultured brain endothelial cells with [3–^{14}C] docosapentaenoic acid (22:5ω-3) in the presence of serum, radioactivity is primarily recovered in eicosapentaenoic acid (EPA, 20:5ω-3); however, DHA, 24:5ω-3, and 24:6ω-3 were also labeled. Therefore, brain ECs can synthesize and secrete DHA and it 24-C precursors. In addition, one study demonstrated that mouse cerebral endothelium converted 18:3ω-3 into 22:5ω-3, but could not accomplish the last desaturation. The brain capillary ECs are highly enriched in DHA and arachidonic acid and important for the supply of nutrients to the brain, but it is thought that ECs do not play a major role in DHA synthesis. On the other hand, it has been demonstrated that rat astrocytes appear to be a major site for DHA and arachidonic acid synthesis. Indeed, astrocytes, not neurons, elongated and desaturated the 18- and 20-carbon precursors and released DHA and arachidonic acid into the culture medium. It has also been shown that the amount of DHA synthesis from ω-3 PUFA precursors in astrocytes may be regulated by the availability of DHA or other PUFA in the brain tissue or cerebral circulation. Furthermore, in vitro data indicate that DHA synthesis from ω-3 PUFA precursors takes place primarily in astrocytes and that these cells supply some of the newly formed DHA to the neurons and BBB endothelium. In order to examine the participation of astrocytes in this synthesis, cocultures of endothelial cell and astrocytes mimicking the in vivo BBB were used. Endothelial cells cultured alone weakly converted the precursor fatty acids into 20:4ω-6 and 22:6ω-3. Astrocytes play a major role in the delivery of essential PUFAs to the barrier itself and to the brain. It was discovered based on experiments using cocultures of astrocytes and ECs that astrocytes synthesize DHA from ω-3 PUFA precursors and contribute to the ability of brain ECs in the reconstituted BBB to synthesize DHA and arachidonic acid from their 18-carbon precursors. When endothelial cells were cocultured with astrocytes, their content of PUFA increased dramatically. These fatty acids were released by astrocytes after they were synthesized from the precursor fatty acids that passed through the endothelial cell monolayer into the astrocyte medium. Astrocytes play an important role in the brain by elongation of free fatty acids and desaturation action of ω-3 and ω-6 of fatty acid precursors of arachidonic acids and DHA. Astrocytes may thereafter complete the conversion of precursors to DHA, releasing it for uptake by neurons and brain ECs. Studies of cultured cells suggest that astrocytes are the main site of DHA and arachidonic acid synthesis in the brain. Astrocytes may contribute positively to the high level of fatty acid desaturation necessary for capillary endothelial cell functions such as those carried out in the BBB.

Regulation of Tight Junction Formation by Fatty Acids

Fatty acids are major constituents of the phospholipid bilayer of the epithelial cell membrane, and there have been a few reports on the effects of fatty acids on tight junction permeability; fatty acids have been shown to affect occludin protein expression in the umbilical vein endothelial cell line ECV304 and in brain capillary ECs. It has been demonstrated that the TER and the level of occludin mRNA were increased by fatty acids in capillary ECs isolated from brain, and the expression of occludin protein paralleled the change in the pattern of its mRNA expression. The first reported such finding was that the changes in tight junction permeability induced by EPA and gamma LA (GLA) in brain capillary ECs are due to the increase in TER and expression of occludin protein, respectively. Subsequent reports demonstrated the effect of a range of oleic acids, LA, GLA, alpha LA, arachidonic acids, eicosatrienoic acids, and EPA on the permeability of tight junctions and the protein level of occludin in the human umbilical vein endothelial cell line ECV304. GLA, alpha LA, and EPA significantly increased the TER and protein expression, whereas LA significantly decreased the TER of ECV304 cells. These changes in TER were related to alterations in paracellular permeability, which was significantly reduced by EPA and GLA, and significantly increased by LA in ECV304. Furthermore, it was recently shown that PUAC induces tight junctions to form in brain capillary ECs. In brain capillary ECs, the effects of GLA, EPA, and LA on tight junctions were studied in cell monolayers. In those studies the mRNA expression of occludin and the involvement of tyrosine phosphorylation, protein kinase C, and PI 3-kinase were investigated. In vitro studies have shown that fatty acids, EPA, and GLA affect TER and apical-basol permeability. The effect of LA, however, was different from that reported in the umbilical vein endothelial cell line ECV304. Namely, in the in vitro study using ECV304 cells, it was demonstrated that LA decreased the TER. This finding suggests that the difference in the effect of LA is due to a difference of response to fatty acids between umbilical vein ECs and brain capillary ECs, although the mechanism of the response remains unknown. In addition, the rise in TER induced by EPA and GLA was inhibited by tyrosine kinase inhibitors and protein kinase C inhibitor in brain capillary ECs. In contrast, the rise in TER induced by EPA and GLA was not inhibited by the PI 3-kinase inhibitor. EPA and GLA have the ability to increase the TER and the expression of occludin mRNA in brain capillary ECs. This GLA- and EPA- induced assembly of tight junctions is likely to be regulated by protein kinase C and tyrosine kinase activity. The tight junction barrier is regulated by phosphorylation. Various reports have shown that phosphorylation of occludin is a key step in tight junction assembly, which in turn affects the localization of occludin in the cell. The high-molecular-weight forms of occludin are the functional forms that participate in the formation of the tight-junction barrier. The localization of different phosphorylated forms of tight junction–associated proteins in the cell may be especially important. It has been demonstrated that in Madin-Darby canine kidney (MDCK) cells, the less phosphorylated low-molecular-weight forms of occludin are found in the basolateral membrane and cytosol, whereas the more highly phosphorylated high-molecular-weight forms are concentrated exclusively in the tight junction. Differential phosphorylation of occludin might be important for generating tight junctions with different permeability properties. Indeed tyrosine phosphorylation of occludin is known to occur during the assembly of the tight junctions in MDCK cells. Recently the effects of tyrosine kinase inhibitors, genistein, and PP2 on the response to polyunsaturated fatty acids have been reported. It was found that tyrosine kinase inhibitors inhibited the EPA- and GLA-induced increases in TER in brain capillary ECs. The data suggested that EPA and GLA stimulated the tyrosine phosphorylation of multiple proteins. Furthermore, the results indicated that GLA and EPA act through the phosphorylation of protein tyrosine residues. On the other hand, the absorption-enhancing effects of the sodium salts of two medium-chain fatty acids, capric acid and lauric acid, have been studied in monolayers of intestinal epithelial Caco-2 cells derived from colonic carcinoma. Both fatty acids induced a rapid increase in epithelial permeability to the hydrophilic marker molecule sodium fluorescein in the Caco-2 cell line. These reports showed that diverse reactions of free fatty acid depend on differences of the organization. However, the role of fatty acids in tight junction assembly in brain capillary ECs in vivo is not yet well understood.

Conclusion

In summary, in vitro studies have demonstrated that fatty acids induce tight junction formation in brain capillary ECs. On the other hand, brain endothelial cells take up preformed PUFA and transfer them into the brain. Furthermore, astrocytes can complete the conversion of precursors to DHA and arachidonic acid. Astrocytes may modulate tight junctions through provision of fatty acids.

CHAPTER 66

Microcirculation in Peritoneal Exchange

Michael F. Flessner
University of Mississippi Medical Center, Jackson, Mississippi

Introduction

The importance of the peritoneal microcirculation is dependent on its use as an exchange organ, and this chapter will focus on those aspects of the transport barrier that affect the use of the peritoneal cavity in therapy. Therapy can be divided into two broad categories: (a) removal of waste metabolites and water by peritoneal dialysis from the body of a renal failure patient and (b) regional drug delivery, exemplified by intraperitoneal (IP) chemotherapy for metastatic ovarian or colorectal cancer. Whereas the goals of intraperitoneal chemotherapy are different from those of peritoneal dialysis, the transport mechanisms are basically the same. In intraperitoneal chemotherapy drugs are dissolved within a 2- to 3-L solution of dialysis fluid, which is instilled into the peritoneal cavity and allowed to absorb into the surrounding tissue. While in the cavity, the drugs diffuse across the peritoneum, through the tissue space, and into the blood vessels. A prime concern is maximizing the concentration in the targeted peritoneal metastases. In contrast, the goal of dialysis is to maximize transfer of water and solutes from the blood of anephric patients to the solution in the cavity. As illustrated in Figure 1, blood circulates through microvessels in the tissue below the peritoneum, and solutes and water must transport across the endothelium of the capillary, through the tissue interstitium, and across the peritoneum to the dialysis fluid, which is drained every 2 to 6 hours and replaced with fresh solution.

This functional view of the peritoneal microcirculation calls for an integrative approach that includes discussion of the lymphatic drainage of the cavity, the microvasculature, the interstitium surrounding the microvasculature, and the anatomic peritoneum. The system elements are made up of cells that are highly reactive to immunologic stimuli and which in turn affect transport across the peritoneum. In addition to the elements of the transport system, the area of contact between a solution in the peritoneal cavity and the tissue determines the route of absorption, metabolism, and rate of transfer. Each of these elements will be integrated to provide a conceptual model of the transport of solutes and water across the peritoneum.

Description of the System

Peritoneal Development and Anatomy

The peritoneal cavity has not been designed as an efficient organ of solute or water exchange, in the same fashion as the kidney. The yolk sac of the primitive embryo is the progenitor of the peritoneal cavity. Analogous to the collapse of an inflated balloon around a tube, the peritoneal cavity develops as a potential space due to intricate folding of the yolk sac into which grow associated elements of the digestive and genitourinary systems. The surface area of the peritoneum approximates the body surface area, and therefore there is potentially a large area of transfer with a multitude of well-perfused organs in the abdominal and pelvic cavities. The peritoneum covers a portion of the diaphragm and liver, a large part of the stomach and spleen, the small and large intestines, the uterus, ovaries, fallopian tubes, retroperitoneal muscles, kidneys, and a broad expanse of the anterior abdominal wall. The multiple tissues with their different blood circulations lead to the question of which parts are most important to the transport processes.

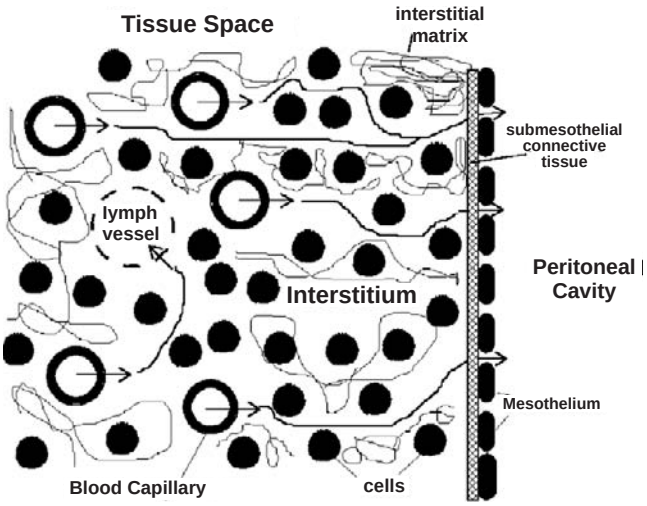

Figure 1 Distributed model concept of peritoneal transport in dialysis. Solutes in the blood transport across the wall of the capillaries distributed in the subperitoneal tissues. Solutes must follow a tortuous path through the interstitium, restricted by matrix molecules and by cells. The final barrier is the peritoneum, made up of a single layer of mesothelial cells and several layers of connective tissue. All solutes must pass across the peritoneum to the therapeutic solution in the cavity, which is replaced with fresh solution periodically to maintain the blood-to-peritoneal cavity concentration gradient that drives diffusion.

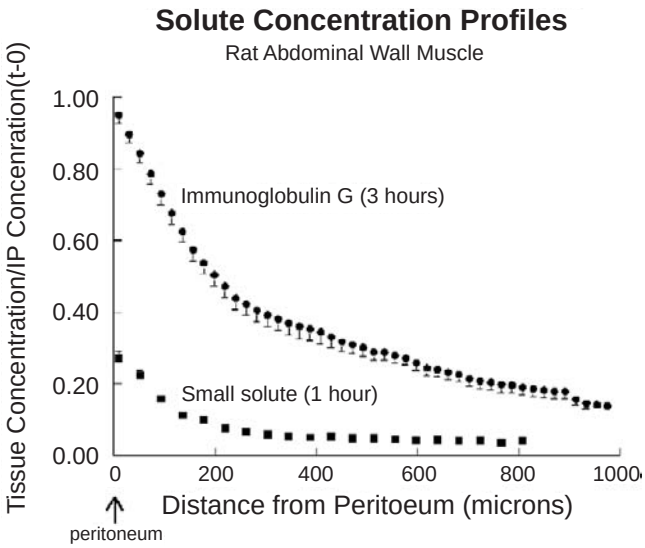

Figure 2 Solute concentration profiles measured by quantitative autoradiography in the abdominal wall of rats after 1 to 3 hours of dialysis with an isotonic solution containing either radiolabeled immunoglobulin G (MW = 150,000 Da) or a small solute (MW = 340 Da). Intraperitoneal pressure was 3 to 4 mmHg. The tissue concentrations have been normalized by the concentration in the original solution infused into the cavity. The degree of penetration of the profiles (0.5–0.6 mm for small solutes and >1 mm for macromolecules) demonstrate that transperitoneal transport involves much more than the peritoneum itself.

The Anatomic Peritoneum

Careful dissection of the human intestinal peritoneum reveals six layers with a total thickness of somewhat less that 100 μm. The most superficial layer is the mesothelium, a continuous monolayer of cells that closely adhere to each other, which is a potential resistance to transport. Separating the mesothelial layer from the underlying connective tissue is a basement membrane. Under the basement membrane are networks of collagenous and elastic fibers. These five layers, making up the most superficial 30 to 40 μm, are devoid of blood and lymphatic vessels. The final layer is the deep latticed collagenous layer that ranges from 50 to 60 μm thick and contains most of the blood vessels of the anatomic peritoneum. The total thickness of the intestinal peritoneum of the human is 80 to 95 μm. Thus after passing the mesothelium, a solute transporting from the peritoneal cavity towards the blood must pass through 25 to 35 μm of tissue before reaching any blood vessels, which are scant in the deep collagenous layer. In the intestine, the layer of tissue under the peritoneum is the smooth muscle of the gut. There are at least 1,000 to 3,000 μm of muscle between the peritoneum and the extensive blood vasculature of the human intestinal villi. As discussed in the following section, the blood supply available to the cavity is chiefly from the smooth muscle of the gut.

The rat has been used as a model of peritoneal transport for more than 30 years, and the normal rat peritoneum resembles that of the human in many respects. Differences are that there is not a collagenous layer with blood vessels and that the peritoneum has a total thickness of 25 μm. Because the rat has very few blood vessels in the normal peritoneum, transport occurs between blood vessels in the parenchymal tissue below the peritoneum and the peritoneal cavity. Recent research has shown that the rat anatomic peritoneum has very little resistance to the passage of small solutes and macromolecules. Viral vectors, such as adenovirus, are the exception to this; they are completely absorbed into the mesothelial cell layer and do not pass beyond the normal anatomic peritoneum.

The Transport System Extends Well Beyond the Anatomic Peritoneum

The microcirculation of the underlying tissues is essential to transport of solutes and fluid between the peritoneal cavity and the circulating blood. The microcirculation of the anatomic peritoneum makes up only a small part of the microcirculation that is involved in transport of solute and water across the peritoneum. The blood supply to the mesentery exemplifies the microcirculation of the intrinsic peritoneum. The membranous-like structure of the mesentery with the sparse population of blood capillaries is a convenient means of study of the microvasculature, but it may not be representative of the microcirculation involved in transperitoneal exchange. Evidence for the amount of tissue involved with transport across the peritoneum is best obtained through the study of solute penetration into this tissue from the peritoneal cavity. Figure 2 demonstrates the degree of penetration of small solutes (MW = 200 to

5,000 Da) and a larger molecule such as immunoglobulin G (IgG, MW = 150,000 Da). In both of these experiments, a rat was dialyzed with large volume in the peritoneal cavity with a radiolabeled compound of mannitol or IgG. At 60 to 180 minutes after the introduction of the solution into the peritoneal cavity the animal was rapidly euthanized, the fluid was drained, and the tissue was rapidly frozen to preserve the concentration profile. Tissue was subsequently collected and analyzed with quantitative autoradiography. The profiles demonstrate that in the case of diffusion-dominated, small molecules (MW less than 5,000 Da), the penetration is on the order of 500 to 600 μm or approximately 1 mm. This is well beyond the thickness of the peritoneum, which in the rat is approximately 25 μm. On the other hand, the profile of a large molecule such as a protein, which is dominated by hydrostatic pressure-driven convection, demonstrates a much greater degree of penetration within the abdominal wall, because of tissue binding and relative lack of lymphatics that could remove the protein from the tissue. From this figure, it can be concluded that the tissue underlying the peritoneum that is involved with transport is a minimum of 0.5 to 1 mm thick and involves a significant amount of parenchymal tissue below the anatomic peritoneum.

The Subperitoneal Blood Circulation

Despite its continuous surface, there is an anatomical division of the peritoneum into the *visceral portion*, covering the intra-abdominal and pelvic organs, and the *parietal peritoneum*, which adheres to the retroperitoneal structures, the diaphragm, and the anterior abdominal wall. The abdominal aorta is the large vessel that passes through the diaphragm and supplies all of the abdominal tissues. The vena cava is the large vein to which all abdominal vessels ultimately drain. The visceral circulation supplies all of the internal organs including the liver, spleen, stomach, and intestines. The celiac artery divides into the splenic, left gastric, and hepatic arteries supplying respectively the spleen, stomach, and liver. Two other major vessels, the superior and inferior mesenteric arteries, form the arcade of vessels supplying the small and large intestines. Branches of the inferior mesenteric artery anastomose with branches of the superior mesenteric, which in turn anastomose with branches of the celiac. The venous drainage of the subperitoneal tissues is a distinguishing feature of the visceral and parietal peritoneum. The veins that correspond to the arteries for these tissues combine to form the portal vein, through which blood is delivered first to the liver prior to reaching the vena cava. Therefore substances that transport into the blood from either the luminal side or the peritoneal side of the hollow organs will transit through the liver before reaching the central circulation and experience a "first-pass effect" of hepatic metabolism.

In contrast to the venous system draining the visceral tissues, blood from the parietal tissues drains directly into the vena cava. Separate arteries supply the kidneys and the ovaries, while their respective veins drain to the vena cava. The right and left deep circumflex iliac arteries supply the sublumbar muscles of the abdominal wall, and at the level of the sacrum approach the skin. Five lumbar arteries branch from the abdominal aorta and supply the para-axial and lumbar muscles, the skin, and the spinal cord, while the epigastric arteries supply the remaining muscles of the abdominal wall. The veins corresponding to these arteries that supply the retroperitoneal tissue and the inferior abdominal wall are close to the arteries and essentially drain into the vena cava directly without going through the liver. The phrenic arteries supply the diaphragm, and the corresponding veins drain to the ipsilateral renal veins, which lead directly to the vena cava.

From a pharmacokinetic point of view, the important information to note from this discussion is that the parietal peritoneal circulation is separate from the visceral circulation and that the drainage from the parietal circulation does not transit through the liver before joining the general circulation. Thus substances that transport into the tissue of the diaphragm, lumbar muscles, or the anterior abdominal wall are transferred directly to the vena cava and to the central circulation without passing through the liver. On the other hand, substances that transport into the tissues of the gut, liver, spleen, and pancreas will transit through the liver prior to entering the central circulation. Figure 3 is a diagram of a

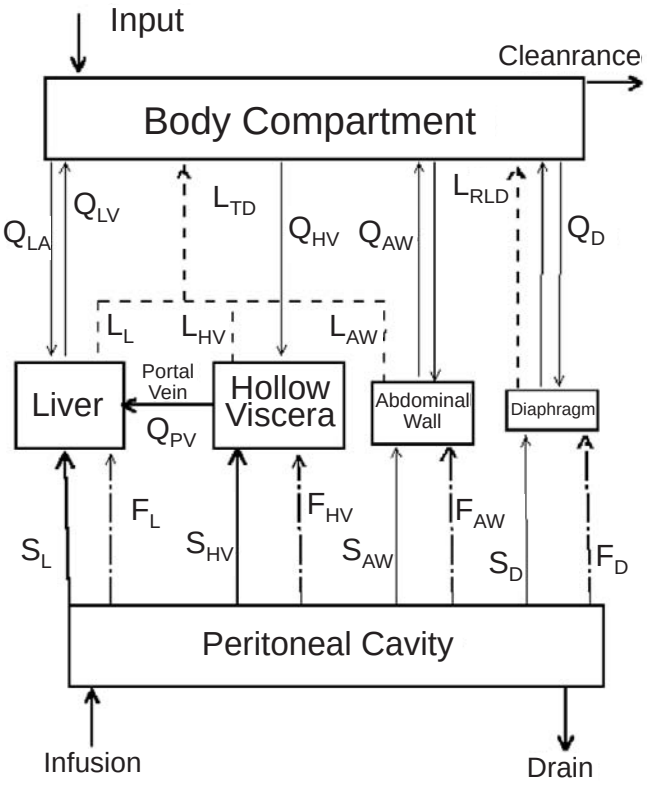

Figure 3 Multicompartment model of intraperitoneal drug delivery. The four tissue compartments result from the anatomy of the cavity and the blood and lymph drainage of the tissues. In the figure: Q, blood flow; L, lymph flow; S, solute transport; F, volume flow. Subscripts: AW, abdominal wall; D, diaphragm; HV, hollow viscera; L, liver; LA, liver artery; LV, liver vein; PV, portal vein; RLD, right lymph duct; TD, thoracic duct. (Data replotted from M. F. Flessner, *Am. J. Physiol*. 1985, *Cancer Res*. 1994.)

multicompartment model that includes this division of the circulation and which is particularly useful in consideration of drug absorption and mathematical modeling.

Peritoneal Microcirculation Involved in Transport

The classic description of the peritoneal microvasculature was provided by Chambers and Zweifach more than 50 years ago. The typical capillary network consists of arterioles, terminal arterials, precapillary sphincters, arterial venules and anastomotic thoroughfare channels, capillaries, postcapillary venules, and venules. Blood flows into the capillary system through the arterioles and exits through venules. Arterioles and thoroughfare channels control actual blood flow to the exchange vessels, which are the capillaries and the venules. Although most data have been collected in studies of the mesenteric bed because of the convenience of imaging these vessels, they may not be the best representation of the major microcirculation involved in transperitoneal transport. As discussed earlier, the transport involves vessels within approximately a millimeter of the mesothelial surface. The mesentery is a double-walled fold of the mesothelium with a single layer of sparse vessels making up the mesenteric circulation. The vessels tend to be much greater distances apart than the vessels in the abdominal wall or in the wall of the gut. Because the largest percentage of the anatomic peritoneum is made up of muscle (either smooth muscle of the hollow viscera or the skeletal muscle of the abdominal wall or of the retroperitoneum), it may be better to think of the peritoneal circulation involved with transport to be similar to that of muscle. This circulation is only bathed by solution in the cavity on one side, whereas the mesentery is bathed on both sides of a single layer of vessels. Although nonfenestrated capillaries of the liver and spleen are extremely permeable and are likely a source of protein loss during peritoneal dialysis, the amount of direct exchange is limited because their surface exposure is a small fraction (about 10%) of the potential surface area.

Transendothelial Transport: The Three-Pore Model

Because of the importance of muscle capillaries, the remainder of this discussion will be focused on this type of nonfenestrated capillaries. Rippe and colleagues have recently published a detailed description of the microcirculation and has described the endothelial barrier in terms of a three-pore model as illustrated in Figure 4. One to two percent of the total pore surface area is made up of transcellular pores or "aquaporins" of radius 0.1 to 0.5 nanometers (nm) in diameter that permit only water to cross. Most of the pore surface area (about 95%) is made up of "small pores" with a radius of 4.0 to 6.0 nm. The remaining 2 to 3 percent of the total pore area is made up of "large pores" on the order of 20 to 30 nm, across which the hydrostatic pressure dominates the transport forces. The figure also depicts the endothelial cells coated on the luminal side with a glycocalyx, which is typically 0.1 to 0.2 μm thick but can be as thick

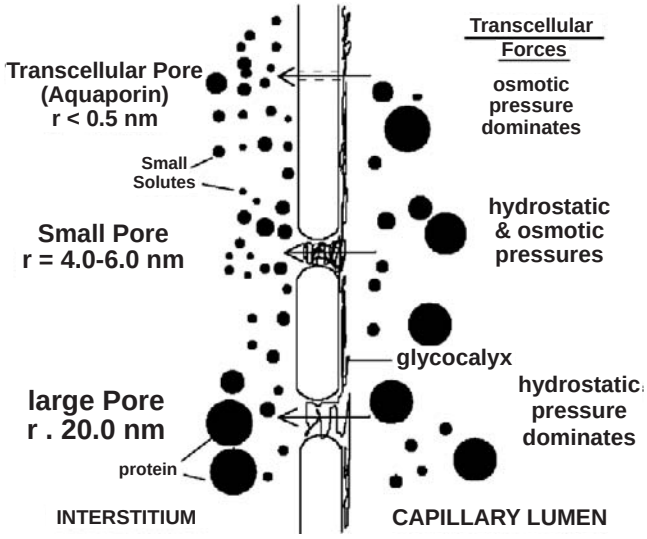

Figure 4 Pore-matrix theory of transendothelial transport. See text for details.

as 0.5 μm. The pore-matrix theory hypothesizes that this glycocalyx restricts the passage of molecules across the endothelium and may be responsible for the membrane properties of the "pores." In this theory, the pore sizes, which have been estimated from the transfer of different molecular size solutes across the capillary wall, may be in fact made up of similar-sized interendothelial gaps that are filled with different densities of glycocalyx. Mathematically, each theory can be shown to be equivalent to the other.

Water, which transports during dialysis in response to an osmotic pressure difference across the capillary wall, flows chiefly through endothelial aquaporins, unique structures in the cell membrane that allow only water to pass through the membrane. The portions of endothelium containing these very small pores are perfect semipermeable membranes, and therefore the entire osmotic pressure difference is effectively exerted. In experiments in an aquaporin-knockout mouse, approximately 50 percent of the osmotic filtration during dialysis was eliminated, demonstrating that these water-only pores are responsible for half of the osmosis during dialysis. The remaining 50 percent of the water transport occurs across the small pores and the large pores.

Small pores make up approximately 95 percent of the total pore area and are primarily responsible for transendothelial transport of substances with a molecular weight of less than 5,000. Permeability of the small pore decreases with increasing molecular size up to a radius of 3.0 nm. Larger solutes are excluded from these pathways and pass through the large pore. Since these openings are too large to restrict macromolecules, there is essentially no osmotic pressure difference across these pores. Because the hydrostatic pressure in the capillary or venule lumen is typically higher than in the interstitium, solutes and water are driven out of the bloodstream under hydrostatic pressure–driven convection. Although some have postulated

that there is a vesicular transport of macromolecules across the endothelium, this has been discounted by functional studies in which macromolecular transport continued to be observed under conditions in which vesicular transport should be near zero. Additional evidence comes from direct histologic observation in serial thin sections, which demonstrated that the so-called vesicles were actually invaginations in the cell wall.

Blood Flow and Limitations of Transport

In the transfer of solutes and water, there has been disagreement on whether blood flow limits the transport. In theory, very low blood flows may limit transfer of very small solutes such as urea (MW = 60 Da). However in experiments in rats, the blood flow perfusion to individual organs was decreased to 20 to 30 percent of its original level without change in the mass transfer rates of urea across the peritoneum of the cecum, stomach, or abdominal wall. The transfer across the liver was significantly altered with a decrease in blood flow. In analogous experiments, water transport was decreased across all of these surfaces, but only approached statistical significance across the liver peritoneum. In another approach to the problem, animals were bled to decrease their blood pressure to shock levels, which resulted in minor but statistically significant changes in rates of mass transfer in small solutes. However, even under these extreme conditions the rate of transfer was sufficient to support dialysis. From these studies it can be concluded that under normal circumstances, there are no significant blood flow limitations for water-soluble molecules, but there may be limitations in removal of water during states of systemic shock.

Peritoneal Lymphatic System

The lymphatic system that drains the peritoneal cavity can be divided up into two parts. In the subdiaphragmatic system, which drains 70 to 80 percent of the lymphatic flow from the peritoneal cavity, the diaphragm acts as a pumping mechanism that pulls fluid from the pelvic regions of the cavity toward itself. As the diaphragm moves upward in expiration, the lymphatic plexus expands and a negative pressure is established in the lymphatic vessels. Penetrations in the basement membrane called lacunae open to take in fluid, solutes, and particles up to 25 μm in diameter. When the diaphragm contracts, the tension in the lymphatic wall is released and the lacunae are closed. The fluid is then propelled upward toward the right lymphatic duct or into the thoracic duct. The remaining 20 to 30 percent of lymph flow from the peritoneal cavity travels through the visceral lymphatics. These drain to the mesenteric lymphatics and ultimately to the cisterna chyli at the base of the thoracic duct. In healthy peritoneal dialysis patients, the total lymph flow has been determined to be between 7 and 21 mL/hour. The capacity of the lymphatic system can increase significantly in states of massive cirrhotic ascites to rates of greater than 30 mL/hour or decrease to near zero with carcinomatous obstruction of the lymph channels.

Subperitoneal Interstitium and Effects of Intraperitoneal Pressure

Although some transport models neglect the presence of interstitium and portray the peritoneal barrier as a capillary endothelium, the interstitial space, which surrounds the blood vessels and parenchyma cells of the subperitoneum, presents a significant barrier to transport. This was demonstrated most clearly by the absorption of inert gases from the peritoneal cavity of pigs, which demonstrated a one-hundredfold range of clearances that correlated with the log of the aqueous diffusivity. If the resistance in the barrier were equivalent to just the blood capillary wall, then the transfer of gas would be limited by blood flow as it is in the lung, and the rates of inert gas absorption would have been the same. Correlation with diffusivity of water implies that the resistance in the tissue interstitium limits the transport of these inert gases.

The space between the cells, termed interstitium, is a very ordered structure of the tissue. At one time the interstitial matrix of molecules was considered an amorphous mixture of interstitial ground substance. However, now it is known to be a highly ordered matrix made up of collagen fibers that are anchored to the surrounding cells by adhesion molecules called integrins. Collagen fibers have been demonstrated to hold the cells and extracellular matrix in active tension that can be disrupted in states of inflammation or tissue damage. Wrapped around the collagen molecules are large hyaluronan molecules, which imbibe water and bind proteoglycans such as chondroitin sulfate, keratin sulfate, and heparin sulfate. The hyaluronan molecules are negatively charged and together with the collagen present a major barrier to the passage of negatively charged proteins. These molecules also restrict proteins to approximately 20 percent of the extracellular space. These interstitial molecules in the subperitoneal tissues link the parenchymal cells, fibroblasts, and other cells and force solutes to take a very tortuous path when transiting from the blood to the peritoneal cavity or vice versa. The presence of the interstitium and cells surrounding the exchange blood vessels in the tissue has the effect of decreasing the rates of diffusive transport from the blood to the peritoneal cavity 30 to 100 times from the rate of free diffusion of the same molecule through water. The greater the distance between the capillary and the peritoneal surface, the more significant the resistance of the interstitium becomes. The portion of resistance attributable to the interstitium in the diffusion of a small solute such as sucrose is estimated to be 20 percent if the capillary is located 50 μm from the peritoneum. However, it increases to more than 80 percent of the total peritoneal resistance if the capillary is located 600 μm from the peritoneum.

During a therapeutic procedure in which a volume of 2 to 3 L is infused into the cavity, pressures are 2 to 20 mmHg,

depending on the size of the patient, the volume administered, and the position of the patient (sitting position has the highest pressure; supine, lowest). In the abdominal wall, even a relatively low pressure of 4 mmHg causes the extracellular volume of the abdominal wall of the rat to expand by 100 percent, which results in a marked decrease in the resistance to diffusion or convection. Therefore, the interstitial portion of the peritoneal transport system during a large abdominal dwell of fluid can potentially be quite variable in its characteristics.

Quantitative Approach to Peritoneal Exchange

Distributed Model of Peritoneal Transport

Because of the complex relationships between the various parts of the peritoneal transport system, an integrative approach needs to be taken in order to quantify the system. The distributed model was devised as a simplification of the actual system. In this concept, the blood capillaries are distributed uniformly throughout the tissue space, surrounded by parenchymal cells and the interstitium, which is also assumed to have uniform concentrations of interstitial matrix molecules. A layer of mesothelial cells and the underlying connective tissue of the peritoneum overly the tissue space. These principles are portrayed in a simplified fashion in Figure 1. Lymphatic vessels, which are typically at the tissue planes in the parietal tissue or distributed within the multiple layers of smooth muscle of the visceral tissues, are modeled as a separate flow from each tissue compartment (see Figure 3). Within this system, diffusion of small molecules (MW less than 6,000 Da) between the blood and the peritoneal cavity is a symmetrical process, that is, small molecules from blood to the peritoneal cavity or from the peritoneal cavity to the blood follow an equivalent path. An asymmetry in transport exists in the case of larger molecules, which can transfer across capillary walls from the lumen to the interstitium via "large pores" but can only return to the blood via the lymphatics.

An engineering approach to the transfer of small solutes across the peritoneum is illustrated in the following equation:

$$\textit{rate of mass transfer} = \frac{d(C_{pc}V_{pc})}{dt} = \sum_i MTC_i \bullet A_i(C_{plasma} - C_{pc}) \quad (1)$$

where C_{pc}, C_{plasma} are concentrations in the peritoneal cavity and the plasma respectively. V_{pc} is the volume in the peritoneal cavity and in this version is assumed to remain constant. The terms MTC_i and A_i are, respectively, the mass transfer coefficient and the contact surface area of each tissue element "i" of the transport system. In this equation, the peritoneal volume is assumed to be well mixed with a uniform concentration, and the total transport resistance of each tissue element has been lumped into the term MTC_i.

The MTC_i can be related to the tissue diffusivity and the capillary permeability with the following equation:

$$MTC_i = \sqrt{D_i(pa)_i} \quad (2)$$

where D_i is the effective solute diffusivity for each tissue and $(pa)_i$ is the capillary permeability (p) times the area density (a) for the tissue. The term p incorporates the contributions from the two pores that permit passage of solute. This equation implicitly assumes that there are no blood flow limitations.

For a diffusion-limited solute (MW less than 6,000 Da), the concentration profile in the tissue can defined as

$$\frac{C_i - C_{plasma}}{C_{pc} - C_{plasma}} = \exp^{-\sqrt{\frac{(pa)_i}{D_i}}x} \quad (3)$$

where C_i is the tissue concentration and x is the distance into the tissue.

Peritoneal Surface Contact Area

In consideration of Equation (1), a major factor that determines the rate of mass transfer across the peritoneum is the peritoneal surface contact area (A_i) between the peritoneal solution containing a therapeutic drug or dialysate and the peritoneum. As illustrated in Figure 1, transfer will not occur between the vessels located in the tissue and the cavity without contact of fluid on the overlying surface. Although some authors have discounted the three-dimensional nature of the transport barrier and equate the perfused vascular area to the peritoneal surface area, animal and human studies have demonstrated that rate of solute transfer is directly dependent on the peritoneal contact area. In human studies, increasing the volume of fluid within the peritoneal cavity increases the surface contact area, which increases the creatinine mass transfer proportionately. With the use of relatively large volumes in rodents and human dialysis patients, only 30 to 40 percent of the total anatomic peritoneal surface area is in contact with the solution.

Contact surface area is likely not distributed proportionally between parietal and visceral tissues. Although the visceral peritoneum makes up approximately 60 to 70 percent of the mammalian anatomic peritoneum, evisceration in rodents has been shown to decrease the peritoneal mass transport only 10 to 30 percent. Transfer rates of small solutes across different surfaces of the visceral and parietal peritoneum, independent of surface area, have been shown to be essentially equivalent. Therefore, the actual distribution of the fluid contact area may not make a difference in determination of the overall average mass transfer rate. Pathological changes in the peritoneum, such as the development of adhesions that restrict free flow of fluid in the cavity, may alter the distribution.

Modulation of Transport Barrier: Normal Physiology

ALTERING SURFACE CONTACT AREA

A problem may develop in IP chemotherapy if the residence time of the solution in contact with the carcinomatous target is short. The goal of intraperitoneal chemotherapy is to expose 100 percent of the peritoneal surface to the therapeutic solution for a maximal duration. Typically, this is performed in humans by infusing 2 L of peritoneal dialysis fluid into the cavity and allowing it to be absorbed. Rates of fluid transfer are typically unimportant to the chemotherapist, since most of these patients have intact kidneys and can excrete the absorbed fluid. Increased surface area during intraperitoneal chemotherapy would be very advantageous to treatment of metastatic carcinoma. If the solution containing the drug is in contact with the surface of the tumor for 10 minutes out of a 24-hour period there will likely be very little drug deposited into the tumor. Use of relatively high concentrations of diacetyl sodium sulfosuccinate (DSS) in rodents resulted in 100 percent of the peritoneal surface area in contact with the fluid, but toxicity was observed. A further problem occurs in some patients with extensive carcinomatoses who develop severe adhesions, which bind together portions of the visceral and parietal peritoneum, restricting the movement of fluid to all parts of the peritoneal surface and limiting therapy. Surface-active agents may be useful in patients with end-stage carcinoma, but testing in animals should be undertaken prior to use in humans to elucidate potential toxicity.

In Equation (1), which describes the rate of mass transfer across the peritoneum in quantitative terms, the rate is directly proportional to the surface contact area. Enhancement of the peritoneal surface area by even 20 percent would increase the rate of mass transfer by 20 percent and could provide enough additional dialytic therapy to improve dialysis efficacy. Increasing the volume from 2 to 3 L in average-sized humans has been shown to improve the rate of transfer of creatinine by 25 percent, proportional to the increased surface area in contact with the fluid. In animals, the use of surface-active agents such as DSS has been shown to increase the surface contact area and to proportionally increase the rate of mass transfer. In small rodents, this was shown to also increase the rate of protein loss during the dialysis. Since in chronic dialysis, the fluid is removed from the body and discarded, this additional loss of protein could be detrimental to the patient. At this time, there is no data on the use of surface active substances in the human peritoneal cavity. Low doses of surface-active substances should first be tested in animal models and demonstrated to be safe for chronic use prior to their utilization in human beings.

Use of larger volumes to cover more of the peritoneal surface is currently the simplest method of increasing surface contact area. The major factors that determine the tolerable peritoneal volume are the size of the patient, the expansion capability of the abdominal wall, the length of time of the procedure, and the position of the patient. For ambulatory peritoneal dialysis, the volumes are typically 2 to 3.5 L. Very few people can tolerate more than this volume in their peritoneal cavity, while carrying out their activities of daily living. On the other hand, a patient undergoing radical resection of metastases in the peritoneum and who is anesthetized might tolerate very large volumes in the cavity while supine and anesthetized. During experimental IP chemotherapy, rates of transfer have also been markedly enhanced by placing two catheters into the cavity after surgical debulking of tumor and perfusing at a very high flow rate into one catheter and removing the fluid from the other. By maintaining a very high drug concentration in the peritoneal cavity and by perfusing the peritoneal surface with a rapid flow rate, the surface area and the concentration difference between the cavity and the blood in the underlying microcirculation were maximized, and these measures caused a doubling of the mass transfer rate of low-molecular-weight drugs from the cavity.

ALTERING THE MASS TRANSFER COEFFICIENT

A second method of altering transperitoneal transport is adjustment of the mass transfer coefficient (MTC). As shown in Equation (2), the MTC is equal to the square root of tissue diffusivity times the capillary permeability–area density product. By altering any of these terms, one can obtain a modest increase or decrease in the MTC in proportion to the square root of the factor. In the setting of dialysis where maximal rates of transfer are desired, many studies have demonstrated that the use of drugs such as nitroprusside does increase the clearance of urea, creatinine, inulin, and protein in a dose-dependent fashion. Although there are no data on which term within the (pa) is actually altered, it is assumed that vasodilators increase the vascular surface area per unit volume of tissue or a. Vasodilator substances diffuse into the tissue from the peritoneal cavity and set up a concentration profile similar to the small solute profile in Figure 2. Thus the most marked effect would be close to the peritoneal surface, whereas the vasodilation more than 500 μm from the surface would be much less. Unfortunately, intraperitoneal nitroprusside appears to be limited by a loss of effect after approximately five exchanges with the drug. Removal of the drug from the dialysis solution causes a decrease to the baseline of the permeability. In addition, there may be effects on systemic blood pressure that limit the use of vasodilators in the peritoneal cavity.

In contrast, vasoconstrictors cause an acute decrease in the rate of mass transfer. It is presumed that they work in the opposite fashion by decreasing the perfused vascular surface area. These might be useful in chemotherapy where local absorption into tissue should be maximized, but systemic absorption into general circulation should be minimized. Experiments in animals have shown that these drugs acutely will cause a change, but there is little data in humans. Theoretically none of the vasodilators or vasoconstrictors should change the intrinsic capillary permeability, nor should they change any characteristics of the tissue diffusivity.

The tissue diffusivity can be altered by changing the structure of the extracellular space. As described earlier, a large volume dwell tends to increase the extracellular space of the subperitoneal tissue. Even at very low intraperitoneal pressures of 4 mmHg, the extracellular space of the rat abdominal wall doubles. This will translate to a doubling of the effective diffusivity for small solutes, which are restricted to the extracellular space. This may also cause an increase in the rate of diffusion of larger solutes, such as immunoglobulins, which distribute to a much smaller portion of the tissue space because of interactions with the negatively charged matrix molecules. Alteration of the extracellular matrix by decreasing the concentration of hyaluronan or collagen will lead to less macromolecular restriction and a higher rate of transport.

Pathological States and Alterations in the Peritoneal Transport System

Metastatic Cancer in the Peritoneum

In the patient undergoing intraperitoneal chemotherapy, the peritoneum has been altered by metastasis of the primary tumor. The subdiaphragmatic lymphatics may become obstructed, and the outflow of cellular materials, protein, and fluid may be markedly decreased. In addition, metastasis to the liver may cause an increase in transhepatic ascitic fluid production, which, coupled with the loss of outflow through subdiaphragmatic lymphatics, will result in accumulation of fluid in the peritoneal cavity and marked distention of the abdominal wall with an increase in intraperitoneal volume and pressure. Additionally, metastasis to specific areas of the peritoneum will cause the mesothelium to be altered and will result in adhesions between the parietal and visceral peritoneum or between tumor and normal peritoneum. This leads to reduction of peritoneal volume, dysfunction of the gastrointestinal tract, decreased access of a therapeutic solution to the entire peritoneum, and nonuniform distribution of the peritoneal fluid in the cavity. The presence of ascitic fluid and extensive adhesions decreases the effectiveness of intraperitoneal chemotherapy. Only with radical peritoneal surgery can the cavity be restored to a state appropriate for treatment of metastatic abdominal cancer. Recent evidence has shown that peritoneal stripping of intra-abdominal carcinomatosis results in restoration of the distribution of the therapeutic solution and the anticipated rates of mass transfer across the peritoneum.

Chronic Inflammation from Sterile Dialysis Solutions

With the use of the peritoneal cavity as a dialysis system, the requirements are significantly different from those of chemotherapy, and the types of pathology that alter the tissue barrier are somewhat different. Although some patients have had prior cases of peritonitis or abdominal surgery that have produced adhesions, the vast majority of peritoneal dialysis patients do not have the same problem that patients with peritoneal carcinomatoses have. Over the past 10 years knowledge has grown concerning the chronic state of inflammation that the peritoneum experiences with long-term, continuous peritoneal dialysis. The solutions, which typically have a low pH, a high osmotic pressure due to glucose, and glucose degradation products from heat sterilization, have been shown to cause significant changes in the peritoneum, subperitoneal interstitium, and transport microvasculature. The high glucose content, which varies from 15 to 42.5 g/L, sets up a diabetic state within the cavity. Twenty-four hours a day the mesothelium is bathed with these solutions. The resident macrophages in the peritoneal cavity and the mesothelial cells have both been shown to react to these glucose solutions. Human studies have demonstrated that in as little as 8 months, the peritoneal mesothelium changes from an epithelioid cell type to a fibroblastic phenotype. This is not due to repeated infective peritonitis but merely constant exposure to sterile, hypertonic solutions. Although the low pH and hyperosmolality have been implicated in these changes, current evidence points to glucose degradation products and glucose itself. Biopsy studies of long-term peritoneal dialysis patients have shown that the submesothelial compact zone, which is typically less than 60 to 80 μm thick, increases in thickness to as much as 2,000 μm after 6 to 7 years. Simultaneously, the degree of angiogenesis and vasculopathy in the layer directly under this subcompact mesothelial layer increases in approximately 90 percent of patients after 6 years of exposure. The rate of solute transfer is often enhanced while the rates of fluid removal with osmotic ultrafiltration are markedly depressed. This results in loss of capacity to remove fluid from the patient and necessitates an alternative mode of therapy.

Peritoneal Inflammatory Response

Figure 5 illustrates the peritoneal cellular system and some of the mediators of the inflammatory cascade. Mesothelial cells overlie the connective tissue of the peritoneum, and within the tissue space, there are fibroblasts, muscle (parenchymal) cells, and endothelial cells. The glucose solutions stimulate the production of interleukin 1 (IL-1) and tumor necrosis factor alpha (TNFα) and the peroxidatic activity of macrophages that reside in the peritoneal cavities of dialysis patients. Mesothelial cells also respond directly to glucose solutions and spontaneously release hydrogen peroxide, IL-1, and TNFα. Whereas in vitro exposure of mesothelial cells to low pH dialysis solutions causes marked toxicity, these solutions are buffered in 10 to 15 minutes in vivo. Therefore the solution pH may not be a major factor in a chronic inflammation. However, bicarbonate-buffered solutions have been shown to decrease production of transforming growth factor-1 (TGFβ-1) and to improve the overall health of the mesothelium. The

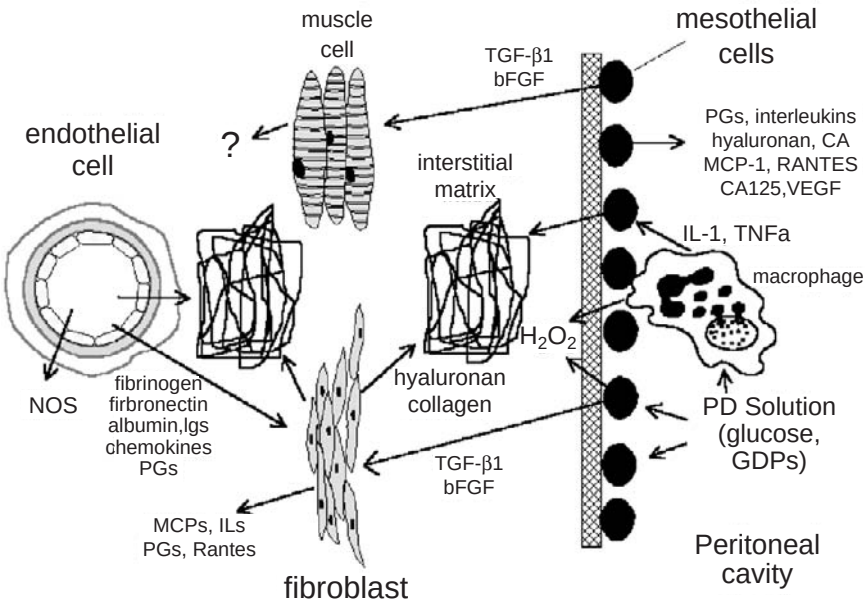

Figure 5 Cellular system in peritoneal inflammation. Dialysis solutions in the peritoneal cavity contain glucose and glucose degradation products (GDPs) that activate macrophages and mesothelial cells to secrete numerous cytokines. These in turn stimulate fibroblasts and attract leukocytes to migrate through activated endothelium. This chronic inflammatory process results in scarring of the subperitoneal tissue and vasculopathy in the parenchymal vessels. See text for definitions of cytokine acronyms. (see color insert)

mesothelial cells, once stimulated by glucose or by the IL-1 and TNFα from stimulated macrophages, produce prostaglandins, interleukins, hyaluronan, cancer antigen 125 (CA125, a marker for mesothelial cell number), monocyte chemoattractant protein (MCP-1), RANTES, vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and TGFβ-1. In vivo gene transfer of an active TGFβ-1 into rat mesothelium via an adenoviral vector resulted after 7 days in a markedly thickened peritoneum with increased vascularization and extensive collagen deposition. The infected animals demonstrated an increased transport of solutes and decreased ultrafiltration in response to hypertonic solutions.

Stimulated fibroblasts produce a series of cytokines as well as hyaluronan and collagen. It is likely that they play a major role in the fibrosis in the subcompact area of the peritoneum during long-term peritoneal dialysis. Coupled to cells in the interstitium are activated endothelial cells in the vessels through which white blood cells pass through the endothelium into the tissue space. Nitrogen oxide synthetase (NOS) has been shown to be upregulated and to result in a state of vasodilation. A constant state of hyperosmolality due to high glucose concentrations essentially sets up a diabetic state within the tissue, with the possible formation of advanced glycation end products. These are correlated with many of the fibrotic and angiogenic changes within the tissue. Whether parenchymal muscle cells or other cells such as pericytes associated with endothelium within the tissue take part in this product state of inflammation is unknown.

Intravital microscopy has recently been used to analyze the vasoactive effects of peritoneal dialysis solutions on the mesenteric vessels. Low-GDP solutions have caused transient vasodilation, whereas conventional 4.25 percent dextrose solutions result in maximal vasodilation, doubling of the arterial flow, and a 20 percent increase in perfused capillary length/area. Neutral, lactate-buffered solutions had only transient effects. Peritoneal NOS has been shown to rise fivefold in long-term dialysis patients. It also correlated with increased vascular density and endothelial area in biopsies. VEGF was colocated in the peritoneal endothelium with advanced glycation end products. Filtered dialysis solutions contain far less of the glucose degradation products that occur with heat sterilization. Treatment of patients with these more biocompatible solutions typically produces lower concentrations of hyaluronan (a marker of inflammation) in the peritoneal dialysate, higher concentrations of CA125, and higher concentrations of procollagen-1-C peptide and procollagen–3-N-terminal peptide.

In summary, mesothelial cells that are continually exposed to the high concentrations of heat-sterilized, glucose-based peritoneal dialysis undergo a cellular transition from an epithelial cell type to a fibroblastic phenotype. High levels of TGFβ-1 and VEGF appear to promote fibrosis and angiogenesis in these subperitoneal tissue spaces. Attempts to block specific modulators of this inflammatory system have resulted in decreased proliferation in vitro. In vivo investigation will likely proceed in the next several years.

Integration of the Peritoneal Transport System

The complexity of the peritoneal transport barrier requires an integrated approach toward its description. Figure 3 is a useful conceptual model when the system is modeled mathematically. Quantitative flows of blood and lymph must be assigned to all of the various pathways in this illustration. Rates of mass transfer with individual mass transfer coefficients and surface contact areas must be assigned to each tissue group. The system in Figure 3 must then be integrated into a total-body system with multiple compartments for each organ system. Quantitative values for the various parameters have been suggested by Flessner and Dedrick (see Further Reading).

The distributed model concept of Figure 1 requires tissue-specific transport coefficients that cannot be obtained from the compartmental model of Figure 3. Solutes transport from the cavity through the peritoneum, which has been shown to be an insignificant barrier, through the tissue interstitium and are absorbed either directly into the distributed blood system throughout the subperitoneal tissues or into the lymphatic vessels, if macromolecules. Characteristics of the interstitium and its variability during a large-volume dialysis or chemotherapeutic procedure must be taken into account. In addition, the vascular system is highly reactive to hypertonic solutions often used in dialysis. Therefore in the early stages of dialysis, there may be a localized vasodilation in the layers of the tissue closer to the anatomic peritoneum. However, after 15 to 20 minutes, this tends to disappear and a rather uniform rate of blood flow appears to be the rule. Rates of small-solute transport appear to be the same whether in the direction from the cavity to the blood or from the blood to the cavity. Larger solutes, however, experience an asymmetry in their transport. They leave the blood vessels via large pores and transport through the tissue interstitium to the peritoneal cavity. However, if administered into the peritoneal cavity, they transport across the peritoneum and through the interstitium, but cannot be reabsorbed directly across the endothelium; they must be taken up by lymphatics. The restrictive properties of the peritoneal interstitium must be taken into account when describing the transport. Although a small portion of the peritoneal surface area is made up of solid organs such as the liver and spleen, the vast majority of the tissue microcirculation can be represented by vessels of the muscle.

The cells illustrated in Figure 5 need to be considered as a system. Although each of these cell types can be studied in vitro, it is only through their interaction that the clinically observed pathology is created. It is also only through this interaction that an improved understanding of the complex process of chronic inflammation will come about. The integrated cellular system within the peritoneal tissue reacts to multiple stimuli. In bacterial peritonitis, the interaction of the organisms with the macrophages and the mesothelium results in a rapid response of the local inflammatory cascade. This affects the underlying tissue space in the short term but appears to be rapidly reversed if the infection is brought under control. On the other hand, chronic inflammation occurs at a very slow rate and is due to the exposure of the peritoneum to noncompatible dialysis solutions. It is not known whether any solutions other than an isotonic salt solution could be truly compatible with these cells. The macrophages and the mesothelial cells are both stimulated by dialysis solutions to produce a myriad of cytokines, prostaglandins, and matrix proteins, such as collagen and hyaluronan. Hyaluronan is secreted into the peritoneal cavity and is deposited within the tissue. This along with fibronectin and other macromolecules that escape the inflamed endothelium results in a thickening and scarring of the submesothelial peritoneum. Stimulation of tissue fibroblast results in greater deposition of matrix materials with further scarring. Parenchymal cells such as skeletal muscle may just be innocent bystanders, but their true role has not been elucidated. It is anticipated that the system in Figure 5 will become more complex and more specific over the next several years.

To truly understand the peritoneal transport system in living human beings who utilize this for solute and water excretion over many years, one must combine Figures 1 and 5. Overlying the physiologic transport resistances of the various portions of the tissue space is a highly reactive cellular system of resident macrophages, mesothelial cells, fibroblasts, and endothelial cells. All of these combine in an integrated system of inflammatory response, which has the capacity to bring about over time marked alterations in the peritoneal transport system and its functional characteristics. It is anticipated that many advances will be made in the description of these changes and how to combat them and improve intraperitoneal therapies.

Glossary

Distributed model: A conceptual and integrative model of transperitoneal transport in which the microvasculature is distributed uniformly in the tissue.

Intraperitoneal chemotherapy: Regional treatment of peritoneal metastases with intraperitoneal solutions containing high concentrations of chemotherapeutic agents.

Peritoneal dialysis: A therapeutic technique used to remove waste metabolites and excess water from patients with kidney failure.

Three-pore model: A classic conceptual model of transendothelial transport.

Introduction

It is well known that peritoneal solute transport rate (PSTR) increases during peritonitis in peritoneal dialysis (PD) patients. However, there was great concern recently over the possibility that long-term PD itself increases PSTR. An increasing number of studies report that an increased PSTR may have a negative impact on both the technique survival and the patient survival in PD patients. Furthermore, it was reported that encapsulating peritoneal sclerosis, which is a serious complication for PD patients, is related to high PSTR.

Several factors such as increases in the peritoneal contact area, tissue diffusivity, capillary surface area, and capillary permeability could conceivably explain an increase in PSTR. The contact area between the dialysate and the peritoneum is the first barrier to solute transport between the underlying microvessels and the dialysis solution. The wall of microvessels is considered to be the main functional barrier to the peritoneal solute transport as demonstrated by Flessner et al. It is conceivable that increasing vascular surface area could be caused by both increase of the amount and dilatation of peritoneal perfused capillary.

Peritoneal Microvascular Architecture

Like other tissues, a series of systemic vascular flows can be recognized in the biopsy specimens of peritoneal tissue. Specifically, the series is composed of a small artery, arteriole, precapillary arteriole, capillary, postcapillary venule, venule, and small vein.

The small artery has a triple-layered structure including intima that is covered with endothelial cells, media constituting a layer composed of smooth muscle cells, and adventitia that is composed mainly of collagen and a few fibroblasts. The first two layers are distinguished by the formation of internal elastic lamina; the adventitia, however, is an aggregate of collagen fibers that does not form a membranous structure like an internal elastic lamina. The arteriole is composed of two layers—one of endothelial cells and the other of the media. The latter is made up of one or two layers of smooth muscle cells, but the growth of the elastic lamina is not well developed. The inner vascular diameter is less than 15 μm. The morphological characteristics of the capillary are low muscular volume and composition of only endothelial cells, basement membrane, and a few pericytes that form a reticular periphery; they also lack an intima and media. The inner diameter is less than 10 μm for the capillary. More peripherally located postcapillary venules are of diameter 10 to 30 μm and have a richer loose media component composed of reticular frame lamella and smooth muscle cells. The larger venule and small vein are composed of

endothelial, intima that is made up of cells, and smooth muscle cell–based media. The inner diameter is less than 50 μm for venules and 100 μm for small veins.

Three-Pore Theory

Three-pore theory explains water and solute transport across the peritoneal microvessel during peritoneal dialysis. For this transport process, there are three kinds of pores: a large number of small pores (radius 40 to 50 Å) for low molecular weight, a very low number of large pores (radius 250 Å) for macromolecules, and ultrasmall pores (radius 3 to 5 Å) for water transport but rejecting the transfer of solutes. Aquaporins, especially aquaporin-1, which was identified recently, are the proteins constituting these transendothelial water channels; they are assumed to be ultrasmall pores.

Estimation of Peritoneal Solute Transport Rate

The peritoneal transport of low-molecular-weight solutes has traditionally been investigated with the peritoneal equilibration test (PET). Parameters that can be calculated from such a standardized test are the mass transfer area coefficient (MTAC) of a solute, its dialysate-to-plasma (D/P) ratio, and the clearance of that solute. The MTAC or the D/P ratio is determined mainly by the peritoneal vascular surface area, because this solute transport is the major process in PD. It is suggested that under basal circumstances only about 25 to 50 percent of the peritoneal capillaries are perfused. Based on D/P creatinine, practically used as small solute transport rate, patients have been classified into four transport categories: low, low-average, high-average, and high.

The Relationship between PSTR and Alterations of Peritoneal Microvessels in PD Patients

As described earlier, many reports have been published with the theory that peritoneal transport is related to peritoneal vascular surface area; however, there is only one report, from the present authors, that investigated this phenomenon as the clinical fact. We reported alterations in the peritoneal capillary and postcapillary venule (i.e., the main part of water and solute transport; named "microvessel" in the report) in biopsy specimens of peritoneum obtained from PD patients.

The parietal peritoneal tissue was obtained from PD patients and stained by the modified Masson-Noguchi method (Figure 1) before using an image analysis program. The relative microvessels area (RVA, calculated as total area of microvessels/total area of peritoneal field) and relative microvessels number (RVN, calculated as number of microvessels/total area of peritoneal field) were determined for each specimen. The ratio RVA/RVN was used to assess the average area of microvessels. The D/P for creatinine showed a significant positive correlation with both RVA (Figure 2) and RVA/RVN (Figure 3), but not with RVN (Figure 4). This indicates that the dilatation of each perfused microvessel has an impact on PSTR. The D/P for β2 microglobulin (middle size molecule) correlated with RVA (Figure 5) with weaker correlation than the D/P for creati-

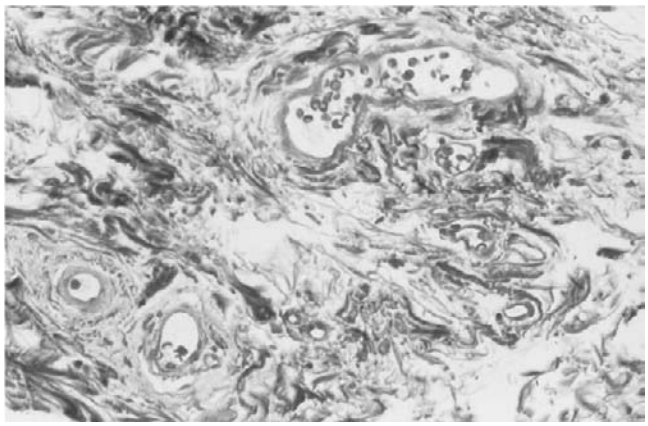

Figure 1 Human peritoneal membrane stained with Masson-Noguchi modified stain (original magnification 200×). (see color insert)

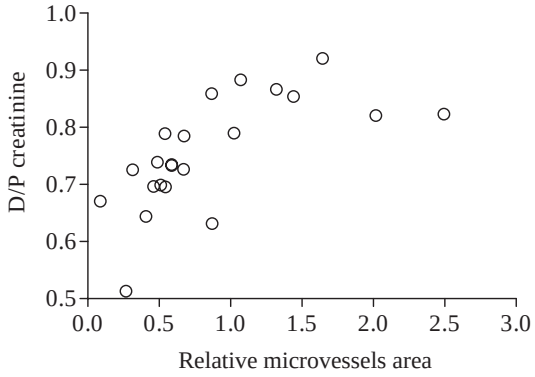

Figure 2 Correlation between the relative microvessels area and D/P creatinine (rho = 0.77, $p < 0.001$, $n = 22$).

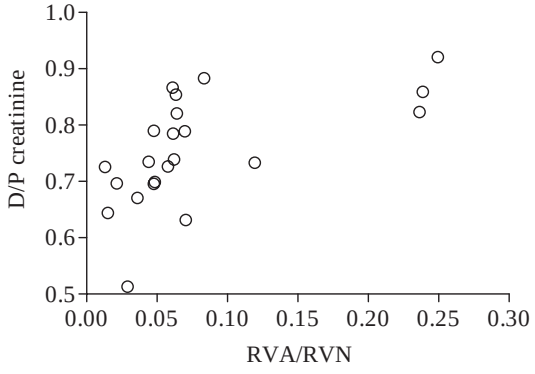

Figure 3 Correlation between D/P creatinine and microvessel cross-section (RVA/RVN) (rho = 0.66, $p = 0.003$, $n = 22$).

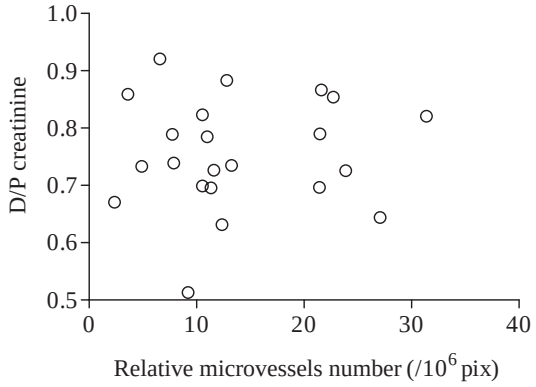

Figure 4 Relationship between D/P creatinine and relative microvessels number (rho = 0.02, p = NS, n = 22).

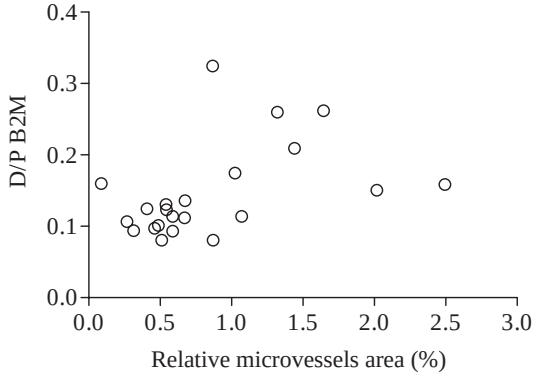

Figure 5 Correlation between the relative microvessels area and D/P β2 microglobulin (rho = 0.52, p = 0.018, n = 22).

nine, but not with RVN and RVA/RVN. No correlation was found between D/P albumin (large molecule) and RVA (Figure 6) or RVN. These observations cannot be explained only by the presence of microvessel dilatation, and therefore other pathology may be present in the PD peritoneum as well.

Increased microvessel surface area may be well reflected by the perfusion volume. In the study mentioned earlier, it was not possible to take into consideration the possible influence of the actual perfusion state of the microvessels. The various microvascular networks are open or closed at different times, and this might have an impact on the transport properties of the membrane. Recently intravital microscopy was introduced in the PD field. It may be helpful to clarify the peritoneal microvessels status during PD.

In PD animal models, the peritoneum has been reported to gain in thickness, and presumably this occurs also in patients on PD. Thus, it can be speculated that the thickening of the peritoneum may provide an increase in the total capillary length, while the density of microvessels does not decrease. However, this has not been elucidated in the clinical study.

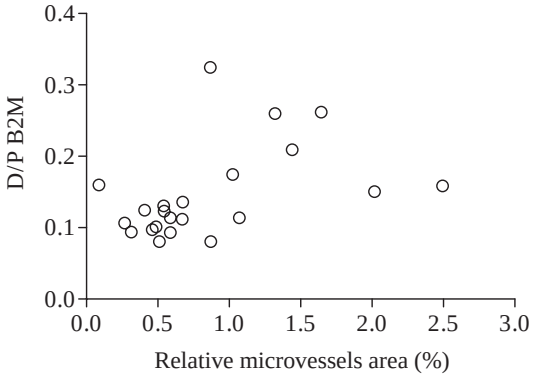

Figure 6 Relationship between the relative microvessels area and D/P albumin (rho = –0.01, p = NS, n = 22).

Candidate Molecules Related to Angiogenesis and/or Dilatation

The main pathology that alters the vasculatures of the PD peritoneum has not been clarified in patients on PD. However, accumulating studies have reported the important role of some cytokines.

Based on the experimental study, vascular endothelial growth factor (VEGF) is assumed to be the main factor enhancing angiogenesis and vascular permeability. It is expressed in the endothelium lining peritoneal capillaries in the human peritoneal membrane. VEGF is detected in the dialysate from both PD rat model and PD patients. In the rat model it was reported that the dialysate level of VEGF correlates with small-solute transport. Furthermore, VEGF concentration in the effluent is increased as a function of time on CAPD, and it is very closely related with PSTR in PD patients. It was reported that VEGF blockade normalized PSTR in streptozotosin-induced diabetic rats.

VEGF stimulates nitric oxide synthase (NOS) production, leading to the production of nitric oxide (NO). Endothelial NOS (eNOS) is required for angiogenesis and vascular permeability driven by VEGF, and VEGF upregulates eNOS production. Therefore, NO plays an important role in the regulation of vascular tone and permeability. In fact, it is reported that NOS production is increased in the peritoneum of long-term CAPD patients. There is an interesting recent report that eNOS4(a/b) gene polymorphism is associated with PSTR at the start of PD in uremic Chinese patients.

Vasculopathy

It is suggested that change of peritoneal vascular characteristics develops in PD patients. Honda et al. has reported that peritoneal vascular hyalinization is observed especially in the media of postcapillary venules to small venules in long-term PD patients with high PSTR. They observed that formation of carboxymethyl lysine (CML), an advanced

glycation end product (AGE), in the peritoneum correlates with the development of microvascular sclerosis in PD patients, and this vascular change is associated with high PSTR. They also pointed out that the morphological changes of the peritoneal vasculature are similar to those associated with diabetic microangiopathy.

AGE accumulation in CAPD peritoneum, especially in the vascular area, increases with time on CAPD, and it may be directly related with PSTR and peritoneal fluid absorption rate. AGE formation could be driven by several factors such as high-glucose solutions, glucose degradation products (GDPs), which are present in the unused PD solution as well as the uremic circulation. It was reported that GDPs could induce VEGF production; on the other hand, NO inhibits AGE (pentosidine) formation by scavenging free radicals and by inhibiting carbonyl compound formation.

AGEs influence cellular properties that allow the binding of AGEs to specific receptors, of which the best characterized is the receptor for AGEs (RAGE). RAGE is a member of the immunoglobulin superfamily and is expressed by the endothelium, smooth muscle cells, and mononuclear phagocytes, cells central to both vascular homeostasis and pathogenesis of vascular lesions. Recently it was reported that RAGE is expressed in peritoneal mesothelial cells and that anti-RAGE antibody does not affect the PSTR, but does affect submesothelial fibrosis in diabetic rat. These findings suggest the possible role of mesothelium for developing high PSTR through AGE–RAGE interaction.

In summary, it is suggested that the dilatation of microvessel, the increasing number of microvessels, and the progression of vasculopathy play a role in increased PSTR. However, at present, there is little clinical information about cause(s) and mechanisms for the observed alterations in the peritoneal microvessels in PD patients. Further studies are needed in this area.

Glossary

Advanced Glycation Endproduct: The products by non enzymatic chemical reaction between glucose or glucose degradation products and proteins.

Peritoneal dialysis: Dialysis method using peritoneal membrane. Dialysate are infused in and remain in the peritoneal cavity for a time and are drained. The wall of microvessels is considered to be the main functional barrier to the solute transport between dialysate and blood.

Peritoneal solute transport rate: It is associated with an increased surface area of peritoneal microvessels. At the same time, other factors such as increases in the peritoneal contact area and tissue diffusivity could conceivably explain an increase in PSTR.

Capsule Biography

Miwako Numata, M.D., PhD, is a nephrologist in Jikei University Hospital, Tokyo, Japan. She worked at Baxter Novum, Karolinska Institutet, as guest scientist in 2001–2003. Her research focuses on alteration of peritoneal function and peritoneal structure in peritoneal dialysis patients.

Masaaki Nakayama, M.D., Ph.D., is a lecturer in the Department of Nephrology and Hypertension, Jikei University School of Medicine, which is one of the leading centers of peritoneal dialysis in Japan. His research focuses on the pathology of peritoneal injury in CAPD patients.

Bengt Lindholm, M.D., Ph.D., has been head of the Division of Baxter Novum, Karolinska Institutet, Stockholm, Sweden, since 1993. His research focuses on peritoneal dialysis, malnutrition, inflammation, and atherosclerosis and the role of genetics in these conditions in end-stage renal disease patients. His work is supported by Baxter Healthcare and Karolinska Institutet.

Makio Kawakami, M.D., PhD is a pathomorphologist in the Department of Pathology, Clinical Service, at Jikei University Hospital. He has long worked on the functional unit of the various organs from the viewpoint of structural alteration. Now, his interest is focusing on the peritoneal device as an analog of the nephron.

CHAPTER 68

The Gastrointestinal Microcirculation

Thorsten Vowinkel and D. Neil Granger

Department of Molecular and Cellular Physiology, Louisiana State University Health Sciences Center, Shreveport, Louisiana, and Department of General Surgery, University of Münster, Münster, Germany

More than 25 percent of cardiac output normally flows through the gastrointestinal tract. However, the rate of blood perfusion through the gastrointestinal (GI) tract is dynamic, responding to both the metabolic requirements of local tissue and the needs of vital organs. For example, the ingestion of a meal is associated with large increases in GI blood flow, while profound reductions in flow are elicited by stresses (e.g., hemorrhage) that threaten to deprive the brain and heart of their normal blood supply. Although blood vessels in the different organs comprising the GI tract share common mediators and mechanisms of blood flow regulation, some differences related to tissue function have been demonstrated. The vascular supply to the gastrointestinal mucosa is particularly well suited for the absorptive and secretory functions of this tissue in that it allows for a high rate of blood flow, has a large exchange surface area, and exhibits characteristics that allow for easy permeation of nutrients and water, yet proteins are largely retained within the plasma compartment. Disease processes affecting the GI circulation can be associated with either impaired blood perfusion (e.g., ischemia) or over-perfusion (portal hypertension).

Gastric Microcirculation

Gastric blood flow plays an important role in sustaining the normal physiologic functions of the stomach, and it helps to protect the gastric mucosa against ulcer formation. Intrinsic regulatory mechanisms have evolved to ensure that blood flow is adjusted to meet the energy-demanding processes of gastric secretion and motility. Gastric blood flow also helps to maintain a barrier against back-diffusion of luminal acid, thereby preventing mucosal damage and ulceration. Impairment of gastric blood flow renders the mucosa vulnerable to the damaging actions of gastric juice as well as ingested agents, such as ethanol, aspirin, and bacteria (e.g., *Helicobacter pylori*).

The parallel-coupled capillary networks of the gastric muscular layer and the mucosa are under separate control, responding independently to tissue metabolism, other local factors, and extrinsic neural input. Between meals, blood flow in the mucosal layer is about six times higher than that of the muscle layer, and approximately 75 percent of total gastric blood flow is distributed to the mucosa, with 25 percent directed to the muscle layer. This intramural distribution of blood flow is altered when either of the two layers becomes functionally active—that is, when the mucosa is stimulated to produce acid, mucosal blood flow (and its percent of total flow) preferentially increases.

Gastric blood flow is controlled by neural, humoral, and metabolic factors. Sympathetic activation elicits reductions in total gastric blood flow and mucosal flow through arteriolar constriction. Parasympathetic nerves exert a tonic vasodilatory influence on gastric arterioles, with vagotomy resulting in a reduction in blood flow. Gastrin and histamine, both powerful stimulants of gastric acid secretion, increase mucosal blood flow. Oxygen consumption by the stomach increases in proportion to acid production. Changes in both blood flow and oxygen extraction assist in meeting the demand for additional oxygen in the acid-secreting stomach. When gastric blood flow is reduced, however, acid secretion and blood flow may fall in parallel, owing to the fact that the rate of oxygen delivery to the parietal cells is limited by blood flow.

The gastric microcirculation contributes to gastric ulcer formation in several ways. Capillary transport of parietal cell–derived bicarbonate normally plays an important role in protecting the surface epithelium against acid-induced injury and ulceration. The mucosal capillaries originating near the gastric pits transport bicarbonate toward the mucosal surface, where it can diffuse into the interstitial compartment beneath the surface epithelial cells. The latter cells transport bicarbonate into the gastric lumen where it can buffer luminal acid. As a consequence, there is an inverse relationship between gastric mucosal injury and the rate of vascular bicarbonate delivery to the mucosal surface.

Intestinal Microcirculation

The blood circulation plays an important role in the support of intestinal functions, such as propulsion of chyme and assimilation of ingested nutrients. Intrinsic regulatory mechanisms allow the intestine to adjust the distribution of blood flow between the muscular and mucosal layers in accordance with local metabolic needs. An extensive network of collateral channels within and external to the gut wall helps to ensure adequate intestinal blood flow.

Intestinal blood flow accounts for 10 to 15 percent of the resting cardiac output (500 to 750 mL/min) in the adult human. There appears to be an oral-to-anal gradient in blood flow (mL/g tissue) along the small intestine. In the resting state, approximately 65 percent of the total intestinal blood flow is directed to the mucosa, 25 percent to the muscularis, and the remainder to the submucosa. This distribution of flow within the bowel wall is usually attributed to the greater metabolic demand of the mucosa. Stimulation of epithelial transport processes favors improved mucosal perfusion while enhanced motor activity redistributes blood flow toward the muscle layers.

Extrinsic control of intestinal blood flow is exerted by neural and humoral factors. Activation of parasympathetic nerves usually results in vasodilation (increased blood flow) mediated by acetylcholine. Sympathetic nerve stimulation elicits vasoconstriction (decreased blood flow) that is mediated by norepinephrine. This α-adrenergic vasoconstriction is short-lived because intestinal arterioles escape from the constrictor influence of norepinephrine, resulting in partial restoration of normal blood flow (autoregulatory escape). Local release of adenosine appears to mediate this autoregulatory escape. Hormones such as VIP, cholecystokinin, and secretin can induce vasodilation and increase blood flow, while angiotensin II and vasopressin are potent constrictors of intestinal arterioles. Indeed, a large proportion of basal vascular tone in the intestine can be attributed to circulating angiotensin II and vasopressin.

Intrinsic control of intestinal blood flow is mediated by both metabolic and nonmetabolic factors. Ingestion of a meal results in an increase in both intestinal oxygen consumption and blood flow. The postprandial hyperemia is directly coupled to the increase in intestinal oxygen consumption. For any given increase in oxygen consumption, a greater initial oxygen extraction results in a larger postprandial hyperemic response. If the initial oxygen extraction is low, then the postprandial hyperemia is minimal and the increased oxygen demand is met primarily by an increase in oxygen extraction. The opposite holds if the initial oxygen extraction is high.

The postprandial hyperemia is confined to that segment of intestine directly exposed to chyme; segments distal to the bolus of chyme have normal resting blood flow. Of the hydrolytic products of food digestion, luminal glucose and oleic acid are capable of eliciting an intestinal hyperemia. Intraluminal glucose presumably elicits a hyperemia due to stimulation of absorptive processes, since 2-deoxyglucose (which is not absorbed) does not elicit a hyperemia. The glucose-induced hyperemia is mediated by metabolic factors, such as low tissue po_2, and adenosine release. The same metabolic factors contribute to the oleic acid–induced functional hyperemia; however, a portion of the hyperemia can be attributed to oleic acid–induced irritation of the mucosa, which is linked to local release of vasoactive intestinal peptide. The importance of active transport of nutrients to the postprandial hyperemia is best exemplified by the differential responses of the jejunum and ileum to luminal bile or bile salts. In the jejunum, bile does not elicit a hyperemia, whereas in the ileum (where bile salts are actively transported), luminal bile produces a profound hyperemic response.

Pathophysiology of the GI Circulation

Ischemia–Reperfusion (I/R)

Ischemic damage to the GI tract occurs when splanchnic blood flow falls to a level at which delivery of oxygen and other nutrients is insufficient to maintain oxidative metabolism and hence cell integrity. Reduced blood flow to the gastrointestinal tract may occur during generalized nonocclusive ischemia (e.g., circulatory shock and congestive heart failure, especially in those treated with cardiac glycosides) and in occlusive disorders (e.g., emboli, atherosclerosis, thrombosis) that primarily involve the mesenteric circulation. Occlusion of a major intestinal artery does not result in the expected reduction in intestinal blood flow. In adult animals, occlusion of a branch of the superior mesenteric artery results in only a 30 to 50 percent reduction in intestinal blood flow, which is attributed to the extensive network of intramural and extramural collateral channels. In neonatal animals, which have less developed collateral channels, a similar arterial occlusion reduces intestinal blood flow by 70 percent. This may explain why the neonatal intestine is more vulnerable to ischemic necrosis than adult intestine.

Increases in the capillary filtration coefficient and a reduction in the osmotic reflection coefficient have been demonstrated in the GI tract after I/R. The permeability

response is derived from an increase in the number of large (200 Å radius) pores, while the small-pore (50 Å radius) population is unaffected. In the intestine, the increase in the capillary filtration coefficient observed after I/R is not solely a result of increased capillary surface area.

Ischemic injury in the intestine appears to be related, either primarily or secondarily, to the effects of tissue hypoxia. Possible mechanisms of mucosal injury induced by tissue hypoxia include depletion of high-energy phosphates necessary to produce protective substances; accumulation of histamine, leading to increased microvascular permeability; production of metabolic acidosis, leading to release of lysosomal enzymes and cellular digestion; conversion of xanthine dehydrogenase to xanthine oxidase, an enzyme that can produce cytotoxic oxygen-derived free radicals during reoxygenation; and the attraction and activation of circulating granulocytes that can injure tissue by producing proteases and oxidants. There is considerable evidence that implicates both reactive oxygen species and infiltrating granulocytes in I/R injury in the GI tract. The I/R-induced microvascular responses in the GI tract are comparable to those observed during an intense inflammatory response. With the reintroduction of molecular oxygen at reperfusion endothelial cells assume both a proinflammatory and prothrombogenic phenotype that is characterized by the recruitment of adherent leukocytes and platelets in postcapillary venules. The platelets act to amplify the neutrophil activation response while neutrophils per se appear to mediate the endothelial barrier dysfunction associated with I/R. Extravasated neutrophils then contribute to the mucosal dysfunction and epithelial cell necrosis after I/R by releasing a variety of proteases and reactive oxygen metabolites.

Chronic Portal Hypertension

Whereas an acute elevation in portal venous pressure is likely to elicit a myogenic-mediated constriction of splanchnic arterioles, chronic portal hypertension tends to exert a vasodilatory influence on the splanchnic vasculature. Furthermore, chronic portal hypertension has a significant impact on other regional vascular beds and on systemic hemodynamics. Blood flow to the gastrointestinal tract, kidneys, and skeletal muscle is significantly elevated. This presumably results from an increase in circulating vasodilators (e.g., glucagon) and a decrease in vascular sensitivity to vasoconstrictors (e.g., norepinephrine). The widespread dilation of arterioles results in a reduction of peripheral vascular resistance and a corresponding reduction of arterial blood pressure. In addition, cardiac output is elevated as a consequence of the increased venous return associated with the splanchnic and peripheral vasodilation. The elevated portal pressure results in the opening of portosystemic shunts to divert portal blood from the liver and reduce portal pressure. The increase in portal pressure impairs venous drainage from the spleen into the portal vein. This results in the accumulation of blood within, and distension of, the spleen (splenomegaly).

Organ blood flow is determined by the arterial–venous pressure gradient and vascular resistance. It follows then that portal pressure is determined by portal venous inflow and portal venous resistance. When portal vascular resistance is normal, an increase in portal venous flow will produce a proportional increase in portal pressure. However, when portal vascular resistance is increased, the relationship between portal pressure and portal venous flow is shifted upward and to the left. At any given portal venous inflow, an increased portal vascular resistance will result in an increase in portal pressure. Portal pressure can be further increased when there is a concomitant increase in portal venous flow and portal vascular resistance. Indeed, the latter instance appears to reflect the vascular changes that account for the elevated portal pressure that is observed in some experimental models of chronic portal hypertension and is likely to account for the portal hypertension associated with some forms of liver disease. With a portal vascular resistance that is 40 percent higher in the portal hypertensive than in the control state, it is predicted that increased portal inflow and increased portal vascular resistance account for 40 percent and 60 percent of the increase in portal pressure, respectively.

The portal hypertensive state leads to the development of collaterals (mostly along the esophagus; esophageal varices) to shunt blood from the congested portal vein, around the liver, to the systemic circulation (portosystemic shunting). Since a large proportion of portal venous blood bypasses the liver via portosystemic shunting, the hepatic degradation of different compounds, including circulating vasodilators, such as glucagon, is reduced. The diminished catabolism of circulating vasodilators increases their concentration in the plasma, allowing these agents to relax arteriolar vascular smooth muscle and reduce splanchnic vascular resistance. Another important action of some of the vasodilators that accumulate in chronic portal hypertension (e.g., glucagon) is to reduce the sensitivity of splanchnic arterioles to vasoconstrictors such as norepinephrine, vasopressin, and angiotensin. The net result of the direct and indirect actions of the accumulated circulating vasodilators is an increased splanchnic blood flow, which serves to perpetuate the portal hypertensive state.

Glossary

Chyme: Hydrolytic products of food within the lumen of the intestine.

Portal hypertension: An abnormal elevation of hydrostatic pressure within the portal veins that drain the GI tract and empty into the liver.

Portosystemic shunting: Diversion of blood flow from the portal vein away from the liver, through either existing or newly formed channels (shunts).

Postprandial hyperemia: Increase in gastrointestinal blood flow that results from ingestion of a meal.

Reperfusion: The restoration of tissue blood flow following a period of ischemia.

Capsule Biography

Thorsten Vowinkel earned his M.D. degree from the University of Würzburg, Germany. He is a resident at the Department of General Surgery, University of Münster, Germany, and currently works as a postdoctoral fellow at the Department of Molecular and Cellular Physiology at Louisiana State University Health Sciences Center in Shreveport. His research interests include microvascular responses to intestinal ischemia–reperfusion and inflammation.

D. Neil Granger, Ph.D., is Boyd Professor and Head of the Department of Molecular and Cellular Physiology at Louisiana State University Health Sciences Center in Shreveport. He has served as President of the Microcirculatory Society, Editor-in-Chief of *Microcirculation*, and was elected to serve as President of the American Physiological Society.

SECTION D

Hematopoietic System

CHAPTER 69

The Bone Marrow Vasculature

Jorge Domenech and Pierre Charbord
Faculty of Medicine, University François Rabelais, Tours, France

The bone marrow (BM) is the site of hematopoiesis in the adult mammal. The BM vasculature that comprises a specific structure, the sinus where exchange between BM parenchyma and circulating blood takes place, not only has a structural role, but also is actively regulating hematopoietic stem cell (HSC) self-renewal/differentiation and hematopoietic cell trafficking. The molecular mechanisms accounting for HSC homing and engraftment and for HSC mobilization from BM to blood begin to be understood. The BM vasculature contributes to the physiopathology of a number of blood neoplastic diseases.

Hematopoiesis and Its Microenvironment

Hematopoiesis is the process of blood cell formation. In adult mammals it takes place in the bone marrow (BM). In normal humans hematopoietic BM is located in flat bones (skull, sternum, ribs, pelvis) and vertebrae. It may extend in case of increased hematopoietic demand (e.g., in anemias) or in some blood neoplastic diseases (e.g., chronic or acute leukemias) to long bones (humerus, femur, tibia). In rodents long bones are hematopoietic under normal conditions.

During development hematopoiesis occurs at different sites. In the embryo, hematopoiesis is first detected in the yolk sac and on the ventral floor of the dorsal aorta. In the fetus, hematopoiesis develops in the liver. By the second half of gestation, hematopoiesis finds its final location, that is, the BM. Spleen also constitutes a late fetal site of hematopoiesis, transient in humans, but persisting into adulthood in the mouse.

All blood cells derive from a small compartment of hematopoietic stem cells (HSCs). HSCs are characterized by two cardinal properties: They are multipotent and they self-renew. HSCs give rise to hematopoietic progenitors, in turn the progeny of precursors. The mature cells having completed their differentiative cycle must enter the circulating blood to be delivered to the different peripheral tissues. The finely tuned process of release into blood of mature cells is taking place in a vascular structure specific for the BM, the BM sinus.

In the adult mammal, HSCs are located in the BM. During development HSCs migrate from one site to the other. For example, in the fetus HSCs migrate from the liver to the BM via the circulating blood where HSC concentration is high. In the adult such HSC migration is restricted and the HSC blood concentration is small. When patients lacking BM hematopoiesis because of a blood disease (aplastic anemia) or following myelotoxic treatment (heavy radio- or chemotherapy) are given allogeneic HSCs by intravenous injection, the stem cells circulate until they settle within the marrow tissue. This process called engraftment is experimentally duplicated by injecting allogeneic or syngeneic BM HSCs to animals that have been lethally irradiated and can be rescued by the marrow graft. Instead of being recovered from the BM, HSCs can be mobilized from BM to peripheral blood using myelotoxic chemotherapeutic agents and/or hematopoietic growth factors (HGFs), in particular granulocyte colony-stimulating factor (G-CSF). This procedure is in wide use since it allows the collection of HSCs from the peripheral blood, avoiding the surgical act of marrow collection under general anesthesia.

The BM tissue is made essentially of hematopoietic cells packed in the hematopoietic parenchyma (the marrow cords or "logettes"). The nonhematopoietic cells found in the BM constitute the hematopoietic microenvironment, consisting of endosteal cells lining bone trabeculae, of scattered fat-laden adipocytes, and of vascular cells forming the various vascular structures. The description of long-term marrow cultures where HSCs are maintained for months in mice and weeks in humans has shown that "stromal" cells generated in the adherent layer are required for survival, proliferation, and differentiation of HSCs. A subset of stromal cells forms the hematopoietic niche where HSCs in physical contact

with stromal cells maintain the adequate balance between self-renewal and differentiation. In vivo, the BM counterpart for stromal cells appears to be a subpopulation of microenvironmental cells with vascular smooth muscle cell characteristics. Such a cell population belongs to the BM vasculature. Cells from the BM vasculature are therefore essential for blood cell formation since they regulate both HSC self-renewal/differentiation and hematopoietic cell trafficking.

The Vascular Network

As for other vasculatures throughout the body, the BM vasculature is a network of arteries, arterioles, capillaries, and veins. However, there is a structure highly specific for the BM, which is the marrow sinus that connects capillaries to the venous system.

The Network

In mouse long bones, the arterial blood supply comes from two sources. The first source is the nutrient artery that penetrates the bony cortex through the nutrient canal. In the marrow cavity it bifurcates into ascending and descending arteries, which give rise to radial branches that travel to the inner surface of the cortex and penetrate it. In the cortex, they become capillaries forming the bone canalicular system, then reenter the marrow parenchyma where they give rise to the branching network of marrow sinuses. Blood from the sinuses is collected in a larger, central sinus from which emissary veins depart, crossing back the cortex to enter the systemic venous circulation. The second source of blood supply is derived from muscular arteries giving rise to periosteal capillaries that enter the cortex, where they anastomose with the radial capillaries issuing from the nutrient artery.

In long bones (in particular in rodents where they have been extensively studied), the concentric structure of the vascular network is conspicuous, with vessels running along the bone longitudinal axis, that is, the nutrient artery and the central sinus. However, in flat bones and in vertebrae, the marrow vascular network appears to be more complex, bony trabeculae of significant thickness being found within the central region and large sinuses being observed in the immediate juxtaosseous region.

BM arteries and arterioles are similar to structures found in other tissues, comprising an intima, a media, and an adventitia. The intima is made of endothelial cells (ECs). The media comprise one or several layer(s) of vascular smooth muscle cells (VSMCs). The adventitia is made of loose connective tissue, with often nerve structures. In mice, a particular cell type, the periarterial adventitial cell, concentrically surrounds both nerves and arterioles.

BM capillaries comprise, as for other capillaries throughout the body, an endothelial lining and, on the abluminal or adventitial side of the ECs, pericytes forming a discontinuous cover.

Sinuses are usually small (5 to 30 μm in diameter in mouse long bones, but they may be larger in human flat bones). They are made of an endothelial lining flanked on the abluminal side by cells with VSMC characteristics. These abluminal cells are called by different names—adventitial reticular cells, myoid cells, barrier cells—depending on the author who first described them. Abluminal cells are separated from ECs by a thin and interrupted basement membrane.

The Cells

ECs express, as usual, the membrane antigens CD31 and CD34 and, in the cytoplasm, the von Willebrand factor. Sinusal ECs are broad and flattened with often overlapping and interdigitated junctions. In some cells, away from the prominent nucleus, the cytoplasm thickness may attenuate to a diameter approaching that of a double plasma membrane, forming fenestrae with a diaphragm. The looseness of the junctions, the presence of fenestrae, and the interrupted underlying basement membrane are features specific for the BM sinus endothelial lining.

VSMCs contain, as usual, myofibers expressing alpha-SM actin (ASMA). Pericytes also express ASMA. Abluminal cells from BM sinuses are all believed to be contractile cells akin to VSMCs: Adventitial reticular cells contain bundles of microfilaments, myoid cells are ASMA-positive, and barrier cells are similar to wound-healing myofibroblasts. Abluminal cells are flattened cells covering, in the unperturbed mouse, approximately 65 percent of the endothelial abluminal surface. However, in situations of stress or in leukemias the coverage may substantially decrease. Abluminal cells also present long cytoplasmic extensions within the cord, being in contact with many surrounding hematopoietic cells. Some myoid cells might even be observed within the parenchyma, without obvious relation to a BM sinus. Hence, myoid or barrier cells form a network joining one sinus to the other. The network is reinforced in case of stress. In particular, in the mouse after administration of the proinflammatory cytokine interleukin-1, the network extends almost continuously from bone endosteal surfaces to medullary sinuses, coursing within the parenchyma and enveloping hematopoietic cells.

In conclusion, the BM sinus is characterized not only by a particular endothelial lining, but also by a sheath of abluminal contractile cells forming a regulated outer vascular coat. The highly specialized cell types found in these specific structures are involved in the regulation of hematopoiesis, that is, both proliferation/differentiation of HSCs and hematopoietic cell trafficking.

The Vasculature during Development

In human long bones, at 6 to 8 gestational weeks (gw), the bone rudiments are entirely cartilaginous. Numerous CD34-positive capillaries are found in the perichondral limb

mesenchyme, running parallel to the rudiments. At 8 to 9 gw BM cavities appear: chondrolysis is actively proceeding and capillaries invade the rudiments. At 9 to 10.5 gw the vascular bed develops between ossifying trabeculae. In the diaphyseal region loose connective-tissue chambers are observed. They are centered by an arteriole with an intima of CD34-positive cells and a media of ASMA-positive VSMCs. They are limited from the surrounding vascular space by an endothelial lining of CD34-positive cells flanked by ASMA-positive myoid cells. At this stage, these structures, called *primary logettes*, do not contain hematopoietic cells. At 11 to 15 gw hematopoietic cells appear within the primary logettes. The chambers then extend considerably within the diaphyseal vascular space, being attached to the juxtaosseous tissue by a short pedicule. They are now centered by an artery. The number of myoid cells lying in an abluminal position to the outer endothelial lining or observed within the logette increases. Maximal extension of the primary logette is observed by 15 gw. The central artery is on some sections connected to a perforating artery, a situation similar to what is observed in long bones of adult rodents. From gw 16 onward the hematopoietic parenchyma fills almost all the space within the diaphyseal medullary area, hampering the visualization of logettes. It is only after birth that BM human hematopoiesis declines in long bones. In rodents the sequence of events before and after the onset of BM hematopoiesis (by day 16 post-coitus) has not been studied in detail.

In conclusion, vascular structure formation precedes the onset of hematopoiesis and vascular organization appears to be a prerequisite for hematopoiesis.

The BM Blood Flow

Measurements made after injection of flow tracers (in particular microspheres) whose distribution to the various organs mirrors organ blood flows indicate that in humans the BM blood flow is approximately 10 mL/min/100 g tissue; the hematopoietic BM receives therefore approximately 2 to 4 percent of the cardiac output. Similar values have been found in animals.

Various factors regulate the BM blood flow: cytokines conveyed by the bloodstream such as erythropoietin (Epo) or secreted locally such as G-CSF, endothelium-derived vasoactive substances such as nitric oxide (NO), neurotransmitters, and neuropeptides released by efferent nerve terminals or by vascular or hematopoietic cells.

BM blood flow increased threefold in rats with 50 percent blood loss and in rats supplemented with high doses of Epo. The administration of G-CSF to rats also caused a twofold increase in the BM blood flow. Following injection of either cytokine, cardiac output, mean arterial blood pressure, and ventilation rate remained unchanged, which excludes a generalized systemic effect of the cytokines on the vasculature. The increase in blood flow after Epo was found not only in BM, but also in bone. The increase in blood flow after G-CSF was restricted to the BM; blood flows in nonhematopoietic organs (muscle, small bowel, skin, kidneys), in spleen, and even in the bone itself were unchanged. Epo and G-CSF appear therefore to cause different perfusion patterns, with different effects on the blood supplies of the nutrient artery versus the muscular arteries, as well as on venous collection. Inhibition of NO formation in BM greatly decreased the increase in blood flow observed after bleeding or administration of G-CSF, indicating that the cytokines may induce the synthesis and/or release of the vasodilatory substance by ECs. NO may then affect the tone of nearby VSMCs.

Nerve fibers are observed in BM of humans or rodents, most conspicuously in association with the vasculature. In the mouse, approximately 92 percent of the efferent nerve terminals with many synaptic vesicles have been found nearby arteries and arterioles (in contact with VSMCs or periarterial adventitial cells), while only 3 percent were in contact with sinuses and 5 percent within the hematopoietic parenchyma. In humans, approximately 75 percent of the arteries and arterioles and 6 percent of the capillaries are associated to nerve fibers. In spite of so widespread a BM innervation, whether there is neuronal control of BM blood flow remains controversial; noticeably, the increase in BM blood flow induced by bleeding or administration of G-CSF has not been modified by denervation.

The Marrow Sinus

The sinus is the exclusive site of exchange between the hematopoietic and the circulating blood. It is at this sole location that mature hematopoietic cells (polymorphs, platelets, and red cells) enter the circulation to finalize their life cycle as blood cells and that hematopoietic stem cells (HSCs) enter the marrow parenchyma during engraftment.

BM Sinus ECs: Molecular Aspects

BM sinus ECs express in a specific way a number of molecules. Some cell adhesion molecules (CAMs), such as E-selectin or vascular cell adhesion molecule-1 (VCAM-1), are expressed constitutively while in ECs from nonhematopoietic tissues, their expression is usually induced by proinflammatory cytokines. The heparan sulfate (HS) proteoglycans present on the luminal face of BM ECs bind, with an affinity depending on the sulfatation patterns of the composing disaccharides, chemotactic cytokines (chemokines), such as interleukin-8, macrophage inhibitory protein-1α (MIP-1α), growth-related activity-α(GRO-α), and stromal-derived factor 1 (SDF-1), known to be the major chemotactic factor for HSCs. A current model hypothesizes the existence of a SDF-1 gradient within the hematopoietic parenchyma, with increasing concentration from the sinus wall to the depth of the parenchyma, which would explain how HSCs are maintained within the marrow cords.

Release of Mature Cells

As opposed to diapedesis, where leukocytes migrate between two endothelial cells to enter peripheral tissues (interendothelial migration), the egress of mature cells from BM occurs through pores within endothelial cells (transendothelial migration). When cell maturation is achieved, reticulocytes or polymorphs go through a fenestra with a diaphragm creating a pore whose diameter (of approximately 2 μm) is far less than the cell size. Active movements of ECs favor the cell release into the vessel lumen. In the case of platelet release, pseudopods arising from the megakaryocyte membrane flow through pores into the sinus lumen where platelet fragmentation takes place.

The release of hematopoietic cells must occur when cells are fully differentiated and not before. One mechanism is via extracellular matrix (ECM) to integrin receptor recognition. Fibronectin is such an ECM protein widely expressed in the BM cords. Precursors of red cells express fibronectin receptors (integrins VLA-5) up to the stage of reticulocytes. It is generally assumed that the lack of adhesion of reticulocytes to fibronectin is a critical factor for the release of these cells into circulating blood. Similar, but less known, interactions involving other integrins and ECM molecules might be at play for leukocytes, or even for immature cells in pathological conditions. Other mechanisms might also be operative, in particular those involving abluminal cells whose number and endothelial coverage are tightly regulated.

HSC Homing and Mobilization

Homing of circulating HSC to BM requires sequential specific signals for, first, attachment to sinus ECs; second, transendothelial migration; and third, anchoring within the hematopoietic parenchyma. This multistep process, comparable to transendothelial migration of leukocytes in response to inflammatory stimuli, involves interactions of HSCs with CAMs expressed on sinus vascular cells and with ECM adhesive molecules. These interactions are modulated by HGFs and SDF-1. Present data, provided mainly by studies in vitro, suggest the following scenario (Figure 1A). In the first step, HSCs must reduce their speed by tethering to, and rolling along, the endothelial lining. The sinusal blood flow is relatively slow, allowing weak interactions between P-selectin glycoprotein ligand-1 (PSGL-1) expressed on HSCs and E- and P-selectins expressed on BM ECs. Chemokines, such as SDF-1, or HGFs, such as Flt3-ligand or thrombopoietin, located on the endothelial membrane or bound to proteoglycans, may then activate VLA-4 and LFA-1 integrins on the rolling HSCs. VLA-4 and LFA-1 activation would convert to firm adhesion the interactions of these molecules with CAMs of the Ig superfamily (VCAM-1 and ICAM-1) on the endothelial cells, resulting in HSC arrest. Actin polymerization would then be activated in HSCs, leading to their migration through the endothelium. The transendothelial migration would be mediated by VLA-4 and VLA-5 expressed on HSCs and fibronectin present in the sinusal ECM. The platelet endothelial cell adhesion molecule-1 (PECAM-1/CD31) expressed on both ECs and HSCs could also be involved in this process through homotypic interactions. In the last step, HSCs would polarize and migrate following a SDF-1 gradient to reach the hematopoietic niche. The final anchoring might depend on interactions of HSC VLA-4 with microenvironmental cell VCAM-1 and of HSC VLA-5 with parenchyma ECM fibronectin; the c-Kit ligand produced locally might enhance the anchoring; moreover, the continuous production of SDF-1 by stromal cells would allow HSCs to be confined within the niche.

Mechanisms leading to the mobilization of HSC are less well understood. Among the multiple CAMs involved in HSC adhesion to the microenvironment, HSC VLA-4 interacting with microenvironmental cell VCAM-1 appears critical. It is now well established that HSC mobilization is associated with an increased local production of proteases within the BM, such as leukocyte serine proteases (elastase, cathepsin G) or matrix metalloproteinases (MMP-9), able to degrade the ECM. Elastase is known to disrupt VLA-4/VCAM-1 interactions (by degrading VCAM-1) and CXCR-4/SDF-1 interactions (by degrading both CXCR-4, the SDF-1 receptor, and SDF-1), while MMP-9 can also cleave SDF-1. Collectively, the increase in BM protease activity can explain the decrease, observed after G-CSF-induced HSC mobilization, in BM SDF-1 levels and in CXCR-4 expression on circulating CD34-positive hematopoietic cells. A model showing the main factors involved in HSC trafficking is proposed in Figure 1B.

Pathology

Increased BM blood flow has been described in cases of increased hematopoietic demand such as that observed in hemolytic anemia, which is in agreement with experimental data on animals after bleeding. Similarly, some authors have related the bone pain experienced by patients administered with G-CSF to the increased blood flow associated to an increase in the interstitial fluid pressure in the BM.

The myeloproliferative syndrome associates neoplastic blood cell diseases (polycythemia vera, chronic myelogenous leukemia, myelofibrosis) affecting HSCs and resulting in overproduction of blood cells, fibrosis of the hematopoietic parenchyma, and reactivation of liver and spleen hematopoiesis. In this syndrome the BM blood flow is increased. In myelofibrosis there is novel vessel formation (angiogenesis).

Angiogenesis is also a major anatomo-pathological feature of acute leukemias and multiple myeloma. Neoplastic cells (leukemic blasts or plasma cells), by producing angiogenic factors -cytokines such as fibroblast growth factor-2 (FGF-2) or vascular endothelial growth factor (VEGF) and/or metalloproteases (MMP2, MMP9), induce endothelial cell proliferation and organization into capillary tubes that provide oxygen and help tumor development.

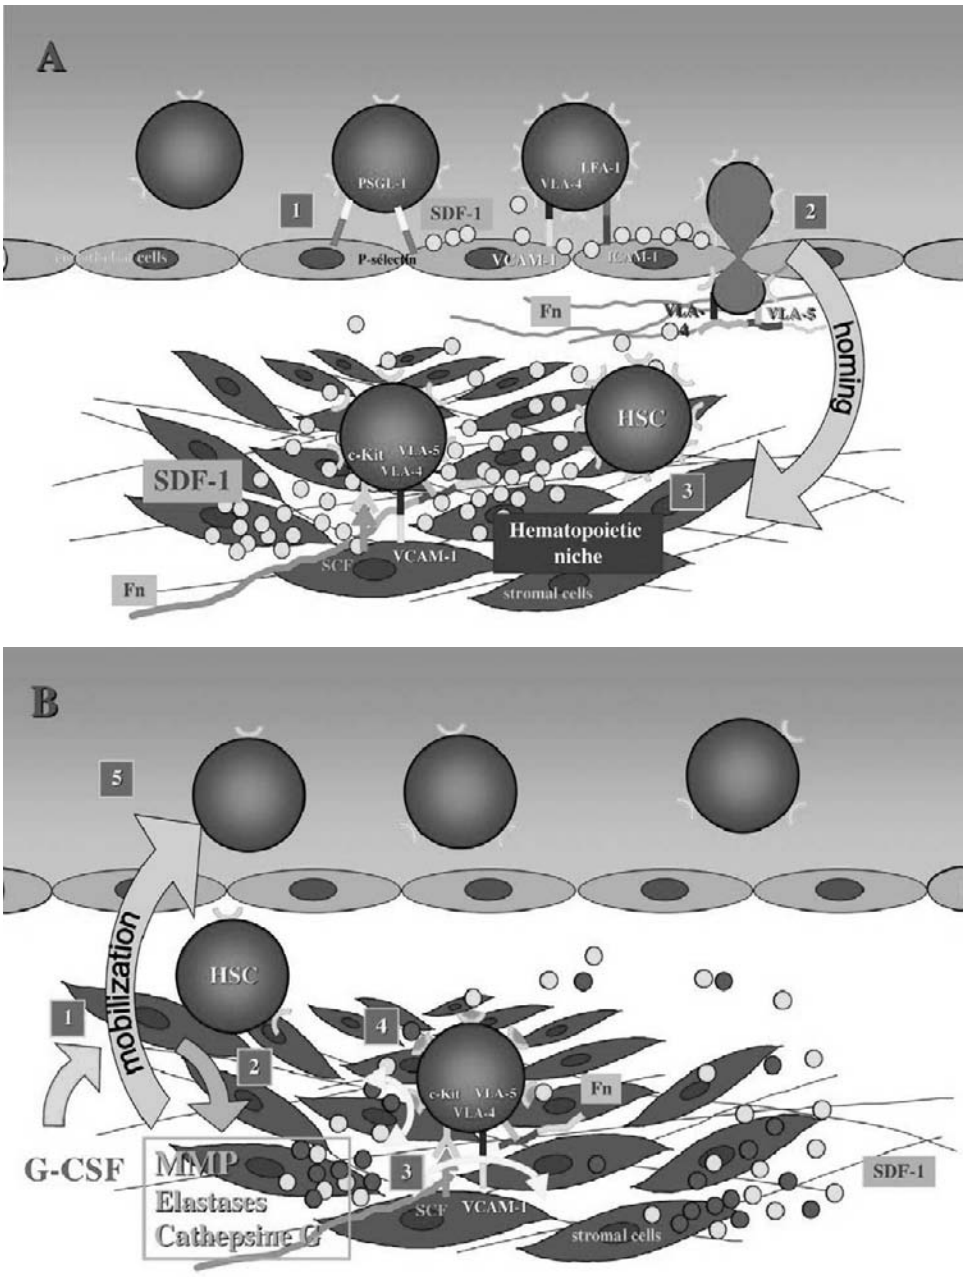

Figure 1 Molecular modeling of HSC trafficking. Data supporting the following models are provided mainly by studies in vitro using HSCs, BM ECs, and stromal cells generated from long-term marrow cultures. **(A) HSC homing. (1)** Weak interactions between P-selectin glycoprotein ligand-1 (PSGL-1) expressed on HSCs and E- and P-selectins constitutively expressed on BM ECs lead HSCs to tether to, and roll along, the BM endothelium. SDF-1 located on the endothelial surface and bound to heparan sulfates induces activation of HSC integrins VLA-4 and LFA-1. VLA-4 and LFA-1 activation converts to firm adhesion their interactions with VCAM-1 and ICAM-1 constitutively expressed on endothelial cells. **(2)** This activation induces the arrest of HSCs and stimulates actin polymerization that favors HSC transendothelial migration mediated by VLA-4 and VLA-5 in the presence of fibronectin (Fn). **(3)** HSCs polarize, migrate along the local gradient of SDF-1 produced by stromal cells, and reach the hematopoietic niche. This anchoring depends mainly on close interactions of HSC VLA-4 with stromal cell VCAM-1 and of HSC VLA-5 with Fn of the ECM. Moreover, the continuous production of SDF-1 by stromal cells allows the confinement of HSC within the hematopoietic niche. **(B) HSC mobilization. (1)** Addition of G-CSF induces **(2)** a local production of proteases (MMPs, elastases, and cathepsin G). **(3)** These molecules are able to degrade the ECM. Moreover, elastase can cleave VLA-4/VCAM-1 and **(4)** CXCR-4/SDF-1 interactions by degrading both CXCR-4 and SDF-1. The loss of attachment to stromal cells and to the ECM together with the loss of SDF-1 activity **(5)** favors the release of HSCs from the hematopoietic niche. (see color insert)

Angiogenesis is characteristic of diseased BM since in normal conditions there is little, if any, novel vessel formation. Antiangiogenic compounds are therefore promising novel therapeutics for leukemias.

Glossary

Cell adhesion molecules (CAMs): These molecules, expressed on the cell membrane, are involved in cell-to-cell and cell-to-extracellular matrix interactions. They include integrins (e.g., VLA-4 and VLA-5), selectins (e.g., P-, E-, and L-selectins), sialomucins (e.g., CD34 antigen), and immunoglobulin superfamily molecules (e.g.,VCAM-1 and ICAM-1). Interactions between selectins and sialomucins are of low affinity while integrin activation transforms interactions between integrins and immunoglobulin superfamily molecules into the high-affinity state. Integrins can be transiently activated by growth factors, such as c-Kit- and Flt3-ligands and thrombopoietin, or by chemokines, such as SDF-1 and IL-8. This induces changes in the cytoskeleton structure that affects cell motility.

Chemokines: Chemotactic cytokines with low molecular mass (8 to 17 kDa) showing approximately 20 to 50 percent sequence homology among each other at the protein level. These molecules mainly exert a chemotactic activity on leukocyte subpopulations induced during inflammatory reactions. They are divided into four groups (CXC, CX_3C, CC, and C) according to the positioning of the first two closely paired and highly conserved cysteines of the amino acid sequence. Chemokine receptors belong to the large group of G-protein-coupled seven-transmembrane-domain receptors.

Hematopoiesis: The process of blood cell formation. Blood cells derive from hematopoietic stem cells (HSCs) that are multipotent: They give rise to cells of all blood lineages, and that self-renew. In the progeny of a mother HSC there is a daughter HSC with identical capacity for proliferation and differentiation. HSCs give rise to hematopoietic progenitors with great proliferative potential but that are unable to self-renew, being already committed to a hematopoietic lineage, in turn giving rise to precursors (differentiating cells). The process is extremely dynamic since several billion hematopoietic cells need to be generated from a small compartment of HSCs each day to replace dying blood cells.

Microenvironment: The set of nonhematopoietic cells found in the BM parenchyma (cells from the vasculature, fat cells, and endosteal cells). Cells from this compartment derive from a specific population of mesenchymal stem cells (MSCs). One finds therefore in the BM parenchyma two different types of stem cells: HSCs giving rise to blood cells and MSCs giving rise to microenvironmental cells. In long-term marrow cultures hematopoiesis can be maintained for several weeks to months, provided there is generation of adherent stromal cells, therefore considered to be the population associated to HSCs and critical for their maintenance. A subset of stromal cells forms the hematopoietic niche where HSCs in physical contact with stromal cells maintain the adequate balance between self-renewal and differentiation. In vivo, the BM counterpart for stromal cells appears to be a subpopulation of microenvironmental cells with vascular smooth muscle cell characteristics.

Migration: A fundamental process in cell biology that allows cell locomotion. This property is essential during development, particularly embryogenesis, but also throughout adult life. It is a mandatory process for cell renewal such as occurs in hematopoiesis. Two classical types of migration are known: *chemotaxis*, where cell migration is directed by concentration gradients of soluble extracellular agents, and *chemokinesis*, characterized essentially by an undirected movement of cells. The main molecular factors involved in the migration process are cell adhesion molecules, chemotactic factors such as chemokines, and proteases, particularly matrix metalloproteinases (MMPs).

CHAPTER 70

Renal Medullary Microcirculation

Thomas L. Pallone, Janos Pittner, and Whaseon Lee-Kwon
University of Maryland School of Medicine, Baltimore

Introduction

The purpose of this chapter is to review the current state of knowledge concerning the microcirculation of the renal medulla. This is a broad topic that touches on many areas. Perhaps the best recognized function of descending and ascending vasa recta (DVR and AVR) is to trap solute through countercurrent exchange. The classical notions of diffusive exchange have been revised to account for endothelial expression of aquaporin-1 water channels and the UTB-facilitated urea carrier. In addition to transport-related functions, DVR are contractile microvessels that regulate regional perfusion of the medulla. Medullary perfusion is of great importance, not only to the urinary concentrating mechanism but also to the maintenance of oxygen tension and renal salt handling. Evidence has accumulated that reduction of medullary perfusion can be accompanied by ischemic insult because oxygen tensions in the renal medulla are particularly low. Also of great interest is the finding that reduction of perfusion can lead to experimental forms of hypertension.

Tubular Vascular Relationships in the Renal Medulla

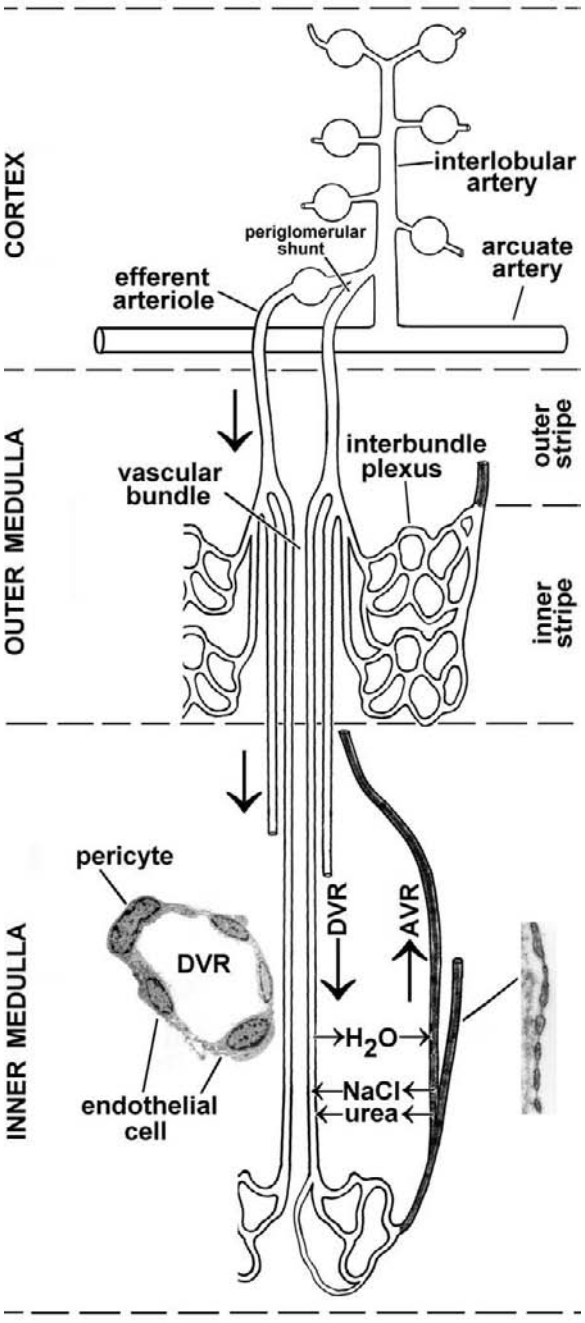
Blood flow to the renal medulla is provided by descending vasa recta, microvessels approximately 15 μm in diameter that are predominantly derived from efferent arterioles of juxtamedullary glomeruli. As efferent arterioles cross the corticomedullary junction to the outer stripe of the outer medulla, the muscular layer is diminished and replaced by smooth muscle–like cells called "pericytes" (Figure 1). Pericytes impart contractile function and are less prominent as DVR penetrate to the inner medulla. The outer medulla is characterized by its separation into vascular bundles and the interbundle capillary plexus. The "simple" vascular bundle (rabbit, guinea pig, dog, cat, monkey, man) is made up of DVR and AVR separated by a minimum of interstitium. Close apposition of DVR and AVR in vascular bundles provides opportunity for exchange of solutes and water. The capillary plexus of the interbundle region arises from DVR that peel off from the periphery of the vascular bundles in the inner stripe, suggesting a role for DVR to regulate regional blood flow within the medulla. Based on this arrangement it seems likely that modulation of perfusion of the interbundle capillary plexus regulates oxygen delivery to the thick ascending limb in the hypoxic medulla. Below the inner–outer medullary junction, vascular bundles disappear and vasa recta become more evenly dispersed among loops of Henle and collecting ducts. DVR terminate at various levels to form a sparse capillary plexus that coalesces to form AVR. DVR have a continuous endothelium with tight junctions. Fenestrations appear in the DVR wall as they terminate and fenestrations cover the majority of capillary plexus and AVR surface area. AVR return to the renal cortex from the inner medulla by traversing outer medullary vascular bundles. AVR that arise from the interbundle plexus reach the cortex independent of the bundles [1].

Countercurrent Exchange and Transport Properties

General Concepts

It is broadly accepted that the microcirculation of the renal medulla is a countercurrent exchanger that traps NaCl and urea deposited to the interstitium by the loops of Henle and collecting ducts. Textbook illustrations generally show parallel vessels that equilibrate by diffusion. Most simply, DVR blood flow is concentrated by diffusive influx of NaCl and urea as blood flows from the corticomedullary junction

toward the papillary tip. Conversely, blood flowing toward the corticomedullary junction in AVR is diluted by diffusive efflux so that solute is trapped and recycled. Recent studies have shown that this depiction of a purely diffusive "U-tube" exchanger is oversimplified. Osmotic removal of water from DVR across water channels occurs, sieving NaCl and urea to concentrate these solutes in DVR plasma. Thus, both molecular sieving and diffusion contribute to equilibration of DVR plasma with the interstitium. As discussed later, shunting of water from DVR to AVR in vascular bundles might play a role in optimization of urinary concentrating ability by reducing blood flow rate to the deep medulla.



Efflux of Water from DVR

DVR plasma protein concentration rises along the direction of blood flow, indicating water loss from plasma to renal medullary interstitium. Thus, DVR and nephrons deposit water to the renal medulla and AVR take up that water, accounting for overall mass balance. Water efflux from DVR raises two paradoxes. First, the purpose of depositing water from DVR plasma to the hypertonic medullary interstitium seems enigmatic. Second, Starling forces (hydraulic and oncotic pressure) do not account for the direction of DVR water transport because intraluminal oncotic pressure that favors water uptake exceeds the hydraulic pressure that favors efflux. NaCl and urea gradients generated by the lag in equilibration of DVR blood with interstitium favor water efflux and could account for osmotic water abstraction from DVR, but this requires the presence of a "small pore" pathway across which such small solutes exert effective osmotic driving force. The discovery of the aquaporins led to the molecular identification of that route (Figure 2A). Blockade of aquaporin-1 (AQP1) with mercurial agents or AQP1 knockout eliminates water efflux driven by abluminal hypertonic NaCl [3, 5]. Thus, transport of water across the DVR wall must be described by at least two parallel pathways, the properties of which are summarized in Table I. One is the highly water-selective AQP1 molecule. Another is a "large pore" route, likely paracellular, that conducts the majority of water movement driven by Starling forces. Evidence is consistent with the notion that the paracellular pathway offers little or no restriction to convective small solute flux (small solute reflection coefficient nearly 0, $\sigma_{SS} \approx 0$) while the AQP1 pathway is completely restrictive ($\sigma_{SS} \approx 1$). In addition to AQP1, another mercurial insensitive pathway conducts water efflux across the DVR wall when the driving solute is urea, glucose, or raffinose.

Figure 1 Anatomy of the medullary microcirculation. **Cortex:** Interlobular arteries arise from the arcuate artery and ascend toward the cortical surface. Juxtamedullary glomeruli arise at a recurrent angle from the interlobular artery. The majority of blood flow reaches the medulla through juxtamedullary efferent arterioles; however, some may also be from periglomerular shunt pathways. **Outer medulla:** In the outer stripe, juxtamedullary efferent arterioles give rise to DVR that coalesce to form vascular bundles in the inner stripe. DVR on the periphery of vascular bundles give rise to the interbundle capillary plexus that perfuses nephrons (thick ascending limb, collecting duct, long looped thin descending limbs, not shown). DVR in the center continue across the inner–outer medullary junction to perfuse the inner medulla. Thin descending limbs of short looped nephrons may also associate with the vascular bundles in a manner that is species dependent (not shown). **Inner medulla:** Vascular bundles disappear in the inner medulla and vasa recta become dispersed with nephron segments. AVR that arise from the sparse capillary plexus of inner medulla return to the cortex by passing through outer medullary vascular bundles. DVR have a continuous endothelium (inset) and are surrounded by contractile pericytes. The number of pericytes decreases with depth in the medulla. AVR are highly fenestrated vessels (inset). As blood flows toward the papillary tip, NaCl and urea diffuse into DVR and out of AVR. Transmural gradients of NaCl and urea abstract water across the DVR wall across aquaporin-1 water channels. Reproduced with permission from Ref. [2]. Renal Medullary Microcirculation in Encyclopedia of the Microcirculation, edited by David Shepro, Elsevier Inc.

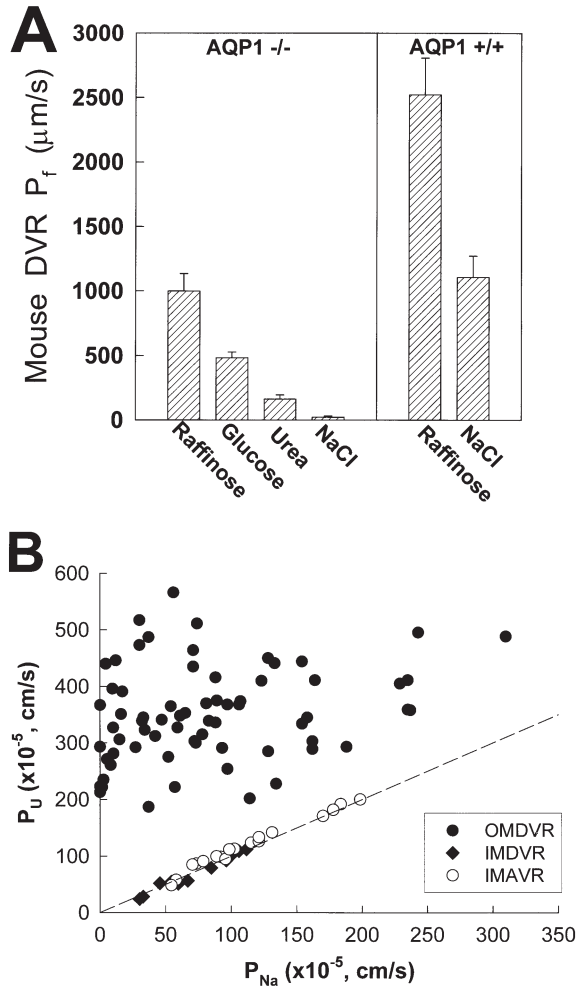


Figure 2 Osmotic water permeability of murine DVR. **(A)** All P_f measurements are summarized (ordinate, mean SE) for AQP1 –/– (*left*) and +/+ mice (*right*). The solute used to drive water movement is shown on the abscissa. Transmural NaCl gradients failed to induce water flux across AQP1-deficient DVR; however, larger solutes (glucose, urea, raffinose) were effective. Reproduced with permission from Ref. [3]. **(B)** Simultaneous measurement of ^{14}C-urea (P_U) and ^{22}Na (P_{Na}) permeability was performed by dual isotope microperfusion of outer medullary (OMDVR), inner medullary descending vasa recta (IMDVR), or inner medullary ascending vasa recta (IMAVR). OMDVR were studied by in vitro perfusion while inner medullary vessels were perfused on the surface of the exposed papilla in vivo. OMDVR P_U was always high, independent of P_{Na}. This is due to expression of the UTB urea carrier in DVR endothelia. Reproduced with permission from Ref. [4]. Renal Medullary Microcirculation in Encyclopedia of the Microcirculation, edited by David Shepro, Elsevier Inc.

The UTB urea transporter is expressed by DVR endothelia and exhibits mercurial insensitive water channel activity. The role of UTB to conduct water as well as urea flux across the DVR wall has yet to be examined. Simulation of these various transport pathways has been the underpinning of recent mathematical models of medullary microvascular exchange [7].

Mathematical simulations showed that DVR AQP1 might improve medullary concentrating ability by providing a route through which DVR water is shunted to AVR. The effect of that activity in the superficial medulla is to reduce blood flow to the deep medulla where interstitial gradients of NaCl and urea are most steep. A broadly unsettled question concerns regulation that might shift DVR equilibration between diffusive influx and water efflux/molecular sieving. High DVR solute permeability favors diffusive influx while low permeability favors water efflux across endothelial AQP1 water channels. If DVR permeability is acutely or chronically regulated, effects on "solute washout" and perfusion of the deep medulla would be expected to occur.

AVR Water Uptake

As required for overall mass balance in the medulla, AVR must remove the water deposited to the interstitium by nephrons, collecting ducts, and DVR. Transmural oncotic pressure gradients favor water uptake across the AVR wall and AVR hydraulic conductivity is very high [8, 9]. In vivo, transmural gradients in the AVR generated by the osmotic lag between blood and interstitium are directed to favor water uptake (luminal concentration greater than interstitial concentration). For AVR water uptake to be augmented by those gradients, the AVR wall must have nonzero reflection coefficients to NaCl and/or urea and transmural gradients of those solutes must be of significant magnitude. Rigorous measurements of AVR NaCl and urea reflection coefficients have been thus far impossible to obtain, but the general hypothesis that NaCl might augment transmural volume flux has been tested. In contrast to similar experiments in DVR, in vivo microperfusion of AVR with buffers made hypertonic or hypotonic to the papillary interstitium yielded no measurable water flux [10], suggesting that AVR reflection coefficients to small hydrophilic solutes is negligible ($\sigma_{SS} \approx 0$).

Vasa Recta Solute Permeability

As blood flows from the corticomedullary junction toward the papillary tip, rising interstitial concentrations of NaCl and urea are encountered. Those solutes equilibrate with the DVR lumen; however, the lag creates transmural gradients so that interstitial NaCl and urea concentrations exceed their respective concentrations in DVR plasma. Diffusive influx of NaCl and urea is favored. Additionally, the transmural gradient abstracts water across AQP1 water channels leading to molecular sieving of NaCl. Thus both diffusion and sieving across AQP1 contribute to DVR plasma equilibration. Quantification of diffusive permeabilities of the DVR wall to NaCl has been achieved by measurement of the rate of efflux of radiolabeled tracers from microperfused vessels. Those experiments have been performed both in vivo, on the surface of the exposed papilla, and in vitro, in isolated microperfused DVR. A summary of reported permeability measurements is provided in Table II. In vivo perfusion can underestimate permeabilities if the rate of diffusion of the isotopes away from the vessel in the surrounding interstitium is too low. In that case, ^{22}Na or [^{14}C]urea concentrations on the abluminal surface accumu-

Table I Hydraulic Conductivity (L_p), Osmotic Water Permeability (P_f), and Reflection Coefficients of Vasa Recta.

Parameter	OMDVR	IMDVR	IMAVR	Driving force

late, violating the assumption of zero abluminal concentration. In vitro perfusion, due to the presence of a continuously flowing bath, is less likely to yield errors from such boundary layer effects, but necessitates the trauma of isolation and exposes the vessel to artificial buffers that could alter transport properties. In addition, DVR permeability is strongly dependent upon perfusion rate. Whether this rate dependence exists in vivo is uncertain but has important implications. If the true DVR NaCl permeability is very low, then abstraction of water across AQP1 might be the dominant mode of NaCl equilibration. That mode of equilibration may reduce blood flow to the deeper regions of the medulla and enhance interstitial osmolality. DVR urea permeability is the sum of transport via phloretin-sensitive transcellular, carrier-mediated route(s) and other, for example pericellular, pathways (Figure 2B). Histochemical evidence and in situ hybridization have identified the DVR urea transporter as the same as that expressed by the RBC-UTB.

AVR solute permeability has not been as thoroughly evaluated as that in DVR because AVR have not been isolated and perfused in vitro, owing to technical difficulties. Transport properties have been measured only by the difficult approach of in vivo microperfusion of vessels on the surface of the exposed papilla of rats and hamsters (Table II). The values so obtained exceed DVR permeabilities but, even so, are probably underestimated because the ^{22}Na and ^{14}C-urea tracers might have accumulated in the interstitium to significant levels.

Vasoactivity of DVR

Constriction and Dilation of DVR by Vasoactive Agents

DVR are contractile microvessels (Figure 3). A large number of mediators have been shown to constrict or dilate DVR, and a number of receptors have been identified in medullary vascular bundles by ligand binding, autoradiography, RT-PCR, or immunochemistry. Table III summarizes the findings. The entries listed in Table III include observations of pharmacological effects on vasomotion of microperfused DVR isolated from vascular bundles of the rat as well as receptor studies that have employed a variety of methods. We attribute constriction to the action of pericytes. Vasopressin (compared to angiotensin II and endothelin) is a weak DVR vasoconstrictor. Endothelins constrict primarily via the ET_A receptor and are thought to exert a self-limiting vasodilatory effect through ET_B receptor stimulation. ET_1 and ET_2 isoforms are ET_A and ET_B receptor agonists and have proven to be the most potent vasoconstrictors of DVR thus far observed [11]. Angiotensin II (AngII) also reliably constricts isolated DVR. AT_2 receptor antagonists enhance AngII constriction and AT_2 receptor expression has been verified in DVR by RT-PCR. Effects of adenosine effects are concentration dependent. At low concentration, adenosine A_1 receptor stimulation induces DVR constriction. At high concentration, A_2 effects predominate

Table II Solute Permeability of Vasa Recta.

Permeability $\times 10^{-5}$ cm/sec	OMDVR[a]	IMDVR[b]	IMAVR[b]	Species
P_{Na}		28	51	Hamster
P_{Na}	76	75	115	Rat
P_{Na}		67	116	Rat
P_{Urea}		47		Rat
P_{Urea}	360	76	121	Rat
P_{Urea}	343 → 191[c]			Rat
P_D	476[d]			Rat
$P_{raffinose}$	40			Rat
Permeability ratio	**OMDVR[a]**	**IMDVR[b]**	**IMAVR[b]**	**Species**
P_{Urea}/P_{Na}		1.09	0.98	Rat
P_{Cl}/P_{Na}	1.33			Rat
$P_{raffinose}/P_{Na}$	0.35			Rat
P_{Inulin}/P_{Na}	0.22			Rat

Abbreviations: OMDVR, outer medullary descending vasa recta; IMDVR, inner medullary descending vasa recta; IMAVR, inner medullary ascending vasa recta.

[a] Values obtained with in vitro microperfusion are highly dependent upon perfusion rate.

[b] Values obtained with in vivo microperfusion in the exposed papilla are probably underestimated due to boundary layer effects.

[c] Values are before and after inhibition with 50 mM thiourea.

[d] Diffusional water permeability measured with ^3H_2O efflux. References to original data in Ref. [6].

Table III Mediators That Constrict and Dilate DVR.

	Constriction[a]	Dilation	Receptor studies[b]
Angiotensin	+++ AT_1	+ AT_2	AT_1, AT_2
Endothelins	++++ $ET_A > ET_B$	–	ET_A, ET_B
Vasopressin	++ V_1	+ V_2	V_1
Adenosine	++ A_1	+ A_{2a}, A_{2b}	A_1, A_{2a}, A_{2b}
Prostaglandin E_2	–	+	–
Nitric oxide	–	+	–
Kinins	+ B_1	+ B_2	–
Acetylcholine	++	+	–
Norepinephrine	++	–	α_{2B}

[a] Table entries refer to observations of constriction or dilation in response to receptor specific or nonspecific agonists. The intensity of constriction is graded from (–) to (++++).

[b] Table entries show the receptor subtypes expressed in DVR. Information is derived from studies that employed various methods, including RT-PCR, radioligand binding, and immunochemistry.

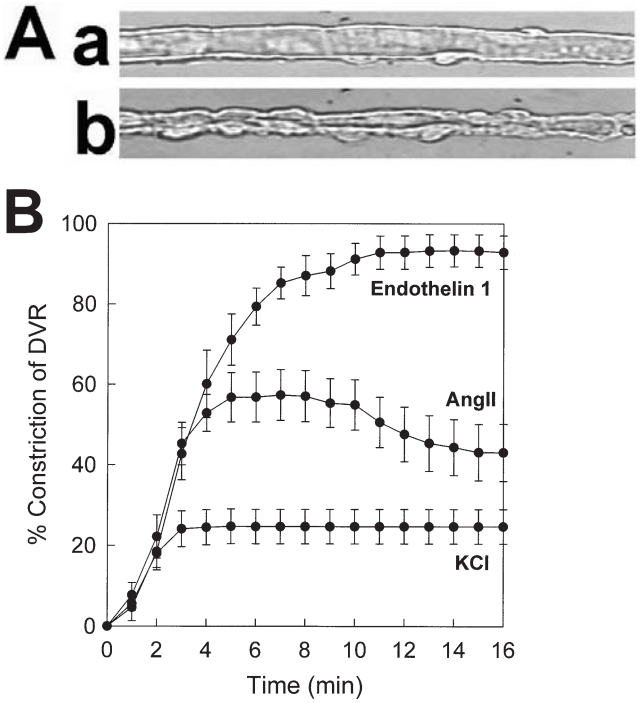

Figure 3 Vasoconstriction of outer medullary DVR. **(A)** DVR isolated and microperfused in vitro is exposed to AngII (10 nM) by abluminal application from the bath. Panels **a** and **b** show the vessel prior to and after constriction. Two cell types can be seen. Pericyte cell bodies project from the abluminal surface and endothelia line the lumen. **(B)** The graph shows quantification of DVR constriction through measurement of luminal diameter. Results are expressed as percent constriction = $100 \times (D_o - D)/D_o$, where D_o is basal diameter and D is after constriction. The mean luminal diameter of perfused DVR is ~14 µm. Constriction has been induced by abluminal exposure to endothelin 1 (0.1 nM, $n = 6$) or AngII (10 nM, $n = 15$), or by raising extracellular K^+ concentration from 5 to 100 mM by isosmotic substitution for NaCl ($n = 6$). Reproduced with permission from Ref. [2]. Renal Medullary Microcirculation in Encyclopedia of the Microcirculation, edited by David Shepro, Elsevier Inc.

and adenosine dilates preconstricted DVR. Kinins increase DVR endothelial intracellular calcium concentration and promote nitric oxide generation through the bradykinin, B_2 receptor. The cataloging of agents in Table III does not provide an integrated hypothesis of renal medullary function; however, the large number of agents to which DVR respond is clear. We assume that, in vivo, DVR vasomotor tone is governed by the integrated response to many hormonal and paracrine influences.

Pericyte Ca^{2+} Signaling and Channel Architecture

Recently, the mechanisms by which AngII induces vasoconstriction have been evaluated using fluorescent probes of intracellular calcium concentration and membrane potential and by electrophysiological recording. As expected for signaling via the AngII AT1 receptor, a classical peak and plateau $[Ca^{2+}]_i$ response is elicited in globally fura2-loaded pericytes. Both electrophysiological recording and measurements with a potential-sensitive fluorescent probe showed that AngII depolarizes the pericyte, mediated primarily through activation of a Ca^{2+}-sensitive Cl^- conductance that

shifts membrane potential away from the equilibrium potential of K^+ ion toward that of Cl^-. An 11 pS Ca^{2+}-sensitive Cl^- channel has been identified in DVR pericytes. Membrane potential of AngII-treated pericytes often oscillates and voltage-clamped cells held at −70 mV exhibit classical spontaneous transient inward currents (STICs) typical of various smooth muscle preparations [12, 13].

The role of membrane depolarization to gate Ca^{2+} entry had been well established in the afferent arteriole. Until recently, however, the existence of voltage-gated calcium entry pathways in the efferent circulation and DVR pericyte was uncertain. RT-PCR, immunochemistry, and examination of vasoreactivity in isolated arterioles verified expression of T-type and L-type calcium channel α subunits in efferent arterioles of juxtamedullary (but not superficial) glomeruli and in DVR [14]. Indeed, the L-type channel blocker diltiazem vasodilates AngII constricted DVR and reduces $[Ca^{2+}]_i$ of AngII-treated pericytes. Both high external K^+ concentration and the L-type agonist BAYK8644 are weak DVR vasoconstrictors. Finally, agents that repolarize pericytes, bradykinin and the K_{ATP} channel opener pinacidil, are effective vasodilators (Figure 4) [15]. The many downstream effects of pericyte AngII and endothelin receptor activation remain unknown, however actions independent of $[Ca^{2+}]_i$ elevation must occur. Principally, depolarization in the absence of agonist induces far less intense constriction than does AngII or endothelins. Phosphorylation events that sensitize the intracellular contractile machinery to the effects of Ca^{2+} are likely to be implicated.

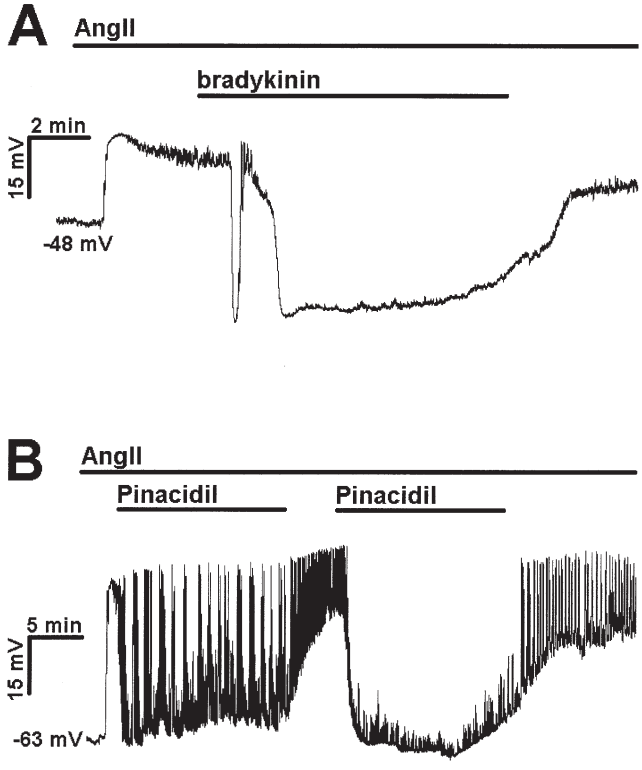

Figure 4 Repolarization of AngII depolarized pericytes by vasodilators. **(A)** Recording of membrane potential from a DVR pericyte successively exposed to AngII (10 nM) and then bradykinin (100 nM). A biphasic repolarization occurs after exposure to bradykinin. **(B)** Similar recording from a DVR pericyte exposed to AngII (10 nM) and then the K_{ATP} channel opener, pinacidil (10 μM). Both bradykinin and pinacidil repolarize pericytes and vasodilate preconstricted DVR. Reproduced with permission from Ref. [2]. Renal Medullary Microcirculation in Encyclopedia of the Microcirculation, edited by David Shepro, Elsevier Inc.

Endothelial Ca^{2+} Signaling and NO Production

The calcium-sensitive fluorophore fura2 loads avidly into DVR endothelia (to the near exclusion of pericytes) and so it has been possible to examine global intracellular Ca^{2+} transients generated by endothelium dependent vasodilators. Bradykinin (BK) generates a peak and plateau calcium response, enhances NO generation, and induces vasodilation. An unexpected finding is that the vasoconstrictor AngII suppresses basal calcium and inhibits BK, acetylcholine, thapsigargin, and cyclopiazonic acid induced calcium responses in DVR endothelia [16]. This is surprising because the effect is inhibited by high concentrations of the AT1 blocker losartan and modulated by AngII AT2 receptors [17]. AngII and AT1 receptors mediate the vast majority of effects by signaling through IP_3 generation and calcium mobilization. Second, infusion of AngII has been observed to lead to secondary enhancement of NO levels within the medulla and in isolated cortical microvessels. Given that eNOS/NOS3 is a calcium-dependent isoform of nitric oxide synthase (NOS), suppression of calcium would be expected to block rather than enhance endothelial NO generation. Possibly, adjacent nephrons that also express NOS isoforms might be responding to generate NO on the vascular bundle periphery, providing a feedback loop through which those structures regulate their own perfusion. It has been hypothesized that AngII might suppress DVR endothelial Ca^{2+} signaling as a means of turning regulation of DVR vasoactivity away from the endothelium to the medullary thick ascending limb (mTAL).

The physiological roles of NO cannot be thoroughly evaluated without considering interactions with oxygen free radicals. Oxygen radicals result from reductions of O_2 to generate superoxide ($O^{\cdot}{}_2^-$), hydrogen peroxide (H_2O_2), hypochlorous acid, and hydroxyl radical ($^{\cdot}OH$), the "reactive oxygen species" (ROS). $O^{\cdot}{}_2^-$ reacts with NO to form peroxynitrite ($ONOO^-$), a product that is a weak vasodilator. ROS are generated by "leak" of electrons from the mitochondrial electron transport chain and a variety of enzymatic processes. Intrinsic mechanisms limit cellular levels of ROS. Several isoforms of superoxide dismutase (SOD) convert $O^{\cdot}{}_2^-$ to O_2 and H_2O_2. The SOD mimetic tempol has been shown to enhance medullary perfusion. NO production by, and AngII constriction of, isolated DVR are both enhanced by tempol. Given the importance of NO in the maintenance of medullary blood flow, it is inviting to speculate that the level of "oxidative stress" in the renal medulla has physiological and pathophysiological regulatory roles.

Medullary Oxygen Tension and Perfusion of the Medulla

Oxygen tension in the medulla of the kidney is low, 10 to 25 mmHg. This is predicted to be a consequence of the countercurrent arrangement of vasa recta because oxygen in DVR blood diffuses to AVR to be shunted back to the cortex. Several hormonal systems play a role in the protection of the medulla from ischemic insult. Each shares the ability to enhance medullary blood flow and inhibit salt reabsorption by nephrons. Hypothetically this should have a dual effect to enhance the supply of oxygen and simultaneously reduce the demand for O_2 consumption. One example is cyclooxygenase (COX) production of vasodilatory prostaglandins. Medullary perfusion is sensitive to COX inhibition, and renomedullary interstitial cells release prostaglandin E_2 (PGE_2) in response to AngII and bradykinin. Apparently, the cylooxygenase-2 isoform is responsible because AngII reduces medullary blood flow in COX2- but not COX1-deficient mice. In most vascular beds, ischemia favors generation of adenosine, a paracrine agent that enhances blood flow through local vasodilation. Within the renal medulla (but not the cortex) adenosine acts as a vasodilator and inhibits salt reabsorption by the medullary thick ascending limb of Henle (mTAL). It is reasonable to hypothesize that adenosine produced by the mTAL diffuses to and dilates DVR on the periphery of vascular bundles. Adenosine A_1 and A_2 receptor stimulation constricts and dilates DVR, respectively.

The Importance of Medullary Blood Flow and Nitric Oxide in Hypertension

Renal medullary NOS activity and NO production exceeds that in the cortex. NO acts in autocrine and paracrine fashion to modulate both vasoconstriction and epithelial NaCl reabsorption. NOS isoforms have specific effects [18]. NOS1 inhibition reduces NO levels in the medulla and induces salt-sensitive hypertension without altering medullary perfusion. Global inhibition of NOS1, NOS2, and NOS3 isoforms decreases medullary NO levels, medullary blood flow, and tissue oxygen tension and leads to salt-dependent hypertension [19]. NO generation may be important to abrogate tissue hypoxia that would otherwise arise from release of vasoconstrictors. AngII, norepinephrine, and vasopressin stimulate release of NO in the medulla. Subpressor infusion of N(ω)-nitro-L-arginine methyl ester (LNAME) into the renal interstitium does not affect medullary blood flow or p_{O_2} but enables otherwise ineffective doses of AngII, norepinephrine, or vasopressin to reduce perfusion. Data broadly support the conclusion that medullary NO production has a tonic effect to maintain perfusion, favor saliuresis, and protect from ischemic injury and hypertension.

Glossary

Hydraulic conductivity: Proportionality constant generally denoted L_p that relates the rate of vectorial water flux that occurs across a membrane in response to driving forces imposed by osmotic, oncotic, and hydraulic pressures.

Juxtamedullary: Refers to the deepest region of the renal cortex. Glomeruli that lie in the deep, juxtamedullary cortex have efferent arterioles that extend into the outer stripe of the outer medulla where they break up like a horse's tail to form descending vasa recta.

Osmotic water permeability: Proportionality constant generally denoted P_f that relates the rate of vectorial water flux that occurs across a membrane in response to driving forces imposed by osmotic, oncotic, and hydraulic pressures. Can be converted to hydraulic conductivity by the relationship $L_p = (P_f V_w)/(R T)$, where V_w is the partial molar volume of water, R is the universal gas constant, and T is absolute temperature.

Solute permeability: Proportionality constant for the ith solute generally denoted P_i that relates the rate of diffusive solute flux across a membrane that occurs when a transmural concentration difference of that solute exists across the membrane.

Vasa recta: System of parallel microvessels that traverse the renal outer and inner medulla. Descending vasa recta carry blood flow from the juxtamedullary cortex to the medulla and are sometimes referred in older literature to as arteriolar vasa recta. Ascending vasa recta carry blood flow from the inner and outer medulla back to the cortex and are sometimes referred to as venous vasa recta.

Capsule Biography

Thomas Pallone obtained the bachelor's degree in engineering at the Massachusetts Institute of Technology (1977) and the Doctor of Medicine degree from the Pennsylvania State University (1981). Subsequently, his graduate studies in the Health Science and Technology program at M.I.T. were mentored by William M. Deen, Ph.D. in Chemical Engineering. His interest in the renal medullary microcirculation was kindled as a thesis project (S.M., 1982). After completing medicine residency training at the University of Maryland (1985), he obtained clinical and laboratory fellowship training in the Nephrology Division at Stanford University under Rex L. Jamison, M.D. (1988). He has held staff positions at Penn State University (through 1995) and the University of Maryland at Baltimore, where he is currently Professor of Medicine and Physiology.

CHAPTER 71

Renal Cortical Microcirculation

William J. Welch
Georgetown University, Washington, D.C.

Introduction

The kidney maintains homeostasis by regulation of fluid and electrolyte balance, as well as the elimination of nitrogenous and toxic products. The kidney has adapted an intricate vascular network that contains as much as 20 percent of the cardiac output at any given time. This high throughput is critical to the function of the glomerular capillaries, which filter the fluid component of blood. Fluid and electrolytes filtered at the glomerulus are reabsorbed by the nephron and mostly returned to the circulation. The glomerular capillaries are located exclusively in the cortex and give rise to cortical (superficial) and juxtamedullary nephrons. Cortical nephrons have short loops of Henle passing only a short distance into the medulla. Juxtamedullary nephrons, with long loops of Henle, pass deep into the medulla to the papilla. Cortical glomeruli give rise to short efferent arterioles that pass into a peritubular capillary that bathes the proximal tubule of cortical nephrons and is structurally similar to nonrenal capillaries. Juxtamedullary glomeruli also give rise to efferent arterioles, some of which lead to peritubular capillaries and some that lead directly to small venules, the vasa recta. The main determinant of filtration, glomerular capillary hydrostatic pressure, is tightly regulated by the highly resistant afferent and efferent arterioles, which are subject to humoral, neural, and physical factors. In this review, I will summarize studies that make new and important observations on renal cortical microcirculation and are representative of recent research in this area.

Control of Renal Cortical Microvascular Resistance

Methods of Evaluation

Much of the recent focus on cortical microcirculation research has been on identification of the systems that regulate vascular tone, affecting segmental and overall renal vascular resistance. Access to the important resistance vessels is limited, but recent methodological gains have provided new information. Both in vivo and in vitro observations continue to be made in hydronephrotic kidneys, developed by prolonged ureteral occlusion. However, there is concern that responses in this nonfiltering kidney model are not fully representative of normal function. The recent use of intravital microscopy, with improved optics and imaging analysis, shows promising results suggesting that in vivo inspection of renal cortical microcirculation in normal kidneys is possible. Isolated segments of the interlobar, arcuate, and interlobular arteries continue to provide data, though they often are similar to nonrenal vessels. However, more studies have emerged from direct perfusion of the isolated afferent arterioles and in some cases the efferent arterioles, which provide more renal specific responses. These extremely small (15 to 30 μm) vessels have been isolated from rabbits, mice and more recently rats and microperfused in temperature-controlled baths. Though many of these observations may be limited to the experimental species, they provide a sensitive resistance vessel model with which to test several hypotheses. Renal micropuncture also continues to provide data on the control of cortical vascular tone.

Angiotensin II

Angiotensin II is the major end product of the proteolytic enzyme renin, which is primarily produced in the kidney in the afferent arteriole. Ang II is a potent vasoconstrictor in vascular beds mediated by abundant type 1 (AT_1) receptors. Type 2 receptors (AT_2), which are much less abundant, may cause vasodilation when activated, but supporting evidence for a physiological role is currently lacking. Ang II may have unique vascular control in the kidney, since it is well established that the level of Ang II–dependent constriction

varies between afferent and efferent arterioles. Several new studies have focused on the relative contributions of Ang II–dependent constriction of the AA and EA. In an attempt to characterize Ang I and Ang II actions in these arterioles, Marchetti et al. [1] measured changes in intracellular Ca^{2+} (Ca_i) concentrations as a parameter of vasoactive responses in isolated rat juxtaglomerular arterioles. They studied three populations of arterioles isolated from juxtamedullary glomeruli, the afferent arterioles (AA), efferent arterioles terminating as peritubular capillaries (EA-T), and EA terminating as vasa recta (EA-M). Ca_i was increased in all arterioles by both Ang I and II and was blocked in all arterioles by losartan, an Ang II receptor blocker. Lisinopril (an angiotensin-converting enzyme inhibitor) blocked the increase in Ca_i due to Ang I in the AA and the EA-M, yet had no effect in EA-T. The ratio of EC_{50} values for Ang I to Ang II was also much higher in EA-M. The authors suggest that local ACE acts to convert Ang I to Ang II, which then activates AT receptors and initiates Ca_i mobilization and constriction. However, in the EA-M, which may have no ACE activity, Ang I either activates the Ang II receptors or is converted to some other active form. The authors fail to identify a physiological role for this arteriolar heterogeneity. The same group also assessed expression of AT_{1a}, AT_{1b}, and AT_2 receptors in these microdissected arterioles. All three receptors were expressed in AA and EA-M. Yet, only modest levels of mRNA for AT_{1a} and AT_2 were expressed in EA-T. The expression of the receptor subtypes correlates with the Ang II effects on Ca^{2+} mobilization.

The arteriolar diameter responses to systemic infusion of Ang II were also evaluated in the dog kidney using intravital microscopy [2]. This improved imaging method may provide direct evidence of differential responses to Ang II. However, renal artery injections of Ang II reduced diameters in EA and AA similarly in superficial glomeruli. Total constriction differed only modestly between the AA and EA in the juxtamedullary glomeruli. Inhibition of prostaglandins enhanced the Ang II response only in the juxtamedullary AA, suggesting that PG vasodilating products offset Ang II in the juxtamedullary AA, but not in the cortical AA. However, nitric oxide may also contribute to the Ang II response in juxtamedullary AA. This study was able to demonstrate zonal heterogeneity of Ang II control of vascular tone. The lack of sufficient resolution made it difficult to distinguish major differences between AA and EA responses to Ang II, which has been demonstrated more clearly in isolated perfused arterioles. Another weakness of this technique is the inability to inject vasoactive agents directly into the microvasculature in the video field to ascertain local responses.

Adenosine Receptors

Adenosine, acting on type 1 receptors (A1-R) in the afferent arteriole, constricts the AA, reduces the GFR, and also mediates tubuloglomerular feedback (TGF). Local adenosine levels are increased during elevated Na^+ transport in the nephron and subsequent metabolism of adenosine triphosphate (ATP). The relationship between Ang II and adenosine on the regulation of afferent arteriolar tone has been the focus of several studies. These agents act through AT_1 and A1 receptors that have been localized in the AA. Both acute and chronic suppression of the renin–angiotensin system (RAS) reduces A1-R vasoconstriction. The dependence of Ang II on A1-R is not as clear. In the hydronephrotic kidney, A1-R inhibition had no effect on Ang II constriction. However, in isolated perfused rabbit AA, A1-R inhibition reduced Ang II constriction by 50 percent. With the development of A1-R knockout mice, this question was readdressed to test the chronic effects of A1-R inhibition. Hansen et al. [3] measured renal function in anesthetized mice and in separate experiments tested the tone of the isolated perfused AA in response to Ang II. The GFR did not differ between wild type and mice lacking A1-R during the control period. An acute pressor dose of Ang II raised MAP similarly in both groups (+11 to +13 mmHg). However, Ang II reduced GFR by 40 to 50 percent in the wild-type (+/+) mice, but only by 20 percent in the A1-R (–/–) mice (Figure 1). Ang II reduced the renal blood flow (RBF) more in the knockout mice, similar to its effect on GFR. In the microperfused AA the baseline diameters were similar between the groups. However, Ang II was more effective in the A1-R (+/+) than in the A1-R (–/–) in reducing AA diameter. At a physiological dose (10^{-10} M) Ang II reduced the diameter in A1-R (+/+) by 50 percent, yet had no effect in A1-R (–/–). These differences were probably not due to differences in AT_1 receptor density, since the expression of mRNA for AT_1 was not different between AA from the two

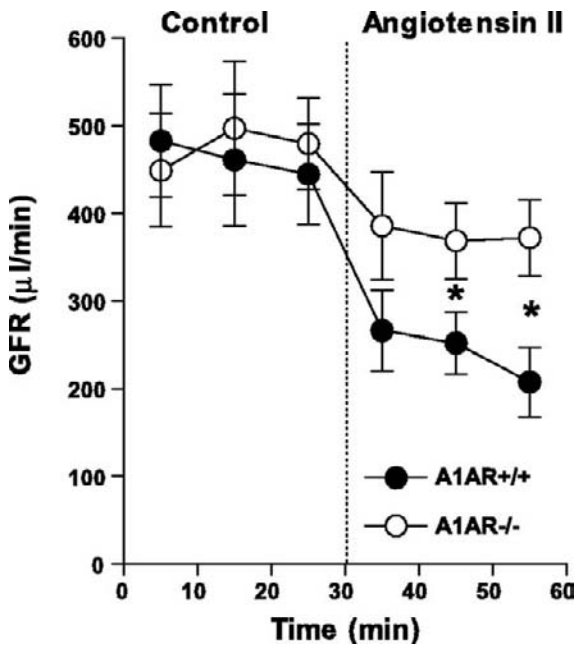

Figure 1 Glomerular filtration rate (GFR) of wild-type and A1 adenosine receptor (A1R) knockout mice in three consecutive 10-minute periods during control and during intravenous infusion of Ang II at 1.5 ng/min. Values are means of 6 experiments SE. *Significance between A1R +/+ and –/– for a given period ($p < 0.05$).

groups. This study provides clear evidence that the full effect of Ang II constriction in the AA requires a functioning A1-R, and presumably activation by increased adenosine release. Alternately, the level of interaction could be mediated by G-protein coupled signaling of these two receptors.

Purinergic Receptors

The vascular control mediated by adenosine and its A1-R may be closely related to ATP-linked purinergic receptors, particularly in the renal cortical circulation where both families of receptors are abundantly expressed. The P2X (ATP) and P2Y (UTP) families of receptors, specifically $P2X_1$, $P2X_3$, and $P2Y_2$, mediate increases in intracellular calcium concentration in vascular smooth muscle cells and perhaps vascular tone in the afferent arterioles. Activation of both types of receptors in freshly harvested preglomerular smooth muscle cells increases intracellular calcium concentration, presumably through different mechanisms. To test this hypothesis in a vascular preparation, Inscho and Cook [4] measured the diameters of rat juxtamedullary AA in response to perfusion of ATP and UTP with and without treatment of diltiazem, a calcium channel blocker. The P2 agonists α,β-methylene ATP, ATP, and UTP reduced the diameters of AA by 8 to 30 percent (Figure 2). The constrictive response to the specific $P2X_1$ agonist α,β-methylene ATP was completely blocked by diltiazem, which suggests that this receptor acts to increase calcium concentration from extracellular sources. The constrictive response to ATP at doses less than 10 μM was also blocked by diltiazem. However, the response to UTP was similar before and during diltiazem. These physiological observations confirm previous studies in cells that ATP and UTP increase intracellular calcium, which is consistent with the increased tone of the AA elicited in this study. Further, the increases to ATP appear to be mediated via L-type channels from extracellular sources and the increases to UTP from release of intracellular stores.

Arachidonic Metabolites

The major product of cyclooxygenase activity in the kidney is prostaglandin E_2 (PGE_2), which mediates vasodilation through activation of the EP_2 receptor. Four G protein–coupled EP receptors have been identified in the kidney, and the physiological effects of these have not been fully established. In an attempt to clarify these roles, Imig et al. [5] tested the effects of PGE_2 in mice with disrupted EP_2 receptors. They used a preparation in the isolated perfused mouse kidney that surgically exposes the juxtamedullary glomeruli. PGE_2 added to the perfusate dilated the preconstricted afferent arteriole in EP_2 (+/+) mice, but further constricted the AA in EP_2 (–/–) mice (Figure 3). This suggests that the renal vasodilation associated with PGE_2 is mediated specifically by the EP_2 receptor. In the absence of EP_2, PGE_2 activates other EP receptors, which causes vasoconstriction. Selective inhibition of EP_1 and EP_3 receptors prevented the PGE_2-associated constriction. In addition this constriction was also blocked with ACE inhibition, demonstrating the link between PGE_2 and Ang II. EP_2 receptors may be critically involved in maintenance of renal blood flow or glomerular filtration, specifically by mediating the vasodilation associated with PGE_2.

Endothelially Derived Hormones

The relative resistance of preglomerular arteries and the afferent arteriole is often considered when assessing total renal vascular resistance and its hormonal control. Larger arteries are more accessible and are often used for isolated in vitro studies, yet the well-established dominant resistance

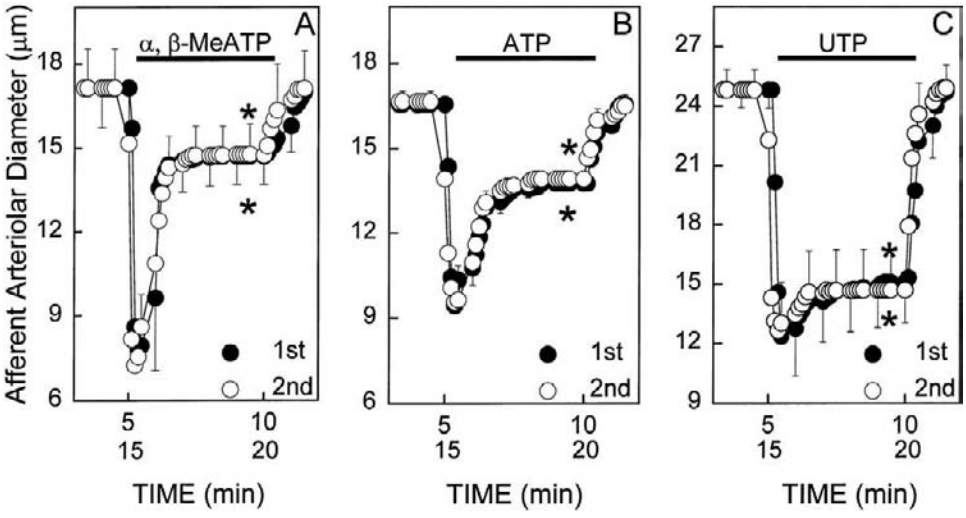

Figure 2 Afferent arteriolar responses to repeat applications of P2 agonists. *Significant reduction in diameter compared with the preceding control diameter ($i < 0.05$).

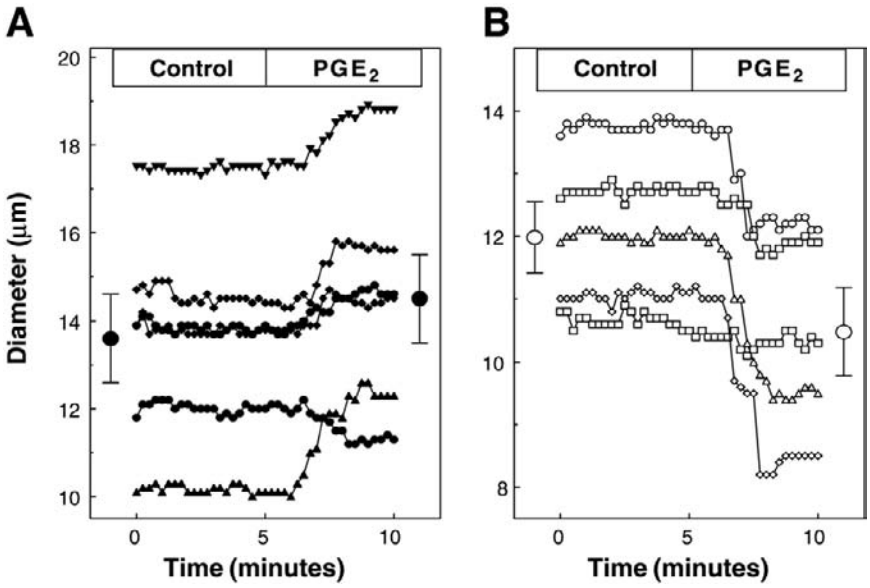

Figure 3 Afferent arteriolar diameter responses to PGE_2 in EP_2 +/+ and EP_2 –/– mice. The afferent arteriolar PGE_2 responses in EP_2 +/+ mice are shown in **A**, and PGE_2 –/– mice are shown in **B**. Diameter measurements at 15-second intervals are depicted under control conditions (first 5 minutes) and after addition of PGE_2 (second 5 minutes).

capacity of the afferent arteriole makes this tissue more applicable in control of glomerular hydrostatic pressure and RBF. However, because of the small size and fragility of this tissue, there have been only a few in vitro observations in this key resistance vessel, and these have been limited to rabbits and mice. Several hormones have been implicated in the control of larger artery resistance in studies using isolated preglomerular vessels. Wang et al. [6] recently evaluated several vasodilators in the isolated perfused rabbit AA. Nitric oxide (NO) and endothelium-derived hyperpolarizing factors (EDHF) mediate acetylcholine-induced vasodilation in small vessels, and the relative effects of these have been fully investigated in the larger preglomerular arteries. EDHF may be more important in smaller resistance vessels, yet the relative roles have not been studied extensively in the AA. The epoxide product epoxyeicosatrienoic acid (EET) may mediate vasodilation in these vessels, but another epoxide 20-hydroxyeicosatetraenoic acid (20-HETE) acts as a vasoconstrictor and may offset its effect. Wang et al. tested the roles of EDHF, NO, and prostaglandins on the Ach-induced dilation in isolated preconstricted AA [6]. COX inhibition had no effect on the Ach-induced vasodilation, whereas more than 50 percent could be blocked with inhibition of NO. Most of the remaining dilation was blocked by inhibitors of Ca^{2+} activated K^+ channels or by high extracellular K^+, which suggests EDHF. In an effort to characterize the EDHF, the tissue was treated with a competitive inhibitor of 14,15-EET, the vasodilating epoxide identified in other renal arteries. During NO inhibition 14,15-epoxyeicosa-5(*Z*)-enoic acid (14,15-EEZE) blocked much of the remaining dilation, equal to K^+ channel blockade. Both inhibitors, however, did not account for all of the Ach-induced vasodilation in this model. Though this study identified a novel dilator in the AA, the level of NO-dependent dilation was greater than in studies with other small-resistance vessels.

Rho/Rho Kinase

More novel pathways that may regulate renal vascular tone continue to be described and investigated. In vascular smooth muscle cells (VSMC), one of the final steps for contraction is the increased intracellular Ca^{2+} activation of myosin light chain (MLC) kinase, which leads to MLC phosphorylation (MLCP). However, several studies have shown that MLCP inhibition increases Ca^{2+} sensitivity and contraction in VSMC. One endogenous mechanism that checks MLCP is the activation of Rho kinase (ROK) by the G protein RhoA. Recently developed ROK inhibitors have been used to characterize its role in constriction. The early use of these compounds reduced in vitro vascular contraction, which is consistent with the theoretical control of ROK on Ca^{2+} sensitivity. However, since ROK increases stress fiber formation and actin polymerization, the vasoconstriction could occur via these mechanisms. Cavarape et al. [7] were the first to test the effects of ROK inhibitors on the renal vascular tone. In the in vivo hydronephrotic rat kidney, they showed that ROK inhibition increased glomerular blood flow and dilated interlobular arteries, and afferent arterioles more than efferent arterioles. They further tested agonists to three small renal artery constrictors that all increase intercellular Ca^{2+}: endothelin B receptors (ETB), adenosine 1 receptors (A1-R), and guanylyl cyclase (GC). ETB and A1-R are more effective on AA and GC is more effective in EA. ROK inhibitors prevented the constriction associated with each agonist in nearly all vessels. ROK

inhibitors had no effect on expression of actin; therefore the authors conclude that the action of ROK inhibition is on renal VSMC Ca^{2+} sensitivity.

Ischemia

The recent development of miniaturized video imaging and improved image analysis has spurred the study of cortical microcirculation under normal and experimental conditions. With a pencil-like lens of 1 mm diameter, this video system is capable of visualizing the glomerular and pre- and postglomerular circulation, as well as interlobular arteries. This improved instrument has been validated by confirming microcirculatory responses to Ang II and TGF stimulation originally observed by in vivo renal micropuncture. Early use of this instrument was made in anesthetized dogs, but now applications are made in the rat, as well. Evaluations of microcirculatory changes due to pathophysiology and responses to vasoactive agents are now emerging.

In a study that demonstrates the capabilities of this new tool, Yamamoto et al. [8] observed peritubular capillaries, glomerular arterioles and interlobular arteries before and after 45 minutes of renal artery occlusion in the rat (Figure 4). By measuring the velocity of red blood cells (RBC), they showed that blood flow quickly returned to normal levels during the first 1 to 2 minutes after release of the occlusion. However, capillary flow dropped to levels 10 to 20 percent of normal during the first 2 to 5 minutes after release and gradually improved over the next 60 minutes (Figure 5). Similar observations were made in the glomerular blood flow, except that flow was fully restored after 60 minutes. This could not be explained by interlobular artery flow, since these vessels tended to dilate after occlusion. A second finding was that flow through the peritubular capillaries was always orthograde during the control period, but after ischemia the authors noted a mixture of orthograde, retrograde and no flow. The lack of perfusion of all peritubular capillaries confirms and strengthens the "no-flow" theory of postischemic vascular damage, directly demonstrating profound and sustained reduction of flow. The authors conclude that 45 minutes of renal ischemia can induce vascular nephropathy.

Vascular Resistance in Transplanted Kidneys

Chronic allograft failure of transplanted kidneys is often related to hemodynamics rather than immunological rejection, which usually occurs more acutely. Therefore the vascular compliance of transplanted kidneys is now being considered as another predictive parameter in long-term survival of renal transplants. Using an animal model to assess the role of changes in vascular resistance in transplanted kidneys, Gabriels et al. [9] measured the responses of excised small renal arteries to a series of vasoactive agents. Small arteries (200 to 270 μm) were obtained from kidneys donated from Fischer rats (Fl) transplanted into nephrectomized Lewis rats. Several control animals were also studied: rats with syngeneic transplants, uninephrectomized, uninephrectomized with denervated kidneys, and kidneys made ischemic, as well as native kidneys. All animals were treated with cyclosporine. After 18 weeks, the coronary, femoral, and mesenteric arteries and small arteries from the kidney were excised and placed in a myograph. The reactivity was assessed by the responses to constrictors (norepinephrine, epinephrine, Ang II, vasopressin) and dilators (Ach, sodium nitroprusside). Histology showed that only the kidneys from FL rats had glomerular lesions and vasculopathy. However, renal vessels from both allogeneic and syngeneic transplants were more sensitive to all

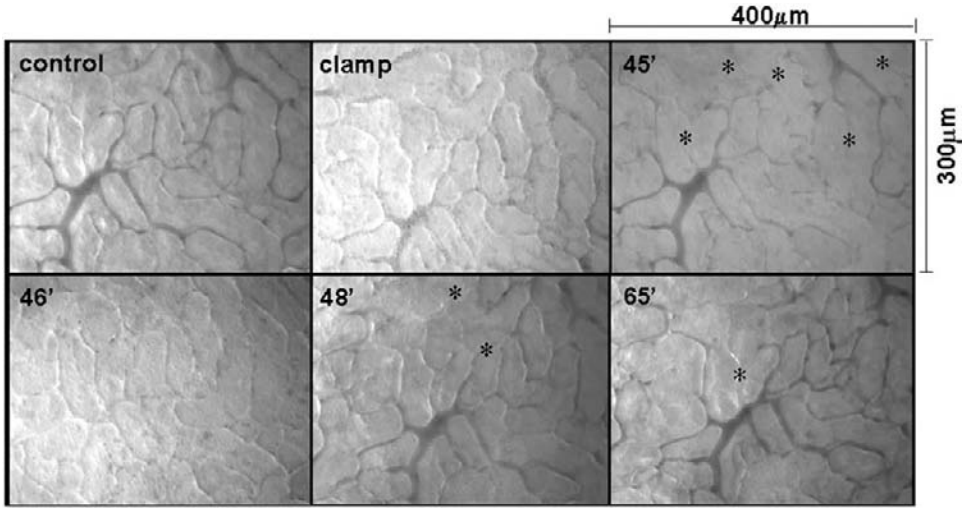

Figure 4 Sequential images obtained from a representative field of superficial peritubular capillaries before renal artery occlusion and after release of the clamp. Note the initially interrupted blood flow abated after the renal artery was clamped and 1 to 2 minutes after release of the clamp (frame 46′). Of note, not all capillaries seen at the initial image remain perfused on the subsequent postischemia images.

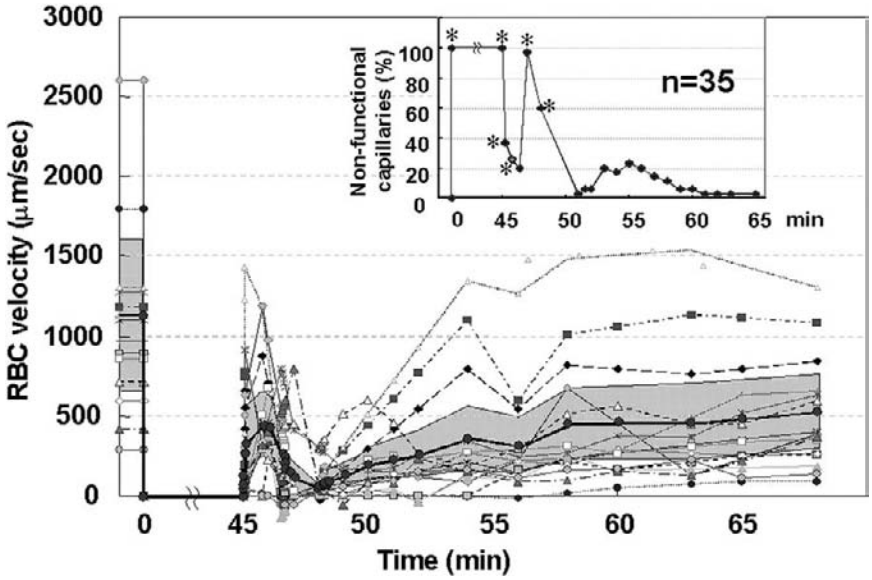

Figure 5 Time course of changes in red blood cell (RBC) velocity in postischemic peritubular capillaries. Shaded area, means SE. Individual experimental sequences are represented by different symbols. **Inset:** Proportion of nonfunctional peritubular capillaries in the postischemic kidney.

vasoconstrictors, compared to the control groups. Similarly, the vessels from transplanted kidneys were less responsive to the vasodilators than was the control tissue. There were no vessel reactivity differences in nonrenal arteries. This study demonstrates that small-artery reactivity is reduced in transplanted kidneys, regardless of their source. Further, the small arteries in all the transplanted kidneys appeared more constricted, which may contribute to reduced function and survival in transplanted kidneys.

A recent clinical study used a similar hypothesis to identify the predictive value of vascular resistance on allograft survival. In a prospective study of 601 transplanted patients, renal segmental arterial index (RI) was measured at least 3 months after surgery in order to exclude acute rejection causes [10]. RI was determined by the percent reduction of the end-diastolic flow compared with the systolic flow in renal segmental arteries, measured by Doppler ultrasonography. This value reflects primarily renal cortical vascular resistance. They divided the subjects into RI of greater than 80 (122 patients) and less than 80 (479 patients) and tested the hypothesis that lower renal resistances (an RI of less than 80) predicted long-term allograft survival. The combined end point that defined survival was a reduction in creatinine clearance of 50 percent. Patients were followed for up to 3 years. Sixty-nine percent of the high-RI patients showed a 50 percent reduction in creatinine clearance compared to only 12 percent of the low-RI patients. In addition, 47 percent of the high-RI patients and only 9 percent of the low-RI patients required dialysis. Though this study did not evaluate nonresistance issues in rejection, it confirmed that high vascular resistance predicted poor allograft performance.

Summary

The renal cortical microcirculation delivers blood to the glomerular capillaries, where blood is filtered into the nephron. Pre- and postglomerular arteriolar tone is closely regulated to maintain a sufficient filtering pressure. The systems that control resistance of these arterioles remain a rich source of investigation. The goals of these studies are to better understand the physiology of glomerular blood flow and the potential dysfunctions that may contribute to renal failure and hypertension. Advances have been made both in methods to study these small-resistance vessels, such as intravital microscopy and isolated perfused afferent arterioles, and in studies of the hormones that regulate arteriolar resistance.

Glossary

Afferent arteriole: The small artery leading into the glomerular capillary, providing the major vascular resistance in the kidney.

Efferent arteriole: The smallest artery in the cortex, which emerges from the glomerular capillary and leads to either a peritubular capillary (in the outer cortex) or vasa recta (in the juxtamedullary cortex). This vessel has a relatively high resistance capacity.

Glomerular capillary: A capillary containing an intricate network of branches and anastomoses, where the filtration of the fluid component of blood passes into the nephron. Located only in the renal cortex.

Renal vascular resistance: The change in hydrostatic pressure due to the tone of the downstream vasculature.

Capsule Biography

William J. Welch has worked extensively on intrarenal hormones that regulate tubuloglomerular feedback and its effect on renal function. He has used in vivo micropuncture to access the renal cortical vasculature and cortical nephrons. The interaction between single nephron function and vascular consequences has been the primary focus of his more than 60 published studies. He has used both normal and hypertensive models to show modulatory roles for angiotensin II, thromboxane, nitric oxide, and superoxide in the control of GFR.

Liver

CHAPTER 72

Hepatic Microvascular Responses to Inflammation

Claudine S. Bonder and Paul Kubes
University of Calgary, Calgary, Alberta, Canada

Introduction

A hallmark feature of hepatic inflammation is the activation of resident nonparenchymal cells, the upregulation of proinflammatory mediators, and the recruitment of leukocytes from the blood to the afflicted site. The liver is a unique organ that houses an elaborate vasculature to handle an enormous volume of blood and monitors for any pathogens that may have breached the gut wall. In this article we highlight cells and substances that mediate hepatic inflammation. We also discuss the adhesion molecules that are key for leukocyte recruitment to the liver during an inflammatory response.

The Hepatic Microvascular System

The liver receives as much as 25 percent of the cardiac output, and much of this blood has already passed through the intestinal tract. In conjunction with handling such a large quantity of incoming blood, it also responds to potential infectious agents that have entered the blood. To do all this, the liver has evolved to maximize vascular spaces and developed mechanisms to fight foreign entities.

The hepatic microvascular system consists of a portal circulation including portal venules, sinusoids, and central venules and an arterial circulation (hepatic arterioles). Blood leaving the gut via the portal venules enters the sinusoids via the sphincter-like cells. Arteriole blood enters the sinusoids through branches of the hepatic arterioles. Both portal and arterial vessels can contract and therefore regulate blood flow within the sinusoids. The sinusoids take blood through the lobule from the portal tract to the central (terminal) vein. Close to the portal tract the sinusoids form an interconnecting network that becomes organized into parallel vessels. As blood leaves the sinusoids it flows through outlet sphincters. These sphincters control the rate of blood flow entering the central veins.

The portal blood represents a route through which infectious gut-derived organisms can enter the liver. Specific mechanisms have evolved to instigate and regulate inflammatory responses against invading pathogens. The close proximity and cross-talk between the different cells within the liver dictates that many of the hepatic cells are involved in an inflammatory response. Unfortunately the development of an inflammatory response, if uncontrolled, can manifest in permanent liver injury. Indeed, there is irrefutable evidence for the involvement of inflammatory cells in a large number of known liver diseases, including alcoholic hepatitis and cirrhosis, viral hepatitis, ischemia–reperfusion injury (transplantation, tumor resection, shock), sepsis- or endotoxin-induced liver injury, acute and chronic rejection, primary biliary cirrhosis, and primary sclerosing cholangitis. Following is an overview of the inflammatory cells, molecules and mechanisms used by the liver to combat and regulate liver injury and dysfunction. As this review is brief, we strongly encourage the readers to turn to our list of suggested reading, and elsewhere, for more information.

Liver Constitution

The liver is formed by parenchymal cells, that is, hepatocytes, and nonparenchymal cells. In contrast to hepatocytes that occupy almost 80 percent of the total liver volume, nonparenchymal liver cells occupy only 6 percent. Notably,

it is the nonparenchymal cells of the liver that regulate an inflammatory response. For the following section we recommend reviews [1–3].

Endothelial Cells

Liver endothelial cells line the portal venules as well as the sinusoids. Whereas the endothelium of the portal venules can be likened to endothelium in other parts of the body, the sinusoidal endothelial cells are morphologically unique. The sinusoidal endothelial cells are characterized by an absence of tight junctions between cells, by a lack of basal lamina, and by the presence of open fenestrations that are arranged into characteristic sieve plates. These cells perform an important filtration function, as these small fenestrations allow free diffusion of many small substances between the blood and the hepatocyte surface. Sinusoidal endothelial cells have also been shown to endocytose many ligands including glycoproteins, components of the extracellular matrix (such as hyaluronate, collagen fragments, and fibronectin) and immune complexes. Sinusoidal endothelial cells may function as antigen-presenting cells in the context of both MHC-I and MHC-II restriction and are also active in the secretion of cytokines, eicosanoids, (i.e., prostanoids and leukotrienes), endothelin-1, nitric oxide, and some extracellular matrix components.

Kupffer Cells

Kupffer cells are intrasinusoidally located tissue macrophages (Figure 1) and have endocytic and phagocytic capabilities. Hepatic macrophages are in constant contact with gut-derived portal blood. Exposure of Kupffer cells to bloodborne pathogens (e.g., endotoxin) can lead to the intensive production of inflammatory mediators and the formation of liver injury. Liver macrophages modulate immune responses via antigen presentation and interaction with T cells. Among the many inflammatory mediators produced by Kupffer cells are reactive oxygen species, eicosanoids, nitric oxide, carbon monoxide, cytokines (TNFα), and chemokines [CXCL10 (IP-10) and CXCL9 (Mig)]. The activation of these cells identifies them as regulators of the early phase of liver inflammation and an important part in innate immune defense.

Hepatic Stellate Cells

Hepatic stellate cells are present in the perisinusoidal space. They are positioned with their well-branched cytoplasmic processes in close proximity to the endothelial cells (Figure I). In the normal liver, hepatic stellate cells control turnover of extracellular matrix and are important in regulating the contractility of sinusoids. In the event of hepatocyte damage, stellate cells transform into myofibroblast-like

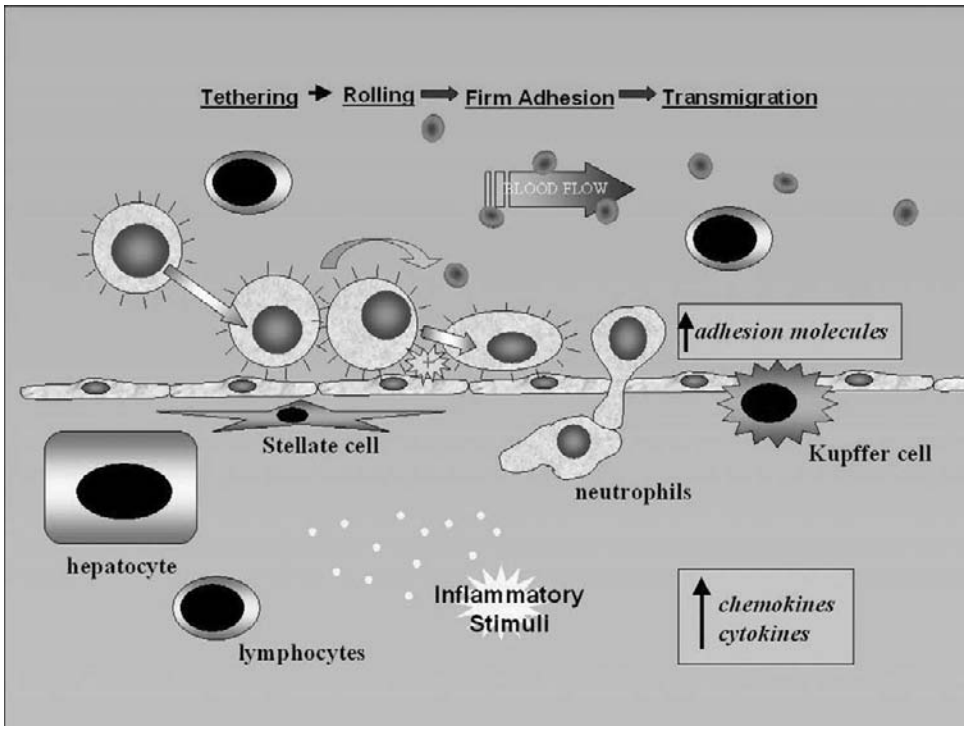

Figure 1 The leukocyte recruitment cascade. Fast-moving leukocytes in the bloodstream tether and roll on activated endothelium via interactions between adhesion molecules. Chemokines or other proinflammatory mediators released by various sources within the tissue are presented on the endothelium to rolling leukocytes, resulting in firm adhesion. Leukocyte transmigration across the endothelium and entry into inflamed tissue ensues. (see color insert)

Table I Adhesion Molecules and Chemokines Upregulated during Hepatic Inflammation.

	Inflamed portal vessels	Inflamed sinusoids
ICAM-1	++	+
VCAM-1	+	+

CCL4 (MIP-1β)	++	+
CCL5 (RANTES)	++	+
IL-8	++	++
CXCL9 (Mig)	+	++
CXCL10 (IP-10)	+	++
CXCL11 (I-TAC)	+	++

cells and mediate the fibrotic response during inflammation. Activated stellate cells, like Kupffer cells, are potent sources of several chemokines including CXCL-10 (IP-10) and CCL-2 (MCP-1).

Lymphocytes

Intrahepatic lymphocytes comprise 25 percent of nonparenchymal cells in the normal liver (Figure 1). In contrast to peripheral blood, the major lymphoid population in the normal liver are pit cells (i.e., NKT cells, 30%), then T cells (20% TCR-αβ and 10% TCR-γδ), NK cells (20%), and very few B lymphocytes (5%). Natural killer T cells are a unique population of cells that express both CD3 and NK1 on their cell surface, secrete IL-2, IL-4, and IFNγ, and recognize antigen in association with CD1. After NKT cells, the predominant intrahepatic T cells are CD8+. Notably, this predominance of CD8+ T cells in the liver differs from the CD4+ T cell majority observed in peripheral blood and spleen. CD8+ T cells, NKT cells, and NK cells all possess cytotoxic activity. Activated CD8+ T cells can be retained by the liver via their interaction with sinusoidal endothelial cells. These "trapped" activated T cells can then cause liver injury by releasing inflammatory cytokines and by apoptosing. Alternatively, circulating lymphocytes can be activated within the liver by Kupffer cells or hepatocytes. Prior to their "activation-induced" cell death, these nonspecifically trapped T cells can also mediate liver damage by secreting mediators of inflammation (e.g., IL-12 and IFNγ).

Neutrophils

Neutrophils are an essential component of innate host resistance and the adaptive responses to inflammation. Although neutrophils constitute a relatively small percentage (1 to 2%) of the nonparenchymal liver cells in a normal (uninfected) mouse, a dramatic tenfold to twentyfold increase in neutrophils occurs within 2 hours following viral infection. Previous observations suggest that neutrophils are the first cell type to arrive at sites of inflammation and as such form the first line of immune defense. In response to chemotactic factors released at inflammatory sites, neutrophils migrate from the bloodstream through the vascular endothelium and adhere to parenchymal cells (Figure 1). Once at the inflammatory site, neutrophils can act as effector cells in an attempt to resolve the inflammation. Alternatively, neutrophils may be cytotoxic and cause necrotic tissue destruction by releasing proteases or reactive oxygen species. Neutrophils can also release chemokines such that more inflammatory cells are recruited to the afflicted site. A detrimental effect of neutrophils in acute and chronic liver disease processes has been shown in hepatic ischemia–reperfusion injury, endotoxemia, sepsis, and alcoholic hepatitis.

Taken together, the unique structure and constitution of the liver, such as the open fenestrations and position of the Kupffer cells, dictate that the barriers against inflammation differ from those in other parts of the body. Indeed, it has repeatedly been shown that inflammatory mediators have easy access to hepatocytes.

Mediators of Hepatic Inflammation

When microbes and other inflammatory stimuli first enter the hepatic circulation, they activate sinusoidal endothelial cells and Kupffer cells. These cells then produce a cocktail of proinflammatory mediators such as prostanoids, nitric oxide, cytokines, chemokines, many growth factors, and reactive oxygen species. With the increased expression of these inflammatory mediators comes (1) the recruitment of leukocytes into the inflamed area, (2) the killing of the invading microbes, and in some cases (3) damage to liver parenchymal cells. For more elaborate discussions on the mediators of hepatic inflammation, we recommend the following reviews: Ref. [4–7].

Vasocontriction and Vasodilation

Alterations to blood flow within the liver have a significant impact on liver function. Several vasoactive substances can affect constriction and relaxation of hepatic stellate cells. These mediators have been shown to come from stellate cells themselves (endothelin-1, NO) as well as hepatocytes (carbon monoxide, leukotrienes), endothelial cells (endothelin, nitric oxide, prostaglandins), and Kupffer cells (prostaglandins, NO). Notably, during the early phase of sepsis both nitric oxide (NO) and carbon monoxide (CO) act as antagonists of vasoconstrictors (e.g., endothelin-1) by mediating relaxation of sinusoidal vessels such that there is an increase in vasodilation. In acute and chronic hepatic

inflammation, dysregulation of the vasoactive substances can result in a circulatory collapse within the liver.

Reactive Oxygen Species

Reactive oxygen species (ROS) are important cytotoxic and signaling mediators in the pathophysiology of inflammatory liver diseases. They can be generated by resident and nonresident liver cells following stimulation. ROS are essential for host-defense functions of phagocytes. In addition, ROS have been shown to indirectly affect vasoconstriction and liver regeneration. Although ROS are able to induce cell damage, they also modulate signal transduction pathways by regulating transcription factors such as NF-κB. By regulating NF-κB, ROS can indirectly affect the pathophysiology of the liver by (1) directly inducing and/or regulating apoptotic and necrotic cell death and (2) modulating the expression of inflammatory mediators and adhesion molecules.

Eicosanoids

Prostaglandins and leukotrienes are ubiquitous mediators of liver function and disease. In the inflamed liver, Kupffer cells produce prostaglandins to modulate hepatic glucose metabolism. Upregulation of glucose correlates with the increasing demand for energetic fuel by the inflammatory cells such as leukocytes, sinusoidal endothelial cells, and Kupffer cells. Studies have also demonstrated a protective role of PGE_2 in viral hepatitis as it abrogates the induction of TNFα, attenuating the expression of antigens on hepatocytes, and may inhibit viral replication. By contrast, in cirrhosis and fulminant hepatic failure a dysregulation of prostaglandin metabolism has been noted. Leukotrienes (e.g., LTB4) have vasoconstrictive and metabolic effects in the liver. These mediators have been shown to cause liver injury in ischemia–reperfusion and endotoxemia.

Cytokines

Experimental data have demonstrated a critical role for proinflammatory cytokines (e.g., TNFα, IL-1, and IFNγ in the development of liver injury. Although TNFα is required for normal hepatocyte proliferation during liver regeneration, it is also involved in inflammation. TNFα is known to induce the transcription factor nuclear factor-kappaB (NF-κB) which regulates many proinflammatory mediators (e.g., TNFα and IL-1). Overexpression of TNFα (from Kupffer cells or infiltrating neutrophils) has been shown to correlate with hepatotoxicity in endotoxemia, alcoholic liver disease, and viral hepatitis. Another cytokine noted for its involvement in liver injury is IFNγ. In alcoholic hepatitis, overexpression of IFNγ mediates liver injury. By contrast, in viral hepatitis it is a lack of functioning IFNγ that permits the liver damage.

Chemokines

The recruitment of inflammatory cells to the liver is a critical step to the development of liver disease. Chemokines have emerged as one of the most important regulators of leukocyte trafficking and activation. In the noninflamed liver resident cells express and secrete low levels of CCL5 (RANTES), CCL2 (MCP-1), CCL3 (MIP-1α), CCL4 (MIP-1β), and IL-8. These chemokines have been detected on the vascular endothelium in portal tracts as well as the sinusoids. Interestingly, inflammation-induced chemokine expression varies between portal and sinusoidal vessels. Chemokines CXCL9 (Mig), CXCL10 (IP-10), and CXCL11 (I-TAC) are detected on sinusoids in association with liver inflammation, whereas relatively little induction of CCL5 (RANTES), CCL2 (MCP-1) or IL-8 is observed. By contrast, elevated levels of CCL5 (RANTES), CCL3 (MIP-1α), CCL2 (MCP-1), and CCL4 (MIP-1β) have been detected on the portal vessels. Although the reasons for these differences are still unclear, it may reflect that the sinusoidal endothelium is fundamentally distinct from the portal endothelium. In fact, these observations may suggest a selective process for regional leukocyte recruitment during liver injury.

Cellular Adhesion Molecules

Cellular adhesion molecules (CAMs) are cell surface glycoproteins involved in cell–cell and cell–matrix interactions. CAMs are critical for leukocyte adhesion to endothelium, transmigration, binding to target cells, and cytotoxicity. Following is a review of CAMs that have been shown to be relevant to inflammatory liver disease, and we suggest the following articles to readers: Ref. [6, 8–10].

Integrins

Resident liver cells (e.g., Kupffer cells and pit cells) as well as newly recruited monocytes, T lymphocytes and neutrophils have β_1 and β_2-integrins on their surface. LFA-1 ($\alpha_L\beta_2$) is highly expressed on all leukocytes. By contrast, Mac-1 ($\alpha_M\beta_2$) is present primarily on neutrophils, Kupffer cells, and monocytes, and to a small degree on pit cells. VLA-4 ($\alpha_4\beta_1$) is expressed mainly by T cells, pit cells, and monocytes, and to some degree on Kupffer cells and under limited conditions neutrophils. The activation of integrins has been observed in situations akin to liver injury in vivo. Indeed, increased Mac-1 expression on neutrophils was observed during reperfusion after hepatic ischemia, endotoxemia, and sepsis.

Intercellular Adhesion Molecules

Intercellular adhesion molecules (ICAM-1, -2 and -3), vascular adhesion molecule (VCAM-1), and platelet

endothelial adhesion molecules-1 (PECAM-1) are also important in an inflammatory response. In the normal liver, no ICAM-1 is found on hepatocytes or stellate cells and low expression of ICAM-1 can be found on the entire hepatic endothelium and Kupffer cells. During inflammation, ICAM-1 is strongly upregulated by TNFα, IL-1β, and IFNγ on all liver cells (Table I). This induction is promptly followed by the recruitment of leukocytes into the liver, where they attach to and subsequently damage the liver cells. In normal livers there is low VCAM-1 expression on venule, arteriole, and sinusoidal endothelial cells. No constitutive or inducible VCAM-1 has been observed on hepatocytes. With exposure to TNFα or IL-1β both Kupffer cells and endothelial cells upregulate VCAM-1 (Table I). Vascular adhesion protein (VAP)-1 is constitutively expressed on human sinusoidal endothelial cells and has been shown to mediate lymphocyte recruitment and possibly transendothelial transmigration. PECAM-1 has been shown to be important for leukocyte transendothelial migration. Studies have shown PECAM-1 to be constitutively expressed on large vessel endothelial cells but not sinusoidal endothelial cells. PECAM-1 is not inducible with inflammatory mediators (Table I).

Selectins

The selectin family includes three molecules, that is, L-, E-, and P-selectin. L-selectin is constitutively expressed on neutrophils and is shed from the cell surface during activation. Notably, this shedding coincides with Mac-1 upregulation on neutrophils. There are important differences in the expression of selectin adhesion molecules between vascular and sinusoidal endothelium. P-selectin is stored in secretory granules (Weibel-Palade bodies in endothelial cells). Liver sinusoidal endothelial cells do not contain WP bodies and consistent with this lack of WP bodies, sinusoidal endothelial cells do not express P-selectin (Table I). By contrast, under inflammatory conditions, P- and E-selectin can be strongly induced on the portal vascular endothelium (Table I). These differences may reflect a lack of requirement for selectin-mediated tethering in the low-flow environment of the sinusoid. Indeed, leukocyte recruitment to the sinusoidal area has been shown, in vivo, to occur in the absence of selectins.

Conclusion

In conclusion, the liver is unique in its histoarchitecture compared to other organs. Additional differences exist within the liver itself, and these become more obvious during an inflammatory response. Herein we have touched on the concept that the disruption of the normal liver occurs through a multitude of cells and proinflammatory mediators. The challenge in the future is to define various models that best describe the mechanisms that are critical to induction and/or maintenance of liver damage. Understanding the precise mechanisms of hepatic injury or inflammation may permit the development of specific anti-inflammatory strategies. Only then can we aim at preventing effector cell recruitment while leaving general homeostatic liver functions intact.

Glossary

Adhesion molecules: Molecular determinants that regulate homeostatic recirculation and tissue-specific trafficking of cells.

Inflammation: A localized protective response elicited by injury or destruction of tissues, which serves to destroy, dilute, or sequester both the injurious agent and the injured tissue. Histologically, it involves a complex series of events, including dilation of arterioles, capillaries, and venules, with increased permeability and blood flow, exudation of fluids, including plasma proteins, and leukocyte migration into the inflammatory focus.

Liver: A solid organ located in the right upper quadrant of the abdomen that plays a major role in metabolism, digestion, detoxification, and elimination of substances from the body.

Mediators: Substances released from cells as a result of the interaction between antigen and antibody or by the action of antigen with a sensitized lymphocyte.

Recruitment: The collection or increased abundance of cells into a defined area, such as antigen-experienced lymphocytes into inflammatory effector sites via specific vascular addressins and chemokines.

Capsule Biography

Dr. Bonder is a Canadian Association of Gastroenterology postdoctoral fellow with Dr. Kubes at the University of Calgary. Her work focuses on the recruitment of leukocytes to splanchnic organs during inflammation.

Dr. Kubes is chair of the Immunology Research Group in the Department of Physiology and Biophysics. His laboratory is supported by grants from the Canadian Institutes for Health Research (CIHR) and a CIHR group grant.

CHAPTER 73

Liver Microcirculation

Robert S. McCuskey
University of Arizona, Tucson, Arizona

The purpose of this chapter is to provide an overview of what is known about the dynamic structure, function, and regulation of the hepatic microvascular system in health and some of its basic responses to disease.

Blood Supply to the Liver

It is important to recognize that the liver has a dual blood supply. Approximately 80 percent of the blood entering the liver is poorly oxygenated blood supplied by the portal vein containing venous blood flowing from the intestines, pancreas, spleen, and gallbladder. The remaining 20 percent of the blood supply is well oxygenated and delivered by the hepatic artery. Both the hepatic portal vein and hepatic artery enter the liver at the hilus, where efferent bile ducts as well as lymphatics also exit the organ.

Branches of the hepatic artery, hepatic portal vein, bile duct, and lymphatic vessels travel together in portal tracts through the liver parenchyma. After repeated branching, terminal branches of the blood vessels (portal venules and hepatic arterioles) supply blood to the sinusoids, which are the exchange vessels in the liver. Branches of hepatic arterioles also supply the peribiliary plexus of capillaries nourishing the bile ducts and then drain into sinusoids or occasionally into portal venules. After flowing through the sinusoids, blood is collected in small branches of hepatic veins termed central venules (central veins, terminal hepatic venules). These course independently of the portal tracts and drain via hepatic veins, which leave the liver on the dorsal surface and join the inferior vena cava. Occasionally, branches of hepatic arterioles bypass the sinusoidal bed to supply the walls of hepatic veins.

Lymphatic vessels originate as blind-ending capillaries in the connective tissue spaces of portal tracts. The fluid contained in these lymphatics flows toward the hepatic hilus and eventually into the cisternae chyli.

Microvascular Functional Units

The organization of each liver lobe into structural or functional units related to function and/or disease has been the subject of considerable debate during the past century. Several models, none of which are mutually exclusive, have been proposed as follows and as illustrated in Figure 1.

The classic hepatic lobule is a polygonal structure having as its central axis a central venule, with portal tracts distributed along its peripheral boundary. The peripheral boundaries of these lobules are poorly defined in most species, including humans. (In some species, e.g., the pig, there is considerably more connective tissue present in the liver and the connective tissue is distributed along the peripheral boundary of classic lobules, thus making them very distinct.) Considerable sinusoidal anastomoses occur between adjacent lobules, and thus the blood collected by each central venule is supplied by several portal venules. For these reasons, and because of intralobular regional differences in oxygenation, metabolic functions, and responses to some disease, an acinar concept was proposed to define the hepatic functional unit.

The hepatic acinus is a unit having no distinct morphologic boundaries. Its axis is a portal tract and its peripheral boundary is circumscribed by an imaginary line connecting the neighboring terminal hepatic venules (central hepatic venules of the classic lobule), which collect blood from sinusoids. Contained within the acinus are three zones, each having different levels of oxygenation and metabolic function. Although the acinar concept has been widely accepted, it fails to account for those mammalian species (e.g., pig, seal) that have connective tissue boundaries circumscribing the classic lobule. Additional inconsistencies increasingly have been identified in three-dimensional studies of metabolic heterogeneity and microvascular structure.

In yet another model of hepatic organization, the unit is defined by bile drainage. So-called portal lobules have at

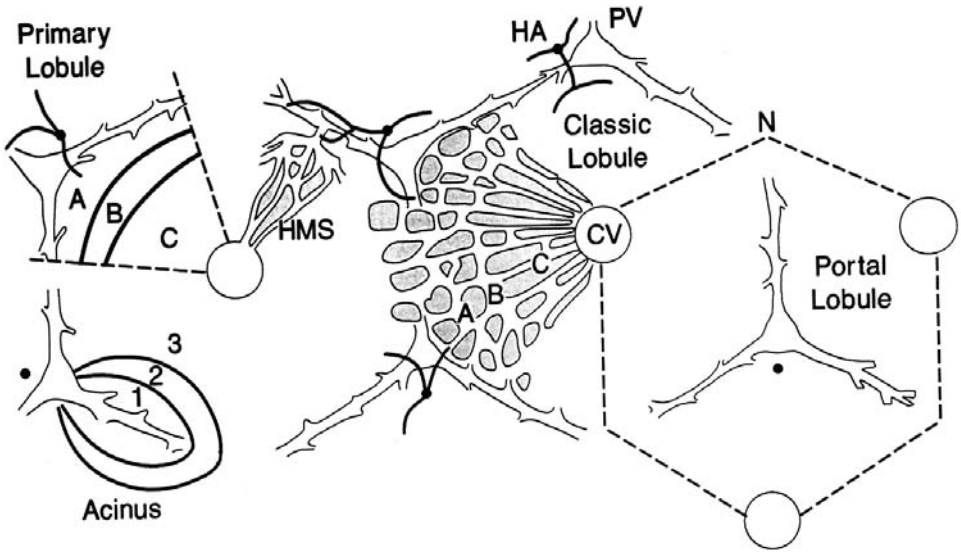

Figure 1 Contiguous hepatic lobules illustrating the interconnecting network of sinusoids derived from two portal venules (PV). Note that the sinusoids become more parallel as they course toward the central venule (CV), which forms the axis of the classic lobule. Hepatic arterioles (HA) supply blood to sinusoids near the periphery of the lobule, usually by terminating in inlet venules or terminal portal venules. As a result, three zones (1, 2, 3) of differing oxygenation and metabolism have been postulated to compose a hepatic acinus, with its axis being the portal tract (*lower left*). Several acini would compose the portal lobule (*lower right*). Each classic lobule contains several cone-shaped subunits having convex surfaces fed by portal and arterial blood at the periphery and apices at the central venule (*upper left*). A, B, and C represent hemodynamically equipotential lines in a "primary lobule." A recent modification further subdivides lobules into conical hepatic microcirculatory subunits (HMS), each being supplied by a single inlet venule. (see color insert)

their center a portal tract, with central veins present around the periphery of each lobule. This concept has received little support.

Currently, the concept of subunits of the classic lobule forming functional units is the most consistent with existing evidence. In this model, each "classic" lobule consists of several "primary lobules." Each primary lobule is cone-shaped, having its convex surface at the periphery of the classic lobule supplied by terminal branches of portal venules and hepatic arterioles, and its apex at the center of the classic lobule drained by a central (terminal hepatic) venule. These "primary lobules" were renamed *hepatic microvascular subunits* (HMS) and were demonstrated to consist of a group of sinusoids supplied by a single inlet venule and its associated termination of a branch of the hepatic arteriole from the adjacent portal space. Further confirmation of this HMS concept was obtained by studying their development in neonatal livers. Accompanying the HMS are hepatic parenchymal cells and the associated cholangioles and canaliculi. Hepatocellular metabolic gradients also have been demonstrated to conform to this proposed functional-unit concept.

Studies using three-dimensional reconstruction of sectioned livers, scanning electron microscopic examination of corrosion casts, and in vivo microscopy of several species support this concept of the functional unit being a conical microvascular subunit of the classic lobule.

Hepatic Microvascular System

The hepatic microvascular system comprises all blood and lymphatic vessels immediately involved in the delivery and removal of fluids to and from the hepatic parenchyma, namely, portal venules, hepatic arterioles, sinusoids, central venules, and lymphatics. Figure 2 is a diagram illustrating the afferent and efferent microvascular connections to the sinusoids within a single hepatic lobule.

Most blood enters the sinusoids from portal venules. These inlets are reported to be guarded by sphincters composed of sinusoidal lining cells termed the afferent or inlet sphincters. Arterial blood enters some of the sinusoids, principally through branches of the hepatic arterioles. These vessels, arterio-sinus twigs, terminate in sinusoids near their origins from portal venules. In addition, occasional direct connections (arterio-portal anastomoses, APA) have been observed with the terminal portal venules. The frequency of these APAs appears to be species-dependent. Because all of these structures are independently contractile, the sinusoids receive a varying mixture of portal venous and hepatic arterial blood. Finally, some evidence suggests that the fraction of blood delivered to the sinusoids by the hepatic artery differs between the hilus and periphery of hepatic lobes. Within the network of sinusoids, blood flow is reportedly regulated by contractile sinusoidal lining cells that control not only the velocity of flow but also its distribution within the network.

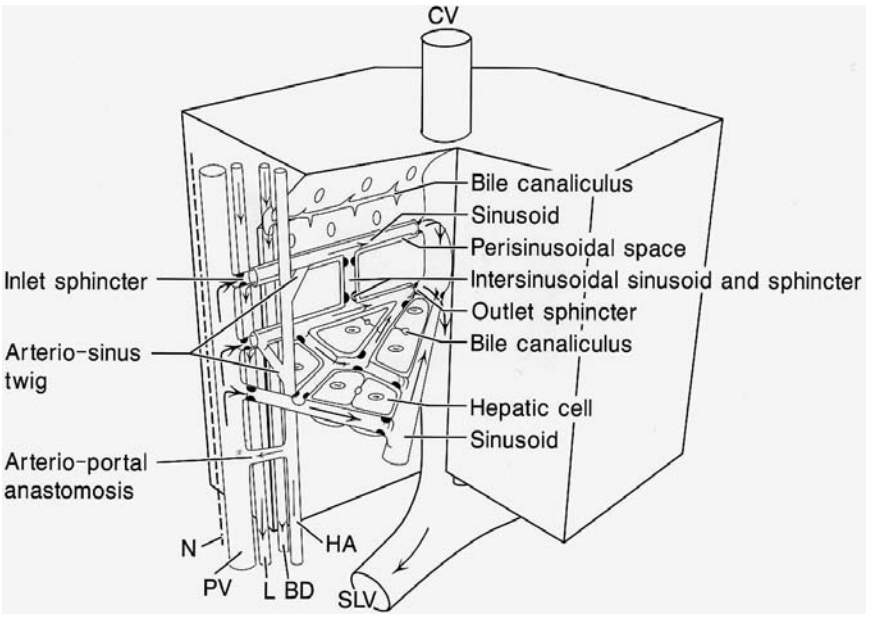

Figure 2 Hepatic microvasculature as determined by in vivo microscopic studies. PV, portal venule; HA, hepatic arteriole; L, lymphatic; BD, bile ductule; N, nerve; CV, central venule; SLV, sublobular hepatic vein. Arrows indicate direction of flow. (see color insert)

Blood leaves the sinusoids by flowing into central (terminal hepatic) venules, reportedly by passing through outlet or efferent sphincters composed of sinusoidal lining cells.

Structure and Function of Hepatic Sinusoids

The sinusoids are unique exchange vessels composed of specialized nonparenchymal cells that exhibit structural and functional heterogeneity.

Structure

The structure of the sinusoid is illustrated in Figure 3. The endothelial cells are highly fenestrated and lack a supporting basal lamina. The fenestrae are organized in clusters known as sieve plates. As a result, there is continuity between the plasma in the sinusoid lumen and the perisinusoidal space (of Disse). The sinusoidal endothelial cells contain numerous endosomes and scavenge a number of substances including breakdown products of connective tissue. They also are the source of several cytokines, eicosanoids, nitric oxide, and endothelins.

Stellate cells (fat-storing cells of Ito) lie external to the endothelium in the space of Disse. They are pericytes that frequently contain lipid droplets serving as storage sites for vitamin A. Multiple cytoplasmic projections of these cells surround and embrace the abluminal surfaces of the endothelial cells. When activated, these cells produce collagen and become contractile. As a result, they are thought to play a role in the regulation of sinusoidal blood flow.

Kupffer cells are attached to the luminal surfaces of the endothelium. These are highly phagocytic, specialized fixed macrophages of the liver and contain numerous lysosomes and phagosomes. Kupffer cells are involved in a number of host defense mechanisms and immune functions and are the source of a number of cytokines, eicosanoids, free radicals, and nitric oxide.

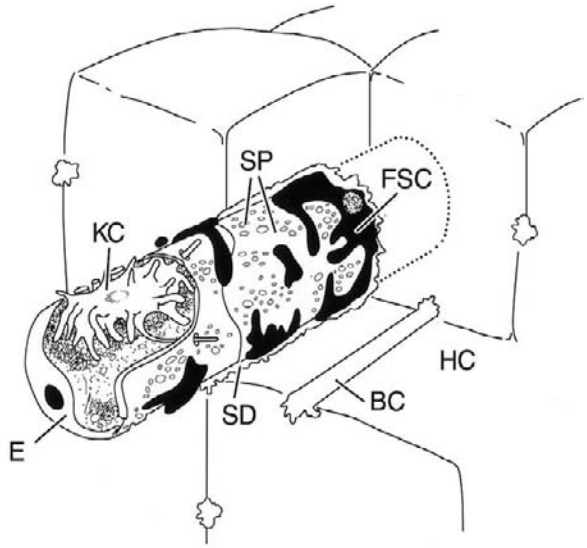

Figure 3 Sinusoid and contiguous hepatic parenchymal cells (HC). E, endothelium; KC, Kupffer cell; SD, space of Disse; SP, sieve plate composed of endothelial fenestrae; FSC, fat storing cell (stellate) cell; BC, bile canaliculus.

Heterogeneity

The organization of the sinusoid network exhibits heterogeneity. Near portal venules and hepatic arterioles, sinusoids

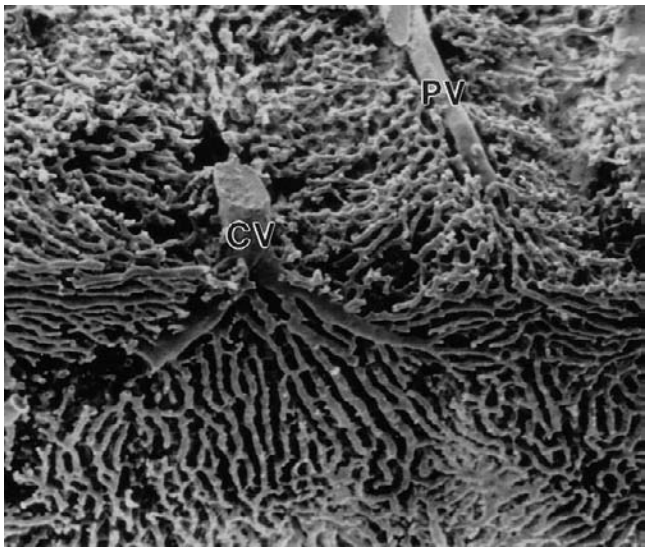

Figure 4 Vascular cast of the hepatic microvasculature illustrating the tortuous, anastomotic sinusoids adjacent to the portal venule (PV) and the more parallel and larger sinusoids near the central venule (CV). (see color insert)

are arranged in interconnecting polygonal networks; farther away from the portal venules the sinusoids become organized as parallel vessels that terminate in central venules (terminal hepatic venules). Short intersinusoidal sinusoids connect adjacent parallel sinusoids. Figure 4 is a microvascular cast illustrating these regional differences.

In the periportal area, the volume of liver occupied by sinusoids is greater than that surrounding central venules. However, because of the smaller size and anastomotic nature of the periportal sinusoids, the surface available for exchange in this area (surface/volume ratio) is greater than in centrilobular sinusoids. The size and pattern of distribution of endothelial fenestrae differs along the length of the sinusoid. At the portal end, the fenestrae are larger but comprise less of the endothelial surface area than they do in the pericentral region. The functional significance of these regional differences is unclear but relates to the functional metabolic heterogeneity that has been demonstrated for hepatocytes in different regions of the lobule. This, in turn, may depend on the recognized portal-to-central intralobular oxygen gradient and the unique microcirculation in the liver.

Morphologic Sites for Regulating the Hepatic Microcirculation

There are several potential morphological sites for regulating blood flow through the sinusoids. These include the various segments of the afferent portal venules and hepatic arterioles, the sinusoids themselves, and central and hepatic venules. These vessels contain several potentially contractile cells—smooth muscle cells in arterioles and venules, and in sinusoids, endothelial, stellate, and Kupffer cells.

Portal venules and central venules contain limited amounts of smooth muscle in their walls relative to their luminal size, but nevertheless are contractile and respond to pharmacologic agents. Hepatic arterioles are more responsive because of a complete investment of smooth muscle and relatively small lumens. The principal site of regulation of blood flow through the sinusoids, however, is thought to reside in the sinusoid itself, where the major blood pressure drop occurs in the liver.

The sinusoidal lining cells are responsive to a wide variety of pharmacodynamic substances. By contracting (or swelling), they may selectively reduce the patency of the sinusoid lumen, thereby altering the rate and distribution of blood flow. The relative roles of Kupffer versus endothelial cells in this process are not yet resolved, but both appear to be involved. The participation of perisinusoidal, stellate cells (fat-storing, Ito cells) in regulating sinusoidal diameter also has been reported. All three cell types contain filaments, tubules, and contractile proteins suggestive of contractile activity.

Because of these structures, blood flow through individual sinusoids is variable. At sites where the lumen is narrowed by the bulging, nuclear regions of sinusoidal lining cells, flow may be impeded by leukocytes that transiently plug the vessel and obstruct flow. Transient leukocyte plugging is more frequent in the periportal sinusoids, which are narrower and more tortuous than those in the centrilobular region. The more plastic erythrocytes usually flow easily through such sites unless the lumen is reduced to near zero. Some sinusoids, however, may act as thoroughfare channels and have relative constant rates of blood flow, while others have more intermittent flow. This may depend on not only the distribution of intrasinusoidal sphincter cells but also on the distribution of arterio-sinus twigs (AST) and the contribution of arterial blood flowing to individual sinusoids. For example, arterial blood flowing into an individual sinusoid through a dilated AST may increase the rate of sinusoidal blood flow. Because of the delivery of arterial blood at higher pressure, some arterial blood may even reverse the entry of portal blood into the sinusoids. As a result, the AST in concert with the initial segment of the sinusoid in which it terminates may form a “functional” arterio-portal anastomosis so that arterial blood is delivered into the portal venules. In the anesthetized, healthy animal, however, terminal branches of the hepatic arteriole containing flow are seen infrequently so that most blood delivered to the sinusoids is derived from the portal venules. Consistent with this is the in vivo microscopic observation that the velocity of flow in sinusoids and portal and central venules located near the capsule of the liver is not significantly altered by hepatic artery occlusion in healthy anesthetized rats. However, arterial inflow to the sinusoids may be more significant in regions near the hepatic hilum.

The frequency distribution of the wide variations in blood flow in the sinusoids exhibits a polymodal pattern composed of several Gaussian distributions. These wide variations in flow are due to the structural features previously described for sinusoids and also are due to intermittent arterial inflow into the sinusoids. Blood pressures in portal and central venules have been measured to be about 6 to

7 cmH_2O and 1.5 to 3.0 cmH_2O, respectively. Arterial blood enters the sinusoid at pressures ranging from 12 to 25 cmH_2O.

Pathophysiology of the Hepatic Microcirculation

Significant interactive roles for endotoxin, cytokines, chemokines, reactive free radicals, nitric oxide (NO), endothelin (ET-1), carbon monoxide (CO), sinusoidal lining cells, leukocytes, and platelets have been demonstrated in the pathophysiology of hepatic microvascular disturbances and parenchymal injury resulting from infection, toxicants, and ischemia/reperfusion following hemorrhage or liver transplantation. The responses of the hepatic microvasculature are of two basic types: (a) an inflammatory response involving paracrine activation of the sinusoidal endothelial cells (SEC) by mediators released from adjacent Kupffer cells and/or hepatic parenchymal cells following stimulation by toxicants, leading to the upregulation of adhesion molecules and the subsequent adhesion of leukocytes to the SEC, as well as swelling of the SEC, both of which restrict sinusoidal blood flow; and (b) direct injury of the SEC, resulting in loss of fenestrae, formation of gaps, penetration of the sinusoidal lining by blood cells, destruction of SEC, and obstruction of the sinusoid by SEC debris. The inflammatory response results from endotoxemia, sepsis, ischemia–reperfusion injury, and acute alcohol ingestion while direct injury is elicited by acetaminophen (APAP) or during hepatic venoocclusive disease by pyrrolizidine alkaloids. Both types of injury may occur together or sequentially, as is seen when ethanol sensitizes sinusoidal lining cells to other toxicants such as APAP or endotoxin, which exacerbates the extent of injury. It should be noted that because of the highly anastomotic nature of the hepatic sinusoid bed, plugging of single or scattered segments of sinusoids results in redirection of blood flow into adjacent unplugged vessels. However, unless the injury is highly localized, these latter vessels eventually become plugged, resulting in microcirculatory failure.

Glossary

Hepatic lobule: A polygonal structure having as its central axis a central venule, with portal tracts distributed along its peripheral boundary; major functional unit in the liver.

Hepatic microvascular system: Comprises all blood and lymphatic vessels immediately involved in the delivery and removal of fluids to and from the hepatic lobule and its parenchymal cells, namely, portal venules, hepatic arterioles, sinusoids, central venules, and lymphatics.

Hepatic sinusoids: Unique exchange vessels in the liver composed of specialized nonparenchymal cells (sinusoidal endothelial cells, Kupffer cells, and stellate cells) that exhibit structural and functional heterogeneity.

During 2003–2005, he also is President of the American Association of Anatomists. Dr. McCuskey has been studying the hepatic microvasculature in health and disease for more than 40 years.

CHAPTER 74

Gaseous Signal Transduction in Microcirculation

Makoto Suematsu and Nobuhito Goda

Department of Biochemistry and Integrative Medical Biology, School of Medicine, Keio University, Tokyo, Japan

Gaseous signal transduction is an event where gaseous molecules produced or utilized in the body transfer biological signals to their receptors. Molecular oxygen (O_2) is not only necessary to maintain aerobic ATP synthesis in mitochondria but also serves as a primary substrate to synthesize the signaling gases, such as, nitric oxide (NO) and carbon monoxide (CO). These gaseous monoxides are generated by oxygenases, such as, NO synthase (NOS) and heme oxygenase (HO), respectively, and both play important roles in regulation of microvascular functions. Aerobic consumption of molecular oxygen occurs concurrently with glucose oxidation and thereby upregulates synthesis of CO_2 in the Krebs cycle. On the other hand, 3-phosphoglyceric acid, a product of glycolysis, serves as a substrate for serine, which interacts with methionine to generate cysteine. Besides its roles in synthesis of glutathione, taurine, and sulfate ion, this amino acid serves as a substrate for cystathionine β-synthase and/or cystathionine γ-lyase to generate hydrogen sulfide (H_2S) (Figure 1). Among these gases, this article focused on the roles of O_2, NO, and CO in microvascular signal transduction where molecular mechanisms for their reception have been revealed with physiologic implications.

Signal Transduction by O_2

Cytochrome *c* Oxidase (CCO)

Molecular oxygen (O_2) functions primarily as a terminal acceptor of electrons on mitochondria and is consumed through this enzyme to generate H_2O. This reaction is coupled with active transport of protons from the inner to the outer side of mitochondrial inner membrane. Reflux of the electron across the membrane through ATP synthase is necessary to maintain oxidative phosphorylation. Considering that more than 95 percent of oxygen consumed in our body is used for this reaction, it is not unreasonable to hypothesize that the enzyme per se serves as an oxygen sensor. Experiments using the photochemical action spectrum by Wilson et al. [1] first suggested that CCO serves as an oxygen sensor in the carotid body. The hypoxia-induced activation of the afferent neural burst of glomus cells in the body was CO sensitive, suggesting that the sensor is a heme protein, and the sensitivity profile of the CO effect to monochromatic light followed the absorption spectrum of CCO as a function of the wavelength of the light. However, mechanisms by which the CCO changes transfer the hypoxic signal to glomus cells are quite unknown in these experiments. Hypoxia-induced alterations in the CCO reaction trigger a number of events leading to remodeling of cell functions. Active transport of protons across the membrane is automatically reduced. NADH in the matrix is increased to inhibit dehydrogenase reactions in the Krebs cycle; this event secondarily decreases ATP and increases AMP to accelerate anaerobic glycolysis to compensate ATP synthesis. Cessation of oxygen consumption and accumulation of NADH causes generation of reactive oxygen species from the midpoint of the mitochondrial electron transfer system. In addition, a reduction of ATP synthesis inversely increases adenosine, a potent vasodilator. At present, it is unknown which of these events could play a critical role in transducing the hypoxic signal toward critical intracellular components to regulate vascular functions.

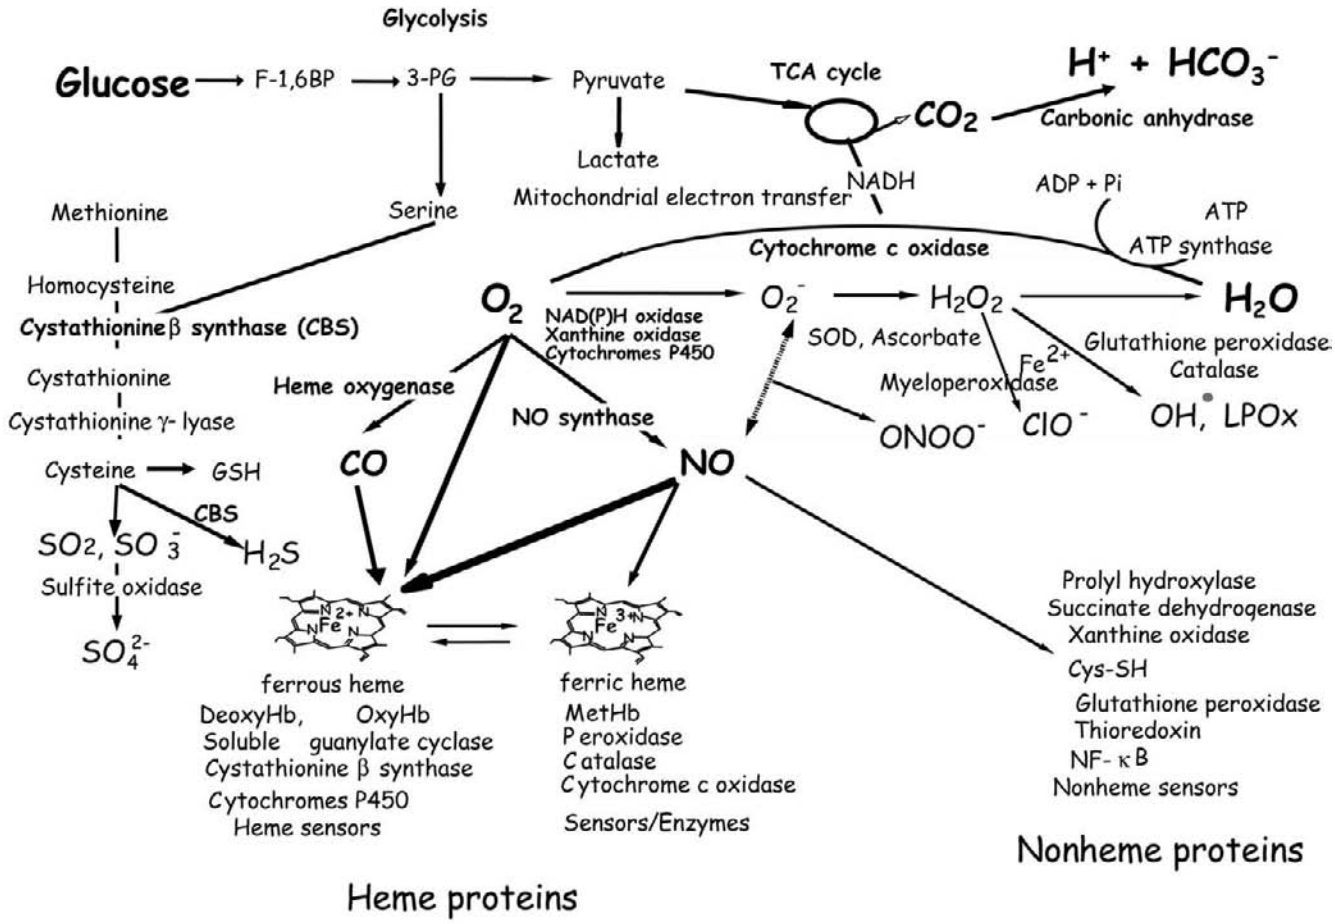

Figure 1 Landscape view of gas mediators and their receptor systems. From Ref. [17] with permission.

Oxygenases and Hemoglobin as a Class of Oxygen Sensors

Oxygenases constitute another class of oxygen sensors, since some of these enzymes accept molecular oxygen as a substrate and generate biologically active compounds as messenger molecules. Cyclooxygenases, cytochromes P450, NO synthase (NOS), and heme oxygenase (HO) are such candidate oxygenases that produce potent vasoactive mediators for hypoxic remodeling. NOS has largely been examined for its roles in regulation of neurovascular systems, but few studies showing its role in oxygen sensing have been available. Although a reduction of molecular oxygen in the cells could decrease the generation of the gas from the enzyme, it is unlikely that hypoxia causes a decrease in NO, since the half-life of NO by itself in vivo greatly depends on local oxygen tension [2]. Recent studies suggest that not only endothelial cells but also erythrocyte-dependent recycling mechanisms for NO serve as resources of the gas available in microcirculation. Under hypoxic conditions, erythrocytes alter their hemoglobin allostery toward the T-state, and thereby increase the conductance of band III on their membranes; this reaction causes an increase in outflow of NO-glutathione into circulation [3]. Such sequential reactions in and around the erythrocyte membrane also trigger the release of ATP which could secondarily stimulates NO in endothelial cells [4]. Besides endothelial and neural NOS in situ, these circulating resources of NO or NO stimulators could explain an endothelial cell-independent fraction of NO supplied into microvascular beds in vivo [5].

Prabhakar et al. [6] suggested that HO-2 serves as an oxygen sensor in the carotid body; CO constitutively generated by HO-2 in glomus cells is decreased upon hypoxia and secondarily causes depolarization of the cells, leading to neural burst of their dopaminergic fibers. Interestingly, NOS and HO can be induced upon hypoxia as a result of transcriptional upregulation of the inducible enzymes, and compensate blood supply in hypoxic regions. Such events are mediated by nuclear translocation of hypoxia-inducible factor (HIF-1) upon hypoxia as described next.

Hypoxia-Inducible Factor (HIF)-1α and HIF Prolyl-hydroxylase

In the early 1990s, a novel hypoxia-inducible transcriptional factor, HIF-1, was identified. This factor binds at the 3′ region of the hypoxia response element (HRE) of the erythropoietin gene after exposure to hypoxia [7]. HIF-1 is a heterodimeric transcription factor that consists of two

distinct components, the oxygen-sensitive α subunit (HIF-1α) and constitutively expressed β subunit that is also known as the aryl hydrocarbon receptor nuclear translocator. Genes regulated by this transcription factor involve erythropoietin, transferrin, cyclin E, VEGF, inducible NO synthase, heme oxygenase-1, and a series of glycolytic enzymes.

Until recently, mechanisms by which organisms sense alterations in oxygen concentration and subsequently induce HIF-1 activities remained unknown. Under normoxia, HIF-1α binds to a von Hippel-Lindau tumor suppressor gene product, pVHL, that rapidly leads to ubiquitin-dependent proteolysis of HIF-1α [8]. On the other hand, HIF-1α does not bind to pVHL and is rapidly accumulated in nuclei within a few minutes, suggesting structural alterations in HIF-1α upon hypoxia. Two distinct molecular mechanisms by which HIF-1α alters its structure to escape from the pVHL binding involve oxygen-dependent hydroxylation of specific amino acid residues. First, hydroxylation of prolyl residues of the protein (Pro402 and Pro564) is necessary to escape from pVHL-dependent ubiquitination and requires a prolyl-4-hydroxylase, a member of a subfamily of novel protein hydroxylases distinct from those for collagen stabilization. In mammals, three homologs termed HPH-1, -2, and -3 have been cloned, constituting the superfamily of dioxygenases, and require molecular oxygen and 2-oxoglutarate as cosubstrates. Second, hydroxylation of a critical asparagine residue (Asn803 in HIF-1α) occurs in an oxygen-dependent manner and in turn renders it unable to associate with CBP/p300 transcriptional coactivators. Lando and colleagues [9] determined that the asparagine hydroxylase involved in the catalytic reaction is identical to factor-inhibiting hypoxia-inducible factor-1 (FIH-1), which was initially identified by Semenza and coworkers as a novel HIF-1-binding protein. This enzyme is a 2-oxoglutarate-dependent dioxygenase that utilizes molecular oxygen to modify its substrate. Through these mechanisms, oxygen tension not only affects HIF-1α degradation but also dictates its subcellular localization.

Microvascular Actions of CO

CO is a gaseous product of the HO reaction that utilizes molecular oxygen to oxidatively degrade protoheme IX into biliverdin-IXα, ferrous iron, and the gas. CO has been considered a gaseous mediator analogous to NO that activates soluble guanylate cyclase (sGC) as a common transducer to relax vascular systems. In mammals, HO exists in two forms: HO-1 and HO-2. HO-1 is induced by varied stressors such as cytokines, heavy metals, ROS and hypoxia. Excess NO could also cause the HO-1 induction. Microvascular actions of endogenously generated CO was first demonstrated in the liver [10]. Liver constitutes a major organ responsible for detoxification of the hemoglobin-derived heme and biliary excretion of bilirubin-IXα, a product generated from biliverdin-IXα through biliverdin reductase. We demonstrated intrahepatic distribution of two major HO isozymes immunohistochemically, with the finding that the two isozymes have distinct topographic patterns; HO-1, the inducible form, is expressed prominently in Kupffer cells, while the constitutive HO-2 is abundant in hepatocytes [11]. CO derived from HO-2 is necessary to keep sinusoids in a relaxing state through mechanisms involving sGC in hepatic stellate cells (HSC), also known as Ito cells, that constitute microvascular pericytes in this organ. HSC cultured on silicon membrane–coated dishes exhibited wrinkling formation through their intercellular connection of cytoplasmic processes and can respond to micromolar levels of CO to reduce the density of wrinkles, suggesting a relaxing response (Figure 2). Considering the microanatomical orientation of the liver cells in and around sinusoids, HO-2 in parenchyma stands in a reasonable position for the gas reception by HSC where CO released from hepatocytes can directly access to the cells and thereby modulate their contractility without being captured by hemoglobin in circulation. When exposed to disease conditions such as endotoxemia and advanced cirrhosis, liver could upregulate HO-1 in Kupffer cells and hepatocytes as a result of cytokine responses [12]. In experimental models of endotoxemia, such an induction of HO-1 expands the ability of liver to degrade heme and to trigger overproduction of CO. Under these circumstances, CO turned out to contribute to maintenance of blood perfusion as well as that of bile excretion.

How can our neurovascular systems distinguish these two gases for sGC-mediated signaling events? As widely

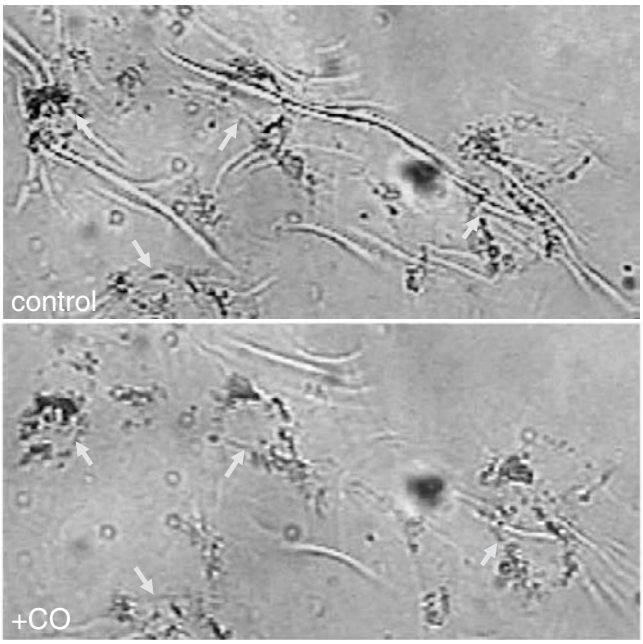

Figure 2 Effects of CO on wrinkling formation of hepatic stellate cells in culture. The cells were cultured in dishes coated with a thin silicon membrane that displays wrinkles in response to spontaneous contraction of the cells. Note that the spontaneous wrinkles disappear in response to 15-minute superfusion of 10 μmol/L CO.

known, in the case of hemoglobin, CO stabilizes the six-coordinated form of the prosthetic heme and increases the affinity of molecular oxygen in other subunits, whereas NO binds to the α subunit of the heme and breaks the proximal histidine–Fe bond, forming a five-coordinated nitrosyl heme complex to decrease the affinity of oxygen in β subunits [13]. Similar to the case of hemoglobin, differences between NO and CO in the heme structure in the β-subunit of sGC appear to cause distinct activation states of the catalytic α-subunit of the enzyme. Because of such a structural difference in the heme coordination between NO and CO, the interaction of the two gases on the prosthetic heme of the enzyme leads to a unique regulatory response of the enzyme: Low tissue NO makes CO a modestly stimulatory modulator of the enzyme, whereas high tissue NO makes CO an inhibitory one. Observation that vascular smooth muscle cell-specific heme oxygenase-1 transgenic mice exhibit systemic hypertension rather than hypotension supports such a possibility [14]. This notion was also confirmed by our recent studies by showing that the interactions between the two gases cause fine-tuning of the sGC function in vivo [15]. In this study, we applied the newly developed monoclonal antibody (mAb) 3221 against sGC that can recognize the specific structure produced by the enzyme activation. Immunohistochemical analyses of rat retina where the background NO-generating activities appear heterogenous among different neuronal layers revealed that light-induced upregulation of HO-1 activates sGC in retinal pigment epithelia (low NO), while it suppresses the enzyme in the inner plexiform layer (high NO). The physiological roles of CO in biological systems have not fully been investigated. However, distinct from NO, retina could benefit from the nonradical CO to maintain housekeeping cGMP without a risk of potential degradation of retinoids. Such a method of using CO is likely to be the case in relaxation of hepatic stellate cells to guarantee sinusoidal patency or in apoptotic control of spermatogenesis, where NO-breakable DNA or vitamin A is abundantly stored, respectively [16].

Glossary

Carbon monoxide: a gaseous monoxide produced through the breakdown of heme catalyzed by heme oxygenase.

Gas biology: a new concept proposed by authors. A new research field that investigates biological functions of gaseous molecules produced and/or consumed in cells and tissues.

Nitric Oxide: a gaseous signal molecule produced by nitric oxide synthases. It has numerous functions including relaxation of vascular smooth muscle cells and neural signal transduction.

Oxygen sensing: the ability of biological systems to sense the changes of oxygen concentrations in and around the cells.

Oxyradical bioimaging: a method for real-time imaging of behavior of oxygen radicals such as superoxide anion and nitric oxide.

CHAPTER 75

Lung Endothelial Cell Heterogeneity and the Microvasculature

Abu-Bakr Al-Mehdi, Kane L. Schaphorst, and Troy Stevens
Departments of Pharmacology and Medicine, Center for Lung Biology, University of South Alabama, Mobile, Alabama

Introduction

Although all individual endothelial cells share some properties in common, the vascular endothelium taken as a whole represents a conglomerate cell system that exhibits diverse biological functions. All endothelial cells lie on the luminal surface of a vascular basement membrane, thereby forming a continuous interface between blood (or lymph) and the tissue interstitium. In this position the endothelial cell is strategically positioned to fulfill an essential bidirectional signaling role. A critical function of the vascular endothelium is the formation of a semipermeable barrier that limits bulk water and protein transport from the vascular space, while specifically trafficking particular protein molecules, such as hormones and immunoglobulins, across the barrier. Under homeostatic conditions, the endothelial cell barrier is antiadhesive but may, in response to certain chemical stimuli, become proadhesive to facilitate the directed recruitment of white blood cells to sites of injury or infection. An additional role for the vascular endothelium apart from its ability to regulate permeability is its role in regulating vascular tone and distribution of flow. Endothelial cells produce multiple vasoactive autocoids that regulate vascular tone moment by moment. For example, nitric oxide and prostacyclin are well-recognized vasodilators, whereas endothelin and angiotensin-converting enzyme are well-recognized vasoconstrictors. These physiologic roles, which are essential vascular functions, clearly establish that the vascular endothelium is a key regulator of homeostasis.

While endothelial cells in all vascular beds or segments share certain features in common, there is a growing recognition of their phenotypic diversity as well. For example, endothelial cells lining different organs exhibit a discernible histological structure. Endothelium that lines the blood–brain barrier, skin, muscle, and connective tissue is continuous, whereas endothelium that lines the sinusoids of the hepatic or splenic circulations, red bone marrow, adrenal and parathyroid glands, and the carotid body is not continuous. Indeed, fenestrated endothelial cells (with transcytoplasmic vacuoles) are observed in vessels of glomeruli, some endocrine glands, pancreas, and intestinal villi. Whereas fluid readily permeates renal glomerular and liver sinusoidal endothelium, brain endothelium is nearly fluid impermeable. Similarly, striking diversity may also be found within a single organ and, in some instances, within the same vascular segment such as described by Majno and Palade [1], who observed histamine-induced intercellular gaps between the endothelial cells of postcapillary venules, but not in all immediately adjacent cells. Although the notion of heterogeneity of endothelial cells and its potential role in organ specific function is appreciated, the origins and mechanisms of heterogeneity are poorly understood.

Heterogeneity may be broadly defined as secondary diversity in a grossly "homogeneous" population. Morphological and functional cellular heterogeneity among a "homogenous" type of cell population can be related to developmental origins, anatomical and histological location, local environmental influences, and, most importantly, the pattern of gene expression. For example, in any particular

cultured cell type, considerable variation is seen with regard to cellular morphology and function. Some of the variations can be attributed to different stages of cell cycle, but others may be due to a differential organization, regulation, or expression of genes (i.e., due to epigenetic controls). The study of cellular heterogeneity and its origins not only is interesting from a theoretical biological viewpoint, but also is important in predicting the fate of a cell and, consequently, its contribution to the development of disease. Individual susceptibility to a particular disease, vulnerability to particular disease risk factors, or responsiveness to a particular treatment are all factors that likely represent manifestations of cellular heterogeneity.

Endothelial Cell Heterogeneity in the Pulmonary Circulation

The pulmonary circulation is unique among vascular beds in that it is the only organ system to receive 100 percent of the cardiac output through a low-resistance, low-pressure circuit. Within this unique circulation, different anatomical compartments can be distinguished between the macro- and microvascular segments and between the bronchial and pulmonary circulations. Whereas the bronchial circulation delivers oxygenated arterial blood from the left ventricle to support the bronchial and large airway tissues, the pulmonary circulation delivers mixed venous blood from the right ventricle through the pulmonary artery to the alveolar septal network for gas exchange. This oxygenated blood is then returned through pulmonary venules and veins to the left atria and ventricle for delivery to the systemic circulation. Considerable structural and functional diversity has been described among endothelial cells in these various compartments within the pulmonary circulation.

Heterogeneity among pulmonary endothelial cells of large vessels and capillaries is now well recognized both morphologically and physiologically. Morphologically, cells in larger vessels under laminar shear rates are elongated and aligned in the direction of flow, whereas those in the capillaries are not aligned in the direction of flow. Because of their exposure to different magnitude and types of shear stress, part of the heterogeneity may be attributed to adaptation to blood flow, suggesting that lung macro- and microvascular endothelial cells differ in their interpretation of and response to mechanical forces.

In addition, physiologic heterogeneity has also been demonstrated by various groups who have examined segment-specific permeability features of lung endothelium. Early work in this area illustrated most of the baseline fluid flux occurred across capillary (46%) and venous segments (38%). Segment measurements rely on subtracting arterial or venule permeability from total filtration. To ascertain these values, high airway pressure is typically used to collapse alveolar capillaries segments, stopping continuity of blood flow. Although it is unlikely that flow is completely abolished through corner vessels, these findings are broadly reflective of segment-specific responses. In fact, a series of subsequent studies have borne out these initial results, demonstrating pulmonary artery/arteriole segments account for 16 to 24 percent of basal water permeability, while capillary (36 to 50%) and venule/vein (33 to 46%) segments each account for the bulk of the circulation's total basal water flux [2]. Although this work illustrates that capillary endothelial cells account for a substantial portion of basal permeability, they do not suggest capillary endothelial cells are highly water and protein permeable. Indeed, when standardized to relative surface area, it becomes immediately apparent that the capillary endothelial cell barrier is 58 and 26-fold more restrictive to flux than either the pre- or postcapillary barrier segments, respectively.

It is of particular importance that precapillary (artery/arteriole), capillary, and postcapillary (venule/vein) vascular segments are differentially targeted by physiological and pathophysiological stimuli. In the case of increased airway pressure, which is relevant to ventilator-induced lung injury, increased permeability occurs primarily across capillary segments [2]. Similar results were observed by West and colleagues [3] in capillaries subjected to high vascular pressure that illustrated endothelial cell "stress failure" by electron microscopy. In the case of oxidant-mediated injury, which is relevant to lung transplantation, and in the case of hydrogen peroxide- and xanthine oxidase–induced vascular injury, postcapillary venule/vein segments are the preferential targets [4]. Increased permeability arising from either segment can eventually cause frank pulmonary edema if the rate of fluid accumulation exceeds the rate of reabsorption and clearance through the lymphatics. Thus, it is critical to understand the basis for such site-specific heterogeneity.

In 1997 our group demonstrated that the plant alkaloid thapsigargin activates store operated calcium entry and increases lung endothelial cell permeability. These findings indicate that calcium entry across the cell membrane is sufficient to produce intercellular gaps that form a paracellular pathway for water and protein transudation, similar to earlier work using G_q agonists such as histamine, thrombin, and substance P. However, upon close inspection of the pulmonary circulation, we resolved that not all segments were equally effected by thapsigargin [5]. Indeed, this agonist only induced intercellular gaps in arteries and veins larger than approximately 75 to 100 μm (Figure 1A). These findings suggested that rises in cytosolic calcium, through store-operated calcium entry channels, selectively targeted large vessel segments, prompting a more sophisticated evaluation of mechanisms of endothelial cell heterogeneity.

Evidence that thapsigargin increases permeability in pulmonary artery and vein segments, but not in capillary segments, suggests that neither drug concentration nor site-specific "environmental" influences underlie the heterogeneity in response. Another possible explanation is that endothelial cells within the large and small blood vessels arise from different progenitor cells and become imprinted

by their unique (site-specific) environments to achieve a differentiated phenotype. As these endothelia are genetically identical, multiple epigenetic (i.e., beyond the gene sequence) mechanisms likely account for the stable modifications in cell phenotype, including methylation of promoter sequences that inhibit gene expression, and acetylation of histone proteins that control access of transcription factors to promoter sequences [8].
