SITE PRESERVATION

Henk Kars
Geo- and Bioarchaeology, Faculty of Earth and Life Sciences, VU University, Amsterdam, The Netherlands

Definition

In situ preservation of archaeological heritage means the preservation of sites and remains in their original location within the burial environment, with the purpose of leaving archaeological sites intact, authentic, and as undamaged as possible. This is contrary to archaeological excavation, which can be seen as preservation ex situ.

Introduction

Subsumed within the idea of cultural heritage are structures, constructions, groups of buildings, developed sites, moveable objects, monuments of other kinds, as well as the context of all the aforementioned, whether situated on land or under water. This proposition was stated in the European Valletta Convention of 1992 (or the revised European Convention on the Protection of the Archaeological Heritage) as well as in the World Heritage Convention of UNESCO, which also includes natural heritage. For many years, there has been an awareness of the importance of preserving ancient monumental buildings; however, most of our archaeological heritage, reflecting many significant human activities of the past, is invisibly hidden in the soil. Archaeological resource managers realized several decades ago that preserving archaeological remains underground rather than excavating them should be the main policy in order to protect them for future generations. This policy of sustainable site preservation or preservation in situ using the burial environment as a storeroom has become a challenging research subject for geoarchaeologists. Nevertheless, in situ preservation is not always the best choice. Excavations can be conducted in order to make a significant contribution to our knowledge of the past, and this should be the case when the archaeological remains in question are threatened by any human or natural agency, such as urban developments, erosion, and changing environmental conditions. Sometimes, in situ preservation and excavation can be combined for optimum outcomes (see Figure 1).

Background

Recent developments in archaeological resource management have had a tremendous impact on perspectives regarding the sustainable protection and development of our archaeological resources. The archaeological record that lies beneath the ground surface – encompassing artifacts, sites, and former landscapes – is now seen as a resource for present and future generations rather than a static fabric of the past. This view is based on the rationale that research questions might evolve over time due to changing paradigms and that research methods will

Site Preservation, Figure 1 Sometimes excavation and site preservation are combined. The photograph shows a partially preserved burial mound. The open parts were excavated, while the remaining parts are protected and remain available for future investigations (Photo: Dutch Archaeological Monument Watch, 2007).

most certainly improve, including numerous technological advancements of the past few decades described in this volume as obvious examples. With changing questions and techniques, new excavations would need to be conducted on similar archaeological remains to reexamine old conclusions in the context of fresh ideas and capabilities. This also implies that archaeological sites will be preserved by inclusion within development schemes and not simply excavated as a quick solution to clearing the land for improvements. Both scientists and policy makers in the field realize that this proactive approach to heritage management must deal with several gaps in our knowledge. One major knowledge gap, for example, is how to preserve artifacts, sites, and landscapes within the burial environment when we understand that nearby land modifications or natural processes might over time affect soil parameters and impose secondary impacts on buried remains.

It is perhaps safe to assume that more than 95 % of the archaeological record worldwide is hidden in the soil and therefore invisible to the untrained eye. This means that, in terms of its perception by the general public, the cultural value of this archaeological record is close to zero. A convincing argument to the public might establish the value of preservation as a mostly intrinsic quality reflecting a potential source of knowledge about our past. How can the information present in features and artifacts within the soil tell us something about early people and former societies? These intrinsic qualities are first determined by the age and character of a site; however, the state of preservation of a site, i.e., how much of the original remains are intact or sufficiently undamaged, is the limiting condition with regard to the amount and clarity of information that can be retrieved from them. Sound and reliable knowledge of degradation mechanisms in relation to soil parameters is therefore essential in the decision-making process regarding the decision over excavation today versus in situ preservation. Yet, an informed decision requires material science specialists as well as experts in the fields of soil science, hydrology, geochemistry, and biogeochemistry.

An archaeological site and the burial environment

The site

With regard to the preservation of archaeological site contents, the first and major concern is the presence of artifacts made of vulnerable materials, like iron, bronze, glass, wood, leather, and bone, and of faunal remains, including human bones. Such remains are most likely to be adversely affected by changing burial conditions. Equally important to the archaeologist are the features in the soil that represent postholes, graves, ditches, storage pits, and extended cultural layers or earthworks. These anthropogenic soils provide much information pertaining to the type of site, its internal structure, and its relationship to the surroundings. These soils can be recognized and separated from natural soils by noting structural and textural differences and by determining their differing compositions, such as increased organic matter or oxides of iron and manganese, which are apparent in color variations compared to natural soils adjacent to the anthropogenic feature.

It is clear that a successful site preservation policy requires sustainable preservation of these anthropogenic soil features in addition to the artifacts and structures found in the site. Therefore, gaining insight into the depositional and postdepositional processes that have formed an archaeological site and preserved it up to the present is an important issue in site preservation studies. Effects of recent and future changes in soil conditions within the burial environment must also be understood. It is important to note that an archaeological site or landscape has to be considered an accumulation of physicochemical and biochemical metastable equilibria in artifact-soil systems, governed by many materials science and soil science parameters, and that these equilibria are critical to achieving sustainable site preservation. This insight is essential to provide decision makers with a risk assessment.

The burial environment

The basic approach in determining and measuring degradation processes in archaeological sites is to characterize their burial environment. By measuring specific soil parameters, degradation processes that might occur in the archaeological materials can be determined. Organic matter is the most reactive solid component in anthropogenic and other soils. The presence or absence of organic matter determines the impact of oxygen and other oxidizing substances (such as iron and manganese oxides, sulfate, and nitrate) on degradation processes, whether reducing conditions or pyrite formation occurs and whether oxygen can penetrate to the buried archaeological materials. Transport of water and reactive components is determined by the geohydrological setting and by the bulk density and porosity of the soil. Another important factor is the presence or absence of lime, which buffers the soil against increased acidity (low pH).

The advantage of this approach is that measurements can be taken relatively simply and with little or no damage to the archaeological site. An important drawback, however, is that these measurements do not provide direct information about what is happening to the archaeological material, nor do they measure active degradation in a particular situation. An additional problem is that very little is known about the rate of the degradation reactions impacting different archaeological materials in the ground. Deducing how rapidly such processes are likely to happen from the moment the burial environment changes and how severe the impact will be is not an easy matter. Therefore, a risk assessment of the site has to be assembled in order to develop a well-defined and cost-effective monitoring plan that will help to maintain the site in its present condition.

Monitoring

The first step in any monitoring plan is to gather information on the properties of the burial environment in relation to the archaeological contents of a site. This is needed for a balanced decision as to what cost-effective measuring methods should be applied and how frequently data should be collected. First, the contents of an archaeological site must be assessed in terms of the kinds of material represented, including especially the presence or absence of extremely vulnerable botanical remains, bone, and inorganics such as metal and glass. Second, the burial environment should be defined, which requires at least information on soil type, parent material, grain size, and organic matter content. In addition to this, the hydrological situation at the site should be described in terms of variations in groundwater level, seepage, drainage, or infiltration and the presence or absence of salt water.

Important soil parameters such as oxygen content and pH, which influence the preservation of archaeological materials, are governed by the dynamics of groundwater and the distribution of soil moisture. Knowledge of the present and likely future behavior of soil moisture at a site is therefore essential.

For many archaeological materials, the presence of oxygen is the key factor controlling degradation. Oxygen causes corrosion, and it is essential for biodegradation by aerobic microorganisms. With regard to the role of oxygen in the degradation of archaeomaterials in soils, a distinction should be made in soil moisture between the unsaturated and saturated zone. It is generally assumed that archaeological materials remain intact in the saturated zone, which is mainly true for areas with stagnating groundwater where the limited oxygen supports anaerobic microorganisms, which inflict minimal destruction. However, in areas with infiltration or seepage of oxygen-bearing groundwater, degradation gradually continues. In the unsaturated zone, empty pore spaces permit oxygen to penetrate directly into the soil, and thus it is available to fuel chemical and biological degradation.

This degradation involves redox reactions, with the transfer of electrons from an oxidizing agent (e.g., oxygen) to a reducing agent such as organic matter, which is present in almost any archaeological site. In addition to measuring the groundwater table, the use of redox probes is a common component of a monitoring program in order to gain insight into the activity of oxygen.

Additional methods can be integrated into the monitoring plan when needed. An example would be the use of micromorphology for gaining insight into the oxidation state of organic matter together with textural changes in the anthropogenic soils. Another example would be the examination of bones to assess their state of preservation not only for morphological study but also for their potential for (stable) isotope and ancient DNA analysis (Figure 2).

In addition to monitoring the preservation state of a site, mitigation measures have to be taken to avoid further degradation in some cases. An example of this is the World Heritage Site of Bryggen in Bergen (Norway), a preserved sector of the old harbor area with houses from as early as the fourteenth century. Monitoring has shown

Site Preservation, Figure 2 Postdepositional processes might have an effect on the usefulness of bone for future bioarchaeological investigations. This section through the root of a medieval human tooth reveals many framboidal pyrite (FeS_2) grains on the surface of the pulp cavity and root canals, and in places, it almost completely fills the root canals. The cementum and dentin of this tooth are stained yellow and orange, indicating infiltration by iron compounds possibly due to oxidation of the pyrite (see Hollund, 2013; Hollund et al., 2013).

damaging settling rates caused by degradation of the archaeological deposits underlying the present-day harbor front of Bryggen. It was established that building activities in the 1970s that erected a modern hotel among other constructions had a dramatic influence on the local groundwater regime, partially draining land beneath the old harbor structures, permitting them to decompose, which in turn initiated compaction of the weakened organic supports and caused them to settle. Infiltration of additional water was needed to stop the degradation of the organic deposits. Examples of solutions that have been designed and implemented include directing shallow infiltration of rainwater from local downpipes and a rainwater garden as a buffer between the upstream urban area and the heritage site (de Beer et al., 2008; Matthiesen, 2008).

Research topics

The current state of knowledge about degradation and preservation of most kinds of archaeological remains, together with an overview of methods for quality assessment of archaeological sites and methodologies for site monitoring, is given in Huisman (2009).

The research community in this field meets at the international Preservation of Archaeological Remains In Situ (PARIS) conferences, which have been held in London (1996, 2001), Amsterdam (2006), Copenhagen (2011), and Kreuzlingen, Switzerland (2015). The aim of these meetings is bringing practitioners (scientists and archaeologists) and stakeholders (cultural resource managers and policy makers) together in order to discuss the latest issues emerging from studies on degradation and monitoring of sites in urban, rural, and marine environments. Based on 20 years of multidisciplinary research, the following four themes can be recognized (Kars and van Heeringen, 2008; Gregory and Matthiesen, 2012):

1. *Degradation of archaeological remains*. Apart from understanding the processes of degradation in archaeological features and objects, can degradation rates under changing conditions be identified and assessed? What rates of deterioration are acceptable before mitigation must be conducted?
2. *Monitoring and mitigation studies*. What kind of monitoring strategies can be developed and for how long should a site be monitored to gain insight into the effects of changing conditions in the environment? Are geotechnical measures available and suitable to slow down processes of decay?
3. *Development of protocols and international standards*. Apart from diverging national legislations and policies, is it possible to develop standards for site monitoring and preservation when sites in relation to their burial environment are so extremely variable?
4. *State of the art of in situ preservation strategies*. Can the effectiveness of in situ preservation research be recognized and documented? Has it led to an improvement of site preservation?

SOIL GEOMORPHOLOGY

Vance T. Holliday[1] and Rolfe D. Mandel[2]
[1]Anthropology and Departments Geosciences, University of Arizona, Tucson, AZ, USA
[2]Department of Anthropology, University of Kansas, Lawrence, KS, USA

Introduction

Few aspects of the environment are as intimately linked to the landscape as are soils, and this linkage emphasizes the important role of soils in geoarchaeology. At its most fundamental level, soil geomorphology is the study of genetic relationships between soils and landscapes (e.g., Ruhe, 1956; Ruhe, 1965; Schaetzl and Anderson, 2005). Its focus is on pedogenic and geomorphic processes and sometimes a strong component of hydrology in order to understand the distribution of soils in the present (contemporary soil geography) and in the past. In a much broader sense, however, soil geomorphology includes the investigation of soils as a means of studying and reconstructing the past, with a focus on soils as (1) clues to past environments (especially vegetation and climate) and past landscapes (Gerrard, 1992; Birkeland, 1999; Schaetzl and Anderson, 2005), (2) age indicators, and (3) stratigraphic markers (see the entry on "Soil Stratigraphy" in this volume). The focus here is on the relation between soils and landscapes and soils and time.

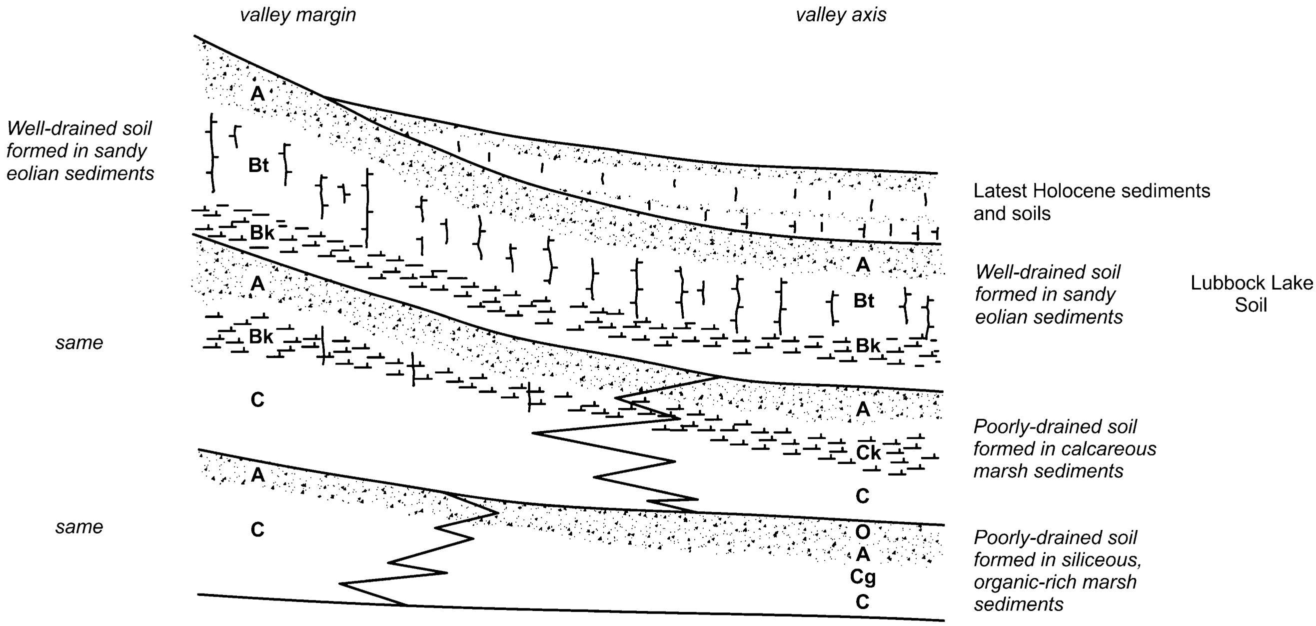
Soils and landscapes

Soils and archaeological sites are intimately related to the landscape. Investigating soils across past and present landscapes provides a means of reconstructing and understanding the regional environmental and geomorphic context of archaeological site settings and specific site locations, as well as regional site formation processes and aspects of the resources available to people in a region. Archaeological sites tend to occupy small segments of the landscape, but human activity may affect a much larger area, and in any case, people wander widely, well beyond the confines of sites, and in the process interact with the environment, including the landscape.

Soils are also important in reconstructing the evolution of landscapes and, consequently, the evolution of archaeological sites. Landscape evolution is an important external component of site formation processes. Landscapes form the physical framework or underpinning for people and their activities, and therefore for their resulting sites. As landscapes evolve, so do human activities, and so do sites. Soils are a key to recognizing and interpreting the evolutionary processes that shape the landscape and associated archaeological sites. The concept of landscape evolution is also (1) linked to soil stratigraphy because it places such stratigraphic sequences in three or even four dimensions; (2) an environmental indicator because landscape evolution can be linked to environmental change and because the evolution of the landscape itself, regardless of changes in other factors, represents a change in the environment from a human perspective; and (3) a means by which site locations can be predicted.

The variability of soils across a landscape due to topographic and hydrologic variability makes soils uniquely suited as indicators of past landscapes. Understanding the processes that produce soil variability and result in catenas (see the entry on "Soils" in this volume) provides an approach to making interpretations regarding past landscapes. This variability is related to the slope position and drainage characteristics of the soil. Ultimately, these factors are related to water movement over and through the soil. The rate and amount of water moving across the upper and middle segments of a slope are important in determining the presence or absence, and the amount and type, of erosion (in addition to determining vegetation characteristics), and the amount of water that moves into the soil is important in understanding weathering and solute transport. On lower slopes or at the foot of slopes, these factors, combined with groundwater characteristics, strongly influence sediment accumulation and solute input, in addition to vegetation and drainage, and they can contribute to soil *cumulization* (see entry on "Soil Stratigraphy" in this volume). The relative importance of surface movement of sediment and subsurface movement of solutes is dependent on slope angle and distance from slope crest, in addition to climate. A catena, therefore, results from the complex interplay between soil and slope processes and will be driven by the varying rates of erosion vs deposition on different parts of the slope. All landscapes with relief include zones of removal, transference, and accumulation.

Both stable and unstable catenas are present in middle and late Holocene strata at the Lubbock Lake site, Texas (Holliday, 1985a; Holliday, 1985b; Holliday, 1985c). The Lubbock Lake soil, formed in middle Holocene eolian sediments, illustrates a stable catena (Figure 1) where soil variability is due to varying topographic and hydrologic factors (and some parent material variation). The soil exhibits a valley-axis facies with a thicker, darker, locally cumulic surface horizon due to the more moist setting resulting from proximity to local marshes and high organic matter production, as well as local, slow



Soil Geomorphology, Figure 1 Generalized catenary relationships of soil-stratigraphic units at the Lubbock Lake site, Texas (Modified from Holliday, 2004: Figure 9.3).

aggradation. The valley-margin facies, in contrast, has a weakly expressed A horizon over a Bw-Bkw horizonation up to 2 m thick. The thickness of the soil is the result of rapid throughflow of water due to the coarse texture of the parent material, but the lack of illuvial clay and weaker expression of the A horizon is because less water moved into the soil due to rapid runoff and some erosion. The Lubbock Lake soil was buried along its middle and lower slopes during the late Holocene by slopewash and eolian deposits. Episodic sedimentation resulted in the formation of multistory, weakly expressed buried soils (Figure 1). This scenario is an example of an unstable catena.

A soil-geomorphic approach to an ancient paleocatena was used to reconstruct the paleo-landscape of hominins in Olduvai Gorge, Tanzania. Ashley and Driese (2000) identified a buried paleocatena in proximity to wetlands and dated it to ~1.75 Ma. The buried soils were then used to reconstruct the evolution of the local paleohydrology. The paleocatena was identified within a "cumulative red paleosol" formed in volcaniclastic parent material, and it was differentiated into an upslope and a downslope facies (over a distance of about 1 km). Compared to the downslope facies, the upslope facies was characterized by less evidence for plant rooting, greater clay translocation, and greater zeolitization (i.e., greater weathering of the volcaniclastic parent material). The downslope soil exhibited strong redoximorphic mottling, which was attributed to its proximity to an ancient lake. Also, the downslope soil exhibited evidence for two generations of redoximorphic features, separated by a phase of clay translocation, indicative of a shift from poorer drainage to better drainage and back to poor drainage. The changing drainage characteristics were attributed to fluctuations in lake level, among other factors (Ashley and Driese, 2000). By contrast, the upslope soil was oxidized and lacked redoximorphic features. Hence, the upslope setting was probably a drier and better drained site than the downslope one.

A reconstruction of soil-geomorphic relations was used in northwest Yucatán to answer questions about the degree of agricultural productivity necessary to support apparently high populations of ancient Maya in an agriculturally limited environment (Beach, 1998). The region is a -low-gradient plain. Soil variation results mostly from relatively minor topographic differences that divide the landscape into a coastal zone, a swamp estuary zone, a savanna zone, and a karst plain. The regional soil diversity is described largely on the basis of microrelief, which determines local drainage conditions.

In the coastal zone, the topography consists of beach ridges and swales. The soils are weakly expressed due to the youthfulness of the landscape (<5000 year BP), which apparently is "rejuvenated" by severe storms that cause erosion and uprooting of vegetation. Inland from the coastal zone is an extensive wetland estuary with mangrove swamp. Inland of the swamp estuary is a gradually rising zone of weathered limestone divided into a topographically lower and upper savanna characterized by swales and hillocks. In the lower savanna, groundwater seepage causes widespread precipitation of calcium carbonate and the formation of a dense calcrete. Thin but redder and more clayey soils are common throughout the upper savanna, in both depressions and hillocks. Soil development is significantly stronger in the upper savanna, probably because the landscape is better drained and drier, and because active precipitation of calcium carbonate, which maintains a relatively youthful landscape, is much less common. On the upland karst plain, soils are generally similar to those of the upper savanna in being relatively well developed. Soil variability is due to parent material lithology and to topographic setting. The soil studies in this region illustrate the severe limitations on agriculture (Beach, 1998, 786–787). About 50 % of the landscape has no soil. Only about 20 % of the soils are deep and fertile. Erosion probably was not and is not a factor in the soil patterns owing to the very low relief. If intensive agriculture had been practiced, it might have been within walled mounds and fields, where water and fertilizer were easily accessible.

Soils and time

The influence of time on soil formation is a unique characteristic of pedogenesis among geomorphic processes that, like topographic variability, serves to distinguish soils and soil-forming processes from other geomorphic phenomena. The passage of time allows pedogenic processes operative at a given location to alter the parent material and produce a soil. The physical, chemical, and biological processes of soil formation generally are much slower than many if not most processes of sedimentation and erosion. Moreover, most soil-forming processes are so slow that their effect on the soil is markedly time dependent (Birkeland, 1999, 144).

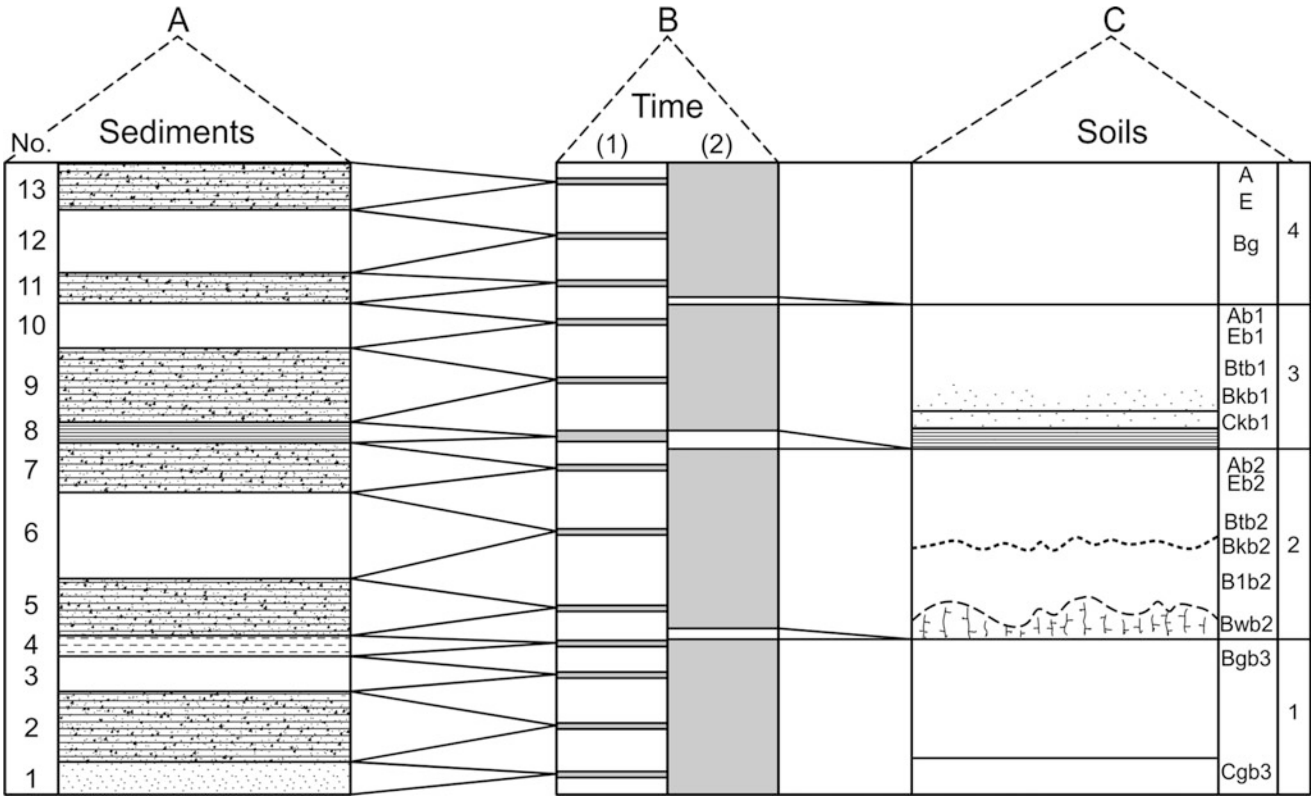
Time as a factor of soil formation is a key concept in soil geomorphology and has driven much soil-geomorphic research (Yaalon, 1975; Yaalon, 1983; Knuepfer and McFadden, 1990; Birkeland, 1999). Because time is an important consideration of much archaeological research, the time-factor concept of soil genesis can also play a significant role in geoarchaeological research (Holliday, 1990; Holliday, 1992; Holliday, 2004). The concept that some time must elapse before a soil can form is a significant aspect of soil development in an archaeological context.

The association of archaeological materials with a soil or the presence of a soil or soils in a stratigraphic sequence at an archaeological site is of direct and fundamental significance to the interpretation of the archaeological record. Soils require some amount of time to form, and the development of a soil requires a relatively stable landscape, one that is neither aggrading nor eroding at rates that exceed pedogenesis. Thus, a soil denotes the passage of time under conditions of relative landscape stability. A buried soil in a stratigraphic sequence, therefore, denotes a hiatus in deposition, i.e., a kind of unconformity. In such a sequence, the sediment (which is the parent material for the soil) may have accumulated rapidly or slowly, but a significant period of no deposition and no erosion had to occur in order for the soil to form. Under some circumstances, deposition can occur quickly – possibly in a matter of days, years, or decades. Soil formation, in contrast, almost always takes longer: usually at least a century or several centuries and commonly millennia (Figure 2), though see exceptions below (e.g., Birkeland, 1999; Holliday, 2004). In a stratigraphic sequence, the accumulation of deposits represents the passage of time sedimentologically, and the alteration or weathering of those deposits represents the passage of time pedologically. In settings where sedimentation is episodic and buried soils are common, soil formation may take up a significant amount of the time represented in a stratigraphic sequence (Figure 2) (e.g., Kraus and Bown, 1986; Holliday, 1992).

> In archaeological investigations, consideration of landscape stability, as indicated by soil development, is important in locating cultural deposits, interpreting artifact associations and contexts, defining site stratigraphy, reconstructing the depositional and landscape history, and establishing cultural chronologies. (Mandel and Bettis, 2001a, 175)

These fundamental characteristics of soil formation and time are of paramount significance in geoarchaeological research. In searching for archaeological sites or other evidence of human activity in stratigraphic sequences with buried soils, the surfaces of the soils (i.e., the A horizons) will be more likely than other parts of the soil or parent material to contain artifacts and features because (1) they represent surfaces that were stable for some duration of time, and (2) human occupation is more likely on a stable surface than it is on a landscape undergoing rapid sedimentation. This aspect of A horizons has influenced the development of strategies in surveying and prospecting for archaeological sites, especially in buried settings (Michlovic et al., 1988; Ferring, 1992; Picha and Gregg, 1993; Stafford, 1995).

Furthermore, the degree of soil development can be of considerable help in deciphering the archaeological record associated with buried soils and buried surfaces. Put simply, buried soils can be viewed as representing time in two basic stratigraphic forms: (1) as weakly developed soils, each representing a relatively short time (i.e., a relatively brief interval of soil formation between periods of deposition or between periods of deposition and erosion), or (2) as better developed soils representing longer intervals of nondeposition and landscape stability (though soil development is expressed in a wide continuum of degrees of development). The relative amount of time taken up by pedogenesis in these settings will still greatly exceed that taken up by deposition (Holliday, 2004, 140–144), but the time will be parceled out among the individual deposits and soils (Figure 2). Archaeological sites in these settings will be well stratified with superposition of artifacts and features that resulted from serial occupation of sites (Ferring, 1986).



Soil Geomorphology, Figure 2 Illustration of a hypothetical alluvial sequence consisting of layers 1 through 13 (column A) and associated soils 1 through 4 (column C) (Modified from Kraus and Bown, 1986: Figure 1). Column B indicates the relative proportion of time occupied by deposition (B1) and soil formation (B2) (Modified from Holliday, 2004: Figure 7.1).

In contrast to weakly developed soils, more strongly expressed soils represent long intervals of soil formation between periods of instability. Archaeologically, this is particularly significant because slow deposition during multiple episodes of occupation results in accumulation of archaeological debris as mixed assemblages on paleosurfaces (Ferring, 1986). That is, the archaeological evidence for repeated occupations is compressed into the A horizon of a single surface, thereby forming archaeological palimpsests. Assuming "that the probability of cultural utilization of a particular landscape position is equal for each year, it follows that the surfaces which remain exposed for the longest time (i.e., the surfaces of the better developed soils) would represent those with the highest probability of containing cultural remains" (Hoyer, 1980, 61). The formation of a soil at an archaeological site, therefore, can profoundly influence the nature of the archaeological record and interpretations of the cultural history of the locality. Long spans of time are represented by the surface of a well-developed soil and, therefore, long records of habitation can be compressed into zones only a few centimeters thick. In searching for archaeological sites, the A horizons of well-expressed buried soils are more likely than weakly developed ones in the same area to contain occupation debris, but that debris is more likely to be a mixture of artifacts from multiple occupations.

There are several notable, archaeologically significant exceptions to the concept of brief, relatively rapid intervals of sedimentation or erosion separated by relatively lengthy intervals of stability and pedogenesis. Bogs or marshes (Histosols) are characterized by prolonged accumulation of organic matter, and they do not necessarily require surface stability to form. Other cumulizing or accretionary settings, locally found on many landscapes, also are exceptions. In some floodplain or toe slope settings, multiple, very weakly developed soils occur, formed during brief intervals (a few years) of stability between episodes of deposition. These soils are products of gradual accumulation of organic matter derived from in situ vegetation and detrital sources. A recent systematic study of late Quaternary landscape evolution in the US Central Plains documented widespread, deeply buried cumulic paleosols with weakly to moderately developed profiles that represent Paleoindian-age landscapes in terrace fills of high-order streams, in alluvial fans, and in draws in areas of the High Plains (Mandel, 2008). These paleosols have become targets in archaeological surveys that focus on the early record of human occupation in the Great Plains (Mandel, 2006).

With archaeological surveys, the problem of locating sites of a particular cultural period is one of determining where in the landscape sediments of that period are preserved (Artz, 1985; Mandel, 1992). In other words, knowledge of the distribution of the various-age deposits that comprise landscapes is essential in order to evaluate those landscapes for evidence of past human occupation (Bettis, 1992, 132; Mandel and Bettis, 2001a; Mandel, 2006; Beeton and Mandel, 2011). In most areas, soil variability across the landscape is an important indicator for estimating the age of landforms and sediment assemblages that underlie them. Many studies have demonstrated that the magnitude of soil development provides important clues to the relative ages of geomorphic surfaces and underlying deposits (e.g., Yaalon, 1971; Vreeken, 1975; Gile et al., 1981; Harden, 1982; McFadden and Weldon, 1987; Birkeland and Burke, 1988; Karlstrom, 1988; Dethier, 1988; Bettis, 1992; Holliday, 1992; Birkeland, 1999). Because surface soils can provide relative time control and can be mapped (see the entry on "Soil Survey" in this volume), they may be used to devise "quick and dirty" strategies for assessing the cultural resource potential of a survey area.

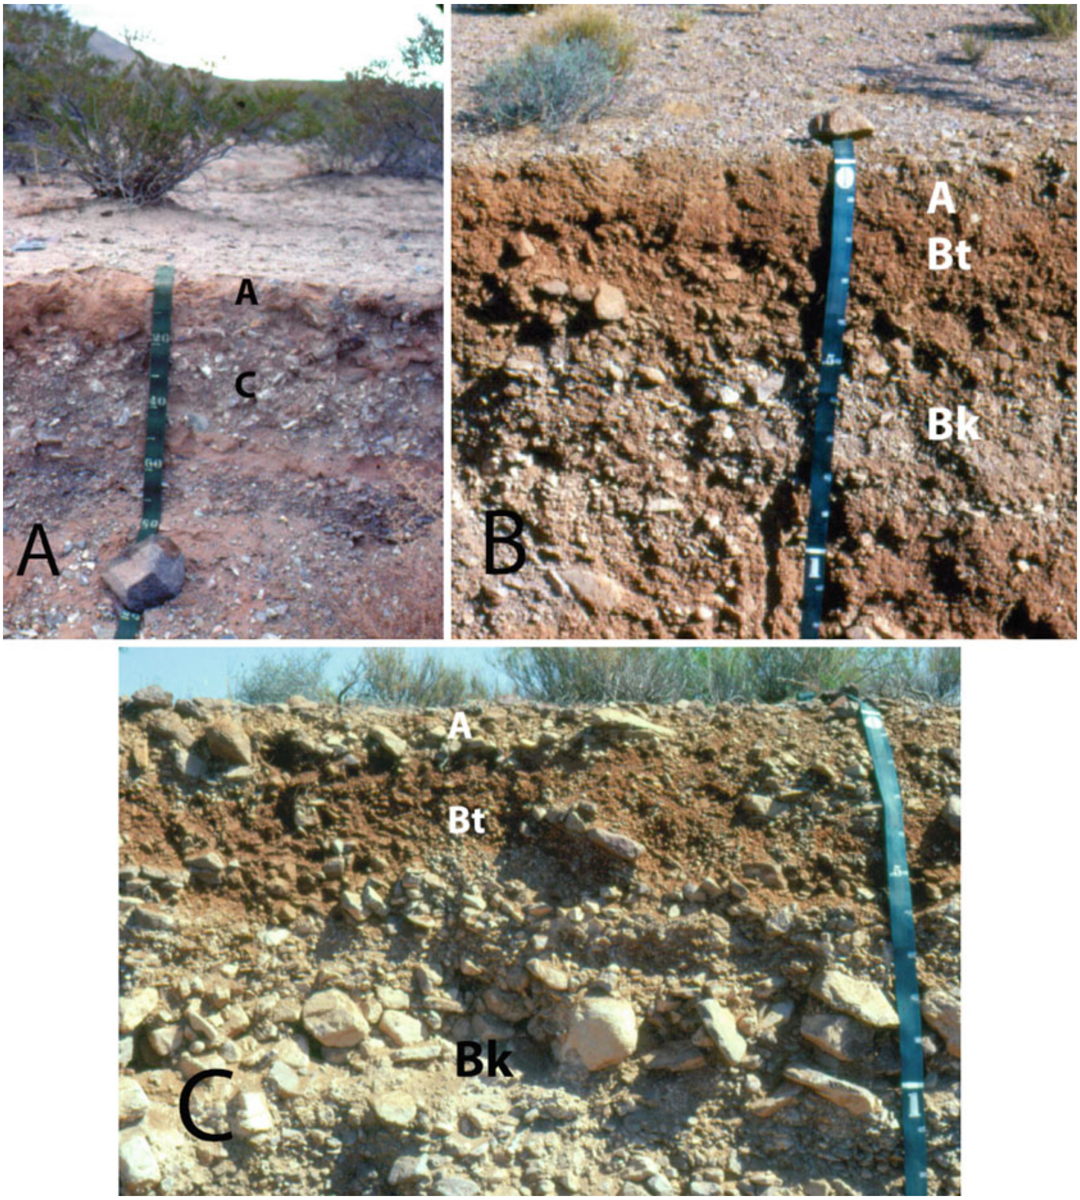
Soil "chronosequences" are especially useful in finding or interpreting archaeological sites at the surface. A soil chronosequence is a group of soils whose properties vary primarily as a function of age variability (Figure 3). The soils in a chronosequence formed in similar parent materials in similar landscape positions under a similar climate and vegetation. The primary difference in the genesis of the soils is that their age is different from landscape to landscape. For example, many chronosequences are defined for the surfaces of a set of alluvial terraces whose ages vary but where the parent materials and landscape settings are the same and the climate and biota have changed little (or the changes can be controlled for). In such a terrace chronosequence, the soils on the higher terraces typically will have more strongly developed profiles than the soils on the lower terraces because the higher terraces are older, and there was more time for pedogenesis (Figure 4) (e.g., Holliday, 2004: Table 7.2). As a corollary to this definition of a chronosequence, in an area where there are a number of soils and where the influence of parent material, landscape position, climate, flora, and fauna was similar among the soils and did not vary through time, the soils with stronger profile development probably are older than those that are less developed.

Soil chronosequences also occur across terraces where laterally inset alluvial fills aggraded to approximately the same elevation. For example, in the South Fork Big Nemaha River valley of southeastern Nebraska, Mandel and Bettis (2001b) observed a complex mosaic of soils across the T-1 terrace, with a well-developed Mollisol characterized by a thick A-Bt profile occurring near the valley wall, a less-developed Mollisol with a thin A-Bw profile occurring in the middle of the terrace, and a poorly developed Mollisol with an A-C profile near the modern channel of the river. A long cutbank that formed perpendicular to the axis of the valley revealed that at least three laterally inset fills occur beneath the T-1 terrace, and subsequent radiocarbon dating of the fills indicated significant time-transgression going from the proximal to the distal portions of the T-1 terrace (Figure 5). Hence, soil variability on the terrace represents the effect of time, with the most poorly developed soils occurring at the top of the youngest alluvial fill, proximal to the channel, and the most strongly developed soils occurring at the top of the oldest fill, distal to the channel.

Once a chronosequence is identified and investigated, it can be used as a dating tool in several ways. One application is simply for stratigraphic correlation of modern surfaces. Knowing that a soil of a given age in a particular landscape setting will exhibit a certain morphology is very useful for estimating the age of soils and, hence, landscapes throughout a region. Understanding the age of a landscape can then aid in predicting the age limits of archaeological finds on the surface and predicting the likelihood for sites below the surface. For example, in North America, the surface of an alluvial terrace with soil development suggestive of tens of thousands of years of stability and soil genesis could have the full age range of archaeological occupations known on the continent (i.e., the past ~15,000 years).

Bettis (1992) and Bettis and Hajic (1995) have developed a model to predict the ages of alluvial landscapes, alluvial deposits, and associated archaeological remains for Holocene streams in the Midwestern United States (Table 1). The model is intended to aid archaeologists in adequately sampling the archaeological record, predicting site locations, and estimating the ages of sites. The distinguishing criteria for differentiating Historic, late Holocene, and early and middle Holocene alluvial deposits are easily observed properties of deposits and soils that can be recorded by archaeologists with only modest knowledge of soils and geomorphology (Bettis, 1992, 120). The model is based on soil morphology and on color and mottling characteristics in the subsoil alluvium. The resulting model is a good example of increased soil development as well as mottling and subsoil iron oxidation with time.

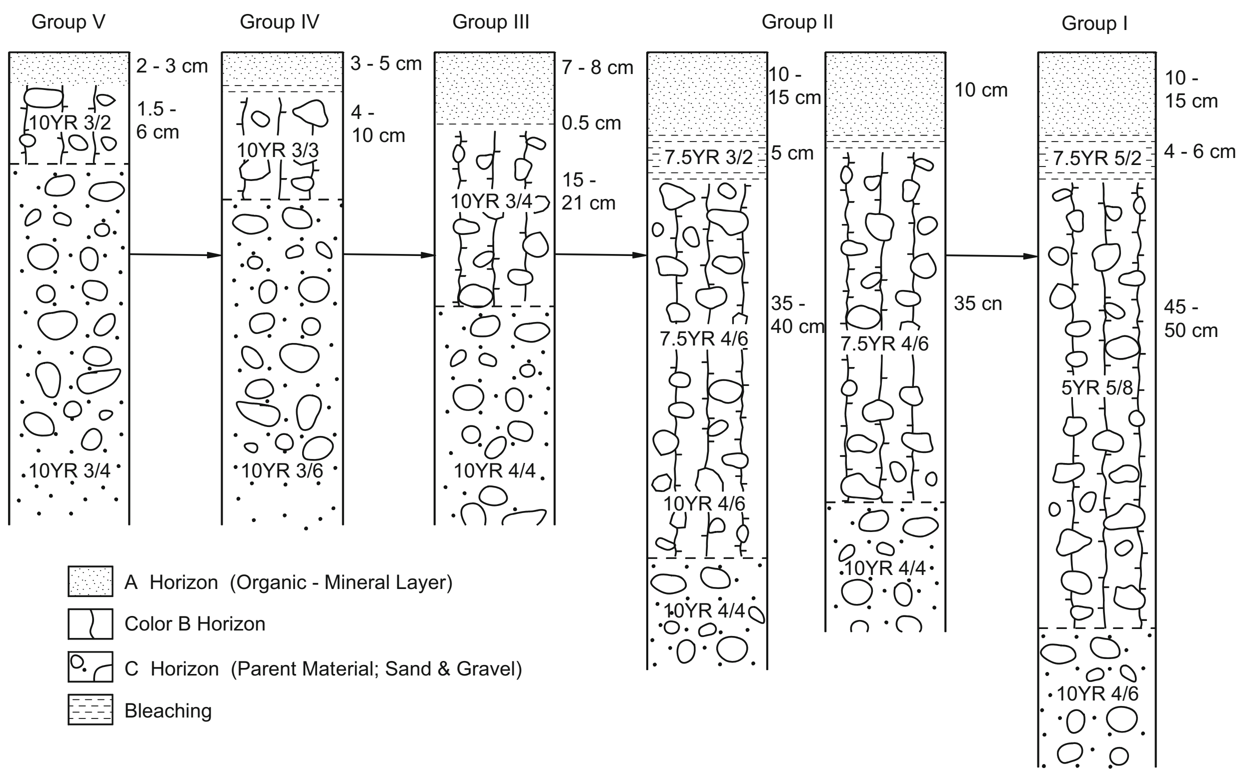
In a study of eight archaeological sites in the central Upper Peninsula of Michigan, Anderton (1999) used soils to provide temporal context for cultural deposits. The sites, which are associated with mid- and late Holocene paleoshorelines of the ancestral Great Lakes, contain stone flakes and fire-cracked rock but rarely yield temporally diagnostic artifacts or ^{14}C-datable materials. Based on the ages of the former shoreline, most researchers had assumed that the sites represented Archaic occupations dating to ca. 5000–2000 BP. However, Anderton (1999) suspected that former shorelines were also occupied by later Woodland cultures. By considering the expected pedological and archaeological characteristics, he developed



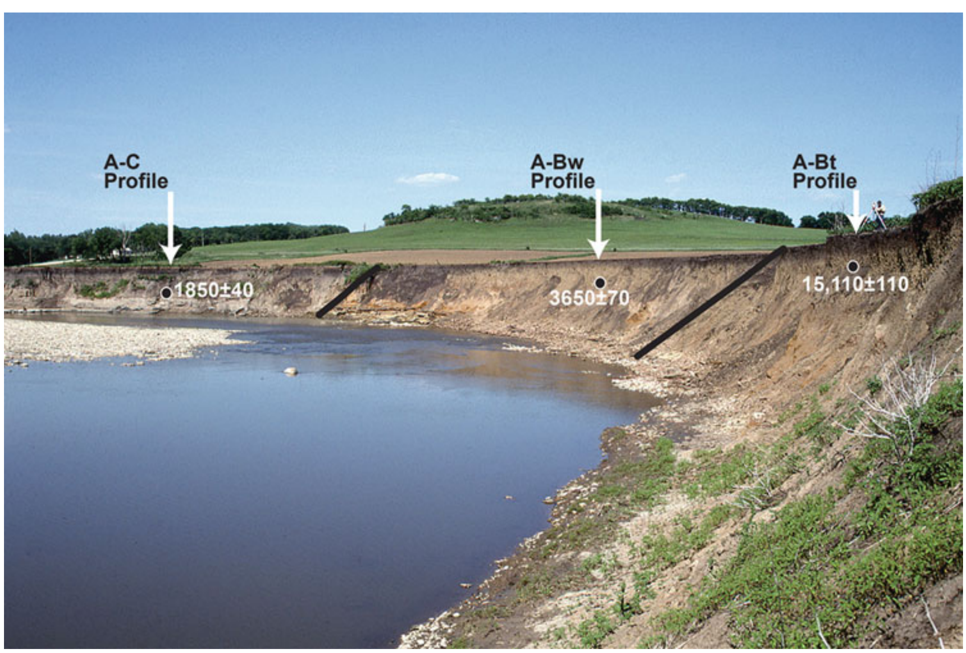
Soil Geomorphology, Figure 3 A soil chronosequence illustrating the development of the Bk horizon (zones of secondary carbonate accumulation) in piedmont alluvium along the Rio Grande River near Las Cruces, New Mexico (following Gile et al., 1981): (**a**) Alluvium <1000 years old with minimal carbonate accumulation or horizonation; (**b**) alluvium ~6000 years old with weak but distinct carbonate accumulation; (**c**) alluvium >25,000 year old with well-expressed Bk horizon. The Bt horizon is better expressed with time, but its characteristics (reddening and increased content of illuvial clay) are not well illustrated in photos. Scales are in centimeters (Photos by Vance Holliday).

a soil-artifact context model that provided a preliminary means of relative dating. Specifically, sites that were correlative with shoreline development (i.e., Archaic occupations) have artifacts that are deep within the soil profile; they reveal soil horizon boundaries that cut across middens, and some recovered artifacts are iron stained from spodic horizon development. By contrast, sites that post-date shoreline development (i.e., Woodland occupations) have artifacts that are at or very near ground surface. Also, Woodland cultural features, if present, cut across soil horizons, and the artifacts generally are not iron stained.

In the Old World, the chronosequence approach has been successfully applied in geoarchaeological contexts in Greece. Research on late Quaternary stratigraphy, geomorphology, and geoarchaeology resulted in the definition of soil "maturation stages" (MS 1–6, ordered youngest to oldest) based on the degree of color (rubification) and structural expression and clay film and



Soil Geomorphology, Figure 4 An example of soil development through time as illustrated by soil formation in a terrace chronosequence in Scotland (Robertson-Rintoul, 1986: Figure 5) (Modified from Holliday (2004: Figure 7.17)). The alpha-numeric notations with "YR" are Munsell soil colors and indicate progressive reddening due to iron oxidation.



Soil Geomorphology, Figure 5 The north bank of the South Fork Big Nemaha River in southeastern Nebraska showing a series of laterally inset alluvial fills beneath the T-1 terrace. The magnitude of soil development varies across the terrace and is an example of a chronosequence directly related to the age of the fills. All of the radiocarbon ages were determined on charcoal (Photo by Rolfe Mandel).

Soil Geomorphology, Table 1 Criteria used to group Upper Midwestern alluvial deposits into age-morphologic groups[a]

Age-morphologic group	Bedding	Weathering zone[b]	Mottles	Surface soil (horizon sequence; B horizon color)
EMH[c]	Restricted to the lower part of the section	O, MO, R, or U in part of some sections	Common; brown, reddish- brown, and/or gray	A-E-Bt or A-Bt; brown B horizon
LH[d]	Usually restricted to the lower part of the section	Color usually 10YR hue,[e] values 4 or less, chroma 3 or less; disseminated organic carbon imparts dark colors; may be O or U, but the matrix colors are dark because of organic carbon content	Rare; usually not present	A-Bw; dark-colored B horizon
Historic	Present throughout section if >50 cm in thickness	O; MO; R; some sections dark colored because of high organic carbon content	Can be present or absent; brown, reddish brown, or gray	A-C; no B horizon

[a]From Bettis (1992: Table 4–3)
[b]*O* oxidized, *M* mottled, *R* reduced, *U* unoxidized
[c]*EMH* early and middle Holocene
[d]*LH* late Holocene
[e]Munsell color designation

Soil Geomorphology, Table 2 General soil-stratigraphic and soil-geomorphic characteristics of alluvium on the Argolid and Argive Plain of southern Greece[a]

Soil name	Horizon sequence	Diagnostic features	MS[b]	Age of alluvium
Kranidhi	A-C	Thin to nonexistent A horizon; stratified parent material	1	
Upper member Flambouro	A-C	Thin A horizon; some mixing of parent material stratification	1	
Lower member Flambouro	A-Bw/Bk-C	Well-developed A horizon; weak Bk 10YR 4/3 B horizon	1	
Pikrodafni	A-Bt/Btk-C	Well-developed A horizon; weak-moderate Bk 5YR 4/4 Bt horizon w/few, thin clay films	2	2700–1400 BC
Upper Mbr Loutro	A-Btk-C	Eroded A horizon; moderate Bk 7.5YR 4/4 Bt horizon w/common, thin clay films	3/4	45,000–32,000 year
Middle Mbr Loutro	A-Btk-C	Eroded A horizon; moderate-strong Bk thick 5YR 4/6 Bt horizon w/thin, common clay films; no stratification in upper 2 m	5	>60,000 year
Lower Mbr Loutro	A-Btk-C	Eroded A horizon; strong Bk thick 2.5YR 3/6 Bt horizon; no stratification in upper 3 m	6	>250,000 year
Upland soil	A-Bt-C	Thick, dark A horizon; thick Bt horizon w/thick, continuous clay films		

[a]Data from Pope and van Andel (1984: Tables 1 and 2) and van Andel (1998: Figs. 6) (Modified from Holliday, 2004: Table 6.1)
[b]Maturation stage

calcic horizon development (Table 2) (Pope and van Andel, 1984; van Andel, 1998). The sequence is calibrated on the basis of numerical dating methods. One geoarchaeological example of the use of the MS index is in assessing the association of mid-Paleolithic artifacts with buried soils throughout Greece. Many artifacts are found in areas that were once internally drained basins with ponds, associated with sediments expressing little or no pedogenesis, implying brief occupation of an active landscape (van Andel, 1998, 383). Other artifacts are found within "very mature Bt horizons," suggesting occupation of a slowly aggrading but otherwise stable landscape lacking in the attractions offered by the wetlands (van Andel, 1998, 383).

Definitions

Birefringence fabric (b-fabric): patterns of orientation and distribution of interference colors in the micromass seen in crossed-polarized light.

Fabric (micro): the spatial arrangement of the soil constituents, including solid material, pores, and their shape, size and frequency.

Groundmass: the coarse and fine material that forms the basic material of the soil in thin section.

Microfacies: the body of sediment seen in thin section with microscopic characteristics such as composition, grain size, and sedimentary structures that are recognizably different from surrounding sediments.

Pedofeature: discrete fabric units in soil material. They are characterized by different concentrations in one or more components or internal fabric from the adjacent groundmass.

Petrographic or polarized light microscope: a microscope equipped for observation of thin sections in transmitted polarized light.

Sedimentary structures: bedding and surface features produced at the time of deposition.

Structure (micro): size, shape, and arrangement of particles, voids, and aggregates of the soil.

Soil micromorphology: the study of undisturbed soil and related materials at the microscopic level.

Thin section: a thin slice (ca. 30 µm thick) of intact material glued onto a glass slide.

Introduction

Soil micromorphology is the microscopic study of the soil, and since it usually employs the use of petrographic thin sections, it is similar to the geological discipline of petrography. The basic analytical equipment of soil micromorphology is the petrographic or polarized light microscope. Invented in the nineteenth century, the petrographic microscope was initially used to identify rock-forming minerals, and its application to sediments (sedimentary petrography) was undertaken by the English geologist Henry Clifton Sorby in the 1860s. Nowadays, petrographic microscopy is applied to numerous disciplines, including pedology, biology, archaeology, and environmental as well as material sciences. The application of petrographic microscopy to geoarchaeological contexts is relatively recent, but it is a corollary of the development of soil micromorphology and the interest of pedologists and geologists in archaeology.

History of application

In pedology, the use of the petrographic microscope began with Kubiëna (1938), who was primarily interested in using the internal organization of a soil to interpret its genesis. Soils are generally fine grained and form by sub-macroscopic processes, such as vertical transportation of fine material, solution and colloidal movements, and chemical alterations. The soil groundmass is part of a dynamic system that responds to these processes and leads to the formation of microscopic fabrics and pedofeatures that are related to soil development and origin. Therefore, the microscopic study of soils is a physical continuation of macroscopic observations of their morphology. A considerable body of literature exists on the application of soil micromorphology in pedology, including studies of fossil soils (paleosols) that have provided significant data for the study of Quaternary environments (Macphail, 1986; Macphail et al., 1987; Goldberg and Macphail, 2006).

As early as the end of the nineteenth century, petrographic methods were used to understand the genesis of limestone, and later, in the early 1950s, the concept of microfacies was employed in the study of carbonate and similar sediments (Flügel, 2004). However, clastic sedimentology is first concerned with field observation of bedding and sedimentary structures. Most sedimentary

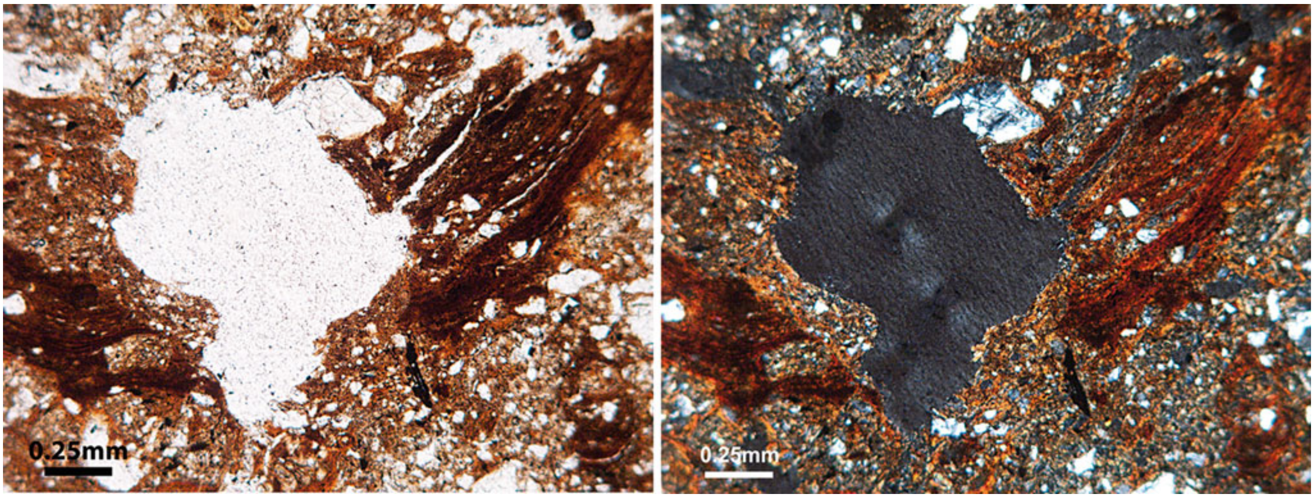
Soil Micromorphology, Figure 1 Micromorphological sampling. Carved out blocks of sediment (**a**) are jacketed with gypsum cloth (**b**) to ensure safe removal. Note that the lowermost sample (no. 157221) was encased in plaster of Paris to prevent collapse of the loose sand in its lower part. Caves PP5-6, Mossel Bay, South Africa.

environments are characterized by a variety of textures, and fine-grained sediment represents a fraction of the continuum. Therefore, very few petrographic studies of fine-grained sediment outside of carbonate sediments have been conducted. Such studies are mainly focused on marine muds (Förstner et al., 1968; Kuehl et al., 1988, 1991) or colluvial and mass wasting deposits (Mücher et al., 2010, and references therein).

Cornwall (1958) was the first to apply micromorphology in an archaeological context, but it was not until the 1980s that micromorphology really began to be applied in archaeology (Goldberg, 1980; Courty et al., 1989). The need for a contextual approach in archaeology has found its implementation in micromorphological analysis. Archaeological deposits, in most cases, are difficult to study and interpret through field observations alone. They have a complex macrostructure, are mostly fine grained, have diverse organic and minerogenic compositions, and commonly lack obvious macroscopic sedimentary structures. Thus, microscopic study is the most logical tool to provide the basis for characterizing archaeological deposits. Similarly, depositional processes can be studied to provide the initial and basic framework for applying other techniques that can further elucidate details of formation processes. Micromorphological applications in archaeology have increased markedly during the last three decades, resulting in increased recognition of anthropogenic sedimentary processes. A new dimension in the application of micromorphology in archaeology is the introduction of microfacies as used in sedimentology (Courty, 2001). Realization has gradually emerged that, in order to provide a better integration of microscopic techniques into the archaeological record, concepts and methods of sedimentology have to be adopted. Sediments dominate archaeological settings, and therefore microfacies analysis provides a new tool for refining visual classification of features. Classification of facies across strata is based on morphological and lithological similarities that are assumed to have similar origins and relate to the same mode of deposition (Courty, 2001). More and more studies on site formation processes are using the concept of microfacies with successful results (Macphail et al., 2004; Goldberg et al., 2009; Kourampas et al., 2009; Díaz and Eraso, 2010; Karkanas et al., 2011).

Methodology and techniques

The major methodological difference between a petrographic thin section and micromorphological thin section is in the preparation of the samples: petrography normally employs rocks and indurated materials, whereas micromorphological samples are typically nonconsolidated. The first step in micromorphology is to take an undisturbed, oriented sample from excavated or natural profiles, or even cores (Figure 1). Several techniques are employed, each having its limitations (Goldberg and Macphail, 2003). One of the most typical sampling techniques is the use of Kubiena boxes, metal boxes with double lids. During sampling, one lid is removed, and the frame of the box is inserted into the soil. Then, the frame is dug out, and the lid is replaced. Kubiena boxes are suitable for relatively firm and stone-free soils or sediments. However, archaeological deposits are very heterogeneous and not always consolidated. There is substantial lateral and vertical variation, and sediments can change from very coarse to fine grained over only a few mm; they can also commonly contain coarse clasts of rock, pottery, lithics, or bones, which interfere with sampling. Complex layering and lamination as well as inclined contacts are often observed in archaeological profiles. In order to understand how these changes were formed, they must be included in a single sample that preserves all features intact. It is thus not practical to use Kubiena boxes, and a large monolith is obviously required (Figure 1).



Soil Micromorphology, Figure 2 Photomicrograph of compound layered dusty clay and silt infilling and juxtaposed silt coating; *left*: plane-polarized light (*PPL*) and *right*: crossed-polarized light (*XPL*). Note the *bright red* birefringence due to orientation of clay laminae in XPL. Such pedofeatures have been attributed to human-induced soil disturbances (e.g., cultivation). Vashtëmi, Albania.

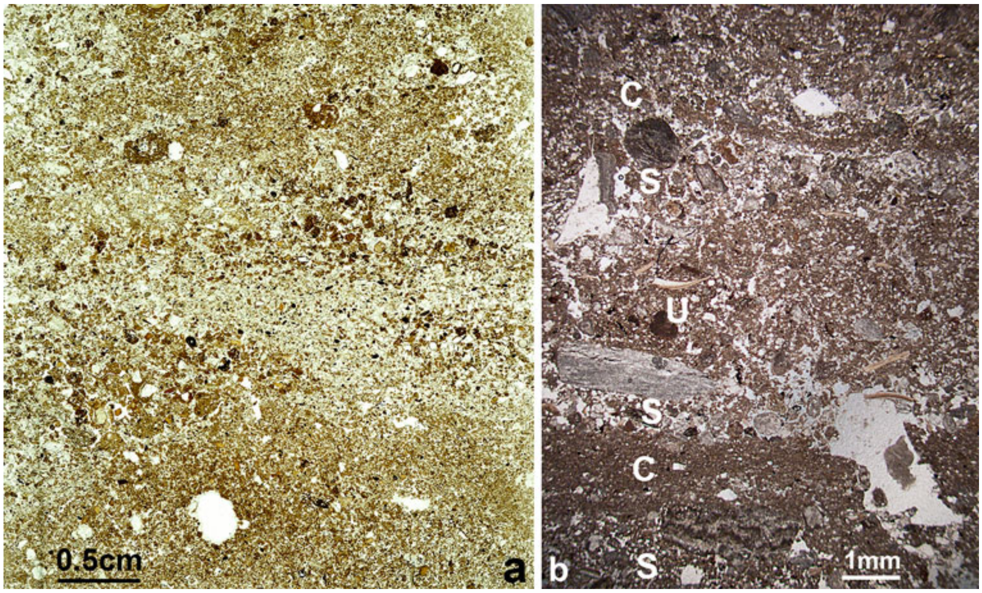
There are several techniques for sampling monoliths, such as cutting blocks of appropriate dimensions using hammer and chisel out of strongly consolidated sediments or carving blocks using a sharp knife in relatively firm sediment, or applying plaster of Paris or gypsum cloth to the surface of blocks carved from loose stony sediments (Figure 1) (Goldberg and Macphail, 2003). The dimensions of the sampled blocks vary according to the type of sediment, the stratigraphy of the site, the aim of the analysis, and the size of the finished thin section. Although monoliths of 15 × 15 × 40 cm are commonly collected, 10 × 10 × 15 cm-size blocks are more typical. It also follows that the stratigraphy of the site will dictate the number and location of samples and if the sampling will be systematic or selective. The samples are oven-dried at 50 °C for several days and then impregnated – under vacuum if a large enough chamber exists – with polyester resin diluted with styrene or acetone. Finally, petrographic thin sections of various large formats (7 × 5 cm up to 8 × 15 cm) are prepared.

The finished thin sections are studied with stereomicroscopes and petrographic microscopes at magnifications ranging from 1 to 500×. It is best to examine the thin sections first over a large area with a stereomicroscope, which permits observation of the nature of peds (natural soil particulate aggregates) in soils and the geometry of some relatively large features often encountered in archaeological deposits. Indeed, several of the patterns of arrangement of microscopic elements are best observed with a stereomicroscope or by observation of high-resolution scans of the thin sections (Arpin et al., 2002). Polished slabs of the blocks should also be examined before the thin sections are studied for the same reason. In addition, the same thin sections or polished parts of them can be studied using an SEM to magnifications of several thousand times; at the same time, selected spots can be analyzed chemically for their elemental content with electron microprobe techniques.

One of the main limitations of micromorphology in archaeology is the representation of results (see, e.g., Weiner, 2010, 74). The size of a thin section is relatively small in relation to the distribution of relevant variations observed in the sampled unit, and therefore the scale of these variations should also influence the sampling strategy. However, field observation is a prerequisite of good micromorphology, so the best sampling strategy is to establish while in the field the main facies that constitute the stratigraphy. The number and types of facies will determine the number of samples and the type of sampling. Microscopic examination of the main facies types eventually will lead to the creation of sub-facies, and in this way a refinement of the original sampling strategy will follow. As has been summarized by Courty (2001, Figure 8.3), a long-term iterative field/laboratory strategy provides the best representation of materials for interpretation.

Micromorphological analysis

Under the microscope, the coarser grains (sand size and larger) are examined for mineral and organic composition, abundance, size, shape, and distribution. The finer matrix material (silt and clay) can be observed only with respect to its internal organization, which is expressed under crossed-polarized light by interference colors and birefringence. For instance, clay particles in fine textured sediments are horizontally oriented as a result of gradual settling, and this orientation displays birefringence orientation in the form of parallel extinction when observed in thin section between crossed polarizers (Figure 2).



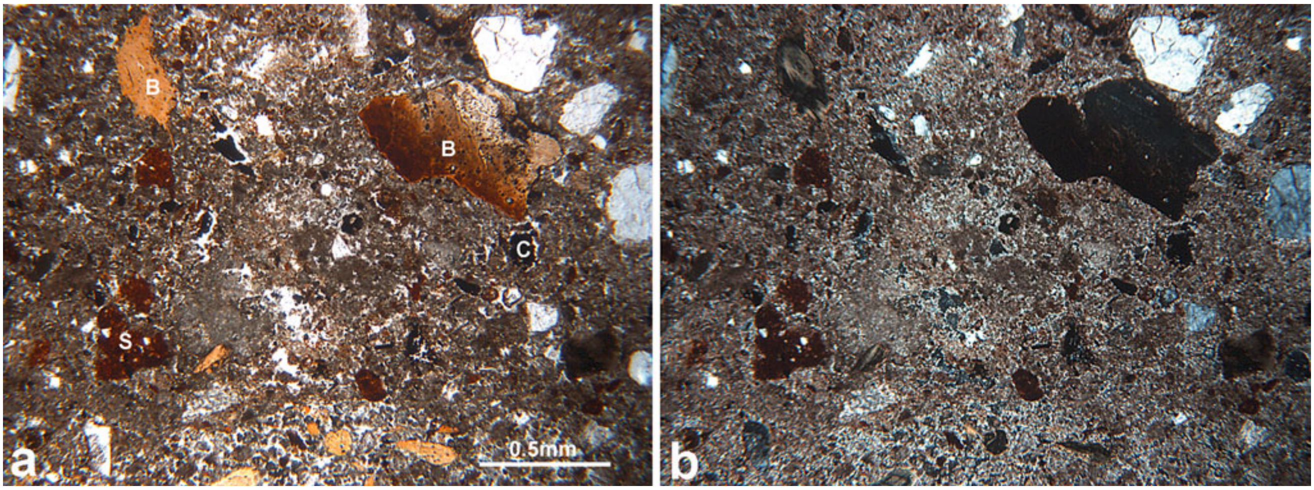
Soil Micromorphology, Figure 3 Examples of shallow sheet wash sediments: (**a**) Macroscan of a thin section showing laminae of well-sorted silt and sand inside crudely sorted fine-grained sediment. The sand fraction consists of single grain and aggregated material. Theopetra Cave, Greece. (**b**) Interbedded clay silt laminae (*C*), moderately sorted single-grained sand (*S*), and unsorted sandy-silt clay (*U*). Grading is observed in the lower part. PPL, Makri, Greece.

At a higher level of order is the fabric, which describes the total organization of the constituents described above, including their spatial arrangement, shape, size, and frequency of occurrence. Features that reflect the history of the material can be grouped into three types:

1. *Sedimentary features* relate to the source of sediments, mode of transport, deposition of clastic grains, or chemical accumulations. Deposition produces sedimentary structures, which are the direct manifestation of the depositing medium (air or various types of fluid) and energy conditions prevalent at the time of deposition (Reineck and Singh 1980, 8). They include all the bedding and surface features produced during sediment deposition (Figures 3 and 4).
2. *Pedologic and postdepositional features* refer to modifications of existing materials by biological, mechanical, or chemical processes. Examples include clay coatings (in voids and around grains or aggregates), excrements, and precipitation of carbonates or oxides resulting in the formation of nodules and mottles (Figure 2).
3. *Anthropogenic features* result from human activities and are manifested mainly by ashes, charcoal, bone, organic matter, lithics and pottery, and construction materials (Figures 5, 6, and 7).

Soil Micromorphology, Figure 4 Photomicrograph of sedimentary crusts (PPL). Each crust has a coarse texture at the bottom and grades upward to finer material. Kolona, Aegina, Greece.

The modern terminology of soil micromorphology is largely descriptive (Bullock et al., 1985; Stoops, 2003) and commonly uses similar descriptive approaches found in sedimentology. This objective terminological approach is unlike the heavily genetic one first conceptualized by Brewer (1964), which was designed for the needs of describing soils. As such, it is quite unsuited to describing



Soil Micromorphology, Figure 5 Photomicrograph of burnt remains, (**a**) in PPL and (**b**) in XPL, showing burnt bone (*B*), charcoal (*C*), and oxidized burnt soil aggregates (*S*) inside a *dark gray* (in PPL) calcitic mass consisting of ash crystals with dotted appearance (in XPL) that have begun to recrystallize (*light grey* areas in XPL). Lakonis Cave, Greece.

sediments or even the sedimentary aspects of soils. The textbook on soil micromorphology in archaeology by Courty et al. (1989) used a more balanced approach, however, and more recent publications also use terms derived from sedimentary petrography and even from metamorphic petrology (Phillips et al., 2011).

Micromorphology and other techniques

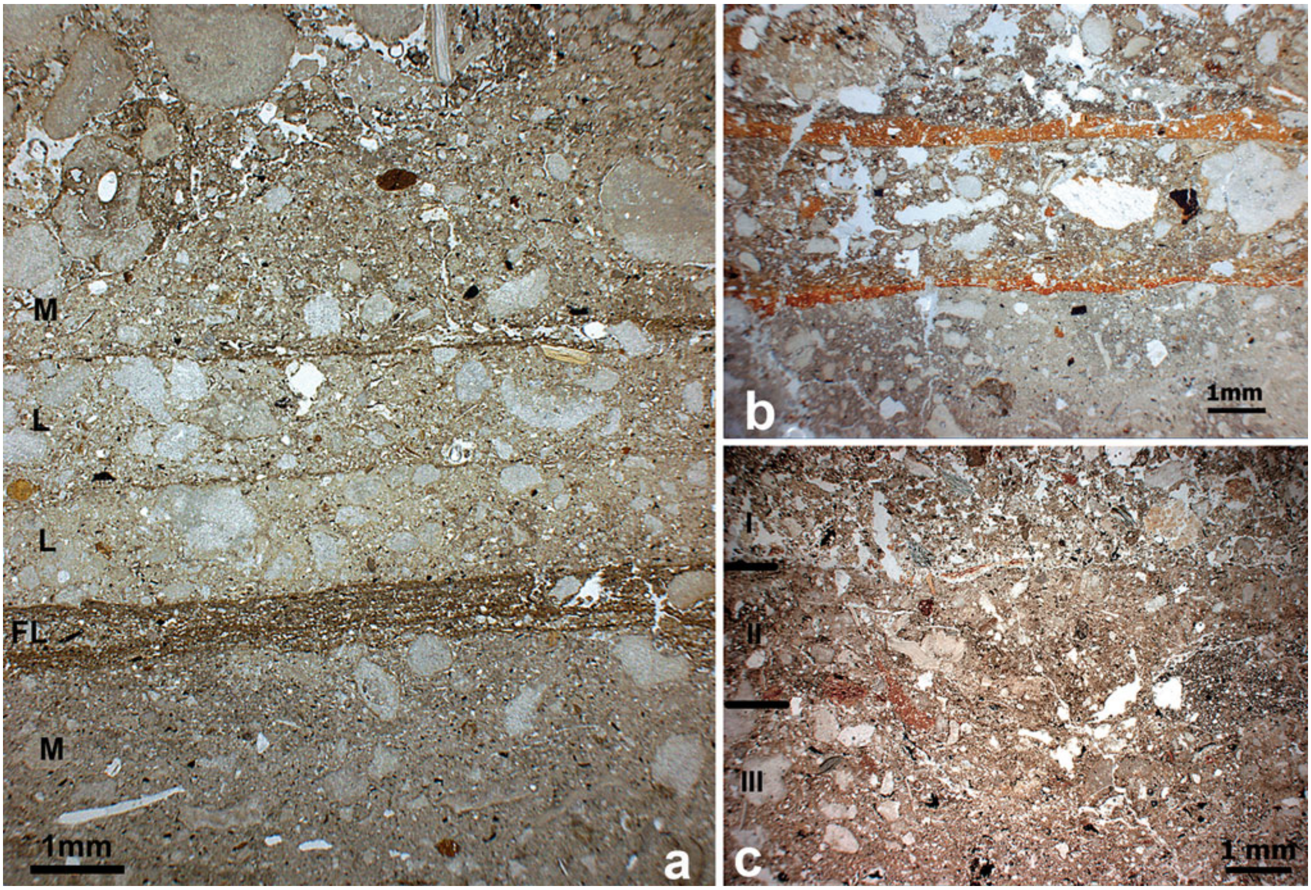
Micromorphology is often combined with other instrumental techniques to further decipher the nature of non-recognizable microscopic features. For example, the nature and origin of amorphous phosphate features in archaeological deposits have been recognized through synchrotron X-ray scattering analysis of thin sections (Adderley et al., 2006) or microprobe analysis (Karkanas et al., 1999; Macphail and Goldberg, 2000). Furthermore, there are several examples where data derived from other disciplines have been integrated with those of micromorphology to provide a more holistic interpretation of site formation processes (e.g., phytolith analysis (Albert et al., 2008), isotopic analysis (Shahack-Gross and Finkelstein, 2008; see also Weiner, 2010). However, it is important to know how the objects under analysis are organized within the sediment. For example, spores and seeds recovered from bulk, homogenized samples cannot inform us as to whether they come from layers associated with stabling remains or with burnt remains, even though they themselves are not burnt. Thus, we need to know the context of these remains, for without it, the interpretation is not only incomplete but could be erroneous. It is thus the thin section of the intact deposits that can provide the context of these organic remains.

A common strategy involves systematic geological sampling of the profiles whereby sedimentological analysis of bulk samples yields quantitative information. Bulk samples are taken back to the laboratory where a variety of analytical methods are used, such as grain-size analysis, clay and heavy mineral determination, phosphate content, organic matter and acidity, carbonates, iron content, and magnetic susceptibility among others. Although some of these methods can provide valuable information on strictly naturally deposited layers, they are of limited value in studying cultural deposits. We cannot interpret excavated earth by treating it as bulk material, because there is no possibility of unraveling the compound effects of two successive events superimposed on the same material, and we cannot differentiate between materials that produce the same analytical measurements (Courty et al., 1989). For example, wood ash and calcareous pedogenic features consist of the same mineral, calcite. Wood ash can be recrystallized to produce indurated features resembling cemented calcareous silt sediments (Karkanas et al., 2007; Figure 5).

A more recent advance in micromorphology is the use of image analysis techniques (Goldberg and Whitbread, 1993; Adderley et al., 2006). Processed images are used to identify pores, grains, and dark (organic) material and to measure area, number or frequency, and shape and size parameters of objects and voids. One way of using image analysis is to compare features like void space between different microfacies or to enhance the visibility of subtle fabrics like deformation features. Quantification measurements provide a more secure basis for interpretation, but as Goldberg and Macphail (2006) acutely notice, researchers must know exactly what they are counting.

Applications

The analysis of microstratigraphy and microstructure of archaeological sequences as well as the examination of



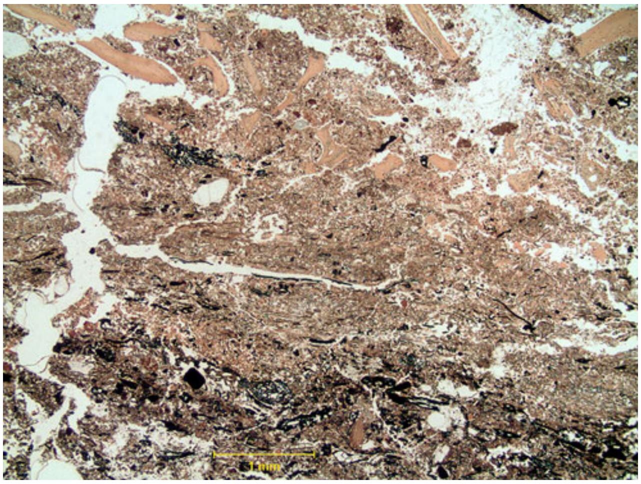
Soil Micromorphology, Figure 6 Photomicrographs of plaster floors with characteristic dense mosaic fabric. The overall homogeneity is correlated with the degree of processing of the material in antiquity. (**a**) Pure lime replastering (L) between impure lime floors (M). Note the dusty appearance of the lower floor due to the large amounts of finely dispersed, flaky charcoal and ash inclusions. All surfaces are covered by dark organic-rich microstratified debris. The lower one (FL) is much better developed, consisting of finely laminated decayed organic matter interbedded with coarser sediment having a dense mosaic fabric. (**b**) Red clay finishing coats on well-prepared lime floors. The upper one was laid on a replastering surface. (**c**) Surface of a poorly prepared floor enriched in lime (II) relative to its clay-rich substrate (III). The overlying material is loose, mostly ashy debris (I). Note also the general dirty appearance of the floor and the occurrence of some vughs. PPL, Makri, Greece.

relationships among construction features, sediments, and their archaeological findings has been employed successfully to interpret natural depositional processes and paleoenvironmental changes, human-induced soil formations and disturbances, land management, the use of space, and the structure of sites.

Human-induced soil formations and disturbances

One of the earliest applications of soil micromorphology in archaeology was the study of soil development throughout the Holocene and how humans have affected this pedogenesis (Macphail, 1986; Macphail et al., 1987). Early Neolithic cultivation resulted in extensive disturbance of parent soil material. The direct effect of tillage is reworking of the fabric, and, consequently, mobilization and translocation of loose soil material by water and formation of pedofeatures such as dusty clay coatings, void infills, and intercalations (Figure 2) (Macphail et al., 1987). Eventually, such processes led to the depletion of soil nutrients and the formation of acid soils (podzolization). In northern European countries, the woodland cover was succeeded by poor heath lands caused by clearance, burning, and cultivation or grazing (for a review see Goldberg and Macphail, 2006, 193–210).

Land management practices in the past, like manuring and disposal of urban waste in arable lands, have been successfully recognized with soil micromorphology (Davidson and Carter, 1998; Adderley et al., 2006). Evidence of manuring may include higher amounts of organic fragments with compositions indicating that they are derived from humic layers, animal dung, or hearth ashes. This activity may lead to overthickened homogeneous



Soil Micromorphology, Figure 7 A photomicrograph from Sibudu Cave, South Africa, showing the contact between laminated organic matter and charcoal at the base, and a weakly bedded phytolith layer above it; trampled bone at the top occurs in a partly disaggregated phytolith-rich layer. PPL.

dark gray upper soil horizons known as plaggen soils (Courty et al., 1989, 134). Such material may later be used in site constructions, which can be readily seen in thin sections (Simpson et al., 2006).

Micromorphological data on cultivation practices have to be treated with caution, however, because other processes can also produce features suggestive of cultivation. Goldberg and Macphail (2006, 203) suggest that all human and environmental factors have to be taken into consideration when studying cultivated soils. Furthermore, such micromorphological studies are often supplemented by other methods and techniques like pollen, chemical, grain-size, and image analysis, which provide additional evidence on cultivation and manuring.

Natural processes in archaeological sites

In archaeological sites, natural formation processes contribute significantly to the accumulation of sediment and to the preservation or destruction of archaeological patterns. Aeolian, colluvial, high-energy, or low-energy water flow features are easily identified by micromorphology, even when they occur as mm-thick layers inside a predominantly anthropogenic deposit. Fine-scale grading, crude sorting, and orientation of particles are revealed through the microscope (Figures 3 and 4). Each of these features can be attributed to a particular natural sedimentation process, and thus the depositional regime can be identified (Courty et al., 1989). For instance, lenses of laminated and well-sorted increments of juxtaposed mineral sand and well-rounded sand-sized soil aggregates are common inside generally massive fine-grained sediment (Figure 3; Karkanas, 2001; Goldberg et al., 2007). They are related to flow events with relatively moderate to high sediment concentration, such as shallow sheet wash (overland flow) along sloping surfaces, where poor separation of bedload and suspended particles is expected (cf. Bertran and Texier, 1999). Microscopically stratified deposits with angular clasts showing inclined, preferred orientations parallel to the slope and floating in a dense, finer, poorly sorted, sandy-silt matrix are interpreted as flow of liquefied sediments (Karkanas and Goldberg, 2010). In urban sites, sedimentary crusts are among the most secure evidence for the identification of outdoor facies (Matthews, 1995). They consist of alternating fine- and coarse-grained laminae with evidence of grading (Figure 4). They can also be associated with vesicles and horizontal planar voids.

Construction materials

Various construction materials include natural soil or sediments and manufactured materials (Macphail and Goldberg, 2010, and references therein). Natural sediments and soils can be in their raw state or mixed with mineral and plant tempers to produce daub, mud brick, floors, walls, roofs, and other constructions. Anthropogenic sediments like ash, charcoal, dung, bone, and organic refuse have been used in varying proportions in construction materials (Milek and French, 2007). When the context is not clear, or when constructions have decayed or been reworked, their identification is not easy. Micromorphology can aid us to identify these materials, which are usually anomalous, exotic, or characterized by unique features (e.g., straw imprints) and can place the associated archaeological findings in the right context. Furthermore, deciphering the techniques used for producing these materials may lead to inferences on craft specialization and cultural interchange (Goren and Goldberg, 1991; Karkanas, 2007).

Most construction materials are characterized by microscopic features that reflect intentional human preparation. Dense mixing of constituents in the wet state produces a characteristic mosaic fabric where coarser components are embedded in a dense fine groundmass. The overall microscopic appearance, however, can be quite homogeneous because of even distribution of all clast sizes (Figure 6). Furthermore, puddling and working of material in a semi-plastic state can produce domains with oriented fabrics, silty or clayey intercalations, vughs, and vesicles (Macphail and Goldberg, 2010). Adding of plant temper is also characteristic of some construction materials like mud bricks and daub (Courty et al., 1989, 119–120). Tubular-shaped voids that are pseudomorphs of the plant temper are readily observed in thin sections. Lime plasters and mortars are characterized by a dense recrystallized fine calcitic matrix with partially burnt carbonized lime lumps that are well welded in the groundmass (Figure 6; Karkanas, 2007).

It has to be stressed that in all cases, differentiation between types of construction materials is site specific. For instance, mud bricks, daub, and clay floors can be very similar. In each site, the best-preserved constructions have to be studied as a reference, and the sampling strategy should focus upon establishing the sequential decay of all types of construction material (Goldberg, 1979; Friesem et al., 2011). At the same time, the geometry and spatial distribution of the decayed construction features in the field have to be taken into consideration in addition to the micromorphological results in order to identify the original construction type.

Use of space

Different human activities can be clearly demonstrated from the content and fabric of the sediments themselves. In prehistoric, non-constructed sites, cultural deposits are commonly burnt (Figure 5). In the Paleolithic site of Kebara Cave, Israel, distinct types of fire-related features have been identified together with remains of in situ burning as well as sediments that were dumped or moved aside in the process of cleaning and modifying living areas (Goldberg et al., 2007; Meignen et al., 2007). Burning features in undisturbed, primary context are characterized by a bright red (rubified), clay-rich substrate overlain by a black, thin, charcoal-rich layer and an often thicker, bedded, whitish ashy layer with burnt bone and red soil (rubified) inclusions. Microscopically, pristine ash consists of calcite pseudomorphs after plant structures (Wattez and Courty, 1987; Canti, 2003). The composition of raked-out hearths is similar, but the arrangement of the constituents is totally different. Bone, charcoal, calcareous ashes, and reddened soil can occur in the same stratigraphic unit or can be mixed between stratigraphic units. In addition, porosity is elevated. Trampled hearths resemble raked-out hearths, but they are more compacted and thus display reduced porosity (Meignen et al., 2007).

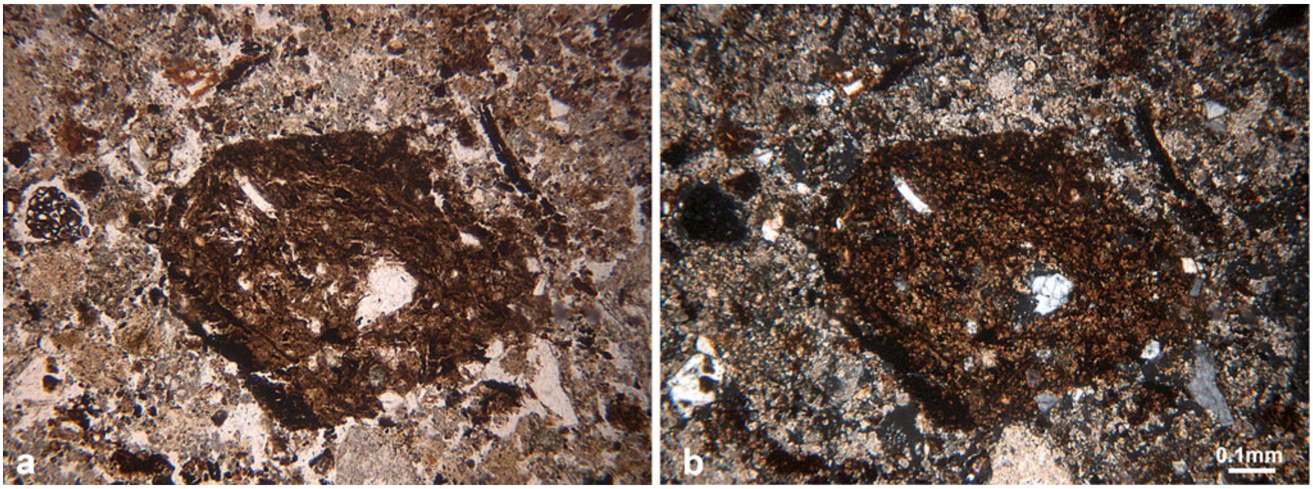
In the Middle Stone Age of Sibudu Cave, South Africa, individual anthropogenic activities were identified, including the construction of hearths and bedding, as well as the maintenance of occupational surfaces through the sweep out of hearths and the repeated burning of bedding. Overlapping series of laminated microfacies were identified, consisting of microlaminated charred or humified organic fibers that often contained stringers of crushed charcoal or phytoliths oriented parallel to the bedding and associated with partially dissolved plant ash (Figure 7). These features were interpreted as intentionally burnt plant material used for surface preparation (bedding) (Goldberg et al., 2009).

In sites characterized by human constructions, such as tells, detailed micromorphological studies of living floors, their maintenance, and the associated occupational debris have provided clues to the use of space at the site (Matthews, 1995; Matthews et al., 1994; Shahack-Gross et al., 2005; Karkanas and Efstratiou, 2009) as well as insights into pyrotechnological activities (Berna et al., 2007). Spatial and contextual variation in the type, thickness, and frequency of plaster floors and occupational deposits within and between buildings has been attributed to different uses of space (Matthews et al., 1996). In Neolithic Makri, Greece, it was noted that a series of well-prepared lime-plastered floors reoccurred at relatively regular intervals over large areas of the settlement (Karkanas and Efstratiou, 2009). It was also noted that these floors were kept exceptionally clean, that they often preserve a finishing coat of red clay or laminated debris of dusty, dark organic-rich material (Figure 6), and that, rarely, a lamina of articulated phytoliths is recovered that may represent decayed organic matting (cf. Gé et al., 1993; Matthews, 1995). Between these well-prepared lime floors, layers of overlapping and randomly recurring, poorly prepared floors were identified. The top of some of these layers occasionally preserved smooth slaked surfaces, enriched in lime, that resulted from final finishing of the top of a floor or lime replastering (Figure 6c). In addition, it was possible to define microlaminated organic-rich debris on top of some of the compacted layers, particularly when these were protected by the construction of a well-prepared floor above (Figure 6a). The identification of such planar structures was a decisive criterion for defining them as in situ floors (see Macphail et al., 2006).

In the investigation of ancient pastoral activities, micromorphology enables us to differentiate between animal species and possibly food sources and grazing processes on the basis of differences in the nature of the components as well as the structure and arrangement of dung remains (Figure 8) (Courty et al., 1991; Boschian and Montagnari-Kokelj, 2000; Macphail et al., 1997; Karkanas, 2006). Further progress in the understanding of stabling deposits was made by characterizing soil microfabrics formed in contemporary abandoned pastoral sites (Shahack-Gross et al., 2003, 2004). The Neolithic cave of Arene Candide in Liguria, Italy, comprises a sequence of gray, homogeneous, and stratified sediments (Macphail et al., 1997). Detailed micromorphological analysis indicates that the cave was used both for herbivore stabling and for domestic occupation. The dung layers consist of a basal, phosphate-rich, stained sub-layer of mainly uncharred plant material. This sub-layer is overlain by ashed and semi-ashed material with burnt, coarse convolute fragments of sheep and goat coprolites and finally by wood ashes. This sequence suggests that the stabling remains were frequently burnt most likely for cleaning purposes. The homogeneous sequence represents mainly domestic occupational deposits that consist of multiple layered, articulated phytoliths and plant tissues used for domestic bedding and thin red soil layers with indications of processing in a wet state. The spatial and temporal organization of domestic occupation and herbivore stabling enabled an interpretation of the changes in cave use during the Neolithic.

Postdepositional alterations

Sediments are affected by a large variety of physical and chemical transformations after they have been deposited. From both sedimentological and archaeological



Soil Micromorphology, Figure 8 Photomicrographs (**a**) PPL and (**b**) XPL of a slightly charred ovicaprine dung fragment inside loosely aggregated sediment consisting mainly of calcitic ashes. Bright spots in the dung shown in XPL are dung spherulites (silt-sized, ~5–15 μm calcareous spheres with a pseudo-uniaxial interference under crossed-polarized light; see Shahack-Gross et al., 2004). Kouveleiki Cave, Greece.

perspectives, pedogenesis can also be included in postdepositional alterations (Courty et al., 1989). Physical, chemical, or biological processes produce certain features that are recognizable in thin sections. Each kind of microfauna produces excrements of specific shape and sometimes size (Bullock et al., 1985). Movement of materials through the sediment or soil produces microscopic textural features like void coatings and infillings (Stoops, 2003). Crosscutting relationships between these micromorphological features provide evidence for the sequence of mineral development in soils. Moreover, minerals in the process of alteration document the progress of chemical reactions (Karkanas, 2010). Analysis of all these processes contributes significantly to understanding paleoenvironmental conditions and provides insights into the completeness of the archaeological record.

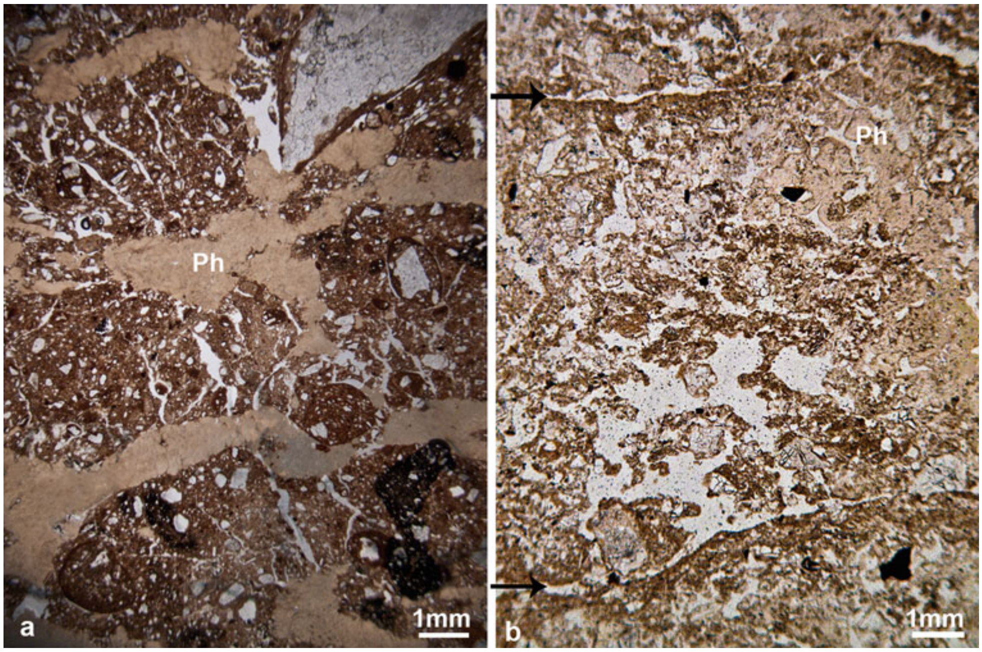
Commonly, archaeological deposits of Pleistocene age are affected by cryogenic processes. Evidence of freezing in sediments is revealed by a characteristic platy and lenticular microstructure (van Vliet Lanoë, 2010). In Theopetra Cave, Greece, freeze-thaw and chemical alteration have acted on the same deposits, producing a complex sequence of postdepositional events (Karkanas, 2001). In some layers, authigenic phosphate minerals fill cryogenic cracks that postdate the freezing event. In other layers, however, phosphatic features are themselves affected by freeze-thaw activity (Figure 9). Therefore, the spatial distribution of microscopic frost features and chemical alteration features permits differentiation of the superimposed cryogenic events and thereby enables a better understanding of the paleoclimatic changes in the area. Moreover, the presence of certain phosphate minerals is associated with the dissolution of bone and alteration of calcareous materials such as wood ash (Karkanas et al., 2000). Instrumental mineralogical and microchemical techniques have been used to identify the mineral phases seen in the thin sections.

In old sites, stratigraphic gaps are not readily identified by field observations due to postdepositional alterations. Identifying and separating the sequence of events that have affected the same sediment is of major importance in reconstructing the depositional history of a site. An example comes from Geißenklösterle Cave, Germany, where micromorphological analysis was able to confirm a major change in the diagenetic regime between the Middle and Upper Paleolithic sequences (Goldberg and Berna, 2010). Middle Paleolithic phosphatized sediments are sharply overlain by unweathered, calcareous Upper Paleolithic sediments. This finding helped to elucidate the nature of the so-called Middle–Upper Paleolithic transition at this particular site and placed finite constraints on what can be said about it.

Summary

Applications of micromorphology in archaeology have witnessed a steady increase over the last 30 years. The microscopic study of soils and paleosols within and surrounding archaeological sites continues to provide important information for paleoenvironmental reconstructions and insights into the role of humans in shaping the environment. Human-induced soil formation and disturbances are especially relevant in this respect, and micromorphology provides basic information about how soils are constructed and how they develop.

The application of micromorphology to the study of site formation processes has proved to be a very powerful tool in placing archaeological findings in their proper context.



Soil Micromorphology, Figure 9 Examples of postdepositional alterations: (**a**) phosphates (*Ph*) filling planar cracks produced by freeze-thaw action; (**b**) frost cracks (*with arrows*) crosscutting phosphate deposits (Ph). PPL, Theopetra Cave, Greece.

Archaeological sites comprise a complex array of natural and anthropogenic processes, and therefore, petrographic and micromorphological methods, including ideas and concepts from different earth science disciplines, should be combined in order to yield the best results. Applying micromorphology to the study of archaeological deposits provides valuable results because the structure and fabric of sediment constituents reflect the forces and agents that deposited them. Organization of the coarser components can be readily seen with the naked eye, but the finer fractions can be seen only under the microscope. The study of archaeological sediments will greatly benefit from observations at all scales.

Introduction

Soil stratigraphy or *pedostratigraphy* is a way of grouping and correlating sediments and rocks based on soil-related, or pedogenic, criteria. This contrasts with *lithostratigraphy* (classification based on lithological characteristics such as color or grain size), chronostratigraphy (classification based on age of deposits or rocks), and *biostratigraphy* (classification based on biological characteristics such as pollen or vertebrate fauna) (see the entry on "Stratigraphy" in this volume). It has been defined as "the study of different soil associations formed in an area during past periods of varied soil-forming conditions" Catt

(1990, 169). Here, the term *association* refers to a group of related soils that vary laterally due to changes in soil-forming factors. This is a more generic use of the term compared to the soil-mapping parlance of the USDA (see the entry on "Soil Survey" in this volume). The unique physical and chemical properties that distinguish soils from sediments make soils quite useful for stratigraphic subdivision and correlation. In particular, pedologic features, most notably soil horizons, are often the most visually prominent features in stratified deposits.

The recognition of soils and their differentiation from sediments in archaeological contexts (discussed below) is one of the most fundamentally significant aspects of geoarchaeological stratigraphy. Because soils indicate periods of stability or hiatuses in deposition (so that the soils have a chance to form), the identification of soils or the lack thereof in a stratigraphic sequence provides information on the number of depositional episodes and intervals of stability. The identification of specific soil horizons also provides clues to the degree and duration of soil development (see the entry on "Soils" in this volume), the nature of the soil-forming environment, and the kinds of soil-forming processes that may impact the archaeological record (see entry on "Site Formation Processes" in this volume).

Soil stratigraphic units have been defined in several ways. They are formally referred to as *pedostratigraphic units* in the North American Stratigraphic Code (NACSN, 2005, 1576–1578). A pedostratigraphic unit is a "buried, traceable, three-dimensional body of rock [or sediment] that consists of one or more differentiated pedologic horizons" developed in and overlain by "one or more formally defined lithostratigraphic or allostratigraphic units" (NACSN, 2005, 1576–1577).

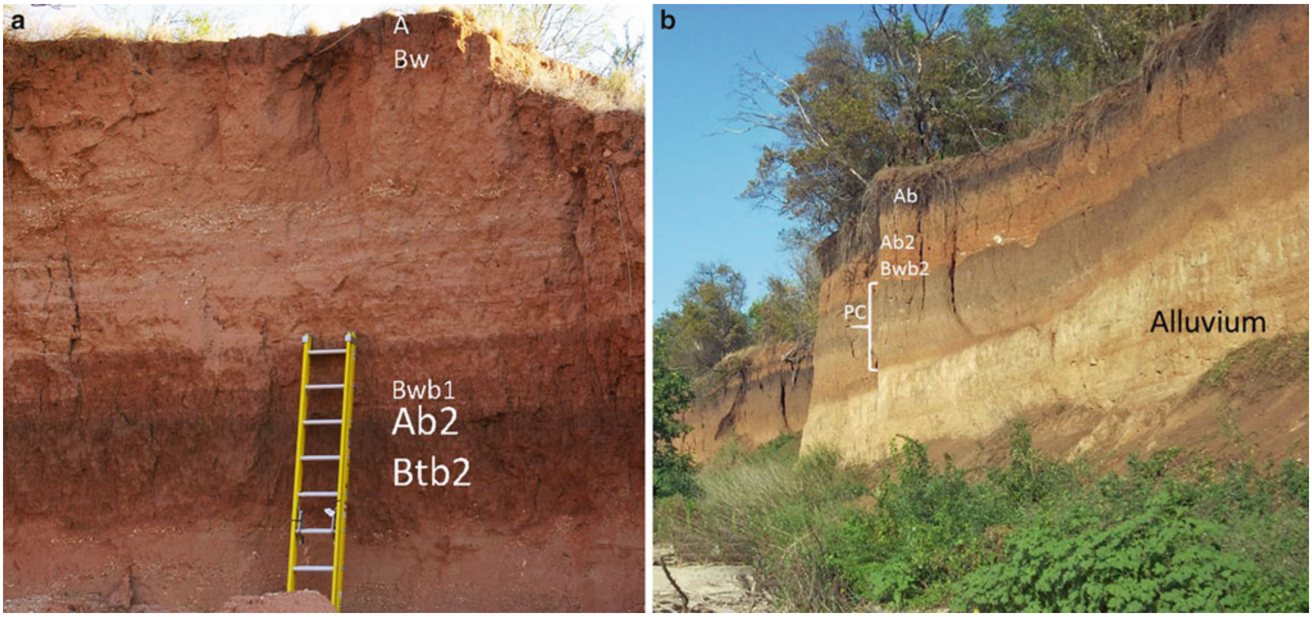
There are several disadvantages to the NACSN definition, particularly in geoarchaeological contexts. The requirement that the soils be buried is illogical and in any case impractical in many field situations. The processes that govern whether or not a soil is buried can be variable and highly localized, particularly in Holocene deposits such as dunes and floodplains where paleosols may be exposed by erosion. The NACSN definition can result in a situation where a clearly traceable soil that is locally buried or exposed is a pedostratigraphic unit in some places but not others. Likewise, the requirement that pedostratigraphic units be developed in and overlain by formally defined stratigraphic units is impractical and unrealistic because formally defined Holocene strata are rare, and formally defined Quaternary units are only locally common. Finally, the NACSN does not indicate how far a buried soil must be traceable for it to be classified as a pedostratigraphic unit. For example, a buried soil that is developed in Holocene alluvium may be traceable in a particular drainage basin or even a small part of a basin, but it may not occur beyond this area. Hence, there may be uncertainty as to whether that soil can be classified as a pedostratigraphic unit.

Several terms have been proposed as the "fundamental unit" of pedostratigraphic classification (i.e., a term equivalent to *formation* as the fundamental unit of lithostratigraphic classification). In the North American Stratigraphic Code, *Geosol* was adopted as the fundamental unit. "Geosol" was chosen over "soil" apparently because of the many different definitions and connotations of "soil," but there is rarely any confusion over the meaning of "soil" among geoarchaeologists, geomorphologists, or Quaternary stratigraphers. Other terms with a connotation more or less similar to Geosol include *groundsurface* (Butler, 1959), *pedolith* (Crook and Coventry, 1967), *pedo-morpholith* (van Dijk et al., 1968), and *pedoderm* (Brewer et al., 1970). Using "soil" to refer to pedostratigraphic units seems the most straightforward approach, however. Ultimately, field investigators should choose the terminology that best suits their situation.

A wide variety of sometimes confusing terminology has been proposed and used to describe the many possible stratigraphic relationships between and within buried soils and soil stratigraphic units. Most of the terms are seldom used, largely because they lack utility in illuminating depositional or landscape history. A review of these terms, however, is a good way to examine them systematically and explain possible stratigraphic relationships among buried soils.

A classical, vertically stacked sequence of buried soils common in many alluvial, colluvial, eolian, and glacial landscapes is a multistory sequence (Figure 1a, b). Closely spaced, multiple buried soils are described by a number of stratigraphic terms. If pedogenic processes from an upper soil extend down into or "overlap" with a lower soil, the process is referred to as soil *welding* and produces a set of *welded soils* (Figure 2) (Ruhe and Olson, 1980). Welded soils are also referred to as *polypedomorphic soils* (Bos and Sevink, 1975; Duchaufour, 1982, 144), *composite soils* (Morrison, 1967, 25, Morrison, 1978, 83–84), and *complex soils* (Bos and Sevink, 1975, 224–225). Soil welding is an important process of post-burial alteration of soils. In Europe, the term *pedocomplex* is often used to describe closely spaced sets of either welded or unwelded soils and also to describe overthickened or cumulic soils (Figure 1b) (see below). In the field, workers will find any combination of welded soils, unwelded soils, pedocomplexes of both, subdivided polygenetic soils, deeply buried soils, and shallowly buried soils. Lateral variation in rates of sedimentation, for example, on a floodplain, can also produce facies between multistory soils, welded soils, and a cumulic soil (Figure 3).

A significant aspect of soil stratigraphic units is that, like surface soils, they vary as the factors that influenced their development (parent material, topography, vegetation, biota, and time) varied. This is a very useful concept in soil



Soil Stratigraphy, Figure 1 Examples of different expressions of buried soils. (**a**) A typical multistory sequence from the headwaters of the Brazos River system on the Rolling Plains of northwest Texas. Below the surface soil and above the first buried soil (Bwb1) is sandy and gravelly alluvium and, immediately above the buried soil, finer muddy alluvium. The soil structure in the A-Btb2 is very well expressed due to high clay content. More sandy and gravelly alluvium is apparent at the base of the section (Photo by Vance T. Holliday). (**b**) Buried soils exposed along the Dnieper River, Ukraine. The Ab-Ab2-Bwb2 multistory sequence and the pedocomplex (*PC*) formed in late Pleistocene loess, but are separated by a distinct erosional unconformity. The PC includes both cumulic and welded soils. The PC rests unconformably on bedded alluvium (Photo by Vance T. Holliday).

stratigraphy because buried soils, like surface soils, can vary laterally. For example, a buried soil that formed in several different parent materials will exhibit different lithological facies. A soil stratigraphic unit that is buried in some places but not in others will exhibit facies variations due to the differences in the age of the soil, i.e., in the amount of time the soil had to form, and possibly due to environmental variations. Soil facies are lateral variations in soils due to variations in one or more of the soil-forming factors (Morrison, 1967, 13, 15; 1978, 86–87).

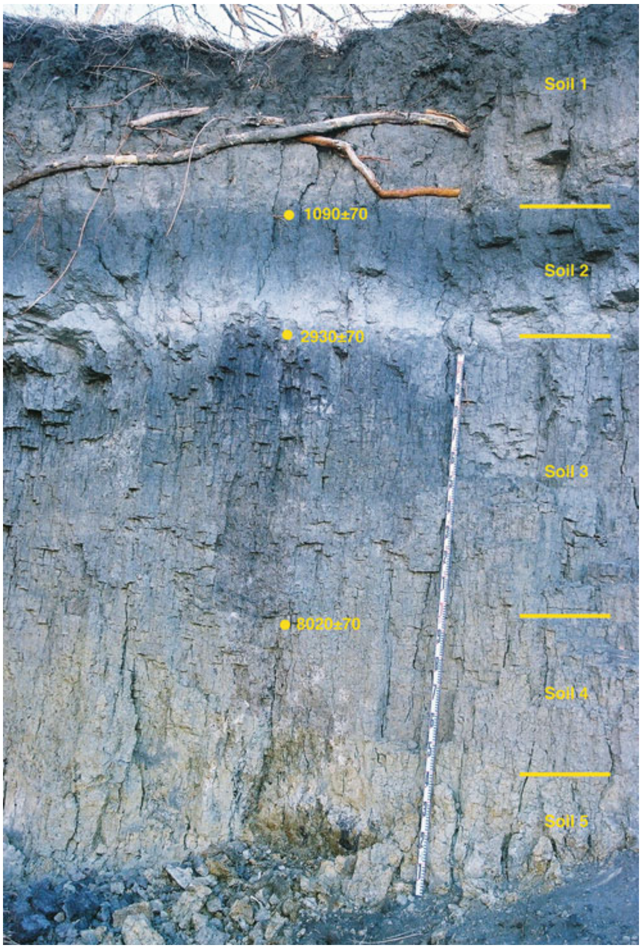
Of particular significance when using soils as age indicators is that buried soils, just like lithostratigraphic units and contemporary surface soils, are diachronic or time transgressive. The age of the upper boundary of the pedostratigraphic unit can vary as the age of the paleo-landsurface associated with the soil varied. Rapid burial over a large area can also produce a buried soil with an isochronous upper boundary (at least within the limits of most dating methods), however.

Variation in a buried soil or soil stratigraphic unit due to variation in the topography and drainage conditions during soil genesis produces a *paleocatena*. Most typically, a paleocatena is simply a buried catena (see entry on "Soils" in this volume). The concept of a buried catena or paleocatena is important because this is a unique aspect of soils relative to other kinds of stratigraphic units and is a key to the recognition of buried soils. Soil stratigraphic units should and do vary just as modern soils at the surface vary today.

Soil stratigraphy versus soil horizonation

The many variables in local and regional soil-forming factors mean that the number and thickness of soil horizons in a soil stratigraphic unit and the position of the lower boundary of the soil can vary significantly. The individual soil horizons and the lower boundary of the soil, therefore, have no stratigraphic significance whatsoever other than to define the soil stratigraphic unit. The lower boundary can be, like the upper one, time transgressive or diachronic. It represents the lowermost significant alteration of the parent material by pedogenic processes.

Soil horizons are not geologic layers; horizons represent an alteration of the layers. The concept of soil horizonation and the specific spatial succession of soil



Soil Stratigraphy, Figure 2 Soil stratigraphy of an alluvial fan exposed in a stream bank along Oak Creek in southeastern Nebraska. Soil 2 has a well-expressed A-E-Bt profile, with the Bt horizon welded to the A horizon of Soil 3 just beneath. In the upper 35 cm of Soil 3, soil welding accounts for the prominent prismatic structure and clay films typical of a Bt horizon, but a dark gray matrix color typical of an A horizon (From Mandel, 2013a: Figure 94).

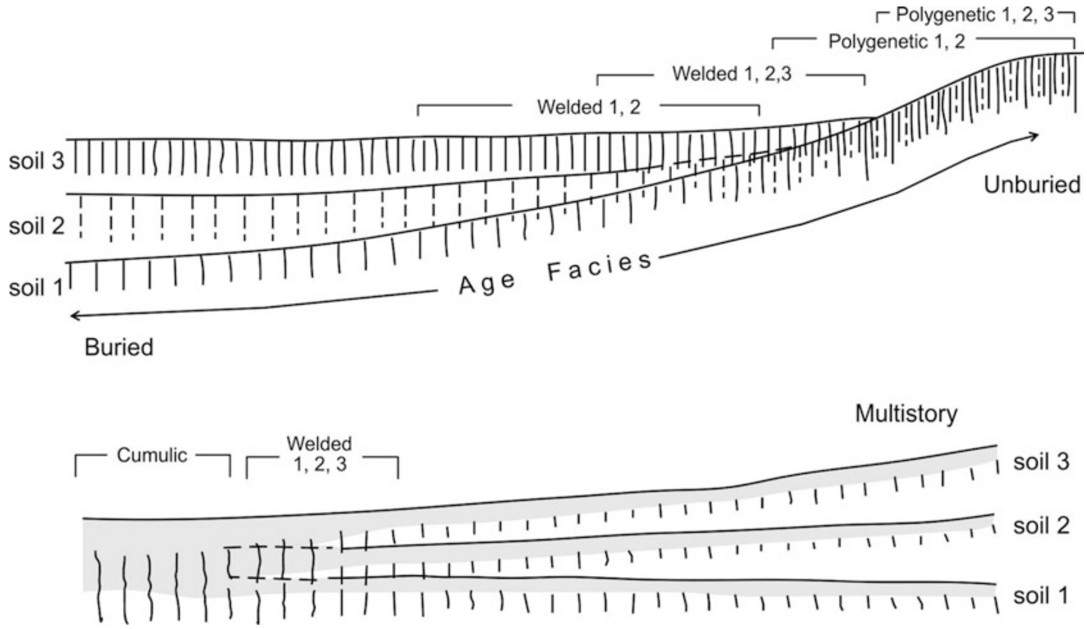
horizons is a significant pedologic paradigm with important stratigraphic ramifications. Soil horizonation extends from the surface downward through the parent material, as a function of pedogenic processes, and thus, individual soil horizons should not be understood as individual stratigraphic entities. Soil horizons are separated in space but are not necessarily separated in time, though some horizons may evolve sequentially after others form (e.g., an A-C profile evolving into an A-Bw-C soil and then into an A-Bt-C sequence) (Figure 4). Moreover, soil horizons, particularly the A, can be thoroughly churned due to the effects of floral and faunal mixing and argilliturbation (see the entry on "Site Formation Processes" in this volume).

Buried soils

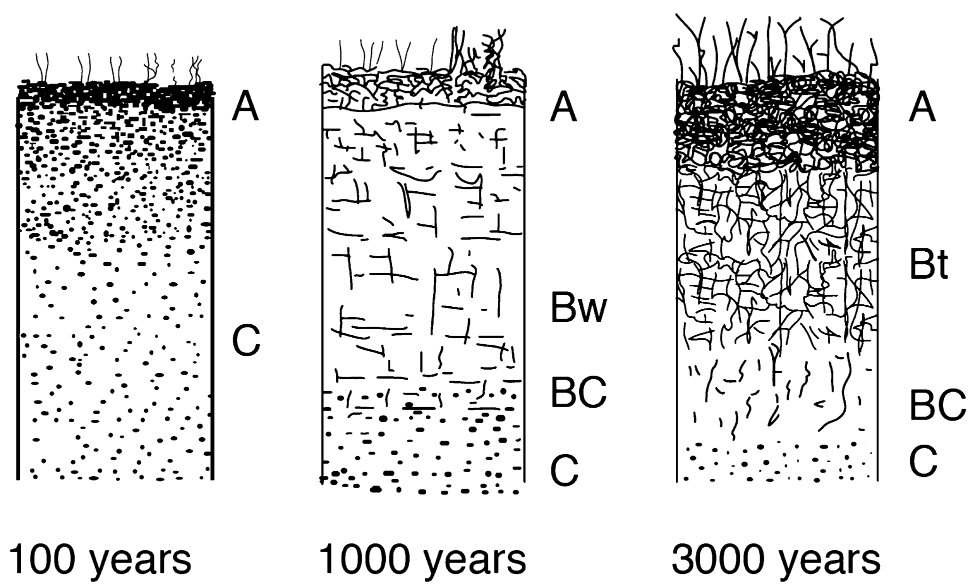
Soil stratigraphy deals with buried soils, which is to say, it deals with buried landscapes. They are three-dimensional bodies, and because soils require some time to form, they can be considered four-dimensional entities. Waters (1992, 82–83) provides a good description of the evolution of strata, one particularly appropriate to the visualization of buried soils (see also Kraus and Brown, 1988; Kraus, 1999; Kraus and Aslan, 1999):

> The nature and structure of a stratigraphic sequence in any environment is determined by the number, timing, areal extent, magnitude, and duration of individual periods of deposition, degradation, and stability.... Over a given interval of time, individual episodes of deposition, stability, and erosion may be of long duration, with changes occurring infrequently, or they may be of short duration and alternate frequently. Furthermore, these episodes may affect a large region or only a small area. Consequently, different. . .sequences of lithostratigraphic units, pedostratigraphic units, and erosional contacts are created.
>
> The total duration of deposition, degradation, and stability determines how much of the time continuum of a stratigraphic sequence is recorded by. . .depositional units (lithostratigraphic units) versus the combined time represented by. . .surfaces of erosion (erosional unconformities) and surfaces of stability (pedostratigraphic units). Episodes of landscape degradation [and/or] stability create gaps in any depositional sequence and thus leave an incomplete geologic record of lithostratigraphic units. The ratio of the total amount of time represented by nondepositional and erosional contacts between lithostratigraphic units produces a measure of the completeness of the stratigraphic sequence.... Generally this ratio is low because the contacts between and within lithostratigraphic units represent the passage of more time than the physical sediments themselves.... (Waters, 1992, 82–83)

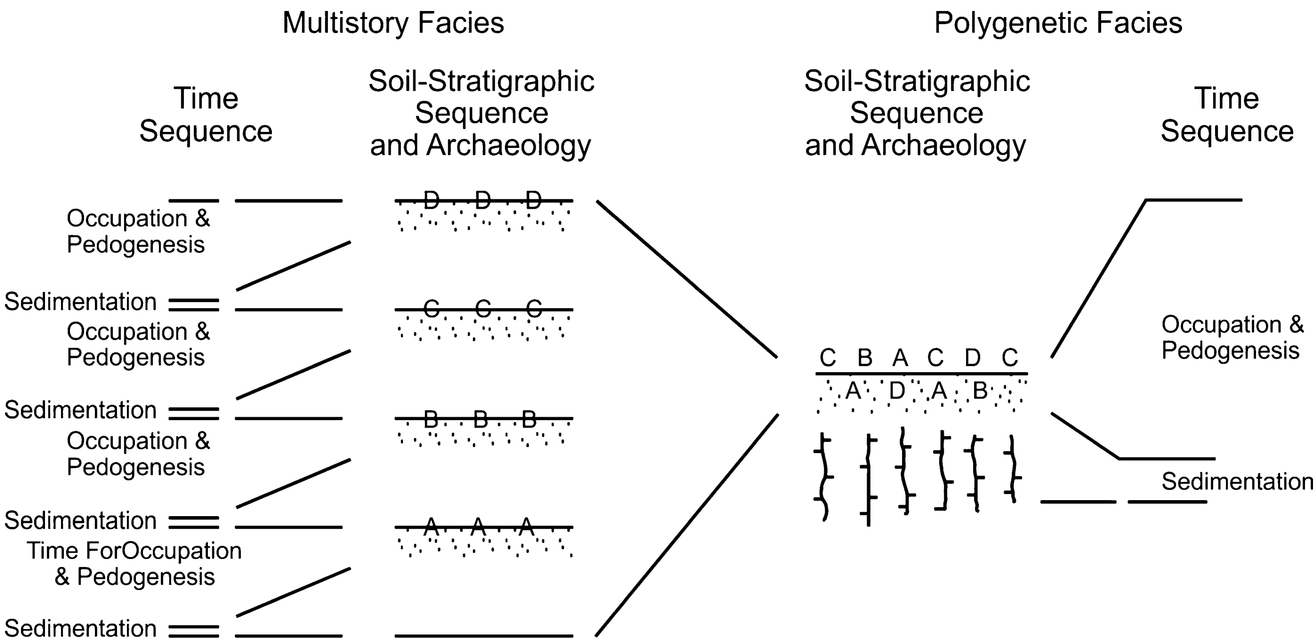
An important point raised in this quote is that soils represent gaps in the sedimentological record – i.e., periods of generally stable landscapes – because there was little or no deposition or erosion. More broadly, recognizing buried soils and establishing soil stratigraphic relationships are important for a wide array of geoarchaeological questions and interpretations. For example, a multistory sequence of weakly expressed buried soils is indicative of rapid sedimentation interrupted by relatively brief periods of stability and soil formation. Such settings could preserve discrete occupation surfaces (Figure 5). On a floodplain, as described above and in Figure 3, this geoarchaeological record could have a facies of a welded, or cumulic, or unburied soil with a mixed or palimpsest archaeological record.



Soil Stratigraphy, Figure 3 Schematic diagrams illustrating the soil stratigraphic and facies relationships of buried, unburied, and cumulic soils and associated terminology. In the *upper* diagram, duration of pedogenesis in the unburied, polygenetic soil is equal to the combined duration of pedogenesis for soils 1, 2, and 3, plus the time of sedimentation (Modified from Holliday (2004: Figure 5.3)).



Soil Stratigraphy, Figure 4 Diagrams showing the hypothetical development of a soil through time, keeping all other soil-forming factors constant. The setting is on the valley floor of a stream in the tallgrass prairie of eastern Kansas, a region with a mean annual rainfall of about 82 cm.



Soil Stratigraphy, Figure 5 Diagram illustrating the impact of varying rates of deposition on the archaeological record. On the *left* side, frequent episodes of flooding and sedimentation produce multistory facies with multiple, weakly expressed soils (indicated by stippling) containing relatively discrete occupation zones (A, B, C, and D), whereas on the *right* side, prolonged stability results in a few polygenetic soils or a single one with a palimpsest or mixing of different occupation debris (Modified from Holliday (2004: Figure 7.2)).

Recognition

Recognition of buried soils depends on (1) the degree of preservation of the soil (which in turn depends on the nature of the burial processes and post-depositional alterations) and (2) the experience of the investigator, including experience working with surface soils and with stratigraphic studies in the given field area. Fundamentally, buried soils can be recognized using the same characteristics used to recognize surface soils (Yaalon, 1971a, 154, 157; Valentine and Dalrymple, 1976, 209–213; Fenwick, 1985, 5–11; Jenkins, 1985; Catt, 1986, 173–174; Catt, 1990, 6–7; Birkeland, 1999, 24–28). In the field, these characteristics include the absence of geologic bedding, recognizable soil horizons, horizons in a typical vertical sequence, typical soil horizon boundaries (sharper upper boundary, more gradual lower boundary), and the formation of stone lines in some environments. Bettis (1992, 129) provides a useful summary of criteria for differentiating soil A horizons from organic-rich alluvium, criteria also applicable to distinguishing other kinds of soil horizons: (1) a gradual or clear lower boundary for A horizons as opposed to an abrupt lower boundary in geologic deposits, (2) absence of bedding in A horizons and its presence in geologic deposits, and (3) the presence of granular or crumb soil structure in A horizons and its absence or weaker development in geologic deposits.

One significant problem in the identification of buried soils is that a number of sedimentary, hydrogeologic, and pedogenic processes can produce zones that look like buried soils (Pyddoke, 1961, 37–39; Tamplin, 1969, 153–154; Brewer, 1972, 332; Rutter, 1978; Catt, 1986, 173; Thorson, 1990, 402–403, 405–406; Ito et al., 1991; Tandon and Kumar, 1999, 131–135; Mandel and Bettis, 2001, 175–180). These processes and deposits include (1) deposition of organic-rich sediment in lacustrine, palustrine, or alluvial settings (which can be confused with A horizons); (2) deposition of red, reddish brown, or brown sediment (which can be confused with Bw or Bt horizons); (3) deposition of clay-rich sediment (which can be confused with Bt horizons); (4) deposition of gray sediment (which can be confused with a redoximorphic horizon); (5) deposition of volcanic ash (which can be confused with Bk or in particular E horizons); (6) illuviation of humus in a Bh or Bhs horizon below a leached, sandy E horizon (which can be confused with an

Soil Stratigraphy, Figure 6 A buried soil with an overthickened Ab horizon developed in late Holocene alluvium at the Alum Creek site (14EW171) in central Kansas. The Ab horizon is 1.2 m thick and contains stratified Middle Ceramic cultural deposits (Modified from Mandel and Bettis, 2001: Figure 7.3).

A horizon buried below unweathered sand); and (7) deposition of calcium carbonate, soluble salts, or iron oxides in lacustrine, palustrine, alluvial, spring, or groundwater settings (which can be confused with Bk, K, By, Bz, or Bs horizons). Post-burial processes such as black, manganese staining and nodule formation also can produce zones that may be mistaken for soil horizons.

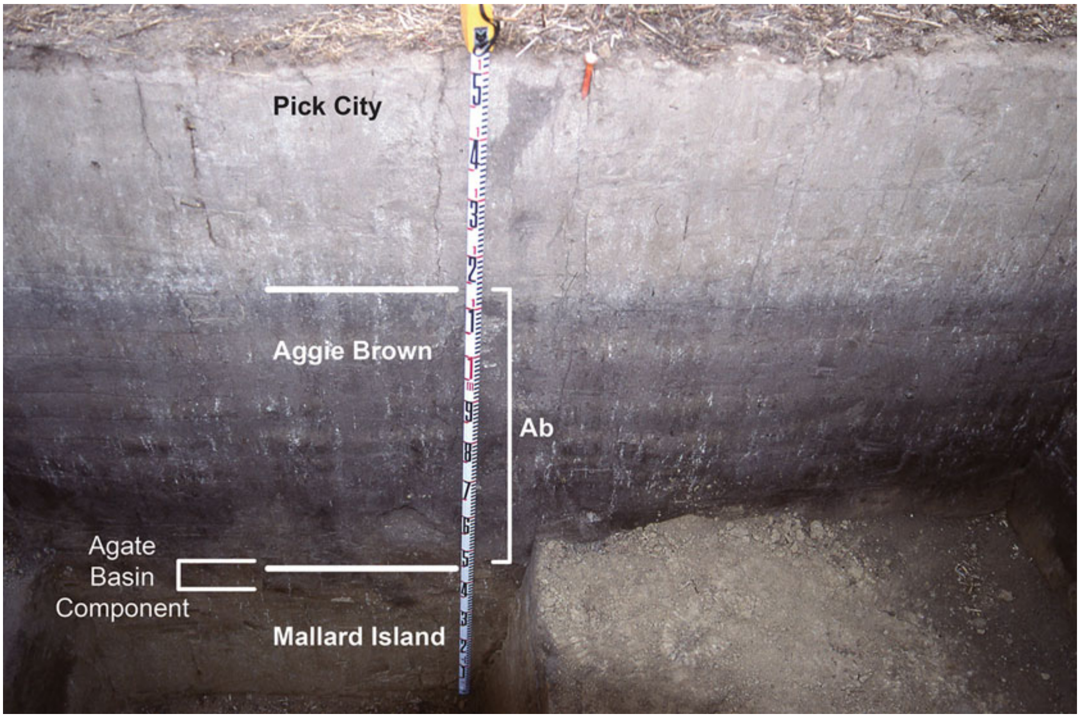
A particularly important characteristic that can be crucial in identifying a buried soil is predictable, lateral variability in morphology ("constancy of relationships" of Brewer, 1972, 333) due to topographic variability (i.e., it is part of a *paleocatena*) and due to parent material variability, both discussed above. The topographic and catenary variability of soils is a unique characteristic particularly important in the identification of buried soils; one not likely mimicked by other geological phenomena (Brewer, 1972; Valentine and Dalrymple, 1975, 1976; Finkl, 1980; Catt, 1986, 168–169). This characteristic of soils allows them to be traced in three dimensions over varying paleotopography. Individual layers of sediment, in contrast, will be confined to particular depositional environments and will thin to nothing as one moves away from that environment (Mandel and Bettis, 2001, 180).

Burial processes

The recognition and interpretation of buried soils can be complicated by several processes that take place before, during, or after burial. As a landscape is buried, some or all of the following processes can operate, depending on landscape position and the nature of the burial process(es).

1. Rapid burial that leaves a complete soil profile preserved under younger sediment. Processes of rapid sedimentation alternating with periods of relative landscape stability and weathering produce multistory sequences of buried soils (Figures 1a, 3, and 5).
2. Erosion prior to burial resulting in a truncated soil profile preserved under younger sediments.
3. Slow burial that allows pedogenesis to keep pace with sedimentation. The result is *upbuilding* (Johnson and Watson-Stegner, 1987) or *overthickening* or *cumulization* of a soil (Buol et al., 1997, 91). Overthickening means that a particular horizon literally becomes thicker than average (relative to more typical horizons associated with similar soils in similar settings in the region) (Figure 6). Overthickened soils are referred to as *accretionary* (Catt, 1990, 6) or *cumulative* (Nikiforoff, 1949, 227–228; Birkeland, 1999, 165–167), and overthickened horizons are called *cumulic* in *Soil Taxonomy* (Soil Survey Staff, 1999, 155). *Soil Taxonomy* (Soil Survey Staff, 1999, 155) further distinguishes between *cumulic* and *pachic* horizons: cumulic horizons can exhibit evidence for stratification (Figure 7), whereas a pachic horizon is overthickened with no evidence of stratification (Figure 8). In general parlance, however, cumulic is usually applied to both situations.

In describing the processes of overthickening, some investigators distinguish between the effects of slow rates of burial and moderate rates of burial (Follmer, 1982, 120; Cremeens and Hart, 1995, 23–24). The difference between an overthickened soil and several welded soils, therefore, is related to local rates of sedimentation. A set of welded soils and a single overthickened soil could be



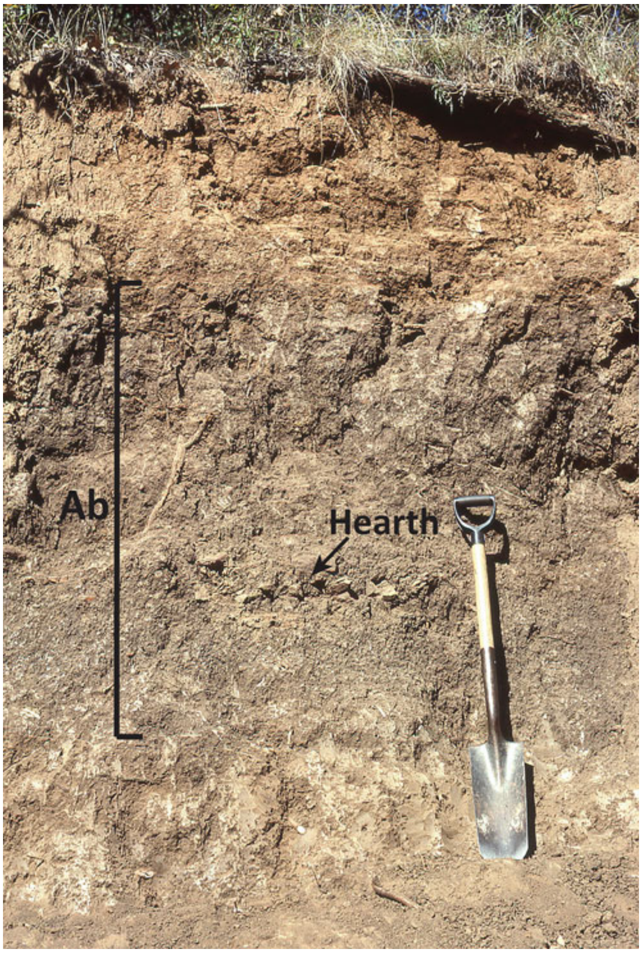
Soil Stratigraphy, Figure 7 The cumulic Ab horizon of a buried paleosol developed in the Aggie Brown Member at the Beacon Island site, an Agate Basin (Paleoindian) bison kill in northwestern North Dakota. The Ab horizon exhibits faint bedding typical of many cumulic soils (Modified from Mandel et al., 2014: Figure 8).

facies of one another (e.g., Kemp et al., 1997). This facies relationship could be at the scale of a floodplain or valley or at a regional scale. Geoarchaeologically, variation in rates of burial of soils and occupation debris will significantly affect where in a soil an archaeological horizon will occur.

Most typically, overthickening affects the A horizon and results from moderate rates of sediment accumulation and burial, where organic matter additions and bioturbation more or less keep pace with sedimentation. Overthickened A horizons are archaeologically significant because they can preserve stratigraphic relationships among artifacts, features, and living surfaces that are otherwise obscured or destroyed in the more typical A horizon. Some accretionary A horizons have weakly expressed stratification, which further aids in archaeological correlation and dating. In some places, the catena variation in soils produces a cumulic A horizon adjacent to an abruptly buried A horizon as in a floodplain abutting a footslope near Cancuen in Guatemala's Peten region (Figure 9).

Pedogenic features are clearly the primary clues to the presence of buried soils, but the morphologic and chemical characteristics typical of soils can undergo moderate to profound changes following burial. Yaalon (1971b) grouped soil horizons and features according to their relative persistence after burial. Generally speaking, the likelihood of preservation or persistence is related to the rate of development of the horizon. Soil features that form rapidly, such as the A horizon, tend to be the least persistent after burial, though many persist for at least 2000 years in the Maya Lowlands (Beach et al., 2015), whereas soil horizons that form more slowly, such as the Bt horizon, tend to be more persistent in buried soils.

The process of soil burial and then post-burial alterations can effectively obscure a buried soil. To summarize, the following questions can be posed as a means of identifying the partial or modified remains of a buried soil (modified from Catt, 1990, 6–7):



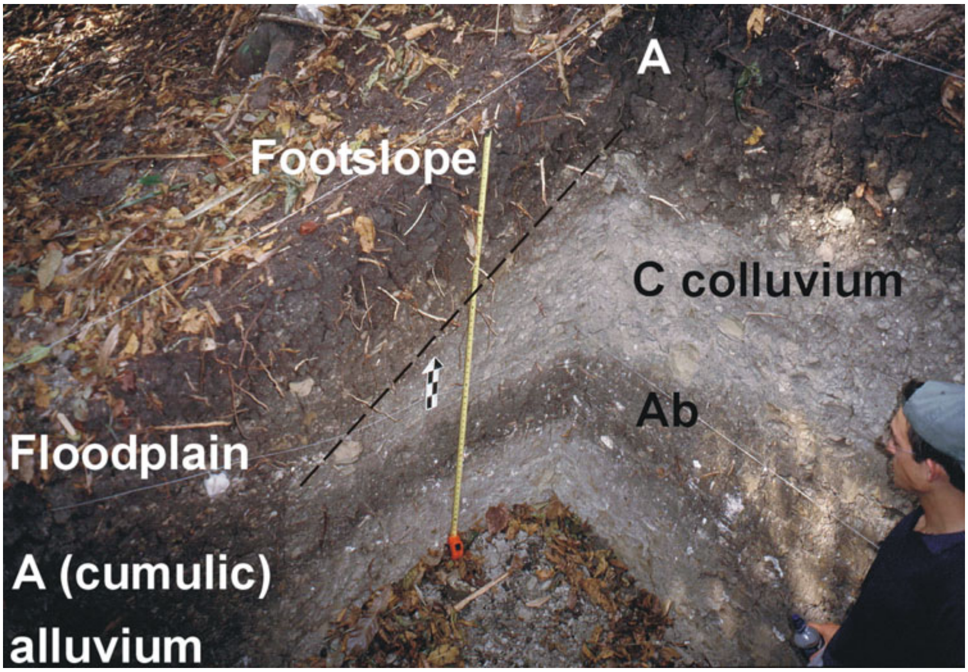
Soil Stratigraphy, Figure 8 A buried soil with a pachic Ab horizon developed in late Holocene alluvium in Fish Creek valley, north-central Texas (Mandel, 1992a). There is no evidence of stratification in the overthickened Ab horizon (Photo by Rolfe D. Mandel).

1. Do the layers concerned contain fossil remains of plants (e.g., roots, charcoal), or artifacts, or geochemical evidence (Beach et al., 2008) indicating the former presence of a land surface?
2. Do the layers display a vertical sequence of horizons that partly or wholly resembles what is typical of known types of modern surface soils?
3. If they are traced laterally, do the layers transgress bedding planes or other rock structures? If so, they are likely to be soil horizons, though in some soils, horizons develop parallel to bedding planes.
4. If they are traced laterally, do the transgressive layers change in character, not only in relation to changes in the underlying sediments or rock type but also in response to changes in the slope of the associated buried land surface? That is, do they form a paleocatena?

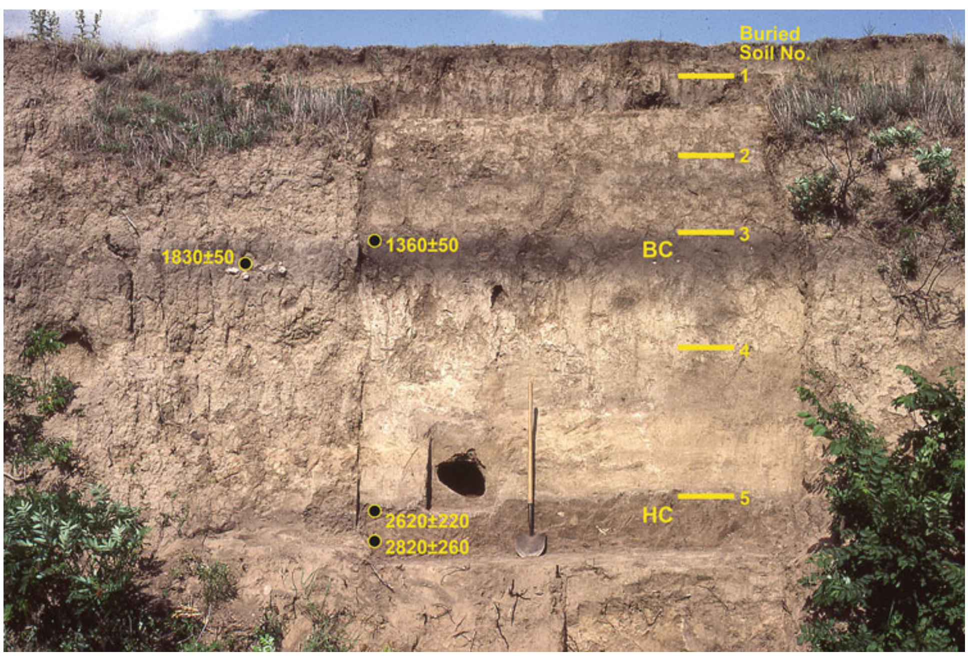
Applications of soil stratigraphy

Recognition of soil stratigraphy has many applications in archaeological investigations. At regional scales, buried soils can be used for stratigraphic correlation of occupation zones and archaeological sites. More locally, in archaeological surveys, buried soils may serve as stratigraphic "markers" used to target particular landform sediment assemblages for deep testing. Buried soils also may be used to determine the boundaries of a site, and where time-diagnostic artifacts and radiocarbon-datable materials are absent, they may be used to estimate the age of cultural deposits. At some archaeological sites, soil stratigraphy is crucial to understanding landscape evolution and site formation processes. A few examples of the application of soil stratigraphy in archaeological investigations are presented below.

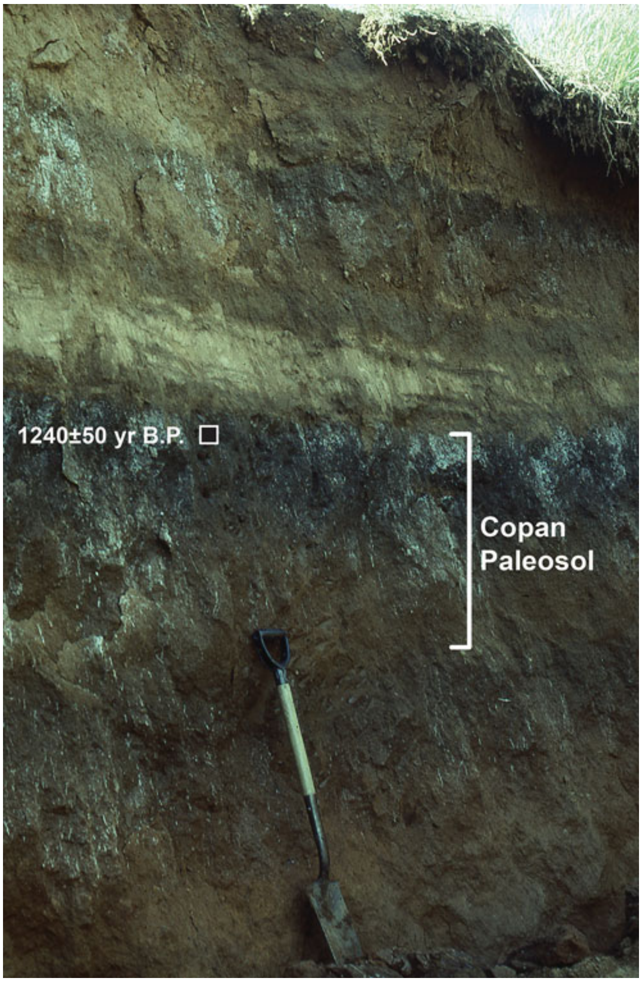
An archaeological survey of the Pawnee River watershed in southwestern Kansas was preceded by an intensive, basin-wide study of alluvium and buried soils to determine their potential for buried cultural deposits. In the valleys of small streams (<5th order), the Hackberry Creek Paleosol and the Buckner Creek Paleosol were identified beneath the lowest terrace (T-1) (Figure 10) (Mandel, 1988; Mandel, 1992b; Mandel, 1994). Radiocarbon ages indicate that the Hackberry Creek Paleosol formed ca. 2800 to 2000 years BP, and the Buckner Creek Paleosol developed around ca. 1700 to 1000 years BP. These two buried soils have thick, moderately expressed Ak-Bk profiles and occur in the valleys of all small streams in the Pawnee River basin. Other buried soils in the late Holocene alluvium comprising the T-1 fill have thin, weakly expressed A-C profiles reflecting only tens of years of pedogenesis (Mandel, 1992b). Stratified late Archaic and Plains Woodland cultural deposits were recorded in the Hackberry Creek and Buckner Creek paleosols, respectively, whereas buried soils with A-C profiles were consistently sterile of archaeological materials (Mandel, 1988; Mandel, 1992b; Mandel, 1994). This finding underscores the axiom that the longer the period over which a soil has developed, the higher its potential for containing cultural deposits at any given location. The Hackberry Creek and Buckner Creek paleosols were targeted for exploration during the subsequent archaeological survey of the Pawnee River basin (Timberlake, 1988).



Soil Stratigraphy, Figure 9 A cumulic soil developed in floodplain alluvium (*left*) is laterally inset against colluvium on a footslope. The buried soil developed in the colluvium dates to ca. 1200 BP (Beach et al., 2006).



Soil Stratigraphy, Figure 10 Soil stratigraphy of the T-1 alluvial fill exposed in the east bank of Buckner Creek at the Buckner Creek site (14HO306) in southwestern Kansas. There are five buried soils, but only two – the Buckner Creek (*BC*) and Hackberry Creek (*HC*) paleosols – can be traced throughout Buckner Creek basin and other drainage systems in the region. The radiocarbon ages were determined on charcoal from cultural features (Modified from Mandel (1992b: Figure 2–13)).



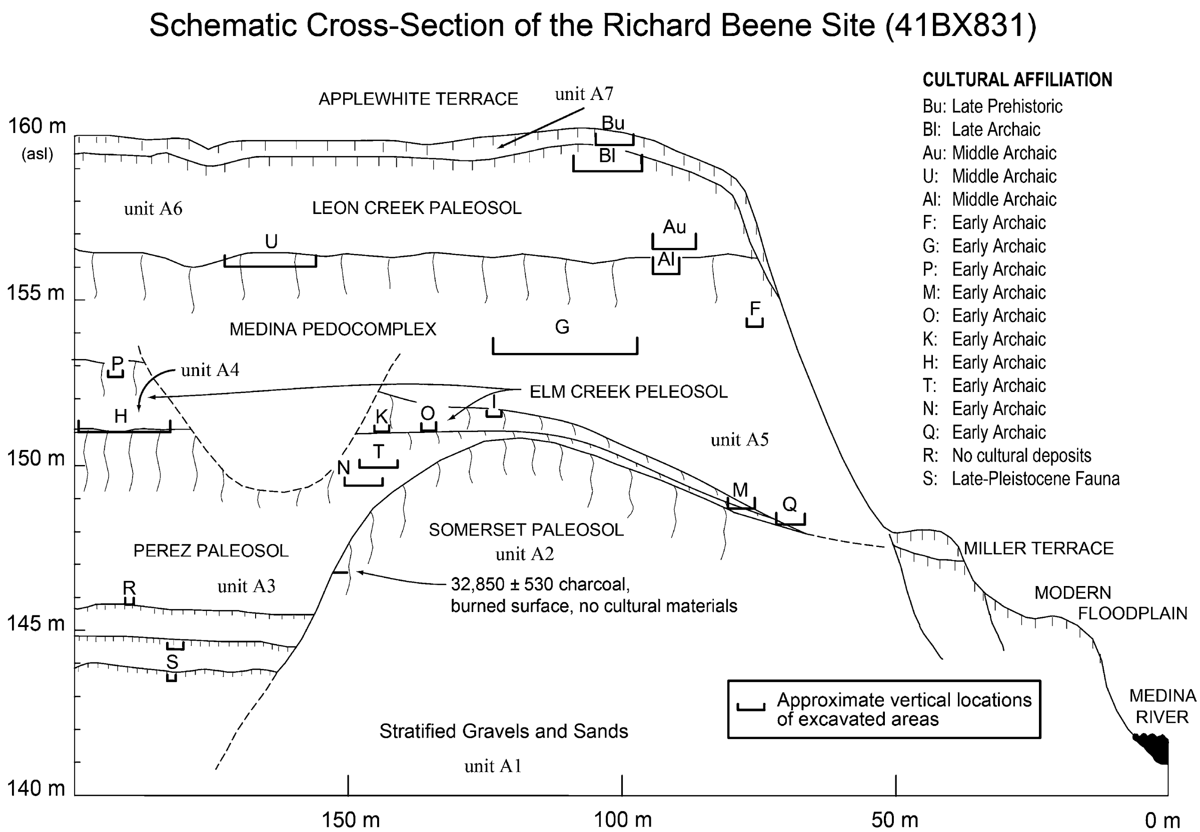
Soil Stratigraphy, Figure 11 The Copan paleosol developed in the T-1 alluvial fill of Elm Creek in Barber County, south-central Kansas. The dark, organic-rich cumulic Ab horizon is 50 cm thick. The radiocarbon age was determined on soil organic matter (Photo by Rolfe D. Mandel).

In situations where time-diagnostic artifacts and radiocarbon-datable materials are absent at a site, buried soils may be used as time-stratigraphic markers to estimate the age of cultural deposits. For example, in eastern Oklahoma and southeastern and south-central Kansas, a buried soil with a distinct overthickened (cumulic) A horizon is developed in late Holocene alluvium (Figure 11). This soil, which is often referred to as the Copan paleosol (Hall, 1977; Artz and Reid, 1984; Artz, 1985; Ferring, 1986; Mandel, 1993a; Mandel, 1993b) or Caddo paleosol (Hall, 1980; Ferring, 1982; Lintz and Hall, 1983), developed between ca. 2000 and 1000 years ago. Because the buried soil is well dated and easy to recognize in late Holocene alluvial sections, it is a time-stratigraphic marker and has been used to estimate the age of cultural deposits contained in its horizons (e.g., Mandel, 2013b).

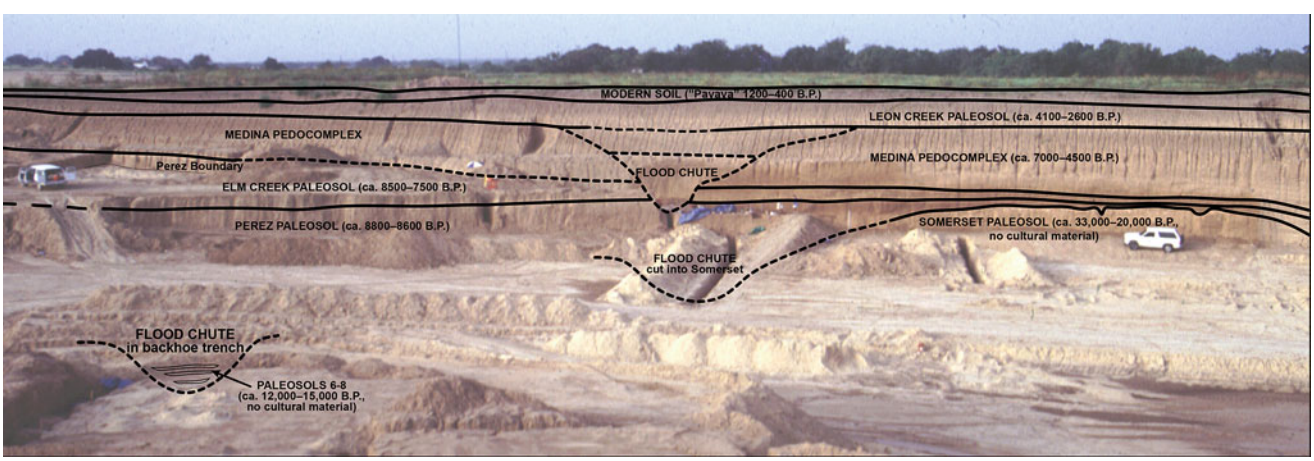
The boundaries of deeply buried archaeological sites may be difficult to determine by traditional excavation methods for logistical reasons. However, if the buried materials are on former stable surfaces (i.e., associated with distinct buried soils), soil stratigraphy, combined with deep testing, may be used to determine the spatial limits of cultural deposits. For example, investigation of deeply buried cultural deposits in alluvium at the Richard Beene site (41BX831) in the Medina River valley of south-central Texas identified seven major depositional units beneath the Applewhite terrace (Figure 12) (Mandel et al., 2007). Soils are developed at the top of each unit, and archaeological materials are on and within the buried soils. The thickness of the fill terrace (>20 m), combined with complex stratigraphy that is a product of alluvial cutting and filling, presented a challenge to document the lateral extent of the cultural deposits. Mandel et al. (2007) defined the spatial limits of each buried cultural zone by using cores and a long, deep trench to trace the artifact-bearing buried soils, all designated as paleosols, and to identify their stratigraphic complexities (Figure 13). These findings were critical to the development of excavation strategies that targeted some areas of the site for investigation while avoiding other areas (Thoms, 2007).

In the Maya Lowlands, soil catena excavations at Blue Creek, Belize, uncovered a series of paleosols lumped together at the Eklu'um paleosol buried by colluvial, alluvial, hydrogeological, and anthropogenic processes from 2000 to 1000 years ago (Beach et al., 2008) (Figure 14). The general driver was human slope alteration creating erosion along the slope but with aggradation in adjacent karst sinks, alluvial fans, footslopes, and the Rio Bravo floodplain. In the floodplain and some karst sinks, aggradation occurred by water table rise with gypsum precipitation and Maya adaptation with canalization and field raising, both obliterating and burying Vertisol, Mollisol, and Histosol paleosols.

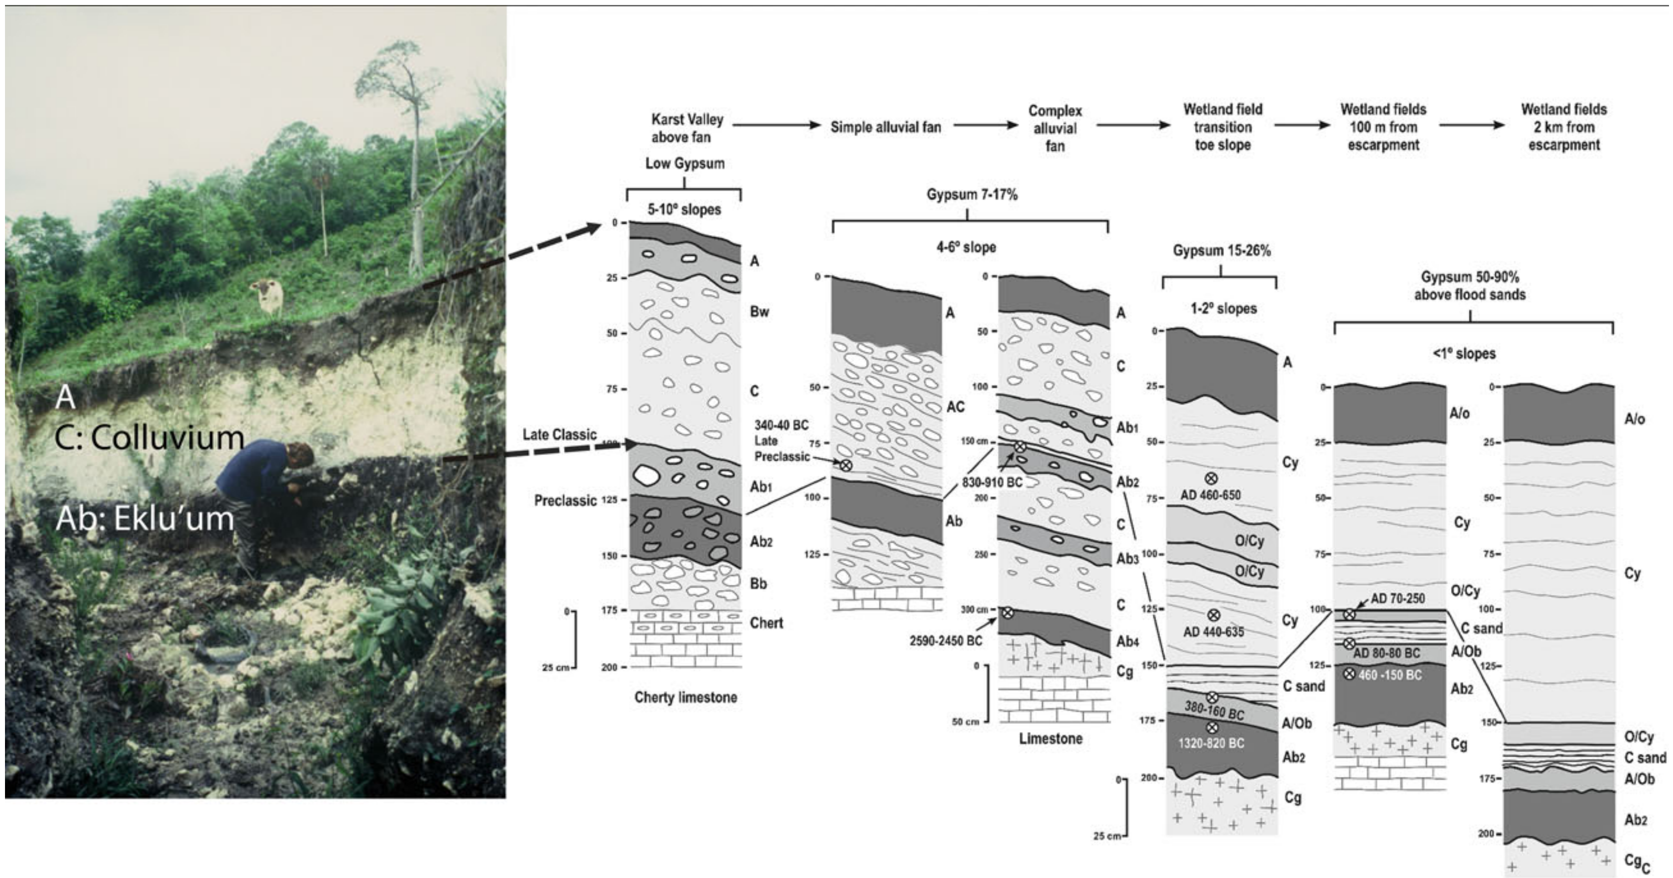
Soil stratigraphy has long been applied for correlation of geologic deposits in Europe and Asia. This work also has been carried over into geoarchaeological correlations. In Tajikistan, buried soils in the loess record combined with paleomagnetic data have been used to correlate the Paleolithic archaeology and to provide age estimates for occupation zones at specific sites (see "Loessic Paleolithic, Tajikistan" entry in this volume). More locally, soils in the alluvial stratigraphic record of



Soil Stratigraphy, Figure 12 Schematic cross-section of the south wall of the 20-m-deep spillway trench at the Richard Beene site showing stratigraphic units, soils, excavated areas, and archaeological stratigraphy (Modified from Mandel et al. (2007: Figure 3.3)).



Soil Stratigraphy, Figure 13 The central section of the south wall of the 20-m-deep spillway trench at the Richard Beene site showing the paleosols and associated radiocarbon ages determined on charcoal (Modified from Thoms (2007: Figure 4.6)).



Soil Stratigraphy, Figure 14 A catena near Blue Creek, Belize, showing the Preclassic Eklu'um paleosol predating 2000 BP buried by colluvium and alluvium with secondary accumulation of gypsum (Beach et al., 2008).

terraces of the Don River in southwestern Russia have been similarly applied to correlate and date the several dozen late Middle and Upper Paleolithic sites in the Kostenki-Borschevo area (see "Kostenki, Russia" entry in this volume).

Introduction

Soil survey and mapping is one of the most fundamental and best-known activities in pedology. The production of soil maps based on systematic soil surveys was one of the primary driving forces in pedologic research in both academic and governmental settings in the USA and worldwide through much of the twentieth century (Simonson, 1987, 1997; Yaalon and Berkowicz, 1997). Soil maps have been prepared for a variety of uses at scales ranging from a few hectares to continental and global. Published soil surveys contain a wealth of data on landscapes as well as soils, but they are generally an underutilized (and likely a misunderstood) resource in geoarchaeology, probably because of their agricultural and land-use orientation.

Many countries in the world have national soil surveys whose primary mission is mapping and inventorying the nation's soil resources. In the USA, soil survey is a cooperative venture of federal agencies, state agencies, including the Agricultural Experiment Stations, and local agencies, coordinated by the National Cooperative Soil Survey (Soil Survey Division Staff, 1993, 11). The principal federal agency involved in soil survey is the National Resource Conservation Service (NRCS) (formerly the Soil Conservation Service, SCS) of the US Department of Agriculture (USDA). Published county soil surveys are their most widely known and widely used product. These surveys contain information regarding soils and land-use capability, and many include descriptions of soil properties of interest to engineers. The surveys also are a remarkable source of maps and air photographs. Most archaeologists are aware of this resource, but its usefulness sometimes seems to be overestimated or misunderstood in some cases or underused in others (Voight and O'Brien, 1981), as illustrated below. The county soil surveys have potential for archaeological applications, but their purpose and limitations must be recognized.

The USDA county soil surveys and those of most nations are prepared for land-use planning, especially for soil conservation programs, planning agriculture programs, financial credit, zoning, construction and engineering purposes, and land evaluation (Butler, 1980, 1–7; King, 1983, 102–103; Broderson, 1994; Buol et al., 2011, 32–34). The photomaps in the soil surveys are produced at a variety of scales, ranging from 1:7,920 to 1:31,680, and at various levels of detail (Soil Survey Division Staff, 1993, 47–46). Most of the photomaps, however, are at a scale of 1:20,000. The NRCS digitized these maps so they can be electronically accessed. More generalized soil maps of individual states in the USA typically are in the range of 1:250,000–1:2,000,000. In contrast, King (1983) describes soil maps for a part of Cyprus produced at two scales: 1:25,000 and 1:200,000. Globally, FAO (2006) produced a 10-volume set of soil maps of the world at 1:500,000.

Limitations of soil surveys

The purpose and preparation of soil surveys impose a number of limits on their utility in archaeological research. One limit on their use for site-specific interpretations is the generalization inherent in defining mapping units. Soil variability and how to deal with it in mapping is a significant issue in the pedologic literature (e.g., Wilding and Drees, 1983; Mausbach and Wilding, 1991). The distribution of soils across a landscape may be too complex to map accurately either due to complexities in their evolution (i.e., variability in the factors or processes of soil formation) or due to variability in their taxonomic classification (see entry on Soils in this volume).

> Because limitations imposed by scale and legibility do not permit exact representation of all detail observed (or inferred) in the field, *mapping units cannot correspond exactly to the taxonomic or genetic units that they represent*. . .. Mapping units therefore typically include areas of soils other than those specified in the legend. . .. An important practical problem in most national soil surveys is that *the map user has no way to learn of the amount, character, and pattern of these variations, because he or she must rely completely upon the map, its legend, and the accompanying report, which usually presents little detail on such matters*" (emphasis added). (Hole and Campbell, 1985, 113)

For example, the minimum size area permitted for delineation on most county soil surveys is 1 ha. Depending on the scale of the map, the maximum size permitted may be as large as 4 ha (Soil Survey Division Staff, 1993, 52–55, Table 2.1). Therefore, the scale of many archaeological sites is smaller than most soil mapping units and the variability inherent in those mapping units. The problem of scale in dealing with soil mapping units and archaeological sites has been confronted in archaeological surveys around the world (e.g., King, 1983; Jones, 1990).

The boundaries of a particular mapping unit do not always represent actual soil boundaries because soils may grade from one type into another rather than having sharp contacts like many geologic units. Soil boundaries are rarely as distinct as the map lines used to symbolize them (Hole and Campbell, 1985, 101). The fundamental issue of scale in soil mapping is that the soils that can be seen at an archaeological site may not necessarily be those indicated on the published soil survey of the area.

The focus on the *soil series* further inhibits the geoarchaeological applications of county soil surveys. The soil series is the fundamental mapping unit in county soil surveys. Soil series are defined on the basis of one or more of the following characteristics: kind, thickness, and arrangement of soil horizons along with the color, texture, structure, consistence, pH, content of carbonates and other salts, content of coarse fragments, and mineralogy. A *soil association* is a more generalized mapping unit (e.g., used on county-scale or state-wide soil maps), typically based on two or more similar series plus inclusions. The soil series is the most homogeneous grouping of soils made in Soil Taxonomy (Buol et al., 2011, 33, 212–214). Soil series are defined strictly as subdivisions within the classificatory system (see Soils entry) and are intended to "record pragmatic distinctions, i.e., to be keyed to soil usefulness" (Simonson, 1997, 80). The emphasis on specific physical or chemical characteristics to define soil series results in mapping units that are rarely related to one another except taxonomically. For example, "the soil classification relates an Aquept [an Inceptisol] in a certain map unit to other Inceptisols throughout the world. But it does not address the relationship between the map unit containing the Aquept and other map units that occur adjacent to it in the survey area" (Swanson, 1990, 52).

The heavy emphasis on the soil series but the lack of information regarding genetic relationships among series tends to promote a view of the soil landscape as if the soil series are independent segments, like tiles in a tile floor. For this reason, as well as others discussed below, the soil series may not be relevant in regional geoarchaeological or soil-geomorphic investigations. Instead, the *great group* or perhaps *subgroup* level of Soil Taxonomy may be more meaningful and informative, though investigators will need to be familiar with series names in order to read soil maps. However, as discussed later, in some cases soil series may be used to map landform sediment assemblages dating to specific periods. Such information is useful for understanding the geomorphic settings of archaeological sites and predicting and assessing temporal and spatial patterns of cultural deposits across a region.

Typically, soil surveys are not designed for use as guides to local geology or geomorphology or to aid in interpreting or reconstructing the past, and few contain substantive data on local soil-forming processes and factors. In the USDA county surveys, genetic and factorial relationships among series as well as geologic and other "physiographic" aspects were expressly de-emphasized, despite work that showed a good relationship (Simonson, 1997; Holliday et al., 2002). The degree to which the USDA county surveys accurately depict soil-geomorphic relations will vary tremendously from survey to survey, depending on the size of the features of interest, the area, and the training and experience of the mappers.

There are several other reasons why the distribution of modern soil series may be poor indicators of site distributions (following Warren et al., 1981):

1. The factors and processes of soil formation can and do change over time, and the more time that passes since occupation of an archaeological site, the more likely that the environment has changed and the more likely that such change was significant in terms of either settlement or soil formation or both.
2. Human perceptions of soil quality or environmental quality change through time, i.e., successive groups of occupants may have different criteria for what constitutes "good" or attractive soils or environments even though there were no substantive changes in these characteristics.
3. Finally, soils are not necessarily the best indicator of past environments (e.g., Voight and O'Brien, 1981).

Archaeological applications of soil surveys

The characteristics of soil surveys described above have resulted in their being minimally used in geoarchaeological research. Nevertheless, they have some utility in addition to providing maps and aerial photos. Specific soil series sometimes are associated with specific landforms, and thus they can provide clues to archaeologically significant settings (Saucier, 1966; Almy, 1978; Litwinionek et al., 2003; Mandel, 2006a; West, 2012). There are several examples in which the distribution of specific soil series was used to predict the presence or absence of sites by simply looking at the correlation between soil series and site frequency (Almy, 1978; Voight and O'Brien, 1981; Warren et al., 1981; Warren and O'Brien, 1981, 1982; Warren, 1982a). Research on soils, geomorphology, and geoarchaeology along the Kansas River (Johnson and Martin, 1987; Sorenson et al., 1987; Johnson and Logan, 1990; Mandel, 1995, 2006b) provide a good illustration of the relationship between traditional soil survey mapping, soil series, and soil-geomorphic relationships along terraces.

More broadly, drainage characteristics of soils, emphasized on soil surveys, can be useful for archaeological site prediction, as better-drained soils are more likely to contain sites (i.e., prehistoric occupants probably preferred better-drained settings for most of their activities) (Saucier, 1966; Plog, 1971; Lovis, 1976; Almy, 1978; O'Brien et al., 1982; Warren, 1982b; Mandel and Bettis, 2001, 182).

The soils themselves have some interpretive value for archaeological research. Assessing relative landscape age based on soil classification is perhaps the most useful yet most underutilized aspect of soil surveys in geoarchaeology and geomorphology. Soil Taxonomy was not designed to be a means of estimating soil age or to make other sorts of genetic interpretations, but with some experience and caution, age assessments can be offered based on horizon characteristics, particularly the B horizon, and based on classification (Artz, 1985; Bettis, 1992; E. A. Bettis, 2001, "personal communication").

A number of studies (e.g., Bettis and Benn, 1984; Artz, 1985; Bettis, 1992; Mandel, 1992, 1994, 2006a; Monger, 1995; Stafford and Creasman, 2002; West, 2012) have considered the relationship between magnitude of soil development and age of geomorphic surfaces to develop archaeological predictive models. These models use soil classification and taxonomy presented in soil surveys to estimate the relative age of surface soils, which in turn provides a minimum age for associated landforms (Holliday, 2004) (see entry on "Geomorphology" in this volume). The estimated ages then can be used to assign an archaeological potential to specific landforms, which are generally described as having low, medium, or high potential (Mandel, 1992, 1994). For example, on the valley floors of streams, strongly developed surface soils with an argillic (Bt) horizon have a higher potential to yield prehistoric cultural deposits than weakly developed soils that lack a B horizon. Such estimated ages can even be used to identify landforms, such as floodplains, natural levees, terraces, and alluvial fans, that have potential for yielding archaeological materials dating to specific cultural periods, such as Paleoindian, Archaic, and Woodland (Artz, 1985; Stafford and Creasman, 2002; Mandel, 2006a, 2006b).

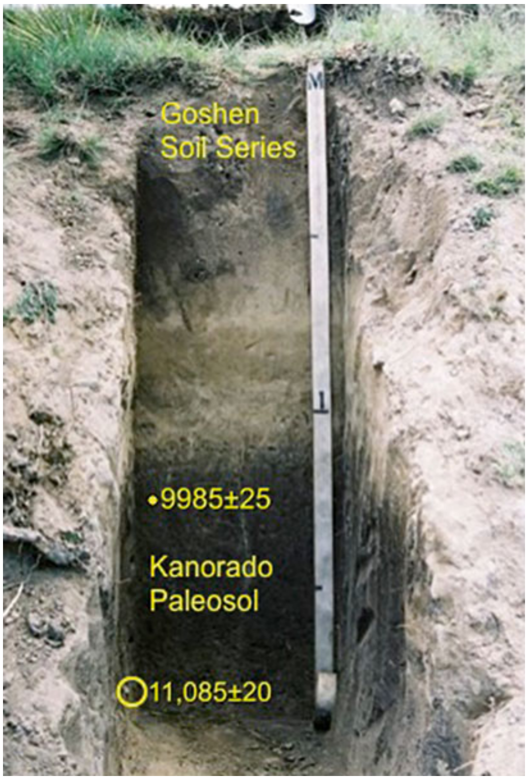
In a study of the central Des Moines River valley, Bettis and Benn (1984) demonstrated that certain properties of surface soils developed in the Holocene alluvium of Midwestern streams are age diagnostic. For example, surface soils formed in early and Middle Holocene alluvium are Mollisols with Bt horizons or Alfisols. In contrast, surface soils developed in late Holocene alluvium are Mollisols or Inceptisols with cambic (Bw) horizons, or Mollisols that lack B horizons. This soil information, much of which was gleaned from soil surveys, was used to construct maps that show the distribution of landform sediment assemblages dating to different periods of the Holocene. In turn, archaeologists used the maps to devise sampling strategies for locating cultural resources in the valley landscape (see entry on "Geomorphology" in this volume). Such soil-based information also can provide archaeologists with estimates of past landscapes removed by fluvial processes (Mandel and Bettis, 2001, 182).

Some soil surveys in the USA were prepared with the type of background information that permits their use as guides to archaeologically significant soil-geomorphic relationships. From the late 1950s into the 1970s, the USDA sponsored a series of research projects focused on understanding soil-geomorphic relations in various environments in the USA. One of these projects focused on late Pleistocene and Holocene landscapes in the Willamette River valley of northwestern Oregon (Balster and Parsons, 1968; Parsons et al., 1970). The model of fluvial landscape evolution that resulted from this work has been used for mapping soils along rivers in the region (e.g., Gerig, 1985) and on the Pacific coast (e.g., Shipman, 1997). These county soil surveys should be useful in predicting the likely presence or absence of archaeological sites, and their age, either buried or at the surface. In south-central New Mexico and far western Texas, soil-geomorphic mapping was carried out to predict archaeological site locations and to interpret archaeological finds in the desert terrain of Fort Bliss (Monger, 1995). The work built on the considerable USDA soil-geomorphic research in the Rio Grande Valley just to the west (e.g., Gile et al., 1965, 1966, 1981).

Likewise, the USDA soil surveys have been used for some geomorphic mapping, which has geoarchaeological potential. Areas with strongly contrasting parent materials and landforms are a key component in linking soil series to specific rock types, deposits, and geomorphic features (e.g., Lindholm, 1993, Lindholm, 1994a; Lindholm, 1994b). Brevik and Fenton (1999) used soil surveys to map late Pleistocene strandlines of Glacial Lake Agassiz in eastern North Dakota. As part of a geomorphological and geoarchaeological investigation of the National Tallgrass Prairie Preserve in the Flint Hills of east-central Kansas, Mandel (2006a) used the USDA soil survey to map the spatial pattern of Holocene and late Pleistocene alluvial lithostratigraphic units in Fox Creek valley. This was possible because certain soil series are associated with specific lithostratigraphic units in the Flint Hills region. Ultimately, a 1:24,000-scale map showing the geologic potential (high, medium, and low) for buried cultural deposits was generated based on the spatial pattern of the lithostratigraphic units (Mandel, 2006a: Figure 29).

Beyond the county soil surveys produced by the USDA, a wide variety of soil maps exists, produced in many different scales for an array of purposes by a wide range of agencies. Many of these maps probably have archaeological applications, especially the larger-scale ones (i.e., maps covering small areas). In the Netherlands, a soil survey produced at 1:10,000 proved useful in predicting likely site locations (beach ridges and natural levees) and site age because it was prepared by linking soil types to specific late Quaternary deposits and land forms (Dekker and De Weerd, 1973). The Soil Survey of Scotland (1981) was put to good use in a geoarchaeological context as part of a study of ancient land management in Orkney (Simpson, 1997). One phase of a soil series in the area was identified as a *plaggen* (see entry on Anthrosols in this volume) (Davidson and Simpson, 1984). The soil survey could, therefore, be used in a study of the origins of plaggen soils and their implications for land use in the region in the thirteenth to nineteenth centuries.

Soil surveys also have been carried out for expressly archaeological purposes with considerable success. In the Midwestern USA, soil surveys along alluviated valleys have been important components of some archaeological site prediction studies (e.g., Bettis, 1992; Mandel, 1992, 1994, 2006a; Stafford and Creasman, 2002; Gottsfield, 2009; Beeton and Mandel, 2011; West, 2012). The work entails (1) looking at the distribution of soil types (taxonomic great groups and soil series) and their parent materials (i.e., the sediments comprising the alluvial fill); (2) dating the sediments, soils, and associated landforms (typically stream terraces); (3) modeling the environmental evolution of the sediments and soils; and (4) using the resulting data to predict the location and age of archaeological sites, buried and at the surface, and to interpret the distribution of sites once surveys are completed. Not only are these surveys important for locating sites, but they can also indicate likely areas where sites



Soil Survey, Figure 1 Soils exposed in a streambank at 14SN106, one of three sites at the Kanorado Locality in northwestern Kansas. At all three sites, the Kanorado paleosol, which represents a buried Paleoindian-age landscape, contains Folsom and Clovis-age cultural deposits. In draws on the High Plains of western Kansas and eastern Colorado, the Kanorado paleosol typically occurs where the Goshen soil series is developed in alluvium underlying a low terrace. This relationship allows NRCS soil survey data to be used to target areas with high potential for buried Paleoindian cultural deposits.

will be absent, either because the sediments and landscapes likely to be associated with archaeological sites are missing or because the extant deposits and landforms are too young. A similar, and equally successful, approach to locating and interpreting sites, but at a longer time scale, based on mapping of soils and landforms was also carried out in Jordan (Cordova et al., 2005).

In a recent study, West (2012) developed a soil-based methodology for predicting the location of buried Paleoindian cultural deposits in small, intermittent streams, or draws, on the High Plains of western Kansas and eastern Colorado. Results of geomorphological investigations at the Kanorado locality in Middle Beaver Creek, a draw in northwestern Kansas, suggested that a buried soil – the Kanorado paleosol – typically occurs where the Goshen soil series is developed in alluvium underlying a low terrace (Figure 1) (Mandel et al., 2004; Mandel, 2008). The Kanorado paleosol is developed between ca. 14 and 10.4 ka (Cordova et al., 2011) and contains Clovis-age and Folsom cultural deposits (Mandel, 2015). West (2012) used the USDA-NRCS Soil Survey Geographic (SSURGO) database to map the distribution of the Goshen series throughout Middle Beaver Creek basin. He then examined stream cutbanks and cored areas where the Goshen series occurs. Based on the results of his ground truthing, 71 % of the localities with the Goshen series had a buried soil that fits the description of the Kanorado paleosol. Radiocarbon dating of soil organic matter confirmed that the buried soil is the same age as the Kanorado paleosol. Hence, the co-occurrence of the Goshen series and Kanorado paleosol is not a coincidence, and alluvial terraces mapped with the Goshen series have high potential for yielding stratified Paleoindian cultural deposits (West, 2012).

In southwestern Greece, soil mapping was a component of long-term investigations in and near Nichoria (McDonald and Rapp, 1972; Rapp and Aschenbrenner, 1978). The mapping was a traditional soil survey and provided relatively little data of archaeological significance. But the surveys did show significant differences in soil morphology (Alfisols and Inceptisols) in and near the field area (Yassoglou and Nobeli, 1972; Yassoglou and Haidouti, 1978). This difference in soil types was attributed to differences in landscape stability and soil age (Alfisols = older, more stable landscape; Inceptisols = younger, disturbed landscape) due to human impacts.

A survey designed expressly to identify relict arable soils was carried out on the Lofoten Islands of Norway (Simpson et al., 1998). Traditional field survey was combined with analysis of pollen cores to detect the onset of agriculture and examination of soil micromorphology in thin sections (see entry on Soil Micromorphology in this volume) to complement field evidence for agriculture or other human impacts.

In Britain, data derived from digital maps of both soils and surface geology provided information on groundwater levels, oxidation and reduction in soils, soil acidity, and soluble salts and salt content. These data have proven useful for understanding near-surface site preservation throughout the country (Ward et al., 2009).

Site-specific soil surveys have proven helpful in solving particular archaeological research questions. At the Altofts site, West Yorkshire, UK, an area identified as a henge (a circular or oval area enclosed by a bank and an internal ditch) was investigated to determine whether, in fact, it was a henge (Weston, 1996). In western Belize, soils provide insights into the location of Maya cacao orchards (Muhs et al., 1985). Cacao was one of the most important crops of the lowland Maya, but evidence of where the cacao was grown is rarely evident. In addition, cacao macrofossils are rarely preserved, and cacao sheds little pollen. Muhs et al. (1985) addressed the problem by mapping and analyzing soils at an ethnohistorically documented cacao-growing center and extrapolating to areas that may have produced cacao in antiquity.

Several site-focused soil surveys have helped resolve issues of site location and age. A soil survey around the ancient Bronze Age city of Harappa in Pakistan (Pendall and Amundson, 1990; Amundson and Pendall, 1991; Belcher and Belcher, 2000) used a soil-geomorphic approach to reconstruct the Holocene evolution of the landscape in the site area and to understand the relation of the site to the adjacent Ravi River. In a somewhat similar approach, Jones (1990) conducted soil surveys at a series of sites on the North Island of New Zealand. Using published, regional soil surveys combined with data from studies of local fluvial geomorphology, he was able to apply local soil data to estimate the maximum ages for construction of fortified settlements.

In sum, soil surveys can provide useful information in archaeological investigations, but it is important to recognize the limitations of the data presented in the surveys. Because soil surveys are generalized, they should be used only to establish initial impressions of soil-geomorphic relationships in a study area (Mandel and Bettis, 2001, 182). Detailed field investigations are required to confirm and elaborate on those impressions and to refine them to the scale (both spatial and temporal) needed by most archaeologists (Artz, 1985).

Introduction

Archaeologists generally realize that there is an important relationship between cultural deposits and associated soils. Yet, their understanding of what a soil is, as well as what soils can reveal about site formation processes, landscape development, and environments of the past, varies greatly. Although archaeologists should not be expected to have a complete grasp of pedology, they should be capable of recognizing and interpreting soils in an archaeological context in order to comprehend fully the record of the human past (Mandel and Bettis, 2001).

Soils are a part of the stage upon which humans evolved. As an integral component of most natural landscapes, soils also are an integral component of cultural landscapes. Furthermore, soils are indicators of the nature and history of the physical and human landscape, they record the impact of human activity, they are a source of food and fuel, and they reflect the environment and record the passage of time. Soils also affect the nature of the cultural record left to archaeologists. They are a "reservoir" for artifacts and other traces of human activity, encasing archaeological materials and archaeological sites. Soil forming processes also are an important component of site formation processes. Pedogenesis influences which artifacts, features, and environmental indicators (floral, faunal, and geological) are destroyed, which are preserved, and the degree of preservation. Most of these many aspects of soils are dealt with elsewhere (see the entry on Site Formation Processes in this volume).

A soil is a natural three-dimensional entity that is a type of weathering phenomenon occurring at the immediate surface of the earth in sediment and rock and serving as a medium for plant growth. Soil is the result of the interaction of climate, flora, fauna, and landscape position, all of which act on sediment or rock through time (modified from Schaetzl and Anderson, 2005, 9; Soil Science Society of America, 2008). The surface supporting soil development (i.e., the rock or sediment in which the soil forms) is referred to as *parent material*. This concept of soil has important corollaries (Holliday, 2004, 2–3; see also Schaetzl and Thompson, 2015, 6–7):

1. Soils form in, or represent an alteration by weathering of, sediments and rocks over time, i.e., soils are a type of surface weathering phenomenon.
2. Pedogenesis includes some interaction with flora and fauna and the accumulation of organic matter.
3. There is some movement or redistribution (typically downward) of clastic, biochemical, and ionic soil constituents (e.g., clay, organic carbon, iron, aluminum, and manganese compounds, as well as calcium carbonate in ionic solution).
4. Soils are an intimate component of the landscape; they form on relatively stable land surfaces and are approximately parallel to the land surface.
5. Soils are dynamic components of the ecosystem representing the interface of the atmosphere, the biosphere, and the geosphere.
6. Soils are extremely complex systems.

Soils are laterally extensive over entire landscapes. They form across various landforms and in a variety of parent materials, and they vary in a predictable manner according to changes in erosion, deposition, drainage, vegetation, and age of the landscape. Soils also vary as the microclimate and macroclimate vary. In buried soils (see below and the entry on Soil Stratigraphy in this volume), this predictability allows them to be traced laterally over varying paleotopography. In contrast, individual layers of sediment are confined to particular depositional environments; they will thin to nothing as one moves away from that environment (Mandel and Bettis, 2001, 180).

Soil science is a broad discipline that involves both the earth and agricultural sciences and includes the study of soil formation, classification, mapping, chemistry, mineralogy, physics, biology, and fertility (Soil Science Society of America, 2008). The principal subfields of soil science most widely applied in archaeology and geoarchaeology are pedology, soil geomorphology, and soil chemistry.

Pedology is the study of soils as three-dimensional bodies intimately related to the landscape, and it focuses on their morphology, genesis, and classification. Soil geomorphology is the study of relationships between soils and landscapes (e.g., Ruhe, 1956; Ruhe, 1965; Daniels and Hammer, 1992; Gerrard, 1992; Birkeland, 1999) (see the entry on Soil Geomorphology in this volume). In its broadest sense, soil geomorphology considers the influence of climate, flora, fauna, topography, and geologic substrate on pedogenesis, all operating over time (e.g., Birkeland, 1999). Soil chemistry deals with the chemical makeup of soils and how it relates to agricultural productivity (see the entry on *Anthrosols* in this volume). Soil chemistry has long been studied both by soil scientists and archaeologists for clues to human impact on the landscape, especially for reconstructing agricultural activity and for detecting human occupation (e.g., Arrhenius, 1931; Solecki, 1951; Cornwall, 1958; Arrhenius, 1963; Berlin et al., 1977; Eidt, 1977; Eidt, 1984; Eidt, 1985).

All of these subdisciplines of soil science share important perspectives with archaeology. Soil geomorphology focuses on reconstructing landscapes, and pedology and soil chemistry deal with soils as resources. The agriculture tradition in soil science provides a unique perspective for archaeologists who are trying to understand the origins, evolution, and characteristics of agriculture. Pedologists can also provide important insights into understanding human impacts on soils, such as soil erosion. Soil stratigraphy and soil chemistry rather than pedology and soil geomorphology are perhaps the best-known and oldest applications of soil science in archaeology (Holliday, 2004).

Soil genesis

Soil genesis or *pedogenesis* is a complex system of physical, chemical, and biological processes that alter parent material (geologic sediment or rock). These processes are driven by a broad array of environmental variables that operate over time. Soil scientists, geologists, and geographers have attempted to describe and model the processes of soil formation, the factors that drive the processes, and the evolution of soils as their landscapes evolve (summarized by Smeck et al., 1983; Johnson and Watson-Stegner, 1990; Gerrard, 1992, 1–50, 217–220; Schaetzl and Anderson, 2005, 295–346; Minasny et al., 2008). The task is a difficult one due to the complex and variable sets of processes responsible for soil development and the fact that these processes operate in a historical framework. Several of the resulting approaches have, however, proven useful for conceptualizing pedogenesis and, more importantly, for interpreting soils in a geomorphic/geoarchaeological context. In addition to understanding soil-forming processes for interpreting soil profiles, an understanding of soil formation processes is crucial for interpreting archaeological site formation. The conceptual approaches particularly useful in soil-geomorphic and geoarchaeological research are summarized below.

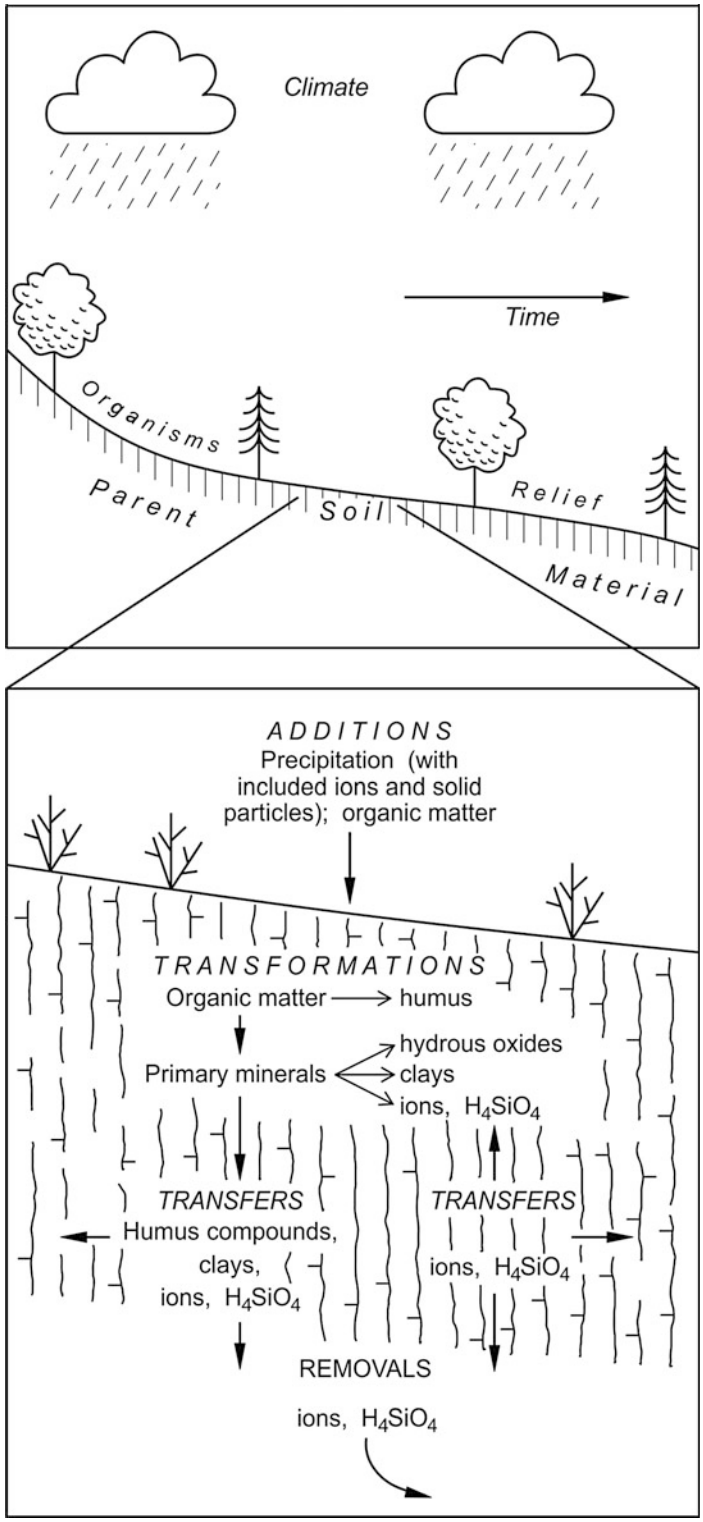
Soils are the result of biogeochemical processes determined by and driven by the ecosystem (following Schaetzl and Anderson, 2005, 3–4, 295–296; Buol et al., 2011, 11–16, 85–151). This relationship is more simply described as “internal soil forming processes” driven by “external soil forming factors” (after Buol et al., 1989). A useful approach to categorizing the many and varied internal soil forming processes responsible for pedogenesis is the multiple process model of Simonson (1959, 1978), who grouped the internal pedogenic processes into four categories: additions (e.g., water and organic matter), losses (e.g., leaching of carbonate), transfers (e.g., clay and iron illuviation), and transformations (e.g., organic residues decomposing to form humus) (Table 1; Figure 1).

The presence, absence, or degree of activity by these internal processes is a function of the complex interaction of external environmental factors. Consideration of these factors produced the “state factor” approach to soil genesis (Jenny, 1941; Jenny, 1980), which has been successfully applied in soil geomorphology (e.g., Birkeland, 1999) and has had many applications in archaeology (e.g., Holliday, 2004). Jenny (1941, 1980), following the work of many others (see Johnson and Hole, 1994; Tandarich and Sprecher, 1994 for a historical perspective), defined the state factors of soil formation (Figure 1 above) as climate (*C*), organisms (flora and fauna) (*O*), relief (or landscape setting) (*R*), parent material (*P*), and time (*T*) (the “clorpt” factors). There are also unspecified factors of local or minor importance (e.g., dust fall, groundwater fluctuations). Jenny (1941, 1980) proposed studying the variation in a soil as a function of one factor, keeping the other factors constant or accounted for. For example, variation in soils due to differences in climate could be studied by keeping all factors except climate constant. A group of soils forming as a function of any one state factor are called sequences (*climosequence*, *biosequence*, *toposequence*, *lithosequence*, *chronosequence*). The state factor approach to the study of soil genesis is not without criticism, which is summarized by Birkeland (1999, 144–145), Johnson and Watson-Stegner (1990), and Gerrard (1992, 3–7). In particular, Paton et al. (1995) attempt to overturn what they see as the “clorpt paradigm.”

Soils, Table 1 Soil forming processes, grouped according to Simonson's fourfold classification[a]

Process	Fourfold categorization[b]	Brief definition
Eluviation	3 hz	Movement of material out of a portion of a soil profile as in an albic horizon
Illuviation	3 hz	Movement of material into a portion of soil profile as in an argillic or spodic horizon
Leaching (*Depletion*)	2	General term for washing out or eluviating soluble materials from the solum
Enrichment	1	General term for addition of material to a soil body
Erosion	2 hp	Removal of material from the surface layer of a soil
Cumulization	1 hp	Eolian, hydrologic, and human-made additions of mineral particles to the surface of a soil solum
Decalcification	3 hz	Reactions that remove calcium carbonate from one or more soil horizons
Calcification	3 hz	Processes including accumulation of calcium carbonate in Bk and possibly other horizons of a soil
Salinization	3 hz	Accumulation of soluble salts such as chlorides, sulfates, and bicarbonates of sodium, calcium, magnesium, and potassium in salic horizons
Desalinization	3	Removal of soluble salts from salic soil horizons
Alkalization (*Solonization*)	3 hz	Accumulation of sodium ions on the exchanges sites in a soil
Dealkalization (*Solodization*)	3	Leaching of sodium from natric horizons
Lessivage	3 hz	Mechanical migration of small mineral particles from the A to the B horizons of a soil, producing B horizons relatively enriched in clay as in argillic horizons
Pedoturbation	3 hp	Biologic, physical (freeze-thaw and wet-dry cycles) churning and cycling of soil materials, thereby homogenizing the solum in varying degrees
Podzolization	3,4 hz	Chemical migration of aluminum and iron and/or organic matter, resulting in the concentrations of silica (i.e., silication) in the layer eluviated
Desilication (*Ferrallitization*, *Ferritization*, *Allitization*)	3,4 hz	Chemical migration of silica out of the soil solum and thus the concentration of sesquioxides in the solum (e.g., goethite, gibbsite), with or without formation of ironstone (laterite; hardened plinthite) and concretions
Resilication	4	Formation of kaolinite from gibbsite in presence of excess H_4SiO_4 (silicic acid) in solution or formation of smectite from kaolinite in presence of large amounts of H_4SiO_4 at higher pH values
Decomposition	4	Breakdown of mineral and organic materials
Synthesis	4	Formation of new particles of mineral and organic species
Melanization	1,3 hz	Darkening of light-colored, unconsolidated, initial materials by admixture of organic matter (as in a dark colored A horizon)
Leucinization	3 hz	Paling of soil horizons by disappearance of dark organic materials either through transformation to light-colored ones or through removal from the horizons
Littering	1	Accumulation on the mineral soil surface of organic litter and associated humus to a depth of less than 30 cm
Humification	4	Transformation of raw organic material into humus
Paludization	4 hp	Processes regarded by some workers as geogenic rather than pedogenic, including the accumulation of deep (>30 cm) deposits of organic matter as in mucks and peats (Histosols)
Ripening	4 hz	Chemical, biological, and physical changes in organic soil after air penetrates previously waterlogged material
Mineralization	4	Release of oxide solids through decomposition of organic matter
Braunification; *Rubification*; *Ferrugination*	3,4 hz	Release of iron from primary minerals and the dispersion of particles of iron oxides or oxyhydroxides in increasing amounts. Progressive oxidation or hydration of the iron colors the soil mass brownish, reddish brown, and red colors, respectively
Gleization	3,4 hp	Reduction of iron under anaerobic soil conditions, with the production of bluish to greenish gray matrix colors, with or without yellowish brown, brown, and black mottles, and ferric and manganiferous concretions
Loosening	4	Increase in volume of voids by activity of plants, animals, and humans and by freeze-thaw or other physical processes and by removal of material by leaching
Hardening	4	Decrease in volume of voids by collapse and compaction and by filling of some voids with fine earth, carbonates, silica, and other materials

[a]From Buol et al. (1997, Table 3.1)
[b]Soil forming processes: 1 Addition; 2 Removal; 3 Translocation; 4 Transformation; "hz" indicates processes that promote horizonation; "hp" indicates processes that promote haploidization (destruction of soil horizons)



Soils, Figure 1 Schematic illustration showing the relationship of the five external (or environmental) factors of soil formation (*above*) to the internal processes of soil genesis (Table 1) (Modified from Holliday, 2004, Figure 3.1).

At the most general level, the state factors represent natural conditions and do not deal with the processes that form soils, but instead they describe co-occurrences of state factors and specific soil properties. In archaeology and other areas of Quaternary research, the external factors are often the object of concern, and soils can be a means of reconstructing them; this means that soil properties are used as proxies to reconstruct former environmental conditions. The state factor approach also tends to treat the factors individually as independent variables, although they always act together, such as climate and biota. The time factor is the only truly independent variable, but the passage of time in and of itself does not form a soil; it is the historical framework in which the other factors operate.

The factors of soil formation generally of most concern in archaeology are time and environment (which includes climate and vegetation). State factor analysis examines soils to (1) determine the effects of climate and organisms and (2) determine how soils vary as a function of time. The resulting data then can be applied to soils in similar contexts as a means of environmental reconstruction or for estimating the age of deposits. An understanding of soil variability as a function of topographic position or parent material variation, which also can be investigated via state factor analysis, may also be important in reconstructing local environments and soil stratigraphy.

The state factor approach in a geoarchaeological context is further complicated by consideration of human activity as another factor of soil formation (Bidwell and Hole, 1965; Amundson and Jenny, 1991). For example, people have altered the biotic factor by removing forests and replacing them with farm crops; they have modified the topographic factors by digging canals, constructing terraced fields, or forming tells; and they have produced new soil types–anthrosols (see the entry on *Anthrosols* in this volume).

Soil profiles and horizons

A *soil profile* is the vertical arrangement of soil horizons, typically seen in a two-dimensional exposure down to and including the parent material. This series of layers is similar to a standard archaeological profile that may exhibit one or more soils. The *pedon* is the smallest body of one kind of soil large enough to represent the nature and arrangement of horizons (Soil Survey Division Staff, 1993, 18). Essentially, the pedon is the soil profile in three dimensions–a conceptual unit of soil defined for sampling purposes (see Schelling, 1970, 170; Soil Survey Staff, 1999, 10–14; Schaetzl and Anderson, 2005, 33–35; Buol et al., 2011, 30–31, 36).

Soil horizons are zones within the soil (i.e., subdivisions of the soil) that are parallel to the land surface and have distinctive physical, chemical, and biological properties. Soil horizons result from mineral alteration; additions of organic matter; leaching of soluble materials; and translocation of fine particles, humus, and chemical compounds. Together, a sequence of genetically related horizons produces a soil profile. Soil profiles vary due to the complex interaction of climate, the biota living on and in the soil, the nature of the soil parent material, landscape position, and the age of the landscape (i.e., the soil forming factors).

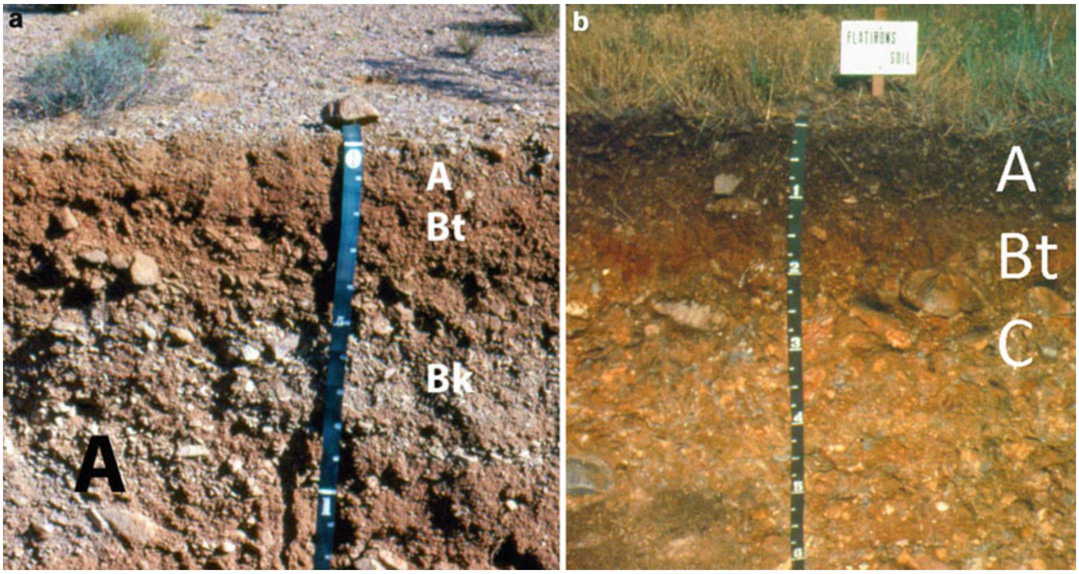
Soil horizons are the most obvious features of soils in the field because of their unique physical and chemical characteristics, such as soil structure and color (Figure 2a and b). Moreover, the development of soil horizons is a characteristic of soils unique among geomorphic processes and features. The ability to recognize soil horizons is a crucial first step in developing the ability to recognize soils. The visual distinctness of soil horizons and soils is one of the principal reasons they have long been used as stratigraphic markers. Careful scrutiny and description of soil profiles and horizons are critical elements of pedology and field geoarchaeology, and they require considerable training and practice to accomplish effectively.

Soil horizon nomenclature includes a few master or major horizons (the well-known A-B-C sequence), a considerable number of subhorizon symbols that act as modifiers of the master horizons, and additional descriptive terminology (Table 2). This system is fully explained by the Soil Survey Division Staff (1993; http://soils.usda.gov/technical/manual/).

Distinguishing soil from sediment

Archaeologists and soil geomorphologists alike must distinguish between deposits that are a product of sedimentary processes and those that are indicative of secondary alterations related to weathering at a land surface (i.e., soil formation). This distinction is important because in most cases a soil signifies a break in deposition; hence, it is an indicator of a relatively stable land surface (i.e., an often lengthy hiatus in sedimentation). The zone of soil formation (depth from the ground surface within which a soil develops) represents a significant time interval during which human activities can be recorded. This aspect distinguishes a soil from adjacent nonsoil deposits.

Many factors interplay to produce the characteristics of soils, but as noted above, one characteristic all soils have in common is a vertical sequence of genetically related horizons produced by soil-forming processes acting on geologic materials over time. The concept that soil horizons require the passage of some duration of time to form is one of the most fundamental and significant aspects of pedology in archaeology (Holliday, 1990, 530). Another important consideration is that soil development requires not only time but also a relatively stable landscape, one that is neither rapidly aggrading nor eroding (Catt, 1986, 166–167). Exceptions are bogs and marshes, where organic soils (histosols) form as a result of the accumulation of organic matter. Also, some soils, especially those on floodplains and toeslopes (gently inclined bottom of valley slopes), may receive influxes of parent material



Soils, Figure 2 (**a**) A moderately expressed soil formed in Holocene alluvium of the Rio Grande valley in semiarid southern New Mexico. The A horizon has very little organic matter owing to the low biological productivity. The Bk horizon illustrates the early stages of calcium carbonate accumulation. Scale in centimeters (Photo by Vance T. Holliday). (**b**) A strongly expressed soil formed under grassland in middle Pleistocene alluvium on the Great Plains of eastern Colorado. Scale in feet (Photo by Vance T. Holliday).

while pedogenesis is underway; that is, soil formation and deposition proceed concurrently and form cumulic soils (Nikiforoff, 1949; Birkeland, 1999). Disregarding these exceptions, the presence of a soil indicates that the landscape has been relatively stable for a period of time. In general, landscapes that have been stable for long periods have soils that are better expressed than those that have been stable for shorter periods, all other soil-forming factors being equal.

A soil in a stratigraphic sequence, whether at the surface or in a buried context, indicates a hiatus between depositional events. Holliday (1992, 103) stressed that, in such a sequence, "the sediment, which is the parent material for the soil, may have accumulated rapidly or slowly, but a significant period of nondeposition had to occur for the soil to form." Although large volumes of sediment may be deposited instantaneously, as with a debris flow, soil formation usually requires at least a century, or several centuries, and commonly millennia (Holliday, 1992; Birkeland, 1999).

In archaeological investigations, consideration of landscape stability, as indicated by soil development, is important in locating cultural deposits, interpreting artifact associations and contexts, defining site stratigraphy, reconstructing the depositional and landscape history, and establishing cultural chronologies. The first step is identifying which parts of the sedimentary deposits present in the site or study area have been modified as a result of soil formation. While this can be a fairly straightforward task, it often becomes complicated when pedogenically unaltered deposits have properties that mimic some properties of soils.

The first requirements in the recognition of a soil are identifying soil horizons and learning how to differentiate between soil horizons and sedimentary deposits that show soil-like properties (see the section on soil profiles above). Soil horizons often parallel a land surface, and they have distinctive properties that result from the complex interactions among many physical, chemical, and biological processes acting on surficial materials over time. The nature and magnitude of the influence of these processes, and the resulting properties of soils, are in large part controlled by various environmental factors. Both soils and unlithified geologic materials that are not soils can be described according to the following properties: color, texture, consistency, soil structure (or lack thereof), cutans (coatings), nodules or concretions, voids, reaction to hydrochloric acid (carbonate content), boundary characteristics, and horizon continuity. Specifics on the nomenclature for describing soil horizons and surficial materials are provided by Birkeland (1999), Soil Survey Staff (1999), Schoeneberger et al. (2002), Buol et al. (2011), and Schaetzl and Thompson (2015).

Distinguishing soil from sediments on the basis of the presence or absence of horizons is not always a simple procedure. For example, organic- or clay-rich alluvium that has not been modified by pedogenesis sometimes exhibits properties that mimic those of A and B horizons of soils, respectively. Several criteria may be used to discriminate a soil horizon from a depositional unit in an

Soils, Table 2 General definitions of soil horizons used in the USA[a]

Soil master horizons

O horizon or layer: Horizons or layers dominated by organic material. Some consist of undecomposed or partially decomposed litter, such as leaves, needles, twigs, moss, and lichens, that were deposited on the surface; they may be on top of either mineral or organic soils. Other O layers are organic materials that were deposited under saturated conditions and have decomposed to varying stages

A horizon: Mineral horizon that formed at the surface or below an O horizon, and that exhibits (1) obliteration of all or much of the original rock structure, and (2) an accumulation of humified organic matter intimately mixed with the mineral fraction

E horizon: Mineral horizon characterized by the loss of silicate clay, iron, aluminum, or some combination of these, leaving a concentration of sand and silt particles behind. This horizon exhibits obliteration of all or much of the original rock structure. An E horizon is usually lighter in color than an overlying A horizon and an underlying B horizon

B horizon: Horizon that forms below an A, E, or O horizon and is characterized by the obliteration of all or much of the original rock structure and shows one or more of the following: (1) illuvial concentration of silicate clay, iron, aluminum, humus, carbonates, gypsum, or silica, alone or in combination (brought down from overlying horizons by the action of water); (2) evidence of the removal of carbonates; (3) coatings of sesquioxides that make the color of the horizon conspicuously lower in value, higher in chroma, or redder in hue (Munsell color descriptors) than overlying and underlying horizons without apparent illuviation of iron; or (4) alteration that forms silicate clay, or liberates oxides, or both, and that forms granular, blocky, or prismatic structure

C horizon or layer: Horizon or layer, excluding hard bedrock, that is little affected by pedogenic processes and lacks the properties of O, A, E, or B horizons

R layers: Hard (minimally weathered) bedrock

Horizons dominated by properties of one master horizon but having subordinate properties of another. Two capital letter symbols are used: AB, EB, BE, or BC. The master horizon symbol is given first and designates the horizon whose properties dominate among the transitional properties (e.g., an AB horizon has characteristics of both an overlying A horizon and an underlying B horizon, but it is more like the A than the B)

Horizons in which distinct parts have recognizable properties of the two kinds of master horizons indicated by the capital letters. The two capital letters are separated by a virgule (/, or forward slash): E/B, B/E, or B/C. Most of the individual parts of one of the components are surrounded by the other

Subhorizons or subordinate horizons of the master horizons

a *Highly decomposed organic material*: Used with "O" to indicate the most highly decomposed of the organic materials

b *Buried soil or horizon*: Used in mineral soils to indicate identifiable buried horizons with major genetic features that were formed before burial. Genetic horizons may or may not have formed in the overlying material, which may be either like or unlike the assumed parent material of the buried soil

c *Concretions or nodules*: Indicate a significant accumulation of cemented concretions or nodules. The cementing agent is not specified except it cannot be silica. This symbol is not used if concretions or nodules are dolomite or calcite or more soluble salts, but it is used if the nodules or concretions are enriched in minerals that contain iron, aluminum, manganese, or titanium

e *Organic material of intermediate decomposition*: Used with "O" to indicate organic materials of intermediate decomposition

f *Frozen soil*: Indicates that the horizon or layer contains permanent ice. Symbol is not used for seasonally frozen layers or for "dry permafrost" (material that is colder than O° C but does not contain ice)

g *Strong gleying*: Indicates either that iron has been reduced and removed during soil formation or that saturation with stagnant water has preserved a reduced state. Most of the affected layers reveal a chroma of 2 or less and many have redox concentrations. The low chroma can be the color of reduced iron or the color of uncoated sand and silt particles from which iron has been removed. Symbol "g" is not used for soil materials of low chroma, such as some shales or E horizons, unless they have a history of wetness. If "g" is used with "B," pedogenic change in addition to gleying is implied. If no other pedogenic change in addition to gleying has taken place, the horizon is designated Cg

h *Illuvial organic matter*: Used with "B" to indicate the accumulation of illuvial, amorphous, dispersible organic matter-sesquioxide complexes. The symbol "h" is also used in combination with "s" as "Bhs" if the amount of sesquioxide component is significant but value and chroma of the horizon are 3 or less

i *Slightly decomposed organic material*: Used with "O" to indicate the least decomposed of the organic materials

k *Carbonates*: Accumulation of calcium carbonate

m *Cementation or induration*: Continuous or nearly continuous cementation. If the horizon is cemented by carbonates, "km" is used; if by silica, "qm"; if by iron, "sm"; if by gypsum, "ym"; if by both lime and silica, "kqm"; if by salts more soluble than gypsum, "zm"

n *Sodium*: Accumulation of exchangeable sodium

p *Plowing or other disturbance*: Disturbance of the surface layer by mechanical means, pasturing, or similar uses. A disturbed organic horizon is designated Op. A disturbed mineral horizon is designated Ap even though it was clearly once an E, B, or C horizon

q *Silica*: Accumulation of secondary silica

r *Weathered or soft bedrock*: Used with "C" to indicate root restrictive layers of soft bedrock or saprolite, such as weathered igneous rock; partly consolidated soft sandstone; siltstone; and shale. Excavation difficulty is low or moderate

s *Illuvial accumulation of sesquioxides and organic matter*: Used with "B" to indicate the accumulation of illuvial, amorphous, dispersible organic matter-sesquioxide complexes if both the organic matter and sesquioxide components are significant and the value and chroma of the horizon is more than 3. The symbol is also used in combination with "h" ("Bhs") if both the organic matter and sesquioxide components are significant and the value and chroma are 3 or less

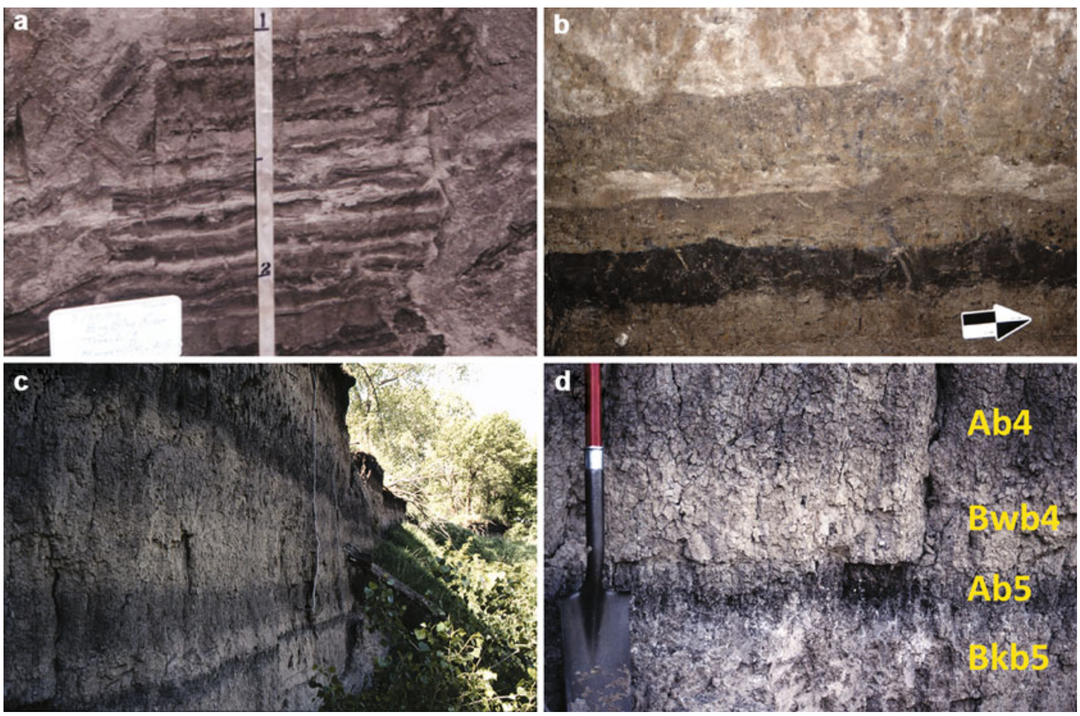
ss *Slickensides*: Presence of slickensides or sides of fault cracks, which result directly from the swelling of clay minerals and shear failure, commonly at angles of 20–60° above horizontal

t *Silicate clay*: Accumulation of silicate clay translocated within the horizon or moved into the horizon by illuviation, or both. At least some part should show evidence of clay accumulation in the form of coatings on surfaces of peds or in pores, or as lamellae ("clay bands"), or bridges between mineral grains

Soils, Table 2 (Continued)

v *Plinthite*: Presence of iron-rich, humus-poor, reddish material that is firm or very firm when moist and that hardens irreversibly when exposed to the atmosphere and to repeated wetting and drying
w *Development of color or structure*: Used with "B" to indicate the development of color or structure, or both, with little or no apparent illuvial accumulation of material
x *Fragipan*: Genetically developed layers that have a combination of firmness, brittleness, very coarse prisms with few to many bleached vertical faces, and commonly higher bulk density than adjacent layers
y *Gypsum*: Accumulation of gypsum
z *Salts more soluble than gypsum*: Accumulation of salts more soluble than gypsum

Combinations of symbols: A B horizon that is gleyed or that has accumulations of carbonates, sodium, silica, gypsum, salts more soluble than gypsum, or residual accumulation of sesquioxides carries the appropriate symbol–g, k, n, q, y, z, or o. If illuvial clay is also present, "t" precedes the other symbol, for example, Btg
[a]Modified from Soil Survey Division Staff (1993, 118–126). These symbols are used for describing soils in the field. For more complete definitions, see Buol et al. (1997), Birkeland (1999), Schoeneberger et al. (2002), or Soil Survey Division Staff (1993)



Soils, Figure 3 (**a**) Stratified modern alluvium beneath a floodplain. The dark, organic-rich flood drapes could be confused with buried A horizons. (**b**) The lower boundaries of the individual beds of alluvium, including the dark flood drapes, are abrupt and wavy. Hence, the flood drapes are not A horizons. The photo scale is 20 cm long. (**c**) Stratified early and middle Holocene alluvial fan deposits that have been altered by pedogenesis, as indicated by multiple buried soils developed at the top of the upward-fining sequences. (**d**) Note the smooth, gradual boundaries between the (**a**) and (**b**) horizons of the buried soils, compared to the abrupt, wavy boundaries separating flood drapes in (**a**) and (**b**) (Photos by Rolfe Mandel).

alluvial setting. To illustrate, the lower boundary of an A or B horizon is usually clear, gradual, or diffuse, rather than abrupt or wavy (Figure 3). Pedogenically unaltered clay- and organic-rich depositional layers often have abrupt and wavy boundaries or graded bedding produced by sedimentary processes. As bioturbation and other soil-forming processes affect the deposits, the abrupt boundaries that separate individual beds are obliterated.

Micromorphological studies (see the entries on Soil Micromorphology and Microstratigraphy in this volume) may help distinguish soil horizons from sedimentary zones in these situations by identifying fabrics indicative of mixing, soil-forming processes, or sedimentary processes (Courty et al., 1989; Courty, 1992).

Soil structure, which is the shape of soil aggregates (peds), can be used to distinguish organic-rich sedimentary deposits from A horizons of soils. Flood drapes, which tend to be clayey and enriched with organic matter, often contain clay minerals that shrink and swell with drying and wetting. The shrinking and swelling of these minerals gives the dark alluvium an angular blocky "structure" that may be misinterpreted as having formed by processes associated with a relatively stable land surface during a hiatus in sedimentation. An A horizon, however, typically has granular structure produced by the activity of worms and other soil organisms in this biologically active zone of the soil. In buried soils, the granular structure may be transformed into blocky types of structure during compaction, but evidence for the former A horizon may include greater porosity or granular aggregates that can be detected only in thin section via micromorphology (Courty et al., 1989; Courty, 1992). Patterns of rooting and burrowing also provide useful information for identifying former land surfaces and for distinguishing soils and unaltered sediments. Unaltered sediments are usually capable of supporting plant life and often become burrowed, but surfaces stable enough for soils to form are subject to more intensive rooting and potentially more burrowing activity simply because they represent more time per volume than unaltered deposits. The upper horizon of a soil, therefore, should be more heavily rooted, especially with fine roots, and contain more evidence for bioturbation than unaltered deposits. Because of the dark color of many soil surface horizons, and the rate of bioturbation and the small scale of many bioturbators, such as worms and ants, much of the conclusive rooting- and burrowing-pattern evidence for distinguishing soil horizons from unaltered deposits is at the microscopic scale (Courty, 1992).

In arid and semiarid regions, deposits that have been affected by nonpedogenic accumulations of calcium carbonate can be easily confused with calcic soils (Mandel and Bettis, 2001). For example, laterally flowing, $CaCO_3$-rich groundwater often forms calcretes that are misidentified as soils with petrocalcic horizons (Machette, 1985). Development of a groundwater calcrete is a nonpedogenic process that occurs when calcium-charged groundwater discharges onto a stream bottom or reaches a near-surface position where calcium is concentrated by evaporation. Supersaturation of calcium causes precipitation of $CaCO_3$ and subsequent cementation of relatively porous sands and gravels (Machette, 1985). Further complicating matters, surface runoff may add or redistribute the $CaCO_3$, producing laminar zones that resemble laminar petrocalcic horizons (Bachman and Machette, 1977). Nevertheless, with careful field observations and micromorphological analyses, it is possible to distinguish groundwater calcretes from calcic soils. For example, groundwater calcretes are often strongly indurated to depths of 10 m or more (Machette, 1985). Petrocalcic horizons, however, are rarely more than several meters thick. When viewed in thin section, groundwater calcretes typically consist of simple cement fills enclosing clasts with grain-to-grain contact, whereas the cement of petrocalcic horizons is micritic and replaces or surrounds scattered detrital grains that appear to float in a matrix of carbonate (Mann and Horowitz, 1979; Machette, 1985; Arakel, 1986; Jacobsen et al., 1988). Also, groundwater calcretes generally lack the horizonation and morphological structures common in calcic soils (Bachman and Machette, 1977; Wright, 1982; Machette, 1985; Allen, 1986).

In an archaeological investigation, it is important to distinguish between a groundwater calcrete and a petrocalcic horizon because of the temporal, soil-stratigraphic, and environmental implications inherent in either identification. Groundwater calcretes form over the course of tens to hundreds of years, they are not products limited to periods of landscape stability, and they develop in a wide range of environments (humid to arid). Petrocalcic horizons, however, require thousands of years of carbonate accumulation in relatively stable arid or semiarid soil-forming environments (Gile and Hawley, 1966; Gile et al., 1966; Gile and Grossman, 1979; Birkeland, 1999; Schaetzl and Thompson, 2015, Figure 13.52).

In some situations, sandy C horizons may be confused with albic (E) horizons of soils. This usually occurs where a light-colored sandy C horizon lies beneath an A horizon and above a truncated Bt horizon. Such confusion may seriously compromise the interpretation of the soil stratigraphy, paleoenvironment, and age of an archaeological site. An E horizon is a product of intensive leaching (eluviation, or the downward transport of soil materials entrained by precipitated water from upper layers of soil to lower levels) that typically spans thousands of years, whereas a C horizon consists of slightly weathered parent material. The best approach to distinguishing a C horizon from an E horizon is to examine the morphology of the soil. For example, all E horizons have soil structure, which involves a bonding together of individual soil particles. In most E horizons, the particles are arranged about a horizontal plane, forming platy structure (Birkeland, 1999). In contrast, sandy C horizons are single grain or massive; hence, they lack soil structure. If the material is single grain, the individual sand particles are easily distinguishable and do not adhere to each other. When the material is massive, individual particles adhere closely to each other, but the mass lacks planes of weakness (Buol et al., 1997). Also, the boundary between an E and Bt horizon is usually gradual and wavy or irregular, and tongues of the E horizon often extend down into a Bt horizon. In contrast, where a C horizon overlies a truncated Bt horizon, the boundary is abrupt and smooth or wavy and lacks tongues.

Soils, unlike most individual beds of sediment, are laterally extensive across the landscape. They extend across various landforms and underlying geologic deposits and exhibit predictable variations in their properties related to changes in drainage, vegetation, and relative age of the geomorphic surface on which they occur. Hence, surface and buried soils can be mapped in three dimensions over varying topography. In contrast, individual beds of sediment tend to be restricted to a certain depositional environment and will pinch out away from that area.

Although identification and study of soils begins in the field with careful observations, it is sometimes necessary to support these observations with laboratory analysis in order to obtain a clear differentiation of soil from pedogenically unaltered sediment. One of the most powerful laboratory methods for distinguishing soil from nonsoil is micromorphological analysis (see Fisher and Macphail, 1985). This procedure, which requires the use of thin sections and petrographic equipment, greatly enhances the ability of the soil scientist to identify micropedological features that indicate pedogenic alteration (Brewer, 1976; Bullock et al., 1985; Douglas and Thompson, 1985; Courty et al., 1989). However, as Wilding and Flach (1985) have pointed out, soil micromorphology is a powerful tool to extend macromorphology and should not be used alone to distinguish soil from sediment. Because many soil properties form by the vertical movement and accumulation of some materials–such as clay, iron, and calcium carbonate–a wide variety of laboratory methods, such as grain-size and chemical analyses, can be helpful in differentiating soil from pedogenically unaltered sediment (Hesse, 1971; Soil Survey Staff, 1996; Buol et al., 1997).

Soils, Figure 4 A buried soil in the Arctic tundra of northern Canada. At the surface is late Holocene eolian sand with minimal soil development. The buried soil formed in glacial sand under boreal forest conditions. Scale in inches (Photo by James Knox).

Paleosols

The term *paleosol* is widely used in archaeology and other Quaternary studies and is variously defined. These definitions include soils of obvious antiquity (Morrison, 1967, 10), ancient soils (Butzer, 1971, 170), soils formed on a landscape of the past (Ruhe, 1965, 755; Yaalon, 1971a, 29; Gerrard, 1992, 202; Catt, 1998) or under an environment of the past (Yaalon, 1983; Schaetzl and Thompson, 2015), a soil with distinct evidence that the direction of soil development was different from that of the present (Catt, 1998), a soil formed during an earlier period of pedogenesis (Allaby and Allaby, 1991), or soils formed under conditions generally different from those of today (Plaisance and Cailleux, 1981, 702).

The study of paleosols is often referred to as *paleopedology* (Yaalon, 1971b; Retallack, 1990; Follmer, 1998). In a broad, holistic sense, the study of paleosols is a component of pedology, soil geomorphology, and soil stratigraphy. Pedology as traditionally taught in the USA and elsewhere does not deal with paleosols, and thus some workers have found it necessary to use the term *paleopedology*, essentially to differentiate a geoscientifically based study of soils from an agricultural one.

Specific types of paleosols include *buried soils*, which are soils covered by sediment (Figure 4), *relict soils*, which are soils formed on past landscapes or under past environments and never buried, and *exhumed soils*, which are soils that were buried and subsequently re-exposed (Ruhe, 1965; Valentine and Dalrymple, 1976) (see Johnson and Hole, 1994 for further discussion of these terms). Among these terms, "buried soil" is probably the least ambiguous, although a distinction between a "buried soil" and a "buried paleosol" has been proposed (Catt, 1998, 84). The former term is used for "soils buried by deposits too thin to seal them from present pedogenesis and not showing evidence of development in a direction different from the present" and the latter term proposed for soils that are buried and "isolated from present pedogenesis" and/or soils that are buried and exhibiting "distinct evidence that the direction of soil development was different from that of the present."

Otherwise, among the definitions and types of paleosols, exactly what constitutes a past landscape or past environment or how old the soil has to be was never defined. Because landscapes are always being subjected to some modification, and the environment is never static, and because all soils take some time to form, arguments have been made that all soils are paleosols and all unburied soils are relict soils, making such terms redundant (see also Bos and Sevink, 1975; Fenwick, 1985; Johnson et al., 1990; Johnson and Hole, 1994; Bronger and Catt 1998a; Bronger and Catt 1998b; Follmer, 1998; Johnson, 1998). Moreover, these definitions require that the history of the soil or the landscape or both be known before the term can be applied. The term "paleosol" seems to have some utility, however, judging from its widespread use (e.g., Follmer et al., 1998), especially in dealing with soils in the rock record, so-called pre-Quaternary soils (e.g., Retallack, 1990).

The terms *monogenetic* and *polygenetic* soils were based on geoarchaeological research (Bryan and Albritton, 1943). A "monogenetic soil" was initially defined as "one developed in one climatic regime" and a "polygenetic soil" as having "developed in more than one climatic regime" (Bryan and Albritton, 1943, Table on p. 477). Catt (1998, 84) provides more up-to-date definitions. A monogenetic soil "formed in a period when the variation in environmental factors was too small to produce detectably different assemblages of soil features . . . (i.e., the direction of soil development was constant)." A polygenetic soil "formed in two or more periods when the environmental factors were sufficiently different to produce detectably different assemblages of soil features. . . (i.e., the directions of soil development were different in the periods involved)." Similar to the criticism of the term and concept of paleosol (vs soil), some argue that there is no such thing as a monogenetic soil and that all soils are polygenetic because environmental factors are always changing to some degree (e.g., Working Group on the Origin and Nature of Paleosols, 1971, 155; Johnson et al., 1990; Johnson and Hole, 1994; Johnson, 1998). With the emphasis now placed on the direction of pedogenesis and the detectability of evidence for these changes, the terms may have merit and utility.

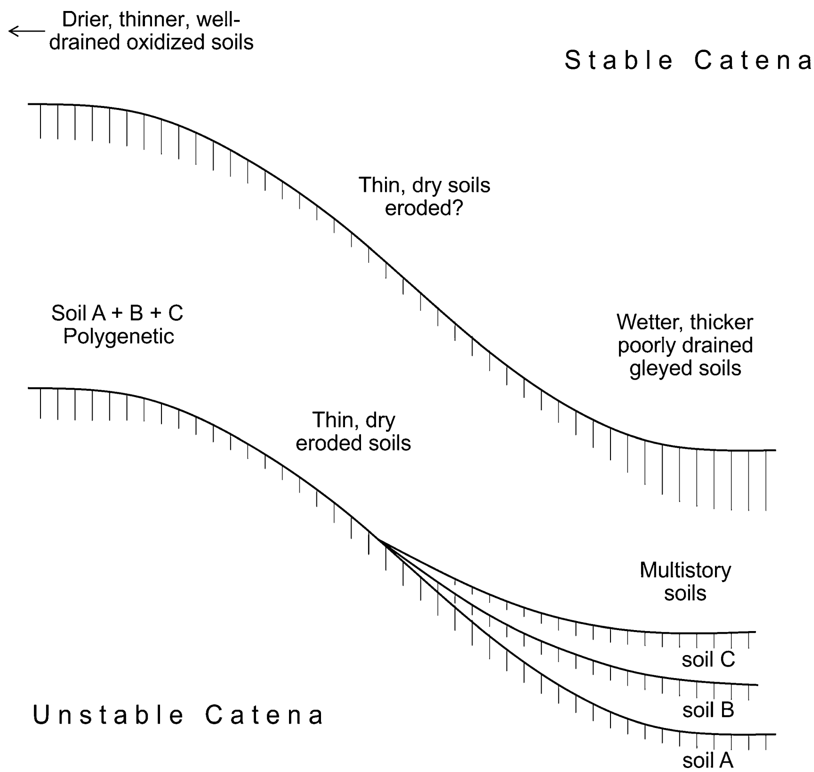
Recognition of buried soils, regardless of whether they are "paleosols," is especially important in archaeological surveys (see the entry on *Soil Stratigraphy* in this volume). Because buried soils represent previous land surfaces that were exposed for sufficient periods of time to develop recognizable soil profile characteristics, they also represent former stable land surfaces. If one assumes that the probability of cultural utilization of a particular landscape position is equal for each year, it follows that the surfaces that remain exposed for the longest time would represent those with the highest probability of containing cultural remains (Hoyer, 1980, 61). Because buried soils represent former stable surfaces, evidence for human occupation would more likely be associated with them (Mandel and Bettis, 2001). This reasoning also implies that a soil that had the most time to develop before it was buried would have the greatest likelihood of containing cultural deposits at any given location. Thus, buried soils are also useful indicators for locating archaeological deposits and for assessing an important aspect of the geologic potential for buried cultural deposits. A corollary to this is that the longer a given surface remains stable, the more likely it will have artifacts deposited on it. Cultural deposits within well-expressed soils therefore are more likely to represent palimpsest assemblages (remains from multiple occupations, most of which are compressed and possibly disturbed) than cultural deposits within weakly expressed soils that represent less elapsed time.

Knowledge of the temporal and spatial pattern of buried soils in a landscape provides archaeologists with a powerful tool for identifying areas with high potential for buried cultural deposits and for assessing prehistoric cultural records. There are many good examples of how this knowledge can be applied in an archaeological survey (e.g., Bettis and Benn, 1984; Mandel, 1985; May, 1986; Bettis and Littke, 1987; Mandel, 1988; Bettis, 1990; Mandel, 1992; Mandel, 1994a; Mandel, 1994b; Mandel, 1996; Mandel, 1999; Ferring, 2001; Mandel, 2002; Mandel, 2004; Mandel, 2006; Mandel, 2008; Mandel et al., 2009; Mandel, 2010; Mandel, 2013).

Catenas and soilscapes

The term *catena* describes a fundamental and significant aspect of soils. As originally proposed (Milne, 1935a; Milne, 1935b), a catena is a mapping unit defining a group or pattern of soils along a slope. In this definition, a catena forms as a result of differential drainage on the slope, with solutes leaching downslope and erosion and deposition occurring along the slope (Figure 5). In the USA, however, the term came to be applied to a sequence of soils developed in uniform parent material on a hillslope, with each soil varying according to drainage (Soil Survey Staff, 1951, 160). The term is often used interchangeably with *toposequence*–a group of soils that vary only in their topographic position but which otherwise formed in the same parent material, under the same climate and vegetation, and over the same amount of time (Jenny, 1980, 280; Hall, 1983, 124; Birkeland, 1999, 235; Schaetzl and Anderson, 2005, 469; Buol et al., 2011, 129–130). The processes of erosion and deposition inherent in the formation of catenas mean that the age of the landscapes will vary, however.

Related to catena is the concept of the *soilscape*. A soilscape is the pedologic portion of the landscape (Buol et al., 2011, 361) or the pattern and distribution of soils across the landscape. In a sense, soilscapes represent the expansion or distribution of catenas across the landscape. Catenary relationships among soils on a slope and the distribution of catenas across soilscapes are unique characteristics of soils, as they form on and across landscapes, and they serve to distinguish soils from other geologic phenomena.



Soils, Figure 5 Schematic illustrations of stable vs. unstable catenas (Modified from Holliday, 2004, Figure 9.1). If the slope is stable, a predictable sequence of soils will be found. If the slope is unstable, a sequence of buried soils will be found in the lower slope position.

Soil classification

Soil classification refers to the categorization of soils into groups at varying levels of generalization according to their morphological and chemical properties and sometimes their assumed genesis (Buol et al., 2011, 4). The purpose of classification is to (1) systematize knowledge about soils and (2) determine the processes that control similarity within a group and dissimilarities among groups (Birkeland, 1999, 29). The classification system used in the USA is the US Comprehensive Soil Classification System, published as the *Soil Taxonomy* (Soil Survey Staff, 1975; Soil Survey Staff, 1999; ftp://ftp-fc.sc.egov.usda.gov/NSSC/Soil_Taxonomy/tax.pdf) and updated in the *Keys to Soil Taxonomy*, ftp://ftp-fc.sc.egov.usda.gov/NSSC/Soil_Taxonomy/keys/2010_Keys_to_Soil_Taxonomy.pdf. Twelve soil orders are recognized in *Soil Taxonomy* (Table 3).

Soil Taxonomy was designed to facilitate classification for soil survey and land-use purposes (see the entry on Soil Survey in this volume) (Soil Survey Staff, 1975, 7–8; Bartelli, 1984). It was not intended to be a tool in soil-geomorphic or other geoscientific research. The system does not provide a means of understanding relationships between soils beyond their spatial relationships on soil maps. Of particular significance to geoarchaeology, *Soil Taxonomy* is not well suited for application to buried soils (see the entry on Soil Stratigraphy in this volume) and inadequately deals with soils heavily altered by human activity (*anthropogenic soils* or *anthrosols*; see the entry on Anthrosols in this volume).

Nevertheless, *Soil Taxonomy* forms the basis for much of the soils terminology in the USA and some of the international soil science terms. Becoming familiar with basic concepts and terms in soil classification will therefore facilitate geoarchaeological research. Basic introductions to *Soil Taxonomy* and some of the other systems are readily accessible (Birkeland, 1999; Holliday, 2004; Buol et al., 2011; Schaetzl and Thompson, 2015). Outside the USA, the most widely used system is the World Reference Base (WRB) for Soil Resources (IUSS, 2006).

Comparisons of the structure, philosophy, advantages, and disadvantages of a variety of soil classification systems, including *Soil Taxonomy*, are provided by Buol et al. (2011, 169–192). The International Institute for Geo-Information Science and Earth Observation (ITC) in the Netherlands has prepared a very useful "Compendium of On-Line Soil Survey Information," including information on, and comparisons among, the major national soil classification systems: www.itc.nl/~rossiter/research/rsrch_ss_class.html.

Soils, Table 3 General concepts of the soil orders in *Soil Taxonomy*[a]

Alfisols	Soils with an argillic horizon, but no mollic; they are lower in bases than Mollisols; typically found in humid, temperate regions
Andisols	Soils formed in volcanic ash and related volcanic parent materials
Aridisols	Soils formed in desert conditions (Entisols can also be found in deserts) or under other conditions restricting moisture availability to plants (high salt content; soils on slopes); some development in the B horizon, often evidenced by slight weathering or by illuvial compounds of calcium, gypsum, or other materials
Entisols	Soils with little evidence of pedogenesis; very few diagnostic horizons
Gelisols	Soils with permafrost within 2 m of the surface; very common in high latitudes
Histosols	Organic soils without permafrost, such as peats; dominated by decomposing organic matter
Inceptisols	Soils exhibiting more pedogenic development than Entisols with the appearance of diagnostic surface and subsurface horizons that are not as well developed as in most other orders
Mollisols	Soils with a thick, dark mollic epipedon that are high in bases throughout; typical of continental grasslands or savanna
Oxisols	Soils that are highly weathered and dominated by oxide, low-activity clays; they have an oxic (Bo) horizon; they are found in tropical regions and include many soils formerly termed Laterites and Latosols
Spodosols	Soils with spodic horizons; translocation and subsurface accumulation of compounds of humus and Al, and sometimes also Fe, have occurred; typical in cool, humid climates under coniferous forests
Ultisols	Highly weathered, acidic soils with argillic (Bt) horizons and very low in bases; typically found on older landscapes in warm, humid climates
Vertisols	Soils high in clay content in climates with distinct wet and dry seasons and that shrink and swell markedly; they develop deep cracks in the dry seasons; typically found in grasslands and savannas

[a]For a complete list with criteria see *Soil Taxonomy* (Soil Survey Staff, 1999). To classify a soil properly, one must follow the guidelines and criteria for diagnostic horizons and classification in *Soil Taxonomy* (Soil Survey Staff, 1999). This table presents only the principal characteristics of the soil orders.

Introduction

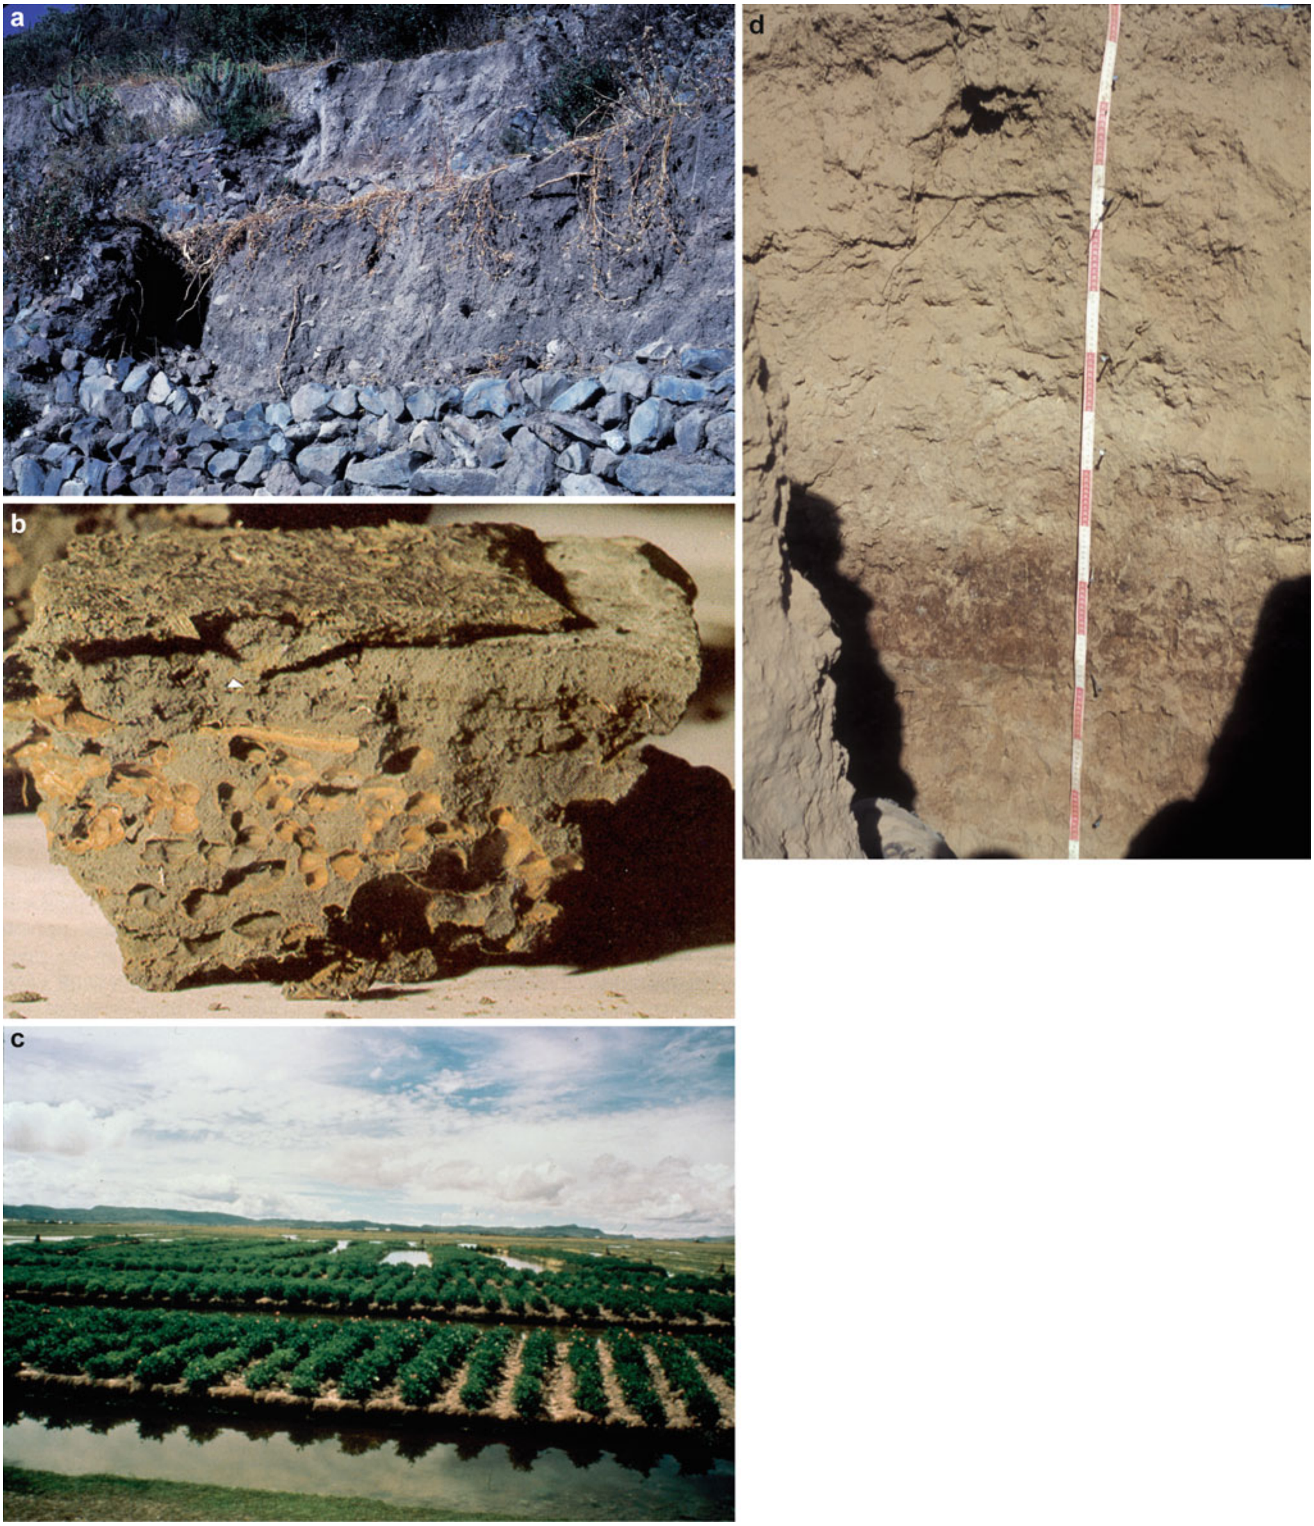
The geoarchaeological record holds key information about past land use and its impact on soils and environment. Among agents of anthropogenic soil change, agriculture's impact on soil is immense in magnitude, spatial extent, and duration. Agriculture has profoundly altered soil properties, processes, and formation pathways worldwide since its inception about ten millennia ago. The deep time perspectives on soil management and change available through geoarchaeology can help us predict long-term effects of agriculture on land resources and test for sustainability. Ancient agricultural systems and soils presented here illustrate the global range of soil use and change in relation to complex, interacting factors such as kind of system, time scale, and environmental setting and resilience.

Kinds of ancient agricultural systems and soils

Certain kinds of anthropogenic soils are associated with agricultural systems that have functioned for centuries to millennia. Some of these soils have been altered to a limited extent from their original form, or buried to varying depths, while others have been transformed into truly anthropogenic soils. Major forms of anthropogenic soils include plaggen soils, Amazonian Dark Earth soils (ADE or terra preta), terraced soils, paddy and other wet-field soils, and irragric soils (Figure 1, Table 1). Although each has a distinct combination of properties, a wide range exists within them as well as some degree of overlap among them due to similar soil-forming processes or equifinality. For example, the upper horizons of plaggen, ADE, terraced, and irragric soils are thickened from deliberate to inadvertent additions of organic matter and sediment. Because water deficiency or excess is of major concern in most agricultural systems, many soils have been altered by water management practices such as irrigation or drainage. Plaggen soils and ADE soils are discussed in greater depth in another article (see Woods and Macphail), so this one emphasizes the latter three kinds along with some comparisons related to soil change.

Terraced soils

Terracing constitutes some of humanity's most enduring efforts to manage soil, water, and geomorphic processes in agriculture and to protect land resources. The stepped topography created by terracing is a characteristic feature of sloping lands on five continents and Oceania. Most of the earliest documented ages for terracing in a number of world regions are similar at roughly 3,000–4,000 year



Soils, Agricultural, Figure 1 (**a**) Ancient terraced soil with thickened surface horizons, Colca Valley, Peru. (**b**) Paddy soil sample. Variegated colors from flooding and alternating reduction/oxidation. Vesicles formed from gases trapped beneath puddled surface soil (Source: Moorman and van Breemen 1978). (**c**) Reconstructed raised fields near Lake Titicaca in Peru (Photo by Clark Erickson). (**d**) Ancient irragric soil, Gila River Indian Community, Arizona. Light-colored irrigation sediment buries natural horizon of clay accumulation. Irrigation in this area spans about 450–1450 AD. Scale band divisions are 10 cm.

Soils, Agricultural, Table 1 Major kinds of ancient agricultural soils

Soil	Oldest age/main age (year BP)	Geographic location (major)	Main features/processes
Plaggen	3000/Middle ages	Northern Europe	Thick, organic matter- and phosphorus-rich surface horizon from long-term additions of manure and other materials. Commonly contains artifacts
Terra preta (Amazonian Dark Earth)	2500/1000	Amazonia	Dark soil from charcoal and additions of other organic materials. Artifacts such as pottery sherds common
Terraced soils	6000/1000–4000	5 continents and Oceania	Thickened A horizons from construction and/or sedimentation upslope of terrace walls
Paddy soils	6000/2000	Southeastern Asia	Anthraquic, redoximorphic features (from reduction and oxidation of iron and manganese), puddled surface, and other properties resulting from wet rice production
Raised field soils	2000–3000/1000	Central and S. America	Soil buildup in ridges on wetlands. Organic and other materials from adjacent drainage ditches added to ridges
Irragric soils	5000 3000 3500 4000	Middle East Central Asia South America North America SW	Sediment accumulation from long-term irrigation. Variable salinity, organic matter, and other properties. Artifacts such as pottery sherds common

BP. Older ages from 6,000 year BP to possibly earlier have been reported.

Besides creating a stable topographic base for crops, functions of terracing include soil retention and erosion control, soil building by construction filling or sedimentation, microclimatic modification, and water control ranging from runoff management to irrigation, ponding, and drainage. In several arid regions, ancient terracing involved relatively subtle landscape alteration in the form of small dam construction to facilitate runoff agriculture. Lynchets, likely created incidentally from cultivation and associated erosion processes in northern Europe, also represent subtle terraced lands. In other regions terracing evolved into such remarkably engineered systems as bench terraces of the Andes and rice terraces of eastern Asia, where entire landscapes were transformed into stepped agroecosystems. Variability in the scale and durability of terrace structures means that some survive in the archaeological record while others have long since disappeared. Archaeological excavation of some terraced systems reveals multiple buried walls and other features that indicate complex histories or incremental construction.

Terraced soils have a wide range of physical, chemical, and biological properties (Sandor, 2006). One of the most distinctive morphological features is increased soil thickness resulting from accumulation of sediment upslope of terrace walls. Thickening within each terrace varies because of the wedge-shaped geometry common in terraced soil fills, wherein fills are thickest nearest the terraced wall and decrease upslope. At the lower end of the range, soils thicken slightly (few centimeters to decimeters) in the case of many runoff terraces on hillslopes and lynchets involving low terrace walls and accumulation by natural sedimentation. Substantial thickening from 0.3 up to several meters is common in bench terrace systems, wet-field terraces, and runoff terraces located in ephemeral drainages. The several traditional methods for filling terraces with soil or sediment by direct construction (versus natural sedimentation processes) greatly influence subsequent soil properties. In mountain terracing, construction filling with material originating on local slopes is common. Soil thickening is often a deliberate practice to create arable land on steep slopes that otherwise lack sufficient soil, or to increase soil rooting volume for water and nutrients. Buried horizons are characteristic of terraced soils where filling has occurred without destruction of the original soil. Where terrace filling is episodic or incremental, or where erosion has occurred, multiple fills and buried soil horizons may develop. Cases of such complex soils and strata in agricultural terraces have been studied in Greece, France, Mexico, Peru, and other locations (e.g., Krahtopoulou and Frederick, 2008; Bal et al., 2010).

Changes in soil texture are common, especially in upper horizons directly changed by construction filling and mixing of soil materials. Artificial gravel layers were placed at the fronts of some Andean terraces to aid drainage and reduce stress on terrace walls. Other textural changes reported in terraced fills ranging from subtle to substantial may result from sediment additions in irrigation water or runoff, or from downward translocation of fine particles, such as in agric horizons of lynchets (Courty et al., 1989). In Ifugao wet-field terraces in the Philippines, a sequence of textures is emplaced through deliberate water erosion upslope and then filling behind terrace walls downslope with coarser sediments first, followed by capping with fine sediments to achieve water ponding. Modification of soil structure and pores by terracing has also been documented.

Changes in several chemical soil properties have been measured in terraced soils, both in soil fills and deeper subsurface horizons. In soil fills, decreases and increases in organic carbon, nitrogen, phosphorus, some micronutrients, pH, carbonate, and cation exchange capacity have been found. Processes inducing increases in nutrients are additions in irrigation or runoff as well as fertilization. Decreases in soil nutrients result from crop removal as well as leaching and erosion processes. Some cases of subsurface chemical change result from translocation of dissolved or colloidal materials and the effects of burial by overlying terrace soil fills. An example is the movement of substantial phosphorus from manure applied as fertilizer in ancient Andean terraces deep into natural subsurface horizons (Sandor and Eash, 1995). Organic chemical compounds that are biomarkers of manure fertilizer have been detected in ancient Minoan terraced soils (Bull et al., 2001).

Under long-term transformation, many ancient terraced soils have acquired properties of anthropedogenic horizons defined in soil taxonomic systems such as the World Reference Base for Soil Resources, US Soil Taxonomy, and Chinese Soil Classification. Examples are plaggen, anthropic, anthraquic, and agric horizons that are recognized in several agricultural and archaeological contexts. Amendments, cultural debris, and other artifacts as well as high phosphorus levels have been identified in ancient terraced soils.

Paddy and other wet-field soils

Paddy soils are anthropogenic soils created for wet rice production (Zhang and Gong, 2003). They are most extensive in Southeast Asia, where fields more than 6,000 years old have been found (Cao et al., 2006). The goal in making paddy soils is to build bordered fields and soils with a sealed subsurface that ponds water during the first phase of the rice growing cycle, followed by field drainage to allow the rice crop to mature. The artificially created anthraquic soil hydrology, involving alternating ponding and draining through the rice growing cycle, results in anaerobic/aerobic biological activity and reduction/oxidation processes that alter soil organic and inorganic chemistry and impart the distinctive characteristics of paddy soils. Some of the main soil properties are puddled surface horizons and redoximorphic features such as reduced or gleyed matrix and redox depletions and concentrations of iron and manganese. Many paddy soils have a base-poor, bleached upper profile in which clay has been destroyed by ferrolysis, a process in which alternating reduction and oxidation from the periodic water ponding leads to soil acidification and albic E horizon formation.

Other ancient wet-field anthropogenic soils occur in various forms of raised fields, which are extensive in Central and South America, where they are as old as about 2,000–3,000 years (Beach et al. 2009). Many of these consist of soil ridges constructed and fertilized by additions of sediments and other materials to keep crops above shallow water tables. These were especially prevalent among the Maya and also occur in Mexico, the Andean Altiplano, and in Amazonia. In an example of "practical archaeology," a raised field system was reconstructed and successfully farmed in wetlands around Lake Titicaca in Peru (Erickson, 2000; Figure 1c).

Irragric soils

Irragric soils have been highly altered by long-term irrigation, especially from long-term deposition of suspended sediment by irrigation water (IUSS Working Group, 2006; Hesse and Baade, 2009). They were first characterized and are most prevalent in arid to semiarid central Asia and Mesopotamia, but are also found in other arid regions with long-term irrigation in southern Asia (India and Pakistan), the North America Southwest, and the western coastal area of Peru. Oldest ages are about 5,000 years in Mesopotamia, 3,000 years in Central Asia, 3,500 years in Peru, and 4,000 years in the North American Southwest. Irragric soil properties vary widely by region depending on the duration of irrigation, management practices, and irrigation water sediment load and chemistry. Common characteristics are thick, relatively homogeneous fine-textured horizons from irrigation sediment. Irragric soils may have higher organic matter levels, well-developed structure, lower to higher salt content than the original soils, and archaeological artifacts (Kostyuchenko and Lisitsyna, 1976).

Evaluating change in ancient agricultural soils

How have ancient agricultural soils changed from their original form, and by what processes? To answer these questions, we need to learn about the magnitude, spatial extent, and duration of soil change across a range of environmental and agricultural contexts (Sandor et al., 2005). Agriculture can alter soils both directly and indirectly by changing both soil morphology and underlying soil-forming processes and geomorphic, hydrologic, and ecosystem configuration. Some changes are intentional management strategies to increase soil productivity, such as soil chemical alteration by fertilization to increase nutrient content and availability. Other changes are unintended ones that lead to degradation such as soil erosion. Agriculture mainly changes surface horizons, though deeper alterations may occur. Some changes are subtle and temporary, while others are far reaching and permanent.

Long-term changes in soils from ancient agriculture have been inferred at landscape to submicroscopic scales using a number of field and laboratory approaches (Holliday, 2004). Methods to detect and measure soil change need to be carefully considered because they underpin all data and interpretation. Recognizing, measuring, and interpreting soil change from ancient agriculture can be difficult for several reasons: the sheer complexity of soils and their interaction with agroecosystems as well as post-agriculture soil change through continued soil development, environmental change, and later land use. In addition to this are the methodological challenges and relatively limited research. While soils in more intensive agricultural systems bear clear marks of change, other ancient agricultural soils can be very subtle. Patterns of soil change emerge, but each case produces its own distinct set of features, so there are no universal criteria. Soil change has been well documented in some areas, but in other areas, ancient agricultural soils remain unrecognized or insufficiently characterized.

Inferring soil change is primarily based on a "space-for-time substitution" method in which ancient cultivated soils are compared with nearby uncultivated reference soils in similar geomorphic and pedogenic settings (Homburg and Sandor, 2011). Because soils are dynamic, reference soils do not represent the original soils, but rather what cultivated soils would be like now had they not been farmed. Most comparative studies involve soils farmed during one discrete or undifferentiated past period. However, there are a few examples of anthrochronosequences in which soils farmed at multiple discrete periods have been identified, so paths of anthropogenic soil change can be traced. Another possible way to detect soil change is to identify dramatic or unique characteristics associated with some agricultural soils whose anthropogenic properties are far beyond the range found in natural soils, such as extraordinarily high phosphorus levels (e.g., Sandor and Eash, 1995).

Soil changes detected in ancient fields can be interpreted as a gradient from degradation to enhancement in the context of agricultural productivity and land resource conservation. Specific kinds of enhancement are A horizon thickening, structural stabilization, increased available water capacity, and gains of organic matter and nutrients. Examples of enhancement discussed in the previous section or elsewhere are the ADE soils, plaggen soils, and some terraced soils. Main forms of soil degradation inferred at ancient agricultural sites are accelerated erosion, structural deterioration, compaction, declines in organic matter and macronutrients such as nitrogen and phosphorus, salt and/or sodium accumulation, and acidification. In other cases, soil change may be indeterminate or intermediate between degradation and enhancement. Inconclusive findings may be due to methodological constraints like absence of reference soils for clear comparisons or insufficient sampling relative to soil variability and scale. Intermediate soil change could result from no net soil change, insignificant change, offsetting, mixed, inconclusive or contradictory change, or soil recovery from degradation or reversion from enhancement. Paddy soils reflect both enhancement and degradation, a kind of "creative destruction" (Johnson and Lewis, 1995). They involve destruction of surface horizon structure and properties resulting from anaerobic conditions, but this is deliberately managed to create the hydrologic conditions suitable for wet rice production.

Soil degradation has plagued agriculture throughout its 10+ millennia history. It has long-lasting consequences that can compromise societies' ability to function (Diamond, 2005). There is justified concern today about soil degradation and its adverse impacts on agricultural productivity and environmental quality. Some examples of soil degradation are presented next.

Accelerated erosion and sedimentation

Erosion resulting from agriculture and other human land use is referred to as "accelerated" because it usually occurs at higher rates than natural erosion; an order of higher magnitude is typical (Montgomery, 2007). Accelerated water erosion as sheet or gully erosion is most widespread, though there are also many instances of wind erosion (e.g., the Dust Bowl) and mass movement. A key reason for increased soil erosion is the loss of protective vegetation cover as natural ecosystems such as forests and grasslands are converted to farmland.

Surface horizons, which generally contain the most plant nutrients and organic matter, are the most immediately vulnerable to erosion. Especially subject to major change are those soils with well-developed, organic matter-rich surface horizons such as Mollisols. Such changes can persist for long time periods, even centuries after abandonment. As surfaces erode more deeply, subsurface horizons become shallower or exposed. If subsurface horizons inhibit plant growth, such as with salt-affected horizons, dense (e.g., claypans, fragipans) or cemented horizons (e.g., petrocalcic horizons, duripans), soil quality is further compromised.

Archaeological, stratigraphic, geomorphic, and pedologic (including micromorphology) studies of ancient agricultural soils have reconstructed complex histories of accelerated erosion in several regions, especially in the Mediterranean area, Europe, Mexico, and the Maya area (e.g., several chapters in Bell and Boardman, 1992; Houben, 2008; Krahtopoulou and Frederick, 2008; Beach et al., 2009). Several cases involve agricultural terraces, both as a response to erosion and as a cause if not maintained.

The counterpart to accelerated erosion is excessive sedimentation downslope, and many studies rely on sedimentation to infer erosion caused by ancient agriculture. The effect of sedimentation on soil productivity is a two-edged sword in that some sediment renews fertility, but excessive deposition is detrimental, burying crops and soils and causing off-site damage.

Organic matter and nutrient loss

Losses of soil organic matter and nutrients, resulting in soil fertility decline, have been most prevalent in semiarid to humid regions. Major causes are organic matter oxidation associated with tillage and cultivation, crop removal of nutrients that exceeds inputs, and clearing of native vegetation. Cases going back 5,000 years in Europe and 1,000 years in the Americas have been documented. Significant decline of soil organic matter, nitrogen, and phosphorus has persisted about nine centuries after the abandonment of some prehistoric fields in New Mexico, in amounts comparable to those in modern cultivated soils in the Midwest USA (Homburg and Sandor, 2011). Losses of soil nutrients, including phosphorus, calcium, magnesium, and potassium, were measured in ancient Hawaiian fields (Hartshorn et al., 2006).

Compaction and structural degradation

Compaction refers to increase in soil bulk density over the natural condition. In agriculture, compaction is usually an inadvertent and undesirable outcome of tillage and cultivation, involving decrease in overall porosity and especially macropores (pores generally >0.075 mm in diameter). As soils are damaged, natural aggregates (especially granular structure in A horizons) degrade to larger blocky structure or massive (cloddy) condition, accompanied by a loss of aggregate stability and formation of surface crusts. Besides direct compression during tillage, compaction is commonly associated with decreased organic matter because organic matter is critical in creating and maintaining stable soil structure. Compaction and degraded soil structure were associated with organic matter loss in the prehistorically farmed New Mexico soils previously discussed. Soil structure degradation has been reported in ancient agricultural fields in Europe as old as about 5,000 years.

Soil acidification and anthropogenic podzolization

Anthropogenic soil acidification and podzolization, including the development of iron-cemented horizons, have been inferred in the UK and elsewhere in northwestern Europe, where there is evidence from about 4,000 years ago to historic periods (e.g., Cunningham et al. 2001; Goudie, 2006). One mechanism seems to involve agriculture indirectly acting through climate and vegetation change. Deciduous forests were increasingly cleared for agriculture during the Bronze Age, but with a cooler wetter climate during the subsequent Iron Age, farms were abandoned. The climate no longer supported regeneration of the original woodland, and acidic heath vegetation took hold. This created conditions under which different soils developed: Spodosols with subsurface accumulations of organic-metal complexes and iron-cemented hardpans.

Salt and sodium accumulation

A common and widespread form of soil degradation associated with ancient through modern irrigation agriculture is the buildup of salt and sodium (Hillel, 1991; Goudie, 2006). This degradation is mostly associated with arid lands and results from poor-quality irrigation water and from rising water tables that bring salts near soil surfaces. Although there is evidence indicating serious salinity in ancient irrigation agriculture (Mesopotamia is the classic case), it is mainly inferred from data other than soil, such as written records indicating crop yield decline and increased use of salt-tolerant crops.

Hardening of highly weathered tropical soils – caused by agriculture?

Irreversible hardening of iron-rich, highly weathered soils (Oxisols) following exposure from cultivation has been inferred in some tropical areas, but this interpretation is controversial. Some observations of soil induration from agriculture seem valid, but the extent is far less than previously thought (Goudie, 2006). Most ironstone is now thought to have been naturally formed long before humans and agriculture and later exposed through erosion.

Summary

Several kinds of anthropogenic soil change from agriculture have been documented in the archaeological record. More research on ancient agricultural soils is needed because of the relative scarcity of quantitative soil studies, methodological limitations, the complexity of agricultural systems and soils, and imprints of multiple land use and environmental change.

Ancient agricultural soils are important sources of long-term information about soil change and related current agricultural challenges involving soil quality and conservation, water resources, climate change, and sustainability.

SOUTHWESTERN US GEOARCHAEOLOGY

Gary Huckleberry
Department of Geosciences, University of Arizona, Tucson, AZ, USA

Definition

Application of earth science methods and concepts to archaeological research conducted in Arizona, New Mexico, and adjacent areas within the USA.

Introduction

Formal geoarchaeological research in the southwestern USA began in the 1920s and focused on geological dating and environmental reconstruction at archaeological sites. Today, geoarchaeological investigations address a variety of topics of interest to the academic and cultural resource management (CRM) communities. Those practicing geoarchaeology in the southwestern USA include geologists, geographers, soil scientists, and archaeologists. Studies of soils, geomorphology, and paleoclimate help to define the environmental context of the cultural record and provide a framework for assessing archaeological site visibility and preservation. Geoarchaeology also increases knowledge of the region's more than 4000 years history of agriculture, including the construction of waterworks for irrigation. Other geoarchaeological applications involve study of site formation processes and the manufacture and sourcing of artifacts and other cultural materials either composed of geological materials or containing chemical signatures related to geology. Geoarchaeological research conducted in the southwestern USA over the past ~25 years is briefly reviewed below.

Environmental context and site visibility

The earliest unequivocal cultural horizon in the southwestern USA begins ca. 13,000 years ago with Clovis at a time of tremendous environmental change associated with the end of the ice age. Geoarchaeological investigations of Paleoindian sites in the region have helped (1) determine the age of the earliest cultural deposits and (2) reconstruct landscape dynamics and paleoenvironment (Holliday et al., 2006; Haynes and Huckell, 2007; Ballenger et al., 2011). Many of these sites contain stratigraphic evidence of climatic and biogeographic change. Stratigraphy from Paleoindian sites in southeastern Arizona that records the Younger Dryas Chronozone, a period of rapid cooling, has provided data used to test the controversial extraterrestrial impact hypothesis (Surovell et al., 2009). Other early sites in the Southwest have been reanalyzed to clarify their stratigraphic integrity and determine the relationship between extinct Pleistocene fauna and humans (Waters, 1986; Huckell and Haynes, 2003).

Younger archaeological sites have also provided clues into past landscape dynamics, including episodes of accelerated eolian activity (Wright et al., 2011) and alluvial cycles marked by arroyo-cutting and channel backfilling (Waters and Haynes, 2001; Karlstrom, 2005). In combination with local geomorphological controls, climate variability, as manifested by changes in flood frequency and magnitude, appears to have played an important role in alluvial cycles, and human activity may have also played a role, especially after the development of agriculture and subsequent increased sedentism and construction of canals.

Archaeological site patterns are a product of both human behavior and geological processes. Changes in erosion and deposition through space and time have affected the preservation and visibility of the archaeological record in the southwestern USA and geoarchaeological research has helped to reconstruct past landscape changes so that the existing archaeological record can be better connected to past human mobility and subsistence. This concept applies not only to Paleoindian sites that have been subject to over 10,000 years of potential postdepositional disturbance but also to the more recent archaeological record (Ravesloot and Waters, 2004). An ongoing topic of geoarchaeological research in the southwestern USA is explaining why early agricultural sites dating to 4000–2000 years BP have yet to be identified in large arable floodplains of major perennial rivers like the Salt and Gila and why there is a paucity of pre-Hispanic canal systems along the Rio Grande. Such discrepancies may have geological rather than cultural explanations.

Geoarchaeology and agriculture

The effect of climate and landscape dynamics on the northward diffusion of domesticated plants from Mexico and the subsequent practice of agriculture in the southwestern USA continues to be a major theme in geoarchaeological research. Climate change, erosion, deposition, and soil formation created opportunities and challenges for indigenous farmers. The distribution of soils and landforms influenced cultivation strategies and placement of agricultural fields (Lightfoot, 1993; Dominguez and Kolm, 2005). These patterns were disrupted by landscape dynamics, particularly in floodplains subject to alluvial cycles. Past episodes of arroyo-cutting disrupted irrigation and have been linked to settlement changes and areas of abandonment (Force and Howell, 1997; Huckleberry and Duff, 2008; Anderson and Neff, 2011; Nials et al., 2011). Larger main stem rivers in lower elevations are less prone to arroyo-cutting but are subject to shifts between single and braided channel patterns that can also be disruptive to water control (Graybill et al., 2006).

Despite the vagaries of climate and landscape changes, agriculture persisted as a predominant subsistence strategy for several millennia in the southwestern USA. This has important implications regarding agricultural sustainability and the effects of prolonged food production on soil fertility. Some areas that supported prehistoric floodwater farming contain evidence of soils with enhanced fertility; whereas other areas contain soils with depleted nutrients relative to adjacent uncultivated soils (Homburg and Sandor, 2011). Likewise, soil quality was improved by prehistoric canal irrigation in some places (Schaafsma and Briggs, 2007); whereas in other areas, the accumulation of canal silt and clay in field areas reduced soil properties (e.g., permeability and bulk density) that are conducive to crop production (Huckleberry, 1992).

Due to the region's overall arid climate, most agriculture in the Southwest requires irrigation for successful crop production. A variety of irrigation strategies were employed, leaving a wide range of archaeological signatures preserved in the landscape. Geomorphology and alluvial stratigraphy are useful in the identification of ancient canals and reservoirs, and they help to understand how these features were constructed and how they functioned (Damp et al., 2002; Bayman et al., 2004). Insights into these ancient waterworks have also been gained from the study of biological materials contained within canals and reservoirs (Adams et al., 2002) and from recent developments in optically stimulated luminescence dating (OSL) of sediments and ceramics associated with irrigation deposits (Berger et al., 2009; Watkins et al., 2011). In some cases, remote sensing has been used to identify ancient agricultural features not readily visible at the surface (Berlin et al., 1990), and new developments in LiDAR technology offer great promise for recognizing subtle features in the landscape that relate to pre-Hispanic agriculture.

Site formation and materials analysis

Geoarchaeological research in the southwestern USA has helped reconstruct erosional, depositional, and postdepositional processes that have modified the cultural record. Many sites contain artifact distributions that were disrupted by natural biological and geological processes, a phenomenon that complicates reconstruction of past human behavior. Exactly how cultural materials have been modified by animal/root mixing, freeze-thaw, soil formation, and other surface dynamics is a topic of concern. Some environments/landforms are more dynamic than others. Given that much of the southwestern USA is arid, eolian landforms are common, and sand dunes that are prone to wind erosion (deflation) frequently consolidate artifacts from previously separate stratigraphic levels and in some cases may even invert stratigraphy such that older artifacts become emplaced over younger cultural deposits (Buck et al., 2002). Floodplains are also dynamic, and the region has a climate conducive to generating high energy, flash floods. Depending on water velocity and sediment load, floods may bury and preserve some cultural materials or transport and redeposit others. Sedimentary structures and grain-size distributions of alluvial deposits in bedrock and alluvial reaches of rivers provide insight into past floods and can be used to reconstruct physical site formation processes (Huckleberry, 2006; Draut et al., 2008). Most archaeological investigations that take place in dynamic geomorphic settings in the southwestern USA, where sites are likely to be buried or modified by surficial processes, usually include a geomorphologist or soil scientist to help interpret site formation processes.

Physical and chemical analysis of artifacts and other types of cultural material that can be related directly or indirectly to geology can also shed light on past human behavior. In the southwesten USA, this includes geochemical analysis of stone tools, ornaments, architecture, and food remains. Strontium isotopes have proven particularly useful at Chaco Canyon, where conifer wood beams (Reynolds et al., 2005) and maize (Benson et al., 2009) have been sourced to distant locations. Oxygen isotopes can be used to determine seasonality of marine shell harvesting in the northern Gulf of California that provided protein and ornamental material for trade (Foster et al., 2012). Mineralogical and geochemical signatures in obsidian (Shackley, 2005), turquoise (Hull et al., 2008), and ceramics (Abbott et al., 2008) help to reconstruct patterns of production, trade, and community interactions through time. Mineralogical and geochemical analyses of architectural adobe and natural soils provide clues to how Puebloan structures were constructed and how they might be stabilized and preserved (Rumsey and Drohan, 2011).

Rock art and constructed rock features such as geoglyphs common to the southwestern USA remain a topic of considerable archaeological interest but have been challenging to date. Pictographs are composed of pigments that often contain organic matter suitable for radiocarbon dating, although sampling is destructive to the art and thus discouraged. Petroglyphs are etched into rock coatings and in turn develop younger accretionary coatings (silica skins and rock varnish) that contain datable carbon (Russ et al., 1992). If carbon in the basal coating is not subject to postdepositional translocation or contamination by younger carbon and can be physically isolated and extracted, then a minimum age for the creation of the rock art can be ascertained. However, rock coatings are open systems, and it is difficult to meet these criteria. Moreover, this method also involves destructive sampling and compromises the rock art. Efforts at radiocarbon dating microlaminations on constructed rock features have yielded some success but are still considered experimental (Cerveny et al., 2006). Nondestructive and reliable methods for dating rock art and constructed rock features are a work in progress.

Summary

Geoarchaeology in the southwestern USA is practiced by people with diverse formal training and academic backgrounds who tend to be employed in academia or CRM (cultural resource management under both private and government auspices). Geoarchaeological research helps answer important questions regarding human adaptation and culture change in the southwestern USA since the end of the last ice age. This includes identification of biophysical processes and environmental changes that have influenced human behavior and modified the archaeological record. Geoarchaeology has also played an important role in identifying and understanding evidence for past human activity, thus assisting archaeologists and government agencies (city, county, tribal, state, and federal) manage cultural properties and resources. Although a considerable amount of geoarchaeological research conducted in the region has been published in books and peer-reviewed journals, considerably more has been published in less accessible "gray" literature (contract reports) associated with CRM. Fortunately, much of this literature is available at academic libraries within the southwestern USA.

SPELEOTHEMS

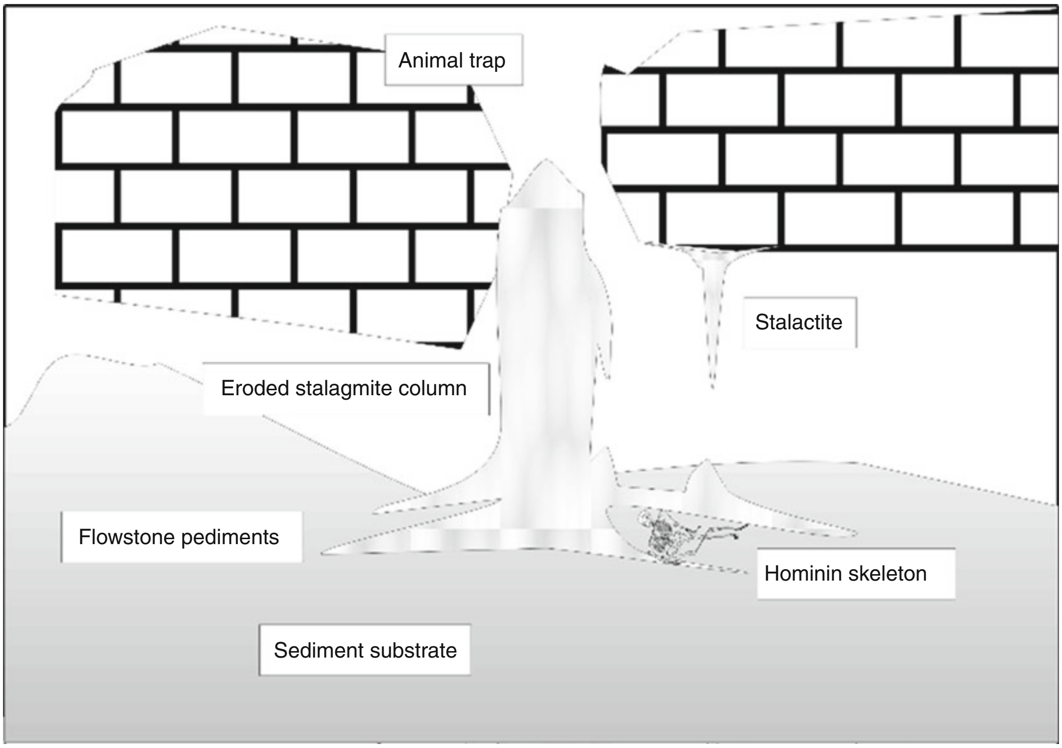
Alfred G. Latham
Archaeology, Classics and Egyptology, Liverpool University, Liverpool, UK

Definition

The term speleothem is used to cover all secondary chemical deposits in caves and, occasionally, of mines in limestone (karst) terrains. Its etymology is from the Greek "spēlaion" (or cave) and "thema" (or deposit). For a more specialist account of karst and speleology, see Ford and Williams (2007).

Introduction

Most people are familiar with the commonest forms of speleothems: stalactites, stalagmites, and flowstones. Their main relevance to the archaeology of caves stems from (1) their association with hominin and faunal remains or with artifacts such as stone tools, (2) the continuous records of climate change they contain, and (3) the fact that they can be reliably dated back hundreds of thousands of years and, in some cases, even millions of years. Thus, the dating of speleothems has contributed significantly to constructing a chronology of the stages of human evolution. This is because hominin remains are frequently



Speleothems, Figure 1 Stalactite, stalagmite, and flowstone are displayed in a diagram showing the growth relationship between the three main types of speleothems and their possible relationship to artifacts and hominin remains. The skeleton in the scenario represents a location similar to that of Little Foot from Sterkfontein, South Africa, which was sandwiched between flowstone layers in the Silberberg Grotto. The upper flow actually bisected and formed underneath part of the australopithecine skeleton after it had slumped on breccia and flowstone.

well preserved in the alkaline environment of caves where speleothems also form, and the pace of human evolution, of climate change, and of karst processes (geomorphological processes in limestone terrains) are commensurate in scale. Caves may also contain speleothems that are not directly related to their archeologically significant layers, and, in such cases, these speleothems may provide relative *ante quem* and *post quem* ages.

Isotope signatures of oxygen and carbon from speleothems have yielded proxy records of changes in climate and ecology for the Quaternary and even earlier periods, and such records are significant in documenting changing environments over the course of human evolution. In addition, speleothems, along with various clastic deposits, provide data for site reconstruction. Many caves show alternations of animal denning and human occupation, and some parts of caves may have acted as animal traps – into which animals fall accidentally and create a fossil record with their accumulated skeletons – as shown in Figure 1.

The importance of speleothems for cave archaeology was indicated very early in the history of excavation by discoveries at Kents Cavern, Torquay, on the south coast of England. Father John McEnery (or MacEnery) excavated stone tools associated with extinct fauna when he broke through a stalagmite-flowstone floor, whose underlying layers provided the first hard evidence for the antiquity of man, though his inferences were not immediately accepted. His excavations took place between 1824 and 1829, 30 years before Darwin published his famous treatise *On the Origin of Species* in 1859. The flowstone-capped layers that contained Acheulian bifaces have been dated to 400–450 ka by the Thermal Ionization Mass Spectrometry, or TIMS, U-series method (McFarlane and Lundberg, 2005; Lundberg and McFarlane, 2007).

By far, the most common mineralogy of speleothems is calcium carbonate, $CaCO_3$, but two crystalline forms are possible: one being calcite (single crystals are known as Iceland Spar) and the other aragonite. The next most common mineral in caves is gypsum, $CaSO_4 \cdot 2H_2O$, a calcium sulfate. There are many other mineral speleothems (Hill and Forti, 1997), though they are seldom associated with fossil bones or artifacts relevant to archaeology.

Carbonate speleothems form from carbonate-rich seepage water as it passes through the soil zones at the surface and into the underlying limestone via cracks in the rock. A related rock type, dolomite, is also found widely, as in

South Africa; whereas limestone is carbonate $CaCO_3$, in dolomite, magnesium (Mg) replaces many of the Ca ions. Carbon dioxide outgases from the feedwater, which contains calcium and bicarbonate (hydrogen carbonate) ions, as it emanates from the rock into the cave passage thus causing the calcium carbonate to precipitate.

$$Ca^{2+} + 2HCO_{3-} \rightarrow CaCO_3 + CO_2\uparrow + H_2O$$

This is not an evaporative process because the atmospheres of most cave interiors are at, or close to, water vapor saturation. But some speleothems do form by the evaporation of dripwater in drafty passages and in well-aerated cave entrances. Those speleothems that formed with the larger aragonite structure may later revert to the more compact calcite form in the presence of water.

Of its many different forms, speleothems occur in three main types (Figure 1).

1. Stalactites form from dripwater at the ceiling and often begin as hollow straws from precipitation around the rim of the drip. When the feedwater moves to the outside, they may subsequently "bulk out" as long narrow cones, or they may form curtains on the underside of sloping ceilings and walls. They are occasionally associated with archeological evidence. In caves known for prehistoric cave paintings, ribbon-like deposits may form down the walls and so may be seen to postdate or antedate the wall paintings. They have provided U–Th dates by the TIMS method because it requires only small samples, as at Tito Bustillo and other caves in Northern Spain (Pike et al., 2012). Most cave paintings dated so far have been by the radiocarbon method on pigment or on associated artifacts. At Arcy-sur-Cure, near Avallon, France, sheet-like coverings on the walls have helped to preserve cave paintings of mammoths and other fauna.
2. Stalagmites form on the floor, either on solid rock or on sediment. In the latter case, the early layers at the bottom of the stalagmite may be contaminated with mud or sand. Stalagmites grow upwards where the calcite layers form long-sided caps. The drip centers occasionally show "work holes" at the impact point, which may or may not have some sediment in them depending on whether the stalagmites are within reach of cave flood water. When stalagmites join with their parent stalactites, they form columns.
3. Flowstones occur in sheet-like forms that grow from the trickle of carbonate water down local slopes. Most of them are associated with rimstone pools (or rimstone dams; also called gours), and they tend to form overlapping cascades. In warmer climates, where chemical reactions are faster, the gours commonly grow to several meters across and as much deep. Flowstones often display micro-gours of a few centimeters or less across.
4. Moonmilk is a noncrystalline flowstone deposit that is thought to form in the presence of bacteria. As it is porous, it is usually not suitable for dating.

Both stalagmites and flowstones can form part of the floor deposits and so are more closely associated with any archeological contexts than are stalactites. Some references, given below, also refer to hot spring deposits, such as spongy tufas that once contained vegetation, but which consist mainly of a carbonate component. As some of them are associated with hominin remains and archeological finds, they may also be dated by U-series and other methods. The main problem is that they also contain detrital components such as windblown sediments, so they have to be treated as contaminated deposits as discussed below.

Pure calcite is translucent, but dissolved elements and minerals may impart color to the forms. The hues are most frequently produced by iron (Fe): red to yellow; manganese (Mn): black; copper (Cu): blue; or varied organic substances: black to brown to yellow to red (Figure 2). Particle impurities of clastic sediment such as mud, clay, or silt form colored opaque layers. The sediment that coated the long stalagmite of Figure 2a (left) was partly washed off down the sides, giving it the grayer appearance. Tiny holes that are filled with air, water, and water vapor are called fluid inclusions; if they are sufficiently dense, they impart a more milky appearance to the calcite. The importance of fluid inclusions lies in their much-studied potential for paleoclimate and paleoecology research that is, in turn, important for an understanding of environmental change in the context of faunal and human evolution.

Dating

The sources of the carbon in the $CaCO_3$ that crystallizes into speleothems are partly the host rock and partly the organic soil zone. The feedwater, however, can continue to exchange carbon before the mineral finally precipitates, so the ^{14}C component derived from organic materials is diluted by variable amounts of carbon contributed by the rock. Radiocarbon dating is limited to ages below about 60 ka, and thus, it is seldom used for dating speleothems. Instead, U–Th dating of speleothems, and particularly of corals, has been used to calibrate the ^{14}C scale back to 60 ka (Weninger and Jöris, 2008).

The main dating techniques for speleothems have utilized the decay series based on naturally occurring radioactive ^{238}U which, being soluble in water, coprecipitates with each newly formed layer of calcite or aragonite. For various applications of U-series methods and details, see Ivanovich and Harmon (1992) or Bourdon et al. (2003). ^{238}U decays by a series of alpha and beta particle emissions, first to ^{234}U and ^{230}Th, and eventually to ^{208}Pb, a stable isotope of lead (Figure 3). The most commonly used dating method is known as U–Th dating. It is based on the observation that the ^{238}U granddaughter, ^{230}Th, is insoluble in water and, therefore, it is always absent in each new layer of a speleothem, which therefore constitutes a reset clock in which the radiogenic ^{230}Th, having a half-life of 75,200 years, grows from zero toward equilibrium with ^{234}U and ^{238}U at a known rate (Figure 4).

Speleothems, Figure 2 The 76 cm-long stalagmite (**a**; *left*) grew from 1,300 years ago to the present. It formed on a sediment bank and was actively forming when sampled. It contains organics (which give it the amber color) and flood-borne detritus, some of which has been washed off to the sides by the dripwater. The markings are in preparation for cutting into subsamples for magnetometry. The 18 cm purer speleothem (**b**; *right*) has been sectioned to show growth layers and crystal growth. Crystals grew at right angles to the morphology of the growth surfaces, hence the curvature, and are said to have a palisade texture with generally elongated crystals.

In the laboratory, a few grams or less of a sample are chipped out and dissolved (as in the small stalagmite in Figure 1). Then, the U, Th, or Pb isotopes are separated by ion-exchange resins before deposition onto spectrometer filaments prior to ionization. Analysis of the U and Th isotopes, which gives the age, involves the chemical separation of these isotopes before measuring their relative abundances by alpha-particle spectrometry or by mass spectrometry. Isotope tracers of the same elements, colloquially known as isotope spikes, are used to trace and correct for different chemical yields in the laboratory process known as isotope dilution analysis.

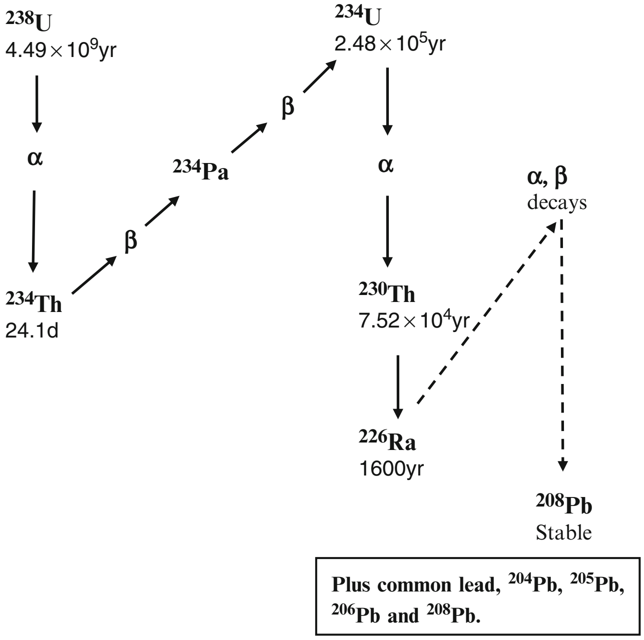
The equation yielding the age for the U–Th method from the isotope ratios is given by Eq. 1:

$$^{230}Th^{234}U = \frac{\frac{1-e^{-\lambda_{230}t}}{^{234}U}}{^{238}U + \frac{\lambda_{230}}{\lambda_{230}-\lambda_{234}}\left(1-\frac{\frac{1}{^{234}U}}{^{238}U}\right)\left(1-e^{-(\lambda_{230}-\lambda_{234})t}\right)} \qquad (1)$$

and t, the age, is worked out using a computer program. λ_{230} and λ_{234} are the activity coefficients (decay constants) of ^{230}Th and ^{234}U.

Older published U–Th ages relied on the alpha-particle emissions of the different isotopes and were counted on semiconductor detectors in which the age limit of the method was 400,000 years for samples with high U concentration. The advent of TIMS and related mass spectrometric techniques (from about 1990 onward), in which individual atoms are counted, has higher precision; its U–Th dating limit is about 600,000 years and, instead of chipping out sample layers of several grams for alpha spectrometry, less than a gram is needed for TIMS.

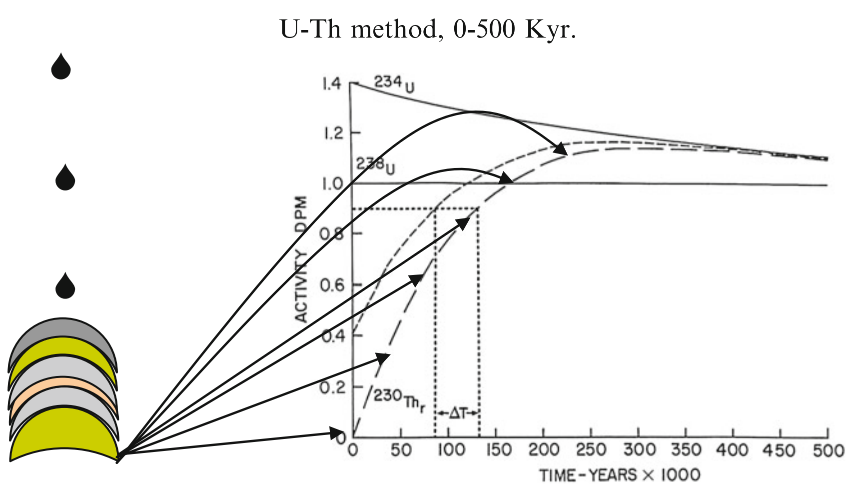
The South African caves around Johannesburg have yielded many hominin remains of *Australopithecus africanus*, *Paranthropus robustus* (or *A. robustus*, a common synonym), *Homo habilis*, and related forms. There are many such sites in South Africa that remain to be examined, and it has become clear that in the period 3–1.5 Ma, the region appears to have witnessed the existence, and possibly even the evolution, of several hominin species. Previously, these hominins were very difficult to date, and consequently, they were somewhat neglected in studies of human evolution.



Speleothems, Figure 3 The radioactive decay schemes from ^{238}U to ^{208}Pb with the relevant half-lives. The details of the more rapid alpha and beta decays from ^{226}Ra (radium) to ^{208}Pb are not shown. Alpha-particles are two neutrons plus two protons, as in a helium nucleus, and hence the resulting atom from alpha decay has an atomic mass four less than the parent. Electrons possess 1/1800 the mass of a nucleon, so there is effectively no mass change in beta decay.

Their importance demanded a means of determining their age, and so the geological chronometry based on the buildup of ^{208}Pb in the ^{238}U decay series has been adapted in cases where concentrations of uranium in speleothems are sufficiently high. In this method, the clock depends upon the decay of ^{238}U to ^{208}Pb. As ^{238}U has a very long half-life of 4.49×10^9 years (Figure 3), amounts of accumulated ^{208}Pb are small. Allowance also has to be made for the contribution of ^{208}Pb that coprecipitated from the feedwater as the so-called common lead. This is done using either the non-radiogenic index isotope, ^{204}Pb, or the radiogenic ^{205}Pb that can be produced by its radiogenic parent, ^{235}U, but occurs in such small quantities from this source that most of the measured ^{205}Pb can be counted as belonging to common lead. The method involves plotting the different concentrations of ^{238}U relative to the common lead in a so-called isochron plot that provides a robust measure of the precision of the age estimates.

Measurement precision errors are propagated to the final age estimates by sophisticated error-handling programs that take into account that some of the errors are correlated. It was common in alpha spectrometry to quote age errors to one standard deviation, known as one sigma (1σ). TIMS-based ages are often quoted to two sigma (2σ). Because of the nature of the growth curve, U–Th ages often have a $+1\sigma$ error that is greater than the -1σ error. The TIMS precision is usually better than 1 % of the age, and thus, a typical age quote for the interglacial thermal maximum of the faunal stage known as the



Speleothems, Figure 4 Growth to equilibrium graph showing how ^{230}Th grows from zero to equilibrium with its parent ^{234}U and then grandparent ^{238}U in a given layer of calcite. If there is initial ^{230}Th detritus, then the effect leads to an apparent increase in age by ΔT. Multiple leachate methods may be used to correct for detrital contamination.

Ipswichian, measured using coral samples from the Barbados Terrace III and corresponding to Marine Isotope Stage 5e, would be 124.0 $^{+1.2}/_{-1.0}$ ka. (Note: absolute time is ka, periods of time are in kyr).

The success, accuracy, and precision of these methods are dependent upon four factors:

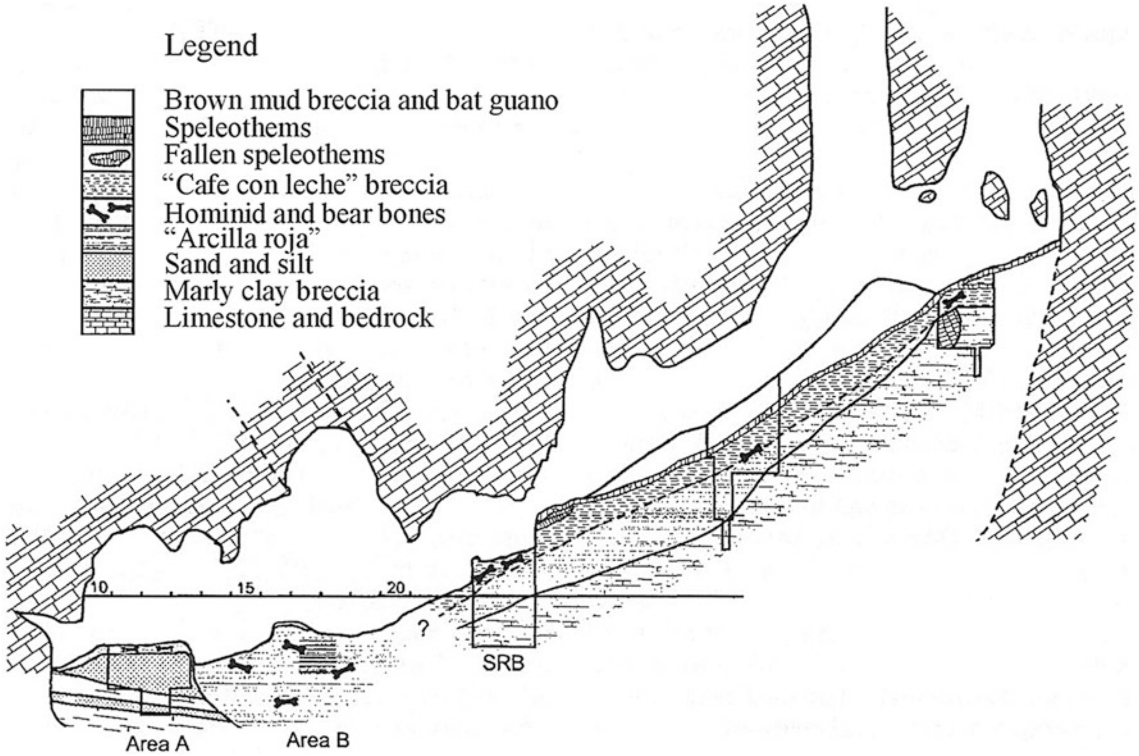
1. Having a sufficient concentration of U – the higher the U, the better the precision in determining the age. Concentrations of U in speleothems are typically in the range of 0.1–10 parts per million (ppm).
2. Knowing the excess of an intermediate decay product, such as ^{234}U, that also contributes to ^{230}Th and to ^{208}Pb – these are usually measured in the same or related analysis. For U–Pb dating, the contribution of ^{208}Pb from the original excess of ^{234}U becomes harder to assess with increasing age. This is because the remaining excess ^{234}U diminishes, making it harder to measure beyond an age limit of 3 Ma.
3. Making an allowance for additional isotopes from any detritus – these can usually be allowed for by analysis of five or more subsamples having varied proportions of the two using isochron plots, but it takes longer to do (Schwarcz and Latham, 1989). For publications before about 1988, age corrections used ^{232}Th as an index for the extra detrital ^{230}Th but not for the extra U isotopes, and so they were only approximate.
4. Ensuring that the system has been closed to migration, in or out, of any of the decay-series isotopes. The transgression of this closed-system assumption is detectable from daughter isotopes in excess of their parents and from anomalous isochrons. It is usually not possible to make allowance for an open-system history unless it can be demonstrated that isotope migration was regular with time such that it can be modeled. Experience has shown that movement of isotopes appears to have occurred at some later stage when speleothems lose some of the U upon recrystallization of aragonite to calcite.

Although U–Pb and U–Th have the same parent, ^{238}U, the daughter products and half-lives are different, and the clocks based on them are independent. Cliff et al. (2010) showed that there was good concordance on a U-rich speleothem from Spannagel Cave (Austrian Alps) between U–Pb and U–Th ages, respectively: 267 ± 1 ka versus 267 ± 5 ka; 291 ± 1 versus 295 ± 11 ka; and 340 ± 2 versus 353 ± 9 ka.

Some archeological caves, such as the South African australopithecine sites, are sufficiently old (on the order of several million years) that their deposits, including flowstones, may have recorded reversals of the Earth's magnetic field. The last main reversal was at 780 ka when the Earth's magnetic field changed from the reversed Matuyama chronozone to the normal Brunhes chronozone. Cave reversal records might be amenable to dating by finding a match to a part of the age-calibrated Global Polarity Time Scale (GPTS) (Gradstein et al., 2012). Neither speleothems nor sedimentary layers are deposited at uniform rates – there may indeed have been depositional hiatuses – and it is not to be expected that their records will be sufficiently long for them to be used as a match on their own. Therefore, another dating method (e.g., from time-sensitive faunal assemblages) is usually required to locate roughly where the match in the GPTS is located. Speleothems must also contain sufficient quantities of iron oxide grains such as magnetite or hematite; otherwise, most speleothems are too pure to provide a measurable characteristic remanent magnetization (ChRM, the stable part of the natural remanent magnetization, NRM). It is pertinent to point out here that if the clastic deposits of caves are to contribute to the reversal record, they must have been laid down subaqueously so that the Earth's magnetic field can influence the direction of settling of the magnetized particles within a depth of water of at least a few centimeters. That is, sediments that have resulted from slumps or debris flows are unlikely to present a faithful reversal record. Flowstones do allow a faithful recording of the ambient magnetic field (Latham et al., 1979; Latham and Ford, 1993).

Applications

The search for speleothems associated with hominin remains and artifacts that could be studied for chronological purposes is now a routine part of archeological cave excavations. The initial development of the U–Th method on speleothems was due to the Russian, V. V. Cherdyntsev (Ivanovich and Harmon, 1992). He applied it to dating the hot spring deposits of Middle Paleolithic Age at Vértesszöllös (Hungary) and at other middle European sites. John Rosholt at the United States Geological Survey made significant contributions in the early 1980s using new isotope dilution techniques to date contaminated precipitations that helped to extend the method to contaminated samples such as those at Vértesszöllös. The McMaster University laboratory in Canada run by Henry Schwarcz and Derek Ford maintained a program from 1973 (for over 35 years) of U–Th dating of carbonate speleothems and hot spring deposits, many of which were directly related to solving chronological problems associated with the Middle and Upper Paleolithic in Europe and Israel. Their work also included related paleoenvironmental and landform studies. Early U–Th dating studies included sites of the Middle Paleolithic such as La Chaise-de-Vouthon, France (Blackwell et al., 1983); Grotte du Lazaret, Nice, France (Falguères et al., 1992); analysis and reanalysis at Caune de l'Arago, France, Tautavel, Eastern Pyrenees (Falguères et al., 2004); Vértesszöllös, Hungary, using U–Th and paleomagnetism (Schwarcz and Latham, 1984); Tata, Hungary (Schwarcz and Skoflek, 1982); Bilzingsleben, Germany, using U–Th and ESR (Schwarcz et al., 1988); Pontnewydd, Wales, using U–Th and TL (Green et al., 1981); and Petralona, Greece, using U–Th and paleomagnetism (Latham and Schwarcz, 1992). Several Iberian cave sites have been dated by Jim Bischoff – Arbreda, by ^{14}C



Speleothems, Figure 5 The Sima de los Huesos pit (Burgos, Spain) and its hominin remains in relation to the capping flowstone layers. The dates in the text refer to the capping flowstones and the magnetic reversals to the underlying sediments (From Bischoff et al., 2003).

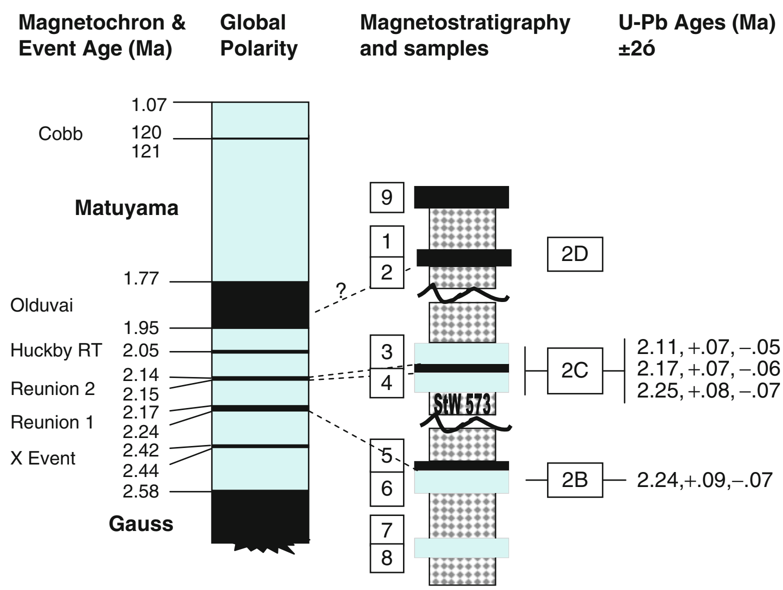
(Bischoff et al., 1989); El Castillo (Bischoff et al., 1992); Abric Romaní (Bischoff et al., 1994) – in the knowledge that several of them contain information on the origin and fate of Neanderthals in Western Europe.

For human evolution studies from cave sites, Ann Wintle, Hélène Valladas, Rainer Grün, and others also developed radiation dose methods of thermoluminescence (TL) and optically stimulated luminescence (OSL), as well as related methods, on burnt flint and of electron spin resonance (ESR) dating on tooth enamel.

Unfortunately, not all caves contain speleothems useful for dating archeological remains. One of the most important localities with sites recording the Middle to Upper Paleolithic transition is the Mount Carmel caves near Haifa, Israel, that had been excavated by the Cambridge University archeologist Dorothy Garrod, and associates from 1924 to 1936. These are Et-Tabun, El-Wad, Es-Skhul, Jamal, and some 13 km to the south, Kebara Cave. The use of speleothems from these sites was compromised by significant alteration that had removed both bone and speleothems through the oxidation of overlying guano deposits and destructive acids released in the process. Nearly all of the samples taken had experienced a degree of open-system movement of isotopes. These Levantine caves have instead yielded results to dating applications using ESR and TL, though not without a considerable amount of reanalysis. One Middle Paleolithic (Amudian) site further south at Qesem (near Tel Aviv) contained speleothems that have produced U–Th ages of 382–200 ka, spanning the Lower Paleolithic Acheulian to the Mousterian (Barkai et al., 2003).

Excavation and reanalysis at the Israeli sites has involved teams of chronologists and researchers familiar with cave deposits. As this was not the case in many other sites, uncertainty still surrounds the stratigraphy and age of the Petralona skull, for example, from northern Greece, which possesses both *H. erectus* and Neanderthal affinities. Related flowstone layers have been dated by U–Th and other methods; the skull is likely to be older, perhaps twice the quoted youngest age of around 170 ka (Latham and Schwarcz, 1992).

Atapuerca near Burgos, Spain, comprises several cave sites such as Trinchera Dolina and Elefante that have yielded remains of *Homo antecessor*, dated to 1.3–1.0 Ma by the magnetic reversal sequence of clastic sediments. Nearby Sima de los Huesos is a 10 m deep pit that has yielded the remains of over 34 individuals of a pre-Neanderthal stage (Figure 5). The remains lay underneath a flowstone floor. Initial attempts to date the flowstone combined U–Th alpha spectrometry with



Speleothems, Figure 6 The U–Th ages and magnetic polarity placement in the Global Polarity Time Scale of the flowstones above and below Little Foot (StW 573) of the Silberberg Grotto of Sterkfontein, from Walker et al. (2006). "Huckby RT" refers to the Huckleberry Ridge tuff event. In the Global Polarity graph, black sections represent normal polarity intervals, while the lighter blue color designates reversed polarity.

paleomagnetic polarity analysis. The age estimate was at or above the U–Th dating limit of 400 ka, but the polarity of the underlying sediments was normal, which was taken to mean that the remains were older than 400 ka but not older than the Brunhes-Matuyama boundary at 780 ka (Bischoff et al., 2003). Subsequently, a higher resolution TIMS reanalysis on samples from the flowstone suggested ages around 600 ka (Bischoff et al., 2007).

Little Foot is the name given to remains of an almost complete australopithecine (possibly *Australopithecus africanus*) enclosed in flowstone layers in the Silberberg Grotto of Sterkfontein Cave near Johannesburg, South Africa. The individual appears to have fallen down the side of a large stalagmite, and subsequently, the skeleton became covered in a calcite flow and red silts derived from the surface. Based upon the fossil morphology, its position in the cave, and the evidence of the breccia infill, it was initially estimated to be around 3 Ma in age. Attempts to date adjacent flowstone layers underlying and overlying Little Foot included a magnetic polarity sequence on the flowstones aided by biochronology, which yielded an age around 3.2 Ma and then by assays of cosmogenically produced ^{10}Be and ^{26}Al in clastic sediments, which yielded an age estimate of 4.2 Ma (Granger and Muzikar, 2001; Partridge et al., 2003). These estimates were thought to be too old, as the faunal assemblages were little different from those of adjacent upper strata known to be around 2 Ma. Walker et al. (2006) used U–Pb isochron dating on the flowstones immediately above and below the skeleton, and Pickering and Kramers (2010) dated the overlying flow to suggest an age of a little over 2.2 Ma. The U–Pb ages indicated that the paleomagnetic signals in the flowstones had recorded the older and younger Réunion Events (short shifts to normal polarity that were discovered in lava from the island of Réunion), which means that the Little Foot age is between 2.4 and 2.2 Ma (Figure 6). The stratigraphy around the skeletal remains has been questioned, but U–Pb analysis of the lowest flowstone should help to settle the question (Bruxelles et al., 2014). The dating of Little Foot and of "Mrs. Ples" from Sterkfontein, another representative of *A. africanus*, also at around 2.2 Ma by magnetic polarity, was an important milestone for the chronology of the South African hominin record; until then, the complex South African cave deposits had eluded a secure chronometric dating analysis, and the biochronology of fossil animal assemblages could only roughly indicate ages of around 2 Ma. Across the valley, Swartkrans Cave, which contained representatives of *Paranthropus robustus*, has yielded dates by U–Pb analysis of flowstones and cosmogenic dates of sediments of 2.19 ± 0.08 Ma and 1.80 ± 0.09 Ma (Gibbon et al., 2014) and has yielded to flowstone U–Th analysis with an upper age estimate of 110 ka for its Middle Stone Age (Sutton et al., 2009).

Similar U–Pb studies in other parts of Sterkfontein and in another australopithecine site at Makapansgat (the Limeworks) have not met with success due to low U content in the speleothems and, in the latter cave, open-system isotopic disturbance in the earlier flowstones. A combination of biochronological dating using known suid (pig) faunal successions and magnetic polarities of flowstones and carbonate-cemented silts indicate ages for the two sets of strata containing the Makapansgat australopithecine hominins, of 2.7 and 2.5 Ma (Warr et al., forthcoming), making this the oldest dated australopithecine site in South Africa. Malapa Cave has yielded fairly complete male and female skeletons of a somewhat younger hominin, dubbed *A. sediba*, from sediment lying above a flowstone. The U–Pb analyses from the flowstone and magnetic polarity of the sediments indicate an age between 1.78 and 2.0 Ma (Dirks et al., 2010; Pickering et al., 2011).

Variations in the relative abundance of isotopes of oxygen (^{18}O and ^{16}O) and of carbon (^{13}C and ^{12}C) in speleothems have been used to establish long continuous records that can serve as proxies for climate and vegetational changes, respectively. Schwarcz and Ford were again instrumental in pursuing the use of fluid inclusions in speleothems as a means to recover paleotemperatures. The number of such studies has mushroomed in the new millennium (see McDermott, 2004), though it has to be said that a reliable and easy method of yielding absolute paleotemperatures has proved elusive.

Nevertheless, very useful climate change proxies have been produced from long stalagmites, particularly from Israel, stretching back to before the last interglacial, MIS 5 (Marine Isotope Stage 5). The long-term work of Miryam Bar-Matthews and coworkers (1997) in their sampling of cave dripwater at Soreq Cave, a show cave located southwest of Jerusalem, established annual correspondence between stable oxygen isotope signatures of rain and the signature in the cave dripwater. That correlation allowed them to interpret isotope signatures from a number of speleothem records from this cave. Amos Frumkin et al. (1999) dated a speleothem by TIMS from Jerusalem West Cave that extended the Near East isotope records back to about 170 ka. Bar-Matthews et al. (1999) elucidated the precipitation records, tested the viability of using speleothem fluid inclusions for paleotemperature work, and analyzed 12 speleothems, with partial overlaps, from Soreq Cave to extend their record back to 60 ka. The original alpha-based dates were replaced by 53 TIMS dates. The O-isotope record showed a good match to the Marine Isotope Stage (MIS) records, including cold peaks in good agreement with the Greenland short ice-core events known as Heinrich events – H1 (16.5 ka), H2 (25 ka) and H5 (46 ka) – and the Younger Dryas between 13.2 and 11.4 ka. In Bar-Matthews et al. (2000), further analyses of the Soreq speleothems appeared to show that four of five low $\delta^{18}O$ events spanning 140 ka corresponded well to organic marine mud (sapropel) horizons in Eastern Mediterranean marine cores and that they were due to enhanced annual precipitation, especially for the intervals 124–119 ka and 8.5–7.9 ka. Speleothems dated to between 90,000 and 53,000 years ago from Pinnacle Point Cave on South Africa's Cape coast demonstrated the correspondences between precipitation and vegetation type, and afforded comparison with the changes in regional lithic cultures and hence, of human ecology (Bar-Matthews et al., 2010). It appears that "Early modern humans in this region confronted a variable climate and adapted quickly in a manner similar to behaviorally modern humans" (Bar-Matthews et al., 2010, 2131).

A long O-isotope record was produced by Hopley et al. (2007) from a very uniformly deposited 2.3 m flowstone from the early Pleistocene Buffalo Cave, Makapansgat, South Africa. A combination of biochronology and reversal stratigraphy indicated an early Pleistocene age between 2 and 1 Ma. Astronomical dating, which uses the known phases of the orbital parameters of the Earth's orbit (ellipticity, 100 kyr; obliquity of the axis, 40 kyr; and precession of the axis, 21 kyr) was then used to fix the record to a period between 1.9 and 1.52 Ma. The carbon isotope part of the record showed that there had been a change in the type of plants using different photosynthetic pathways, known as C_3 and C_4 plants. The emergence of C_4 plants began in the tropics only in the Middle Miocene (20–15 Ma), and was an evolutionary response to cooler, drier climates and decreasing atmospheric CO_2 levels. The old 4 Ma flowstones at the Limeworks, Makapansgat, showed that C_4-type grasses had not yet reached that latitude (15° S) but that they were present by 1.9 Ma. The Buffalo Cave flowstone record shows that they increased in stepwise fashion, most prominently between 1.7 and 1.6 Ma. This was taken to suggest an increase in aridity at these latitudes that favored C_4 over C_3. The changing ecology was represented by an increase in Savannah, which might have contributed to the emergence of new hominins such as *Homo ergaster* and *H. erectus*, both having a body plan better suited to more open environments than had their precursor australopithecines.

Synonyms

Groundwater discharge

Definitions

Spring: a localized discharge of groundwater disgorging from a point source.

Seep: multisource discharge of groundwater as a "spring line" or a broad, diffuse wet area.

Spring-fed river: a drainage way that may contain perennial flow sourced by groundwater despite a negative hydrologic budget.

Spring-fed wetland: an area sourced by groundwater that comprises perennially damp ground and/or standing, shallow water supporting aquatic vegetation.

Aquifer: a geologic formation that contains sufficient saturated permeable material to yield significant quantities of water to springs or wells.

Springs

Geology of springs

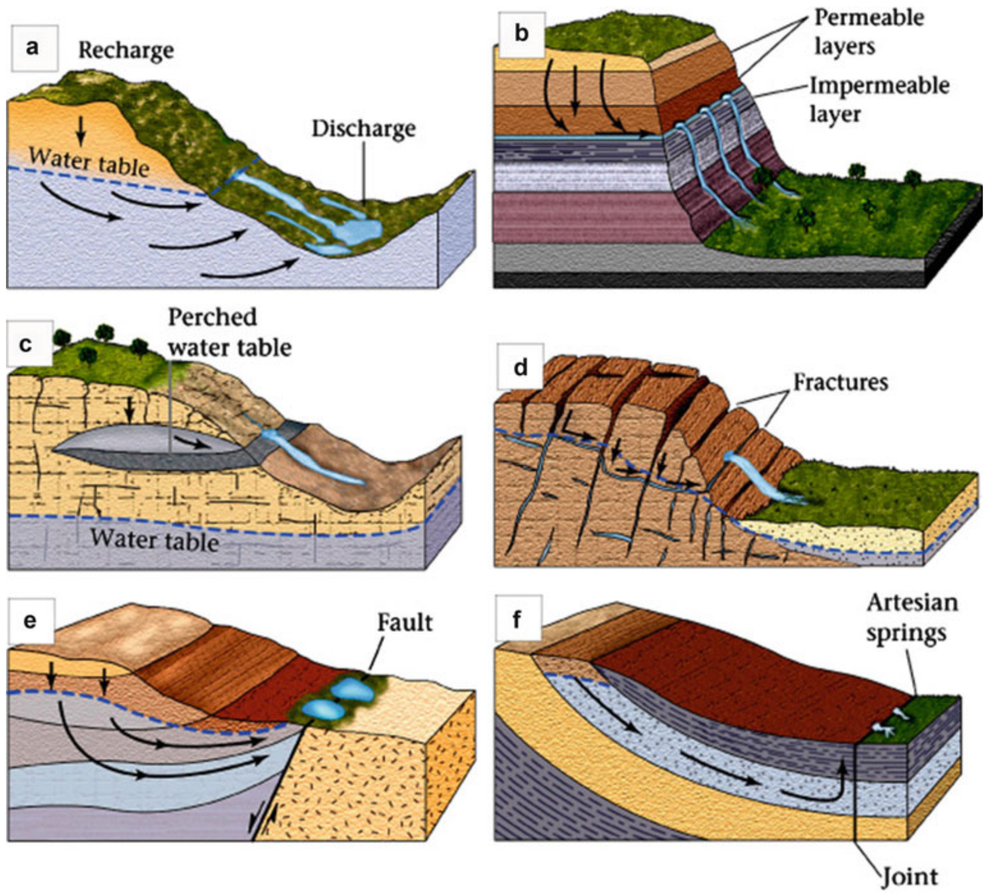
A spring is a localized discharge of groundwater disgorging onto the Earth's surface. The source of the groundwater may be a great distance (tens to hundreds of kilometers) away, and the water may move at a slow rate (meters/year). There are varied natural geologic settings that result in groundwater flowing onto the surface, thereby creating springs and seeps (Bryan, 1919; Fetter, 2001). Common examples include the intersection of the water table – i.e., top of the groundwater – with the land surface (Figure 1a), or when water percolating from the surface meets an impervious layer (Figure 1b). Other examples include a perched water table caused by the local interruption of water percolating downward (Figure 1c) or water moving through, and out of, a set of fractures (Figure 1d). Artesian flow (confined groundwater) may discharge from a fault (Figure 1e) or a joint, i.e., a single fracture with no evidence of movement between adjacent blocks (Figure 1f) (Marshak, 2001). These fractures provide a conduit to the surface for water flowing under hydrostatic head (pressure) (Figure 1e, f). In geologically complex areas, the groundwater is likely to be multisourced, and the location of groundwater discharge can vary temporally due to climate change or tectonic activity that creates faults or changes the gradient of the land (Rosen, 1994).

Hydrology of springs

The ultimate source of freshwater for any region is precipitation (P), but the net amount of water in the system annually depends on additional factors, such as evaporation (E) and type of vegetation present (both strongly influenced by temperature). Temperature is in turn a function of latitude and elevation of the location. Plants utilize some water and return it to the atmosphere by evaporation and plant transpiration (T), or evapotranspiration (ET). The rest of the precipitation enters the surface and groundwater system. The position of the groundwater table fluctuates with short-term and long-term changes in the regional hydrologic budget. $P > E + ET$ would represent a positive budget; $P < E + ET$ would reflect a negative budget. The water table rises when there is a sustained positive budget, and it falls when there is a sustained negative budget. Groundwater flow velocity is slow (meters/year), so there would likely be a lag in time between changes in amount of rainfall and the resulting increase or decrease in the volume of water in the ground. As many factors affect the volume of groundwater, the regional water table can be found anywhere between essentially the Earth's surface to hundreds of meters below the surface.

Water quality of springs

The composition of spring water varies considerably, reflecting the history of the water, including its source, rocks along the flow path, flow rate, etc.



Spring Settings, Figure 1 Geological settings of springs: (**a**) groundwater table intersects the surface; (**b**) water percolating down from the surface intercepts an impermeable layer; (**c**) water percolating from the surface intercepts a localized impermeable layer creating a perched water table; (**d**) in areas of dense bedrock, groundwater typically follows fractures, which act as preferred pathways for flow; (**e**) groundwater moves along fault planes, which act as a conduit for flow to the surface; (**f**) example of artesian flow (water enters the ground at higher elevation and exits upward along joint fractures under pressure) (Modified from Marshak (2001)).

The physiochemical environment, which includes the pH, temperature, and levels of oxygen and carbon dioxide, affects the productivity, abundance, and diversity of plants, microbes, and invertebrates. On the other hand, the biotic component, particularly vegetation, can affect spring hydrology by blocking drainage and retarding runoff. In areas of high heat flow, water in hot springs may reach 100 °C and is typically alkaline (pH = 8−10). Water may be salty if contaminated by surface brines or evaporites at depth. Erupting spring water may reach super saturation of carbonate as CO_2 is degassed when it flows onto the surface; pH tends to rise as degassing occurs, thereby reducing carbonate solubility and causing the precipitation of carbonate deposits near the spring orifice (Figure 2). Blue-green algae, bacteria, and cyanobacteria are the most common microbial forms associated with the precipitation of carbonate and siliceous minerals (Chafetz and Folk, 1984; Jones and Renaut, 1998).

Spring Settings, Figure 2 Photograph of a carbonate deposit (tufa) precipitated at a spring about 1.75 Ma in Lowermost Bed II, Olduvai Gorge, Tanzania. Oldowan stone tools were found in equivalent age strata. Geology hammer (30 cm) gives the scale.

Associated spring-fed environments

Although freshwater springs and seeps may be an attraction for animals and people, it is unlikely that archaeological sites would be found directly at the spring itself. In fact, there are very few examples of archaeological materials occurring in spring deposits, e.g., Florisbad, South Africa (Grün et al., 1996). The inherent dangers associated with the water source, such as carnivores seeking prey (Domínguez-Rodrigo et al., 2007), the possibility of encountering thirsty or frightened animals, and the potential for conflicts with other humans would result in short visits. Archaeological sites interpreted to be linked to springs are usually located a distance away (tens to a few hundred meters) in environments that are associated with groundwater discharge, such as a river bed (Ashley et al., 2011) or floodplain and groundwater-fed wetlands (Ashley, 2001; Ashley et al., 2009).

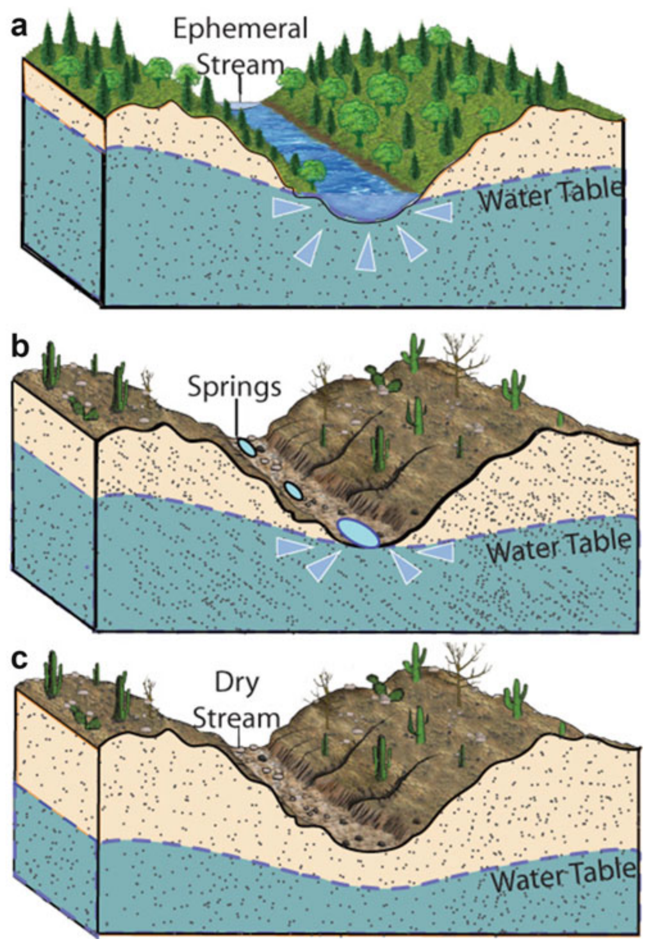
Rivers

Rivers are traditionally considered to be part of the surface water system that conveys discharge within channels from higher elevations of a watershed to lower elevations, where the water finally flows into an interior basin or into the ocean. But, rivers are not separate and distinct from the groundwater system; the two systems are, in fact, interrelated (Figure 3). For example, under wetter conditions, groundwater seeps into the river through channel boundaries (Figure 3a), augmenting water already in the river channel (i.e., increasing groundwater inflow creates a "gaining stream"). If conditions become drier, the river level drops as river water percolates downward, leaving a nearly dry riverbed. Water may completely disappear except for localized pools in the deeper parts of the river channel that are sustained by the uppermost parts of the groundwater flow (Figure 3b). When pools are spring fed, they may persist during even the driest time of the year if the water source is an aquifer being recharged at a distal location. The aquifer would also be protected from evaporation and utilization by vegetation. Under even drier conditions (Figure 3c), the water table would drop further (i.e., creating a "losing stream" where the river channel is located higher than the groundwater). If rainfall or a flash flood occurred in the area, water would soak into the ground until it reached the water table.

Wetlands

The water flowing from springs or seeps and from diffuse areas of groundwater discharge commonly results in freshwater wetlands (marshes, wet meadows, and groundwater forests) that may cover large expanses of landscape (Figure 4). These groundwater-fed sources tend to be persistent, as groundwater reservoirs are less vulnerable to fluctuations in precipitation and evaporation than are surface reservoirs (Liutkus and Ashley, 2003; Johnson et al., 2009; Ashley et al., 2010b). Wetlands can occur in any setting where the water table is near or at the surface. Ephemeral wetlands are linked to seasonal rainy periods or a perched water table (Figure 1c), whereas perennial wetlands occur in settings with a more permanent water source. They are often found at the interface of terrestrial ecosystems (such as upland forests and grasslands) and aquatic ecosystems (such as lakes and rivers), and thus they are often overlooked as part of a natural continuum (Mitsch and Gosselink, 2000).

The geomorphology of a spring and wetland complex is typically low relief and comprises a labyrinth of waterways of open water fringed with peats rooted on slightly higher ground. On increasingly higher terrain, the vegetation changes from marsh to wet meadow to groundwater forest characterized by a succession of plants with a decreasing tolerance for standing water



Spring Settings, Figure 3 Groundwater and surface water (rivers) are interactive systems: (**a**) groundwater enters the river through the sides and bottom of channel creating a "gaining stream"; (**b**) groundwater table is just below the channel bottom but supports springs in low-lying places within an otherwise dry stream bed; (**c**) a "losing stream" occurs where water percolates downward to a subsurface water table and is not accessible from the surface (Modified from Marshak (2001)).

(Mitsch and Gosselink, 2000). Lush wetland vegetation and mineral licks attract grazing and browsing animals, providing hunting and scavenging opportunities for humans (Haynes and Agogino, 1966). Wet ground and marshes were likely used to trap animals for easy slaughter. Groundwater forests offered sources of fruits and vegetables and safe sleeping localities for our human ancestors. Wetland plants such as cattail (*Typha* spp.) and reeds (*Phragmites* spp.) were widely used for food, medicine, textiles, and building materials (Nicholas, 1998). In addition, thermal springs may have had medicinal or therapeutic uses (Griffin and Sattler, 1988).

Although groundwater discharge areas are well known in modern times as water sources for animals, particularly in arid settings (Behrensmeyer, 1978), their presence in the geological record has been recognized only recently (Quade et al., 1995; Ashley, 2000; Deocampo et al., 2002; Smith et al., 2004; Ashley et al., 2009; Ashley et al., 2010a). The bulk of the sediment record is generally silt and clay-sized material: 50–60 % clay, 20–30 % organic matter, and 10–20 % silt. The mineralogy of the clay provides a record of the water quality and is thus useful in paleoenvironmental interpretation. Clay minerals such as smectite and sepiolite indicate freshwater and lower pH; potassium feldspar and illite form in more alkaline-saline conditions (Hay et al., 1986).

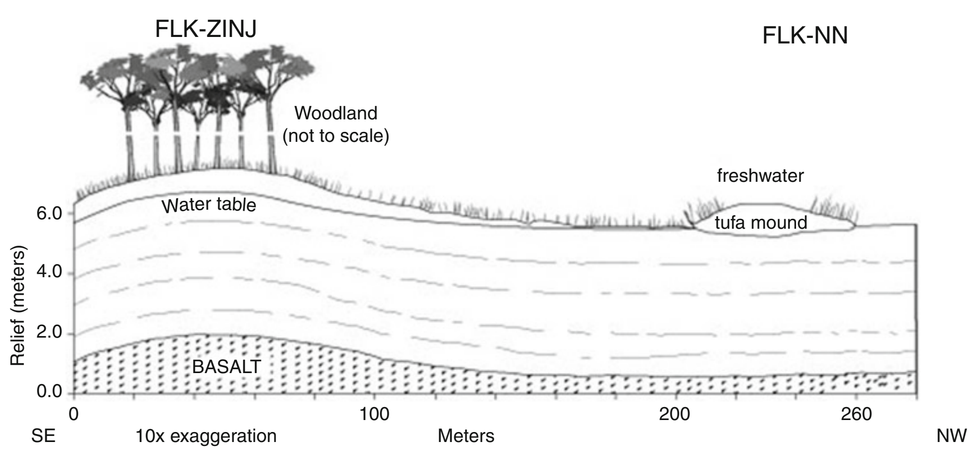
Case study: archaeological site at Olduvai Gorge, Tanzania

Mary and Louis Leakey discovered the hominin fossil *Zinjanthropus boisei* – referred to as "Zinj" and later renamed *Paranthropus boisei* (Leakey, 1971) – in Olduvai Gorge, Tanzania in 1959. Excavations of the surrounding area (~315 m^2) recovered ~2,500 Oldowan stone artifacts and 3,500 fossil bone specimens, including remains of another species, *Homo habilis*. The site (FLK Zinj) is recognized as one of the best co-occurrences of localized, high-density Oldowan tools and fossilized bones in East Africa, but why this unique archaeological site occurred at this specific location in the Olduvai Basin was a mystery for several decades. There were no rivers, and the nearby lake was salty. In 2008, a paleolake was identified, based on a thick carbonate tufa deposit at the site of FLK NN, 200 m from the Zinj fossil locality (Figure 5). The Zinj site itself was situated within a thick woodland, based upon plant remains (pollen and phytoliths) in the sediment associated with the bones and stone tools (Ashley et al., 2010a). The mystery was thereby solved; the most likely reason for the archaeological site being in a wooded locality is that the trees and underbrush provided temporary safety for hominins that were scavenging carnivore kills or perhaps even hunting



Spring Settings, Figure 5 Diagram showing the location of the archaeological site (FLK Zinj) in a woodland about 200 m from a freshwater spring (FLK NN).

animals attracted to the spring. It appears that carcasses were carried to the woodland by hominins for safe consumption.

Summary and conclusions

Springs and archaeology

Potable water sources are foci of human activity, and thus, temporary, seasonal, and permanent occupation sites are commonly associated with them. The inherent dangers of encounters with animals and other humans make it unlikely for such occupations to be established immediately adjacent to a spring or seep, but instead they tend to be located at a discreet distance. Archaeological sites are also commonly found associated with, but at safe distances from, freshwater sources, and many are in areas that have excellent preservation potential. Riverbanks, floodplains, and deltas or margins of permanent water bodies ranging from large lakes to small ponds have long been recognized as areas used by humans. Frequent changes in the water level of rivers and lakes typically include transgressions that cover occupation sites with a blanket of organic-rich sediment that slows the weathering process and helps preserve the archaeological record, as well as associated organic material such as bones and plant remains (Deocampo et al., 2002), and structures such as footprints, burrows, or fire pits (Ashley and Liutkus, 2003).

Springs themselves are usually small in area and may not always leave a mineral record. Therefore, identifying the records of associated groundwater-fed environments, such as rivers and wetlands, is important in interpreting the paleolandscape of the site.

Archaeological sites representing permanent or semi-permanent occupation associated with riverbed springs are likely to be on floodplains or higher terraces (Wright et al., 2007), but some material that has not been fluvially transported may be left on the riverbed itself and later buried (Ashley et al., 2011). The field of wetland archaeology has a long history and a number of excellent records (Coles, 1984; Coles and Coles, 1989; Bernick, 1998; Purdy, 2001). The reducing conditions in wetlands are conducive to the preservation of biological remains and also limit weathering of bones and artifacts.

The nature and longevity of spring environments and their attraction for people and animals is a direct function of the hydrologic budget. The appearances and disappearances of groundwater-fed systems on the landscape in a particular geologic setting vary with climate. These systems occur under both arid and humid environments but would be particularly important in arid regions as a dependable source of water during short- and long-term droughts.

STABLE CARBON ISOTOPES IN SOILS

Lee C. Nordt[1] and Vance T. Holliday[2]

Definition

Stable isotopes of carbon (^{13}C and ^{12}C) in soil organic matter and in pedogenic carbonate provide a means of paleoenvironmental reconstruction because the ratio of these two isotopes is influenced by biological, physical, and chemical reactions. The C_3 and C_4 plant communities that produced the organic carbon can be identified isotopically based on the degree of discrimination against atmospheric $^{13}CO_2$ during photosynthesis (the degree to which a plant favors carbon dioxide containing the lighter $^{12}CO_2$ isotope).

Introduction

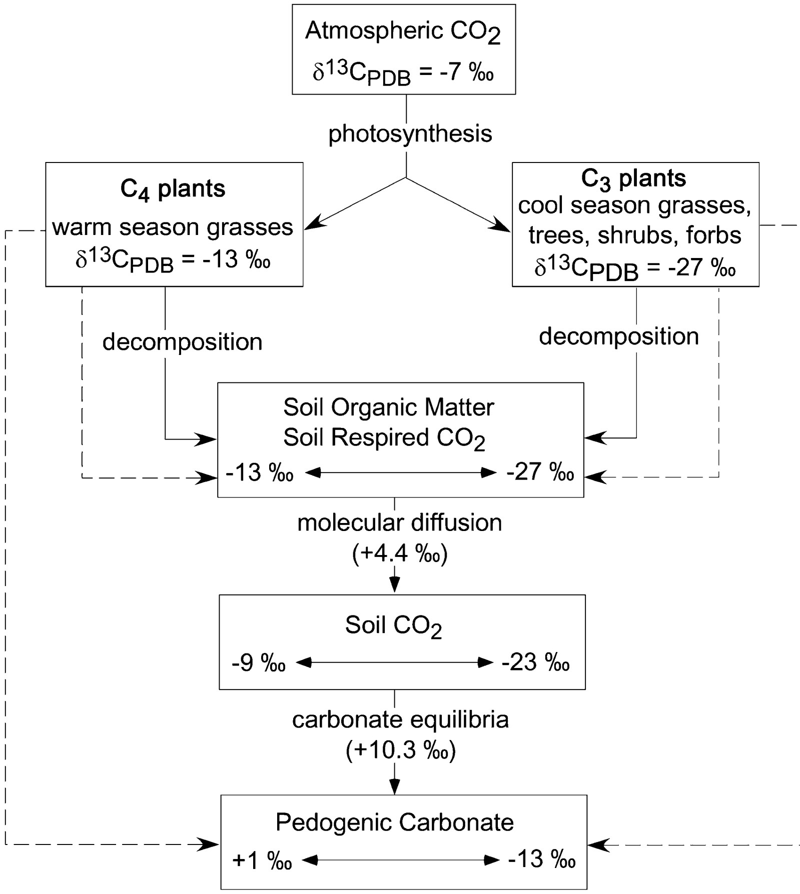
The distribution of stable C isotopes in surface and buried soils is a powerful indicator of many kinds of pedologic and paleoenvironmental interpretations. Stable C isotope analysis of soil organic matter is commonly employed to quantify organic matter turnover rates (Balesdent and Mariotti, 1996; Bernoux et al., 1998) and to reconstruct past vegetation communities (Cerling, 1992; Cerling et al., 1993; Kelly et al., 1993; Wang et al., 1993; Nordt et al., 1994; Boutton, 1996; Nordt et al., 1996, 2008; Fredlu,nd and Tieszen, 1997; Boutton et al., 1998; von Fischer et al., 2008; Hall and Penner, 2013). Stable C isotopes of pedogenic carbonate are used for quantifying rates of pedogenesis, estimating pathways of soil development, and inferring landscape age (Amundson et al., 1988; Marion et al., 1991; Nordt et al., 1996, 1998). As with soil organic matter, stable C isotopes of pedogenic carbonate can be employed as a proxy for paleoclimate reconstruction (Quade et al., 1989; Cerling and Quade, 1993; Cole and Monger, 1994; Humphrey and Ferring, 1994; Monger, 1995).

The primary application of stable C isotope analysis in soils to archaeological research is for paleoenvironmental reconstruction (Nordt, 2001). This method is particularly effective in semiarid to subhumid climates where plant communities have experienced changes in the ratio of C_3 to C_4 species or soil biomass production. These areas typically include tropical/temperate grasslands, semidesert and dry steppes, and tropical shrub/woodlands. Humid or tropical climates that have been continuously forested, or polar regions with cool season grasses, are less likely to have supported a C_4 plant community.

Theory and application of isotope pedology

Surface and buried soils store important paleoenvironmental information applicable to solving archaeological problems because pedogenesis is strongly influenced by climate and vegetation (Birkeland, 1999). Soils contain two components that can be analyzed isotopically for paleoenvironmental reconstruction: organic matter and pedogenic carbonate. Both of these materials contain carbon that is derived from decaying plant matter, which is the link between soil and vegetation/climate.

Organic matter consists mainly of decomposed plant litter in surface and near-surface layers (A or O horizons) that impart a dark color to the soil. Organic matter accumulates in the early stages of soil development until inputs and outputs become equal (steady state), typically within 1,000 years (Birkeland, 1999; Buol et al., 2011; Nordt et al., 2011). The amount of soil organic matter decreases



Stable Carbon Isotopes in Soils, Figure 1 Photosynthetic pathway for C_4 and C_3 plants and associated $\delta^{13}C_{PDB}$ values for soil organic matter, respired soil CO_2, and pedogenic carbonate. *Dashed lines* represent ways by which the proportion of C_4 and C_3 plants can be estimated knowing soil organic matter or pedogenic carbonate $\delta^{13}C_{PDB}$ values (Modified from Nordt, 2001: Figure 15.2).

with depth as biological activity decreases, whereas the whole soil amount of soil organic matter decreases in drier climates where plant biomass production is lower. In contrast, most pedogenic carbonate typically accumulates in lower soil layers (Bk horizons) at the terminus of a wetting front, due to CO_2 degassing and dewatering from evapotranspiration. These processes enrich the soil solution in calcium and bicarbonate ions to the point that a carbonate precipitate forms. Pedogenic carbonate typically accumulates as nodules, filaments, or indurated masses that are morphologically visible in the field and in a disseminated form that is only visible at the microscopic level. In nonleaching environments, and with an abundant source of calcium and carbonate ions, the accumulation of soil carbonate increases with time (Birkeland, 1999; Buol et al., 2011).

There are three carbon isotopes in nature: ^{14}C, ^{13}C, and ^{12}C (Hoefs, 1987). The ^{14}C isotope undergoes radioactive decay and is commonly used for radiocarbon dating of late Quaternary materials. The ^{12}C and ^{13}C isotopes are stable, and the ratio of these two isotopes is influenced by biological, physical, and chemical reactions. The amount of fractionation that occurs between ^{13}C and ^{12}C is measured as the relative deviation between a sample and standard and is expressed in $\delta^{13}C$ notation. Three plant groups can be identified isotopically based on the degree of discrimination against atmospheric $^{13}CO_2$ during photosynthesis (Boutton, 1991a). The C_3 plants discriminate most against atmospheric $^{13}CO_2$ and in normal conditions produce $\delta^{13}C$ values around –27 ‰ (Figure 1). Plants that discriminate much less against atmospheric $\delta^{13}CO_2$ are C_4, which produce $\delta^{13}C$ values near –13 ‰. The C_3 plants consist mainly of trees, shrubs, forbs, and cool season grasses, whereas C_4 plants consist mainly of warm season grasses. CAM plants (Crassulacean acid metabolism) most often have a photosynthetic pathway similar to C_4 plants. However, facultative CAM plants can generate values that span the entire spectrum of C_3 to C_4 photosynthesis.

Virtually no isotopic fractionation occurs during decomposition of plant litter and subsequent incorporation of organic by-products into the soil organic matter pool (Nadelhoffer and Fry, 1988; von Fischer et al., 2008). Thus, the $\delta^{13}C$ value of soil organic matter reflects the proportion of C_3 and C_4 plants contributing organic material to the soil (Figure 1). For example, a pure C_4 plant community would produce soil organic matter with a $\delta^{13}C$ value of approximately –13 ‰, and equal contributions of C_3 and C_4 plants would produce a $\delta^{13}C$ value of approximately –20 ‰. Some authors have discovered that the isotopic composition of plants has fluctuated during the late Quaternary by as much as 2 ‰ in response to changes to atmospheric CO_2 levels (Marino et al., 1992). This amount still does not obscure major shifts in biomass production as reflected in the $\delta^{13}C$ values.

Plants with C_3 photosynthesis may grow in all environmental settings throughout the world, making them difficult to use as a paleoclimatic indicator. Facultative CAM plants are also problematic because they may yield both C_3 and C_4 isotopic signatures. The contribution of C_4 plants to the soil organic matter pool, however, is a reliable proxy for paleoclimatic reconstruction because the abundance of C_4 species (Teeri and Stowe, 1976) and their biomass production (von Fischer et al., 2008) are strongly and positively related to environmental temperature. Therefore, the $\delta^{13}C$ of soil organic matter can be used to interpret past vegetation communities and, from that, provide for general interpretations about past environmental temperatures (Figure 1).

The following mass balance in Eq. 1 illustrates how the proportion of C_4 and C_3 contributions to the soil organic matter pool can be estimated knowing a bulk soil $\delta^{13}C$ value:

$$\delta^{13}C = \left(\delta^{13}C_{C4}\right)(x) + \left(\delta^{13}C_{C3}\right)(1-x) \qquad (1)$$

where $\delta^{13}C$ is the value of the whole sample, $\delta^{13}C_{C4}$ is the average $\delta^{13}C$ value of the C_4 components of the sample, x is the proportion of carbon from C_4 plant sources, $\delta^{13}C_{C3}$ is the average $\delta^{13}C$ value of the C_3 components of the sample, and 1–x is the proportion of carbon derived from C_3 plant sources. Some natural variation exists in the end member $\delta^{13}C$ values for C_3 and C_4 plants (generally ± 1 ‰). Consequently, it may be necessary to construct an isotopic mixing line unique to the area of investigation.

Nordt et al. (2007) developed a transfer function from bulk $\delta^{13}C$ to mean July temperature from soils in the Great Plains (USA), where increasing C_4 biomass contributions related positively to higher summer temperatures. By applying the temperature equation to a suite of buried soils, they showed quantitative evidence for a middle Holocene Altithermal, for example. Hall and Penner (2013) took this method a step further by developing a transfer function for estimating summer rainfall. They were able to establish a rainfall curve from a suite of buried Holocene soils in New Mexico. Nordt et al. (2008) developed a relative scale for estimating changing contributions of C_4 plants using a method that compared the isotopic difference by latitude between the nearest modern soil (surface) $\delta^{13}C$ value to nearby buried soils of different ages throughout the Holocene. They were able to identify isotopically the Younger Dryas (decreasing C_4), Altithermal and Medieval Warm Period (increasing C_4), and Little Ice Age (decreasing C_4) in the Great Plains.

Soil organic matter is converted to respired CO_2 by microbial respiration and does not isotopically fractionate when fluxing from the ground surface (Cerling et al., 1991). During the instantaneous flux of respired CO_2, the lighter $^{12}CO_2$ isotope migrates more rapidly to the surface by molecular diffusion, thus theoretically enriching the remaining soil CO_2 by 4.4 ‰ (Cerling et al., 1991; Amundson et al., 1998). This soil CO_2 component takes part in carbonate equilibria reactions, which leads to an additional 10.3 ‰ enrichment in $\delta^{13}C$ (at 20 °C) as the soil CO_2 is transferred to the solid pedogenic carbonate phase (Cerling et al., 1989). Although this reaction is temperature dependent, the influence on isotopic values is minor within the temperature range of most soils (1–1.5 ‰). Thus, the pedogenic carbonate component of most soils can in theory be isotopically estimated by adding approximately 14–15 ‰ to soil organic matter or respired CO_2 as shown by the equation (Nordt et al., 1998):

$$\delta^{13}C \text{ pedogenic carbonate} = \delta_{CaCO3-CO2}\left(\delta^{13}C \text{ SOM} + 1004.4\right) - 1000 \qquad (2)$$

where $\delta_{CaCO3-CO2}$ is the fractionation factor between pedogenic carbonate and soil CO_2 (1.0103, which calculates to 10.3 ‰) and SOM is soil organic matter. Cerling and Quade (1993) show, however, that ^{13}C-enriched atmospheric CO_2 can mix with biologically produced soil CO_2 in arid regions where biological activity is low. Generally, this is not a factor at the depth at which pedogenic carbonate precipitates in subhumid to humid environments nor below a depth of 50 cm in semiarid or arid climates. Computer modeling provides the best means of estimating the $\delta^{13}C$ of pedogenic carbonate in areas where atmospheric mixing is significant (Cerling, 1984; Quade et al., 1989; Nordt et al., 1998).

Pedogenic carbonate accumulates in disseminated forms, nodular forms, and as indurated layers (Birkeland, 1999; Buol et al., 2011). The $\delta^{13}C$ value of these forms, if not contaminated with lithogenic or detrital pedogenic carbonate, can be used as a paleoclimatic proxy (Cerling and Quade, 1993). This is done by subtracting approximately 14–15 ‰ (at 20 °C) from the $\delta^{13}C$ value of pedogenic carbonate to estimate the proportion of C_3 and C_4 plants contributing organic matter to the soil organic matter pool at the time of carbonate precipitation. For example, a $\delta^{13}C$ value of –20 ‰ obtained from a pedogenic carbonate nodule would indicate equal contributions from C_3 and C_4 plants to soil organic matter production during the time of carbonate formation.

Sources of soil organic carbon

There are two sources of soil organic matter that commonly occur in late Quaternary environments (Nordt et al., 1994). The first is detrital, which is the organic fraction transported with mineral particles in alluvium, colluvium, eolian, or even glacial deposits. For example, if the drainage basin of a stream or the source area of eolian sediment does not cross major climatic or vegetation boundaries, a detrital organic carbon source is desirable because it represents local conditions. On the other hand, detrital isotopic signatures from large drainage basins or from distant eolian sources probably represent an average of several climatic and vegetation zones and cannot be interpreted as one environmental condition. Generally, transported organic carbon originates from the most easily erodible materials in the drainage basin or area in question. This tends to be from upland topsoils or older alluvial topsoils that carry a modern organic carbon isotopic signal. Again, this organic component is desirable for interpreting paleoenvironmental conditions. Some organic carbon may be derived from bedrock, but this component is much more likely to contain low quantities of organic carbon and consequently have its signal suppressed by modern carbon sources. Detrital isotopic values are more likely to be encountered in subsoils (B horizons) where pedogenic organic inputs are lower.

The second source of soil organic matter is pedogenic. This source is clearly desirable for paleoenvironmental reconstruction because the isotopic values reflect the vegetation growing directly in the soil. Pedogenic isotopic signatures of organic matter will be more evident in surface horizons where they are superimposed on detrital signatures. Mixing of detrital and pedogenic sources should also provide favorable isotopic results if the detrital component was transported a relatively short distance.

The stable C isotope composition of organic matter in upper horizons of buried soils may provide a discrete view of the isotopic plant community present during soil formation. This will be true provided that appreciable erosion of the surface horizon did not occur during soil burial or that significant biological mixing did not occur after burial. If the soil developed in uplands from sediments that have never been buried, it becomes more problematic to interpret either surface or subsurface isotopic values because long-term surface exposure may average isotopic conditions from two or more climatic intervals. Surface soils no more than a few thousand years old may also exhibit problems similar to older upland soils, depending on the frequency of climatic shifts in a particular area. In this case, data are needed from younger surface soils that can help partition differing vegetation and climatic intervals preserved in older soils.

Sources of carbon from pedogenic carbonate

Samples for stable C isotope analysis of pedogenic carbonate must also be interpreted with caution. The most common problem occurs when carbonate nodules appear to be pedogenic but instead are (1) lithogenic; (2) pedogenic, but engulfing lithogenic components; (3) pedogenic, but detrital; or (4) produced in association with ground water. Fortunately, most limestone $\delta^{13}C$ values (~0 ‰) are greater than pedogenic carbonate values that form in equilibrium with organic matter produced from C_3 or mixed C_3/C_4 plant communities (Figure 1). Unfortunately, pedogenic carbonate produced in association with organic matter from a pure C_4 plant community will yield $\delta^{13}C$ values similar to limestone (Figure 1). This problem can sometimes be resolved by insuring that the $\delta^{13}C$ of coexisting soil organic matter and pedogenic carbonate isotopically differ by 14–15 ‰ as theoretically predicted for most soils – see Eq. 2. Another technique would be to use petrographic thin section analysis because, in many instances, pedogenic and lithogenic carbonates have different micromorphic attributes (West et al., 1988). One example of this situation is that carbonate formed as root casts normally indicates in situ pedogenesis. Pedogenic carbonate that is eroded and redeposited is also difficult to identify, but the depth of nodules should occur systematically with climate. For example, pedogenic carbonate nodules accumulate at greater depths in subhumid climates than arid climates, all else being equal.

Some carbonate nodules precipitate in equilibrium with ground waters supersaturated with calcium and carbonate ions. This would yield isotopic values that are not in equilibrium with biologically produced soil CO_2. The presence of iron depletion zones or oxidized root channels observed in the field or in petrographic thin section (Vepraskas, 1994) may indicate whether groundwater was associated with formation of the carbonate. Carbonates precipitating within a capillary fringe of a groundwater table, however, probably will not pose a problem because biologically produced CO_2 will take part in the reaction.

Soil-stratigraphic interpretations

Depending on the presence or absence of buried soils, the length and pathway of pedogenesis of the buried soils, and the presence or absence of erosional unconformities, it may be difficult to estimate the timing of organic and inorganic carbon inputs in soil-stratigraphic sections. For example, with cumulic formation where pedogenesis keeps pace with deposition, a combination of detrital and pedogenic organic carbon isotopic signatures will be observed. However, organic inputs from pedogenic sources should dominate the isotopic record and reflect local vegetation conditions at the time of soil formation. In contrast, stable isotope values contained within a rapidly aggrading deposit will reflect basin-wide organic inputs. Yet, another example is an alluvial terrace soil that formed for thousands of years that might contain a mixture of isotopic signatures reflecting differing climate conditions.

Similar problems emerge when interpreting the isotopic signature of pedogenic carbonate nodules. These features form in association with CO_2 produced from organic matter decomposition, but carbonate nodules may take even longer to form such that there may be isotopic disequilibrium between the two carbon sources.

From a soil-stratigraphic perspective, the stable C isotope record should be interpreted within the context of at least several pedological and geological factors: (1) erosion, which removes part of the isotopic record; (2) rapid deposition, which creates a record strongly influenced by basin-wide vegetation conditions and isotopic signatures; and (3) minimal deposition, leading to pedogenesis with local vegetation conditions and isotopic signatures.

Stable isotope laboratory procedures

Bulk soil samples can be collected for stable C isotope analysis on a horizon-by-horizon basis or in predetermined depth increments. Minimum sample size depends on laboratory preparation procedures and mass spectrometer characteristics (Boutton, 1991b; Midwood and Boutton, 1998). Most laboratories use 0.5–1.0 mg of carbon for a single isotopic analysis. To meet this requirement, a minimum of 500 mg of bulk soil with 1–3 % organic matter is typically needed. If the bulk sample contains carbonate, a larger sample will be necessary because removal of the carbonate during pretreatment may significantly reduce the sample size. If a radiocarbon age is desired from the same zone, the sample will be small enough that an AMS (accelerator mass spectrometer) assay will probably be required. It is important to avoid large roots and layers that have noticeable mixing of materials from different horizons. This could occur from erosion, biological mixing, or shrink-swell activity in the soil.

Pedogenic carbonate comes in many sizes and shapes. If the soil developed from noncalcareous parent material, then the carbonate in the bulk sample is probably pedogenic (disseminated) and suitable for stable C analysis for paleoenvironmental reconstruction. Many situations, however, warrant collecting carbonate nodules for isotopic analysis to reduce potential contamination from lithogenic sources. In either case, a minimum of 10 mg of pure carbonate is needed to meet the minimum requirement of 0.5–1.0 mg of carbon for isotopic analysis. In most cases, more will be needed to account for the impurities that occur in most nodules (Boutton, 1991b). Ideally, it would be better to analyze several nodules independently within a soil horizon to get a sense of the isotopic variability likely to be encountered in a particular study area. As discussed in the previous section, avoid sampling large carbonate nodules for isotopic analysis, or else analyze discrete zones within large nodules.

Procedures for soil organic matter

In preparation for $\delta^{13}C$ analysis of soil organic matter, laboratories remove carbonate carbon with HCl (Boutton, 1991b; Midwood and Boutton, 1998). The residue is then converted to CO_2 during dry combustion, typically with CuO. The CO_2 is analyzed for variations in ^{13}C and ^{12}C content with an isotope ratio mass spectrometer. The difference in abundance between ^{13}C and ^{12}C in a particular substance is most commonly reported in units of $\delta^{13}C$, which is the relative deviation of the $^{13}C/^{12}C$ ratio of the sample from a standard. The standard for soil organic matter and pedogenic carbonate is Pee Dee Belemnite (PDB) limestone that has an assigned $\delta^{13}C$ value of 0 ‰. The equation for $\delta^{13}C$ determination is

$$\delta^{13}C_{PDB}(‰) = [(Rsample/Rstandard) - 1] \times 10^3 \quad (3)$$

where $\delta^{13}C$ has units of parts per thousand (per mil or ‰) and R is the mass45/mass44 of sample or standard CO_2. Negative $\delta^{13}C$ values represent a depletion in ^{13}C relative to the standard and positive $\delta^{13}C$ values of enrichment relative to the standard.

Procedures for pedogenic carbonate

For $\delta^{13}C$ analysis, pedogenic carbonate is decomposed to CO_2 by reaction with H_3PO_4 (Boutton, 1991b). As with soil organic matter, isotope ratio mass spectrometers are used to determine the isotopic ratios of carbonate. The standard for $\delta^{13}C$ of pedogenic carbonate is also PDB, with results reported in units per mil.

Laboratory comparisons

The most reliable means of determining $\delta^{13}C$ values for paleoenvironmental reconstruction is by employing stable isotope geochemistry laboratories designed specifically for this task. The $\delta^{13}C$ values are also produced in association with ^{14}C ages generated in radiocarbon laboratories. This is done to correct the $^{14}C/^{12}C$ ratio of the radiocarbon sample for variations in ^{13}C content produced by living organisms during photosynthesis (Trumbore, 1996). If a subsample of the radiocarbon sample is analyzed using standards and procedures of a stable isotope geochemistry laboratory, the $\delta^{13}C$ results should be suitable for paleoenvironmental reconstruction. However, the user must be aware that high level precision and accuracy for the $\delta^{13}C$ correction is not necessary for correcting ^{14}C ages. For example, each per mil difference between the $\delta^{13}C$ value generated by ^{14}C dating and the stable isotope value to PDB accounts for only about 16 years. Therefore, a fluctuation of several per mil in the accuracy or precision of the $\delta^{13}C$ value generated by a radiocarbon laboratory is still within the one sigma standard deviation commonly reported for ^{14}C ages (typically 50–100 years). In contrast, a shift of several per mil in $\delta^{13}C$ from a soil sample indicates about a 21 % shift in the ratio of C_4 to C_3 plants! That is not to say that the $\delta^{13}C$ values produced by ^{14}C laboratories are necessarily incorrect, but rather it is not their primary goal to insure the level of accuracy and precision for paleoenvironmental reconstruction. If the user wishes to obtain $\delta^{13}C$ results for paleoenvironmental analysis, it is important to discuss the matter with the ^{14}C laboratory to obtain assurances as to the desired results.

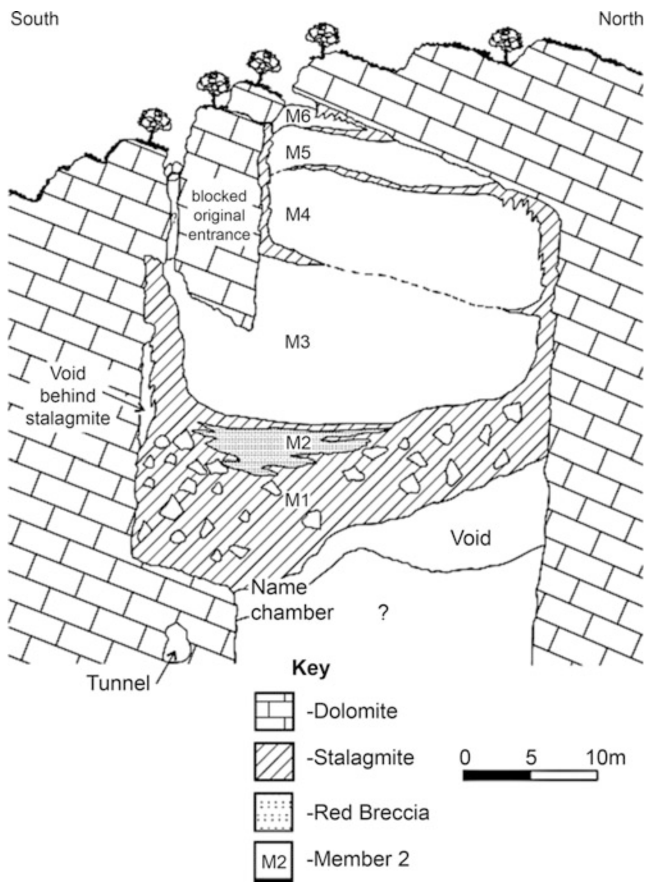
STERKFONTEIN/SWARTKRANS/KROMDRAAI

Dominic Stratford
School of Geography, Archaeology and Environmental Studies, University of the Witwatersrand, Witwatersrand, Johannesburg, South Africa
Sterkfontein Caves Palaeoanthropological Site, Johannesburg, South Africa

Definition

The paleoanthropological sites of Sterkfontein, Swartkrans, and Kromdraai lie within two miles of each other along the Blaauwbank River valley about 50 km northwest of Johannesburg, South Africa, in the UNESCO World Heritage Site known as the Cradle of Humankind. From a paleoanthropological perspective, all three sites have been researched for over 50 years and have yielded specimens of *Australopithecus africanus* and *Australopithecus prometheus* (at Sterkfontein) (Clarke, 2013), *Paranthropus robustus* (at Sterkfontein, Swartkrans, and Kromdraai) (Kuman and Clarke, 2000; Braga and Thackeray, 2003; Pickering et al., 2012), and early *Homo* (at Sterkfontein, Swartkrans, and Kromdraai) (Kuman and Clarke, 2000; Braga and Thackeray, 2003; Grine, 2005). In addition to large assemblages of associated fauna, these sites are of particular interest because they have yielded three of the earliest stone tool assemblages known from South Africa and represent rare examples of sites with associated hominins, fauna, and archaeological material.



Sterkfontein/Swartkrans/Kromdraai, Figure 1 The Sterkfontein Formation (From Clarke, 2006). Originally described by Partridge (1978), this chrono-stratigraphic sequence of the Sterkfontein deposits has been repeatedly updated. The Sterkfontein Formation comprises six main deposits: Member 1 through Member 6 (M1 through M6). M1 is an authigenic deposit formed from the vadose collapse of the cave. Member 2 is currently the earliest allogenic and fossiliferous deposit and has yielded the StW 573 *Australopithecus* skeleton. M3 has not yet been strategically sampled but is highly fossiliferous. M4 is the main *Australopithecus*-bearing deposit and the richest single locality for the hominin genera in the world. M5 contains both an Oldowan and Early Acheulean stone tool assemblage.

These sites, especially Sterkfontein, have been notoriously difficult to date with absolute techniques. Traditionally, a biostratigraphic approach calibrated using East African biochronological sequences has been the dominant indicator of the relative age of the fossils within the deposits. Absolute techniques have focused on either U-Th, U-Pb, or paleomagnetic dating of interbedded or ‘capping’ flowstones and have assumed that these formations represent boundary units between deposits (e.g., Pickering and Kramers, 2010; Herries and Shaw, 2011). This undoubtedly can be applied where true ‘capping’

Sterkfontein/Swartkrans/Kromdraai, Figure 2 A typical vertical opening (avens type) to the Sterkfontein caves, the floor of which lies 25 m below. Notice the concentrated vegetation around the opening – a feature that would have provided shelter for primates, carnivores, and hominins in the past. The opening measures approximately 2 × 3 m (Photo by D. Stratford).

flowstones are found (e.g., Malapa); however, at Sterkfontein many important flowstones have been found to be intrusive and therefore misleading since they would then postdate the sediments into which they grew (e.g., Bruxelles et al., 2014). Recent cosmogenic dating of allogenic components directly associated with deposit sediment (Granger et al., 2015) has led to encouraging results for the oldest hominin fossils and the Oldowan stone tool assemblage, placing the StW 573 australopithecine skeleton at 3.67 ± 0.16 million years ago, far earlier than the intrusive flowstone which has been dated at about 2.2 million years ago. The earliest stone tools at Sterkfontein reveal a date of 2.18 ± 0.21 million years ago based on the same method.

All paleoanthropological assemblages from these sites, and all sites within the Cradle of Humankind area, were yielded from allogenic sediments (externally derived, as opposed to authigenic) accumulated within deep karst caves in the Monte Cristo Formation comprising the 2.6 Ga Malmani dolomitic limestone (Figure 1). The caves, which have characteristic morphologies, formed under phreatic conditions (below the water table) as deep chambers and tall, narrow passages oriented along fissures within the heavily faulted host rock. Passages generally run east to west at these sites. Vadose collapse (above the water table) focused on the same faults enlarged the chambers while they were still below ground and eventually created avens-type openings (small, high, and vertical) in the ceilings of the caves. Once further collapse opened them to the landscape (Figure 2), the caves accumulated sediments, bones, and stone tools that formed large talus deposits on the cave floor over the course of several million years. The nature of the openings meant that they were still mostly inaccessible to fauna and hominins, so bones were accumulated through numerous taphonomic processes, while artifacts were gradually washed into the caves from the area immediately around the cave entrances. Gradual erosion of the landscape, combined with early twentieth-century mining of the travertine deposits, removed the cave roofs and exposed the interred fossil- and artifact-bearing deposits. The paleoanthropological importance of these deposits was first recognized at Sterkfontein in 1936 by Dr. Robert Broom (Broom, 1936).

The changing location, size, and number of openings into the caves have important implications for both (1) the accumulation of sediments, fauna, hominins, and artifacts, which have been deposited through a diverse range of processes, and (2) the resultant stratigraphy of the deposits, which is notoriously complex. The development of cave taphonomy (Brain, 1981) has helped clarify the faunal accumulation processes and in all three sites deathtrap, and carnivore activity (particularly leopard) around the cave entrances has played an integral role in the accumulation of bones from hominins, other primates, and bovids. The relatively restricted catchment area of the cave openings means that artifact presence in the deposits is representative of nearby hominin activity. The presence of artifacts at these sites and their general absence in the other Cradle of Humankind sites may be a result of proximity to river gravels which lie about 300 m from all three sites and provided the preferred raw materials during the Earlier Stone Age (ESA) (Kuman, 2003). Despite this proximity, raw material reduction strategies and levels vary between the sites as evidenced by the core form representation. Generally, bipolar and casual cores dominate the quartz assemblages with relatively high levels of reduction. In contrast, polyhedral and casual cores prevail in quartzite and are often left with remaining unstruck platforms. This pattern can be generally described as resulting from a highly localized and easily sourced raw material.

Sterkfontein and Swartkrans have yielded comparably sized Oldowan assemblages but document slightly different raw material procurement and utilization strategies. Both assemblages reveal a preference for quartz as a raw material, with a higher usage of chert in the Swartkrans collection. This relative preference may be due to the higher abundance of chert in the dolomite exposed within the landscape close to Swartkrans. Assemblage size profiles in the Oldowan assemblages of both Sterkfontein and Swartkrans demonstrate high levels of site capture, that is, mostly intact assemblages were deposited within the caves, and all components (including small flaking debris) are recoverable to some degree from the sediments thereby indicating a relatively high assemblage integrity. Variation in the condition of recovered artifacts may suggest that components of the assemblages were exposed on the landscape surface for differing intervals of time before being washed into the cave. Both collections suffered postdepositional winnowing of smaller flaking debris once in the cave. In the case of the Sterkfontein Oldowan, some of this debris was winnowed and redeposited into another chamber 20 m below. The Oldowan assemblages are associated with *Paranthropus robustus* at Sterkfontein and Swartkrans and with *Homo* at Swartkrans.

The Early Acheulean of Sterkfontein indicates a change in raw material procurement and knapping location, as hominins utilized quartzite cobbles sourced from the river gravels and may have conducted primary flaking phases closer to the gravels as suggested by the absence of small flaking debris. Within this deposit, we find one of the only positive associations between the Early Acheulean and *Homo ergaster* (StW 80) in Southern Africa.

The Kromdraai assemblages are significantly smaller with only two artifacts yielded from the Kromdraai B site, which, based on biostratigraphy, is roughly contemporaneous with the Oldowan at Sterkfontein and Swartkrans. Local conditions may have been very wet, limiting the attractiveness of the site to hominins. Kromdraai A is roughly equivalent in time to the Acheulean of Sterkfontein and has yielded 100 artifacts (Kuman et al., 1997). Quartz dominates this small sample, and those artifacts with remaining cortex indicate procurement from the river gravels. The size profile of the assemblage shows a dominance of flakes and core forms with a noticeable absence of small flaking debris, which suggests either pre-depositional removal of small flaking debris indicative of poor site catchment or postdepositional erosion to lower, unexcavated areas of the deposit or cave.

STONEHENGE

Mike Parker Pearson
Institute of Archaeology, University College London, London, UK

Definition

Stonehenge is the world's most famous stone circle, dating from the later prehistoric period (the Neolithic,

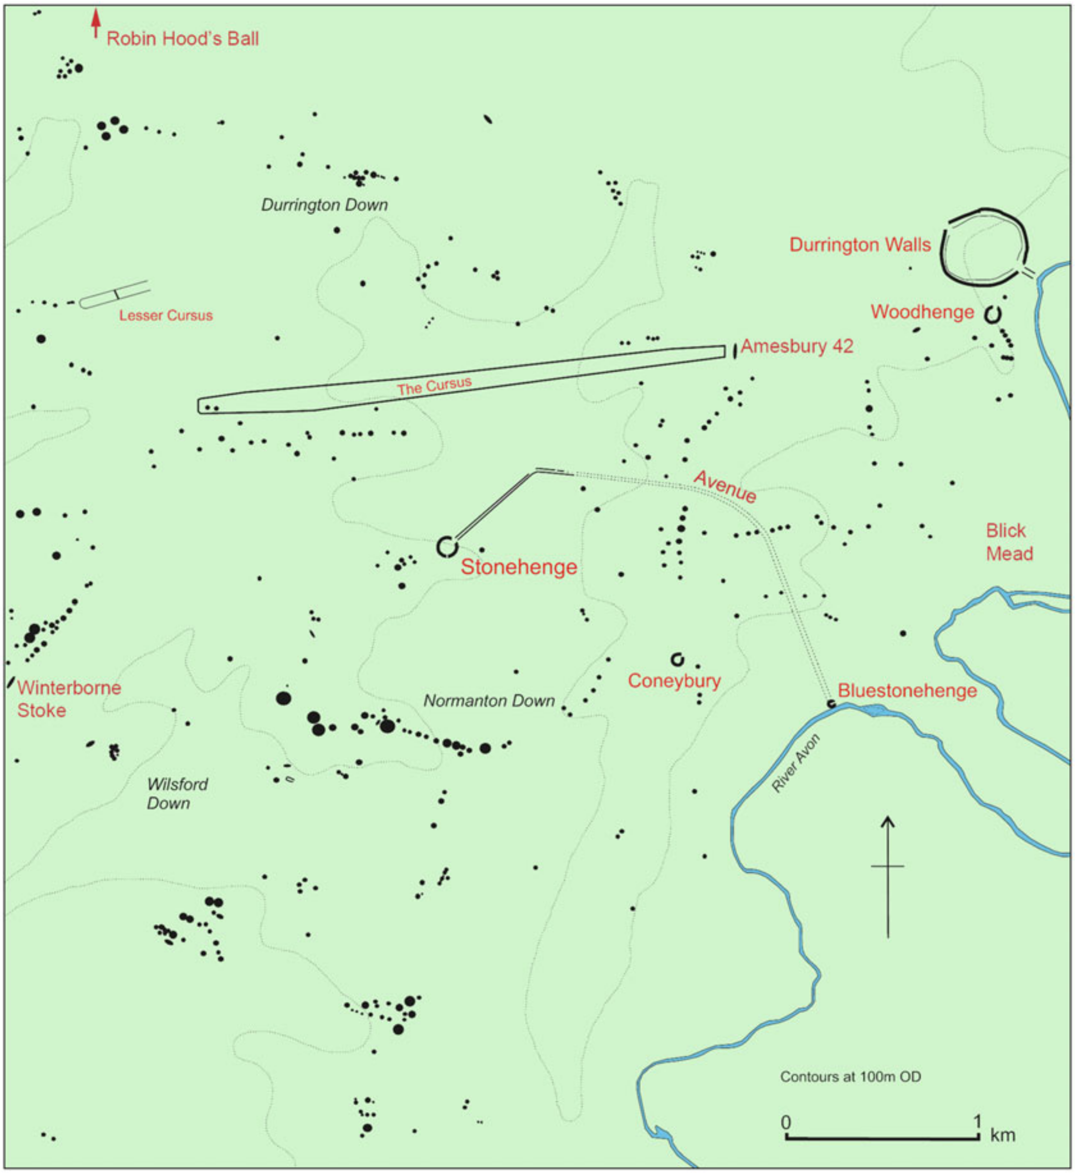
Stonehenge, Figure 1 Stonehenge viewed from the northeast, looking towards the direction of midwinter solstice sunrise (Photo by Adam Stanford of Aerial-Cam Ltd.)

Chalcolithic, and Early Bronze Age). It was built in five chronologically distinct stages, dated by statistical modeling of radiocarbon dates on antler picks deposited in construction contexts associated with each of the stages (Darvill et al., 2012).

Stonehenge is located on the chalk uplands of Salisbury Plain in southern Britain on high ground about a mile northwest of the River Avon. These chalk uplands never developed the dense canopy of postglacial forest found elsewhere in Britain, and Stonehenge's first stage was built within a largely treeless landscape during the interval 3000–2755 cal BC. At this time, Stonehenge consisted of a circular bank and ditch enclosing a ring of 56 pits known as Aubrey Holes, named after the seventeenth century antiquary John Aubrey who surveyed the site. More than 300 postholes found within the center of the monument, within the enclosure's northeast entrance, and forming a passageway towards its southern entrance are also thought to date to this earliest stage (although the only one with any finds contained animal bones radiocarbon dated to the monument's second stage). Holes to support standing stones of sarsen (sandstone of Tertiary silcrete from the local area) outside the northeast entrance and within the center of the monument probably date to this first stage as well. Similarly, there is evidence that "bluestones" – derived from the Preseli Hills in western Wales consisting of mostly spotted dolerite (diorite) as well as unspotted dolerite, rhyolite, volcanic ash, and sandstone – were positioned in the Aubrey Holes in Stage 1 (3000–2920 cal BC).

The second stage of Stonehenge (2620–2480 cal BC) consists of a central group of five sarsen trilithons arranged in a horseshoe plan, surrounded by a setting of bluestones (the Q and R Holes, known as the double bluestone circle, although it appears to have consisted of a single circle along its southwestern circumference). These were surrounded by a circle of standing sarsens connected to each other by stone lintels. Mortices and tenons were carved into these dressed stones of the trilithons and circle, perhaps to give them the appearance of carpentry in stone. There were a further three stages of construction (Stage 3: inner bluestone circle and Stonehenge avenue 2480–2280 cal BC; Stage 4: inner bluestone oval and outer bluestone circle 2280–2020 cal BC; and Stage 5: Y and Z Holes 2020–1520 cal BC), but Stonehenge's essential appearance today derives from Stage 2 (Figure 1).

Excavations in 2008 revealed that Stonehenge was positioned at the southwestern end of a pair of two chalk ridges about 200 m long, natural landforms coincidentally running northeast-southwest along the axis of the midwinter sunset/midsummer sunrise (the monument's architectural axis from Stage 2 onwards). The two ridges were later embellished by the banks and ditches of an avenue in Stage 3, leading along the solstice axis for 500 m before turning towards the River Avon. At the riverside, the



Stonehenge, Figure 2 Stonehenge in its landscape, showing its geographical relationship with the Avenue and Bluestonehenge, Durrington Walls, Woodhenge, and other prehistoric monuments.

avenue arrived at a smaller stone circle, Bluestonehenge, whose 25 or so stones were removed in Stage 3; the shapes and sizes of the holes left by the removed pillars attest to the circle's original existence. The dismantled circle of Bluestonehenge was then enclosed by the bank and ditch of a small henge with an east-facing entrance (Figure 2).

Stonehenge is the largest known burial ground of the third millennium BC in Britain. Some 63 cremation deposits and an inhumation have been recovered from within the enclosing ditch and the interior, dating to Stages 1–3. Many of the cremation deposits were placed in the Aubrey Holes, either within the chalk packing around bluestone pillars or against the sides of already inserted pillars. Most of the burials were those of adult men and women, with remains of only five subadults. Of the few grave goods, one is a beautiful macehead of banded gneiss, likely to have come from the far north or west of Britain.

Remains of a large settlement, consisting of houses and timber circles, have been found nearby at Durrington Walls and Woodhenge, upstream along the Avon; they are broadly contemporary with Stonehenge Stage 2 and are thought to have been inhabited by its builders (Parker Pearson, 2012). Feasting debris from this 17-ha settlement includes bones of cattle and pigs; strontium isotope analysis of their tooth enamel demonstrates that they were brought from different regions of Britain, some of them hundreds of miles away (Viner et al., 2010). Analysis of tooth wear in the pigs reveals that most were culled during winter (Wright et al., 2014).

The first written reference to Stonehenge was in about 1130 by Henry of Huntingdon. The earliest recorded excavations at Stonehenge are those of the Duke of Buckingham in the early seventeenth century, but modern excavations were not carried out until the twentieth century, first by William Gowland in 1901 and then by William Hawley in 1919–1926. Richard Atkinson, accompanied by Stuart Piggott and J. F. S. Stone, excavated Stonehenge during the 1950–1970s, with the results being written up and published after Atkinson's death (Cleal et al., 1995). Aside from various salvage excavations within the Stonehenge World Heritage Site from the 1960s onwards, the next major research investigation was the Stonehenge Riverside Project (2003–2009). This was followed by the Feeding Stonehenge Project (2010–2013) and the Stones of Stonehenge Project (2011–2016), both investigating the sourcing of people, animals, and materials involved in building the monument. Since 2008, a number of other projects have carried out laser scanning of the stones, geophysical and topographic survey of Stonehenge's environs, excavation of a nearby Mesolithic site, and keyhole excavation inside Stonehenge itself.

The bluestones were brought 180 miles from Pembrokeshire in west Wales, the longest distance moved by megaliths in prehistory. Two of the outcrops from which some of them were quarried have been identified through geochemical and petrological provenance and archaeological excavation (Ixer and Bevins, 2011; Bevins et al., 2014; Parker Pearson et al., 2015). The dominant source of spotted dolerite pillars is Carn Goedog on the north flank of the Preseli Mountains. A source for one of the types of rhyolite at Stonehenge has been identified on an outcrop at Craig Rhosyfelin, beside a stream flowing northwards from Preseli. Excavations in 2011–2015 revealed quarrying activity associated with an occupation area dated by radiocarbon assay on hazelnuts to 3500–3120 cal BC, several centuries before the bluestones were erected at Stonehenge. This raises the possibility that the bluestones were initially installed within a monument complex, as yet undetected, somewhere north of the Preseli Mountains.

Just how the bluestones were taken to Stonehenge has long been a matter of speculation. The hypothesis that these 2-t monoliths were taken south from the Preseli Mountains to Milford Haven and then floated around the coast is contradicted by the evidence for quarries on the north side of Preseli and by the reassignment of the sandstone Altar Stone's origins from the Cosheston Beds of Milford Haven to the Devonian Senni Beds, most likely in the area of the Brecon Beacons (Ixer and Turner, 2006). An alternative to sea transport is movement overland along the Welsh valleys, fording the River Severn at Gloucester, and thence to Salisbury Plain. Ethnographic cases from South and Southeast Asia reveal that monoliths of this size can be easily "stretchered" on latticed wooden frameworks by large teams of carriers, thereby protecting such thin pillars from shock caused by direct or indirect contact with the ground.

For over 300 years, the main source of Stonehenge's sarsens has been thought to be the Marlborough Downs, 20 miles north of Stonehenge in the vicinity of Avebury henge and stone circle. In the 1720s, William Stukeley claimed to have seen the holes from which Stonehenge's sarsens were extracted, and he also recorded a group of roughly dressed sarsens on the north bank of the River Kennet that he thought were originally destined for Stonehenge. Despite this promising early start, there has been very little geochemical or petrological work on Stonehenge's sarsens. It is possible that some of them might come from silcrete beds scattered across southern England from Kent to Dorset, though the sources of the largest blocks of tabular sarsen have long been known to have lain on the higher ground of the Marlborough Downs.

The purpose of Stonehenge has been mulled over since Henry of Huntingdon's day. His contemporary, Geoffrey of Monmouth, wrote in his pseudohistory of the kings of Britain that it was built as a memorial to the British dead treacherously slain by Saxons and that the wizard Merlin and 15,000 men went to Ireland to take the stones from a circle, *Chorea Gigantum* (the giants' dance) on Mount Killaurus, built by giants who cured their illnesses by bathing in water splashed on the stones.

In the seventeenth and eighteenth centuries, John Aubrey and later William Stukeley proposed that Stonehenge was a temple. Realizing that it was prehistoric but unaware of its true antiquity, they drew on Caesar's account of his invasion of Britain in 55 BC to describe its priests as druids. In 1965, the astronomer Gerald Hawkins crystallized the growing awareness of Stonehenge's astronomical aspects to propose that it was an observatory for computing solar and lunar eclipses amongst other heavenly events. Although Hawkins' theory was not accepted by most scholars, the understanding that Stonehenge might be a temple to the sun was prominent for a while amongst archaeologists.

Geoffrey of Monmouth's reference to the stones' healing properties led archaeologists Tim Darvill and Geoff Wainwright to propose that Stonehenge was a place of the living, with the "healing" bluestones brought to Stonehenge to create a place of pilgrimage for the sick. The discovery that the bluestones' first installation at Stonehenge was most likely in the Aubrey Holes, intimately associated with the remains of the dead renders this theory unlikely.

Stonehenge is one of many Neolithic monuments in Britain and Western Europe that were built of stone and contain the remains of the dead. In contrast, houses and settlements at this time, such as Durrington Walls, were built of timber. This raises the possibility that stone monuments were considered to be metaphors of the permanent and eternal world of the ancestors. Certain astronomical orientations may also have become associated with this unchanging world of the afterlife. The large stone tombs of Newgrange in Ireland and Maes Howe in Orkney were built around this time, with their passages aligned on the midwinter solstice sunrise and sunset. Stonehenge's first stage was perhaps built as a monument to unite ancestries across southern Britain from west Wales and Salisbury Plain, by incorporating stones that represented these different identities.

Stonehenge was built during a period of growing commonality in material culture styles across Britain at a time when declining links across the English Channel appear to have left Britain in isolation. The far-flung origins of some of the Durrington Walls cattle and pigs in Stage 2 are indicative of its role in uniting groups from across the entire country. Although Stonehenge continued as a place of burial after 2500 BC, these burials were limited to its periphery. No longer a monument to the recently dead, its role in Stage 2 appears to have changed to that of a symbolic meeting place of the more ancient ancestors (Parker Pearson, 2012). If Stage 2 was a monument to island-wide unification of Britain's diverse ancestries, then its impact was short-lived since the construction of this second stage was closely followed by the arrival of Bell Beaker migrants from the Continent, bringing metallurgy and effecting widespread cultural change.

[3]Department of Anthropology, University of Kansas, Lawrence, KS, USA

Introduction

Stratigraphy has an intuitive meaning to archaeologists even if specific definitions vary (see "Archaeological Stratigraphy" entry in this volume). In the more classical geological literature, stratigraphy tends to be viewed at the regional scale: "The crux of much of stratigraphy is the spatial relationships of rocks over geographic areas" (Schoch, 1989). It also encompasses physical characteristics of sediments that include notions of space and time:

> [S]tratigraphy in the broadest sense is the science dealing with strata and could be construed to cover all aspects—including textures, structures, and composition.... Stratigraphers are mainly concerned with the stratigraphic order and the construction of the geologic column. Hence the central problems of stratigraphy are temporal and involve the local succession of beds (order of superposition), the correlation of local sections, and the formulation of a column of worldwide validity. Although these are the objectives of stratigraphy, the measurement of thickness and description of gross lithology are commonly considered a part of the stratigrapher's task. (Pettijohn, 1975, 1)

Archaeologists view stratigraphy, deposits, features, and artifacts at the scale of the site and perhaps its immediate surroundings (Stein and Linse, 1993). For them, stratigraphy can be simply, "the natural and cultural layering of the soil at a site" (Hester et al., 1997) (intuitively correct despite the incorrect use of "soil"). Thomas (1998, p. 205) provides a more holistic definition of stratigraphy: "An analytical interpretation of the structure produced by the deposition of geological and/or cultural sediments into layers, or strata." He includes the interpretative aspects, since stratigraphy does not exist by itself. It is something that is recognized somewhat subjectively. Different researchers, depending on their experience and background (archaeologist, geologist, geographer, pedologist, and other environmentalists), might construct different stratigraphic sequences for the same physical stratigraphic

Stratigraphy, Table 1 Types of Stratigraphic Units and their basis of classification

Classificatory basis	Stratigraphic classification Geoarchaeology	Formal subdivisions	Stratigraphic classification Geology	Formal subdivisions
Lithology (physical and/or chemical composition)	Lithologic unit *time-transgressive*	Layer, sub-layer, inclusion; elemental sediment unit	Lithostratigraphic unit *time-transgressive*	Formation, member, bed
Time	Chronostratigraphic unit *specific time interval*	Set, phase, sub-phase	Geochronologic unit *specific time interval*	Eon, era, period, epoch, age
Fossils	Biostratigraphic unit *time-transgressive*	Biozone	Biostratigraphic unit *time-transgressive*	Biozone
Artifacts	Ethnostratigraphic unit *time-transgressive*	Zone, supra-zone, sub-zone	None	None

profile. In the geoarchaeological sector, Waters (1992, p. 60) takes a traditional, geological, and "depositional" viewpoint, emphasizing deposits and soils that are observed principally on a geomorphologic scale: "Stratigraphy is the study of the spatial and temporal relationships between sediments and soils. Stratigraphic sequences are created because depositional environments are dynamic and constantly changing." On this regional scale, stratigraphic study is useful to organize sediments and soils into objectively identifiable packages that can be arranged in some kind of chronological order and absolute age on the basis of temporal markers, such as soil formation, or perhaps erosion. "Parcels" of soils/sediments can be physically (spatially) or temporally linked and integrated over an area, either on the scale of meters or kilometers.

During the latter part of the nineteenth century, classical geologists realized that it was necessary to separate the physical characteristics of a sedimentary rock (i.e., color, texture, and composition) from the time in which it formed. This came about because they came to see based on fossil content that a geological unit can accumulate over a long period of time and be older in one place than in another (diachronous or "time-transgressive" units: Krumbein and Sloss, 1963; Vita-Finzi, 1973). Deltaic deposits, for example, become progressively younger in the seaward direction, even though the overall "deltaic lithologies" do not change radically and horizontally within the area of the delta. To overcome these issues of time and space, stratigraphy recognized a number of different types of stratigraphic units, embodied in the *International Stratigraphic Guide* (Hedberg, 1976; Schoch, 1989) and the *North American Stratigraphic Code* (NACSN, 2005). Table 1 summarizes the most common types of stratigraphic units. Note that the two major groups of units are delineated on the basis of content or physical limits (Group I), as opposed to those units in Group II, which are defined solely on the basis of time. Thus, the units in Group I are derived, for example, from their mineral composition or texture, biological/fossil constituents, soil characteristics, or stratigraphic boundaries or gaps marked by lapses in time (unconformities).

Lithostratigraphy

Lithostratigraphic units are the most basic and ubiquitous. They are relevant to the majority of geoarchaeological situations and are denoted on the basis of lithological characteristics, such as color, texture, composition, thickness, and upper and lower boundaries. They do not imply any notions of time, just the descriptive aspects of the sedimentary bodies. In regional-scale geological contexts, the primary lithostratigraphic unit is the formation, which is one that can be mapped over a region. It can be represented by a 20-m-thick accumulation of alternating beds of clay and silt or by a 2-m-thick massive layer of limestone. Two or more formations that form a consistently uniform lithological package can be combined into a group. On the other hand, formations can be subdivided into smaller units, such as a member, and even finer units, such as a bed. The latter is the smallest lithostratigraphic unit and is lithologically distinct from units above and below it (but see the "Archaeological Stratigraphy" entry in this volume).

On an archaeological scale, which can be on the order of tens (e.g., living structures) to thousands of square meters (e.g., tell or other types of mound) in area, a lithostratigraphic unit can take the form of a centimeter-thick band of red clay underlying a plastered floor from a Bronze Age house. In caves, a layer of rockfall mixed with clay would also be a common type of lithostratigraphic unit.

Biostratigraphy

Biostratigraphic units are delineated on the basis of the fossils they contain, including the appearance, disappearance, or relative abundance of the remnants of former organisms. The fossils can be either plants or animals and marine or terrestrial. For example, the Tertiary period was subdivided by Lyell on the basis of the abundance of fossil molluscan species that are living today. Only 3.5% of Eocene fossils represent currently living forms, whereas during the Pleistocene, about 90% of the species remain extant today (Farrand, 1990).

The fundamental unit in biostratigraphy is the biozone. In archaeological contexts, however, the most common types of biostratigraphic units are those based on plant remains, particularly pollen, and land mammals. Pollen-based biostratigraphic units are referred to as "Pollen Zones" (Bowen, 1978). The most common and widely used biostratigraphic units based on mammal assemblages are "Land Mammal Ages" (Webb et al., 2004). For example, in North America, the Land Mammal Age that encompasses the earliest (Late Pleistocene) human occupation of the continent is the Rancholabrean Land Mammal Age. It is characterized by the appearance of bison (Mead, 2013).

Soil stratigraphy

Soil stratigraphic units (also referred to as pedostratigraphic units) represent a whole buried soil or part of one that exhibits one or more soil horizons (see the "Soil Stratigraphy" entry in this volume) that are preserved in a rock or sediment and are traceable over an extended area (Schoch, 1989; NACSN, 2005). These types of unit, the foremost of which is the geosol, represent relatively short periods of geological time. Hence, they serve as temporal pegs or "marker horizons" that temporally order the relative ages of deposits and events that overlie and underlie the soil (Holliday, 2004). Geosols also have paleoenvironmental significance (Fedoroff and Goldberg, 1982). The interglacial Sangamon soil in the Midwest of the United States has been extensively used as a stratigraphic tool (Birkeland, 1999), and similar such soils have been documented in the United Kingdom by Kemp (1986, 1999). The Barham soil in eastern England, for example, is a clear stratigraphic marker horizon that denotes a major landscape change and climatic degradation (Rose et al., 1985).

Allostratigraphy

Allostratigraphic units are rock or sediment bodies that are overlain and underlain by temporal discontinuities (unconformities). A prevalent case in point is that of stream terrace deposits produced by successive episodes of alluvial deposition followed by erosion that interrupts the continuous accumulation. Allostratigraphic units are a convenient means to map widespread fluvial deposits for example which may be lithologically homogeneous and otherwise difficult to subdivide lithostratigraphically. They constitute a basic component in documenting the Holocene fluvial geoarchaeological history of much of the mid-continental United States (Brown, 1997; Goldberg, 1986; Mandel, 1995; Ferring, 2001). Such fluvial deposits commonly contain archaeological sites and can be traced over several kilometers within the same allostratigraphic unit.

Chronostratigraphy

Chronostratigraphy is organized on the basis of geochronologic units, which are defined solely on the basis of the time interval that they encompass (see the "Chronostratigraphy" entry in this volume). As such, they do not represent actual or specific rocks but more conceptually represent divisions of time. These units are differentiated on the basis of radiometric dating, such as potassium/argon ($^{40}K/^{40}Ar$) – or now argon-argon ($^{40}Ar/^{39}Ar$) – and uranium-series techniques. They can also be temporally sequenced when they contain mixtures of different types of fossils and lithologies. The Quaternary, which includes much of the geoarchaeological record and all of the recent "Ice Ages," represents the last 2.6 Ma (Pillans, 2013). It is subdivided into the well-known subdivisions of the Pleistocene (2.6 my to 11,700 years ago, and including all glacial-interglacial stages except the most recent interglacial) and the Holocene (the past 11,700 years, representing post-glacial time or the current interglacial period).

Climatostratigraphy

Climatostratigraphy (or climostratigraphy) is the classification of deposits based on inferred intervals of climate change (see the "Climatostratigraphy" entry in this volume). In geology, climatostratigraphy is unique to Quaternary geology and geoarchaeology owing to the evidence for dramatic climate changes, particularly glacial-interglacial cycles, during much of human evolution and the rise of modern societies worldwide. Links between climate change and the Quaternary geologic record were in evidence since the early history of geology in the nineteenth century, but research was hampered until the middle of the twentieth century by incomplete stratigraphic sequences and an absence of firm age control for both climate events and geologic records. Climatostratigraphy was revitalized by (1) the advent of deep ocean coring and the establishment of marine oxygen isotope stages of glacial-interglacial cycles, (2) the development of coring into ice sheets and the recognition of finer-scale glacial and interglacial events (e.g., Dansgaard-Oeschger cycles and Heinrich events) (Labeyrie et al., 2013), and (3) the development of an array of numerical dating methods. Cores from the deep ocean and ice sheets now provide standardized reference markers of climate changes against which terrestrial lithostratigraphic and biostratigraphic records can be compared.

STRONTIUM ISOTOPES

James H. Burton
Department of Anthropology, University of Wisconsin, Madison, WI, USA

Definition

Isotopes: Atoms of the same element that can differ in their weights by having a different number of neutrons in the nucleus.

Introduction

In archaeology, strontium isotope studies are primarily applied to human teeth to identify immigrants and study human mobility. The method has also been used in attempts to determine the provenience of other materials such as wooden beams, maize, wool, glass, and pottery; these exercises have achieved varying degrees of success depending upon the effects of contamination and the intrinsic isotopic variability in geologic materials.

The use of strontium isotopes to study human mobility was first proposed by Jonathon Ericson (1985), who noted the geographic variation in the stable isotopes of $^{87}Sr/^{86}Sr$ and the fact that this ratio is maintained essentially unchanged in the human skeleton from its value in the local environment with no apparent changes imposed by metabolism. When dental enamel develops during the first few years of life, teeth trap this local ratio and keep it unchanged into adulthood and after death. By comparing the $^{87}Sr/^{86}Sr$ in teeth to that of the local ratio, one can identify individuals whose teeth have different ratios and thus who must have experienced childhood in a region with this different $^{87}Sr/^{86}Sr$.

Strontium isotopes

Atoms have different atomic weights, depending upon the number of protons and neutrons in the atom's nucleus. The number of protons defines what element the atom is, i.e., its chemical behavior. The number of neutrons does not affect the identity of an element but nonetheless affects its weight. Strontium atoms are those having 38 protons in the nucleus. They may also have from 46 to 50 neutrons, and thus, strontium atoms can possess a range of atomic weights, 84, 86, 87, and 88, depending upon the number of neutrons. The natural abundances of these isotopes are 0.56 %, 9.86 %, 7.0 %, and 82.58 %, respectively. There is also a radioactive isotope, ^{90}Sr, with 52 neutrons, but this is not a natural isotope and is not relevant here.

Strontium is an alkaline-earth element and behaves much like calcium in its chemistry. It is therefore abundant in calcium-rich rocks such as limestone and also in calcified tissues (bones and teeth). The abundances of its stable isotopes vary geographically because one of the isotopes, ^{87}Sr, is generated by the decay of a radioactive isotope of rubidium, ^{87}Rb. Rubidium is chemically similar to potassium and is common in potassium-rich minerals such as micas (e.g., muscovite), hornblende, and some clay minerals. ^{87}Rb has a half-life of 49 billion years, which means that rocks containing a lot of rubidium (i.e., potassium-rich rocks such as granite, schist, and shale) and that are very old will have accumulated more ^{87}Sr from the decay of ^{87}Rb than young, low-rubidium rocks would accumulate. Thus, the amount of ^{87}Sr varies geographically depending upon the local rock types.

Rocks also vary in ^{87}Sr simply because they have more or less strontium than other rocks, and so isotope chemists compensate for this by dividing the amount of ^{87}Sr by one of the non-radiogenic isotopes. By convention, ^{86}Sr is used because it is similar in natural abundance; ^{87}Sr is about 70 % as abundant as ^{86}Sr, i.e., $^{87}Sr/^{86}Sr \approx 0.7$. The average value of the ratio of ^{87}Sr/^{86}Sr for rocks exposed at the earth's surface is 0.709, and most rocks have ratios fairly close to this average (0.704–0.716). This difference of 0.012 seems small, but it is quite large compared to local variations in the ratio of strontium in once-living organisms, which is typically on the order of ± 0.0002, a quantity that is nonetheless readily measured with modern instrumentation.

Because the half-life of ^{87}Rb is so long, tens of billions of years, the ^{87}Sr/^{86}Sr ratio does not vary within the much shorter time scales of human history or prehistory. Also, because both isotopes are the same element and the atomic weights are so close, the ratio is essentially unaffected by chemical processes such as those involved in human metabolism. The ^{87}Sr/^{86}Sr ratio in bones and teeth is thus that of the local, "biologically available strontium" (see below). Although teeth retain the ^{87}Sr/^{86}Sr ratio of the place of birth, bones continuously remodel themselves chemically, so that if an individual moves, the bones accumulate some strontium from the new location as well. Therefore, the strontium ratio found in teeth reflects the locality of birth and early childhood, whereas that of the bone tends to represent the habitat of later adulthood prior to death. Bones generally continue to accumulate strontium postmortem, so they are not as useful in mobility studies, except in cases where they might provide clues to the ratio at the place of burial.

Local ^{87}Sr/^{86}Sr ratio

In order to apply this technique to humans successfully, we need to know not only the isotope ratio in the enamel of the individual in question but also the ratio in the local environment. Early studies (e.g., Price et al., 1994a; Price et al., 1994b) compared the analytic results from enamel to the ^{87}Sr/^{86}Sr ratio measured in a bone sample from the same individual, which was presumed to approximate the ratio where the individual last lived and likewise was presumed to be the place of death. If the two measurements differed, then the individual could be recognized as an immigrant. However, due to problems of bone contamination, as well as the possibility that a person did not live in the location where he or she died (e.g., in sacrificial burials or reburials), researchers began measuring calcified tissues of local faunal samples and other biological materials. One has to be careful, however, about contamination of ancient faunal bones. Likewise, modern fauna might have different ratios because of access to imported human foods, application of imported fertilizers, or other chronological changes in the landscape such as shifting river courses. Enamel ^{87}Sr/^{86}Sr measurements from ancient humans believed to be local have also been used to assess the local ratio. Although this might seem to be a circular approach, in the absence of evidence of mass immigration, the most commonly observed ratio is parsimoniously that of local individuals, and, in practice, such a sharply defined mode is often found (Burton and Price, 2013). Ideally, several of these methods can be used together to determine a reliable range for the local ratio.

The problem with using geological materials (local rocks and soils) themselves to establish a local isotope ratio is that they generally exhibit ratios with enormously greater ranges than those taken from biological samples (Price et al., 2002). Rocks contain many minerals, each of which possesses its own Rb content, and over the course of its exposure and weathering, each mineral erodes at a different rate. These variabilities make it nearly impossible to determine useful environmental ratios directly from the geosphere. Likewise, geological maps and published ^{87}Sr/^{86}Sr data from geological materials, although useful in planning stages for projects, provide only approximate estimates as to what actual ^{87}Sr/^{86}Sr ratios might be.

Method

Applying the strontium isotope method requires a sample of dental enamel weighing approximately 5 mg and a mass spectrometer capable of high-precision measurements with at least five significant figures. Common quadrupole mass spectrometers and single-collector inductively coupled plasma mass spectrometers (ICP-MS) lack sufficient precision. Normally, either a thermal ionization mass spectrometer (TIMS) or an ICP-MS with multiple collectors (MC-ICP-MS) is required for adequate precision. Cost of analysis is relatively high; at this time, laboratories charge in the range of $100–300 per sample. The result of such an analysis will be the $^{87}Sr/^{86}Sr$ ratio of the material reported with five or six significant digits, e.g., 0.708341, and a measure of uncertainty, which is usually negligibly small (e.g., ±0.0000023).

Case study

As an example of the use of $^{87}Sr/^{86}Sr$ ratios to identify immigrants, Buikstra et al. (2004) analyzed teeth from the Maya site, Copan, including teeth of K'inich Yax K'uk' Mo', the founder of a dynasty that included 15 sequential rulers. Architectural and other evidence suggested that K'inich Yax K'uk' Mo' might have come from Teotihuacan, a contemporaneous power center far to the west, though others thought he could be a local individual who was just adopting the Teotihuacan symbols of power to reinforce his own authority. Buikstra and others measured both human bone and teeth from Copan as well as modern fauna to determine the local $^{87}Sr/^{86}Sr$ ratio of 0.7068 ± 0.0003. Earlier, Price et al. (2000) had done a study of Teotihuacan and surrounding areas and determined a local range there of 0.70463 ± 0.00005, significantly lower than the ratios obtained from Copan. Dental enamel of K'inich Yax K'uk' Mo', in contrast to both of these $^{87}Sr/^{86}Sr$ ranges, yielded 0.7084, indicating unequivocally that K'inich Yax K'uk' Mo' was from neither location.

Other studies (Hodell et al., 2004; Price et al., 2008) show that Mesoamerica can be divided into about eight isotopically distinct regions and that the only region matching K'inich Yax K'uk' Mo's ratio was the Yucatan lowlands north of Tikal, which the authors concluded was his birthplace. This study is unusual in its having been able to constrain the place of origin so narrowly, and this was possible only because baseline data had already been compiled for regions throughout Mesoamerica.

Other applications and future research

Although studies of human mobility remain the principal application of $^{87}Sr/^{86}Sr$, an increasing diversity of target materials beyond teeth and bones is also being analyzed in efforts to determine geographic origins. $^{87}Sr/^{86}Sr$ ratios are now commonly being applied to other species (e.g., van der Merwe et al., 1990; Koch et al., 1992; Hoppe et al., 1999). The rapidly growing teeth of some species such as horse, goat, sheep, and cattle (species exhibiting hypsodonty) additionally can show changes during the development of the tooth, over a span of many months, and this provides a possible window into the detection of seasonal mobility. Other biological materials being investigated include animal fibers in prehistoric clothing (Frei et al., 2009), prehistoric maize (Benson et al., 2009), prehistoric construction timbers (Reynolds et al., 2005), and marijuana (West et al., 2009).

Although minerals and geologic materials generally reveal too much local $^{87}Sr/^{86}Sr$ variation for the method to be applicable, there has been some success in determining the sources of archaeological glass in cases in which the principal source of strontium is a single material such as natron or plant ash (Freestone et al., 2003), especially when augmented by other isotope systems (Henderson et al., 2005). A caution, however, remains the fact that glass is reusable, and waste shards (or cullet) from widely varied sources were often remelted in later historic periods, thereby mixing the chemical and isotopic signatures of more localized production centers.

In addition to extending the method to a greater range of materials, practical applicability of the method is expanding due to the deliberate creation of regional databases (e.g., Price et al., 2008; Evans et al., 2010). With the existence of such databases, researchers in these areas no longer need to acquire their own expensive and time-consuming background data. The power of the method is also being extended through the integration of strontium isotopes with other isotope systems, such as oxygen and lead (e.g., Price et al., 2007; Turner et al., 2009; Price and Burton, 2010; Wright et al., 2010) as well as with trace-element studies (Burton et al., 2003).

SUBMERGED CONTINENTAL SHELF PREHISTORY

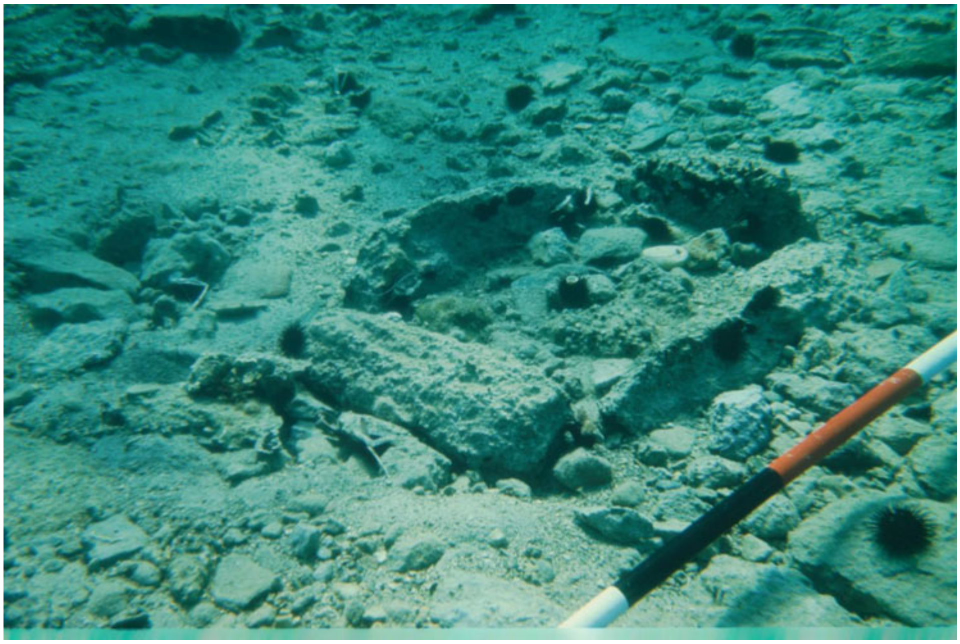
Nic C. Flemming
National Oceanography Centre, University of Southampton, Southampton, Hampshire, UK

Introduction

Over 3,000 submerged prehistoric occupation sites on the continental shelf are known worldwide, varying in depth from the nearshore to about 100 m and ranging in age from 5,000 years to 0.5–1.0 million years. Sites have been found off the coast of every continent except Antarctica. These findings are consistent with the climatic fluctuations of the Pleistocene glacial cycles, the repeated lowering of global sea levels to about −130 m, and the extension of adjacent continental climate, vegetation, freshwater drainage, and fauna onto the exposed continental shelf land surfaces. The inclusion of the prehistoric populations and cultures of the continental shelf into world prehistory has a substantial impact on our understanding of the development of coastal resources, population density and distribution, movements of populations, specialized coastal technologies, diet, and early seafaring. Although submerged sites and submerged Pleistocene terrestrial landscapes have been known for more than 100 years, the ability to search for and work on sites in a systematic way has been possible only in recent decades. Acoustic technology, integrated seabed digital mapping systems, autonomous underwater vehicles (AUVs), diving equipment, and underwater work capability have evolved rapidly to make this possible. International treaties and national heritage legislation in many countries provide protection for seabed prehistoric sites. Most sites found so far are shallower than 10–20 m, with a few deeper than 40 m, and none are in the tropics. The present challenges are to integrate and absorb the significance of known submerged sites; to work in deeper water toward the edge of the shelf in order to detect and examine more sites occupied when sea level was at its lowest during the last glacial maximum; to locate and study submerged sites in the tropics; to integrate the continental shelf data with human genetic indicators of early migrations; and to understand more about how different anthropogenic indicators survive inundation, such as shell middens and occupied caves. The subject is immensely composite, involving all aspects of the seabed earth sciences, research technology, climate change research, paleo-oceanography, and prehistoric archaeology. This entry is a very brief summary.

Background to continental shelf archaeology

The study of prehistoric human and hominin occupation of the continental shelf derives from a simple premise. The logical consequences of this premise are complex, and the task of demonstrating those consequences in practical research and deriving valuable geoarchaeological insights requires the latest understanding and analysis of Pleistocene climate change, sea-level change, and the



Submerged Continental Shelf Prehistory, Figure 1 Cist grave dating from the Middle Bronze Age at a depth of 3 m in the submerged prehistoric town near the islet of Pavlopetri, southern Laconia, Greece. The scale on the colored bar is 25 cm (Photo by N. C. Flemming; see Henderson et al., 2011).

application of modern seabed surveying technology. The premise is that the well-established exposures of the continental shelf down to a depth of about −130 m during glacially controlled low sea levels of the Pleistocene were of sufficient duration for a contemporary terrestrial environment of river drainage, vegetation, and fauna to develop on the shelf during these lowstands, including our hominin ancestors and anatomically modern humans (AMH). On the less fertile desert and polar coasts, the adjacent continental conditions also extended to the exposed shelves, possibly supporting sparse populations suitably adapted. The area of the continental shelf is 5 % of the area of the globe, and this territory would add an area equivalent to that of Africa to the presently existing land area. In archipelago-peninsula regions such as Europe, Southeast Asia, and northern North America, it would add 40–100 % to the present regional land masses, so that this terrain cannot be ignored in our attempts to reconstruct the prehistoric evolution of humans and their diffusion throughout the modern global land areas. Several multi-author edited volumes have attempted to provide an overview of the main issues and the justification for research into these problems, e.g., Allen et al. (1977), Masters and Flemming (1983), Fischer (1995), Flemming (2004a), Yanko-Hombach et al. (2007), Benjamin et al. (2011), Buynevich et al. (2011), Harff and Lüth (2011), Evans et al. (2014), Flemming et al. (2014), and Harff et al. (2015). For a global overview of the origins and development of prehistoric seafaring, which is closely interwoven with questions regarding occupation of the continental shelf, see Anderson et al. (2010).

There are additional contributory technical and scientific subjects on which background understanding is essential to assessing the origins and survival of seabed prehistoric sites. The following review volumes are relevant. For coastal dynamics and the action of waves and currents on deposits in shallow water, see Carter (1993) and Davidson-Arnott (2010); for the structure and surface sediments of the continental shelf in the Quaternary context, see Harff et al. (2007a), Harff et al. (2007b), and Chiocci and Chivas (2014); for a review of Pleistocene climate change, sea-level change, subdisciplines, and techniques, see Shennan et al. (2015).

Human genetic studies have shown in broad terms how different phases of the hominin expansion out of Africa proceeded in successive waves with sequential arrival dates into different continents, and these diagrams of slow migration, usually averaging less than 1 km per year, imply prolonged periods when hominins/humans were living on or slowly traversing the now submerged continental shelf – e.g., Forster (2004), Hill et al. (2007), Pope and Terrell (2008), Soares et al. (2008), and Henn et al. (2012). Genetic data suggest that the successively dispersed groups have sometimes interbred at the margins or overlaps of diffusion zones, but dating based on DNA itself is still subject to revision (Scally and Durbin, 2012). The adaptation of human cultures to coastal and marine exploitation and technologies occurred while the global sea level was many tens of meters lower than it is at present, so that the archaeological deposits recording the processes of that adaptation are now submerged. There is no other way of studying the occupation sites associated with the earliest phases of seafaring and exploitation of marine resources than working underwater (Figure 1).

The following archaeological research themes or objectives for gathering and interpreting data from the continental shelf were listed in Flemming et al. (2014, 42) based on ideas provided by Geoff Bailey. They are modified here to extend the context globally.

1. The attractiveness of coastal regions to human populations is due to their unusual productivity in plant and animal resources, with abundant water supplies, spring lines, coastal meadows and marshes, and sources of raw materials and intertidal mollusks along the shore edge. In some cases, these ancient coastal areas are likely to have presented unique combinations of plant and animal resources with no equivalent analogue on modern coasts, while at the same time being richer than their contemporaneous hinterlands. These attractions are partially demonstrated by caves on the present-day coastline with long archaeological sequences extending back to earlier short-lived episodes of high sea level and situated adjacent to steeply shelving offshore topography or in material being eroded out of ancient coastal and riverine deposits by marine erosion along the modern coast. But the majority of relevant evidence and the key landscapes and paleoenvironments in most areas are likely now submerged and lying on the seabed. On modern desert coasts, it is possible that the effect of subterranean groundwater flow, springs, and flash floods might have provided habitable areas on what is now the outer continental shelf.
2. Closely allied to theme (1), these productive coastal regions are significant as centers of population growth and pathways of population movement and dispersal along continental margins and between land masses during the earliest periods of the Paleolithic era.
3. Nearshore archipelagos are important as “nursery” areas for early experiments in seafaring and maritime economies and also as stepping stones in the coastwise expansion of early populations. This factor is highly relevant in the Mediterranean, the Red Sea, throughout Southeast Asia including early access to Greater Australia, the Caribbean, and into the periglacial and deglaciated regions of the northern continents.
4. Closely allied to theme (3), submerged coastal areas hold clues to the question of the origins of experiments in sea crossings with simple rafts and boats, seal hunting, offshore fishing, and visitation of offshore islands that often offer rich concentrations of nesting birds and marine resources or useful materials such as obsidian.
5. Sea-level changes impose potentially enormous impacts on coastal areas, resulting in alterations to paleogeography and environmental conditions, as well as to the social geography, demography, economic organization, and cultural interaction of ancient populations.
6. The continental shelf holds evidence for a deeper history of coastal sedentism, with year-round settlements, permanent dwellings, and other durable structures and monuments of stone or wood.
7. The significance of coastal regions also lies in providing fertile and cultivable soils and pastures for early farmers globally, as well as serving as pathways for the expansion of farming from the Near East into southern Europe, a process that was underway when sea levels were still considerably lower than the present.
8. There is overriding importance in treating the present-day land surface and the submerged areas of the continental shelf as a seamless whole from the point of view of their prehistoric inhabitants, who are likely to have ranged widely over large territories untrammeled by today’s physical boundaries.

These research themes were matched with a ranked list of objectives in national management of continental shelf prehistoric resources resulting from a survey of national heritage agencies in 13 European countries (Flemming et al., 2014, 40).

Continental shelf prehistoric research, or the process of conducting research into the geoarchaeology of the continental shelf, includes many subcomponents, stages, technologies, and contributory sciences. These can be summarized as follows and will be reviewed later:

1. Determination of site locations in the context of the original landscape and resources when the shelf was exposed as dry land during glacial periods of low sea level
2. The potential for modeling site distribution and possible predictive modeling for site density and survival
3. The terrestrial taphonomy of site survival as well as cultural and noncultural site formation processes before inundation
4. The dynamic geomorphological processes of first marine transgression (when coastal sites are inundated for the first time): transition of the surf zone, degree of erosion or protection afforded by local topography, wind fetch, wave refraction, and lateral sediment transport
5. The effects of multiple marine transgressions and the mechanisms by which prehistoric archaeological sites may survive several glacial cycles of sea-level rise and fall
6. Modern sediment seabed conditions: marine sediment movements, erosion, burial, and processes of site discovery
7. Application of modern oceanographic and commercial acoustic technology to the search for, mapping of, and discovery of submerged prehistoric landscapes and archaeological sites
8. Survey, conservation, monitoring, excavation, and management of seabed prehistoric sites in the context of the UNESCO Convention on the Protection of the Underwater Cultural Heritage

These components will be discussed in a later section, followed by a review of findings and interpretation, and finally by a review of future challenges. Each component is itself complex and can only be summarized here, but the summaries will give documented examples of projects carried out and sites that have survived. The analysis is based on what can be shown to have happened, not a theory as to what should happen.

History of exploration

Chance retrievals of prehistoric artifacts and terrestrial Pleistocene fauna from the seabed were noted repeatedly between 1900 and 1970, and they were correctly understood and interpreted by scholars. An early problem was that individual finds came from different periods, widely different localities, and were out of stratigraphic context so that they were often treated as antiquarian curiosities rather than serious archaeological discoveries.

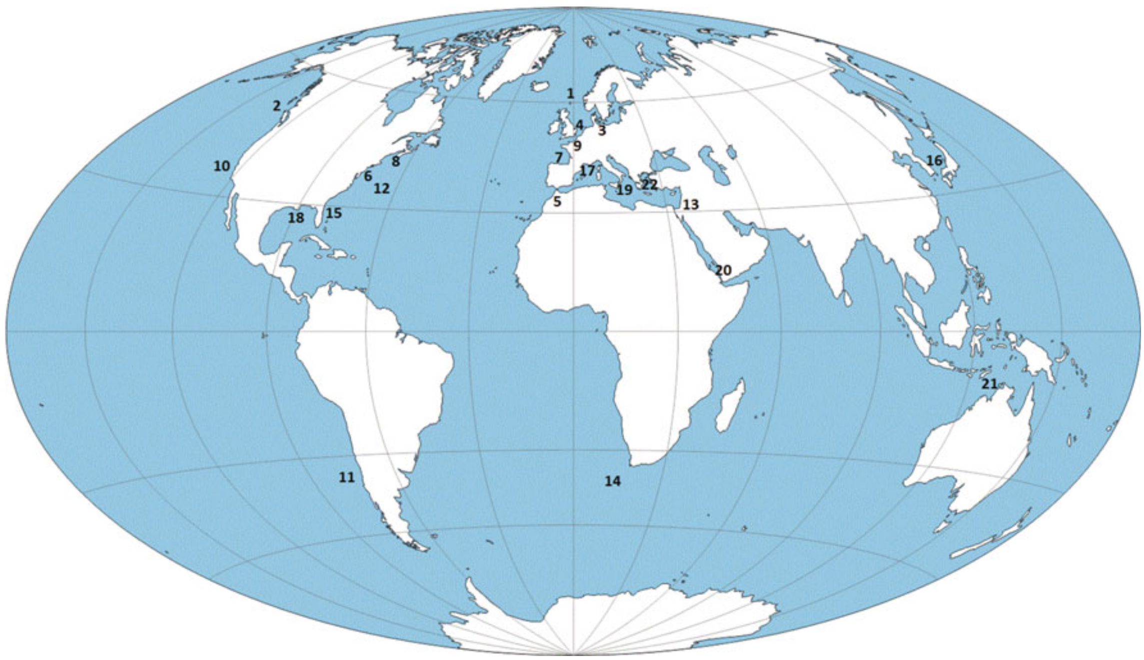
The first realization of the possible human occupation of the continental shelf happened about 1900, and a steady sequence of papers followed from Marcellin Boule (1906) and Clement Reid (1913) through to Burkitt (1932), Blanc (1940), North (1957), Emery and Edwards (1966), Whitmore et al. (1967), Harding et al. (1969), Fladmark (1975), and Clausen et al. (1979). The demonstrable fact that the glacial period shelf had been occupied by Pleistocene fauna and hominins, and that some sites had survived, was established, but motivation from institutions and funding agencies to push the matter further was weak. The lack of support may have been justified on four grounds. First, archaeology had plainly progressed beyond the point of just "finding things." New synthesizing and analytic branches of the subject were growing in academic esteem and influence, often requiring data from many tens or hundreds of stratified and dated sites. These methods could not be applied to the sparse and scattered data from the seabed, where only a few sites were known, and they had been found by chance, so that the subject had an old-fashioned and unsystematic association. Second, the possibility of high-tech scientific search for prehistoric remains on the seabed was still implausible, in spite of the steady advances in acoustics and particularly in side-scan sonar, since no technology from the 1960s to the 1990s could map, survey, or log the data of the seabed with sufficient accuracy to reveal prehistoric sites other than by chance. Third, archaeologists had not formulated intellectual problems or hypotheses that seemed to need data from the continental shelf. Finally, research on the seabed was thought to be expensive, with the constant risk of failing to find worthwhile material. The adjunct to this last point was, paradoxically, the contrasting fact that fishermen, dredgers, and sports divers continued to find and recover more prehistoric artifacts, which, once in their hands, were out of context, even if the recovery was reported quickly to the authorities.

By the late 1980s, enough was known to start systematizing and pointing the way to research strategies. Louwe Kooijmans (1970–1971), Cockerell and Murphy (1978), Ruppé (1978, 1980), Skaarup (1980), Andersen (1980, 1985), Masters and Flemming (1983), Stright (1990), and Galili et al. (1993) collectively showed that there was a definable range of coastal topographies and geomorphological niches within which unconsolidated prehistoric deposits had survived the process of inundation and transition of the surf zone. The key factor required is the near-total protection of the deposit from wave attack either due to prior burial or to protection with an extremely limited wind fetch and wave diffraction or refraction by local topography. Barrier sand islands, calcified dune ridges, lagoons, peat bogs, beach ridges, rias, fjords, estuaries, marshes, wetlands, sinkholes, caves, rock outcrops and ridges, nearshore islands, close-spaced archipelagos, accumulative beaches, river meanders, and sediment progradation and deltas can protect and preserve prehistoric sites during inundation, and evidence shows that they have done so.

The precise topography and combination of bedrock forms and overlying sediments needed to provide protection are quite local and thus have to be measured with an accuracy of a few meters. Geomorphological structures need to be resolved substantially below the 1 km level and preferably below the 10 m level adjacent to the site. As with prehistoric sites on land, most deposits are destroyed by natural processes, but it is possible to identify a range of topographic circumstances that will protect archaeological deposits from destruction by the rising sea. No published charts or standard surveying technique available during the 1960s to 1990s could approach the resolution required.

By the early 2000s, with multibeam sonar, sector scanning, and other technologies becoming available at modest cost, the subject was ready to take off with new vigor. The work of Long et al. (1986), Scuvée and Verague (1988), Crock et al. (1993), Hayashida (1993), Fischer (1995), Clottes and Courtin (1996), Josenhans et al. (1997), Fedje and Josenhans (2000), Werz and Flemming (2001), and Faught (2004) confirmed that prehistoric sites could be found off the shores of nearly every continent (Figure 2) and that some sites had survived multiple glacial cycles with repeated marine transgressions.

A conference was held to review the accumulated finds from the North Sea (Flemming, 2004a), and a European coordinated project was launched in 2008. The SPLASHCOS (Submerged Prehistoric Archaeology and Landscapes of the Continental Shelf) project, 2008–2013, centralized a catalogue of over 2,500 submerged prehistoric sites in European seas (Figure 3) (Jöns et al. 2016), and it is now possible to analyze that database to show the distribution of surviving sites with their age and water depth. These data indicate that most recorded sites are from the last inundation of the shelf with its maximum at about 20,000 years BP, but a small number survive from previous glacial cycles.



Submerged Continental Shelf Prehistory, Figure 2 A selected sample of sites with submerged prehistoric materials or submerged terrestrial landscapes that have been well mapped to locate sites: (1) Orkney coast and Viking Bank; (2) British Columbia; (3) South West Baltic (over 1,500 sites); (4) North Sea (many tens of sites and thousands of paleontological retrievals); (5) Gorham's Cave, Gibraltar; (6) Chesapeake Bay; (7) Morbihan Bay, France; (8) Maine coast (Native American lithics offshore); (9) Fermanville, France; (10) California; (11) Quintero Bay, Chile; (12) Delaware offshore ("Cinmar" lithic); (13) Israeli Mediterranean coast (submerged Mesolithic villages); (14) Table Bay (Acheulean hand axes); (15) Cape Canaveral beach (Paleoindian site); (16) Tokonami River Bay (Jomon site); (17) Grotte Cosquer (cave paintings); (18) Florida coast, Gulf of Mexico; (19) Sicily (submerged Bronze Age tombs); (20) Farasan Islands, Red Sea; (21) Cootamundra Shoals, Australian shelf; (22) Aegean (Agios Petros and Pavlopetri).

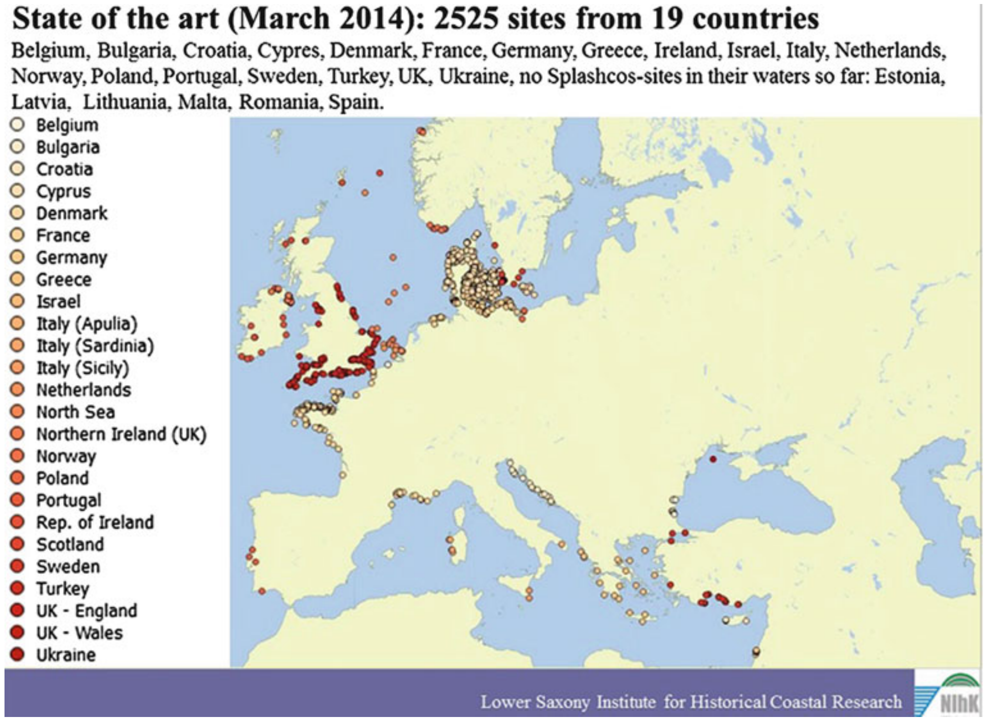
The European Marine Board subsequently commissioned a multiagency report on possible future research on submerged prehistoric landscapes in European seas (Flemming et al., 2014).

Sea-level change and climate

Pleistocene sea-level changes led to repeated exposures of seabed to a depth of 135–150 m, and this area coincides more or less with the geological definition of the continental shelf (Chiocci and Chivas, 2014). There are numerous estimates and models of the global change in sea-level surface through time for the last half million years (e.g., Figure 4). Each local relative sea-level curve through time will depend upon the accumulated effect of the global ice volume extracted from the sea and transferred onto the land as ice sheets, combined with the response of the earth's crust to that transfer of mass – the so-called glacial-hydro-isostatic adjustment (GIA) – and local tectonic earth movements (e.g., Lambeck and Purcell, 2005; Peltier and Fairbanks, 2006; Rohling et al., 2009; Stanford et al., 2011; Lambeck et al., 2014; Shennan et al., 2015).

Although many landscape features are eroded during marine transgression or buried in subsequent deposits of marine and deltaic sediments, many features can be preserved in different environments. There are river valleys, cliffs, moraines, ice tunnels, frost-shattered slopes, screes, marshes, coral reefs, drowned forests of tree stumps, fallen tree trunks, fossil mangrove forests, fossil dunes, beach terraces, beachrock, karstic caves and sinkholes (Figure 5), and many other features of the terrestrial landscape buried under the sea.

These features seldom show up on charts and seabed maps because the mapping process and sampling of depth soundings smooth out abrupt changes in gradient. Submerged cliffs do not appear on navigation charts. The software for digital terrain modeling often makes matters worse by statistical smoothing, although algorithms can be applied to the raw data to detect abrupt features. However, divers, submariners, and fishermen with good echo sounders have always known about abrupt vertical relief on the seabed, and the modern techniques of multibeam sonar can now show the true complexity of the continental shelf landscape (Figures 5 and 6). The main features that have showed up easily on major charts in the past have been (1) the big river valleys and glacial scour valleys which cut broad depressions across the shelf toward the continental margin and the deep ocean, (2) the canyons, and (3) the eroded flatness of terraces formed by coastal marine abrasion under some conditions. Now, smaller



Submerged Continental Shelf Prehistory, Figure 3 Distribution map of submerged and intertidal prehistoric sites in European and northern Mediterranean coastal seas. Data compiled by Hauke Jöns for the European research framework SPLASHCOS COST Action TD0902 "Submerged Prehistoric Archaeology and Landscapes of the Continental Shelf." Most recorded sites are shallower than 10 m depth, but some lie in the range of 20–40 m and a few deeper.

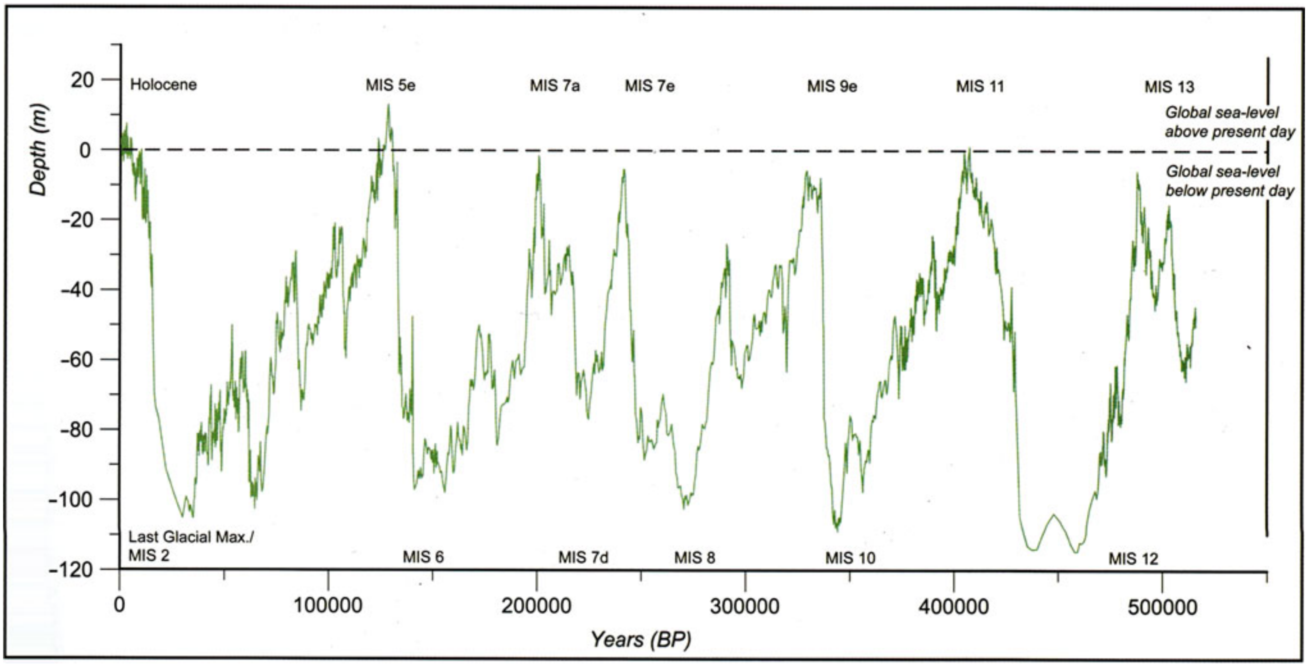
geomorphological features are being added, down to scales of a few meters.

The complexity of global sea-level changes during the Pleistocene, the relatively high frequency events and oscillations with periodicities on the order of 1,000 years, and the distinct differences in details between successive major cycles are now being worked out. From an archaeological perspective, the attention being given to the penultimate glacial cycle overlaps with the critical periods of some early migrations into Europe and Southeast Asia. The rise of sea level toward the last interglacial highstand about 125,000 years ago has been analyzed by Marino et al. (2015).

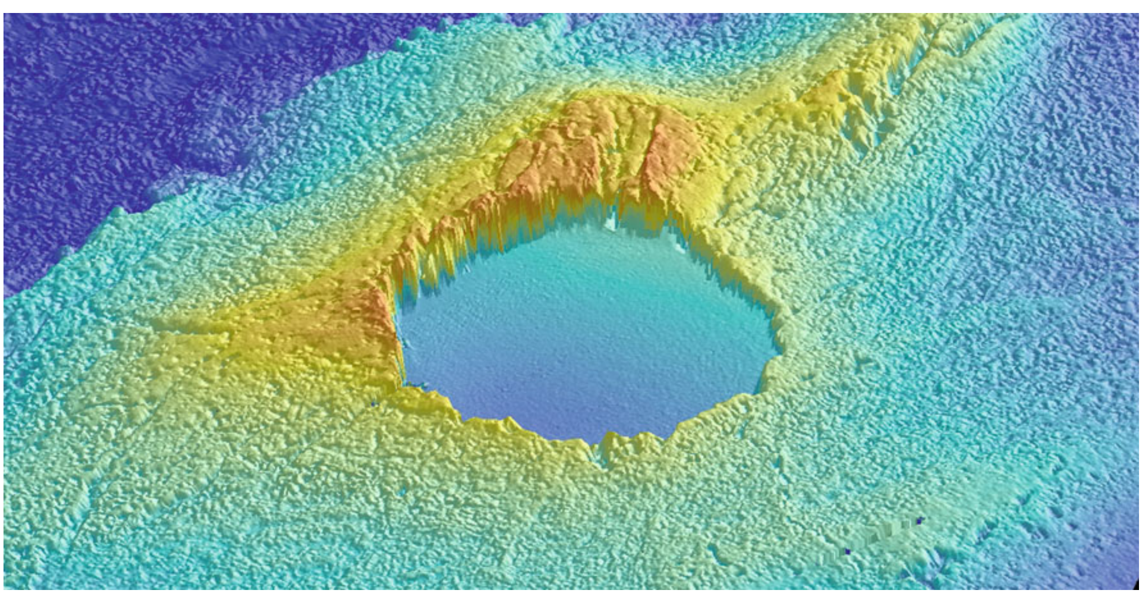
Geoarchaeological components of prehistoric site research on the continental shelf

Determination of site location in the context of the original landscape and resources of an exposed shelf during glacial stages of low sea level

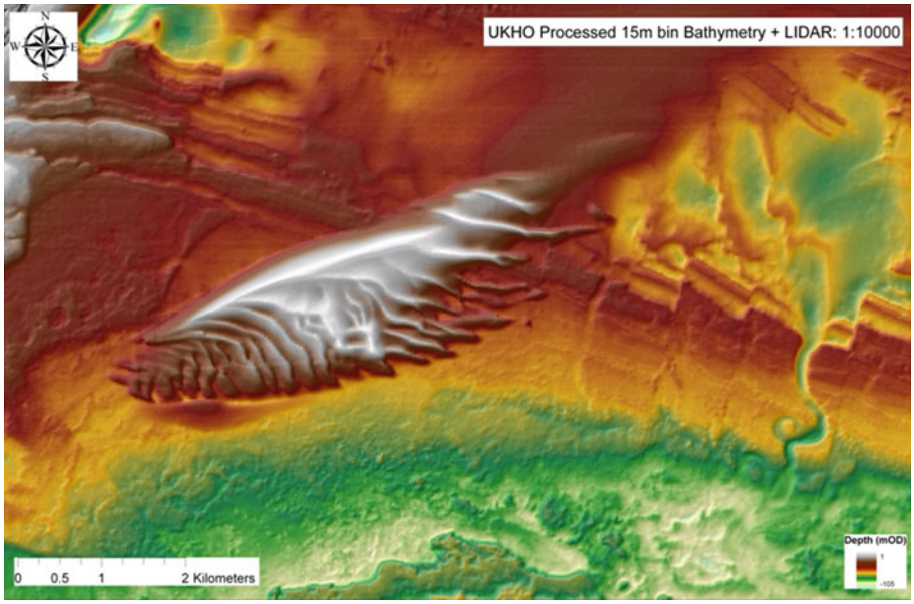
During the last million years, the continental shelf was exposed and completely dry about six times, and for about half of the last million years, the continental shelf has been exposed over about half of its total area (Figure 4). These cycles were driven by the glacial-deglacial cycle of the continental ice caps with a periodicity of approximately 125,000 years, and each cycle was accompanied by shifts in climatic zones, rainfall, and vegetation. During the same period, early hominins evolved from the simpler species (*Homo ergaster*, *Homo erectus*, *Homo heidelbergensis*) through Neanderthal and *Homo sapiens* (see, e.g., Klein, 2009; Fu et al., 2014). The evolution and distribution of hominins was constrained by the geography and climate during each period and by the sea level. The topographic features which welcomed or constrained coastal dwelling and migrations (Westley and Dix, 2006) are now under the sea, as are the sedimentary traces of the environments in which people lived (Bailey and Flemming, 2008; Flemming et al., 2012). Analysis to reconstruct the shelf landscape upon which people lived and through which people would have migrated between the Middle East and Southeast Asia has been carried out by Bulbeck (2007, 315–321) and Erlandsen and Braje (2015), illustrating the very complex and variable landscapes and terrains that would have been encountered. In contrast, Dixon and Monteleone (2014) use seabed data and paleontological and archaeological findings to examine the submerged prehistoric landscape of Beringia. Erlandson et al. (2015) examine the extent to which marine coastal resources facilitated the modern human migration from Northeast Asia to the Americas.



Submerged Continental Shelf Prehistory, Figure 4 Global sea-level curve for the last half million years, showing principal fluctuations within the main glacial cycles. The local relative sea-level change at any point on the coast is altered by the additional regional response to the transfer of mass between land-based ice and the ocean and local tectonics (Based on Rohling et al., 2009, with permission).



Submerged Continental Shelf Prehistory, Figure 5 3D multibeam image of a submerged karstic sinkhole or doline off the coast of Malta. Diameter is 270 m and depth is 11–12 m (From Micallef et al., 2013, with permission).



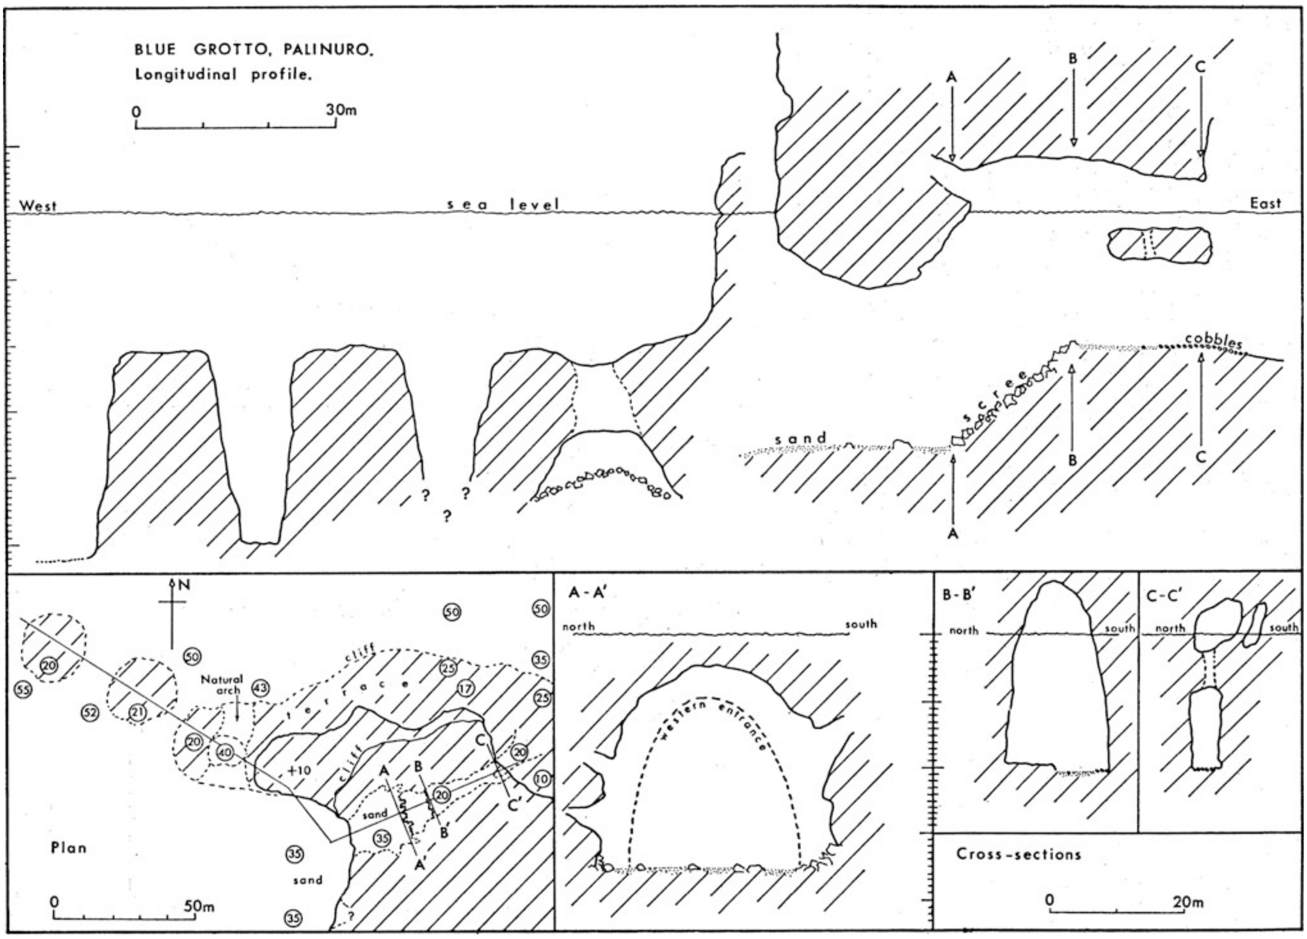
Submerged Continental Shelf Prehistory, Figure 6 Seabed geomorphology in Portland Bay, south coast of England. The shallow sand banks show white, with a sinuous dynamic structure. They overly bedrock with the dipping strata showing rectilinear features, with offset faults. To the east side, an incised river valley cuts through the bedrock and includes an isolated oxbow lake (small circular feature, *lower right*) (Image from Justin Dix, with permission).

The science of detecting or locating the most probable position at which hominins lived or settled, leaving stratified deposits, at different past periods and in widely different climatic and topographic environments is too vast even to be summarized here. There are two chains of logic: the first one positing that determining probable site locations on the shelf should assume that the culture and foraging system on the formerly exposed shelf was the same as that for known equivalent sites explored on present land surfaces and the second one making the assumption that proximity to the coast, or a manifestly different type of terrain now submerged, resulted in different cultural and technological habits.

As on land, offshore prehistoric sites dating from successive glacial stages can be found scattered over the same area, so that sites of widely different dates may be located in proximity or even superimposed. The limiting factor is that no sites were occupied in the time period when that location was submerged. For the Lower Paleolithic, it is reasonable to assume that the effect of proximity to the coast had minimal effect other than the fertility of the coastal plains themselves, although it is not impossible to imagine very primitive rafts of reeds or bamboo being used. Thus, site location is likely to be determined by the fertility, relief, and roughness factors analyzed by King and Bailey (2006) and Bailey and King (2011). The earliest dates for consumption of freshwater mollusks and their use as tools with engraved decorations are more than one million years ago (Joordens et al., 2015), and it is reasonable that people would have exploited marine mollusks from time to time at similar dates. Bednarik (2003) proposes that hominins could construct simple rafts to cross between islands of the Indonesian archipelago more than 0.5 million years ago. For a general history of early seafaring and exploitation of marine resources, see Anderson et al. (2010).

As the skill at exploiting coastal, shoreline, and shallow water resources increased – albeit at a rate that is still under discussion and varying greatly between regions – we can assume that the cultural patterns and technologies possessed by hominins living close to the shoreline, and on the adjacent coastal hinterland, became progressively marine oriented and less like the settlement patterns and hunting-foraging strategies of groups living farther inland or at distances of many hundreds of kilometers from the sea. Most submerged sites studied so far would have been occupied in sheltered locations, either close to the shore or inland, but in open positions, not inside caves.

Coastal caves and shell middens have attracted special attention, research, and debate. Prehistoric shell middens are known in the tens of thousands, globally distributed from Portugal and Denmark to California, Japan, Australia, and many other countries. A large shell mound can contain thousands of tons of shell debris, together with other food remains, charcoal, and tools. The largest middens date from 8 to 7 ka BP (Bailey and Flemming, 2008), but smaller shell deposits have been found associated with caves close to the present shoreline dating from the last interglacial around 125 ka BP (Bailey and Flemming, 2008) and even earlier. The deduction is that



Submerged Continental Shelf Prehistory, Figure 7 Blue Grotto cave, Capo Palinuro, Italy. Plan and profile sections with no vertical exaggeration. The cave penetrates the headland with a floor level at −20 m and then descends with a rubble scree to −50 m, where there are two outlying pinnacles and a natural rock arch, all adapted to a paleo-shoreline wave erosion level at −50 m (Flemming, 1968).

mollusks were a consistent, though possibly minor, component of diet in the coastal zone throughout the last glacial cycle and that most of this food was consumed on the shelf and the shells discarded below present sea level. However, searches for concentrated midden deposits offshore have been problematic, as wave action seems to destroy and scatter the shells even in the most sheltered locations. Faught (2014, 43–44) discusses the problem, and there have been numerous projects to find middens offshore in regions where they are very common on the present shoreline (e.g., Bailey et al., 2015). Negative results seldom appear in the literature, but it is manifest that this problem needs intensive research to evaluate the discrepancy. Faught (2014, 44) describes a suspected drowned midden within a river bed, and shell accumulations are known in muddy deposits in the Baltic, suggesting that a cohesive matrix of sediment or vegetation is needed to preserve a shell midden from wave attack. The present author has observed a shell midden collapsing slowly into the water at Little Swanport, Tasmania, under the influence of waves only a few cm in height. The question remains as to whether a scattered midden would still present a trace distinguishable from a natural shell bed, and this has long been a concern (Gagliano et al., 1982).

Large caves on land are the quintessential location for Paleolithic accumulations of massive deposits, and the search for occupied caves below sea level started in earnest already in the 1950s and 1960s (Figure 7). Caves close to or on the modern beach such as Gorham's Cave, Gibraltar (Carrión et al., 2008; Stringer et al., 2008; Rodríguez-Vidal et al., 2014), and the South African coastal caves at Eland's Bay, Blombos Cave, and Klasies River Mouth typify a sequence containing sparse evidence for the use of marine resources at the last interglacial, with the reappearance of evidence for a marine diet including mollusks, fish, seabirds, and mammals within the last 20 ka. The cave on the Turkish coast at Üçağızlı (Kuhn et al., 2009) provides another example of an occupied Paleolithic cave within a few meters of the present shore. Minor terrestrial deposits with a few bones or worked lithics have been found in a few submerged caves on the coast of France and Italy, but the only discovery of significance has been the so-called Grotte Cosquer (Clottes and Courtin, 1996; Clottes et al., 2005; Collina-Girard, 2005). In this case, a 150-m-long tunnel which has its entrance 40 m below sea level emerges inside a flooded cave above present sea level, on the walls of which there are Paleolithic paintings, dating from 27 to 19 ka BP. This configuration is so curious that nothing like it has been discovered in the last 25 years of searching.

Prehistoric remains have been found in karstic sinkholes, or dolines, on land (e.g., Clausen et al., 1979), but the lack of substantial stratified deposits found in submerged sea caves, in spite of thousands of caves being mapped by speleologists, has been discussed by Antonioli in a section of the report by Flemming et al. (2014, 83). As with middens, the lack of progress does not usually find its way into publications, but the problem needs a renewed level of analysis to identify the reasons and possibly develop a new exploration and probing strategy.

In summary, there are still many problems to be solved regarding site location and discovery, but there is ample field evidence that prehistoric hominins and AMH occupied the exposed continental shelf at many periods and in different parts of the world, in different landscapes, and that large parts of the submerged landscape can be mapped and interpreted so as to reconstruct the living environment and place the sites in context.

The potential for modeling of site distribution and possible predictive modeling for site density and survival

The former occupation pattern on large exposed areas of the shelf can be approximated first by the known contemporaneous population density and site characteristics of the adjacent land mass above present sea level. This is only an approximation, since the climate would have been milder at a lower level closer to the sea, freshwater drainage and reduced gradients may have produced springs (Faure et al., 2002) and increased vegetation or marshlands, and the population itself may have adapted in special ways to the coastal and marine environment and ecosystem. Nevertheless, the existence of cave sites, rock-shelters, and open ground low gradient sites, or – at later periods – built structures of wood, stone, and bone, should be very broadly comparable, taking into account the topographic and geologic data available from the seabed.

Because of the high cost of modern technical searching of the seabed, including the costs of ship time, it has been an ideal goal since the 1980s to use computer modeling to relate probable site occurrence to the mapped submerged landscape so as to increase the probability of finding sites on the seabed for research or protection. As an accurate site predictive system, this has been an unachievable goal. Nevertheless, modeling serves several uses:

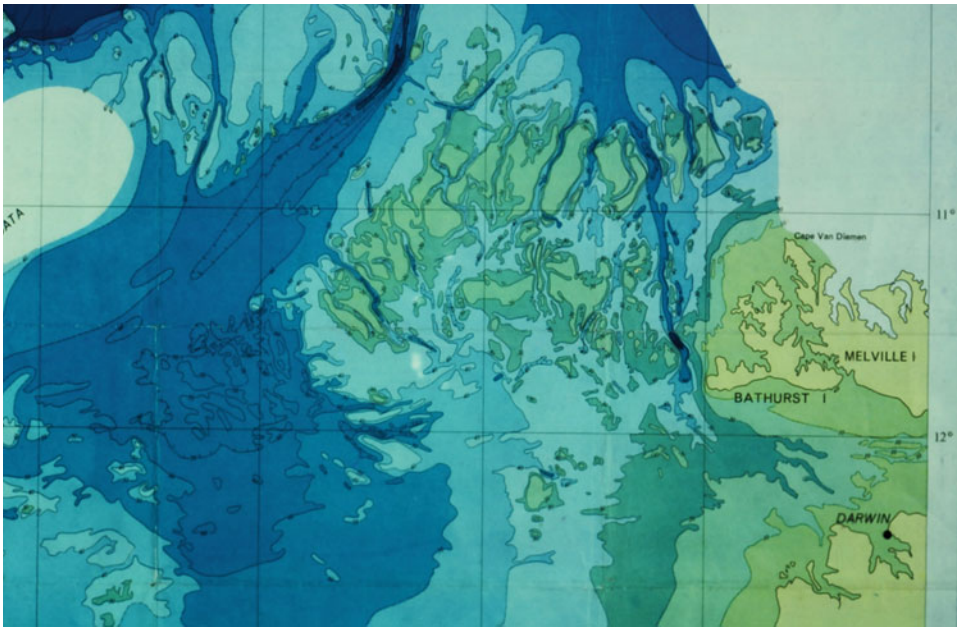
1. To estimate probable original overall site spatial density
2. To interpolate between known sites to reinforce models, calibrate models, and fill gaps
3. To estimate the probability of site occurrence for heritage management, research, and protection, ultimately to grade areas as low or high probability

The extrapolation of known site density from the land to offshore may be based on an assessment of site survival rates on land, but this is usually unknown for the seabed. In effect, as some sites are found offshore, the number that have survived, or have been found, provide by comparison an indication of the number that have probably been lost or buried.

When a few submerged sites have been found, and assuming that they are contemporaneous one with another, it becomes possible to draw parallels with equivalent cultures and landscapes that have already been studied, including the apparent relationship between sites and immediate environmental constraints. Thus, an iterative relationship can be developed in which the models suggest more site locations, and the discovery of more sites, whether deliberate or by chance, is used to improve the model.

For the Mesolithic period in the Baltic, Fischer (1993, 1995) and Pedersen et al. (1997) have developed models for identifying the most probable locations of sites on submerged coastlines (where people would have established fishing sites) and their detection on the seabed by divers. This model has been developed and analyzed by Benjamin (2010). The model has been most effective under the circumstances provided by the low gradient, sediment-rich environment of the Baltic, but the general principles of attention to paleo-landscape and resource utilization can be extended and adapted to rocky coasts and other environments. The value of linking the dynamics of coastal changes during rising sea level to cultural patterns of hunting, fishing, and foraging has been further shown for the Baltic region by Jöns (2011) and by Lübke et al. (2011).

Since many coastal states have accepted the responsibility to manage and protect offshore prehistoric sites, heritage managers require a methodology for estimating the risk to seabed prehistory from different industry licensing regulations. Collaboration with industry can be very beneficial (e.g., Flemming, 2004a; Mol et al., 2008; Weerts et al., 2012; Moree and Sier, 2014), and over-restrictive controls result in chance finds not being reported. Models can therefore be used to classify regions so that appropriate relaxed or highly restrictive obligations can be placed on offshore operators seeking licenses (Flemming, 2004b; Faught and Flemming, 2008).



Submerged Continental Shelf Prehistory, Figure 8 The shoal banks northwest of Darwin, Australia, reveal a topography of planated karstic fossil reef limestone, with steep-sided valleys to 60–100 m, separating flat-topped banks at 30–36 m. At glacial sea-level lowstands, the valleys would have provided extremely sheltered marine environments with a wind fetch of 1–5 km, ideal for mangroves, mollusks, and possible human occupation (Map adapted from Veevers and Van Andel, 1967; see also Nutley, 2014).

Terrestrial taphonomy, site survival, site formation processes

The taphonomy of site abandonment, decay, burial, disturbance by animals or later cultural activities, and final formation of a stratified buried site on the exposed land of the continental shelf is the same as would occur on present land masses given the same climate conditions. Thus, while the factor is important, there is nothing unique about these stages which differentiates them from the usual considerations of site formation processes – up to the time that the site or landscape is inundated by the sea. The phrases "site formation" or "site formation processes" have considerable associated intellectual literature (e.g., Wood and Johnson, 1978; Stein, 2001), which will not be developed further here. Changes to the site deposit after abandonment may be cultural, such as a later period of occupation digging a pit or building a hearth, or noncultural due to soil processes, vegetation roots, diagenesis, rock falls, or landslides.

At this stage, we are concerned only with the mechanistic and sedimentary biogeochemical analysis of how sites survive, or do not, and we are not extending the interpretation to consider the way in which this biases the subsequent state of knowledge about the culture that created the sites. That bias manifestly occurs both before and after inundation and must be considered by future research. The large number of seabed sites that have been lost is probably not a random and unbiased sample of all the sites that have existed below present sea level.

Many submerged prehistoric sites that date from after the last glacial maximum (LGM) may have originated on, or very close to, the contemporaneous shoreline in tidal waters, such as the Bouldnor Cliff site, southern England (Momber, 2006; Momber et al., 2012). In these cases, the pre-inundation site formation may have occurred in wetlands, marshes, lagoons, or on dune ridges. The process of site survival in these conditions has been examined by Kraft et al. (1983), Belknap and Kraft (1981, 1985), and more recently by Boldurian (2006). Kelley et al. (2013) have analyzed site survival in the context of proven prehistoric remains in rocky terrain.

The processes of first marine transgression: transition of the surf zone, erosion or protection by topography, wind fetch, wave refraction, and lateral sediment transport

Masters and Flemming (1983) compiled data that reported several tens of submerged prehistoric sites globally, all in water shallower than 20 m, and each site protected naturally by some combination of lagoon, bay, limited wind fetch, estuary, low gradient beach, or rock protective barrier. In spite of the popular preconception that Bruun's Law (1962) necessarily results in unconsolidated coastal deposits being reworked, displaced, and redeposited downslope, these findings from many different countries have shown that prehistoric sites can and do survive for centuries and millennia in shallow marine environments and at constant sea level. The protecting factor, even during periods of prolonged sea-level stillstand, is local topography, wave climate, and currents. Cooper and Pilkey (2004) have presented a robust case for rejecting the generic application of Bruun's Law, and this would be consistent with the findings of many marine prehistoric sites.

The concatenation of circumstances that protect a site from the first wave attack during marine transgression includes a generally low gradient that dissipates offshore wave energy; restricted wind fetch (Figure 8), most effectively less than 5–10 km; a crenelated coastline of headlands; peat deposits; longshore transport moving sediment in front of the site; and bays, barriers, and islands that refract and diffract incoming waves or create complete wave shadows. Zhang et al. (2010) have constructed detailed three-dimensional analyses of the transgression process in the southern Baltic as it impacted upon the prehistoric coast of mostly unconsolidated sediments. The proposition that prehistoric sites are best protected by a rapid vertical rise of sea level has not been put to the test since the most rapid rates of rise were during the meltwater pulse around 15 ka BP, with a sea level 100 m lower than at present. The spatial density of Paleolithic sites would be low at that date, and the water depth is such that no systematic search has been conducted so far. Depending upon the previous dry-land processes of site formation, a particular site may be already protected or buried by accumulated sediment before marine transgression. Eighty percent of the sites with a recorded depth identified in the SPLASHCOS survey are shallower than 5 m, and some are intertidal, so it is clear that sites can survive in shallow water. Many were certainly destroyed as the sea rose to its present level, but some have survived.

Submerged Continental Shelf Prehistory, Figure 9 Three Acheulean hand axes found offshore in Table Bay, South Africa. They were embedded in red earth on bedrock beneath several meters of marine sands (Werz and Flemming, 2001; photo by Bruno Werz).

The effects of multiple marine transgressions and mechanisms by which prehistoric archaeological sites may survive several glacial cycles

Each glacial cycle tends to be a series of descending sawtooth stadials (Figure 4) during which the ice sheet expands, the sea level drops, and then there is a relatively abrupt partial melting phase. The next cold spell causes the ice sheet to expand even further, and the cycles repeat until, after about 100 ka years, the ice cap reaches a maximum extent, the sea level has dropped about 120–130 m, and then the ice melts over about 15–20 ka years. There are also shorter minor oscillations known as Dansgaard-Oeschger events. This typical sequence means that a prehistoric site dating from before the LGM may have been submerged and exposed several times, if it survives at all.

It has been shown that some sites can survive one inundation and survive hundreds of years in shallow water or deeper. Surviving multiple cycles implies that coastal erosion and redeposition on a large scale, combined with river sediment inputs, result in gradual sediment accumulation in a depocenter, so that prehistoric deposits are sealed in. As an example, the Quaternary multi-cycle paleotopographic evolution of the North Sea basin was extensively reviewed in a special journal issue (Cohen et al., 2014). In such buried conditions, prehistoric deposits are then only likely to be discovered by industrial activity or massive erosion. Thus, anthropogenic materials dating from 340 ka (Wessex Archaeology, 2011; Tizzard et al., 2014) were discovered in the sediments of the southern North Sea. Gaffney et al. (2007) interpret commercial geophysical seismic records to identify sub-bottom buried terrestrial landscape topography, including rivers, creeks, shorelines, marshes, and near-coast islands (Gaffney et al., 2007). Several sites with Neanderthal and Mesolithic skull fragments have been discovered in the southern North Sea (e.g., Hublin et al., 2009). Nevertheless, this generalization has exceptions, and the hand axes found by Bruno Werz in Table Bay, South Africa (Figure 9), have probably survived multiple glacial cycles while buried in several meters of sand and earth on an open exposed low gradient shore (Werz and Flemming, 2001), and an assemblage of flints off Cap Lévi, near Cherbourg, has

Submerged Continental Shelf Prehistory, Figure 10 Standard fish boxes landed at a Dutch port containing terrestrial Pleistocene bones and mammoth molars, obtained from one boat and 1 week of fishing. Tens of tons of Quaternary paleontological materials from the southern North Sea are landed each year (Photo by S. J. Kleinberg).

a date range of 50–100 ka BP, suggesting several periods of inundation and re-exposure (Cliquet et al., 2011). Another example of long-term survival of hominin remains on the continental shelf is the recovery by fishermen of an archaic hominin jawbone from a depth of 60–120 m in the Taiwan Straits, provisionally dated to later than 450 ka BP but likely in the range of 190–110 ka BP (Chang et al., 2015). Globally, there should be other identifiable depressions of the continental shelf that could preserve hominin/AMH deposits, though discovery of such anthropogenic traces is likely to depend on industrial activity and chance finds.

Modern sediment seabed conditions marine sediment movements, erosion, burial, processes of discovery of sites

Modern oceanographic and geomorphological processes are relevant to submerged prehistoric continental research and geoarchaeology for two reasons: (1) because the wind/wave/current forces and consequent sediment transport accretion/erosion determine whether the site is stable, will survive for a period of research, needs immediate rescue study, or should be excavated before it is destroyed and (2) because any operations conducted to examine the site are constrained by the oceanographic conditions, water depth, and distance from shore.

Most submerged prehistoric sites and paleontological finds on the continental shelf are discovered by chance (Figure 10). The exceptions are some sites in the Baltic and off the coast of Israel where the conditions are known so well that local marine archaeologists can monitor sand movements and winter storms and predict areas where they are likely to find new material. Continental shelf mapping programs are conducted by many countries for commercial reasons, but additional studies may be carried out specifically to identify potential preservation of prehistoric sites (e.g., TRC Environmental Corporation, 2012).

Site discovery is best promoted by seabed mapping programs that are sufficiently detailed to reveal submerged terrestrial features, combined with monitoring of chance finds by industrial operations, dredging, bottom trawling or scallop dredging, and good communications with recreational divers. Although sites have survived surprisingly often in shallow water, repeat observation of sites shows that erosion is occurring at some places, and this destroys known sites, while revealing fresh ones. The European project EMODNet (European Marine Observation and Data Network of the Directorate General of Maritime Affairs and Fisheries, European Commission) is extending its geological mapping data integration to include submerged Quaternary landscapes.

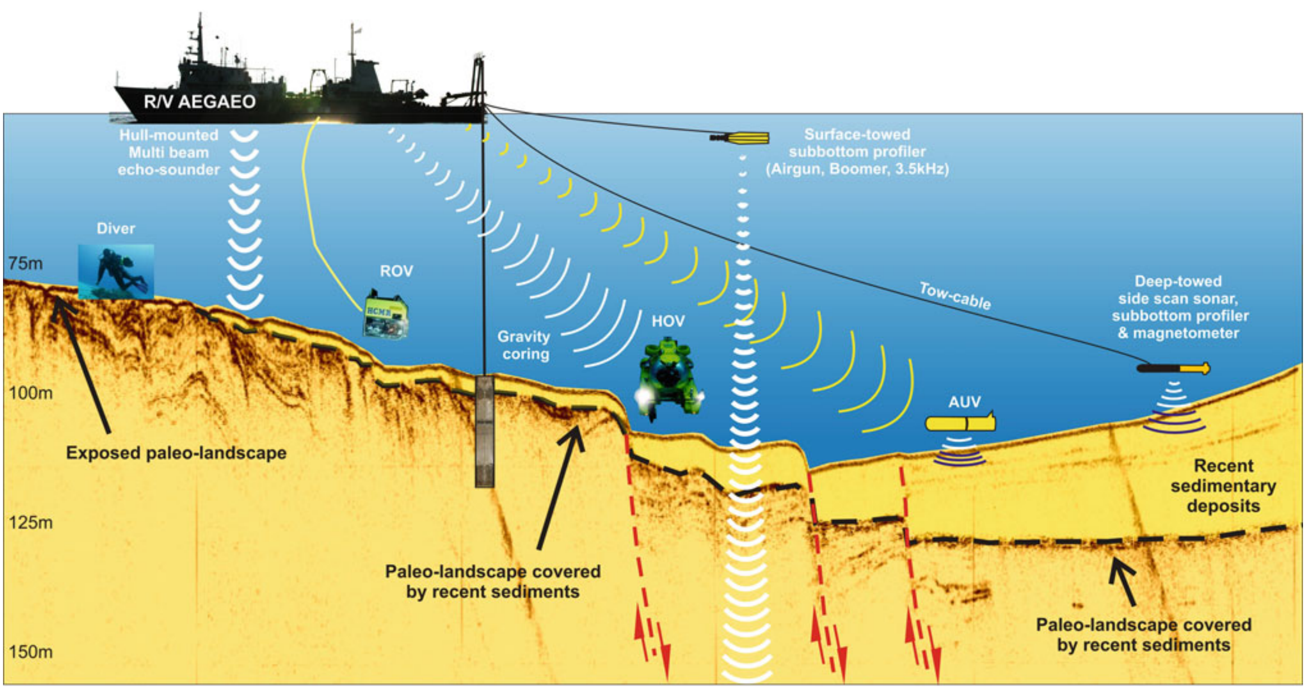
Application of modern oceanographic and commercial offshore technology to the search for, mapping of, and discovery of submerged prehistoric landscapes and archaeological sites

Discovery of seabed prehistoric sites usually occurs either through industry excavation or trawl nets recovering Pleistocene terrestrial bones (e.g., Chang et al., 2015) or through divers observing artifacts or bones or other anthropogenic signals. Detailed mapping, protection, and excavation have always so far required specially trained divers. Manuals written for marine archaeologists (e.g., Muckelroy, 1978; Green, 1990; Delgado, 1997; Ruppé and Barstad, 2002; Ballard, 2008; Bowens and NAS, 2008; Dellino-Musgrave, 2012) tend to devote almost all their attention to shipwreck archaeology, and thus practical guidance for research on prehistoric sites and landscapes is sparse, other than through the academic multi-author volumes already cited or examples from individual projects.

Both the search for high potential locations and the survey or excavation of individual sites can benefit from the utilization of acoustic equipment and techniques developed for the offshore industries (Figures 11 and 12). For detailed definitions of these methods, reference should be to the industrial and marine geoscience literature. A brief overview for submerged prehistoric research is provided in a chapter by Tine Missiaen and Dimitris Sakellariou in the European Marine Board report (Flemming et al., 2014, 95–115).

The logical necessity of linking prehistoric sites to the contemporary landscape and environmental resources has encouraged the publication of several studies of regional submerged landscapes and their evolution through time (e.g., Gaffney et al., 2007; Cohen et al., 2014) in the North Sea, while other projects have focused on building up a geomorphological picture of the regional submerged landscape as a stage in searching for sites in the Red Sea (e.g., Bailey et al., 2015). Such studies mean that

Submerged Continental Shelf Prehistory, Figure 11 In order to map the submerged Bronze Age town of Pavlopetri, Greece, an autonomous underwater vehicle (AUV) was equipped with a GPS navigation system and digitized stereoscopic photogrammetry (see Henderson et al., 2011, 2013; photo by Jon Henderson, with permission).



Submerged Continental Shelf Prehistory, Figure 12 Diagram of acoustic systems and other techniques applicable to prehistoric continental shelf research. Graphic by the Hellenic Centre for Marine Research and courtesy of Dimitris Sakellariou.

as soon as a site is discovered or if sites are already known, they can then be fitted into the landscape, and archaeologists can start to interpret the region from a cultural and paleo-technological perspective.

Wessex Archaeology (2011) and Tizzard et al. (2014) provide an example of commercial offshore technology techniques adapted to the testing and sampling of an important Middle Paleolithic site at a depth of 16–35 m in the North Sea. Grøn and Boldreel (2014) show how acoustic chirp technology can be used to reveal buried materials such as wood in a way that could detect prehistoric timbers such as hut foundations.

Survey, conservation, monitoring, excavation, and management of seabed prehistoric sites in the context of the UNESCO convention on protection of the underwater cultural heritage

Seabed prehistoric sites can and do survive, but erosion of sites is sometimes observed in unconsolidated sediments at all depths both from wave action and tidal currents. Many sites have been lost already. Thus, observation, reporting, surface surveying, and continuous multi-year monitoring are advisable where possible. The UNESCO Convention on the Protection of the Underwater Cultural Heritage applies to submerged prehistoric sites (Flemming et al., 2014, 34; Salter et al., 2014, 155), and coastal states signatories to the Convention have obligations toward protecting sites within their jurisdiction.

Coastal states have conducted assessment surveys (e.g., TRC Environmental Corporation, 2012) identifying terrains which indicate (1) the probability of site occupation and (2) the probability of site survival. As discussed above, these do not amount to accurate site prediction models. Where known sites are fragile or vulnerable to erosion, mapping and sampling can provide data before the material is destroyed. The decision to excavate a site may be taken because of incipient disturbance by industrial development (e.g., Moree and Sier, 2014) or because of continuous erosion (Momber et al., 2012). Experience in many countries is now sufficient to justify excavation to the highest standards of accuracy, recording, and laboratory study of materials (e.g., Galili et al., 2004; Cliquet et al., 2011; Henderson et al., 2011; Andersen, 2013; Carabias Amor et al., 2014) (Figure 13). State heritage agencies in many countries now recognize the importance of continental shelf prehistoric research, and the offshore mapping programs that are primarily funded to support offshore industry, safe navigation, or military purposes can be planned with minimal extra cost to include the components and methods of interpretation that enable reconstruction of past terrestrial landscapes.

Value of discoveries so far: the link between seabed mapping and site detection

Given the persistent skepticism about the possibility of conducting archaeological research on seabed prehistoric sites, one of the main achievements of the last 50 years has been to establish beyond doubt that sites do exist, that they can survive sometimes with intact stratification, that they exist off almost all continents, and that they can preserve organic materials and date to all archaeological periods of the last million years.

Because of the slow rate of discovery in most areas, known sites are scattered randomly and widely in space and time so that it is difficult to apply modern methodology to more than one site at a time. The obvious cure for this problem is to find more sites, but there is still no reliable means using remote sensing to find them. We are limited to the natural to-and-fro collaboration between industry, fishermen, dredgers, amateurs, paleontologist collectors, and the professional academics and cultural heritage agencies to exchange information.

Submerged Continental Shelf Prehistory, Figure 13 Diver at the submerged Bronze Age town of Pavlopetri, Greece, working over a rigid steel survey grid and excavating a large ceramic vessel using a pump dredge (Photo by Jon Henderson, with permission).

Mapped and excavated submerged sites have revealed an extraordinary richness of preserved organics, including human and animal bones, antlers, burials, hearths with charcoal and burnt food, nuts, seeds, leaves, string, leather, clothing, canoes, and paddles. In places where primary stratified deposits can be excavated, as in the Baltic or off the Mediterranean coast of Israel, deposits show Mesolithic multi-family settlements, with a complex structure.

In the southern Baltic and on the Mediterranean coast of Israel (Figure 14), numerous sites in the age range of 5,000–10,000 years BP have been found in proximity so that it has been possible to reconstruct population patterns, seasonal changes in food sources (Fischer, 2002), freshwater supply, fishing methods, population age structure, causes of mortality, and so on. A steady increase in the temporal-spatial density of known sites in the North Sea, based on a growing understanding of the geomorphological and oceanographic changes over the last million years (Cohen et al., 2014), is beginning to create a similar situation at least as a future goal. In contrast, finds on the seaboard of the USA are still sparse but gradually building up a picture of remains enduring over a long time span since the earliest occupation of the Americas (Faught and Gusick, 2011; Stanford et al., 2014).

New frontiers

As of 2015, there remain several technical and geographical challenges that need to be confronted, in addition to improving the detailed geoarchaeological interpretation of known sites and integrating data from the shelf with the hinterland.

These are

1. Gathering more data from the deeper shelf, out to 100–120 m depth, coinciding in most areas with the shoreline of the LGM. Paleolithic site density will be very low, but it could be important to correlate such sites with the population displacement caused by the maximum extent of the ice sheets in Eurasia and the possible earliest movements into North America from Siberia.
2. So far, no multi-layer stratified anthropogenic deposits have been found in submerged sea caves, although many thousands of caves have been mapped by speleologists and enthusiast cave divers. The reasons for this need thorough examination with possible development of a new strategy to discover occupied caves or prove their absence.
3. Shell middens have not been found underwater off coasts where thousands of middens exist above sea level on the modern coast. Some anthropogenic shell deposits have been found associated with muddy or marsh deposits in the Baltic, but in general, they have not been found offshore. This needs checking to see whether all middens are necessarily destroyed by inundation or whether some could have survived, leaving identifiable scattered deposits.
4. There is no remote sensing acoustic or electrical system that can detect prehistoric archaeological deposits on the seafloor. Optical photo-video systems can identify lithics and bones provided they are on the surface, but the visibility range is very restricted and sometimes zero. Logically, geochemical or genetic/DNA detection might be able to define gradients in the proximity of an anthropogenic site that could lead to identification of the center, where artifacts are most likely to be found.
5. The lack of known seabed prehistoric sites in the tropics is an anomaly. A fresh approach to the environmental conditions and landscapes of the exposed shelf in the tropics is needed, followed by searching for anthropogenic signals.
6. Artifacts and sites are already known that predate the LGM, and some have survived two or more glacial cycles. While discovery is most likely to be through industrial excavation or dredging, every effort should be made to respond quickly to chance finds.
7. Humans were living on islands off the Arctic coast of Russia before the LGM. Further work is needed to understand the communities that lived in the polar region before and immediately after the LGM.

Conclusions

The prehistoric geoarchaeology of the continental shelf is a highly complex, multidisciplinary topic that has grown slowly but steadily during the last 50 years. Thousands of seabed prehistoric sites have been discovered and studied by researchers, while improvements in marine technology mean that seabed mapping, landscape interpretation, and site survey, protection, and excavation can be carried out with increased efficiency and reduced cost. Continued progress will provide fundamental data to help understand crucial stages of human evolution, the development of technical skills, and the migration and dispersal of groups throughout the globe.

Synonyms

Low-field magnetic susceptibility; Magnetic susceptibility

Definition

Magnetic susceptibility. The ratio of the magnetization induced in a sample to the inducing (magnetizing) field.

Volume susceptibility. Magnetic susceptibility expressed as susceptibility per unit volume (κ), dimensionless in SI units.

Mass magnetic susceptibility. Mass-normalized susceptibility (χ) equal to volume susceptibility divided by the density of the sample, in SI units of m^3/kg.

Introduction

Magnetic susceptibility quantifies the degree to which a substance can be magnetized in a weak magnetic field similar to that of the Earth's field – i.e., 5–100 μT (microteslas) – (Banerjee, 1981). This is an easily measured property that is commonly used to assess the concentration of magnetic materials in a sample. Magnetic susceptibility, however, depends not only on the concentration of magnetic grains but also on the composition (magnetic mineralogy) and size of those grains. Grain size refers to the size-dependent magnetic domain state, ranging from thermally unstable ultrafine or superparamagnetic (SP) grains to stable single-domain (SD) and pseudo-single-domain (PSD) grains to large multidomain (MD) grains (Hunt et al., 1995). Magnetic measurements in the laboratory allow an examination of the contribution of magnetic concentration, composition, and grain size to the susceptibility signal.

Magnetic susceptibility techniques are most often applied to soils and sediments, although material studies of artifacts may also include susceptibility measurements. Depending on occupation and firing histories, soils from archaeological sites may exhibit enhanced magnetic properties distinct from surrounding "noncultural" or non-site soils (Tite and Mullins, 1971; Mullins, 1974). Contrasting susceptibilities may permit the definition of sites, activity areas, and features. Understanding how these contrasts relate to changes in magnetic concentration, composition, and grain size may inform studies of formation processes and postdepositional alterations (Dalan and Banerjee, 1998).

Magnetic enhancement

Magnetic enhancement refers to changes in the magnetic mineralogy of upper soil layers that result in higher susceptibility values at the surface as opposed to within subsoil horizons. Enhancement can occur as part of pedogenesis or as a result of naturally occurring or human-generated fires, all of which may convert weakly magnetic oxides and hydroxides to more strongly magnetic forms. Pedogenic enhancement occurs through both low-temperature chemical reactions (i.e., inorganically) as well as organically via magnetotactic bacteria, iron-reducing bacteria, and bacterial-induced chemical reactions (Evans and Heller, 2003). Typically, it is magnetite or maghemite in the superparamagnetic to stable single-domain size range that is produced.

Mass magnetic susceptibilities of common environmental materials range from <0.001 to $>30 \times 10^{-6}$ m^3/kg, which represents a five to six order of magnitude range. Topsoil susceptibilities are generally in the $0.01–14 \times 10^{-6}$ m^3/kg range, and burned soils lie in the $0.2–80 \times 10^{-6}$ m^3/kg range (Dearing, 1999, 36). Measurements of unheated soils from 54 Northern Hemisphere sites yielded an average value of about 1×10^{-6} m^3/kg (Maher and Thompson, 1995), while a survey of heated soils from 60 Bulgarian sites documented susceptibility values of up to 10×10^{-6} m^3/kg (Jordanova et al., 2001). Heating experiments on soils from archaeological sites have shown a range of enhancement factors, with some more than 100 times the original soil susceptibility (Tite and Mullins, 1971; Linford and Canti, 2001).

The magnetic enhancement process is both conservative and environmentally sensitive (Maher, 1986). Enhanced soils will persist unless they are gleyed (waterlogging leading to the reduction of iron to a soluble oxide that can be transported away), or the iron minerals are reduced in some other way. Because topsoils may retain an enhanced susceptibility signal even when buried, susceptibility studies can aid in the search for buried archaeological sites. Magnetic enhancement is dependent on the type of material in which the soils form, the time over which enhancement has been allowed to proceed, climatic variables such as precipitation and temperature, the landform in which the soil develops, and the plant and animal (including human) life on and in the soil. All these environmental influences may be investigated via soil magnetic studies of the end products of the enhancement process.

Humans directly influence the degree of enhancement in a number of ways. They alter properties such as soil temperature, soil chemistry, and soil porosity. They can increase organic matter, expose soils to high temperatures through firing, and incorporate fired or other high-susceptibility materials into the soil matrix. In addition, humans redistribute soils and sediments, both horizontally and vertically in such a way as to produce susceptibility contrasts. For example, if a ditch or pit is excavated into a subsoil with low susceptibility, after which the concavity is filled with a magnetically enhanced topsoil, a high-susceptibility feature will result. The distribution of enhanced soils can yield information on the dynamics of archaeological terrains.

Frequency dependence of susceptibility

A companion property is the frequency dependence of susceptibility (χ_{fd}) (Dearing et al., 1996). This is the difference in susceptibility measured at two frequencies differing by a factor of 10 (e.g., 470 Hz and 4,700 Hz). Measurement of χ_{fd} is used to investigate the contribution of thermally unstable ultrafine (SP) magnetic grains, as these show the most pronounced frequency dependence of susceptibility. Due to the delayed response between the application of the magnetic field and the magnetization of these ultrafine grains, a decrease in susceptibility occurs at higher frequencies. An increase in frequency dependence, suggesting an increase in the percentage of ultrafine magnetic grains, in conjunction with an increase in susceptibility, is potentially indicative of a developed soil. Frequency dependence is often expressed as a percentage change, dividing the difference between the low- and high-frequency measurements by the low-frequency value.

Instrumentation

Magnetic susceptibility can be measured both in the field and in the laboratory. Instruments are divided into dual- and single-coil types, and they may also be separated based on the volume that is measured and/or the context of the application. In general, measurements are rapid, economical, and nondestructive, both in magnetic and archaeological terms. Field instruments provide volume susceptibility measurements, while laboratory instruments can be used to normalize susceptibility by mass and to investigate the effects of packing, water, and other inclusions.

Coincident loop instruments are composed of just one coil, with the depth of investigation related to the diameter of the coil. In the field, these instruments are usually directly applied to moderately smooth surfaces. They are used for topsoil measurements or to investigate stratigraphic sections or the walls of excavations. A number of small portable handheld susceptibility meters (e.g., ZH Instruments SM30, the Exploranium KT-9, and the Geologorazvedka PIMV-1M) provide effective penetration depths ranging from 1 to 2–3 cm (Lecoanet et al., 1999). The Bartington Instruments MS2/MS3 system of sensors includes the MS2F and MS2K with similar penetration depths of 1 cm and 2.5 cm, respectively, as well as the larger-diameter MS2D with an effective penetration depth of approximately 10 cm (Dearing, 1999).

In addition to ground surface application, single-coil instruments can be configured to be lowered down an open hole; they are used to investigate contrasts in susceptibility with depth while maintaining a high and constant resolution. Such downhole applications are particularly useful for documenting magnetic enhancement and identifying buried archaeological deposits (Dalan, 2006b). The Bartington MS2H sensor measures magnetic susceptibility down a small-diameter (2.2–2.5 cm) hole over a radial sensing zone of approximately 1.5 cm. In its standard configuration, it allows measurement to 2–3 m in depth, but this can be extended via additional sections of tubing and longer cables. ZH Instruments makes a soil-profiling kappameter called the SM400 designed for application in a 3.6-cm-diameter hole, which allows depths up to 40 cm to be investigated. Downhole applications are difficult in environments where the soil is hard, dry, or sandy or contains stones or large roots. As lateral resolution is limited, multiple downhole measurements must be completed to map the shapes of features or to provide information on broader landscape changes.

Single-coil sensors for laboratory application can be employed to measure individual samples (usually packed in nonmagnetic containers) or whole or split cores. The Bartington MS2/MS3 system includes the MS2B lab sensor for the measurement of susceptibility and the frequency dependence of susceptibility, the MS2C series of loop sensors for volume susceptibility measurements of various diameters of whole cores, and the MS2E surface scanning sensor for high-resolution measurements of split cores.

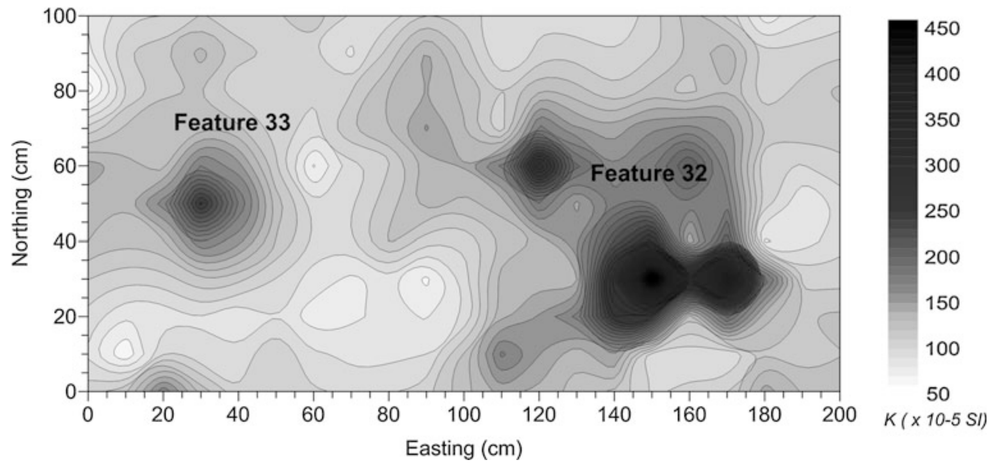
Dual-coil, or slingram, instruments are composed of separate transmitter and receiver coils. Slingram instruments operating in the magnetic susceptibility (i.e., in-phase) mode are less influenced by soil conductivity, and they provide greater penetration depths (but decreased resolution) over single-coil instruments (McNeill, 1986; Tabbagh, 1986; Benech and Marmet, 1999). Effective depths of investigation for slingram instruments used by archaeologists (e.g., the Geonics EM38, the SH3, the CS60, and the CS150) are generally less than 70–80 cm.

Dual-coil downhole options provide opportunities for magnetic susceptibility measurements down larger-diameter holes, although with decreased vertical resolution. For example, the Geonics EM39S, applied down a 5–7.6-cm borehole, has a vertical resolution on the order of a few tenths of a meter (McNeill et al., 1996).

Susceptibility soundings, measured at the surface using the Geonics EM38 (McNeill and Bosnar, 1999), allow a quick estimation of magnetic stratigraphy although the depth of exploration is shallow (approximately 0.5 m) and only a limited number (ca. 3) of magnetic layers may be distinguished. A series of readings is made as the instrument is lowered toward the ground surface from a height of approximately 2 m. Analysis involves comparing the measured and calculated soundings to find the best fit.

Applications

Magnetic susceptibility techniques are broadly applicable (Dalan, 2008). The scale of application ranges from microgeophysical surveys confined to single excavation units, exposures, or core holes to broad investigations of archaeological landscapes. Surveys focus on the location and mapping of archaeological features, activity areas, sites, and cultural and natural soils and landforms. Combined with other soil magnetic and nonmagnetic



Susceptibility, Figure 1 Magnetic susceptibility map of Block 2, 80 cm below datum, Poverty Point State Historic Site. Data collected on a 10-cm grid using a Bartington MS2K sensor. Maps from multiple excavation levels were combined to produce three-dimensional images of the basin-shaped features and to provide data on feature volumes and contrasts useful for comparison to gradiometer surveys. The highest readings correspond to fired-silt artifacts called Poverty Point objects.

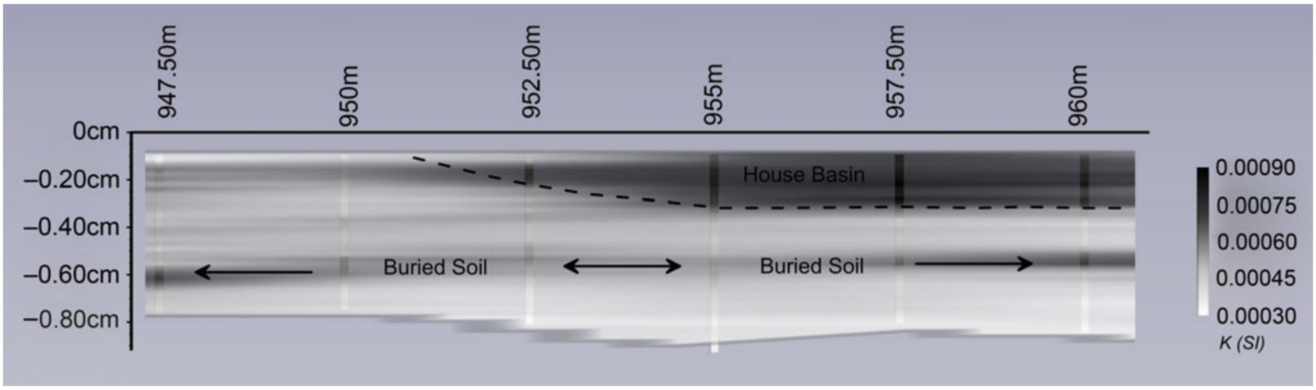
techniques, they can be used to explore site formation and postdepositional processes. Susceptibility studies are often integrated with other geophysical prospection methods such as magnetometry, ground-penetrating radar, resistivity, and electromagnetic conductivity.

Two-dimensional surface maps of magnetic susceptibility are commonly employed in mapping archaeological sites and the features within them. Types of features most frequently investigated are highly magnetic fired features, filled ditches or pits, and other earthen features comprising contrastive soils. Susceptibility instruments can identify subtle features as well as features with gradual boundaries. Susceptibility surveys have also been utilized to identify areas of intense occupation, industrial activity, and agriculturally managed or stockyard soils.

Susceptibility sensors are also employed on exposed sections or excavation walls and floors to identify and map features and even to explore microgeophysical changes within them. These applications integrate changes in geophysical properties with visible and textural changes recorded by excavators. By tracking changes that may be invisible to the excavator, they may also be used to guide and improve excavations. Figure 1 presents an example of a two-dimensional susceptibility map from a 1×2 m excavation unit at the Poverty Point site in Louisiana. *In situ* measurements of volume susceptibility identified features sooner or more clearly than they could be visually identified by excavators (Greenlee, 2009; Dalan and Sharp, 2012). The features shown are basin-shaped pits containing highly magnetic, fired-silt artifacts called Poverty Point objects.

Downhole sensors or susceptibility samples collected by coring allow subsurface features that are beyond the effective depth and resolution of surface sensors to be located, explored, and placed within a stratigraphic context. Thin archaeological horizons at depth or buried paleosols may be mapped by virtue of their enhanced magnetic signal. Susceptibility data sets combining multiple downhole logs or cores, or a series of susceptibility maps at different depths recorded during excavation, provide enhanced opportunities for visualization, including three-dimensional images and animations showing features, use areas, layers, and sites within their cultural and natural contexts (Dalan and Goodman, 2007). Figure 2 provides an exemplary transect of downhole tests across a protohistoric earth lodge at the Biesterfeldt site in North Dakota. Enhanced susceptibility values revealed the presence of a house basin as well as a buried soil (Dalan et al., 2007, 2011). This house was located in a portion of the village that had been plowed during historic times; in this area, neither geophysical surveys conducted at the surface nor topographic changes were effective in identifying earth lodge locations.

Vertical measurements of susceptibility are also useful for examining the effects of postdepositional processes such as soil creep and soil wash. As erosional processes alter spatial patterns of topsoil depth and particle size distributions, patterns in the depth and character of magnetic enhancement can be used to trace relative topsoil-subsoil movements along a slope (Dearing et al., 1985, Dearing et al., 1986; Thompson and Oldfield, 1986). Not only can susceptibility studies be used to identify areas of stability, erosion, and deposition, but this information can even be used to determine the original form of archaeological landscapes or features (Dalan, 2006a). Magnetic susceptibility studies of lake and bog cores, in conjunction with palynological investigations, shed light on erosional histories related to human land use (deforestation, agriculture, and burning) or climate change (Thompson and Oldfield, 1986; Evans and Heller, 2003).



Susceptibility, Figure 2 Cross section along the N914 transect, constructed from downhole tests at six locations spaced 2.5 m apart. Data collected using the Bartington MS2H sensor, with susceptibility values recorded at 2-cm depth increments within each hole. Enhanced susceptibility values distinguish (the western portion of) a shallow earth lodge basin as well as an underlying paleosol.

Magnetic susceptibility surveys are commonly used in conjunction with other geophysical methods (Clark, 1996; Gaffney and Gater, 2003). They often play a supportive role in prediction and preliminary assessment. For example, documenting contrasts in susceptibility between archaeological features and surrounding soils is helpful in evaluating whether a magnetometer survey will work in a given situation, as susceptibility contrasts (alone or in combination with magnetic remanence) produce magnetic anomalies. They are also used to track susceptibility trends across a site, targeting areas for subsequent geophysical work using other methods. They can be used to confirm the presence of an anomaly found by other surveys. Susceptibility contrasts can be used to model the depths and dimensions of magnetic anomalies. Susceptibility studies are also partnered with magnetic measurements accomplished in the laboratory to understand how geophysical anomalies are produced. For example, where surface geophysical surveys have given poor results, soil magnetic studies may shed light on the processes responsible. They have also been used to search for distinctive signatures of archaeological features and anthropogenic soils.

Summary

Magnetic susceptibility is one of a number of geophysical prospection methods used to explore and map archaeological sites. The contribution of this method, however, lies not just in its use as a survey technique but also in its role in exploring questions relating to the formation of the archaeological record and postdepositional alterations.

Just as one would not attempt to characterize a particular soil by examining only one horizon, susceptibility data cannot be fully interpreted without information on how susceptibility varies with depth. Susceptibility sensors designed to be used in excavations and on other exposed surfaces, downhole instruments, and laboratory studies of collected samples extend this method beyond standard surface prospection applications. Vertical measurements can be combined with surface maps for three-dimensional visualization.

As magnetic enhancement is linked to soil formation, investigations of susceptibility and other magnetic properties allow an understanding of the various soil-forming factors, including parent material, climate, topography, time, and living organisms. There is a direct link between human activities and susceptibility through human impacts on the soil environment. In combination with other soil magnetic techniques, susceptibility studies provide an avenue for examining the process of magnetic enhancement and also for tracking the effects of erosion and human earthmoving activities on the archaeological record.

The interpretive potential of susceptibility studies has made them a popular complement to other geophysical methods, in particular electromagnetic conductivity and magnetometer surveys. They are used to assess the potential for magnetometer surveys, separate induced and remanent magnetic components, confirm and interpret anomalies, and generate comparative magnetic models. As many susceptibility instruments investigate volumes similar in size to those analyzed for other physical and chemical properties, susceptibility data are also easily integrated within geoarchaeological studies focused on chemical and physical characterizations of soils and sediments.

Definition

Swanscombe is an internationally famous Middle Pleistocene locality in the Lower Thames Valley, UK. It is dated to the Hoxnian Interglacial of Britain, which corresponds in time to the Holsteinian Interglacial of northern Europe and the Mindel-Riss Interglacial of the Alpine ice age chronology, with a date within Marine Isotope Stage (MIS) 11 (424–374 ka). The various Swanscombe sites have yielded rich archaeological and paleontological assemblages, and it remains a flagship site for NW European Quaternary studies after over a century of research.

Introduction

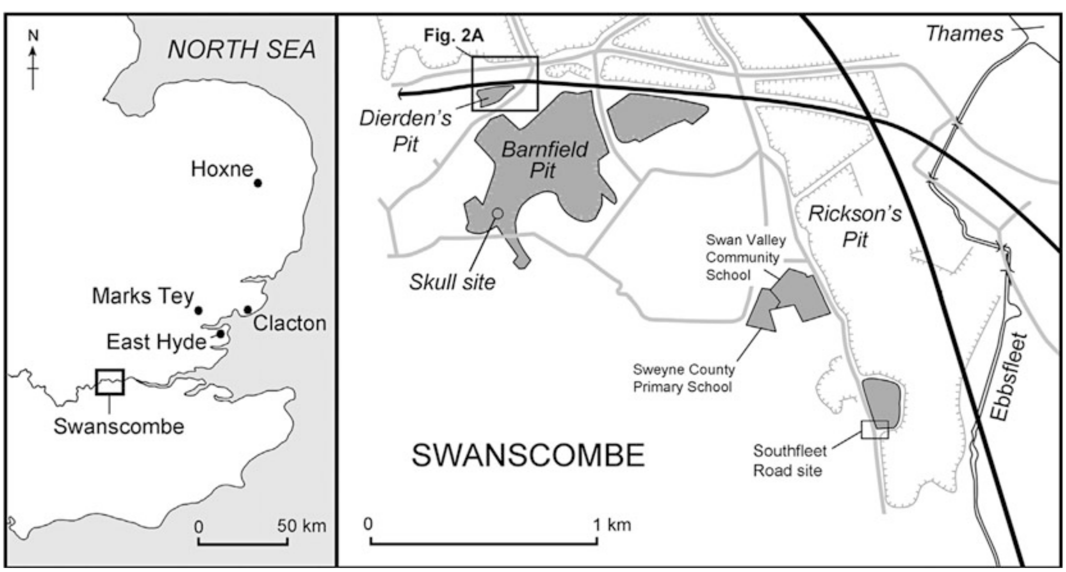
The sand and gravel pits in the vicinity of Swanscombe, Kent, have been the subject of geoarchaeological research since the nineteenth century. The Swanscombe quarries (Figure 1), many of which were subsequently deepened and obliterated as a result of chalk extraction for the cement industry, revealed a complex of gravels, sands, and silts (loams). These strata form part of the Boyn Hill terrace of the River Thames, which is preserved in the Swanscombe area overlapping a remnant of the Paleocene Thanet Sand, which itself rests atop Cretaceous Chalk.

The most important site is Barnfield Pit, where the famous hominin skull was found. The skull has often been attributed to *Homo heidelbergensis* but is now usually regarded as an early member of the Neanderthal lineage (Stringer and Hublin, 1999). The circumstances of its discovery are themselves remarkable; two parts of the cranium (the right parietal and occipital) were recovered in the mid-1930s by a local dentist, Alvan T. Marston, but it was 20 years later when the third refitting part, the left parietal, was found by John Wymer during his 1955 excavation. These discoveries led to Barnfield Pit becoming a Site of Special Scientific Interest (SSSI) and a National Nature Reserve (NNR). Also critical to understanding the Swanscombe sequence are exposures recorded at Dierden's Pit, where optimal preservation of calcareous fossils provided an unparalleled paleoenvironmental and biostratigraphic record (Kerney, 1959; Sutcliffe, 1964; White et al., 2013), and Rickson's Pit, now lost to chalk quarrying and landfill, but once exposing the most complete Swanscombe sequence other than at Barnfield Pit (Dewey, 1932; Wymer, 1968; Bridgland, 1994).

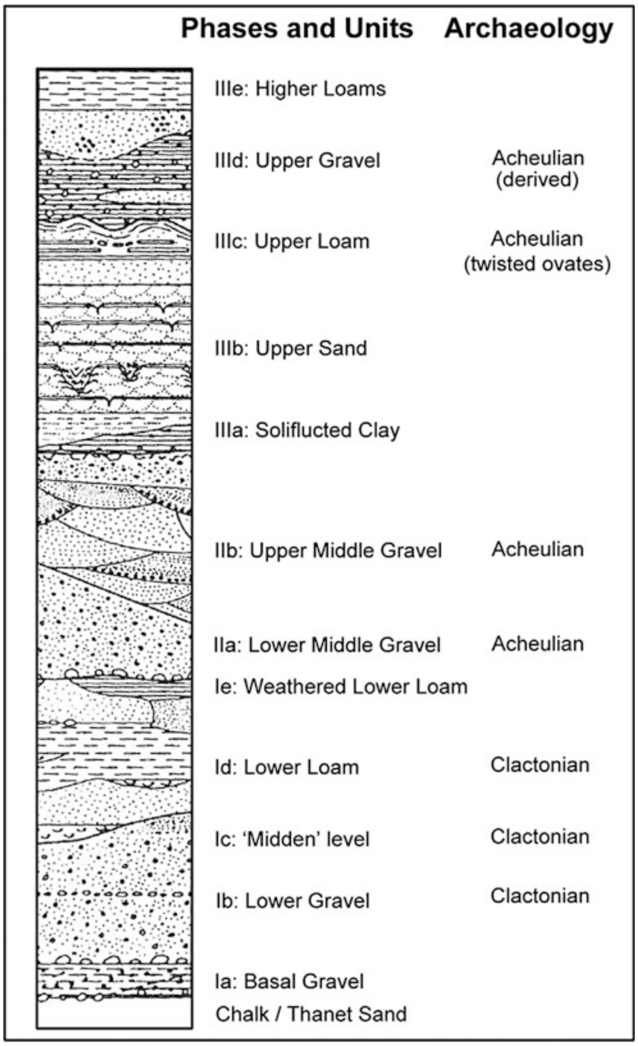
Most recently, research in association with major construction projects has extended our knowledge and understanding of the Swanscombe sequence, particularly during the building of HS1, the high-speed railway linking London with the Channel Tunnel, which revealed laterally equivalent deposits that represent a south-bank tributary system just upstream of its contemporary confluence with the Thames (Wenban-Smith et al., 2006; Wenban-Smith, 2013).

Stratigraphy

The definitive Swanscombe stratigraphy (Figure 2) follows that of Bernard Conway (Conway and Waechter, 1977; Conway, 1996), who made use of surviving exposures that were soon to be concealed or destroyed to establish a more complete sequence than can be observed at



Swanscombe, Figure 1 Maps showing the location of Swanscombe in the Lower Thames Valley and important localities in the Swanscombe area mentioned in the text (Modified from White et al., 2013).



Swanscombe, Figure 2 The stratigraphic and archaeological sequence at Barnfield Pit, Swanscombe (After Bridgland, 1994; Conway et al., 1996).

present in the NNR. Its lithostratigraphic division and hierarchy follows Bridgland (1994). Three subdivided phases are numbered I to III, from bottom to top.

The Phase I deposits at Swanscombe are of restricted occurrence, having been laid down in a paleochannel that was more constricted than the Thames floodplain that existed later in the sequence. The main divisions are the Lower Gravel (Ib) and the Lower Loam (Id); the more localized beds Ia and Ic should be regarded as components of the Lower Gravel, whereas Ie is the weathered upper part of the Lower Loam (Kemp, 1985). The basal clayey bed Ia has been attributed to solifluction during the cold late Anglian glaciation (MIS 12); otherwise, the Lower Gravel consists of bedded sandy medium-coarse gravel, fining upward to shelly sands and fine gravels. Although Waechter et al. (1969) coined the term "midden" for bed Ic, A. P. Currant (in Conway et al., 1996) interpreted it as a naturally fossiliferous channel-fill deposit. The Lower Loam, which is the infilling of an even narrower channel cut into the top of the Lower Gravel, comprises horizontally bedded clayey sands with thin lenses of shelly sand and evidence for channel cuts and fills. Vertical changes in the lithology, together with lithic knapping scatters from hominin tool-making activities and surfaces with animal footprints, suggest intermittent sedimentation and drying out, perhaps in keeping with its interpretation as an overbank floodplain deposit of generally fine alluvial sediments.

The Lower Middle Gravel (IIa) and Upper Middle Gravel (IIb) members of Phase II are considerably more widespread than the Phase I deposits, occurring in several pits such as at Craylands Lane, where they overlay bedrock, Dierden's Pit (White et al., 2013), and Southfleet Road (Wenban-Smith and Bridgland, 2001). The Phase II deposits represent the MIS 11 (Hoxnian Interglacial), however, so they are not coeval with the widespread outcrop of the Boyn Hill Gravel, which is generally of cold-climate (MIS 10) origin (cf. Bridgland, 2006). The Lower Middle Gravel consists of up to 2.5 m of medium-coarse sandy gravel, with a coarser lag deposit at the base, whereas the more variable Upper Middle Gravel is generally much finer, typically consisting of cross-bedded and ripple-laminated sands with thin gravels and silty clays. As a whole, the Middle Gravels can perhaps be interpreted as a typical upward-fining fluvial sequence, although an erosional contact has been observed between the two members (e.g., Wymer, 1968). These are the deposits in which the celebrated Rhenish molluscan fauna appears, as does the Acheulian Paleolithic industry (with hand axes); the Swanscombe skull was recovered from the basal part of bed IIb.

In many ways, the transition into the Phase III deposits appears to be a continuation of the fining upward sequence observed in Phase II, with the thick Upper Loam (IIIc) representing further floodplain (overbank) sedimentation. However, the localized beds IIIa and IIIb, which were recorded by Conway (1996) from the northwestern part of Barnfield Pit, have been attributed to a much colder climate, the former (IIIa) being regarded as the product of solifluction, whereas the latter (IIIb) contained structures interpreted as ice-wedge casts. This is in keeping with paleontological evidence for climatic cooling from the uppermost Phase II deposits, which some claim show evidence of cryoturbation. In contrast, the Upper Loam has been likened to an estuarine deposit, based purely on its sedimentological characteristics, which would imply a warm climate and high sea level. Unfortunately, the Upper Loam and the uppermost Swanscombe sediments in general are oxidized and decalcified and have therefore produced no faunal evidence to corroborate or reject this sedimentological interpretation. Indeed, Conway (1996) interpreted the Upper Loam as a warm-climate deposit, suggesting that it represented MIS 9, in contrast to the MIS 11 age of the Phase I and II deposits.

Schreve (2001a, b), while accepting Conway's climatic interpretation, preferred to assign these upper warm-climate sediments to a later temperate substage of MIS 11 (MIS 11a), an interpretation that was upheld by later work at Dierden's Pit (White et al., 2013).

The final widespread deposit at Swanscombe, the Upper Gravel (IIId), is interpreted as soliflucted overburden during MIS 10; from 0.9 to 1.6 m in thickness, it consists of fine to medium gravel clasts in a sandy clay matrix and has deformed ice-wedge casts as well as, in one of Conway's (1996) sections, a raft of Upper Loam. A highly localized "Higher Loam" (IIIe) has also been recorded, restricted to the southwestern part of the site; it is a horizontally bedded clayey sand with scattered pebbles, perhaps a slopewash (colluvial) deposit.

Paleontology

The various exposures at Swanscombe have yielded many important fossil assemblages, notably vertebrates, mollusks, and ostracods. These have been central to the development of biostratigraphic schemes (e.g., Schreve, 2001a; Schreve, 2001b; White et al., 2013) and the correlation of the Swanscombe sequence with other Hoxnian localities (cf. Kerney, 1971), especially given that pollen is so poorly preserved at Swanscombe. The most recent paleontological research at Swanscombe has focused on non-marine mollusk and ostracod successions from Dierden's Pit, which has shed light on several important issues. First, they provide both a firm basis for correlations with other critical sections at Swanscombe and a secure context for the occurrence of Acheulian archaeological assemblages at Dierden's Pit (see below). Second, they establish a pattern of colonization by the biostratigraphically important "Rhenish" suite of freshwater mollusks, demonstrating that these did not appear in the Lower Thames simultaneously but in an ordered sequence (White et al., 2013). Third, they clarify aspects of the sea-level history in the Lower Thames during the Hoxnian (see below). Fourth, the ostracod assemblages provide the basis for quantitative estimates of paleoclimate using the Mutual Ostracod Temperature Range (MOTR) method.

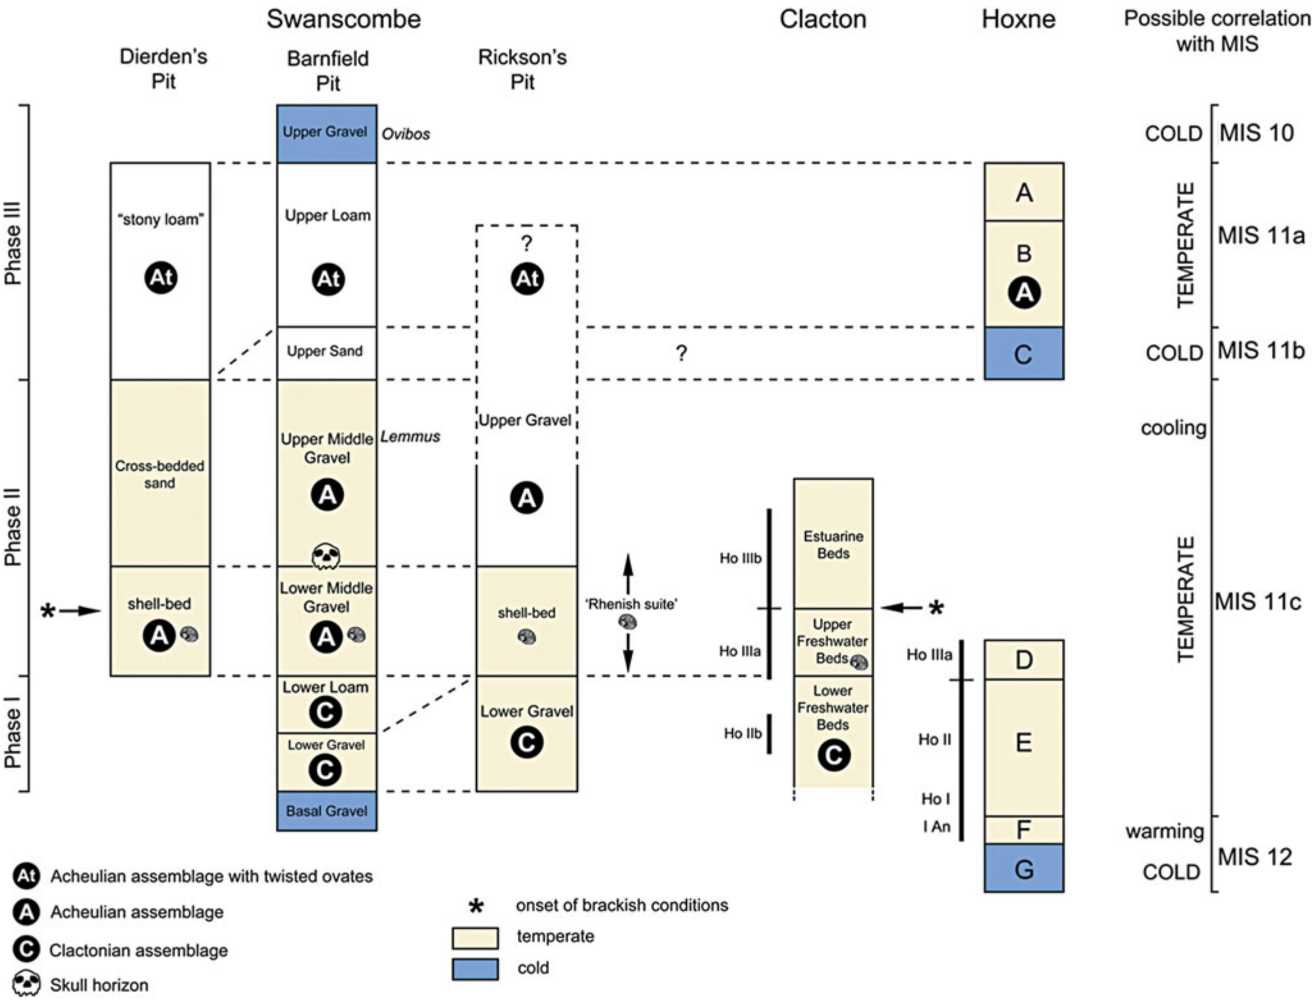
Evidence for sea-level change at Swanscombe

Brackish indicator fossils have previously been reported from Swanscombe in the form of a vertebra of bottlenose dolphin, *Tursiops truncatus* (Sutcliffe, 1964), occasional shells of hydrobiid mollusks (Kerney, 1971), and otoliths of European smelt, *Osmerus eperlanus* (Stinton, 1985). This brackish signal can now be augmented by the occurrence of the ostracod *Cyprideis torosa* (White, 2012; White et al., 2013), which characterizes the upper part of the Dierden's Pit sequence and provides a record for both the onset and strength of brackish conditions in the Swanscombe reach of the Hoxnian Thames. If the above correlations are secure, the first appearance of *Cyprideis torosa* at Swanscombe coincided with pollen substage Ho IIIa (the Hoxnian Glacial Stage is divided into four substages Ho I to Ho IV) but suggests salinities of no more than 5 ‰ (cf. Meisch, 2000; van Harten, 2000). Study of the geochemical composition of ostracod valves has provided quantitative estimates of paleosalinity at Swanscombe, confirming the minimal influence of marine waters there (White, 2012). The evidence from Dierden's Pit provides an index point for the onset of brackish conditions in the Thames and confirms that a single marine transgression can be recognized within the Swanscombe sequence.

Archaeology

Swanscombe is justly famous for its important Paleolithic record, in which Acheulian assemblages, with different types of hand axes, occur stratigraphically above deposits that have yielded a Clactonian industry (e.g., Wymer, 1968; Conway et al., 1996). This celebrated instance of Paleolithic stratification has now been supplemented with the occurrence of twisted ovate hand axes in the upper (Phase III) division of the Swanscombe sequence, whereas the middle division (Phase II) is characterized by pointed hand axes (Figures 2 and 3). Evidence from Dierden's Pit addresses some outstanding issues in the interpretation of this record. The earliest archaeological discoveries from Dierden's Pit were sharp, patinated hand axes, reportedly recovered directly from the shell bed indicated in Figure 3 as lower Phase II coeval with the Lower Middle Gravel in Barnfield Pit (Stopes, 1900, 1904; Newton, 1901; Kennard, 1916; Kerney, 1959; Wenban-Smith, 2007). However, the stratigraphic context for these Acheulian assemblages was thrown into doubt by subsequent work conducted by Smith and Dewey (1914), who failed to recover any hand axes within an assemblage of over 500 cores and flakes. This assemblage was therefore considered to be Clactonian by some authors (e.g., Wymer, 1999; McNabb, 2007), and because it was derived from the base of a "loamy pocket," it was thought to postdate the shell bed, which was consequently correlated with the Barnfield Pit Lower Gravel (Smith and Dewey, 1914; Wymer, 1999; McNabb, 2007). However, an assemblage of ∼100 cores and flakes from Dierden's Pit, some of which were identified as hand axe-thinning flakes, was recovered during the 1950s from an exposure previously examined by Smith and Dewey (Kerney, 1959). The presence of thinning flakes suggests that although the Dierden's Pit assemblages lack hand axes, they are indeed Acheulian.

Little attention has been paid to the deposits recorded above the shell bed in the southern part of Dierden's Pit, from which archaeological material was also recovered. Here, the shell bed was truncated by current-bedded sands (Figure 3) that are considered to be a probable equivalent of the sandy Upper Middle Gravel at Barnfield Pit. Above these sands a "stony loam" was recorded in the uppermost parts of Smith and Dewey's sections A, B, and D, which might therefore be equivalent to the Upper Loam at Barnfield Pit. The hand axes collected by Henry Stopes from the Dierden's Pit shell bed are typologically similar



Swanscombe, Figure 3 Correlation of the important sections at Swanscombe. Note the superposition of Acheulian over Clactonian archaeological assemblages and the later occurrence of twisted ovate hand axes. Units for which there is clear sedimentological or paleontological evidence for the prevailing climate are color-coded. Tentative correlations with the Marine Isotope Stages (*MIS*) of the deep sea record are also shown (Modified from White et al., 2013).

to those recovered in far greater numbers from the Lower Middle Gravel at Barnfield Pit (Wenban-Smith, 2009). However, the assemblage collected by W. M. Newton comprises mostly cordate and sharp, twisted ovate hand axes typical of the Upper Loam at Barnfield Pit. The occurrence of assemblages with a significant proportion of twisted ovates has been assigned to the later part of the Hoxnian (MIS 11) (White, 1998; Bridgland and White, 2014). Assemblages rich in twisted ovates have also been used as a tentative indication of an approximate MIS 11 age for the Old Milton Gravel of the River Solent, which lacks other fossil remains (Westaway et al., 2006). An important observation is that the twisted ovates from Dierden's Pit were reportedly recovered from the south side of the site at a depth of only ~1 m below the topsoil (F. Corner, in Smith and Dewey, 1914). This suggests that the twisted ovates were recovered from the "stony loam" overlying the shell bed; whether or not this represents an equivalent to the Upper Loam at Barnfield Pit remains to be seen, but it is here considered a strong possibility and a connection that has not previously been made (cf. White et al., 2013).

The archaeological succession known from Barnfield Pit has parallels at two other Swanscombe localities: Rickson's Pit (Wymer, 1968) and the Southfleet Road elephant butchery site (Wenban-Smith et al., 2006). At Rickson's Pit (Figure 3), a basal unit of coarse gravel yielded a large assemblage (~680) of cores and flakes (Chandler, 1932; Dewey, 1932; Roe, 1968a) considered to be Clactonian by McNabb (2007). This was overlain by a shell bed containing *Theodoxus* and *Corbicula* (Chandler, 1932; Dewey, 1932) that yielded ~45 hand axes (Roe, 1968a, 184) – assuming that the Middle Gravel at Rickson's Pit (sensu Roe, 1968b) is the same as the "shell bed" (bed c) of Dewey (1932). Above this, Dewey (1932) recorded an "even-bedded ochreous sand" ("brickearth" of Roe, 1968a) that yielded 12 hand axes and an upper unit of current-bedded sand and gravel from which ovate hand axes in fresh condition were obtained (Dewey, 1932, 1959; Roe, 1968a). McNabb (2007), following Dewey (1932, 1959), considered both the basal gravel and the shell bed at Rickson's Pit to be equivalent to the Lower Gravel at Barnfield Pit, on the basis of the absence of hand axes from these units. However, this correlation ignores the occurrence of "Rhenish" elements (Figure 3) in the molluscan fauna from the Rickson's Pit shell bed (Davis, 1953; Kerney, 1959; Castell, 1964), which indicates correlation with the Dierden's Pit shell bed and the Barnfield Pit Lower Middle Gravel. Moreover, the occurrence of all of the "Rhenish" species except *Viviparus diluvianus* suggests that the Rickson's Pit shell bed corresponds with molluscan biozone 4 of the Dierden's Pit sequence (see above). The molluscan assemblage from Rickson's Pit therefore provides the best evidence for relating this site with other Swanscombe localities.

The Southfleet Road site is located to the south of the other Swanscombe localities (Figure 1) and represents a tributary of the Thames. Here, the articulated remains of a straight-tusked elephant (*Palaeoloxodon antiquus*) were discovered within a gray clay, in association with a Clactonian artifact assemblage (Wenban-Smith et al., 2006; Wenban-Smith, 2013). This clay was overlain by sands and gravels containing mostly rolled hand axes. Although no molluscan remains were recovered in direct association with the elephant, shells were found within a calcareous channel fill from which struck flakes were also recovered. The molluscan fauna was similar to that recovered from the Lower Loam at Barnfield Pit and lacked any of the "Rhenish" species or those indicative of closed-canopy woodland known from the Lower Middle Gravel at Dierden's Pit. The archaeological and molluscan records from Southfleet Road are therefore consistent with those from Barnfield Pit and Rickson's Pit (White et al., 2013).

Introduction

Tells are archaeological mounds formed by the built-up remains of sequential buildings and deposits from activities and settlement in specific locations within a landscape. These mounds are of particular importance in archaeology and geoarchaeology as they represent not only places of repeated significance and habitation by human communities but also sites in which cultural and bioarchaeological materials are often well preserved due to rapid burial by deposits from subsequent activities and settlement. Tells have often been preferentially selected for archaeological investigation as they are highly visible sites, rising above the surrounding landscape, and they enable study of continuity and change in social and ecological strategies in a particular locale, often over thousands of years, as at Aşıklı Höyük, Turkey (Figure 1). These mounds, however, are only one node and source of evidence in the complex networks, cycles, and histories of communities. Many other sites are less visible and may have been eroded or deeply buried below later sediments and soils.

This examination of the geoarchaeology of tells begins with a review of their geographic and temporal distribution and their history and techniques of geoarchaeological investigation. It then examines key concepts, theories, and ethics in the study of tells before highlighting the wide range of case studies and insights provided by geoarchaeology in the investigation of these important sites. All dates are calibrated BCE.

Tell distribution, structure, and history of investigation

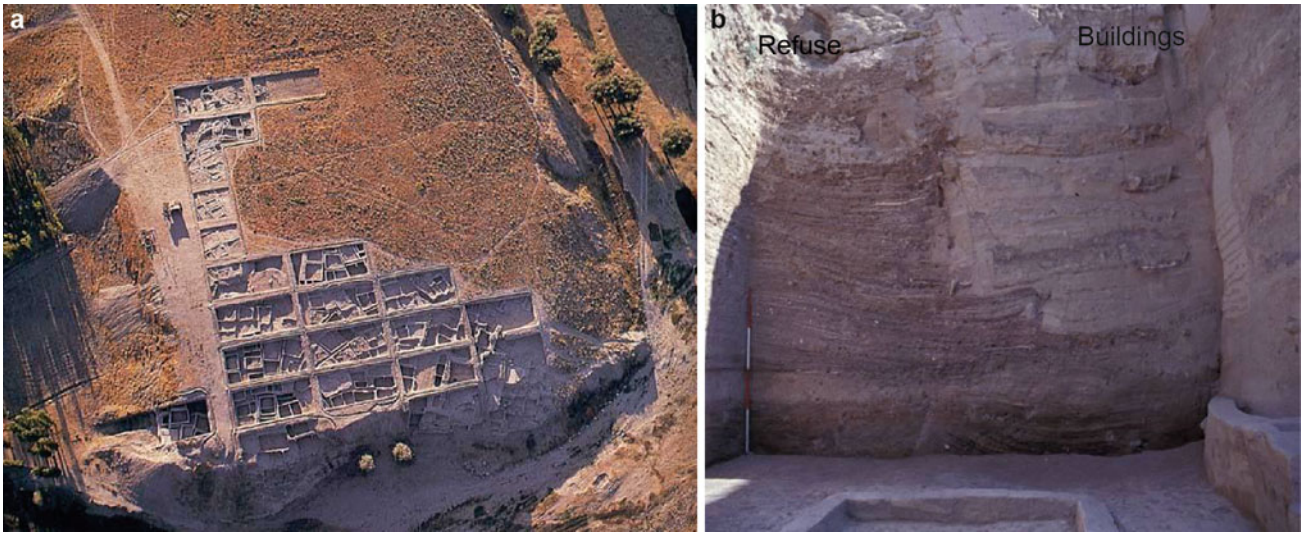
Distribution and structure of tells

The term "tell" is Arabic for mound and is commonly used in archaeology, as here, to refer to settlement mounds in a wide range of regions, including Bulgaria, Hungary, Greece, Turkey, the Levant, Egypt, North Africa, Syria, Iraq, Iran, Pakistan, Afghanistan, and Central Asia. Other common toponyms include "höyük" or "tepe" in Turkish and "chogha" in Farsi. Other types of mounds investigated by geoarchaeological research include shell mounds or middens, burial and/or ceremonial mounds, and accumulated occupation in other regions of the world. Some of the earliest tells began to form when communities became increasingly sedentary with repeated and more extended occupation at particular sites; this process began by at least ca. 12,000 BCE in the Middle East, during global warming at the end of the Pleistocene Ice Age. Tells range in size from <100 m in diameter and 2–3 m high to >1 km across and >40 m high, as at Tell Brak in Syria (Figure 2). They are highly variable in their origin, history of expansion, contraction, and abandonment, as well as in the range of activities and structures represented within them, which may include residential spaces, ritual and monumental buildings, craft and industrial areas, open areas, streets, lanes, and animal pens (Postgate, 1992; Stone, 2013).

History of investigation

Geoarchaeological research on tells began during a period of increasing scientific inquiry and analyses in

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,



Tells, Figure 1 Neolithic tell, Aşıklı Höyük, Turkey, occupied C 8400–7400 BCE; (**a**) aerial view of tell; (**b**) section showing architectural and refuse deposits (After Esin and Harmankaya, 1999, Figure 4).

Tells, Figure 2 Tell Brak, northeastern Syria, >43 m high, 1 km in length. Site areas discussed in the text are indicated on the aerial view (After Trümpler and Gerster, 2005, Figure 32).

archaeology. Some of the earliest research was conducted by Davidson at the Bronze Age tell of Sitagroi in Greece and published in the first book in archaeology that dealt specifically with geoarchaeology (Davidson and Shackley, 1976). He investigated architectural materials and sources by analyzing their particle size and the impact of human activities on the elemental composition of archaeological deposits by analysis of phosphorus. Butzer (1982) was among the first to review geoarchaeological evidence on the nature and formation of settlement mounds and their correlation with populations and their ecological strategies. One of the first systematic geoarchaeological investigations of tells was by Rosen (1986), which studied tell formation and erosion and identified micro-traces of activities. Geoarchaeological analyses have since been applied to other aspects of tells, including new social and ecological research questions, in a wide range of interdisciplinary archaeological projects, some of which are discussed below.

Concepts and theories

Knowledge of the geoarchaeology of tells is fundamental to interpretation of all archaeological materials within them. Study of mound deposits can inform on the context of all material remains, and geoarchaeology is vital to understanding the significance of those remains, as was stated by Renfrew (1976) with regard to the discipline of geoarchaeology more widely. Interdisciplinary concepts and theories are employed in geoarchaeological analysis and interpretation of tells, as their deposits comprise diverse mineral, bioarchaeological, and micro-artifactual materials, which were selected, deposited, and transformed by a range of natural and anthropogenic agencies and processes. Methods, concepts, and theories to study tells have been drawn from environmental sciences (including soil science, geology, and ecology), material and architectural sciences, and the social sciences (including anthropology and art history). Schiffer (1987) identified a wide range of natural and cultural agents and processes in the formation of the archaeological record. His research remains a fundamental guide to analysis and interpretation of the origin, deposition, and postdepositional alterations of archaeological deposits on many sites, including tells. More recent post-processual approaches consider in greater depth the social and ecological context of archaeological materials and the agency, experiences, and life histories of the individuals and communities that selected and modified the varied materials on sites.

This section discusses concepts and theories in architectural and material culture studies that are vital to geoarchaeological interpretation of the stratified settlement within tells, as mound sediments are principally made up of architectural materials and other human-modified (anthropogenic) deposits. Natural agencies and processes are discussed elsewhere in this encyclopedia. In architectural and artifactual studies, it is widely recognized that materials and artifacts are selected, manufactured, used, and discarded according to a range of ecological, technological, and cultural considerations and that contextual analysis of materials and objects can in turn inform about those very aspects of environment, technology, and socioeconomic roles and relations (Sillar and Tite, 2000; Hicks and Beaudry, 2010). The significance of particular materials can be studied using material culture approaches that examine and compare the general and the specific contexts, properties, and life histories of materials (Robb, 2010).

Regarding the interpretation of microstratigraphic sequences of surfaces and occupation deposits within tells, Kramer (1979) was one of the first to suggest that, even when few artifacts were left on floors (as is the case with many sites), archaeologists could readily identify animal pens, courtyards, kitchens, and living areas by studying the type, thickness, and frequency of surfaces and the accumulated occupation residues, as these clearly varied according to context in her ethnoarchaeological research in Iran. Her observations are supported in principle by Schiffer (1987), who established with the aid of experimental studies with McKellar (1983) that it is the smaller archaeological remains that are more likely to become traces of primary activities, as these are less easily removed by cleaning and survive in thin lenses on floors, while larger artifacts are often removed and curated. As to the value of studying surfaces, architects Leatherbarrow and Mostafavi (2002) argue that the history of particular places and the boundaries between them may be marked by and potentially traceable across surfaces. This is because individuals and communities select specific types of materials for surfaces and arrange and renew these according to the intended use of a place, and surfaces are in turn affected by later activities in that area. These principles and observations have been supported by ethnoarchaeological research in Turkey (Matthews et al., 2000a) and India (Boivin, 2000), where vivid examples have been documented of the use of different surface materials to mark particular events and places in the life history of communities. The anthropologist Bloch (2010) also argues that the study of settings, features, and buildings can inform on continuity and change in social concepts and roles and relations because these material remains, by their durable nature, are used to demarcate particular values, places, and the roles associated with them, which can be repeated and renewed or be contested and changed. Decisions in discard of materials, including residues from activities and building debris, also include consideration of the physical, economic, and cultural value of materials, such that the places in which they were deposited and the specific events, functions, and interpersonal relationships represented may be accessible to the archaeologist through analysis of depositional contexts and traces of the life histories of materials recovered (Hodder, 1987).

In summary, a geoarchaeological analysis of tells has the potential to inform us about the natural and built environment as well as the ecological and cultural strategies and practices of its former occupants by drawing upon interdisciplinary methods and theories, ethnographic comparisons, and experimental approaches.

Ethics

Many tells are excavated and studied by international teams, and it is the ethical responsibility of all concerned to respect local customs, discuss sampling strategies, disseminate results by engaging in public outreach as well as rapid publication, and to acknowledge all assistance. While some geoarchaeological analyses can be conducted in the field, many require transfer or export of samples to scientific laboratories with the permission of relevant authorities in the host country, and the country of destination usually has laws governing the importation of soil and plant materials. It is vital that all analyses be conducted following good laboratory codes of practice and that all field and laboratory samples and records be archived and made accessible for reference when appropriate. Excavation and sampling by their very nature are destructive. Extant section profiles and geoarchaeological samples, therefore, can provide archival records of deposits and features that can be revisited and reexamined as new questions, techniques, and expertise develop, both during the campaign of an excavation itself and in the longer term after the site is no longer accessible. Section profiles and geoarchaeology, therefore, have major roles to play in developing greater transparency and reflexivity in practice (Hodder, 1999).

Interdisciplinary methods in the geoarchaeological analysis of tells

A wide range of geoarchaeological techniques have been applied to the study of tells. The analytical principles and methods of many of these are discussed in other sections of this encyclopedia. This section briefly reviews examples of their application to tells in key case studies and highlights the value of multi-scalar and interdisciplinary research.

Remote sensing is widely applied to identify tells and analyze their geographical distribution and regional context in studies of human-environment relations and settlement and landscape histories (Wilkinson, 2003). The earliest technique employed was aerial photography. Satellite imagery is now applied using high-resolution CORONA and SPOT imagery, the Shuttle Radar Topography Mission (SRTM) digital elevation model, and multispectral analysis using Landsat or Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) data. Where possible, the results are tested and augmented by ground survey and geoarchaeological coring. Examples of integrated remote sensing projects on tells include those in northern and western Syria and northern Iraq (Wilkinson, 2003; Menze and Ur, 2012; Wilkinson et al., 2012), southern Iraq (Pournelle, 2007; Stone, 2013) and new projects in Iraqi Kurdistan (Ur et al., 2013).

Insights into the paleoclimate and environment of tells as well as ecological strategies of the ancient inhabitants and their environmental impact are provided by analysis of sediments, soils, and a range of multi-proxy data from landscape geomorphology, cores extracted from lakes, and cave speleothems (Fortin and Aurenche, 1998; Gasche and Tanret, 1998; Wilkinson, 2003; Djamali et al., 2010; Heyvaert et al., 2010; Deckers, 2011). As one example, the Neolithic mega-site of Çatalhöyük in Turkey was surrounded at least periodically by extensive wetlands when it was occupied, but now it currently lies within a semiarid plain (Boyer et al., 2006) (see entry on "Çatalhöyük").

Geophysical exploration is extensively applied to study the nature and variability of subsurface remains within tells and to provide a guide to excavation and sampling strategies. It has been most effectively employed in investigations of extensive areas of settlement on flatter areas of tells and in multi-proxy programs that use integrated electrical resistivity tomography, magnetometry, and ground-penetrating radar. Particularly successful applications include recovery of the plan of extensive sectors of the 3rd millennium BCE lower town at Tell Chuera, Syria (Meyer, 2007) and elite buildings and administrative areas at Kazane Höyük, Turkey (Creekmore, 2010). Geophysical analyses have also enabled a study of the multilayered structure of tell occupations at the 3rd millennium BCE site of Old Smyrna Höyük in western Turkey (Berge and Drahor, 2011).

Geoarchaeological analysis of active areas of erosion and deposition (colluviation) on tells provides insight into the topography and postdepositional alteration of mounds by prevailing winds and rain, for example (see Rosen, 1986). It can also guide archaeologists to the location of structures and deposits immediately below the tell surface, which together with ground survey of surface finds and features can assist in the choice of excavation areas. By such methods, it was possible to pinpoint hitherto underexplored levels of early 3rd millennium BCE date at the large multi-period site of Tell Brak, Syria (Matthews, 2003a). Surface scraping with a hoe to remove shallow topsoil has proven particularly effective in the ground truthing of geophysical surveys (Matthews, 1996) and in uncovering large sectors of tells that were abandoned at particular time periods and not subsequently occupied. More than one-third of the 3rd millennium BCE urban settlement at Tell Abu Salabikh in southern Iraq has been planned by the use of surface scraping, enabling highly targeted excavations and geoarchaeological analysis of a diverse range of industrial, administrative, and residential areas in studies of the anatomy and socioeconomic structure of a Sumerian city (Matthews and Postgate, 1994).

Opportunities for geoarchaeological analysis of the buildings and stratigraphy within multi-period tells are best provided by a combination of open-area excavation to examine architectural plans over a substantial horizontal tract and step trenches at the edge of a mound or in deep soundings to study settlement and community history

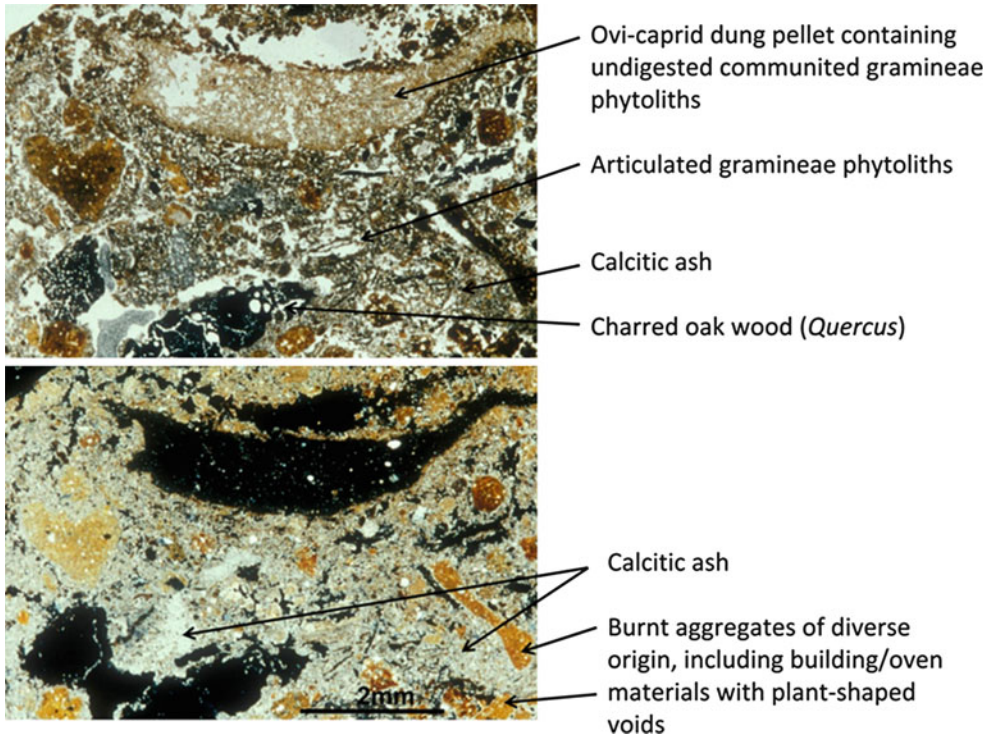
Tells, Figure 3 Multi-scalar approaches linking field and microscopic analyses. Intact block removal from floor deposits and final large resin-impregnated thin section and photomicrograph (Plane-polarized light (PPL)) of fine plastered floors within a Neolithic building, Jani, Iran (Matthews et al., 2013b).

through time. Other opportunities may be provided by analysis and sampling of section profiles through mounds that were cut by river and stream erosion, or road building, as, for example, at the Neolithic site of Jani, Iran (Figure 3; Matthews et al., 2013a). Large section profiles are also available for sampling from older, often large-scale, excavations that can yield significantly enhanced information by the application of new scientific analyses, as at the Neolithic site of Çatalhöyük, Turkey (Matthews et al., 1996). All microscopic or geochemical analyses need to be closely linked to macroscale analysis and recordings of deposits in the field (Courty et al., 1989; McAnanay and Hodder, 2009).

During excavation, it is particularly important that geoarchaeological sampling strategies be discussed with excavators to ensure, first, that samples do not impede nor disrupt excavation aims and objectives and, second, that adequate spot/bulk and intact block samples are collected at key spatial as well as temporal intervals across different rooms, buildings, and areas (Canti, 1995; Farid, 2000; Matthews et al., 2000b). Sampling intervals will vary according to research aims, objectives, analytic and funding resources, as well as macroscopic observations of spatial as well as temporal variations in the character of deposits. Where buildings are small and field analysis of the features and deposits indicates that many different activities were conducted within each space, geoarchaeological sampling intervals may be as frequent as every 0.5–1 m, as has been the case within selected buildings at Çatalhöyük, Turkey (Matthews, 2005a), and Saar, Bahrain (Matthews and French, 2005). Section profiles provide key insights into microstratigraphic histories and may be analyzed at the edge of excavation trenches or gridded squares ca. 1–4 m^2 in size; in half-sections through rooms, areas, or features; or in strategically placed baulks and plinths, ca. 30 cm wide. It is vital that all section profiles be regularly cleaned and examined during excavation and geoarchaeological analysis to enable clear observation of the composition and stratigraphic variation within the deposits as well as the relationships between strata. In order to obtain the sharpest and clearest section profiles, given the complexity and thinness of many deposits on tells, it is recommended that an artist's palette knife be used to cut cleanly through strata and features, followed by removal of dust with a photographer's "rocket" air blower and/or large board for wafting, using a dust mask for health and safety.

Canti (1995: Figure 1) summarizes the strengths and limitations of geoarchaeological analyses that are relevant to tells, as well as differences between micro-contextual analyses of intact block samples (lifted as an undisturbed block) and bulk analyses of loose disaggregated spot samples. With regard to analyses of intact block samples, microscopic analysis of intact depositional sequences in large resin-impregnated thin sections, up to 14 × 7 cm in size, at ×25–400, is proving particularly powerful in analysis of tell deposits (Figure 3), in combination with microanalyses such as scanning electron microscopy coupled with microprobe analyses (e.g., SEM-EDS/X), infrared (IR) and Raman microscopy, synchrotron radiation source micro-IR, micro-X-ray diffraction (XRD), and micro-X-ray fluorescence (XRF) (Courty et al., 1989; Matthews et al., 1997a; Stoops, 2003; Weiner, 2010; Mentzer and Quade, 2013; Anderson et al., 2014). These micro-contextual approaches enable simultaneous high-resolution analysis of diverse mineral, bioarchaeological, and micro-artifactual components and their precise depositional and contextual relationships that are critical to an accurate interpretation of their significance. Many diverse components and depositional lenses are either bulked together or irreversibly separated during standard excavation and sampling procedures. Micro-contextual analyses enable resolution of individual components and depositional units that are not recoverable nor even detectable during routine excavation and sampling, due to their exceedingly fine scale, often <0.1–5.0 mm. Such approaches are thereby providing new high-resolution data on the materials and microstratigraphic histories of tells, examples of which are illustrated in selected case studies below.

One important advantage of micromorphological analyses of tell deposits is that they enable identification of a much wider range of plant types, parts, and materials than other geobotanical or archaeobotanical analyses can accomplish on their own. Most current archaeobotanical

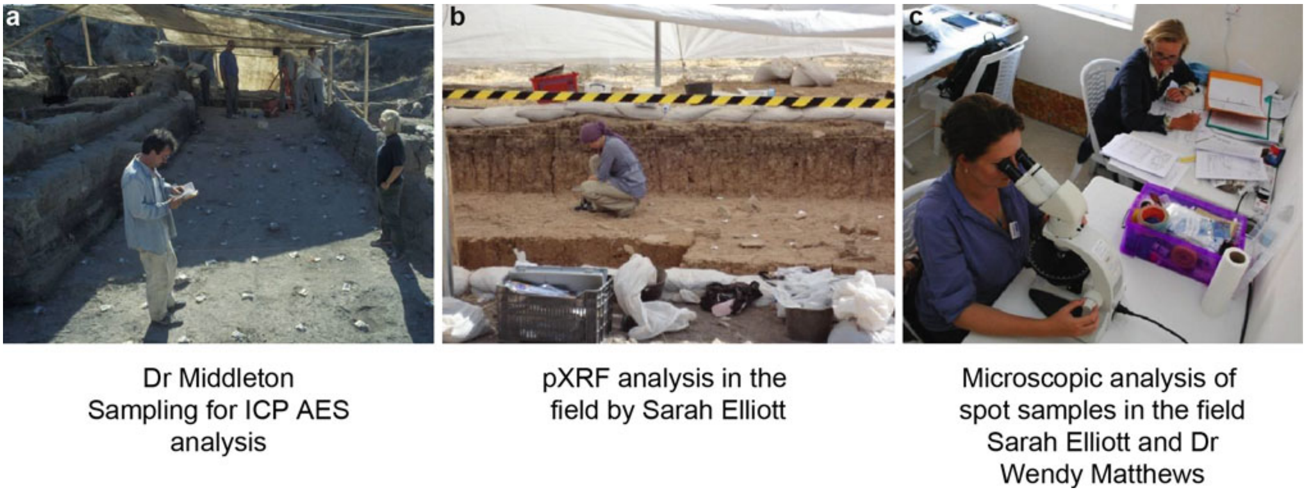


Tells, Figure 4 Diverse plant remains and dung preserved in micromorphological thin sections. Çatalhöyük, fuel in fire-installation, 'Shrine' VIII.25, South Area (PPL (upper); cross-polarized light (XPL) (lower) (Matthews, 2010; Figure 3).

analyses conducted on tells focus largely on charred plant remains recovered by water flotation; this retrieval method yields plants that have been burned at low temperatures, <400 °C. In large resin-impregnated thin sections, it is possible to identify a much broader array of plant materials, including waterlogged or humic plant remains, impressions of plants, silica phytoliths, melted plant silica, calcitic plant ashes, pollen, as well as charred plant remains (Figure 4) (Matthews, 2010; Shillito, 2013). As illustrated in case studies below, plant remains constitute a surprisingly abundant and diverse component of tell deposits, and integrated micro-contextual analyses are providing exciting new insight into the many activities and materials preserved within agricultural and urban sites from as early as ca. 10,000 BCE.

An increasing range of instruments has enabled in situ analysis of tell deposits directly in the field or in field laboratories, providing key data for immediate feedback that can inform ongoing excavation and sampling strategies (Figure 5; Weiner, 2010). One of the more widely used techniques is portable X-ray fluorescence (pXRF) analysis in order to determine the elemental composition of materials (Emery and Morgenstein, 2007) or traces of activities (Frahm and Doonan, 2013; Matthews et al., 2014; Elliott et al., 2015). Spot samples of deposits mounted in clove oil or mineral oil may also be examined using a polarizing light microscope to analyze traces of phytoliths, calcareous dung spherulites, starches, or other mineral and bioarchaeological constituents that can be crucial in identifying specific features such as an early animal pen at Çatalhöyük (Matthews, 2005a) and to inform subsequent sampling. Other field techniques include terahertz imaging to study subsurface layers, such as paintings situated below layers of plaster also at Çatalhöyük (Walker et al., 2013).

Many geoarchaeological analyses are applied to spot and bulk samples in specialist laboratories to characterize the origin, deposition, and postdepositional alteration of materials and deposits recovered from tells. Under controlled conditions in the laboratory, individual components and layers in block samples may be subsampled prior to resin impregnation in order to provide even greater precision in correlating results from spot/bulk samples with high-resolution micromorphological analyses in thin section (Shillito and Matthews, 2013). Elemental analysis by XRF or inductively coupled plasma mass spectrometry (ICP-MS) is used to characterize source materials for provenance studies and to determine the presence of elemental enhancement or depletion in tell deposits by comparing results with those of natural, ethnographic, or experimental materials – see the studies by Middleton et al. (2005) and Davidson et al. (2010) below. Other analyses include particle size to study sources of architectural and natural materials (Davidson and Shackley, 1976) and gas chromatography-mass spectrometry (GC-MS) to identify biomarkers of human and animal feces and lipids



Tells, Figure 5 Geoarchaeological sampling and analyses in the field; (**a**) William Middleton sampling for ICP-AES analysis; (**b**) pXRF analysis in the field conducted by Sarah Elliott; (**c**) microscopic analysis of spot samples in field laboratory by Sarah Elliot and Wendy Matthews.

within settlements and their ecological, dietary, and social significance (Bull et al., 2005; Shillito et al., 2011). Bioarchaeological analyses include study of spot samples of plant silica phytoliths and ashes (Rosen, 1992; Albert et al., 2008; Shillito, 2013). Analyses of residues from combined wet screening and flotation provide a larger comparative sample size of selected microarchaeological remains for study of activity areas (Rainville, 2005; Saeedi, 2010; Parker and Foster, 2012).

Interpretation of results from these analyses requires access to archives and atlases of key reference materials and comparanda to identify components and evaluate similarities and differences. Analyses of local and more distant sediments and geologic samples are conducted to characterize potential source materials and environments. Ethnoarchaeological and experimental studies have aided geoarchaeological investigations of tells. These have included analyses of the composition, technology, frequency, and significance of plastering (Boivin, 2000; Matthews et al., 2000a) and analyses of the origin, morphology, and taphonomy of deposit constituents such as phytoliths (Tsartsidou et al., 2008, 2009), ash (Shahack-Gross and Ayalon, 2013), and animal dung (Shahack-Gross, 2011; Elliott et al., 2015). To examine patterning in the types of materials, surfaces, and residues on tells, many researchers have identified and classified deposits according to key types (facies) and properties (Matthews et al., 1997a; Maghsoudi et al., 2014).

Robust dating programs and modeling are required to evaluate the time intervals represented by specific depositional units and sequences on tells. An intensive high-resolution ^{14}C dating program and Bayesian model is currently being constructed to date the history of buildings and key societal changes at the mega-site of Çatalhöyük, 7100–6000 BCE (Bayliss and Farid, 2012). Estimates of the timescales represented by individual strata and sequences can be calculated by counting the number of layers within well-dated stratigraphic horizons, as at Çatalhöyük (Matthews, 2005b). Although this approach can suggest that the duration of each unit was the same, it follows routine procedures in the environmental sciences, such as the counting of lake varves, for example, and minimally, it provides an estimate of the order of time represented by a sequence. There could be greater application of age-depth models to tells, building on Davidson et al. (2010).

In summary, tells comprise highly complex materials and microstratigraphic sequences formed by diverse agencies and processes, and thus they require interdisciplinary analytical strategies to understand the rich cultural and environmental remains and continuity and change in human occupation at these repeatedly occupied sites. An effective way to study the geoarchaeology of tell sites is to apply a - multi-scalar approach that links field observations and records of section profiles, plans, and sample locations with geomorphological, geophysical, microarchaeological, micromorphological, bioarchaeological, geochemical, and mineralogical analyses.

Geoarchaeological analyses of tells in practice: selected case studies

The following sections review selected case studies to illustrate the range of geoarchaeological analyses conducted on tells. They reveal the characteristics and significance of specific components, materials, features, and contexts at particular sites, and they show how analyses can inform on key research questions in the study of site histories and ecological and social strategies. The discussion begins with examination of architectural materials, occupation deposits, and commonly occurring features and contexts that include fire installations, animal pens, and burials. It then considers the histories of buildings and their destruction, and industrial areas, open areas, and middens. It concludes with a consideration of natural agencies and postdepositional alterations that affect tell deposits.

Architectural materials: mudbricks, mortars, and plasters

A considerable proportion of ancient settlement mounds comprise either in situ architectural materials in walls and buildings or the leveled or collapsed debris from these former structures. Geoarchaeological analyses have been applied to investigate the source, technology, and social significance of architectural materials and the structures in which they were used. Many architectural materials can be identified by their context, form, and composition. Many mudbricks and plasters contain reworked and often homogenized natural or anthropogenic sediments, or a mixture of both, often with traces of vegetal and mineral temper to provide tensile strength and flexibility. For an introduction to modern earthen materials and construction, see Houben and Guillaud (1989).

Mudbricks

Many walls built on tells were constructed from rammed earth or shaped mudbricks and mortar, even where stone was available. Mudbricks at the Neolithic mega-site of Çatalhöyük have been examined using micromorphology, XRD, XRF, particle size, loss on ignition, and magnetic susceptibility, and the results have been compared to analyses of locally available materials. Studies by Tung (2005) and Love (2012) established that there was significant variation in the materials and methods of manufacture between different buildings, suggesting that choice of materials and building traditions were organized at the scale of individual households. Unworked aggregates of original source materials indicate that many of the later mudbricks on the site were manufactured from alluvial deposits (Matthews et al., 1996).

At tells dating to later periods, geoarchaeological analyses have been applied to examine whether architectural materials and structures were the product of large-scale projects and organized labor. At the Egyptian site of El Hibeh, 1064–664 BCE, portable X-ray fluorescence (pXRF) analysis established that the necropolis walls were built from two local sources of sediment by organized groups of laborers working systematically from two opposing corners of the building, providing the first evidence of organized work parties in construction of mudbrick structures in Egypt (Emery and Morgenstein, 2007). Microscopic, mineralogical, and chemical analyses – XRD, XRF, and neutron activation (NAA) – of mudbricks from three Bronze Age sites in East Crete by Nodarou et al. (2008) indicate that although locally available materials were used, there was some cross-community standardization in the manufacturing process. Analysis of Roman and Islamic bricks from Thamusida, Morocco, by Gliozzo et al. (2011) has highlighted more complex production and distribution of architectural materials, with some evidence for importation of bricks in the first century AD, perhaps linked to wider trade networks and use of bricks as ballast.

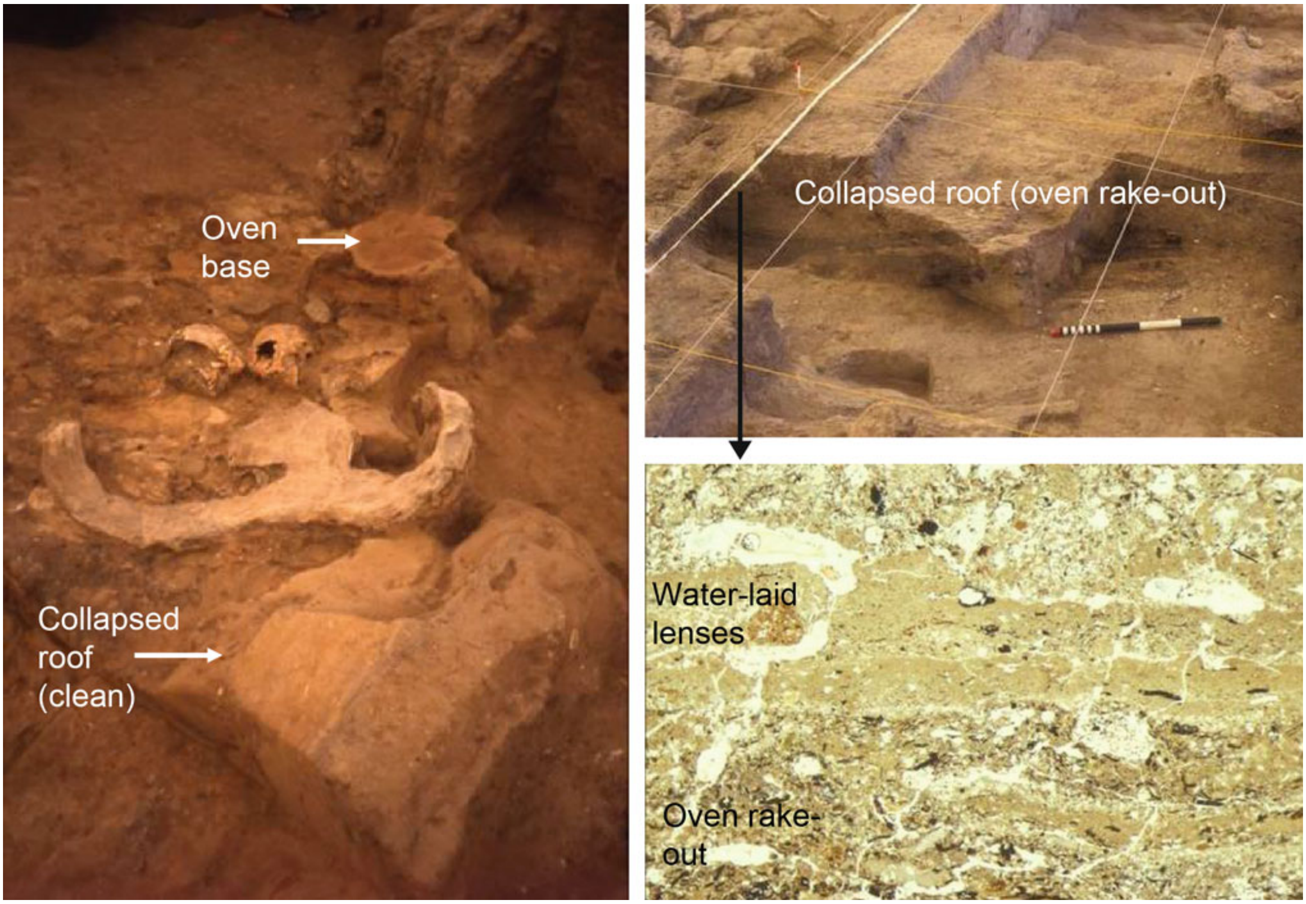
Roofing

Remains of roofing appear to be remarkably rare on tells. They appear mostly to have been reworked during leveling and infilling of buildings. Some of the earliest known roofing that is likely to have afforded year-round and not just seasonal occupation, marking a major transition toward sedentism, has been identified at Tell Qarassa, Syria, by micromorphological, phytolith, and wood charcoal analyses (Balbo et al., 2012). This durable roof was constructed from substantial radial timbers and sedges covered by a layer of grasses and then a thick daub coating with plant temper that would have reduced shrink-swell during wetting and drying and lightened the weight load.

Large, rare slabs of collapsed flat roofing, up to ca. 1 m in length from the later Neolithic of Çatalhöyük, have been analyzed using micromorphology, and the results have identified remarkable spatial and seasonal variation in rooftop activities by study of the multiple sequences of surfaces and occupation in these roof slabs (Figure 6; Matthews, 2012). This research established the presence of a roofed upper story room, as well as an open area on the roof that was used, among other activities, for seasonal cooking probably in warmer drier months, as the fuel rake-out next to an oven was periodically covered by lenses of undisturbed rainwash sediment and crusts that probably accumulated in the winter when the oven was not used. These results highlight the range of activities for which evidence is usually missing in analyses of ground floor plans alone, and they clearly demonstrate the importance of roofs in social interaction as well as food production and processing.

Plasters

The production of fired lime plaster represents one of the earliest manufactured construction materials, used from at least 12,000 BCE to pave surfaces within cave sites and in early Neolithic sites to pave floors and model plaster skulls (Kingery et al., 1988). Distinction between fired and non-fired lime plasters using optical microscopy, SEM EDX, and XRF, however, remains problematic, as both materials have the same mineralogical composition. Regev et al. (2010a, 2010b) have developed an integrated method for distinguishing between non-fired and fired lime and for identifying hydraulic lime. They used FTIR (Fourier transform infrared) spectroscopy and IR microscopy to identify structural changes in minerals affected by heat from firing, in conjunction with acid dissolution, XRF, XRD, micromorphology, and SEM-EDS, at the Iron Age site of Tell es-Safi. Mentzer and Quade (2012) have applied integrated micromorphological, compositional analysis of major and minor trace elements using micro-XRF and oxygen (δ^{18}O) and carbon (δ^{13}C) stable isotopic



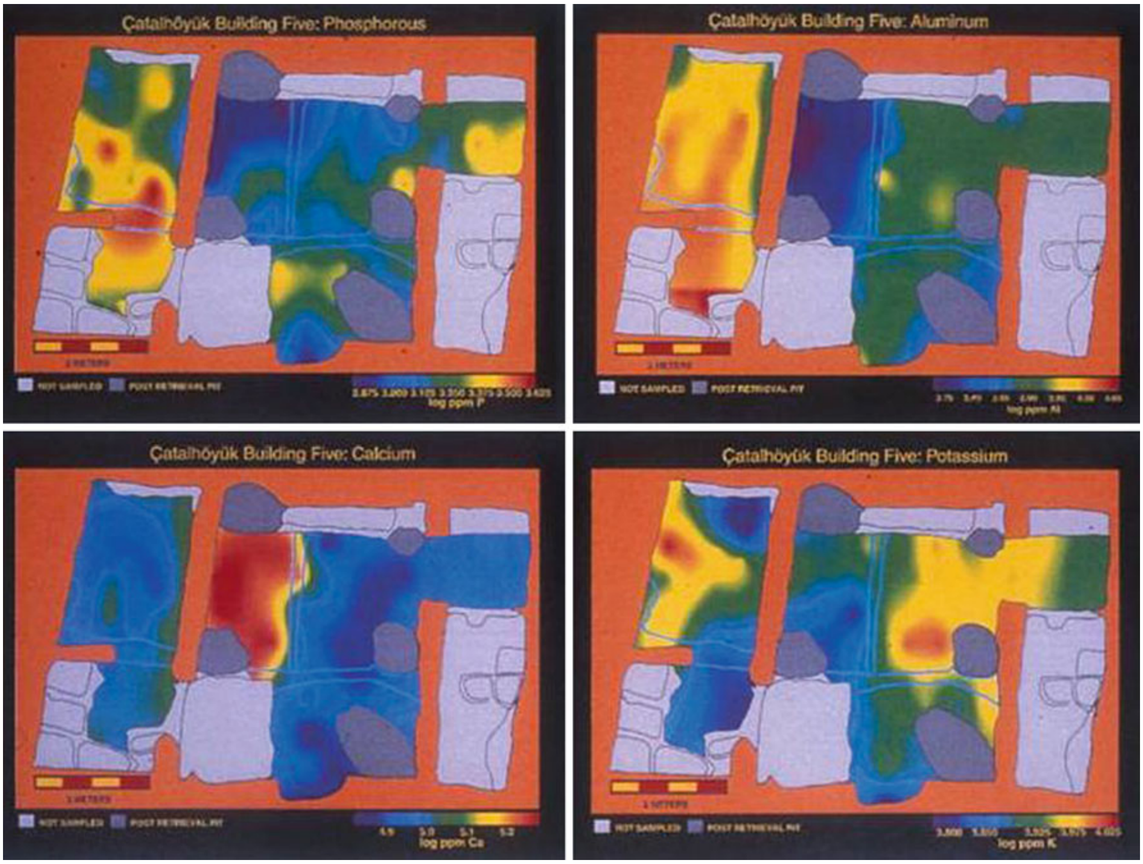
Tells, Figure 6 Collapsed roof: Cycles of oven rake-out and water-laid deposits from periodic cooking on the roof, Building 3, Çatalhöyük, Turkey, ca. 6500 BCE (PPL) (Matthews, 2012).

analyses to distinguish between calcareous ash and lime plasters at the early Neolithic site of Aşıklı Höyük in Turkey. Micromorphology, microanalysis, and 3D mapping of multiple layers of wall plasters and pigment at the Neolithic site of Çatalhöyük are enabling identification of the specific materials that were selected for surface materials and paintings and their probable symbolic significance (Matthews, 2005a; Matthews, 2005b; Matthews et al., 2013b; Anderson et al., 2014). Field and micromorphological analyses of the arrangement and frequency of plasters at a number of sites suggest that these surface materials were used to define particular activity areas and to mark specific events. The evidence for this is discussed below in the section on life histories of buildings in conjunction with consideration of spatial and temporal variation in occupation deposits.

Occupation deposits

As on other types of archaeological site, accumulated occupation deposits from activities on tells comprise diverse materials introduced by many natural and anthropogenic agencies and processes (Schiffer, 1987). As many, but not all, tells are located in semiarid regions, the materials preserved are generally only those that can survive in an oxidizing environment. Some of the most commonly occurring non-burned and burned materials in geoarchaeological samples include rock fragments, minerals, and sediments; aggregates from natural and anthropogenic materials and deposits; fragments of architectural materials or micro-artifacts such as ceramics and lithic debitage; diverse plant species, parts, and materials; food remains; coprolites from humans and animals; other bioarchaeological remains including fragments of animal bone (including fish and bird), mollusks, and microfossils; and a range of postdepositional materials and features discussed below. The associations of these materials with specific activities are discussed in the following sections.

Multielement analyses have been used to characterize occupation deposits on tells with the aim of identifying specific groups of elements that can be linked to particular activities, as at the Neolithic site of Çatalhöyük, Turkey, by ICP-AES (inductively coupled plasma atomic absorption spectrometry) (Figure 7; Middleton et al., 2005). ICP-AES analyses at the Late Bronze Age and Early



Tells, Figure 7 Elemental analysis of floors and activity areas, Building 5, Çatalhöyük (Middleton et al., 2005; Figures 20.1–4).

Iron Age tell of Zenobia in Greece by Davidson et al. (2010) established that contexts were most clearly differentiated on the basis of their phosphorus (P) and chromium (Cr) content, and that elemental loads were highest in occupation deposits overlying floors and in pit fills, and that they were lower for roads, alleys, and yard contexts. At the Classical-Hellenistic site of Düzen Tepe, Turkey, ICP-OES (inductively coupled plasma optical emission spectroscopy) analyses by Vyncke et al. (2011) enabled the identification of cooking and hearth areas, a latrine, and an area of high traffic, for example. Given the diversity of materials and depositional pathways on tells, however, no widely applicable diagnostic criteria have been established. Local variability in elemental composition and sources of materials must be evaluated and further experimental, ethnographic, and geoarchaeological analyses conducted at a range of site types to establish more fully the significance of elemental variation in occupation deposits (Wilson et al., 2009).

Fire installations

Fire is used in many activities on tells, including for daily food processing and cooking, heating and warmth, production of architectural materials such as fired lime or baked bricks and tiles, manufacture of artifacts such as pottery and metal objects, as well as ritual practices. Geoarchaeological analyses have been conducted to investigate (1) sources of fuel and their environmental and ecological implications; (2) use of specific fire installations by studying fuel type, burning temperatures, and residues in and around hearths; and (3) technologies and scales of production, with reference to ethnoarchaeological and experimental studies.

Mentzer (2014) provides a particularly comprehensive review of the wide range of analytical techniques that have been applied to the study of combustion features and the residues from these. Her research shows that, to date, more geoarchaeological studies have been conducted to investigate Paleolithic fire installations than those of later periods, partly because combustion features were a principal focus of activities within cave sites in particular, and they are often among the better preserved features. She provides some examples of burned plant remains from the early Neolithic site of Aşıklı Höyük, Turkey, and explores the characteristics of calcitic ashes further in Mentzer and Quade (2012).

Later Bronze Age and Iron Age fire installations in the Levant have recently been systematically analyzed by

Gur-Arieh et al. (2014) using a range of analyses building upon studies by Berna et al. (2007) and Weiner (2010). In their integrated study, micromorphological analysis was used to identify fuel types and its depositional context and sequence of burning in conjunction with analyses of spot samples of phytoliths and dung spherulites. The principal fuel identified across all sites was wood mixed with some dung, suggesting that this was the preferred source of combustible material across different environments and cultural groups in the Levant. FTIR spectroscopy established that temperatures up to 900 °C could be reached using this mixed fuel in these early urban mud-constructed installations.

Greater variation in the selection of fuel, however, has been identified by micromorphological analysis of the diverse plant remains from a range of hearths and ovens sampled along a geobotanical transect through other regions of the Middle East, with some evidence of variation in selection or access to fuel in different regions as well as by different households and during the life cycle of individual households (Matthews, 2010). Generally, in more temperate steppe-forest regions, wood was used as a significant source of fuel, in conjunction with reeds, grasses, and animal dung, as at the Neolithic site of Çatalhöyük in Turkey (Figure 4). In the more steppic regions of northern Syria and southern Iraq, where there were few trees, there was much greater use of reeds, grasses, and animal dung as fuel, preserved predominantly as phytoliths and calcitic ash, as at the 3rd millennium BCE early urban sites of Tell Brak and Abu Salabikh. On the steppic and desertic island of Bahrain with coastal mangroves, date palm leaflets were widely used as fuel, preserved predominantly as silica phytoliths, which are rarely recoverable by flotation as they burn leaving little residual carbon (Nesbitt, 1993). Integrated geoarchaeological and archaeobotanical analyses, therefore, are making a significant contribution to our knowledge of early agricultural and urban ecology and fuel and plant use at tells across the ancient world.

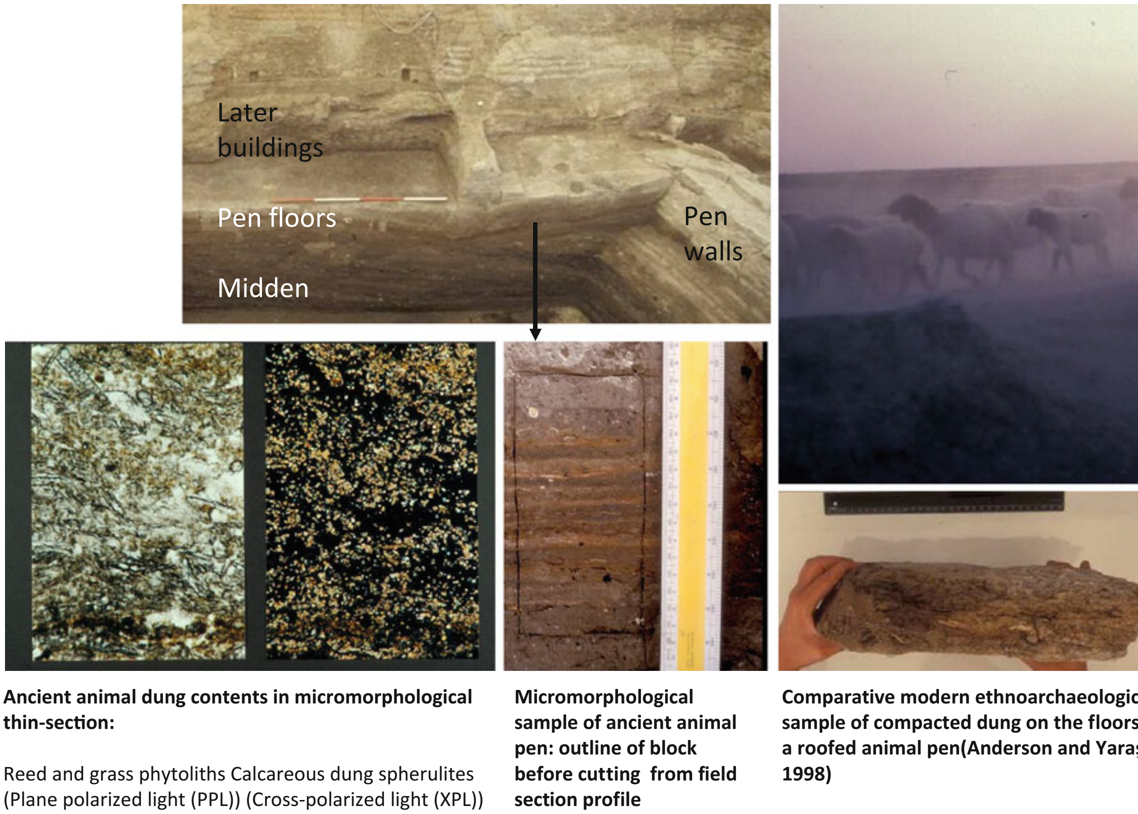
Animal dung and penning

Animal dung is difficult to identify in the field and in bulk archaeobotanical assemblages of charred remains. Dung often fragments during combustion, and its plant contents are released, making it difficult to establish whether the plant residues recovered from tells derive from animal or human consumption, or other human activities (Miller, 1996). Animal dung, however, can be securely identified by micromorphological analysis of dung form, contents, and calcareous spherulites that form in the guts of animals during digestion (Courty et al., 1989; Brochier et al., 1992; Canti, 1999) and by GC-MS identification of coprostanols and bile acids that are species specific (Bull et al., 2005). On tells, these analyses have been complemented by (1) portable XRF analysis of excavated surfaces to detect elevated levels of phosphate in the field, which may indicate the presence of dung residues and can thus serve as a guide to where to sample for better preserved dung, and (2) integrated phytolith analysis to study animal diet, ecology, and seasonality (Figure 8; Albert et al., 2008; Matthews et al., 2013b, 2014; Portillo et al., 2014). As outlined in the methods section above, animal dung can also be readily identified in the field by microscopic analysis of spot samples of deposits, as it is recognizable by the presence of dung spherulites; excavation and other sampling strategies can then be adjusted accordingly, as at Çatalhöyük, Turkey (Figure 5; Matthews, 2005a).

Application of these integrated geoarchaeological analyses to identify animal dung is contributing significantly to our understanding of the origins of agriculture in the Middle East, which is one of the heartlands of the world where many of the animals that we rely on today (goat, sheep, pig, cattle, and dog) were first domesticated. The earliest traces of domestication cannot be recognized by the study of animal bone morphology alone, as changes in species size may not be detectable for more than 1,000 years after domestication (Zeder, 2009). Zooarchaeological research has relied instead upon the detection of changes in kill-off patterns to identify evidence of management strategies. More recently, however, close proximity of animals to sites as well as management of animals by humans has been securely established by identifying the presence of animal dung at several Neolithic tells using integrated geoarchaeological analyses (Figure 8; Matthews, 2005a; Matthews et al., 2013a; Matthews et al., 2013b; Stiner et al., 2014). The identification of animal dung in pens, in open areas, and as a major source of fuel is revolutionizing our knowledge of human-animal interrelations and ecology at the origins of agriculture and early settled life as well as during the later development of cities and early states (Matthews and Postgate, 1994; Matthews et al., 2001; Shahack-Gross, 2011).

Burials

The InterArchive project (InterArchive, 2012) is currently investigating new high-resolution traces of human burial practices and rites by integrated micromorphology, geochemistry, and mineralogical analyses, and this research includes study of tells such as Çatalhöyük. Previously, geoarchaeological analyses of burials on tells have been limited. One exception is the large interdisciplinary investigation of a royal tomb complex at Qatna, Syria (Pfälzner et al., 2013). Another relevant case study is Karkanas et al.'s (2012) investigation of mortuary practices through the study of tomb preparation, burial and memorial rites, and reuse, as depositional acts and events in an integrated field and micromorphological study of the multiuse of Mycenaean chamber tombs at Ayia Sotira, Greece. They established that the floor of the tomb was plastered during construction and reuse and that the tomb was not left open for long between uses as there was little sediment accumulation on the floors. They were also able to identify sequences of backfilling and reopening by studying



Tells, Figure 8 Animal dung in a pen and traces of early animal management at Çatalhöyük, ca. 7000 BCE (Levels XII–XI and VIII) (After Matthews 2005a, Figures 19.25 and 19.26; Matthews et al., 1996, Figures 15.19 and 15.20). *Lower left*: Ancient animal dung contents in micromorphological thin section; reed and grass phytoliths (PPL) and calcareous dung spherulites (XPL). *Lower middle*: Micromorphological sample of an ancient animal pen; outline of the sediment block before cutting it from the field section profile. *Lower right*: Comparative modern ethnoarchaeological sample of compacted dung on the floor of a roofed animal pen; see also Anderson and Ertuğ-Yaraş (1998).

deposit particle size, bedding, and erosional surfaces, providing a framework for understanding the complex sequences of mortuary rites and their wider social significance.

Houses and life histories

One of the first comparative geoarchaeological studies of buildings on tells was conducted at four early urban settlements across the Middle East to investigate the potential of microstratigraphic and micromorphological analyses and to identify and compare traces of activities in different environmental and sociocultural contexts (Matthews and Postgate, 1994; Matthews et al., 1997a). This research was conducted in consultation with Dr Marie-Agnès Courty and Dr Richard Macphail and in collaboration with plant anatomists from Kew to help with identification of the diverse plant remains in thin section, which are one of the most abundant residues of ancient activities on tells. These studies reinforced the value of the new microstratigraphic and micromorphological approaches in analyzing the complex genesis of archaeological deposits through simultaneous study of the diverse components of site earth in their precise depositional context at a resolution not possible with routine excavation and sampling (Courty et al., 1989). They also demonstrated the potential for integrating micromorphological analyses with analysis of microarchaeological residues from wet sieving and flotation, which is widely applied in studies of households (Rainville, 2005; Saeedi, 2010; Parker and Foster, 2012).

These analyses established new diagnostic criteria for identifying specific types of activities on tells and within buildings according to (1) the type, thickness, and frequency of surfaces and (2) the impact of activities on them as well as the residues left on them as determined in the field and later at higher resolution in thin section (Matthews and Postgate, 1994; Matthews et al., 1997a: Table 2, Figure 3). Irrespective of variation in local resources and the scale of cultural complexity and technology, general trends were identified in the selection, placement, and frequency of surfaces for particular areas, and regularities were observed in the types and abundance of residues that accumulated within these areas. Such patterns were suggested in ethnoarchaeological research by Kramer (1979) and by Schiffer (1987) and supported by subsequent theory and research in architecture (Leatherbarrow and Mostafavi, 2002) and archaeology (Bloch, 2010; Robb, 2010), as discussed above. In addition, these microstratigraphic and micromorphological analyses enabled the study of specific and contingent histories of particular buildings and communities on tells at unprecedented temporal resolution by analyzing previously unresolvable single depositional units that were <0.012–5 mm thick and representative of specific events on the order of monthly-seasonal and longer timescales.

In summary, key characteristics and emergent criteria in the identification of specific types of activities and areas include the accumulation of (1) multiple layers of fine plaster, often with traces of mats/coverings, and few occupation residues in reception/sitting rooms or areas; (2) thick layers of packing resistant to insects and rodents and either residues of stored items or scoured surfaces following removal of these in food storage areas; (3) some or rare medium-coarse plasters and periodic fuel rake-outs and occasional sweepings in food preparation and cooking areas; (4) either paved or unpaved surfaces depending on sociocultural context, occasional traces of wind or water-laid deposits, and diverse residues from specific activities in courtyards; (5) reworked and fragmented surfaces and deposits in trampled areas within entrances and rooms of courtyards; and (6) selection of often rare or exotic materials to mark the place or event, including exceptional plaster sources or washes of pigments (often red) or scattering of pigments and specific materials, in ritual areas or in association with events relating to ritual. What tends to vary within each area, building, and community are the source and type of materials, and the articulation, organization, and scale of construction and events, according to environmental and sociocultural context.

The following section briefly summarizes selected specific observations on the particular histories of buildings at each of the four tells and their wider significance. At the Neolithic mega-site of Çatalhöyük, it was established that while many buildings had ritual features such as wall paintings, sculptures of animal heads, and subfloor burials, these buildings were not "shrines" but also housed a full range of residential activities, highlighting and documenting the proximity and history of "domestic" and "ritual" practices (Matthews, 2005b; Hodder, 2010; Matthews et al., 2013b). The repetition of similar patterns across different houses, and through many phases of the sites, suggests considerable conformity, predictability, and continuity in social roles and relations that are likely to have been important factors in the longevity of occupation at this large ca. 13 ha and 20 m high tell. The end life of the buildings, however, was more varied and contingent, ranging from dismantlement and immediate rebuilding suggesting continuity to destruction by fire or use as a human latrine (confirmed by GC-MS) and midden suggesting social discontinuity (Matthews, 2005a). New studies are examining the resource management, use, and ecology of individual houses at this and adjacent sites (García-Suárez, 2014), as well as other Neolithic sites in the Central Zagros (Matthews et al., 2013).

At the ca. 2500 BCE Sumerian city of Abu Salabikh in southern Iraq, there was greater differentiation in building size and number of rooms. Even the smallest buildings, however, had at least one larger well-plastered and clean reception room, highlighting the importance of this social space, in addition to areas for storage, food preparation, cooking, ritual, as well as courtyards and latrines (Matthews and Postgate, 1994). By contrast, many buildings at Tell Brak were monumental in scale (discussed below). At the trading settlement of Saar, Bahrain, ca. 1800 BCE, excavation and sampling in 1 m^2 grid squares revealed remarkably clear separation yet close proximity of a wide range of household activities within the small two-to-three roomed buildings; repetition of this pattern within houses and across houses suggested remarkable community cohesion and consistency in social roles and relations (Matthews et al., 1997a; Matthews and French, 2005). When the copper trade started to shift to sources in other regions, many of these buildings were abandoned and infilled with windblown sand.

In other studies, Portillo et al. (2014) investigated the range and organization of activity areas within buildings to obtain information about spatial and diachronic patterns in household strategies at the Neolithic site of Tell Seker al-Aheimar, Syria, late 8th to early 7th millennium BCE, by analysis of microstratigraphic field observations, and phytoliths and dung spherulites from spot samples in conjunction with ethnoarchaeological research. This research identified areas for storage, cereal processing (wheat and barley), cooking areas where dung fuel was used, and clean well-maintained spaces within large multiroomed rectangular buildings; these deposits contrasted with accumulations of refuse in the open areas, thus highlighting the distinction made in the Neolithic between interior and exterior spaces.

Maghsoudi et al. (2014) have identified and characterized many activity areas at three sites in the Qazvin plain, Iran, between 5350 and 450 cal BCE, and at least nine major deposit types (facies) relating to house construction, food preparation and consumption, combustion features and fuel, waste disposal, and colluvial and alluvial processes. The results are being incorporated into an interpretation of long-term continuity and change in socioeconomic developments from the late Neolithic to the Iron Age that included agricultural intensification and increasing social complexity, long-distance trade, and craft specialization.

One of the aims of geoarchaeological research currently being conducted on tells in Greece is to distinguish between site formation processes on tells and those affecting coeval flat extended sites, which are argued to represent different forms of settlement and socioeconomic strategies from the Neolithic onward. An extensive geoarchaeological study by Karkanas and Van de Moortel (2014) at the Bronze-Iron Age tell of Mitrou (2400–900

BCE) has established that the earliest buildings were repeatedly resurfaced with diverse materials. At the start of the Late Bronze Age, however (ca. 1700/1600 to the early fourteenth century BCE), buildings were less frequently plastered, suggesting less continuity and emphasis on individual houses/domestic units as social arenas, coinciding with the construction of new elite centers.

Monumental buildings

Monumental buildings were constructed on many tells as a focus for particular groups and events from the earliest stages in sedentary life, >9600 BCE. Geoarchaeological analyses have been conducted to study the materials and history of these buildings to discover how they and the people and events associated with them were differentiated from those of other buildings (Matthews et al., 1997b; Shahack-Gross et al., 2005). As one example, the regional center of Tell Brak, Syria, was a particular focus for monumental building (Oates et al., 2001). Micromorphological analyses of the two major building complexes in the mid- to late 3rd millennium BCE, Areas SS and FS, have highlighted how the floors and walls of many rooms and courtyards were differentiated from other buildings by the extensive use of resources such as thick mudbrick walls and foundations, multiple layers of plaster, and use of a composite white plaster manufactured from fired gypsum and fired lime not identified elsewhere. These buildings and their courtyards were also regularly maintained in contrast to more public spaces in adjacent open areas that had rough surfaces and dung accumulations (Figure 9; Matthews, 2003).

Destruction and abandonment

Geoarchaeological analyses are making a major contribution to our knowledge of the history of the destruction and abandonment of buildings and settlements on tells by enabling high-resolution stratigraphic analysis of the sequence of both natural and anthropogenic events. Integrated field and micromorphological analyses of two monumental building complexes at Tell Brak have established that the Area SS complex was deliberately infilled to a depth of up to 5 m, as there are clear tip lines and sorting from rapid infill, and Area FS was burned following a period of looting and the walls then pushed in (Matthews et al., 2001; Oates et al., 2001). Approximately coeval with this destruction, another area of the mound, Area HS3, was abandoned and the walls left to collapse and the street to infill with windblown sediment and building debris, as also shown by integrated analyses. Prior to this abandonment, a hoard of gold and silver items had been rapidly buried beneath a floor and was never retrieved. Other approximately coeval episodes of abandonment have been identified by archaeological and geoarchaeological analyses at sites across northern Syria; their link with possible climatic stress and social unrest is widely debated and dependent on ongoing research and dating of these events (Dalfes et al., 1997; DeMenocal, 2001; Weiss et al., 2012).

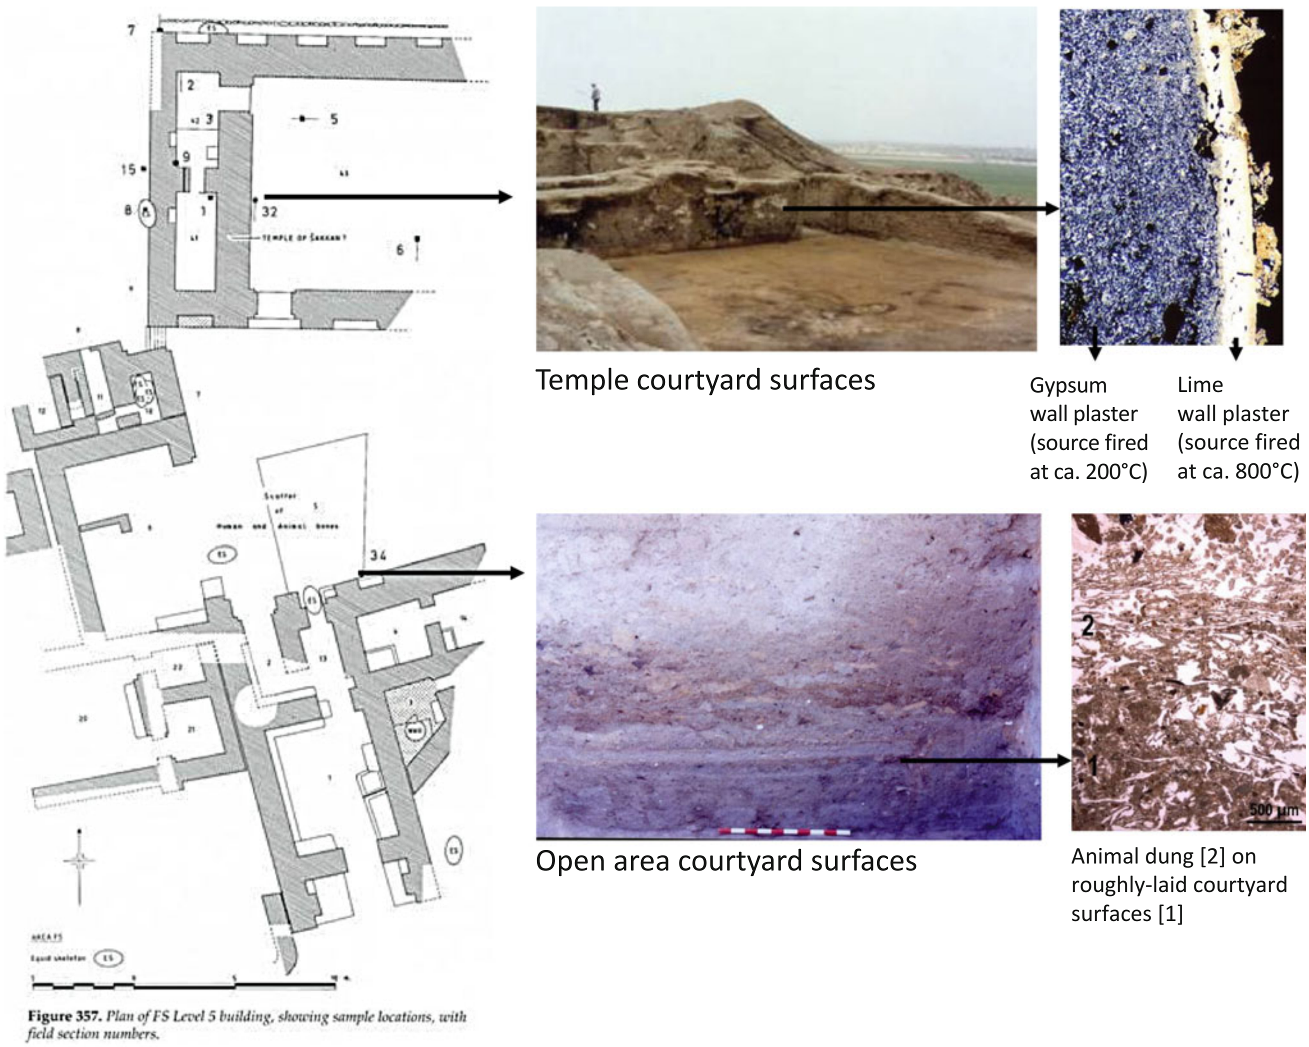
A major destruction layer at Tell es-Safi/Gath, Israel, in the mid-/late ninth century BCE, was investigated by integrated field observations and infrared spectroscopy, phytolith, and ceramic organic residue analysis (Namdar et al., 2011). Analysis of the 80 cm thick destruction horizon indicated several destruction stages spanning decades with different destruction and depositional pathways for specific parts of structures. Some areas were burned, including roof sections; others collapsed or were left standing and eroded over time, providing important insight into the context of the associated artifacts and human residues and of social change.

For buildings that were not destroyed, ethnoarchaeological research has shown that there may be a devolution in use of spaces from living to use for storage and then finally as latrine or refuse areas (David and Kramer, 2001). A similar devolutionary sequence has been identified in an Early Iron Age Phoenician monumental building at Tel Dor by Shahack-Gross et al. (2005). Micromorphological, FTIR, and phytolith analyses suggest that the remains on the well-prepared fired lime floor of the building may not relate to the major period of its administrative or ceremonial use but to the period following this. The floor is covered by a thin layer of sand and clay perhaps from abandonment, followed by evidence of fish processing and eventually ending with animal penning, providing important insight into primary and secondary uses of buildings throughout their life histories. Longer-term processes in the abandonment of tells, processes of erosion, and the formation of topsoil are characterized by Davidson et al. (2010: Figure 3) at Xeropolis, Greece, after its abandonment in the Early Iron Age.

Industrial areas

As major centers of population, tells were often loci for the production of goods and services, and the sedimentary sequences associated with these can provide an important record of these industries. The principal aims in geoarchaeological analyses of the industrial areas of tells are to identify the sources of materials and the nature, scale, and stages of production, as well as to characterize the technological skills required and the socioeconomic context of the industries, whether they were conducted within domestic or larger units. Schiffer (1987) notes that industries producing considerable debris as well as noxious or hazardous by-products, including smoke, may be located at the edge of settlements, and that debris may accumulate and be redistributed within the vicinity of the industrial area due to principles of least effort.

As one example of early industry, micromorphological analysis of production areas for fired lime to be used as plaster in the early levels of Çatalhöyük has established that dung, not wood, was the principal source of fuel and that local marl was the principal source of carbonate (Matthews, 2005a). Analysis of the small size and



Tells, Figure 9 Monumental building sequences and surfaces, Area FS at Tell Brak, northeastern Syria (After Matthews et al., 2001; Figures 357 and 363). *Upper* images: Temple courtyard surfaces showing gypsum wall plaster (source fired at ca. 200 °C) covered by thin white layer of lime wall plaster (source fired at ca. 800 °C). *Lower images*: Open-area courtyard surfaces in section showing in microscopic view animal dung (2) on roughly laid courtyard surface (1).

periodicity of these areas suggests that production was small scale at the household/neighborhood level (Cessford, 2007).

Larger-scale production has been investigated at several later tells occupied in the Bronze Age. At the Sumerian city of Abu Salabikh in Iraq, ca. 2500 BCE, micromorphological analysis of an extensive pottery production area at the northern edge of the settlement established that this prolific kiln-based industry was sustained by using dung as the major source of fuel and that high-firing temperatures were achieved, as some dung is preserved as partially melted silica (>850 °C) and calcitic ashes in the highly fired debris with pottery slag surrounding the kilns (Matthews and Postgate, 1994). Dung is still a preferred source of fuel for some traditional potters, as it burns more consistently than many woods (Sillar, 1998). Micromorphological analyses also established that one room in a small building within the industrial precinct was clearly identifiable as a living room, as the floors were repeatedly plastered and covered in thin lenses of low-temperature ash and burned bone from food cooking. Beneath this floor, a potter was buried with a potter's wheel, and so it is likely that there had been an increased shift toward professional craft specialization, ca. 2500 BCE, with specialists in this instance resident within industrial precincts and not within residential neighborhoods elsewhere on the site.

At other sites, more recent integrated geoarchaeological analysis has identified high-temperature burning, >1,000 °C, associated with casting pits for bronze working (Berna et al., 2007) and iron production in the Iron Age levels at Tel Dor, Israel (Eliyahu-Behar et al., 2008).

Open areas and middens

Significant areas of tell sites were also used as open areas and middens, which have been less intensively studied than houses and buildings until recently. Open areas and middens are likely to have been important loci for activities such as animal penning, craft activities, food processing and preparation, as well as social interaction and are key to understanding past communities and life ways. As many buildings were often kept relatively clean, dirtier open areas and middens also provide an opportunity to investigate a rich inventory of materials used and discarded by communities, as well as their sequence and history, especially where deposition is rapid as materials are often better preserved if only exposed for short periods of time (Mallol et al., 2007).

One of the most recent multi-scalar geoarchaeological analyses of middens is that conducted by Shillito at the Neolithic site of Çatalhöyük where clusters of buildings are separated by extensive midden areas and some buildings may become receptacles for refuse at the end of their use life (Shillito, 2011; Shillito and Matthews, 2013). Field, micromorphological, and micro-IR analyses were combined with high-precision spot sampling for analysis of plant phytoliths and identification of coprolites by GC-MS to investigate the diverse materials accumulated within the middens as well as assess the activities represented. Many periodic and occasionally cyclical residues from specific activities were identified that have important implications for resource use and management of the built environment. Residues in these middens included discarded remains of fuel rake-outs from hearths and ovens, floor sweepings, food processing debris including wheat husks and lenses with abraded rock fragments from the use of grindstones, specific crafts such as wood working, and human coprolites, which are being studied for high-resolution variation in diet (Shillito et al., 2011). Occasionally, there is evidence for periodic in situ activities, such as production of fired lime in the early levels and probable bonfires for pottery firing in later levels, as well as pits for extraction of ashy materials for mortar and brick additives. The finely stratified lenses and remarkable preservation of many materials suggest frequent discard and rapid burial. There are few indications of erosion and long-term exposure; rare exceptions include a bioturbated layer early in the history of the site when it may have been less populated.

Open areas and middens are currently the subject of increased geoarchaeological analyses: examples include several sites in the Central Zagros in Iraq and Iran (Matthews et al., 2013b); Aşıklı Höyük in Central Anatolia, where there is a long sequence of in situ activity areas followed by middens and traces of animal pens (Stiner et al. 2014); and Neolithic-Bronze Age sites in Greece (Koromila, 2012; Kyrillidhou, 2012).

Streets and lanes

Many tell sites include systems of streets and lanes that provide key information on social and economic networks as well as internal settlement organization. Radiating from tells in northern Mesopotamia, in particular, are a series of routeways detectable by remote sensing and field observations as holloways, which have enabled study of hierarchies in the connectivity of sites (Wilkinson et al., 2010; Ur et al., 2013). Geoarchaeological analysis of cross sections through these holloways established that they were infilled by low-energy deposits that were subject to periodic wetting and drying and then reworking by bioturbation and that they were probably initially formed during the 4th millennium BCE when Tell Brak was a major city and center of international trade surrounded by smaller sites.

Micromorphological analyses have established that some streets and lanes were surfaced and well maintained, notably those adjacent to the ceremonial complex at the early Neolithic site of Aşıklı Höyük, Turkey, where the street was repeatedly surfaced with pebbles and kept very clean (Esin and Harmankaya, 1999). At other sites, away from ceremonial areas, streets and lanes were not frequently paved and were used periodically for discard as at Çatalhöyük (Shillito and Ryan, 2013), Abu Salabikh (Matthews and Postgate, 1994), and Tell Brak (Matthews et al., 2001). At the early Neolithic site of Sheikh-e Abad, as noted above, micromorphological and GC-MS identification of widespread traces of non-burned ruminant dung in lanes and open areas indicates that animals were brought within the settlement and lived in close proximity to humans in this early settlement, ca. 7600 BCE (Matthews et al., 2013b).

Natural deposits and postdepositional alterations

Natural depositional agencies and postdepositional alterations on tells may be ongoing both during and post-occupation, but as Butzer (1982) highlights, they will generally have their greatest impact during periods of population decline or abandonment (as at Tell Brak discussed above) and during extreme natural events such as major flooding or tsunamis (see Bruins et al., 2008). Smaller-scale accumulations of natural deposits laid down during episodes of periodic disuse have been observed through micromorphological analysis. One example is an oven on a flat rooftop at Çatalhöyük discussed above (Figure 6), within which were found periodic accumulations of rainwash from probable seasonal disuse. Conversely, anthropogenic deposits are more abundant than natural deposits during periods of population expansion and intensive human activity. Many materials are better preserved when they are rapidly buried by either natural or anthropogenic deposits, as they are exposed for less time to microbial action and to physical disturbance from wind, water, humans, animals, and plant roots, as observed in ethnoarchaeological studies (Mallol et al., 2007).

The nature and extent of natural postdepositional alterations and preservation of materials on tells is dependent upon many factors, and understanding their effects requires interdisciplinary research and collaboration in studies of soil science, microbiology, chemistry, conservation, and paleoclimate/environment, to identify the diverse parameters, agents, and processes affecting organic and inorganic materials. The climate and environment of tells vary geographically from temperate in Hungary, for example, to semiarid in Turkey and to desertic in regions of Sudan; there are also temporal variations: seasonally, annually, and over longer periods. Burial environments also vary topographically within tells themselves, and they may differ significantly at very small scales and time intervals, between and within strata, according to composition, pH, oxidation state, and hydrology. The base of many tells and indeed entire low mounds may be covered by extensive alluvium and colluvium, which in some regions may be up to 4 m or more thick as at Çatalhöyük (Boyer et al., 2006).

In summary, in the semiarid environments where most tells are located, the principal natural agencies and processes affecting them that have been identified by field observation, micromorphology, and elemental, mineralogical, and organic geochemical analyses include (1) organic decay from microbial action in oxidizing conditions that result in the loss of perishable materials, subsequent reduction in the volume and depth of deposits, and deposition of amorphous organic staining; (2) physical disturbance and reworking of deposit structures by burrowing insects, microfauna, animals, and plant or tree roots (Courty and Weiss, 1997; Davidson et al., 2010); (3) dissolution and reprecipitation of salts (gypsum and sodium salts; Maghsoudi et al., 2014) as well as carbonates due to evaporation at the surface or point of contact with plant roots during transpiration; (4) formation of other new or altered minerals such as vivianite in phosphate- and iron-rich deposits and transformation of ash (Weiner, 2010); (5) occasional translocation of fine materials and redeposition, often along edges of voids by water movement; and (6) surface erosion and deposition by wind and water, for example, which may significantly alter the form and height of tells (Rosen, 1986; Davidson et al., 2010).

One of the challenges in excavating tells is identifying intact mudbrick or terre pisé walls, as these are often leveled or eroded and surrounded by collapse or redeposited sediments of the same material. Ethnoarchaeological and geoarchaeological studies are contributing significantly to our understanding of these processes and to detection of both in situ and redeposited construction materials (Friesem et al., 2011).

Cultural postdepositional alterations identified by geoarchaeological analyses at tells include (1) maintenance and cleaning practices, attested by the impressions or remains of mats on floors, sparsity of residues on floors within many houses, and subrounded plaster aggregates from sweeping found within lenses on floors or discarded in hearths or in middens; (2) trampling and physical reworking of deposit components and layers; (3) burning; (4) leveling and remodeling of features, such as horizons with fragments of oven superstructure; (5) dismantling, infilling, leveling, or destruction of buildings; and (6) digging of pits. After abandonment of sites, there is also evidence that tells may be reused as burial grounds or their materials mined for manure and building materials, as well as impacted by plowing, cultivation of crops and tree plantations, grazing of animals, construction of dams and flooding of tells and their landscapes, and illicit looting.

In general, however, many deposits, materials, and features are better preserved in repeatedly occupied tell sites than in single period or shifting occupation in flatter sites because deposition and burial of materials on tell sites is more rapid. Deposits and materials are also better preserved in the oxidized environments of many tell sites in semiarid regions, than those of many sites in temperate regions, where postdepositional processes are accelerated and more marked. Exceptional preservation within tells can occur in arid regions such as Sudan, where many organic materials are well preserved due to the absence of moisture that enables destructive microbial activity (van der Veen, 2007), as well as in waterlogged or locally anaerobic conditions (e.g., from rapid burial by clay-rich materials) within or at the base of mounds due to limited exposure to microbial action (Matthews, 2005a).

Conclusions

One of the great challenges in geoarchaeological analyses of tells is identifying the diversity of materials present and the different agencies and pathways that affect their origin, deposition, and postdepositional alterations. These challenges, however, are at the very heart of archaeology itself, and addressing and examining them requires interdisciplinary multi-scalar approaches and collaboration, as well as consideration of cultural as well as natural agencies. The examples and case studies documented here illustrate the ways in which geoarchaeology is contributing to new high-resolution contextual analysis of a wide range of architectural, bioarchaeological, and micro-artifactual materials on tells and answering key research questions on the ecological and social strategies and histories of the individuals and communities who constructed and occupied them. Future research requires further ethnoarchaeological and experimental research to continue to advance our understanding of past built environments and development and dissemination of reference materials. Geoarchaeological analyses of materials and sites provide crucial data that are relevant to conservation and preservation of artifacts and sites, and further collaborations should also be developed in these fields.

TEPHROCHRONOLOGY

Christine Lane and Jamie Woodward
Geography, School of Environment, Education and Development, The University of Manchester, Manchester, UK

Definitions

Tephra: Unconsolidated pyroclastic material explosively ejected during a volcanic eruption. Tephra includes blocks (>32 mm), lapilli (4–32 mm), and ash (<4 mm). Tephra was often called tuff in the early archaeological literature.

Volcanic ash: The finest and most voluminous tephra fraction composed mostly of shards of glass formed by the rapid cooling and explosive breakup of magma during an eruption.

Tephrochronology: The dating of sequences according to the age of layers of tephra preserved within.

Tephrostratigraphy: The use of volcanic ash layers as relative dating horizons. Tephra layers from a single eruption event can be used to correlate sequences precisely that may be some distance apart.

Cryptotephra: Tephra within a sequence that is not visible to the naked eye and may be detected only using instrumental core scanning techniques or by laboratory processing of sediments.

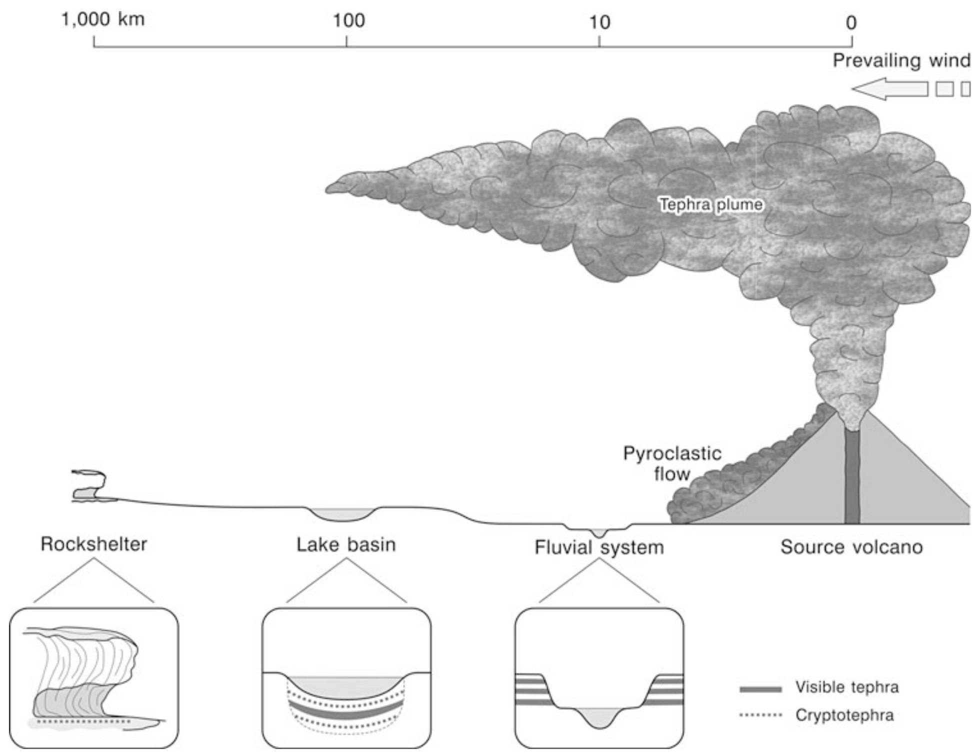
Introduction

Tephra is the debris ejected into the atmosphere during explosive volcanic eruptions. The term was first coined by the Icelandic volcanologist, Thorarinsson (1954), from the Greek for ash (τέφρα). Tephra in fact includes particles that vary greatly in size, density, shape, and chemical makeup, but all varieties can be deposited within archaeological contexts. The largest particles may be blasted to a considerable height, but they typically travel short distances and fall on or close to the volcano itself. The fine-grained ash can be transported much greater distances and deposited in a range of terrestrial and aquatic settings; it is this *distal* tephra that has been the focus of much geoarchaeological research (Figure 1). Even though explosive volcanic eruptions are short-lived, distal tephra can be distributed over a very wide area if atmospheric conditions are favorable. In most cases, a tephra has a distinctive chemistry that allows it to be traced to the source eruption. Tephra layers can therefore assume considerable stratigraphical significance even many hundreds of kilometers from the source volcano because they demonstrate contemporaneity. A selection of archaeological contexts of various ages where distal tephra deposits have been used to refine the dating and establish regional correlations is shown in Table 1. More locally, tephra layers have been used to correlate stratigraphic units across excavation trenches within a single site (Farrand, 2000).

Dating a tephra layer

Tephra can be dated either directly or indirectly by determining the age of material believed to be contemporaneous with tephra deposition (Table 2). The most common direct dating method is $^{40}Ar/^{39}Ar$, which dates the formation of K-rich crystals within a tephra unit. Due to aeolian sorting, these crystals can usually be found in sufficient abundance only in deposits close to the volcanic center. It is therefore essential that the correlation of distal tephra layers to the dated proximal counterparts (i.e., the right volcano and the right eruption) is secure. Where K-rich crystals are not present, indirect dating methods (Table 2) must be used to date a tephra. It is important to establish the relationship between the actual event being dated and the deposition of the tephra layer.

A combination of multiple lines of evidence via a statistical age modeling approach often provides the most precise and accurate age estimate for a tephra layer. Since the early 1990s, Bayesian modeling has been used to combine age information for tephra layers from multiple sites and/or multiple dating approaches (Buck et al., 2003; Blockley et al., 2008), vastly improving the precision with which tephra layers can be dated.



Tephrochronology, Figure 1 A schematic illustration of distal tephra dispersal and deposition in a Quaternary landscape downwind of a volcanic center where three major explosive eruptions have taken place. Three tephra layers have been preserved in the alluvial sediments of the valley floor approximately 10 km downwind of the volcano. About 100 km away, the sedimentary record in the lake basin preserves a faithful record of the two largest eruptions with one visible tephra and two cryptotephra. The rock-shelter sediment record lies at the limits of tephra dispersal and contains a single cryptotephra.

Fingerprinting an eruption

The underlying premise of tephrochronology is that every eruption can be recognized by the chemical composition of the erupted material. Tephra composition is controlled by the chemistry of the magma source region, the path and time taken for the melt to reach the surface, and the dynamics of the eruption. Upon eruption into the cold atmosphere, magma cools and solidifies very rapidly into glass. It is the composition of this glass that is used to fingerprint the tephra, and this can be done in a number of ways. It is now widely recognized that single-grain analyses are preferable for tephra characterization, as these allow the glass and mineral phases to be targeted in isolation. They may also detect any compositional variability within the tephra, which can occur if eruptions are prolonged or if they involve more than one magma body (Smith et al., 2005). Major and minor element compositions are best analyzed using wavelength dispersive spectroscopy on an electron microprobe (WDS-EMP). Typically, SiO_2, TiO_2, Al_2O_3, FeO, MnO, MgO, CaO, Na_2O, K_2O, and P_2O_5 are measured, sometimes with Cl and S, although the latter are present only in trace amounts. Kuehn et al. (2011) provide a detailed discussion of WDS-EMP analyses of volcanic glass.

For many tephra, major and minor element analyses will be sufficient to characterize the eruption. However, multiple eruptions from the same volcano, or different volcanoes in similar settings, may generate tephra with very similar glass compositions. It is therefore useful to measure trace element compositions also using either secondary ion mass spectrometry (SIMS) (Clift and Blusztajn, 1999; Albert et al., 2015) or laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) (Pearce et al., 2007; Tomlinson et al., 2010). In only a few cases, even trace element analyses cannot easily distinguish between multiple eruptions from the same source, for example, the ca. 75 ka Youngest Toba Tuff (Table 1) (Smith et al., 2011; Lane et al., 2012). In such instances, tephra glass shard chemistry is supplemented by mineral analyses.

Cryptotephra

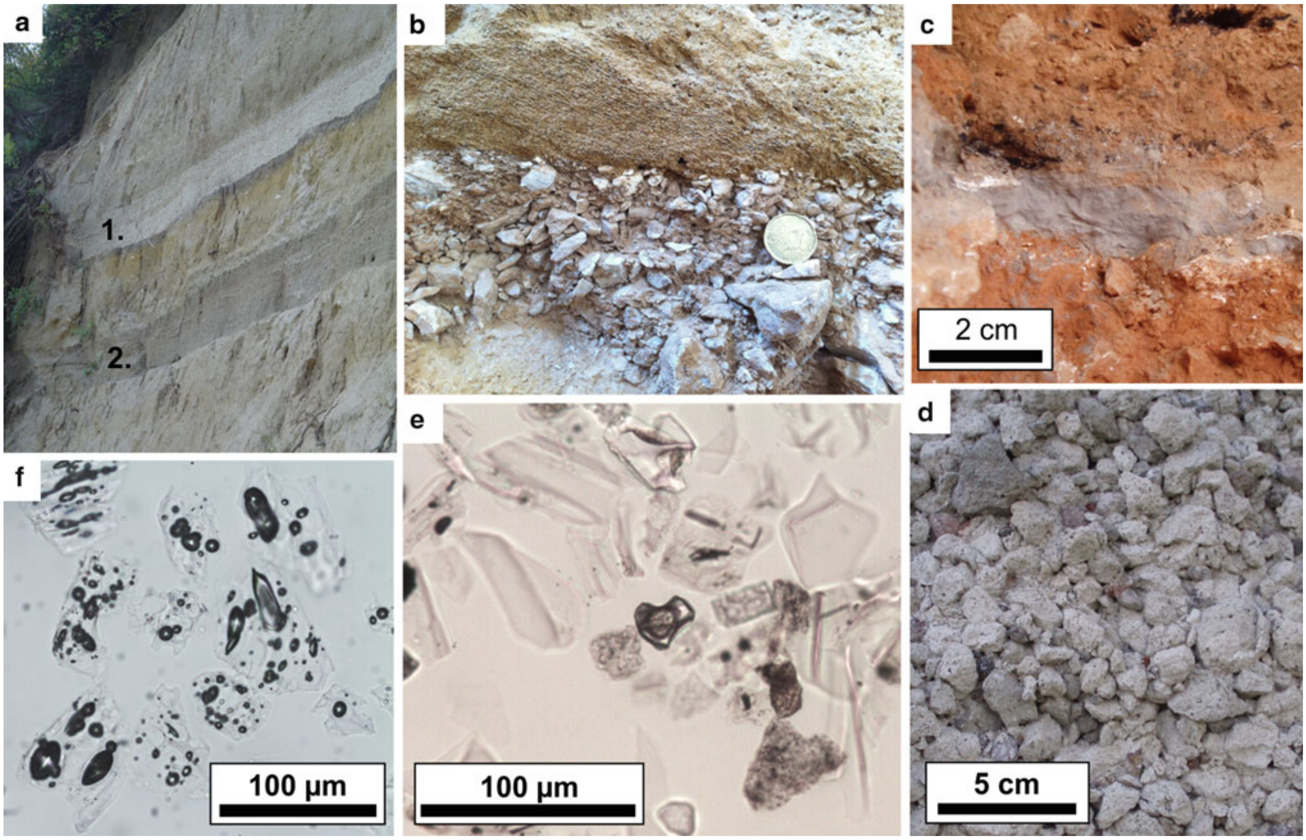
A significant development in tephrochronology, which has led to increased application of the method outside of volcanic regions, has been the detection of cryptotephra layers (Dugmore, 1989; Turney et al., 1997; Davies et al., 2002). Cryptotephra are tephra layers that cannot be detected by the naked eye (Lowe and Hunt, 2001). This

Tephrochronology, Table 1 Notable Quaternary tephra layers that have been widely used as a stratigraphic marker in archaeological research

Time period	Tephra, age, and source	Archaeological context	Dating methods and depositional context	References
Early Pleistocene	Tephra layers in the Konso Formation, ca. 1.90–1.33 Ma, Ethiopian Rift complex	Lower Paleolithic hominin sites in the Rift Valley of East Africa	$^{40}Ar/^{39}Ar$ and correlation within regional marine records	Katoh et al. (2000) and WoldeGabriel et al. (2005)
Middle Pleistocene	Tephra layers in the bedded tuff formation, ca. 235 ka (upper units). Tugen Hills, Kenya Rift Valley	Acheulian to Middle Stone Age transition in East Africa	$^{40}Ar/^{39}Ar$ dating of tephra layers and lavas in the Kapthurin formation	Deino and McBrearty (2002) and Tryon and McBrearty (2006)
Late Pleistocene	Youngest Toba Tuff, ca. 75 ka, Mt. Toba, Sumatra, Indonesia	Middle Paleolithic sites across India	$^{40}Ar/^{39}Ar$ dating of crystals and glass in proximal and distal tephra units	Petraglia et al. (2007), Storey et al. (2012), and Mark et al. (2014)
Late Pleistocene	Campanian Ignimbrite (Y5), ca. 39 ka, Campi Flegrei, southern Italy (Figure 2e)	Middle to Upper Paleolithic cave, rock-shelter, and open-air sites in Europe, South Russia, and North Africa (Figure 2b)	$^{40}Ar/^{39}Ar$, radiocarbon dating, and correlation within marine and lake sediment records	Vitaliano et al. (1981), Pyle et al. (2006), Morley and Woodward (2011), Lowe et al. (2012), and Douka et al. (2014)
Late Glacial	Laacher See tephra, ca. 12.9 ka, East Eifel Volcanic Zone, Germany (Figure 2f)	Final Paleolithic, open-air hunter- gatherer sites and faunal deposits, in western Germany	Age established from annually layered lake sediments and radiocarbon dating	Brauer et al. (1999), Baales et al. (2002), and Riede (2008)
Late Holocene	Thera eruption, ca. 1600 BC, Santorini, Hellenic Arc	Late Bronze Age Minoan civilization, related to destruction of Akrotiri, Greece	Radiocarbon dating of wood within pumice and Bayesian age-model synthesis of dates	Friedrich et al. (2006) and Manning et al. (2006)

Tephrochronology, Table 2 Summary and examples of direct and indirect methods commonly used for dating tephra layers

Method	Description	Material dated	Age range	Example
Direct dating methods				
$^{40}K/^{40}Ar$; $^{40}Ar/^{39}Ar$	Measurement of radiometric decay over time of ^{40}K and daughter product ^{40}Ar	K-rich crystals within tephra deposits or lava flows	^{40}K has a long half-life restricting $^{40}K/^{40}Ar$ to older samples (>100 ka) $^{40}Ar/^{39}Ar$ can date samples as young as Holocene	Dating the Middle Stone Age in East Africa (Morgan and Renne, 2008)
Fission track dating; isothermal plateau fission-track dating	Measurement of tracks accumulated over time by the spontaneous fission of ^{238}U in crystals	Zircon crystals and U-rich glasses in tephra deposits	Dependent on U-content. Typically >50 ka before present	Dating Early-Middle Pleistocene tephra from New Zealand (Shane et al., 1996)
Indirect dating methods				
Radiocarbon	Measurement of radioactive decay of ^{14}C, which is produced in the upper atmosphere and incorporated into all living matter	Organic material immediately below, or within, a tephra unit	A short half-life (~5.7 ka), instrumental detection limits and uncertainties in calibration restrict dating to <50 ka before present	Bronze Age Thera eruption (Friedrich et al., 2006); dating the Campanian Ignimbrite in Kostenki (Douka et al., 2010)
Annual layers	Counting of annual layers formed by seasonal processes in lake sediments and ice core records	Individual layer of sediment or ice containing tephra	Controlled by the length of the record, e.g., layers in the Greenland ice cores can be counted >100 ka	Ice core ages for Vedde and Saksunavatn tephras (Rasmussen et al., 2006) Dating of the Laacher See tephra in laminated lake Meerfelder (Brauer et al., 1999)
Age modeling	Statistical combination of age estimates from a stratigraphic sequence, a number of sites, or different dating methods	Generates a modeled age for the tephra layer	Unlimited	Kaharoa tephra, from New Zealand (Buck et al., 2003), Cape Riva tephra from Santorini (Lee et al., 2013)



Tephrochronology, Figure 2 Images of tephra in the field and under the microscope. **a** Quarry section near Naples, Italy, containing two tephra fall layers: (1) the Mercato tephra from Mt. Vesuvius (~40 cm thick) and (2) the Pomici Principali tephra from Campi Flegrei (~50 cm thick). **b** The Campanian Ignimbrite tephra overlying coarse limestone clasts in the Late Pleistocene sedimentary record of Crvena Stijena rock-shelter in Montenegro. Middle Paleolithic stone tools are found in the deposits below this tephra but not in the deposits above (Morley and Woodward, 2011). **c** The ~17 ka Biancavilla tephra from Mt. Etna is clearly seen as a gray ashfall layer in the sediments of the Haua Fteah rock-shelter in Libya, providing a useful dating horizon for the Epipaleolithic at the site (Douka et al., 2014) (Photo: Robyn Inglis). **d** Example of ash and lapilli size airfall tephra from Gölcük, SW Turkey. **e** Glass shards from the Campanian Ignimbrite tephra seen under the microscope are clear and platelike. This example is taken from the Haua Fteah, Libya. **f** Glass shards from the Laacher See tephra are characterized by lots of gas bubbles (vesicles) trapped within the rapidly cooled magma during the eruption.

is due to their smaller shard sizes, low concentrations, or dilution within the host sediment. Cryptotephra may be found much farther from the volcanic source than equivalent visible tephra units, significantly extending the area over which these isochrons can be utilized (Figure 1). Typically, glass shards (Figure 2e–f) will be the only constituent of cryptotephra deposits, so characterization is carried out in the same way as for visible tephra using EMP and LA-ICP-MS.

Cryptotephra can be detected in a number of ways. Instrumental methods applied to sediment cores, such as magnetic susceptibility and XRF scanning, are effective at detecting layers of relatively high concentration or that are compositionally very different from their host sediment (Gehrels et al., 2008; Kylander et al., 2012). The most reliable way of detecting cryptotephra is by laboratory processing of samples that span the entire sediment record, following a now well-established heavy liquid extraction method (Turney, 1998; Blockley et al., 2005). This method circumvents the need for any chemical treatment of the sediments, which risks chemical alteration and/or dissolution of the glass shards (Pollard et al., 2003; Blockley et al., 2005).

The growth in cryptotephra studies has seen the technique applied widely in dating and correlating Quaternary paleoenvironmental archives from marine and terrestrial environments over continental distances (Turney et al., 2004). Applications in archaeology have been concentrated in Holocene wetland environments where human occupation is closely tied to landscape development and environmental change (Dugmore, 1991; Plunkett, 2009). It is only very recently that this approach has been extended into a wider range of archaeological settings, from open-air sites (Housley et al., 2012) to caves and rock-shelters (Lowe et al., 2012; Douka et al., 2014). Tephra from the 39 ka Campanian Ignimbrite (CI) super-eruption (Figure 2b, e) has been found in multiple cave and rock-shelter sites around the central and Eastern Mediterranean. For example, it is present in Crvena Stijena rock-shelter in Montenegro as a distinctive ~10 cm-thick layer forming the boundary between the Upper and Middle Paleolithic assemblages (Morley and Woodward, 2011). Much farther from the volcanic source, at the Haua Fteah cave in northeastern Libya, it is present as a cryptotephra (Douka et al., 2014). The 39 ka Campanian Ignimbrite tephra is even visible in Late Pleistocene alluvial deposits in southwestern Russia (Table 1). The CI tephra is widely used as a marker layer to correlate Middle to Upper Paleolithic sequences because it provides a precise age estimate that has helped to constrain the timing of this important transition (Pyle et al., 2006; Lowe et al., 2012). Caves and rock-shelters are often complex sedimentary environments (Bailey and Woodward, 1997), so there is a need for careful consideration of the taphonomy of cryptotephra layers, which are unlikely to have entered the site exclusively as direct fallout from the volcanic ash plume (Morley and Woodward, 2011). The development of this approach and the challenges of using cryptotephra to aid the dating and correlation of a wide range of archaeological sites over extended time periods are discussed in Lane et al. (2014).

Summary

The recording of tephra deposits in archaeological contexts is almost as old as the discipline of archaeology itself. A good deal of the classic work on early hominin fossils and Lower Paleolithic stone tools in East Africa is founded upon chronologies derived from the dating of volcanic ash (e.g., Sarna-Wojcicki et al., 1985; WoldeGabriel et al., 2005). Recent developments in the detection and dating of fine distal tephra have substantially enhanced its value as a chronological marker and tool for the correlation of sites. The study of distal tephra is a rapidly growing component of geoarchaeology.

Definitions

Tomb: Any structurally enclosed interment space or burial chamber.

Introduction

Funerary practices are among the most important elements of social life, and although they focus on the disposition of the dead, they probably tell us more about the living (Bettencourt, 2008). From the simplest pits covered with gravel to the highly elaborate structures of the pyramids in Egypt, tombs provide a wide variety of information about past funerary behavior and its social context. The varied grave goods deposited around the deceased – including jewelry, clothing residues, weapons, tools, cooking equipment, and provisions in association with human skeletal remains – place tombs among the most informative archaeological assemblages for the reconstruction of ancient social structures (Pearson, 2003).

Throughout the world, tombs occur in many forms and incorporate structural aspects that are often unique to each society. These include underground carved-out spaces (cists and chamber tombs) sometimes lined with construction material (tholos tombs or vault tombs), large stone constructions covered by an earthen mound (megalithic tombs), or free-standing, aboveground structures (mausolea and pyramids). Tombs may contain one or more interments of individuals or family groups, or they can encompass large public burials (catacombs). Interments can be inhumations or cremations, and the remains can be enclosed within a container or simply placed on or within the ground. Notwithstanding their importance, however, there have been few geoarchaeological studies of tombs, and most of these have focused on geophysical prospection and provenance.

Geophysical prospection

Several geophysical methods are employed for locating and mapping buried or underground tombs. GPR, or ground-penetrating radar (qv), which is based on the transmission of radio waves to image the subsurface, is usually used because it is rapid and nondestructive. Examples include the detection of underground megalithic tombs in Galicia, Spain (Lorenzo and Arias, 2005), the investigation of a subterranean tomb in Japan (Edwards et al., 2000), and advanced three-dimensional GPR investigations to locate and characterize tombs inside medieval chapels (e.g., Böniger and Tronicke, 2010). More recently, near-surface magnetic investigations have also been used successfully to locate buried tombs and other structures associated with the Amenemhat II pyramid complex in Dahshur, Egypt (Abdallatif et al., 2010).

Provenance studies

Since most types of tombs include stone construction, provenance studies are the most commonly applied geoarchaeological analyses. Geological observations supplemented by petrographic (qv) and geochemical investigations are usually employed to characterize the building materials and identify their source. In particular, provenance studies of marble construction in tombs are based on oxygen isotopic (qv) data and chemistry of fluid inclusions, which are compared with well-known quarry sources of high-quality marble (e.g., Walker, 1984; Miriello et al., 2010; Prochaska and Grillo, 2010).

The construction of megalithic tombs between the fifth and the second millennia BC in Western Europe has been the subject of intensive investigations. Most of the studies have confirmed that the tombs were built from stone that was available within a radius of 5 km from the site (Thorpe and Williams-Thorpe, 1991; Patton, 1992; Vicens et al., 2010). This contrasts with provenance studies conducted at the famous megalithic monument of Stonehenge, where transport over a range of several tens or even hundreds of km has been suggested (Thorpe and Williams-Thorpe, 1991; Williams-Thorpe et al., 2006).

The legendary Egyptian tombs have been the stuff of mystery and imagination, as well as curious interpretations. It has been claimed that the blocks comprising the famous pyramids of Giza were not quarried at all. Davidovits and Morris (1988) advanced an unconventional hypothesis that the blocks were man-made and produced by pouring a mixture of disaggregated limestone and a geopolymeric binder that resulted in a material almost indistinguishable from natural limestone. More recently, this idea was resuscitated by Barsoum et al. (2006), who claimed to have identified artificial microconstituents in some blocks using scanning and transmission electron microscopy (SEM and TEM) (qv). Geological observations have provided undisputable proof that the blocks were quarried, however. The evidence includes ripple laminations, repeated layering, calcite-filled tectonic fractures, as well as numerous sharp cross sections of clams and fragile calcite worm tubes and burrows that were formed during deposition of the rock (Folk and Campbell, 1992). In addition, a variety of mineralogical and chemical instrumental techniques like optical microscopy, XRD (qv), SEM (qv), DTA, ICP (qv), and FTIR (qv) were also used to verify their natural origin (Folk and Campbell, 1992; Ingram et al., 1993).

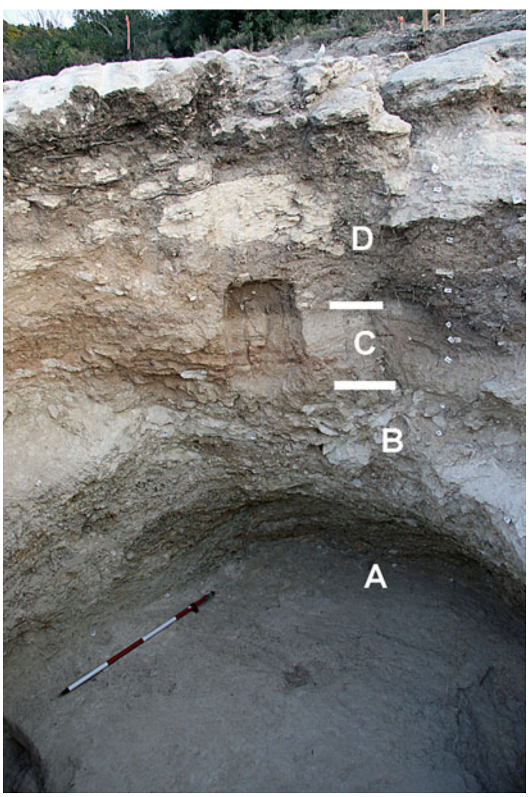
Studies of tomb sediments

The word tomb comes from the Greek τύμβος ("tymvos" or sepulchral mound) and has a strong connotation linking it to earthen structures. Indeed, tombs were very often originally covered with an earthen mound, such as with megalithic and chamber tombs. However, only rarely have geoarchaeological approaches been used to decipher the source and processing of soil and sediment for the building of mounds (Cremeens et al., 1997; Cremeens, 2005; Canti, 2009; Villagran et al., 2009; Sherwood and Kidder, 2011) (see *Mounds and Other Earthworks* for details). Rarer still are studies of the tomb sediments themselves. Although some tombs contain very little accumulated interior sediment, in cases where the tombs were repeatedly used, stratified deposition can occur in association with not only their continual opening and closing but also with their maintenance. Tombs are often looted during modern times, but they were also plundered in antiquity. These activities may have created disturbances and sediment build up inside the tomb. Underground tombs often collapse and fill with breakdown material together with sediment and soil from the surrounding area. Such tombs bearing stratified deposits are nevertheless challenging to excavate because their usually narrow, cramped spaces leave little place between the interments in which to work. Since tombs are highly susceptible to robbing (even during their excavation), leaving a standing balk that may contain artifacts raises the theft risk as well as logistical problems of access. By adjusting excavation strategy according to the type of tomb, however, the study of the interior sediment record can elucidate the complex history of use and provide important information on mortuary behaviors. Applying a soil micromorphology (qv) approach in this way, maintenance practices were identified in the form of fine lime plaster floors in the interior of Mycenaean chamber tombs (Karkanas et al., 2012). This investigation allowed the separation of burial groups based on their relationship to floor surfaces (Figure 1). Moreover, questions about the preparation of the area and mode of corpse deposition have also been answered with soil micromorphology. In the Celtic sanctuary of Ribemont-sur-Ancre (Somme, France), it was concluded that a hanging funerary platform had been constructed with mud-brick and mortar where the corpses remained exposed for a considerable time before they fell to the floor (Courty, 2001: Figure 8.13). Cadaver decomposition usually leaves a chemical signature in the soil consisting of iron- and phosphorus-rich compounds (Żychowski, 2011) or elevated manganese concentrations (Keely et al., 1977). Where remains have already decomposed and no visible remains survive, these soil silhouettes of trace chemical residues can enable the detection of preexisting burials (Keely et al., 1977), and they can probably differentiate primary from secondary burials as well.

Of particular interest are the occasional corridors (singular = dromos in Greek) that lead to the main chamber of some tomb types. Such corridors are usually filled with sediment. In the study of some Mycenaean chamber tombs, field sedimentological observations corroborated with soil micromorphology provided details about the process of backfilling and reopening of the corridors of the tombs and the location, number, and slope of these reopenings (Figure 2) (Wright et al., 2008; Karkanas et al., 2012). Also observed was a suite of sedimentary structures attributed to grain flow and debris fall processes associated with the formation of small piles during shoveling of debris in the tomb. The grain flow resulted from the failure of material on the sides of the piles and is

Tombs, Figure 2 Corridor (dromos) of a Mycenaean chamber tomb (Ayia Sotira, Nemea, Greece). Two phases marked by stones representing the wall blocking the main chamber entrance are seen in the balk at the end of the excavated corridor. Along the balk of the right corridor wall, sedimentary features attributed to the reopening and backfilling of the corridor are marked with *arrows*.



Tombs, Figure 3 Stratigraphy of a collapsed chamber tomb. *A* chamber, *B* collapsed roof, *C* finely laminated water-lain sediment, *D* final filling with colluvium and soil debris. Ayia Sotira, Nemea, Greece (Photo courtesy of R. K. A. Smith).

characterized by ubiquitous particle collisions; the debris fall was produced with collapse of the piles and rapid chaotic movement in the form of dry avalanches. Understanding these processes enables features related to reopenings and regular backfilling to be differentiated. In addition, identifying details of the chamber collapse process offered a better understanding of the taphonomy of the burials inside the tombs (Figure 3).

Regional studies

Finally, regional geoarchaeological studies can shed light on the distribution patterns of some types of tomb, revealing important aspects of former societies. A study by Perry and Davidson (1987) has shown that the distribution of Neolithic chambered cairns on the island of Arran (Scotland) depended generally on factors involving the character of the land and occasionally on geomorphic ones. The most important factor appeared to be proximity to agricultural land, and based on this inference, they recognized that the agricultural component of the island's economy increased through time.

Summary

Geoarchaeological studies in tombs have so far confined to their initial assessment, geophysical prospection, and provenance studies of stone construction materials. Only very recently has a geoarchaeological perspective been applied to the study of site formation processes within and around tombs. This perspective can be applied to many types of tombs and promises to reveal important details about mortuary practices.

TRAMPLING

Christopher E. Miller
Institute for Archaeological Sciences, Senckenberg Centre for Human Evolution and Paleoenvironment, University of Tübingen, Tübingen, Germany

Trampling, also sometimes called scuffage or treadage, refers to the alteration and modification of artifacts and deposits caused by humans or animals walking on a surface. Archaeologists have noted and studied the influence of trampling on artifacts since the 1950s (Bordes and Bourgon, 1951). From that time, researchers have conducted numerous actualistic, laboratory, and ethnoarchaeological studies to investigate the effects of trampling on surface modification of bones, breakage and edge damage of lithics, and vertical and horizontal displacement of artifacts within a deposit. Geoarchaeologists have also conducted studies to investigate the micromorphological effects of trampling on deposits and anthropogenic features.

Zooarchaeologists have looked at the effects of human and animal trampling of bone over a variety of substrates with the goals of distinguishing between cut marks and trampling marks and determining the role that trampling plays in the taphonomy of faunal assemblages. Most of these studies conclude that cut marks exhibit morphological characteristics distinct from trampling marks, which can be difficult to distinguish from sedimentary abrasion caused by other processes such as pedoturbation. Similar studies have been conducted to examine the effects of trampling on damage to lithic artifacts. Some studies noted limited edge damage (Eren et al., 2010), whereas others noted that trampling can cause modifications that mimic the marks of certain tool types (McBrearty et al., 1998). The difference in these results likely reflects variations in the substrates used for the experiments.

Trampling can have significant effects on both the vertical and horizontal distribution of artifacts within a deposit. However, despite numerous studies, researchers report varying or even contradictory results. Some studies note vertical displacement of only 1.5 cm following trampling (Nielsen, 1991), while others report maximum displacement of up to 16 cm (Eren et al., 2010). Similarly, some researchers report horizontal and vertical size sorting and displacement of artifacts by trampling, whereas others do not. The variables that influence these results include (1) the intensity of the trampling, (2) the nature of the substrate, (3) the thickness of the deposits covering the trampled pieces, and (4) the weight, size, and shape of the artifacts (Villa and Courtin, 1983). Of these variables, the type of substrate – and particularly its penetrability – is likely the most significant.

Compaction of the substrate following trampling has been reported from some experiments that also note the presence of in situ crushed and snapped bone, identifiable in micromorphological thin section (Miller et al., 2010). Similarly, Banerjea et al. (2013), in a micromorphological study of building floors at Butser Experimental Farm, reported that trampling causes compaction of sediments that is observable in thin section. They also reported that trampling acts as a depositional process when clods of sediment are brought into a structure on the soles of people's feet. The compacted clods appear as lenses in thin section, and the repeated accumulation of these clods can form a laminated deposit, as described by Goldberg and Macphail (2006). Banerjea et al. (2013) note that these processes are more common when the substrate is damp. On the contrary, Nielsen (1991) reports that trampling can cause loosening of the surface, thereby increasing penetrability. Nielsen's results accord with experiments conducted by Rentzel and Narten (2000), who report the development of a granular microstructure in the upper millimeter of a deposit following trampling.

The results of these trampling experiments have been successfully applied in studies of archaeological deposits. For example, Goldberg et al. (2009) and Miller et al. (2013) describe the various effects that trampling had on the micromorphological character of the deposits in the Middle Stone Age rock-shelters of Diepkloof and Sibudu, South Africa. They noted that, in earlier phases of occupation, trampling led to horizontal reworking of sediment; at Diepkloof, they noted that this horizontal displacement was associated with the formation of a -millimeter-thin granular microstructure at the surface of the deposits, similar to what Rentzel and Narten (2000) reported in their experiments. In later phases of occupation at both sites, horizontal displacement was minimal, but in situ snapped and crushed bones were common. They suggest that this variation in the effects of trampling is related to changes in the type of substrate that was subjected to trampling: horizontal displacement and surficial, granular microstructure developed when people walked on a loose, dry surface. In situ crushing and snapping occurred when people walked on surfaces prepared with plant bedding.

The numerous experimental and archaeological studies of trampling show that it is an important process in the formation of archaeological sites, and its study can provide valuable information about stratigraphic integrity and human behavior. The numerous studies also show, however, that trampling can have diverse effects that vary significantly based on the nature of the artifacts and deposits.

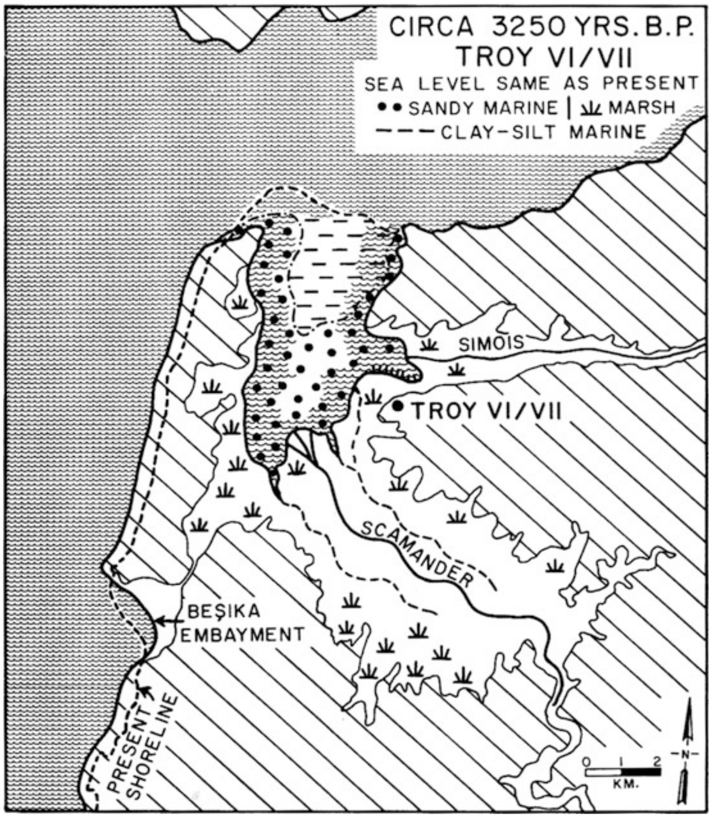
TROY

George Rip Rapp
Department of Geological Sciences, University of Minnesota, Duluth, MN, USA

Troy and the events on the Trojan plain described in Homer's *Iliad* have held a prominent place in history as a focus of human fascination for 3,000 years. Since the time of Strabo, 2,000 years ago, the geomorphic features



Troy, Figure 1 Paleogeographic reconstruction of the Scamander and Simoeis river valleys at the time of Troy VI and VII (thirteenth century BC) showing the marine embayment north of the city and the Beşika embayment to the west on the Aegean Coast where the Greek force might have landed (From Kraft et al. (1982, 36)).

of the Trojan plain (where the battles were fought) have been of scholarly interest. Strabo (1960:13.1.31) recognized that the Simoeis (Dümrek) and Scamander (Küçük Menderes) rivers merged on the plain near Troy, and "since they carry down a great quantity of silt they advance the coastline and create a blind mouth, and saltwater lagoons, and marshes" (Luce, 2003). Much modern debate has centered on the location and geomorphology of the coastline of the Trojan plain at the time of the Trojan War. In the 90 years from 1822 to 1912, Maclaren, Spratt, and Leaf published geographic information about the Trojan plain (Kraft et al., 2003). This also is the period when Schliemann excavated, on and off, at Troy between 1871 and 1890. Maclaren (1822) suggested that in Homeric times, the coast at the mouth of the Scamander and Simoeis rivers was well inland of its present position. Yet Maclaren drew a map of the "Ancient Coast and Greek Camp" with the Greek camp at the nineteenth century mouth of the Scamander, an unlikely situation given the long history of alluvial aggradation within the valley.

Beginning in 1977, an international team began an intensive coring program to detail the geomorphic changes in the Trojan coastline and on the Trojan plain. In a summary paper (Kraft et al., 2003), the authors concluded, "The reality of Homer's description of place, event, and topography correlated with geologic investigation helps show that the *Iliad* is consistent with paleogeographic reconstructions." An excellent summary of the history of work on the Trojan Plain is given by Luce (1998).

Coring determined that the Scamander and Simoeis valleys had become marine embayments with the rising of sea level after the Late Glacial Maximum; they were flooded to the ends of their respective coastal plains by 5000 BC. At the beginning of settlement at Troy (Troy I and II; early to mid third millennium BC), the Scamander Valley had filled with alluvium to a point several hundred meters north of the site, and a narrow coastal plain separated the site from the beach of a marine embayment of some 15 km in length that connected Troy to the Dardanelles Strait and the sea (Figure 1). This beach could have served as a harbor for an early Trojan fleet.

The exposed beachhead within the embayment has seemed to many a poor choice for the attacking Greek fleet at the moment of the Trojan War (Troy VIIa; thirteenth century BC), so a hypothesis has been proposed that the main Greek force landed within the Beşika embayment along the Aegean Coast (Figure 1). This location would have provided more cover yet still provided ready access to the Trojan plain, where combat took place according to the sources (Kraft et al., 1982, 37–40).

Troy was largely in ruins in Homer's day, but the remains of the Troy VI/VIIa citadel likely were still impressive. The ravages of time combined with sediment deposition drastically altered the site over subsequent millennia. In 1988, the Turkish government gave Manfred Korfmann an excavation permit for Troy itself (now known internationally as Troia). He assembled an international team to excavate and study the remains. The excavations have been quite successful considering that Schliemann, Blegen, and others had already done major digging there. A highly significant result of the Korfmann excavations has been the verification of the existence of a lower settlement from the seventeenth to the early twelfth centuries BCE (levels VI/VIIa) outside and south and east of the citadel. Magnetometer surveys and seven excavations since 1993 have shown that this lower city was surrounded at least in the thirteenth century by an impressive U-shaped fortification ditch. The layout of the lower settlement was confirmed by an intensive and systematic pottery survey in 2003. The results have demonstrated that Troy, which now covers about 75 acres, is about 15 times larger than was previously thought.

The results of these excavations and related studies have been published in a yearly series of volumes with the title *Studia Troica*. Volume I was published in 1991; volume 18 appeared in 2009. It should be noted that in addition to the prehistoric levels, extensive Roman remains have been excavated and studied.

TSUNAMIS

Beverly N. Goodman-Tchernov

Synonyms

Seismic sea wave; Tidal wave (erroneous)

Definition

Tsunami: Japanese "harbor wave."

Tsunami: long-length waves in a body of water (usually large lake or sea), generated by the substantial displacement of water.

Introduction

Human populations have long shown a preference for settling in coastal zones. The coastline is a meeting point between different resource zones and a doorway to efficient and economical water-based transport for trade. However, this rich and attractive location can also be vulnerable to forces of nature with gradual or rapid disastrous consequences such as sea-level change, hurricanes, and tsunamis. Tsunamis occur in a relatively short period of time. The warnings, if recognized, are rarely more than a half day in advance and more likely a matter of minutes to hours. The size of a tsunami varies greatly, ranging from waves that only slightly alter a typical day's tide gauge record to mega-tsunamis with the potential of wave heights in the tens of meters and inundation values over 1 km. In recent years, multiple mega-tsunamis (e.g., December 26, 2004, and July 17, 2006, in the Indian Ocean and March 11, 2011, in Tohoku, Japan; see recent discussion in Goff et al., 2012) have heightened the attention and awareness of this phenomenon and directed greater interest into the impact tsunamis have had on coastlines in the past. Archaeological coastal sites have provided some insight into understanding the impact of tsunamis over time, and geoarchaeological studies of coastal sites are at the forefront of this field.

Tsunami dynamics

Tsunamis are propagated by a sudden displacement of water that results in a wave characterized by a substantially long wavelength and greater potential for inshore run-up relative to meteorologically driven waves. The causes of tsunamis include earthquakes (subaerial and terrestrial), landslides, subaerial slumping, volcanic eruptions, meteorites, glacial felling, and explosions. While, at sea, a tsunami's wave height might be considered negligible, its wavelength can be as long as hundreds of kilometers. In contrast, large storm waves have a wavelength of 30–40 m. As the tsunami wave approaches a coastline, the shallower water depth slows the overall speed of the wave and compresses its full volume, resulting in increasing wave heights. This volume of water can then flow far inland until the wave's energy dissipates. Damages to coastal settlements resulting from tsunami impact range from insignificant to completely devastating, depending on the specific dynamics of the wave, the preparedness of the human population (particularly whether evacuation has occurred), the extent of coastal development, and the specific character of the coastline. The most vulnerable sites are those located along the coastlines, especially within harbors or estuaries where the tsunami flow is known to travel even further inland, become magnified due to reflective waves, and sometimes gain wave height.

Historical evidence of tsunami events

Written descriptions of events are important resources for reconstructing tsunami events of the past. Sources range from religious tracts, governmental records, requests for assistance, insurance maps, and historical accounts. These descriptions have been compiled into more comprehensive catalogues, traditionally presented in tandem with earthquake records, but sometimes presented independently (e.g., Lockridge and Dunbar, 1996). In areas more extensively studied, separate catalogues exist for discrete regions (e.g., Australia, Italy, Cyprus, Greece, the Eastern Mediterranean, Turkey, the Pacific Ocean, Central America, the Middle East; Soloviev et al., 1986; Molina, 1997; Fernandez et al., 2000; Riad et al., 2003; Tinti et al., 2004; Dominey-Howes, 2007; Fokaefs and Papadopoulos, 2007; Papadopoulos et al., 2007; Ambraseys and Synolakis, 2010; Altinok et al., 2011; Papadopoulos et al., 2014). These catalogues present a summary of information and known sources that provide information about past tsunamis. Some catalogues contain the source information translated into a single language, together with the original source reference, but unfortunately, the original source is sometimes difficult to access, and only translations are available. This, and other variables, can lead to complications when assessing the reliability of the information.

Common methods for determining the reliability of a written text include determining whether (1) the source is first, second, or third hand; (2) it is contemporaneous with the event or a later recollection; (3) a number of sources corroborate the same event; and (4) related accounts of simultaneous trigger events exist (e.g., earthquakes or volcanic eruptions; see Salamon et al., 2007) and (5) more recently the publication or report of field evidence. Reliability is a problem, as written records sometimes provide erroneous information for a multitude of reasons, including issues with varying calendar systems, tendencies toward exaggeration, poor information transfer, bad translation, the merging of near-contemporaneous events, or the separation of single events into multiple occurrences (Karcz, 2004). Despite these issues, the historical record remains a critical source for reconstructing historical tsunami events.

Instrumentally recorded events are available for the twentieth century to the present. These records come from tidal and wave records, aerial photographs, and more recently satellite imagery, deep-sea wave recorders, and tsunami and earthquake warning systems. Over time, more instruments are being added around the world, and in the future there should be fewer events that occur without being recorded and measured instrumentally.

Paleotsunami research

Reconstructing the occurrence of tsunamis in the past offers a means to estimate the risk for future tsunamis. Tsunamis that date prior to the historical record, or for which there are no written observations, are called "paleotsunamis" (International Tsunami Information Center, 2011). The majority of field research directed at identifying paleotsunamites (sedimentological markers of paleotsunami events) has focused on evidence for marine incursion into terrestrial areas (see discussion in Scheffers and Kelletat, 2003; Dawson and Stewart, 2007). These deposits are especially reliable, as they demonstrate specific movement of marine water above and beyond the usual storm wave zone of influence, an important criterion for properly labeling the event a tsunami rather than storm related (Goff et al., 2004; Morton et al., 2007; Ramírez-Herrera et al., 2012). Stratigraphic sequences in the terrestrial realm, such as those identified during coring or trenching campaigns, might reveal signs of previous tsunami events. Among the proxies that have been used for recognizing these changes include (1) the presence of marine-specific fauna in a setting that is otherwise terrestrial, brackish, or freshwater, (2) changes in sediment grain size, (3) marine-associated organisms within the sands or sediments, (4) erosional bottom contacts, and (5) unusual inclusions of foreign origin (Goff et al., 2012). While, in some cases, affected sites are abandoned after a tsunami strike, some sites are also regularly rebuilt and renewed following the destructive events, and this makes recognizing tsunami deposits or damage within an archaeological site complicated. Therefore, nearby sediment traps in less-inhabited areas (lake bottoms, lagoons, and artificial reservoirs) sometimes preserve more evidence of the event, which can be extrapolated to destruction sequences within archaeological sites based on age.

Evidence of tsunamis at archaeological sites

Coastal archaeological sites are particularly vulnerable to tsunami-related damages. Written records of a tsunami event might be produced when there is an occupied site that is impacted by the event. If a coastline lacks any settlements (or settlements of consequence to those recording the history), it is less likely that the event will be documented in the written record. Simultaneously, the preservation of tsunami deposits is problematic, particularly at occupied sites where rebuilding and post-tsunami cleanup further alters or erases the deposits that may be ephemeral to start.

Evidence for paleotsunami events using field techniques with geoarchaeological components has been published at a few archaeological sites worldwide including Egypt (Guidoboni et al., 1994; Stanley and Bernasconi, 2006; Hamouda, 2009), Lebanon (Morhange et al., 2006), Israel (Reinhardt et al., 2006; Goodman-Tchernov et al., 2009), Crete (Scheffers and Scheffers, 2007; Bruins et al., 2008), the UK (Dawson et al., 1988, 1990), Greece (Vött et al., 2010), and New Zealand (Goff and McFadgen, 2003; Goff et al., 2010). In some cases, studies have been conducted by reviewing and reinterpreting the causes of destruction or abandonment phases published in earlier excavation reports, such as the case of Atlit Yam (Pareschi et al., 2007; as refuted by Galili et al., 2008) and Knossos, Crete (Antonopoulos, 1992; as refuted by Minoura et al., 2000), and New Zealand prehistoric Maori sites (the reassessment by Goff and McFadgen, 2003, of the conclusions of Leach and Leach, 1979). In these cases, a reconsideration of the original findings – and in the Maori case including consideration of nearby physical findings in the non-anthropogenically altered environment – led the researchers to assign a tsunami-related cause to the damage seen at the sites. Tectonic activity and/or tsunami inundation was suggested as the major factor behind the abandonment and movement of North American west coast sites in British Columbia, Canada (Hutchinson and McMillan, 1997), as well as coastal sites in Washington State and Oregon (Woodward et al., 1990; Cole et al., 1996).

A multitude of indicators have been used to suggest tsunami-related damage at archaeological sites. With regard to physical evidence, the most important aspect appears to be the context of the deposit rather than any single feature of the deposits themselves. It is important to note that tsunami deposits can reflect only the materials and sediments supplied at that particular site, so many features may be site specific. For example, if the inhabitants of a site were regularly discarding marine shell into a freshwater lake, then marine shell in the freshwater lake itself cannot be indicative of a past tsunami. However, a sudden change in quantity, species, or individual character of those shells (breakage/wear) would have significance as would the sudden appearance of a shell horizon at a site where such activities were absent. Among the features that have been used to represent tsunamis at archaeological sites (see Goff et al., 2012, for a full summary) are (1) tilted, damaged, or altered marine installations such as harbor features or coastal constructions, (2) unusual changes in grain size distribution within sediments, (3) hiatuses or eroded horizons, (4) burials that appear disturbed or do not fit recognized cultural norms, (5) marine micro- and/or macro-paleontological deposits (e.g., pollen, thecamoebians, foraminifera, ostracods, mollusks, gastropods) distributed out of context or with unusual taphonomic features, (6) abandonment sequences contemporaneous with such features, and (7) unbroken or freshly broken and deposited ceramics or other cultural material offshore without explanatory context (shipwreck, construction fill, garbage pits). All investigations benefit from a wide geographical study of stratigraphic sequences to be able to demonstrate the presence of these unusual horizons, particularly given the common changes in their appearance depending on the dynamics of the particular geography and the variations in local source materials. In Caesarea, Israel, for example, over three tsunamis were identified in offshore cores and in excavations, and each one varied somewhat with regard to tsunami-related indicators. Many of these variations could be attributed to differences in the landscape at the time of the event, especially for events that occurred prior to heavy human occupation and therefore lacked many indicators of anthropogenic origin (ceramics, damaged harbor features, etc.; Goodman et al., 2009).

Summary

The study of tsunamis at archaeological sites is a young field. In time, as the study of field deposits from modern tsunami events advances and knowledge of their expression and dynamics grows, we can expect more descriptions of tsunami-derived deposits at archaeological sites as well. The possibility of tsunami events should always be considered when studying archaeological sites located on coastlines, particularly those in seismically active zones.

'UBEIDIYA

Carolina Mallol
Departamento de Geografía e Historia, Universidad de La Laguna, Tenerife, Spain

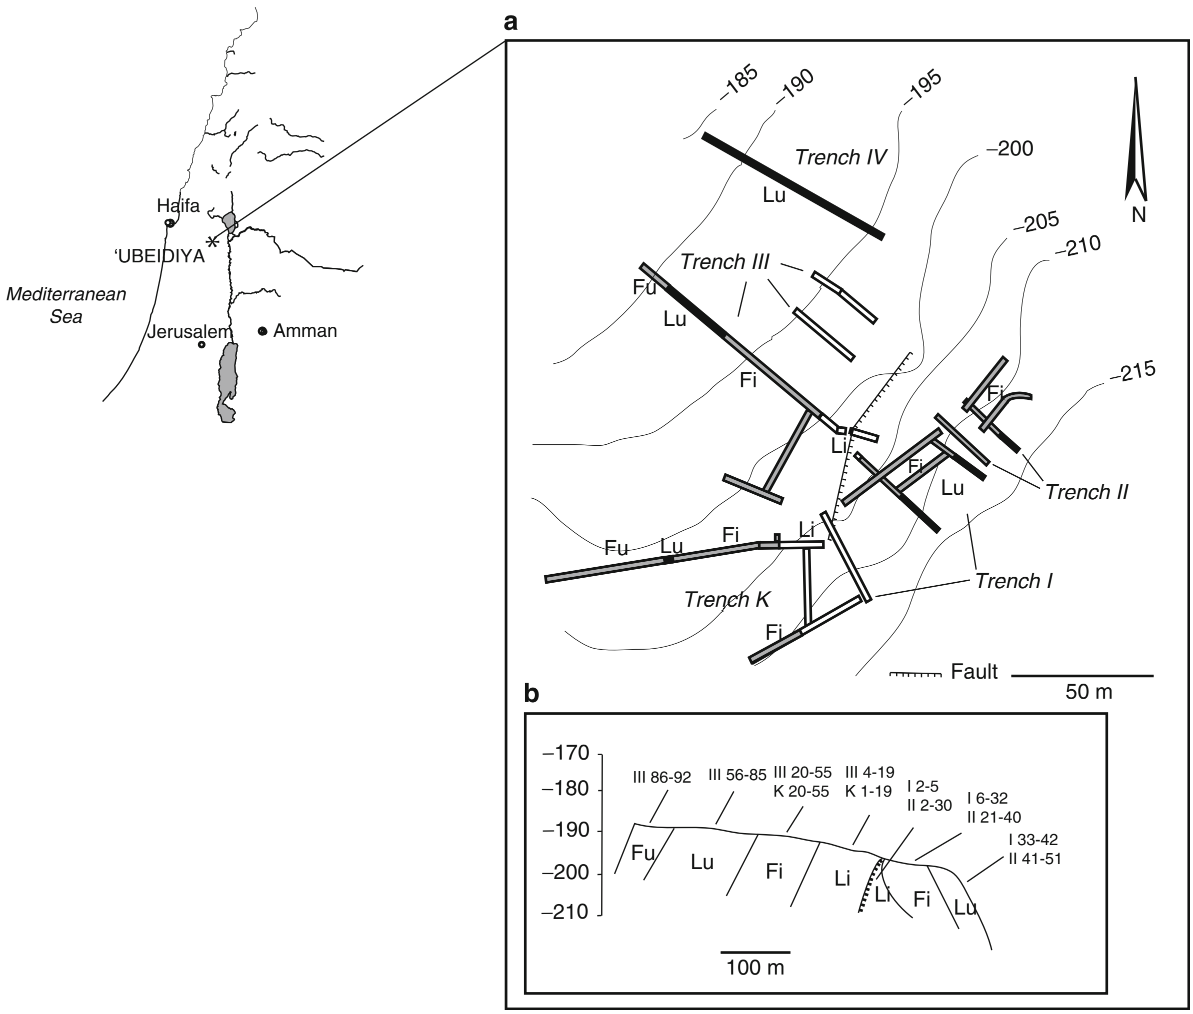
Definition

'Ubeidiya is a Lower Pleistocene archaeological site located in the Jordan Valley, 3 km south of the shores of the present-day Sea of Galilee (Figure 1). The site represents a fluviolacustrine stratified sequence of tilted graben sediments known as the 'Ubeidiya Formation (Picard and Baida, 1966). This formation, which has been dated by paleomagnetism and biochronology to ca. 1.6–1.2 Ma (Tchernov, 1986, 1987; Braun et al., 1991; Verosub and Tchernov, 1991; Heimann and Braun, 2000; Belmaker et al., 2002; Feibel, 2004; Sagi et al., 2005), is faulted and folded as part of an anticline that strikes to the NNE, forming minor anticlines and synclines at the site. As a result, the 'Ubeidiya stratigraphic layers are tilted, some of them up to 90°. The 'Ubeidiya Formation comprises four members representing an alternation of fluvial (F) and limnic (L) facies with a total thickness of about 154 m; in stratigraphic order from lower to upper, they are Li (52 m), Fi (20–30 m), Lu (56 m), and Fu (16 m) (Bar-Yosef and Goren-Inbar, 1993) (see Figure 1a, b).

The site was excavated in phases, first by M. Stekelis in 1960–1966 and later by O. Bar-Yosef and E. Tchernov in 1967–1974. Additional excavations were carried out between 1988 and 1999 by O. Bar-Yosef, E. Tchernov, and J. Shea. The archaeological record reveals abundant Villafranchian and Galerian faunal remains as well as associated Acheulean stone tools representing abandoned early hominin living floors on the marshy and pebbly shores of a lake that were occupied throughout a regressive cycle (Fi) (Bar-Yosef and Tchernov, 1972; Bar-Yosef, 1989, 1994; Bar-Yosef and Goren-Inbar, 1993; Shea, 1999; Shea and Bar-Yosef, 1999; Belmaker et al., 2002; Belmaker, 2006).

Depositionally, the 'Ubeidiya Formation originated as a succession of alternating lacustrine (mudflats and shallow subaqueous muds), palustrine (distal mudflows), and fluvial (deltaic channel and floodplain) deposits, with a prevalence of the last. The Fi cycle deposits (Figure 2) have been distinguished by their micromorphological

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,



'Ubeidiya, Figure 1 Plan (**a**) and section (**b**) views of the excavation at 'Ubeidiya indicating the position and tilt of the different members of the 'Ubeidiya Formation (Li – *white*, Fi – *gray*, Lu – *black*, and Fu – *gray*). The position of some of the key lithostratigraphic units is indicated in (**b**). Roman numerals stand for their corresponding trench (Modified from Bar-Yosef and Goren-Inbar, 1993). The site is located below sea level, so the ground surface slopes downward to the southeast with increasing negative elevation.

features, which taken as a whole and in stratigraphic order suggest a recurrent sedimentation pattern involving deposition of fluvial sediment at the shoreline followed by prolonged periods of exposure under wet conditions (Mallol, 2006). Carnivore refuse and by-products of hominin activity accumulated periodically on the surfaces of each deposit.

Prolonged postdepositional surface exposure during the dry seasons resulted in the formation of archaeological palimpsests through repeated, overlapping hominin occupations, while fluvial discharge during the wet seasons triggered localized artifact and bone translocation and abrasion (Mallol, 2006).

The entire Fi regressive cycle entailed unvarying climatic conditions with seasonal fluctuations and episodic lacustrine incursions. A trend toward arid conditions emerges at the end, as evidenced by an increase in microscopic sedimentary desiccation features toward the top of the sequence (Mallol, 2006).

Human impact on the sediment was minimal at 'Ubeidiya. No signs of trampling or inclusion of microscopic anthropogenic debris have been found in the sediment that makes up the naturally deposited cobble floors (Figure 3), as well as the gravelly and muddy layers associated with the archaeological remains. No signs of anthropogenic fire have been identified.

Thorium-230 (^{230}Th) dating; Uranium disequilibrium (^{234}U/^{238}U) dating; Uranium-lead (U-Pb) dating; Uranium-series disequilibrium dating; Uranium-thorium (U-Th) dating

Definition

Uranium-series dating is a broad term covering a number of geological dating schemes based on the measurement of the natural radioactivity of uranium isotopes U-238 (^{238}U) and U-235 (^{235}U), as well as their daughter isotopes in material which initially contained only the parent uranium.

Uranium-lead (*U-Pb*) *dating* uses the amount of stable ^{206}Pb, the end product of the ^{238}U decay chain, relative to the amount of initial ^{238}U to calculate the time of formation (and thus age) of a sample.

Uranium-thorium (*U-Th*) *dating* is a specific method that uses only a section of the ^{238}U decay chain to calculate the time of formation (and thus age) based on the degree to which equilibrium has been restored between the radioactive daughter isotope thorium-230 (^{230}Th) and its radioactive parent, ^{238}U.

Introduction

U-series dating has had a profound impact on the earth sciences in providing ages for the Earth itself and Quaternary science in particular. It is one of the most widely used dating techniques after radiocarbon. The history of its development begins with the seminal work of Marie Curie in the early 1900s that led to the discovery of the ^{238}U decay chain and natural radioactivity. The years following World War II saw the development of the U-series technique, which was primarily applied to dating deep-ocean sediments. During the 1960s, the method was expanded to include dating of both marine and terrestrial carbonates, which remain the central focus today. As with radiocarbon, U-series dating has benefitted greatly from the application of mass spectrometry, with significant advances taking place during the 1980s, as well as within the last 10 years, yielding improvements in both precision and accuracy.

Uranium (U) is present as a trace element in all natural materials, and it occurs as six isotopes ranging in atomic weight from U-233 to U-238. ^{238}U is by far the most common isotope, making up 99.27 % of all known uranium, with ^{235}U the next most abundant at only 0.72 %. All the other isotopes occur at very minimal levels (Grenthe et al., 2011). The U-series dating technique is based on the natural decay of ^{238}U to lead-206 (^{206}Pb), with a half-life of 4.47 billion years, and of ^{235}U to lead-207 (^{207}Pb), with a half-life of 704 million years (Grenthe et al., 2011) (Figure 1).

The systematics of U-series dating are complicated, and a specialist will generally undertake the analysis. This entry is an overview of the essential concepts behind the method, a summary of the laboratory techniques and advances, and a review of some applications to archaeology. Other very good general overviews are provided by Schwarcz (1989, 1992), Smart (1991), Latham (2001), Pike and Pettitt (2003), and Walker (2005). More detailed, technical reviews of the method and its applications can be found in the edited volumes by Ivanovich and Harmon (1992) and Bourdon et al. (2003). The rapidly advancing field of U-Pb dating of carbonates is reviewed in Rasbury and Cole (2009).

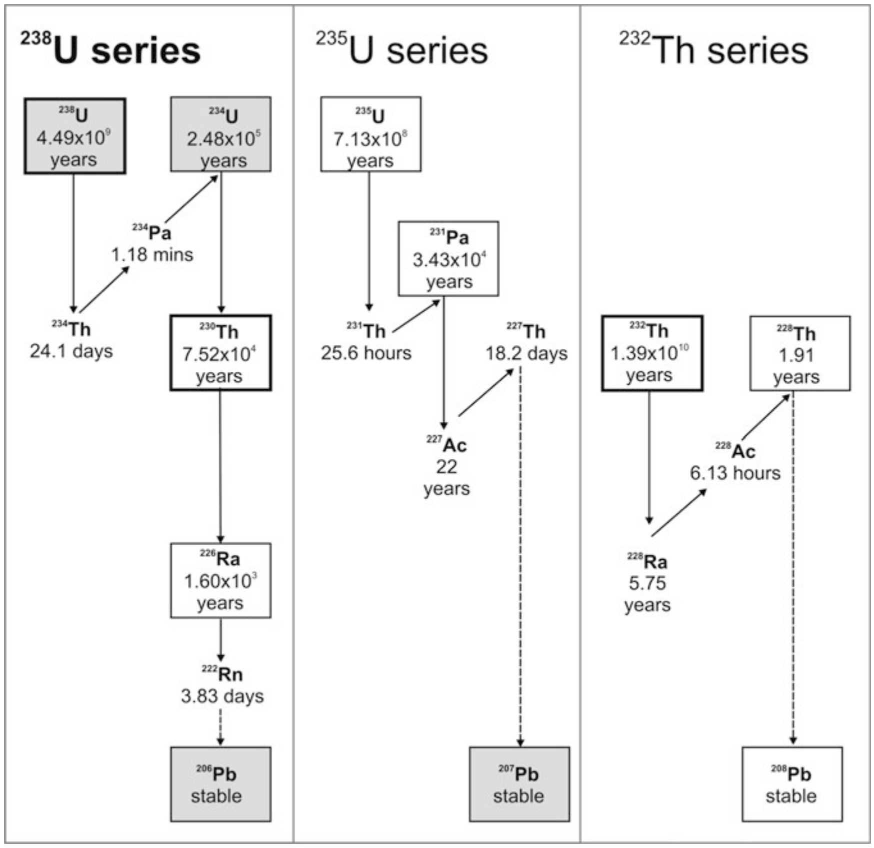
Essential concepts of U-series dating

The U-series decay chain contains radioactive isotopes of many elements, among them U, Th, Pa, and Ra, ending in stable Pb (Figure 1). In a closed system, the intermediate isotopes exist in so-called secular equilibrium, that is, their abundance ratios are such that each isotope decays at exactly the rate at which it is produced. Various natural processes cause the fractionation, or separation, of these elements, disturbing these equilibria among the isotopes. The gradual return to equilibrium conditions allows for a quantification of the time passed since the fractionation-causing event. In other words, the event that disturbed the equilibrium state of the isotopes, such as formation of a speleothem, can be dated by determining the extent to which the isotopes have reestablished equilibrium.

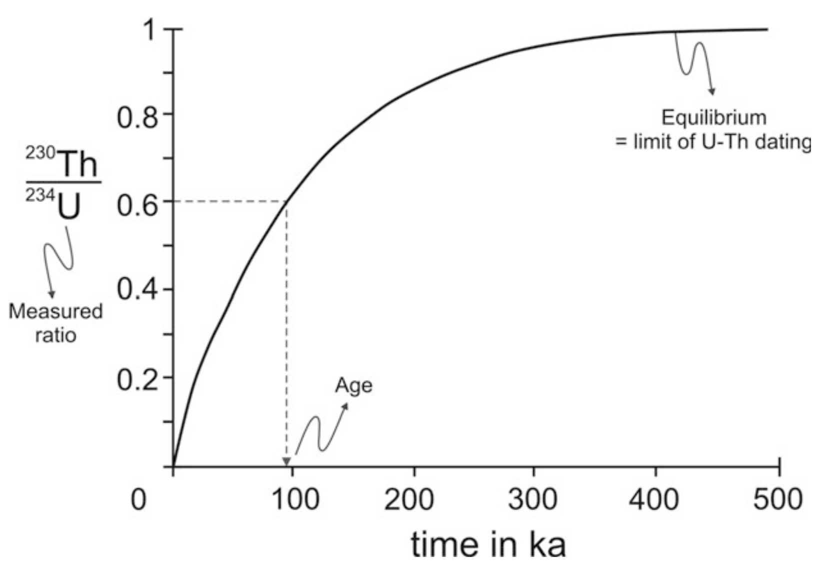
The most common process responsible for the fractionation of the isotopes in the U-series decay chain is the huge difference in solubility between U and Th. U is highly soluble in natural waters, while Th is not. For example, cave-drip waters are rich in U but almost devoid of Th; the stalagmite calcite formed from these waters therefore contains a few parts per million of U, with negligible amounts of Th. The subsequent in situ decay of ^{234}U to ^{230}Th, with a half-life of 245,000 years, can be used to date the material by measuring the present levels of both isotopes (Bourdon et al., 2003) (Figure 2). This U-Th dating method is inherently suitable to carbonate material, such as coral and cave carbonates or speleothems, as these develop from natural, U-rich, Th-poor waters.

However, ^{230}Th is itself radioactive, with a half-life of 75,000 years, so instead of accumulating indefinitely (as is the case for the U-Pb system), it instead approaches secular equilibrium with its parent isotope (Figure 2). This gives the U-Th dating system an upper age limit of around 500,000 years. With advances in mass spectrometry, corals as old as 600 ka can be dated (Andersen et al., 2008), with the other end of the datable age spectrum as young as a few thousand years (Cobb et al., 2003).

The U-series decay chain continues on beyond ^{230}Th and ends in stable ^{206}Pb, with a half-life of 4.47 billion



U-Series Dating, Figure 1 A schematic diagram of the U-series decay chains of ^{238}U, ^{235}U, and ^{232}Th. Isotopes involved in U-Th dating are shown in *bolded boxes*, while isotopes used in U-Pb dating are in *grey shaded boxes* (Image redrawn and modified from Walker, 2005).



U-Series Dating, Figure 2 A graph of the ratio of the radioactivity of ^{230}Th to that of its parent isotope ^{234}U as a function of time. If the initial $^{230}Th/^{234}U$ ratio is zero, then the age (x axis) can be read from this chart using the present, measured $^{230}Th/^{234}U$ ratio (y axis). As the $^{230}Th/^{234}U$ ratio approaches 1, the curve flattens out, producing infinite ages and an effective upper limit for U-Th dating (Redrawn and modified from Schwarcz, 1992).

years (Grenthe et al., 2011), meaning that U-Pb dating is easily suitable for materials belonging to long geological time scales, including the age of the Earth itself (Patterson, 1956). In fact, the challenge of U-Pb dating is applying it to “young” material only a few million years old and to even younger archaeological time scales. At present, U-Pb dating of younger material is restricted to rocks such as carbonates (Rasbury and Cole, 2009), including cave carbonates or speleothems (Woodhead et al., 2006). The advantage of U-Pb dating is that it covers the time period earlier than ~500 ka and picks up where U-Th dating and other Quaternary methods, such as OSL (optically stimulated luminescence), leave off. U-Pb dating of speleothems is a rapidly growing field that is already beginning to make an impact in areas like human evolution (e.g., Pickering et al., 2011a).

The simplest but essential prerequisite for successful U-series (as in U-Th and U-Pb) dating is that the material being dated has acted as a “closed system” (Walker, 2005). This means that since the time of formation, there can be no loss or gain of isotopes. If such a closed system can be achieved, then it is safe to assume that the measured Th in a sample is solely the product of the in situ decay of U. Most carbonates, corals, and speleothems fulfill this requirement, making them good candidates for U-series dating. Biological carbonates, such as bone, teeth, and shell, do not behave as a closed system but rather as “open systems,” with isotopes moving in and out of material post-deposition. In archaeological settings, material such as coral and speleothem may be rare, while bones, teeth, and shells are abundant, so much effort has gone into modeling the open-system behavior of buried bone (Hedges and Millard, 1995; Pike et al., 2002).

Laboratory techniques and advances

In order to undertake U-series dating, the isotopes of interest need to be isolated and concentrated from the bulk sample material. This is achieved through isotope dilution (Faure, 1977), often accomplished through ion-exchange chromatography. Once separated, these isotopes must be measured with the highest possible precision. The original measuring technique was alpha spectrometry, which relied on the alpha-emitting characteristic of ^{238}U as it decays. Very thin (one atom thick) layers of isotopes are placed in the alpha spectrometer, and as alpha particles are emitted, the alpha detectors produce electronic signals that generate a digital spectrum equivalent to the energy of the alpha particles. Tabulating counts vs. energy of the sample produces an alpha spectrum from which the isotopes of interest can be identified and quantified (Smart, 1991; Schwarcz, 1992; Latham, 2001; Goldstein and Stirling, 2003). Using this method, a single U-Th measurement usually takes a few days (Latham, 2001); even with over 10,000 counts, 1σ age errors for each isotope are at best 1 % and usually between 5 % and 10 % (Smart, 1991).

The 1980s saw one of the most significant advances in U-series dating with the rise of mass spectrometer analysis, whereby individual atoms are counted, as opposed to the less abundant alpha particles (for a detailed review, see Goldstein and Stirling, 2003). The mass spectrometer of choice at the time was a thermal ionizing mass spectrometer or TIMS. TIMS had a revolutionary effect on U-series dating; sample sizes and analytical errors dropped considerably, and the precision of age determinations increased (Chen et al., 1986; Edwards et al., 1987). Analysis time was also reduced from a week to several hours, meaning the number of samples analyzed increased substantially (Goldstein and Stirling, 2003). This method was initially developed for corals. The much more precise ages obtainable meant that corals as old as ~120,000 years could be dated, so for the first time, links between past sea levels and Milankovitch forcing could be made with conviction (Edwards et al., 1987). This method spread swiftly and was soon adapted for dating terrestrial carbonates, such as cave carbonates or speleothems, including stalagmites and flowstones (Li et al., 1989). Once dated, these deposits could be analyzed for the paleoenvironmental data contained within them, and the field of stalagmite studies grew rapidly.

The most recent advance in U-series dating is linked to the development of inductively coupled plasma mass spectrometry (ICP-MS). There are major advantages to this method, making it the dominant one for measuring U-series isotopes (Goldstein and Stirling, 2003). The high temperatures achieved in the plasma (~6,000 K) produce ionization efficiencies of >90 % for nearly all elements, and the signal intensity can be easily increased by using a more concentrated solution. Mass bias can be easily corrected for, and sample throughput is typically faster than for TIMS (Goldstein and Stirling, 2003). Multicollector ICP-MS is even more powerful, as multiple isotopes can be measured simultaneously, leading to very precise ages. For a more detailed discussion, see Goldstein and Stirling (2003).

An alternative to isotope dilution techniques is in situ measurements using laser ablation ICP-MS. Eggins et al. (2005) explored the potential of this method and found that dating could be successfully undertaken on samples as small as 100 μm and with U concentrations as low as 1 ppm. Another advantage of this approach is that U and Th concentrations, as well as U-series isotope ratios, can be continuously profiled along a sample, which is especially useful when trying to date bones, teeth, or shells (Eggins et al., 2005; Duval et al., 2011). Laser ablation can also be used to rapidly characterize, screen, and select suitable material from which dates can be obtained using conventional isotope dilution methods (Eggins et al., 2005). Although the amount of material consumed during laser ablation is negligible and the preparation of samples straightforward (Eggins et al., 2005), larger specimens such as stalagmites have to be cut up into ~10 cm slabs, which can be very destructive. An alternative to this is the use of a passive imaging technique, such as phosphor imaging, to create a "map" of the areas of higher radiation, assumed to be U rich, in the sample material prior to dating (Cole et al., 2003; Pickering et al., 2010).

Potential problem areas

The two major problem areas with U-series dating as it is applied to geoarchaeology are (1) the context of the dated material and (2) the suitability and purity of the material being dated. The chronostratigraphic relevance of the dated material to the fossils or archaeological deposits is one of the most common, and also most easily avoided, problems. If a flowstone layer underlies an archaeological deposit, it provides a maximum age (*terminus post quem*) for the deposits. Similarly, if a flowstone overlies a deposit, it provides a minimum age (*terminus ante quem*). However, many thousands to tens of thousands of years may be left unrecorded between the formation of the flowstone and deposition of the archaeological sediments. Ideally, if flowstone layers occur both above and below the deposits, then U-series ages for these layers can be used to infer the age of the deposits sandwiched between them. These circumstances, however, are rare, so the importance of understanding the local geology, site formation processes, stratigraphy of a deposit, and relationships between the dated layers and archaeological deposits, cannot be overstated.

Another frequently encountered problem is the suitability of the material of interest for dating. As already outlined above, speleothems (stalagmites and flowstones) make the best targets for U-series dating because they behave as a closed system. However, materials of greater interest to archaeologists, such as fossil bones, teeth, and shell, are often inherently unsuitable for U-series dating because these organic materials are subject to postmortem open-system behavior. Both uranium and thorium isotopes are mobile, and their uptake and loss needs to be modeled (Hedges and Millard, 1995; Pike et al., 2002; Pike and Pettitt, 2003). One possibility is to use in situ laser ablation to create profiles along material such as bones, teeth, and possibly mollusks to map out the patterns of U migration (Eggins et al., 2005). This approach has also been attempted using the U-Pb system on fossil tooth enamel from the early human (hominin)-bearing cave site of Swartkrans in South Africa (Balter et al., 2008). Again, the problem is that the post-deposition U loss has to be modeled, leading to ages with large uncertainties.

Even material well suited to U-series dating may suffer from contamination, however. The most common contamination is of the daughter isotopes, where some non-radiogenic isotopes are also incorporated into the material at the time of formation, adding to the daughter isotopes that are entirely of radiogenic origin (Walker, 2005). For U-Th dating, the ^{232}Th/^{230}Th ratio can be used as a measure of contamination of ^{230}Th from detrital material, such as dust, clay, or silt. ^{232}Th is not part of the ^{238}U decay chain used in U-Th dating (see Figure 1); it does not occur in pure calcite but does occur in detrital material, so its presence signifies detrital contamination, and the ratio of ^{232}Th/^{230}Th can be used to correct for this (Walker, 2005). This correction is usually made by constructing an isochron (Schwarcz and Latham, 1989). In the U-Pb dating scheme, radiogenic ^{206}Pb can be completely obscured by common ^{206}Pb, meaning that all age calculations are done by multiple sample analysis and isochron construction (Richards et al., 1998; Woodhead et al., 2006). A major issue in U-Pb dating of speleothem material is the initial ^{234}U/^{238}U ratio, both in how this is quantified (measured directly or modeled) and also how this ratio is taken into account in the U-Pb age calculations (Richards et al., 1998; Woodhead et al., 2006; Pickering et al., 2010). Without taking the initial excess of ^{234}U into account, ages are often greatly overestimated.

Examples of geoarchaeological applications

U-Th-dated speleothems associated with fossils and/or artifacts

U-series dating is best applied to speleothems, and their utility for dating archaeological sites has long been recognized (Schwarcz et al., 1979). In an early study at the cave site of La Chaise-de-Vouthon in France, U-Th dating was used to constrain the age of Lower to Middle Paleolithic artifacts and several Neanderthal fossils (Blackwell et al., 1983). The caves at La Chaise-de-Vouthon contain sedimentary deposits including numerous hominin fossils. Flowstone layers are interstratified with the fossil-bearing sediments, and these were dated using alpha spectrometry, providing a range of ages from $245 + 45/-28$ to 97 ± 6 ka and forming the chronology for the sequence. The hominin remains, in this case Neanderthals, consist mainly of fossil teeth that are found in the layers older than 101 ka (Blackwell et al., 1983).

The field of paleoanthropology was shaken up forever in 2004 by the discovery of a small, ~1 m tall hominin fossil nicknamed "The Hobbit" and known formally as *Homo floresiensis*, after the island of Flores where it was found (Brown et al., 2004). Knowing the age of the fossils is key to their interpretation. The deposits of Liang Bua cave have been thoroughly dated using ^{14}C, OSL, ESR (electron spin resonance), and U-series, with fossils and archaeological artifacts recovered from deposits spanning the interval of 95–12 ka (Morwood et al., 2004; Morwood et al., 2005; Roberts et al., 2009).

The cave sites along the Southern Cape coast in South Africa at the site of Pinnacle Point are an example of where U-Th dating of flowstones, coupled with OSL dating of archaeological sediments, has provided valuable age information (Marean et al., 2007). The oldest appearance of modern human behavior, evidenced in the systematic exploitation of marine resources, use of pigment, and production of bladelet stone tool technology, is dated to 164 ± 12 ka at these sites (Marean et al., 2007). The oldest known controlled use of fire, seen in the heat treatment of stone tools, is also documented at Pinnacle Point (Brown et al., 2009).

An alternative to dating flowstone layers, especially when these are absent from the deposits of interest, is to date buried speleothem material, such as buried soda straws, or tubular stalactites (St Pierre et al., 2012). Straws are so fragile that they cannot survive reworking, so their presence suggests rapid burial, and they can thus provide ages close to the time of sedimentation. This approach has been tested at Blanche Cave in South Australia (St Pierre et al., 2012).

U-Th dating rock art

In rare cases, speleothem deposits are directly associated with rock art and can be used to constrain the age of the paintings. This approach is most effective when the paintings are both under- and overlain by flowstone layers. By nature, such flowstones are prone to detrital contamination, so ages must be calculated via isochrons. Direct dating of rock art is complicated, and results must be interpreted with caution (Pettitt and Pike, 2007). One example is from China, where paintings in the Jinsha River area of northwest Yunnan Province have been dated to between 5,738 and 2,050 years old, and the older paintings are shown to be at least 3,400 years old (Taçon et al., 2012). It is also possible to date rock engravings using the same method by dating a thin flowstone layer covering them. Such an approach was used to date the oldest known rock art in Britain, where engravings at Creswell Crags were dated to 12,800 years BP (Pike et al., 2005).

U-Th dating organic material

As mentioned above, U-Th and U-Pb dating of organic material, such as bones and teeth, is particularly useful in geoarchaeology because these are primary archaeological materials (Pike and Pettitt, 2003). However, bones and teeth are also inherently open-system materials, and the need to model this behavior often leads to ages with considerable errors.

There is a long history of using U-Th to date fossil bone from China, where the bones are very well preserved by mineral salts in solution percolating through the deposits, leading to permineralization. While there has been some success in dating the fossils, the best results are obtained by also dating flowstones intercalated with the deposits (Shen et al., 2001). These authors provide ages of between 400 and 500 ka for the "Peking Man" (*Homo erectus*) fossils from the Zhoukoudian Cave site, southwest of Beijing. These U-Th ages imply that human occupation of the Zhoukoudian site occurred much earlier and lasted much longer than previously thought.

A recent example of U-Th dating of bone is at the site of Cova del Gegant in Spain, where a range of dating techniques has been used to constrain the age of the deposits, along with careful work on the stratigraphy and history of sedimentary infilling of the cave (Daura et al., 2010). The deposits themselves are dated to 49.3 ± 1.8 ka, based on the U-Th age of the capping flowstone, and 60.0 ± 3.9 ka, based on the OSL of basal sediments. The U-Th age on the Neanderthal mandible itself falls neatly within this bracket at 52.3 ± 2.3 ka (Daura et al., 2010). Further examples and a discussion of the problems associated with U-series dating of bone are detailed in Pike and Pettitt (2003). U-series dating can also be used in conjunction with ESR dating of fossil tooth enamel and dentine. The Banyoles mandible, from Girona, Spain, anatomically appears to be pre-Neanderthal but is encased in travertine dated to ~45 ka, by which time pre-Neanderthals were thought to be extinct in this region for over 100 ka. Combined U-series and ESR dates give an age of 66 ± 7 ka (Grün et al., 2006), which is still younger than expected, thus highlighting the importance of the context of the fossil and the variation in the Neanderthal fossil record.

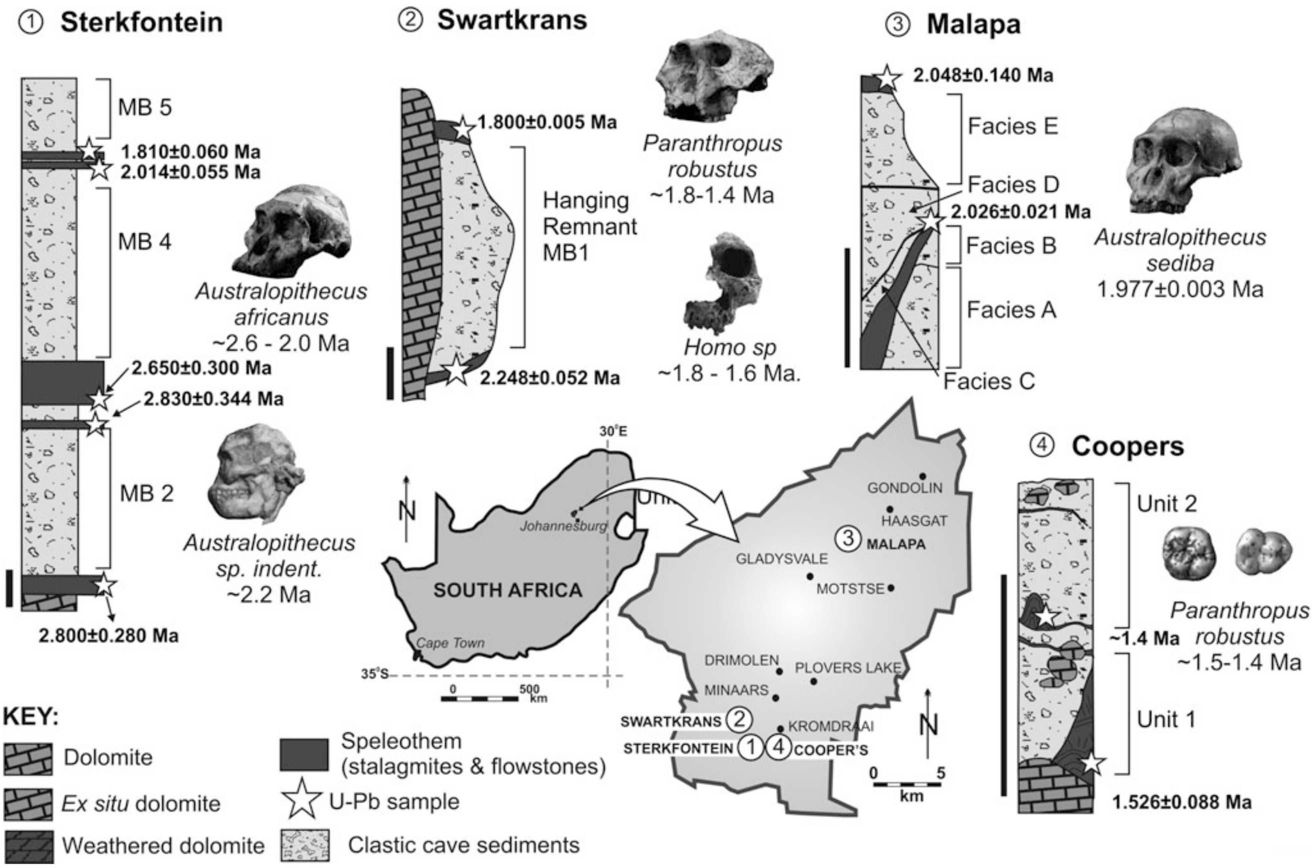
An exciting possible alternative to dating bone or teeth is dating buried wood. A method for this has been successfully applied to buried wood of pre-Holocene age from sediment sequences along the Hudson Bay lowlands in Canada (Allard et al., 2012) and could have many applications in archaeological settings.

U-Th-dated speleothems as records of paleoclimate

Ages from flowstones and stalagmites not directly associated with archaeological deposits are still of interest and can inform on the life history of the caves, their cycles of opening and closing, and their availability for occupation, such as at the Naracoorte Caves in South Australia (Ayliffe and Veer, 1988; Moriarty et al., 2000). The carbon and oxygen isotope records from such speleothem material can also be used to infer past climates and provide the paleo-environmental context for the archaeological deposits, such as at the Pinnacle Point caves in South Africa (Bar-Matthews et al., 2010) and at the *Homo floresiensis* site of Liang Bua on the island of Flores (Westaway et al., 2009).

U-Pb dating of flowstone applied to early hominins

The series of dolomite-hosted caves in the region known as the "Cradle of Humankind" are the richest source of hominin fossils outside East Africa: at least four species of hominin are represented, as well as an abundant fossil fauna. These caves provide ideal targets for the recently developed U-Pb techniques (Pickering et al., 2010): while the cave sediments themselves are complex and not simple layer-cake deposits, flowstone layers are ubiquitous. U-Pb ages for flowstone layers from above and below the major hominin-bearing sediment layers from three of the most important sites – Sterkfontein, Swartkrans, and Coopers – provide broad age ranges for these deposits between ~2.8 and ~1.4 Ma (see Figure 3) (de Ruiter et al., 2009; Pickering and Kramers, 2010; Pickering et al., 2011a; Pickering et al., 2011b), as well as an age of



U-Series Dating, Figure 3 A summary diagram of the cave sites in the "Cradle of Humankind," South Africa, showing the location of these caves, their stratigraphy, the position and age of U-Pb-dated flowstones, and the corresponding ages for the early hominin fossils from each site (Data taken from Walker et al., 2006; de Ruiter et al., 2009; Dirks et al., 2010; Pickering and Kramers, 2010; Pickering et al., 2010; Pickering et al., 2011a; Pickering et al., 2011b).

~2.2 Ma for the flowstones surrounding the "Little Foot" fossil (StW 573) at Sterkfontein Cave (Walker et al., 2006). At present, the U-Pb age ranges are necessarily broad. However, if combined with the paleomagnetic signal preserved in the flowstones and sediments surrounding the actual fossils, much narrower time ranges can be obtained, such as for *Australopithecus sediba* (Pickering et al., 2011a).

Summary

The contribution of U-series dating to Quaternary science in general and geoarchaeology in particular has been considerable. The presence of an alternative chronometer to ^{14}C dating and OSL, reaching back in time well beyond the cutoff for both these methods, is a welcome addition to the field. U-series dating has benefitted from advances in mass spectrometry, and today, large volumes of precise ages can be easily and quickly obtained. Carbonates are best suited to U-series dating, and the ability of U-series to provide both accurate and precise ages on speleothem material is particularly useful in dating cave deposits containing fossils or archaeological remains. This is especially pertinent because caves, functioning either as occupation sites or receptacles for surface material being washed in, provide an environment with potentially high preservation. As such, U-Th, and more recently U-Pb, has had a significant impact on dating early human or hominin fossils. Research into directly dating fossil material, i.e., bones and teeth, is ongoing. The most important aspect of using U-Th dating in geoarchaeology is the context of the dated material and how this relates to the fossils or artifacts of interest.

VOLCANOES AND PEOPLE

Payson Sheets
Department of Anthropology, University of Colorado, Boulder, CO, USA

Introduction

Volcanoes and people have been interacting as long as people have been on earth, and those interactions include beneficial and detrimental aspects. Volcanic activity can provide useful resources, such as stone for building and tools, and parent material from which rich soils can develop. Eruptions can preserve settlements to an extraordinary degree, such as Pompeii, from which we can learn much about ancient peoples and cultures. Volcanic eruptions can have creative repercussions, as people learn about hazardous zones and recoveries, and they alter their locations of settlement and even their belief systems to accommodate to risks. Eruptions can also be destructive, causing many human injuries and deaths, devastation of natural habitats, or even the demise of societies.

Volcanic activity

The Smithsonian Institution provides a comprehensive worldwide website of volcanic eruptions that have occurred during the past few million years at: http://www.volcano.si.edu/index.cfm. Volcanoes can erupt effusively, with hot magma flowing in rivers such as those in Hawaii. They may fill in fertile valleys and take a long time to weather to cultivatable soils, but they rarely harm people directly. During explosive, or Plinian eruptions, volcanic ash and gases are blasted into the air from whence they fall and affect widespread areas, potentially causing significant human impacts. Volcanic ash weathers more rapidly than lava, and thin deposits can be beneficial to soils shortly after they fall to the ground. Volcanic ash deposits are sometimes mobilized by water saturation many years after the last eruptive event and flow as a lahar; this viscous slurry can move very rapidly depending on the slope, and they can fill valleys with devastating effect to everything in its path. A recent summary of the nature of volcanic eruptions also includes their effects as well as controversies about interpretations (Oppenheimer, 2011).

Volcanic eruptions and early human evolution

Our early ancestors of a few million years ago had occasional interactions with volcanoes. Footprints at Laetoli, Tanzania, are preserved in volcanic ash that dates to about 3.6 million years ago (Leakey, 1979). They demonstrate upright bipedal walking by early australopithecines. Olduvai Gorge, also in Tanzania, has yielded fossil bones and stone tools of australopithecines, *Homo habilis* and *Homo erectus*, over a two-million-year time span, dated as at Laetoli by radiometric techniques such as K-Ar and Ar-Ar on volcanic ash layers (Renfrew and Bahn, 2004, 152–153). The skeletons document biological evolution, and the stone tools show increasing sophistication from crude Oldowan pebble tools to sophisticated bifacially flaked implements.

Vesuvius volcano and Pompeii

The most famous interaction of people and volcanoes in ancient times is the eruption of Vesuvius which resulted in the burial of Pompeii and its sister city Herculaneum (Berry, 2007). Pompeii was a resort city for affluent Romans, with elegant public buildings including temples, theaters, baths, brothels, fora, and markets, along with many multistory residences, all encircled by high city walls. Many households engaged in crafts such as making bread. Many residences are decorated with painted murals that depict aspects of everyday life, feasting, and religious scenes. Public notices were painted on walls announcing

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

festivals and political candidates. Graffiti included a wide range of personal matters.

Pompeii was buried by about 5 m of volcanic ash from Vesuvius volcano on 24 August AD 79. There were some warnings, such as strong earthquakes, and many residents fled the city. Evidently, some fled to Herculaneum, where they were eventually killed during the eruption by pyroclastic flows, swift-moving density currents of gases, and rock that flow downward and outward from the erupting volcano and sometimes reach temperatures over 1,000 °C. Hundreds of others remained in Pompeii and were killed, along with their animals, asphyxiated by gases and covered by ash and lapilli – larger pieces of congealed magma that fall with the ash. Apart from the misfortune of those killed and entombed, the volcanic ash preserved the city so well that we can learn much from it.

Pompeii was rediscovered in 1748, and for over a century it was "mined" for marble sculptures by underground tunneling with no recording of where recovered objects came from. The earliest archaeology dates to the 1860s with the work of Giuseppi Fiorelli. He devised the technique of filling with plaster of Paris the hollows left in the volcanic ash where a person had been encased and subsequently decomposed. Once the molds were revealed, the people could be seen in great anguish as they struggled to breathe and eventually died. Excavations have continued into the present, until almost the entire ancient city has been dug, representing the most extensive urban archaeology project in the world. The social, political, economic, and religious life of Romans, at about the apex of their civilization, are revealed by the careful excavations of the well-preserved remains.

Oppenheimer (2011, 111) notes the irony that the Vesuvius eruption that buried Pompeii and Herculaneum is the most famous volcanic-human interaction remembered today, yet it had very little impact on Roman civilization at the time. Probable reasons for its minimal impact include Pompeii's relatively small population, about 10,000 people, compared to the overall population of Rome's thriving and expanding empire, and the fact that the area devastated by Vesuvius was a tiny fraction of the total empire, and agricultural recovery was reasonably rapid in areas buried less deeply than was Pompeii.

The Thera eruption and Minoan civilization

Based on the large island of Crete, the Minoan civilization thrived in the eastern Mediterranean during the centuries from around 2500 BC to about 1500 BC (Doumas, 1983; Castleden, 1990). The civilization is known for elaborate palaces, elegant art in sculptures and wall paintings, and maritime trading all around the eastern Mediterranean. The Minoans produced high-quality wheel-thrown pottery, metal objects, ivory carvings, and other goods that were in high demand by other societies. The relatively thin dusting of volcanic ash from Thera arriving on Crete would not have caused great difficulties, but the tsunami generated by the eruption (Oppenheimer, 2011, 235) would have destroyed the fishing and trading fleets as well as warships.

Minoan civilization went into a decline, marked by the destruction by burning of palaces at about 1450 BC. Civil disorder was widespread, with internal conflict, abandonments of settlements, hoarding, and the emergence of religious "crisis cults" and even human sacrifice and cannibalism (Oppenheimer, 2011, 237). The demise of Minoan civilization allowed its land-based competitor, the Mycenaean civilization, to expand and thrive. As early as the 1930s, scholars suggested the cause of the decline was the eruption of Thera volcano. Located 110 km north of Crete, Thera, on the island now called Santorini, erupted violently and deeply buried a Minoan city called Akrotiri. The residents apparently had sufficient warning and evacuated, as no bodies have been found to date. The architectural preservation is much like at Pompeii, and the multistory buildings have beautiful murals depicting landscape scenes, men boxing, and religious themes. The volcanic destruction and excellent preservation of Akrotiri by the eruption is incontrovertible, but it remains controversial if that eruption was instrumental in the decline of Minoan civilization. Some have argued it was the sole cause for the decline, others propose that it was a contributing factor, and yet others claim that it was not connected. A key issue is whether the eruption and the collapse correspond in time. Initially thought to have occurred around 1500 BC, it is now suspected that the volcanic event happened earlier, with radiocarbon dates and possibly related climatic proxy evidence from other parts of the world suggesting a date around 1628 or at least in the late seventeenth century BC (Friedrich et al., 2006; Manning, 2014).

Highland central Mexico

Teotihuacán (Evans and Webster, 2001, 723–735) was the largest, most highly organized, and most influential city of the New World during the first millennium AD (Figure 1). It was affected three times by volcanic activity: twice early in its growth and once at its apex. The Xitle eruption (Siebe, 2000), about 2,000 years ago in the southern Basin of Mexico, devastated Cuicuilco, the largest polity in the area. Many refugees apparently went to Teotihuacán, contributing to its remarkable growth spurt at that time (Evans and Webster, 2001, 199). Popocatepetl volcano, on the west side of the basin, erupted a little more than 2,000 years ago (Siebe et al., 1996). Its eruption was many times greater than Xitle's and devastated productive lands to the east. Many refugees may also have gone to Teotihuacán and been part of its sudden population explosion. The city grew to be a regional power, with religious, social, and economic impacts throughout most of Mesoamerica even as far as Copan in Honduras.

The Popocatepetl eruption deposited volcanic ash over cornfields and households to the east, preserving them extraordinarily well (Plunket and Uruñuela, 1998).

Volcanoes and People, Figure 1 Teotihuacan was the largest ancient city in Mexico from about AD 100–550. The "Avenue of the Dead" runs north and south past many small pyramids, as well as the huge Pyramid of the Sun on the left. The wooden temples atop the small pyramids were deliberately burned when people lost faith in their religion around AD 550.

The households at Tetimpa were standardized, with multiple buildings facing a central patio. Each patio featured a volcano effigy shrine indicating anxiety about a future eruption and the use of supernatural means to mitigate or avoid it.

The demise of Teotihuacán is not well dated. It could have happened as early as the mid-sixth century or as late as the eighth century. The problem that produces this vagueness is a flattening of the radiocarbon calibration curve, which makes precise dating impossible. If the collapse occurred in the mid-sixth century, then it may well have been caused by a colossal volcanic eruption (see below).

The volcanically caused worldwide atmospheric phenomenon of AD 536

A dry fog dust cloud spread worldwide throughout the atmosphere in AD 536 and was recorded by historians in China, where the prolonged cold and drought caused by reduced solar radiation produced crop failures and the deaths of approximately 75 % of the people in a northern kingdom (Houston, 2000). Other authors in the same volume as Houston's chapter document similar crop failures, starvation, and social instabilities in Europe, North Africa, and the Near East, all beginning at AD 536 and continuing for many years. Larsen et al. (2008) document the most severe cold years of the past two millennia beginning in AD 536 as recorded in tree rings in the Northern Hemisphere. They also note strong sulfur spikes in ice cores in Greenland and Antarctica at the same time and conclude that the cause must have been a large explosive volcanic eruption near the equator. Dull et al. (2010) suggest the massive explosive eruption of Ilopango Caldera in El Salvador at 14° north of the equator probably was the cause. The eruption blasted some 84 km^3 of volcanic ash into the atmosphere, completely eliminating all living flora, fauna, and people in central and western El Salvador. The Miraflores branch of the Classic Maya civilization was completely devastated in that area and in adjoining Guatemala, and it was severely afflicted in its eastern extent around Kaminaljuyu (Guatemala City) (Dull et al., 2001). The eruption may have caused, or at least contributed to, the social disruptions in the Maya lowlands known as the "hiatus" in the sixth century (Robichaux, 2000). In any event, it was the greatest eruption during the last 84,000 years in Central America, and its impact on nearby societies echoed through the centuries. Presently, Ilopango Lake fills the volcanic crater (Figure 2a, b), which covers an area of 28 mi^2 (72 km^2) and lies at an elevation of just under 1,500 ft (450 m).

The Ilopango eruption was certainly the largest of a total of 36 cases of volcanic eruptions affecting ancient societies in Mexico and Central America being studied by Sheets (2001). Arenal volcano in northwestern Costa Rica erupted 10 times during the past 4,000 years (Figure 3), causing the abandonment of scores of villages and forcing the survivors to live in refuge areas until they could reoccupy their settlements. Only a small part of their diet came from domesticated foods (they lived off the abundance of wild foods in the tropical rainforest), and population densities were very low with no evidence of warfare, facilitating relocation to refuge areas. As their

Volcanoes and People, Figure 2 (**a**) Central El Salvador in Central America, with Lake Ilopango in the center. It was the source of the huge explosive eruption that evidently caused the worldwide climatic crisis of AD 536. The eruption occurred through the lake and caused a caldera. The Cerén archaeological site is located in the northwest corner of this image. From Google Maps, terrain view. (**b**) Aerial view of the west end of Lake Ilopango, the caldera formed by the Plinian eruption in the middle of the Maya Classic Period. All people, animals, and vegetation were killed in this area.

Volcanoes and People, Figure 3 Arenal Volcano in Costa Rica, with Lake Arenal in the foreground. Arenal erupted frequently in ancient times, and the egalitarian native peoples learned how to handle the emergencies very successfully.

Volcanoes and People, Figure 4 Bruce Dahlin clearing around a boulder with petroglyphs in the Barriles chiefdom's territory in Panama. The petroglyphs apparently functioned as boundary markers. Baru volcano is in the background.

society was egalitarian (no inherited leadership or centralized authority), decision making in emergencies was local and efficient at the village level and especially at the household level. Despite careful dating and archaeological study, no changes in artifacts, architecture, settlement pattern, or other aspects of culture could be detected that might have been caused or affected by volcanic eruptions. The egalitarian Arenal societies were exceptionally resilient to these sudden massive stresses, especially when compared to hierarchically organized societies in other areas of Central America.

To the southeast of Arenal, just across the border in Panama, were the Barriles chiefdoms that lined both sides of the Rio Chiriqui (Linares and Ranere, 1980). These groups were competitive and engaged in frequent warfare, so it was advantageous for each to have a large population and to occupy and defend all arable land. When Volcan Baru erupted and spread a relatively minor deposit of volcanic ash (Figure 4), the modest decline in life support capacity of the environment was more than the local groups could withstand, and people had to migrate over the divide to the hot and humid Caribbean coast. The environment there was significantly different, forcing them to change their cultigens, their settlement pattern, and their culture, and they never returned to their homeland. They exemplify a society with dense populations living close to the threshold of sustainability; under such conditions, even a relatively minor perturbation was beyond their resilience and required drastic adjustments.

Numerous volcanic eruptions affected other ancient Mesoamerican societies. In many cases, the long-lasting effects were relatively minor. In spite of devastation during the eruptive impact and depopulation of the most severely affected area, people often reoccupied previously inhabited locations and did not exhibit significant societal changes after weathering formed new soils, and flora and fauna recovered near their pre-eruption state. An example is the ca. AD 660 Loma Caldera eruption in El Salvador that buried the Cerén site under 5–6 m of volcanic ash, resulting in the extraordinary preservation of houses, food, plants growing in gardens and agricultural fields, and the landscape (Sheets, 2002). The Cerén residents had to flee, and they never returned, but the eruption affected only a few square kilometers, so that most settlements in the valley were unaffected. The eruption produced no detectable culture change in the overall society through time.

Even the significantly larger eruption of Boqueron (Volcan San Salvador) in the tenth century AD left no long-standing scars on local societies. It caused major adaptive difficulties for an area estimated at 300 km^2 (Sheets, 2001), necessitating abandonment and relocation of refugees for at least a few decades until environmental recovery occurred. The society beyond the devastated area was unaffected and was the source of re-occupants along with the returning refugees, and cultural changes were negligible.

Summary

Volcanoes have posed hazards and opportunities to people for millennia. Volcanic products such as obsidian and basalt-andesite-dacite can be shaped into useful cutting, scraping, and grinding tools as well as construction stone. Volcanoes provide pigments including hematite, limonite, and cinnabar (mercuric sulfide), and volcanic ash weathers into clay that is useful for making pottery and earthen architecture. Volcanic soils have well-deserved reputations for fertility. People living near volcanoes can be affected by earthquakes that occur in association with eruptions, and lava flows can obliterate formerly arable soils, requiring centuries or millennia of weathering to recover fully. Ashfalls weather much more rapidly than

lavas, but many years or decades may be necessary before cultivation can be reestablished.

Societies vary in their vulnerability to volcanic stresses. Generally, the more egalitarian societies that have lower population densities and localized nodes of decision making react more rapidly and effectively. In contrast, hierarchically organized societies possessing high population densities and living close to the carrying capacity of their environments recover far more slowly if at all.

The complex and dynamic linkages between human agency and volcanic phenomena have formed important chapters in the history of our ancestors on this planet, and the significance of those relationships will continue into the foreseeable future.

Definition and context

Water management and engineered landscapes of past civilizations have recently drawn the attention of scholars in book-length examinations (Doolittle, 1990; Crouch, 1993; Scarborough and Isaac, 1993; Ronan and Needham, 1995; Doolittle, 2000; Denevan, 2001; Scarborough, 2003; Wilkinson, 2003; Lucero, 2006; Lucero and Fash, 2006; Ortloff, 2009; Scarborough, in press). The pressing influence of global climate warming today has raised concerns about water extraction and allocation, and the role of archaeology in identifying ancient systems of water use has the potential to inform the management of this most critical of all natural resources – more primary even than food. Past water systems were frequently clever and enduring constructions lasting sometimes for centuries; groups accretionally modified what came before, working within their environmental limitations and emphasizing conservation measures because of the lack of complex technologies and heavy dependencies on physical labor. Implicit in the deep time continuity of these systems is the notion of sustainability. Research into former methods and techniques of moving water to locales advantageous for humans (canalization) as well as extracting it by harvesting shallow water tables (wells) and/or storing it in open-surface reservoirs fills a sizable literature. The focus of this entry is water storage – inclusive of wells – as canalization is treated elsewhere in this volume.

Geoarchaeology of ancient wells and reservoirs

Wells and reservoirs are environmental magnets that accumulate sediments and the carbonate remains of invertebrates (e.g., ostracods and gastropods), carbonized and uncarbonized plant remains, pollen, and phytoliths from their catchment areas. Unless they have been dredged, they can be investigated like natural bodies of water using the same geoarchaeological techniques that integrate geochemistry, geochronology, mineralogy, and sedimentology. Because ancient reservoirs are frequently drained or seasonally depleted, organic indicators of past functions, especially pollen, phytoliths, and macrobotanical remains, can become highly degraded. To understand the complexities of ancient well and reservoir sediments, it is essential first to develop a detailed chronostratigraphy or dated depositional record. Strata and intervals within strata may document the timing of environmental and cultural transitions by preserving the biogeochemical and sedimentological record of the main sedimentary units. This analytical approach reveals the geological processes that create the sediments of wells and reservoirs – that is, the geologic record of the production, transport, and deposition of physical and chemical sediments – and ultimately the rates of environmental and cultural change.

Ideally, well and reservoir chronostratigraphy should be developed using both optically stimulated luminescence (OSL) and accelerator mass spectrometry (AMS) radiocarbon dating, though uncertainties are inherent in both dating methods. Radiocarbon samples can be contaminated with older carbon during transport and deposition or by young carbon from sources such as modern roots or burrowing organisms, and in the radiocarbon calibration curve, uncertainty increases with age. With OSL dating, there are uncertainties in the burial history of the sample, the background dose rate, the sample saturation history, and whether the sample was sufficiently exposed to light to reset the OSL signal. Yet despite these

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

uncertainties, both methods are effective and powerful dating tools that substantially complement one another when used collectively.

Texture is the most important asset controlling the physical, chemical, and hydrological properties of well and reservoir sediments. Classification of their physical characteristics is accomplished using particle size or textural analysis. Particle size distribution (PSD) is determined by separating the gravel, sand, silt, and clay fractions with grading sieves using either a wet or dry method, by sedimentation, by pipette method, or using the faster but less accurate Bouyoucos hydrometer method. PSD is a fundamental geoarchaeological tool and an effective way to assess well and reservoir responses to anthropogenic and environmental conditions such as droughts, water retention, sediment transport, landscape stability, and soil erosion rates (Scarborough et al., 1999, 2010).

Powder X-ray diffraction (XRD) analysis can be used to reconstruct past environments and perhaps climate. Climate-sensitive clay minerals commonly occur in well and reservoir sediments, and their relative amounts correlate with climate episodes (Tankersley and Balantyne, 2010). XRD peak intensity ratios of minerals in well and reservoir sediment layers are diagnostic for different clay source areas and hydrometeorological transport processes in catchment areas. Thus, quantification of clay minerals in sediments by XRD may be used as a paleoenvironmental proxy. Clay-mineral-based climate fluctuations are correlative with marine oxygen-isotope records and provide a relatively simple and cost-effective tool for gaining insight into paleoclimate. Environmental sequences and climosequences of clay minerals in well and reservoir sediments are directly related to the availability and flux of water through the soil, which is a prime factor in weathering intensity. Clay minerals weather differently under climate conditions that vary in average annual rainfall. The amount of surface vegetation and microbial activity in depositional environments also bears a significant but indirect influence on the weathering of clay minerals.

At Tikal, Guatemala, XRD diffraction and petrographic analyses of reservoir sediments identified significant quantities of decomposed volcanic ash in the form of volcanogenic smectite and euhedral bipyramidal quartz crystals (Tankersley et al., 2011). X-ray fluorescence spectrometry (XRF) trace element content analysis using Zr/Y and Ni/Cr ratios of reservoir sediments from Tikal indicates an ash source from Central America (e.g., Guatemalan and Salvadoran). AMS radiocarbon dating of the smectite and crystalline quartz-rich reservoir sediments shows that volcanic ash fell during the Preclassic, Classic, and Postclassic Maya cultural periods (600 BC–AD 1500).

The magnetic properties of clays deposited in wells and reservoirs vary with changes in climate and human activity and can be measured using magnetic susceptibility (SI). Magnetic susceptibility values of core samples and excavation profiles can be obtained digitally using a time-dependent method that results in precise and repeatable data acquisition. Oscillating periods of warm and moist followed by cold and dry environments are potentially identifiable when SI measurements are taken from well and reservoir sediments at controlled depths below the surface. Warm and moist climatic conditions are associated with high SI values in well and reservoir clays, while cold and dry climatic conditions are associated with low SI values. There is also a statistically significant association of SI values and the relative percent composition of illite in well and reservoir clays. The percent composition of illite by depth is directly proportional to the SI values of reservoir clays. The latter pattern is likely the result of nanoparticles of magnetite attached to illite, with animal-sediment interaction partly responsible for the Fe-illite mineral relationship (Tankersley and Balantyne, 2010).

Stable carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotope values associated with insoluble soil organic matter (SOM) from well and reservoir sediments reflect vegetation in the catchment areas with differing photosynthetic pathways, such as C3 trees, shrubs, and herbs versus C4 grasses or CAM cacti and succulents. These carbon isotopes can also be used to distinguish open country versus dense canopy forest. Oxygen ($\delta^{18}O$) isotope values for ostracod and gastropod shells extracted from well and reservoir sediments can be used to evaluate water temperature, relative humidity, and seasonality. Nitrogen isotopes ($\delta^{15}N$) are affected by abiotic factors such as temperature and relative humidity. As a result, sediments in hotter, drier localities have higher $\delta^{15}N$ values than sediments in cooler, moister ones. Ancient polluting algal blooms may also be revealed by conducting $\delta^{15}N$ tests. Combined, these isotopes can be used to tease apart environmental changes, including major transitions in vegetation cover (e.g., shift from C4 to C3 dominance), as well as more subtle changes such as decreasing or increasing forest cover, grasslands, or desertification.

Like stable isotopes, terpenoid biomarkers can be used to constrain and reconstruct floral changes between major phylogenetic plant groups, thereby providing insight into how vegetation within the well and reservoir catchment area changed. Plant terpenoids are prenol lipids that represent one of the largest and most diverse groups of vascular plant compounds. Terpenoids have long been used as biomarkers, or chemical fossils, for higher plants in geologic sediments and oils, and they are diagnostic for plant taxonomy (Diefendorf, 2010). Variations in the abundances of these compounds may be used to constrain the plant groups from which organic matter was derived, and they have been invoked in reconstructions of paleoecology and paleoenvironments from well and reservoir sediments. Production of terpenoids by different plant species – including angiosperms and gymnosperms, and short and long leaf life-spans – has been characterized so that they now provide a basis to interpret abundance patterns in sediments. Terpenoids offer a unique opportunity to constrain floral composition changes in core samples when pollen or macrofloral analyses are not possible due to poor preservation or small sample size of the core or excavation samples.

Wells

The underground harvesting of the water table prior to hydraulic pumps was performed either by traditional hand-dug vertical shafts or by tapping natural groundwater exposures. Seeps and springs were frequently cleared of debris and opened for access via a shallow ponding area in close enough proximity for collecting and storing water, or managing it so as to provide an adequate head to accommodate water flow into a channel or canal. Examples include the thirteenth-century site areas of Glen Canyon (Sharrock et al., 1961) and Mesa Verde systems (Rohn, 1963) in the US Southwest, as well as the very early canalization effort noted from the ancient Olmec springs at Teopantecuanitlan of west Mexico ca. 1200 BC (Doolittle, 1990). Formal wells abound globally, but the earliest of these appear in Highland Mexico (Caran et al., 1996) and again in the US Southwest (Evans, 1951) by 10,000 years ago associated with the hunting and foraging peregrinations of the Paleoindians. In the Old World, the earliest known wells are likely those of Cyprus dating to a comparable period (Peltenburg et al., 2000). Their positioning likely influenced the seasonally structured movements of hunters and foragers in the former, while in the case of Cyprus and early Neolithic populations, more permanent occupation is implied.

Both springs and hand-dug wells have been an important source of water in nearly every society. With time and experimentation, unique adaptations have developed to harvest water more effectively within local environmental contexts. Simple technologies have evolved to accommodate the vertical lifting and containment of water when gravity cannot be used to relocate it. In the Old World, the advent of the *shaduf*, or well sweep, employed first in the Near East and widely used subsequently along the Nile, permitted the raising of water by way of a bucket and dipping line attached to a long pole positioned on a fixed fulcrum – but one allowed to rotate (Scarborough, 2003, p. 40). A heavy counterweight at the end of the pivoting pole, rope, and bucket was designed to drop the bucket into a low-lying well or body of water and then lift and relocate the contained water to a higher elevation. In the case of wells, bucket lifting obviously began with the tapping of shallow water tables manually by way of rope hoisting, though in ancient Mexico simple gallon jars were dipped into elevated groundwater via surficial wells that allowed the *pot irrigation* of individual plants in the immediate proximity (Flannery et al., 1967). In the Old World, horizontal bar and crank systems allowed the winding of rope immediately above a *puteal*, or well curb (Jansen, 1991; Crouch, 1993, p. 231). The subsequent use of the Archimedes screw, the water wheel or *noria*, and the significant role of the pulley further permitted the lifting of water's mass and fluid state, frequently with the aid of beasts of burden (Scarborough, 2003, p. 40).

Walk-in wells were accessed by foot and frequently associated with large subterranean reservoirs recharged by natural springs. One of the more elaborate examples was at thirteenth-century AD Casas Grandes in northern Mexico; identified by a 12 m vertical drop to the water table, it descended by a series of switchback stairs (DiPeso et al., 1974). In the highly karstic northern Yucatan, deep natural caves sometimes permitted ladder access to sizable pools of water. Near Bolonchan, a descent of 100 m below the surface allowed water collection via ceramic pots (Stephens, 1843, p. 96). In the Old World, karst topography allowed rock carved channels and pools as early as the Late Bronze Age (1500–1150 BC) at Mycenae, Tiryns, and Athens (Scarborough, 2003, pp. 146–152). The one at Athens was characterized by a depth below the Acropolis of 40 m and an entrance by means of eight flights of steps and several landings (Broneer, 1939). In Jerusalem, karstic jointing was altered to produce access to the springs of Gihon by 700 BC (Gill, 1991). Perhaps the most elaborate walk-in wells are the celebrated step wells of Gujarat and adjacent portions of western India and Pakistan. They display extremely elaborate architectural detail and were accessed by ornate steps; they were constructed as early as the third century AD with enduring use and alterations into the Mogul period (Livingston, 2002).

The highly sophisticated and labor-intensive *qanat*, *karez*, or *foggara* constructions represent the most expansive and clever of all well-driven systems. Probably originating in ancient Iran – though recent discoveries may indicate an Arabian Peninsula initiation – qanats are extensive "horizontal well systems," frequently running underground for kilometers (Lightfoot, in press). Gravity flow relocates the source to low-lying villages and towns away from the rugged and surficially waterless zone of extraction. Still active in present-day Iran, these systems entail a highly skilled set of craftsmen – guild-like – that excavate vertical shafts to access an aquifer usually below the colluvial/alluvial margins at the foot of a mountainous outcrop where water may accumulate. Once a "mother well" taps water at depths of 20–100 m – though the well shaft at Gonabad, Iran, near the Afghan border drops 300 vertical meters (English, 1966) – lateral tunneling commences (Figure 1). Careful and highly controlled digging entails a gradient of about 1:1,500 so as to prevent either channel course erosion or significant sedimentation. Today, sizable prefabricated, oval-shaped conduit segments of concrete are carried into the tunnel excavations to shore up pockets of sand encountered as the digging proceeds. In Yazd, Iran, attempts are being made to preserve the tradition of *qanat* or *karez* building in a location with a long history of tunnel use; here, horizontal shafts can cross yet deeper tunnels in a complex network of buried waterways (Lightfoot, in press). From the air, *qanat* systems appear as a series of "chain wells" revealing donut-like mounds and the locations of their underground pathways (Figure 2). These "skylights" permit the removal of detritus and excavated waste and remain crucial for maintenance. In the New World, shallow versions of the *qanat* system, *puquios*, are indicated

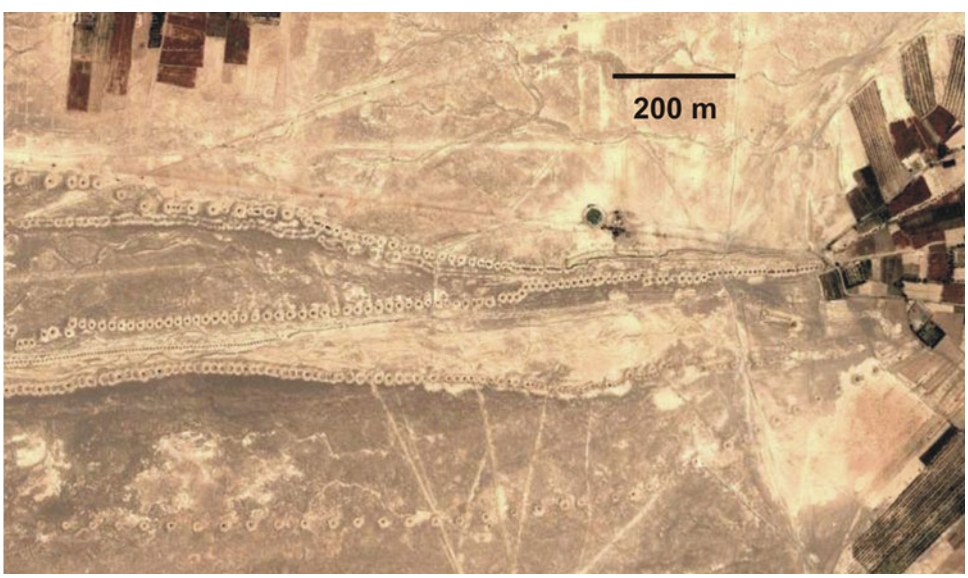
Wells and Reservoirs, Figure 1 Inside a qanat near Quetta, Baluchistan, Pakistan (Courtesy of V. Scarborough).

to have been pre-Hispanic in Peru and northern Chile (Schreiber and Lancho Rojas, 1995; Schreiber and Lancho Rojas, in press), though controversy remains over the prospect that they were introduced by the Spanish (cf. Woodbury and Neely, 1972; Barnes and Fleming, 1991 in Mexico).

Although not designed to extract water for potable uses, the sunken gardens of ancient Peru were excavated to a frequently dropping water table. Near the great Chimu center of Chan Chan, field depression descended 5–7 m before the fields were abandoned (Moseley, 1983; Moseley, in press). On certain Pacific island atolls, pit cultivation, or a less expansive version of the Peruvian adaptation, was practiced (Kirch, 1994, p. 5). And in some dolinen (sinkholes or *rejollada*) identified with elevated water-table soils of northern Yucatan, the ancient Maya grew cacao and perhaps other environmentally temperamental plants (Gómez-Pompa et al., 1990).

Reservoirs and dams

Reservoirs are open catchment basins that hold intermittent surface runoff or water from formal canals or less formal channels. *Storage dams* are frequently associated with reservoirs; *diversion dams* (or *weirs*) are employed by canal users. Dams built at the egresses of reservoirs can slow the velocity of water coursing through them, especially during flash flooding. At other times, they can serve to raise reservoir water levels by slowing outflow into issuing canals. Generally, reservoirs and storage dams are constructed in regions without dependable riverine



Wells and Reservoirs, Figure 2 Satellite view of a section of the qanat system near Abarkuh, Yazd Province, Iran (Imagery © 2012 CNES/Spot Image, Digital Globe, GeoEye, Map data © 2012 Google).

water sources. These features have an ancient past, and many small, deliberately constructed ponding areas have probably gone unnoticed as a consequence of rapid sedimentation following their disuse (Scarborough, 2003, p. 47).

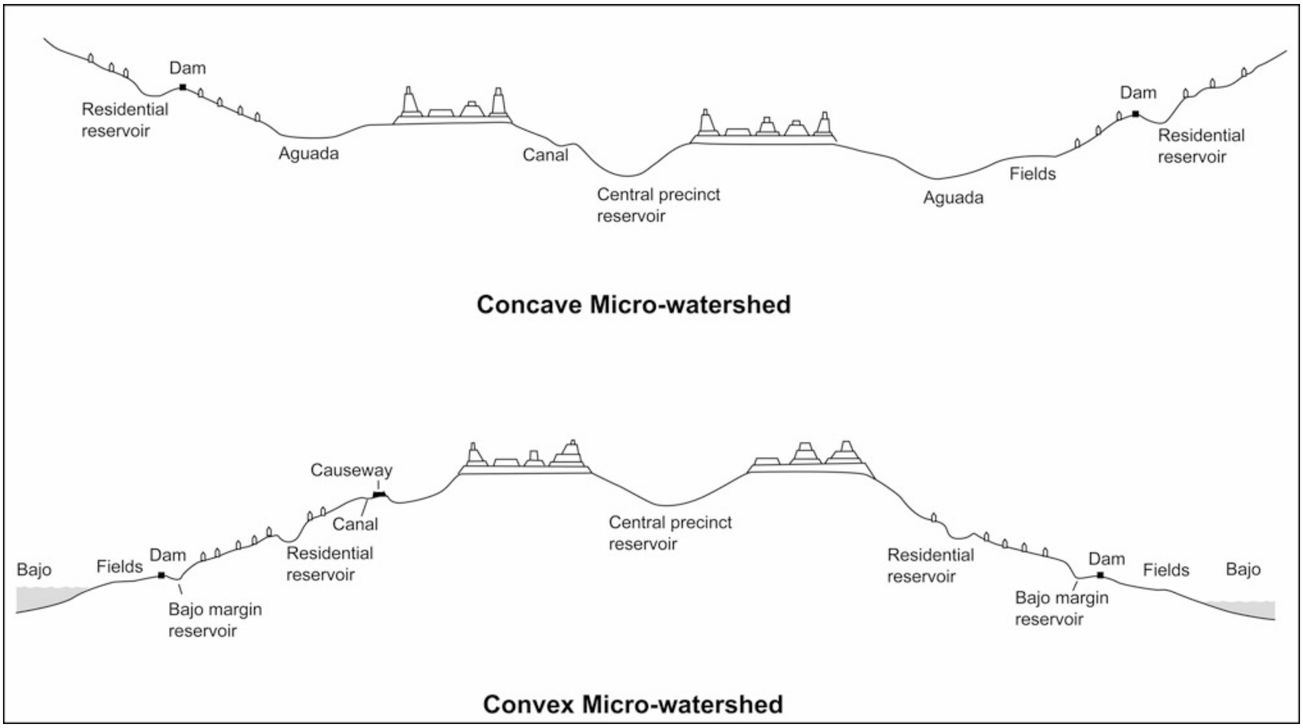
New World

William Doolittle (1990) provides the best overview of early water management systems from ancient Mexico. He notes again the small Olmec site of Teopantecuanitlan and the first appearance of a *gravity dam*, one that contains the perpendicular flow of water due to its mass and not its shape, for water storage in Mesoamerica. The most massive pre-Hispanic dam construction in the New World also occurs in Mexico within the Tehuacan Valley (Woodbury and Neely, 1972; Aiuvalasit et al., 2009). The Perrón Dam has an initiation date of 700 BC, but as early as the Late Formative (400 BC–AD 100), a gravity dam of 100 × 400 × 18 m was constructed. The reservoir was provided with a substantial *cofferdam*, the partitioning of a reservoir system to collect head-end sediment in a *silting tank* before the water entered a greater holding basin and/or to accommodate water storage when the principal reservoir necessitated dredging near the ingress to the sizable main tank. The first reported *arch dam* in the New World appears in ancient Oaxaca, Mexico, near the large center of Monte Albán (O'Brien et al., 1982). This Xoxocotlán Piedmont dam was 10 m high and 80 m long, and it was built between 550 and 150 BC with a V-shaped plan pointing upstream, thereby providing a design as dependent on structural orientation as on mass. At the low-density urban population aggregate of Tikal, Guatemala, a gravity dam of comparable size to that at Xoxocotlán was associated with posited sluices of diminutive size and a nearby cofferdam (Scarborough et al., 2012). Perhaps the greatest investment in dam construction is found during the Aztec period of the Valley of Mexico (AD 1350–1519) in which the freshwater infused embayment surrounding the island city of Tenochtitlan was separated from the adjacent saline Lake Texcoco by the massive Netzahualcoyotl Dike, with the widespread incorporation of *chinampas* – raised field plots (Sanders et al., 1979).

In the arid US Southwest and northern Mexico, reservoirs occur in several contexts. The ancient community of Casas Grandes (Chihuahua, Mexico) again reveals a complex reservoir system with both water retention basins and stone-lined silting tanks (DiPeso et al., 1974). The ancient Hohokam of south central Arizona frequently located their largest reservoirs away from their elaborate canalization schemes but dealt efficiently with evaporative loss by increasing volume via depth while holding surface area constant (Scarborough, 1988; Bayman and Fish, 1992; Fish and Fish, in press). At water-scarce Chaco Canyon, the several pueblos dating to AD 1020–1120 used diversion dams to redirect seasonal runoff into *overflow reservoirs*, small depressions employed to slow the water's erosive effects as well as provide subsequent agricultural use of the ponded resource (Vivian, 1974).

The cisterns of both the Old and New Worlds looked and functioned in a similar manner. Those associated with the ancient Greek atrium fed by an *impluvium*, a shallow and flat-bottomed basin (Crouch, 1993), and the sizable Nabataean cisterns of Petra (Ortloff, 2005) and the extremely dry Negev Desert (Evenari et al., 1971) were functionally mimicked in northern Yucatan. In the Puuc Hills of the ancient Maya Lowlands, large subterranean bell-shaped cisterns, or *chultuns*, used concretized dish-shaped catchments to drain water off elevated housemounds into constricted bottleneck openings at the household level (McAnany, 1990). Elsewhere in the Maya Lowlands, quarry scars resulting from building operations in towns and "cities" were frequently converted to open-surface reservoirs (Scarborough, 1993, 1994). At the Late Preclassic community of Cerros in northern Belize (ca. 200 BC–AD 150), a canal-like feature circumscribing the margins of the site formed a social boundary but also functioned as an elongated moat-like tank receiving runoff from several zones during the rainy season. By using *sills* – horizontally laid stones positioned to extend the reach to ponded water as its level descended during the dry season – access was allowed and collection was enabled in basal depressions or *basin canals* (Scarborough, 1983, 1991). The large site of Edzna, in Campeche, Mexico, also dating to the Late Preclassic, incorporated a system of wide linear canals to drain and harvest water (Matheny, 1976), though some controversy exists over the degree to which these basins may have been large-scale *grikes*, or fissures, eroded naturally along cracks and joints in the limestone (Butzer, 1996). In any case, these Late Preclassic water systems and landscapes were frequently constructed in low-lying settings – called *concave microwatersheds* (Figure 3 upper) – and depended on natural runoff from the adjacent high ground for seasonal recharge. *Aguadas*, or ponds that were frequently human modified from eroding sinkholes, are ubiquitous in the Maya Lowlands and were used widely by rural populations. Also, the *bajos*, huge internally draining, natural depressions of karst origin (*polje*), in this same region are hypothesized by some to have been partially altered to hold water in shallow canals flanking drained or slightly raised fields (Harrison, 1977; cf. Scarborough, 2006; Scarborough, 2007).

During the Classic Period (AD 250–800), several urban settings modeled their water management after a *convex microwatershed* adaptation (Figure 3 lower). Sizable communities located on ridges or hillocks used plastered public architectural surfaces to direct seasonal precipitation into elevated tank systems for subsequent dry season gravity flow release (Scarborough, 1993; Scarborough, 1994; Scarborough and Burnside, 2010). Unlike the earlier Late Preclassic period, these later systems were highly managed and much less passive in terms of catchment controls. One of the grand water management designs



Wells and Reservoirs, Figure 3 (*Upper*) Concave microwatershed in the Maya Lowlands. (*Lower*) Concave microwatershed in the Maya Lowlands.

within an urban context was at Tikal, Guatemala (Scarborough and Gallopin, 1991; Scarborough et al., 2012), where the nested summit was identified by a triangular set of causeways (also serving as dams) enclosing ca. 62 ha of central precinct space, with much of the bedrock sculpted and quarried to erect the adjacent towering pyramids and massive acropolises. With annual rainfall of 1,500 mm, over 900,000 m^3 of precipitation would fall on the central precinct area and easily fill the several elevated reservoirs seasonally to their maximum volume of 250,000 m^3. Through a series of descending dams and tanks, water was gravity released to a surrounding population during the dry season, a community otherwise distant from a year-round surface water source, either lake or stream. Evidence indicates that sand filters were placed at the ingress of tanks to aid in curbing contaminants from the highly trafficked water catchments within the urban core (Tankersley et al., 2011; Scarborough et al., 2012).

Although the semiarid Andean Highlands as well as coastal Ecuador and Peru demonstrate several water management advances (see entry "Canals and Aqueducts in the Ancient World" by Ortloff, this volume), ancient populations were less dependent on reservoirs because of their sophisticated canalization investment in moving water year around. Of special interest, however, was the "geologic water storage" described by Fairley (2003) in which porous sands were introduced into a dammed depression allowing the saturation of the introduced soil while curbing the open-surface evaporation of the water it contained. This human-made aquifer was tapped by way of a specially designed wall that acted as a seep or spring source. In addition to the great modifications made to the margins of Lake Titicaca that permitted the trapping of water for raised field agriculture (Kolata, 1991; Erickson, 1993), the Amazonian lowland systems show a wide variety of landscaping alterations that optimally contained water as well as mechanisms to disperse it based on the highly seasonal swelling of streams and rivers (Denevan, 2001; Erickson, 2006; Erickson, in press). Ring ditch systems clearly defined community boundaries, but also provided a ready fish source as well as other usable animal and plant foods (Walker, 2008).

Old World

The earliest reservoir systems appear in the Near East precociously at the late fourth millennium town of Jawa, Jordan (Helms, 1981). Within an extremely arid setting (150 mm annual rainfall), this highly engineered community maintained ten reservoirs behind gravity dams constructed with downstream *revetments* (stone buttresses), spillways, and sluice gates. Positioned within a small, highly constricted valley, Jawa received 2,000,000 m^3 of water annually, frequently in the form of storm surges. Nevertheless, with the estimated 15,000 tons of basalt devoted to the construction of the hydraulic system alone, perhaps 70,000 m^3 of water was

Wells and Reservoirs, Figure 4 Pastoralist and gathering herd using "oasis" setting at El Fasher, Darfur, Sudan; a living example of "hafir" function (Courtesy V. Scarborough).

contained to sustain a population of about 5,600. In one case, a *waterface apron* of stone extended into the lower reaches of the tank designed for seepage control as well as retarding the effects of wave action. Functioning as a causeway (as noted in the New World examples), the dam was 4–5 m high and 80 m long. Other early dams include Helwan (south of Cairo) which is estimated to have required 60,000 tons of gravel and 40 tons of stone masonry around 2700 BC (Helms, 1981; Hassan, in press).

In the Sahel of northern Sudan, East Africa, sizable reservoirs located far from the Nile and without formal channels leading in or out are called *hafirs* (Crowfoot and Griffith, 1911). Located in proximity to Meroitic communities (350 BC–AD 350), these rain-fed tanks may have been as important to the townsfolk as to a foraging pastoral population moving from tank to tank (Figure 4). In this socioeconomic equation, both groups would benefit from the water source, with the townspeople obtaining the added advantage of milk, wool, and meat (Scarborough, 2003, pp. 57, 82–83). At a comparable period, the Marib Dam of Yemen was constructed to provide a canalized source of water for drinking and irrigation. Although the Marib Dam was the largest such installation (with final expanded dimensions of 14 m in height by 600 m in length), and it was in place by the sixth century BC, 80 smaller dams ranging in scale from 1 to 5 m high by 100–200 m long were built in the surrounding region (Bowen and Albright, 1958; Garbrecht, 1987; Wilkinson, 2003). The North African Maghrib was colonized by early Rome, resulting in the damming of sizable segments of several *wadis*, which are *arroyos* or gullies. The largest of these dams was across the Wadi Caam; it extended over 900 m and was built with a poured concrete core and cut-stone veneer (Shaw, 1984, p. 152). Nevertheless, the hydraulic engineering imposed by the Romans was more effective in the European mainland than it was when applied to North Africa and the Near East because the degree of aridity and kind of topographic relief could result in infrequent but highly damaging runoff surge events. Such events were less controllable with the introduced fixed-dam technology (Kennedy, 1995). The earliest well-reported dam in Europe appears in the Late Bronze Age (1500–1150 BC) within the Argolid, Greece. The Tiryns Dam was a diversion feature, but the dam type continues in use and was little modified by the Romans (Zangger, 1994).

Egyptian Nilotic waters and their annual sediment load were deposited in large basins along the Nile floodplain. These basins acted as reservoirs and silt traps; water was conducted through a series of short canals and embankments into shallow tanks until the silt level was sufficiently high that they could be converted to planting surfaces during pharaonic periods (Hamdan, 1961; Butzer, 1976). A similar condition was also reported along the Euphrates during Old Babylonian times (Hedrick, 1997). Generally, little evidence for centralized hydraulic control by early states exists for this or any other ancient civilization yet noted (Butzer, 1976; Scarborough, 2003). Nevertheless, during the Middle Kingdom (2040 BC) and subsequent intervals of aridity, lake levels in the Faiyum Depression were manipulated by a series of dams and dikes as a consequence of state sponsorship (Hassan, in press).

The largest preindustrial period reservoirs appear in South Asia. The earliest investments in tank construction from this part of the world come from Harappan Pakistan and western India between 2500 and 1900 BC (Possehl, 1997; Scarborough, 2003; Possehl, in press), with the rectangular basin – 219 × 37 m, and walls to a depth of 4.5 m – identified at the Gujarat port community of Lothal (Allchin and Allchin, 1982; Possehl, 1997). The great city of Mohenjo-daro in Sindh Province was defined by a central acropolis containing a rectilinear Great Bath with dimensions of 12 × 7 × 3 m. This structure was built of fired brick, sealed with bitumen, accessed by formalized inset stairs, and drained by a high corbel-vaulted passage at the Citadel's margins. This well-known "bath," identified with a highly sanitized emphasis on purity manifest primarily by waterworks (including sump pits and indoor toilets) at Harappan cities, reflects a degree of ritualized water control unlike any noted for other early civilizations (Possehl, in press).

Much larger reservoir systems were especially elaborated in Sri Lanka's dry zone as early as the first century AD and frequently constructed by damming major rivers and streams. Ancient texts distinguish between large tanks, village tanks, and feeder tanks (Gunawardana, 1971). By the fifth century, the length and height of dams could be enormous; the Kala Wewa tank at the city of Anuradhapura was 27 m high and over 14 km long, resulting in a reservoir 65 km in circumference that fed a canal system extending over 90 km from the reservoir source (Leach, 1959). The comparably huge reservoir called the Parakrama Samudra (Sea of Parakrama I, after the king responsible for its expansion) provided piped water to the royal baths at the subsequent capital of Polonnaruwa. Because of the pressure exerted on the sidewalls of these dams, the sluices releasing those waters were ingeniously adapted. The *bisokotuva*, or cistern sluice, was designed to channel tank waters by routing their release underneath the dam via a series of interlocking vertically nested cylinders – today, bottomless pots – within the deepest reaches of the tank, stacked and descending to a shallow, tightly sealed, subterranean tunnel that issued at the downstream side of the dam (Gunawardana, 1978). With rising or dropping surface water levels within the reservoir, individual cylinder segments were added or removed to accommodate discharge demands. Large tanks of considerable complexity are also identified in Upper Burma (Pagan dynasties – Stargardt, 1983; Bray, 1986), eastern Java (Majahapit kingdom – Miksic, 1999), and among the sophisticated and ornate architectures of the Cambodian Khmer Empire (Groslier, 1979; Higham, 1989; Fletcher et al., in press).

Perhaps the largest city of preindustrial times was Angkor, Cambodia, now estimated to have enclosed an area of 1,000 km^2 (Evans et al., 2007; Fletcher et al., 2008) and supported a population of 600,000 (Higham, 1989). This hydraulic city was reestablished by King Indravarman by the late ninth century with hinterland irrigation extending over at least 167,000 ha (Groslier, 1979; Bray, 1986; Higham, 1989). The highly symmetrical, rectangular-shaped, east-to-west-oriented *baray* (enormous tanks) slowed and contained the movement of water through the city (Evans et al., 2007; Fletcher et al., 2008). The first sizable baray constructed by Indravarman covered 300 ha and had a capacity of 10,000,000 m^3 of water. However, his kingly successors were responsible for the Eastern and Western Barays that held 70,000,000 and 60,000,000 m^3, respectively. When coupled with the moat surrounding the gigantic temple-mausoleum of Angkor Wat and a Northern Baray, another 15,000,000 m^3 was made available. An additional 800 smaller tanks positioned along axial avenues throughout the city demonstrate the scale of water management. Ortloff (2009) has recently proposed that the water system was established and maintained to keep soils saturated and thereby prevent monumental constructions from sinking into the sandy base stratum on which the city rests. Furthermore, the wet seasonal recharge of the baray may well have allowed the predictable and controlled release of north to south, downslope filtering of water into low-lying rice paddies through the porous sands.

Ancient China invested in a highly sophisticated set of water management undertakings with the sponsorship of the state as indicated by several landscape and technological adaptations (Bray, 1986; Ronan and Needham, 1995; Gu et al., in press). Nevertheless, reservoirs tended to consist of small ponds adapted to rice cultivation, especially in the south and central portions of the country where rainfall was adequate and, unlike other regions of Asia, relatively predictable. Late Han grave offerings (AD 25–220) reveal clay models of these systems (Bray, 1986). The Peony Dam, however, constructed at ca. 600 BC, produced a reservoir enclosure with a circumference of nearly 100 km that was capable of the controlled flooding of 24,000 km^2 within a flat valley adjacent to the Yangtze River (Ronan and Needham, 1995).

Summary

Although many more ancient water storage and extraction examples could be drawn from the archaeological record – e.g., the later function of millponds (see Neely, 2011; Brykala and Podgorski, 2014) – those identified here provide a representative sample of the range of adaptations made by humans throughout our deep past. Given the limitations of technology, especially in the New World, these systems provide insights into their reapplication potential in portions of the world today where high-tech energy sources may be limited or lacking altogether. This presentation has focused on the functionality of wells, reservoirs, and their waters put to both potable and agricultural ends. However, the influence of political and ideological decision making by way of the adaptations actually manifest must also be assessed. For the purposes of this entry, functionality has been stressed only (for broader cultural implications, see Scarborough, 1998; Scarborough, 2003; Scarborough and Lucero, 2010).

Synonyms

Bragg diffraction; Bragg scattering; Wave interference from a lattice; X-ray diffraction

Definition

Diffraction: The physical phenomenon of interference produced through the interaction of electromagnetic waves (i.e., X-rays) or particle beams (i.e., electrons, neutrons) with crystals, assumed as atomic lattices.

X-ray diffraction: The diffraction of X-rays by crystals, producing interference effects (i.e., diffracted beams) at specific angles. The geometry of diffraction is described by Bragg's law.

Powder diffraction pattern: The diffraction effects (Debye cones, Debye rings) produced by a polycrystalline powder, that is, a large ensemble of small crystals. The measurements are carried out by powder diffractometry.

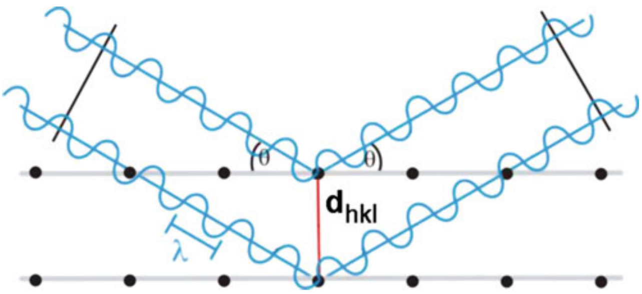
Single-crystal diffraction pattern: The diffraction effects (Bragg spots) produced by an individual crystal, assumed as a coherent crystalline domain having a symmetric, long-range order of atoms. The measurements are carried out by single-crystal diffractometry.

Introduction

Diffraction-based techniques and methods are fundamental tools for the characterization and understanding of materials of quite different nature, including those relevant to investigations in Earth science – e.g., minerals, rocks, sediments, soils, and ore deposits – as well as geoarchaeological explorations of similar materials exploited by humans in the past. X-ray diffraction effects produced by crystals were first observed by Laue and coworkers 100 years ago, and the recent centennial celebrations of 2012 correctly marked the fundamental importance of this discovery (Eckert, 2012; Schmahl and Steurer, 2012). Diffraction techniques developed rapidly during the last century and have become routine tools in the analysis of specific materials in order to inform about (1) phase identification and quantification of crystalline compounds and complex polyphasic mixtures, (2) the texture and orientation of crystalline phases in a material, (3) the atomic and molecular structure of the phases involved, and (4) the physical microstructural state of the material in terms of crystallite size and accumulated strain.

A number of excellent textbooks are available describing the general theory and applications of X-ray diffraction to natural and synthetic compounds (see, e.g., Klug and Alexander, 1974; Warren, 1990; Guinier, 1994; Hammond, 2009; Giacovazzo, 2011). The present focus is the specific contribution of diffraction to geoarchaeological problems. Since geomaterials and other resources of the Earth are fundamental to many aspects of human societies, understanding their provenance, role, and technical uses represents important data for the archaeological interpretation of past cultures (Artioli, 2010). This is especially true for prehistoric times, from which there are no written records to decode human activities, and therefore our comprehension is often limited to the remaining tangible heritage. The analysis of archaeological and geoarchaeological materials by modern diffraction thus serves as an extremely useful tool in understanding the past. Further, the thorough characterization of heritage materials and the processes acting upon them is a mandatory step in heritage management and conservation.

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,



X-ray Diffraction (XRD), Figure 1 Interference of electromagnetic waves of wavelength λ with crystallographic planes of spacing d_{hkl}. The 2θ diffraction angle satisfying Bragg's law is the one defined by the incident and diffracted beams. The figure shows the case in which Bragg's law is satisfied, i.e., the incoming and diffracted X-rays are in phase, as indicated by the bars joining corresponding peaks and troughs of the two beams. At other angles, the refracted beams would be out of phase to varying degrees and thus would cancel out.

Essential concepts

Among the variety of techniques presently available for the characterization of materials, diffraction is unique insofar as it is intrinsically sensitive to the ordered (i.e., periodic, symmetric) atomic structure of crystals. The diffraction effects produced by the interference of electromagnetic waves and particle beams with matter can be simply and directly related to the properties of the crystal phases present in the system. Figure 1 shows schematically the interference process between monochromatic electromagnetic waves scattered by different atoms in the crystal. Bragg's law

$$2d_{hkl}\sin\theta = n\lambda$$

describes in simple terms the geometric relationship among three factors: (1) the spacing between the atomic planes in the crystal (d_{hkl}), (2) the wavelength of the incident radiation (λ), and (3) the diffraction angle (2θ) – that is, the angle between the incident beam and the diffracted beam. For any given λ, positive interference (i.e., diffraction) occurs only at the angles satisfying Bragg's conditions for all possible atomic planes in the crystal. Each family of atomic planes d_{hkl} has a specific orientation defined by the so-called Miller indices (hkl) with respect to the crystallographic base vectors, which define the crystallographic unit cell, i.e., the lattice, and ensure periodicity in Euclidean space.

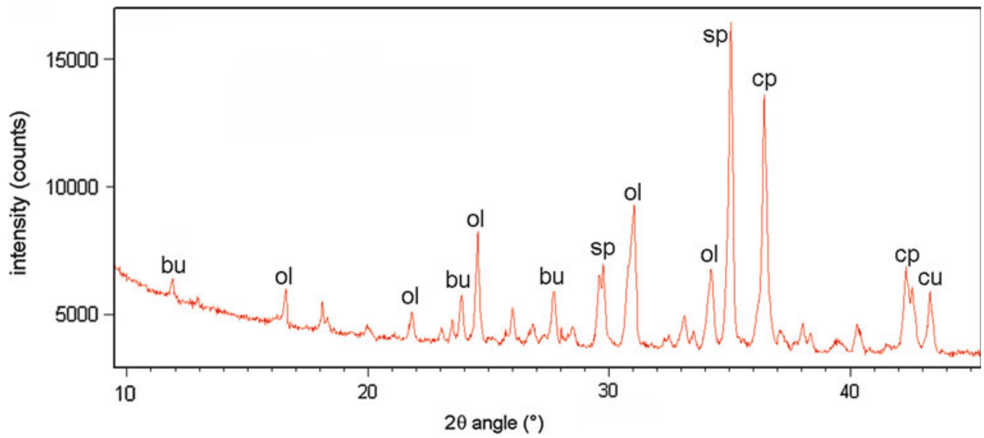
At thermodynamic equilibrium, every solid compound has a specific arrangement of its atoms in space (crystal phase or crystal structure) that minimizes Gibbs free energy, ultimately dictated by the formation of chemical bonds between atoms and molecules. The distinctive crystal structure of each phase at any given pressure and temperature is univocally described by (1) the crystallographic *unit cell*, (2) the *space group symmetry* (see The International Tables of Crystallography, Vol. A: http://it.iucr.org/), and (3) the type and position of each symmetry-independent atom in the unit cell, in terms of *atomic scattering factors* and *positional atomic coordinates*.

Diffraction techniques (Giacovazzo, 2011) in essence yield very basic information on the nature of the material, on its physical state, and on its crystal-chemical arrangement at the atomic and molecular level, providing a means of characterizing and interpreting crystalline compounds from simple elemental and ionic solids to complex macromolecules. The atomic structures of known crystalline compounds are listed in available databases (ICSD: Inorganic Crystal Structure Database, http://www.fiz-karlsruhe.de/icsd.html; CSD: Cambridge Structural Database, http://www.ccdc.cam.ac.uk/products/csd/; MSA-CSD: Mineralogical Society of America Crystal Structure Database, http://www.minsocam.org/MSA/Crystal_Database.html; and others), and they are essential references for identification and analytical purposes.

Concerning the analytical measurements, X-ray single-crystal and powder diffraction techniques are listed among the established and routine tools for the analysis of materials, though one ought not to forget the remarkable recent progress in electron and neutron diffraction. Further, different measurement geometry and instrumentation are required depending on the crystalline nature of the sample. If the sample is monocrystalline (i.e., a single crystal, as most gemmy crystals are), then the diffraction patterns show discrete Bragg diffraction spots derived from the interference of X-rays with the lattice planes. However if the sample is polycrystalline (i.e., the X-ray beam interacts with a large number of randomly oriented crystals), then Bragg's law is satisfied simultaneously by the same lattice plane in many different crystals, and the rotational symmetry of the interference effects produced at each Bragg angle produces a diffraction cone (Debye cones) whose intercept with a flat detector is generally imaged as diffraction rings (Debye rings). This is called *powder diffraction*.

Because of the fact that most geological and archaeological materials are polycrystalline and polyphasic (with the notable exception of gems of course), and because of the inexpensive availability of X-ray sources in scientific laboratories, the preferred diffraction technique universally adopted for analytical purposes of geomaterials is XRPD or X-ray powder diffraction (Klug and Alexander, 1974; Dinnebier and Billinge, 2008; Pecharski and Zavalij, 2009). In its simplest configuration, powder diffractometry scans the reciprocal space and then records an intensity profile as a function of the diffraction angle (Figure 2). The recorded powder pattern corresponds to a one-dimensional section crossing the Debye cones the Debye cones; each measured Bragg peak corresponds to a specific atomic plane of a phase within the sample, and the analysis of the position and intensity of the peaks allows for straightforward identification and quantification of the crystal phases present in the system.

Although it has been used mostly to analyze crystalline compounds, XRD can also be applied to disordered and



X-ray Diffraction (XRD), Figure 2 Example of a measured XRPD pattern obtained from an analyzed sample containing residues of ancient metallurgical activities, including iron-copper ores and smelting slags. Symbols labeling the major Bragg peaks refer to the crystal phases producing those peaks: *bu* bustamite, a calcium manganese silicate, $CaMn^{2+}Si_2O_6$; *ol* fayalitic olivine, an iron silicate, Fe_2SiO_4; *sp* magnetite spinel, an iron oxide, Fe_3O_4; *cu* copper, Cu; *cp* cuprite, a copper oxide, Cu_2O.

amorphous compounds that produce only diffuse scattering (Klug and Alexander, 1974; Guinier, 1994). Furthermore, even materials that are normally considered amorphous, such as glass or vitreous pastes, may contain a significant number of crystal phases that can yield information on their origin and manufacturing techniques (Artioli et al., 2008).

The information ultimately provided by diffraction therefore is related to: (1) phase identification and quantification of crystalline compounds and complex polyphasic mixtures, (2) the texture and orientation of the crystalline phases, (3) the atomic and molecular structure of the phases involved, and (4) the physical microstructural state of the material in terms of crystallite size and accumulated strain. These features will be discussed separately with reference to specific examples.

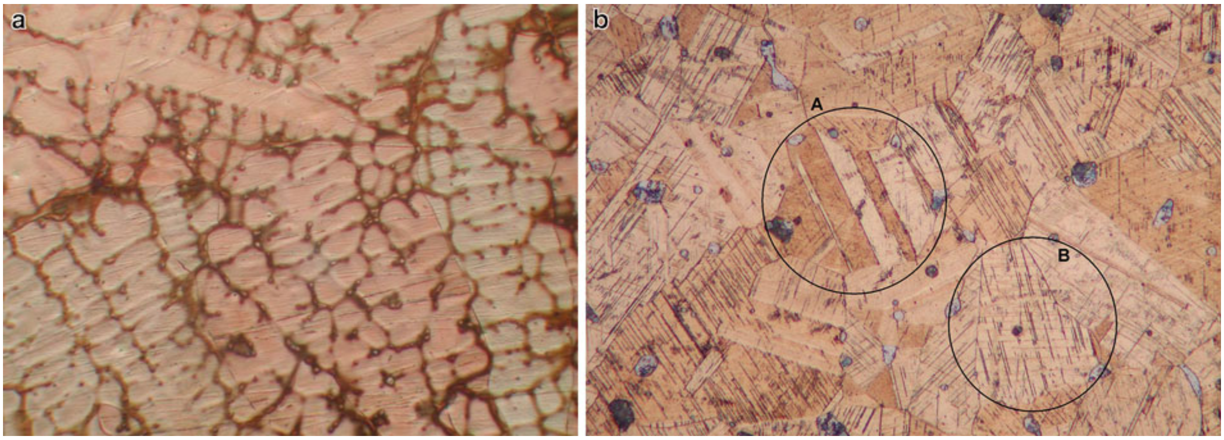
It should be noted that the most advanced method for the modeling and extraction of information from powder diffraction patterns is called *full-profile analysis* (also called *Rietveld analysis* or whole-pattern profile fitting). The method uses a least-squares approach to refine a theoretical line profile until it matches the measured powder diffraction profile (Young, 1993; Dinnebier and Billinge, 2008; Giacovazzo, 2011).

Phase identification and quantification

Any investigation involving Earth materials, or the human-produced artifacts derived from them, necessarily starts with the identification of the chemical system (i.e., chemical analysis) and the identification of the organic and inorganic phases present (i.e., diffraction analysis). Of course by tradition, most mineralogists and petrologists would prefer to carry out analysis by optical microscopy on thin sections or polished sections of the samples, but this depends on the possibility of invasively sampling the material under investigation as well as on the availability of a satisfactory quantity of sample. For many valuable archaeological artifacts, invasive sampling is not possible, so that noninvasive techniques are required. Diffraction is one of these noninvasive means (Artioli, 2013).

Modern laboratory XRPD techniques in fact allow measurements directly on the objects or on minute quantities of material (down to few mg of material) obtained by micro-sampling. The depth of the analysis on an intact object depends crucially on the energy of the probe, on the diffraction geometry, and on the nature of the material. The presence of surface alteration layers, corrosion products, or patinas may substantially influence these measurements, so caution is necessary in interpreting the results. This is especially true when using the new generation of commercial portable probes, designed to perform diffraction measurements in the field or in museums (Chiari, 2008). Some of them adopt the same technology selected for remote measurement that was embodied in the Mars Science Laboratory (MSL CheMin Instrument: Blake et al., 2012). To investigate objects at depth, more penetrating sources should be used, such as neutrons or high-energy synchrotron X-rays.

The reliability and instrumental flexibility of modern diffractometers available in scientific laboratories commonly yields high-quality measured intensity profiles that can be straightforwardly interpreted in terms of phase identification (Figure 2) and quantification, especially if performed through full-profile analysis methods (Madsen and Scarlett, 2008). The diffraction analyses are particularly useful when interpreting complex polyphasic materials, which often comprise tens of mineral phases, such as soils, ceramics, or building materials. Most of these materials – originally composed of clays, carbonates, and other common minerals – have been heavily transformed by human pyrotechnologies, and phases stable at high temperature are now present within



X-ray Diffraction (XRD), Figure 3 Examples of metal textures observed by metallographic analysis in reflected light microscopy: (**a**) copper dendrites in the as-cast metal – a treelike extension of copper crystallization occurring along preferred directions of bonding as the material is allowed to cool slowly; (**b**) thermally recrystallized polyhedral grains in an alpha-bronze metal sample showing features of mechanical working (well-developed slip systems that are the visible effect of the structural dislocations along lattice planes within the material, such as in grain **b**) and thermal annealing (polyhedral grain boundaries and twin planes evidencing individual crystal domains, such as in grain **a**) (Figure 3b courtesy of I. Angelini, University of Padova).

the material. Phase identification is important to reconstruct the firing technology, the oxidation conditions, and the time-temperature path (i.e., the kinetics of the process).

Diffraction experiments can also be performed using special sample-conditioning chambers (to control humidity, oxidizing conditions, etc.) and/or furnaces to attain high temperatures. These measurements yield crucial information on the kinetics of the processes, thereby helping to reproduce ancient technologies (e.g., firing of pottery or faience) or calibrate the rates of alteration or degradation for conservation purposes. Metal corrosion is a specifically important field of investigation for conservation (Leyssens et al., 2005; Adriaens and Dowsett, 2010).

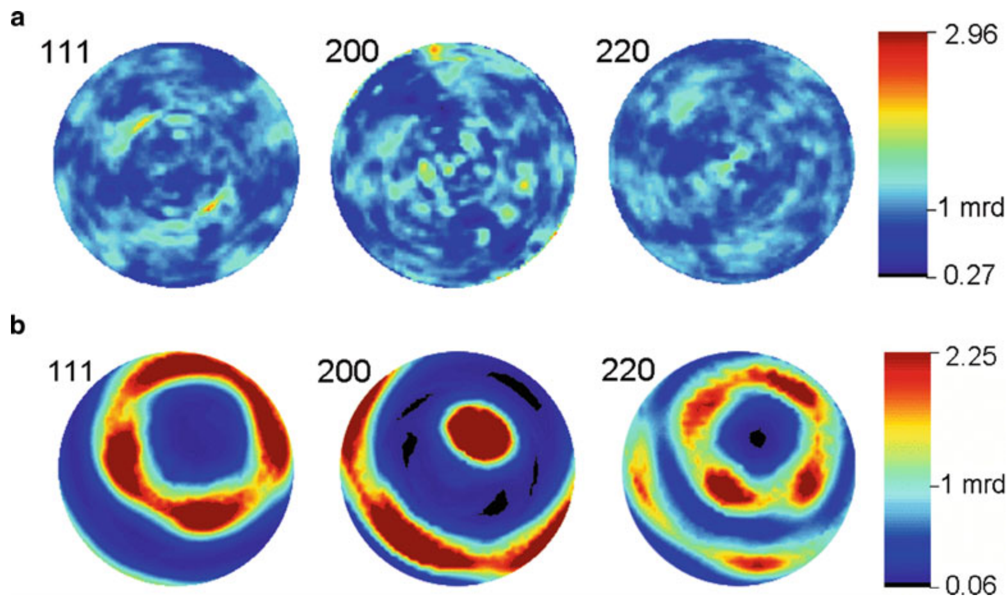
Crystallographic texture analysis

The shape and orientation of crystallites in a solid (i.e., the so-called texture or microtexture) depends on its thermomechanical history. In materials science and engineering, the analysis of the texture is usually performed after the manufacturing of the sample in order to verify and control the produced texture in terms of the shape and size of the grains and their iso-orientation with respect to applied forces. In the analysis of archaeological objects, especially metals, the texture is measured in order to understand and reconstruct ancient manufacturing processes. In archaeometallurgy, this type of analysis is called *metallography* (Scott, 1991), and it is commonly performed by polishing the metal surface, slightly etching that surface to expose the grain boundaries and defects, and then by observing the textural features by reflected light microscopy (Figure 3a, b). Metallography is a powerful tool for interpreting metallurgical processes, its only disadvantage being that sample preparation is invasive and requires several 2D sections at different orientations in order to reconstruct the full 3D texture of the metal.

Diffraction can also be used for texture analysis by measuring and interpreting the nonhomogeneous intensity of Bragg peaks in different directions from the sample, which is related to the nonhomogeneous (i.e., the textured) distribution of crystallites within the sample. The measurement of a substantial number of Bragg intensities along different sample directions allows the recalculation of the orientation distribution function (ODF), which fully describes the statistical crystallographic orientation of the crystals with respect to the sample reference system (Kocks et al., 1998; Popa, 2008). The ODFs are generally visualized by plotting the orientation data in pole figures in sample space (direct space) or in crystallographic space (inverse space) (Figure 4a, b); the units are multiples of the mean random distribution of crystallites. The *crystallographic texture analysis* using diffraction has been proposed as a totally noninvasive metallographic method to interpret the manufacturing of ancient metals, such as prehistoric copper axes (Artioli, 2007), including the well-known 3200 BC copper axe found with the Alpine Iceman mummy, Ötzi (Artioli et al., 2003).

Crystal structure analysis

Despite the fact that X-ray diffraction is the main tool available to investigate crystal structures and derive molecular information, including very complex ones such as proteins and viruses (Giacovazzo, 2011), there is seldom a need to analyze advanced structures in



X-ray Diffraction (XRD), Figure 4 Examples of metal textures measured by crystallographic analysis of neutron powder diffraction data: (**a**) pole figures relative to the (111), (200), and (220) planes of the cast copper shown in Figure 3a. The featureless pole figures are representative of randomly oriented grains, (**b**) pole figures relative to the (111), (200), and (220) planes of the worked metal shown in Figure 3b. The figures show a distinct fiber texture due to the recrystallization of the grains along the working direction. The pole figures are graphical representations of the measured 3D orientation distribution function (*ODF*) of the crystallites along specific sample directions. The color-coded pole figures are in units of mean random distribution (*MRD*), i.e., a sample having the crystallites in a totally random orientation shows a uniform pole figure with MRD = 1 (*blue color*), whereas a sample with preferentially oriented crystallites shows bright colored features in the pole maps.

geo-investigations related to archaeology. As discussed above, the crystal structures and related parameters for mineralogical phases contained with geomaterials are generally taken for granted, and perusal of the existing databases is the major tool for phase identification.

There have been, however, a few cases in which unusual mineral phases were present in materials of cultural interest, e.g., archaeology and art, especially in pigments. In such instances, knowledge of the detailed atomic structure of the phase in question can be of great assistance in understanding the origin of the material, determining its physicochemical properties, and establishing its reactivity. Typical examples are the main crystal phases of two important historical pigments: *Maya blue*, which is an organo-clay hybrid structure composed of indigo partially diffused within the channels of palygorskite clay (Reyes-Valerio, 1993; Sánchez del Río et al., 2011), and *Catalan blue*, which is produced mainly from the pyroxene-related mineral aerinite (Rius et al., 2004).

An interesting example of single-crystal structure analysis using diffraction data applied to archaeological objects is the recent determination of a previously unreported phase of the milarite-osumilite group found in an Egyptian scarab fashioned of glazed steatite (Artioli et al., 2013). This novel phase has a composition different from the other members of the family found in nature, as it was identified as a reaction phase embedded in the contact layer between the surface glaze and the talc body of the scarab. It was formed during the high-temperature application of the glaze, and its structural properties help to define the origin and production process of the object.

Analysis of microstructure

Extraction of information related to the average crystallite size in a polycrystalline sample, and estimation of the presence of lattice strains and defects, is referred to as *physical analysis* or *microstructural analysis* of a sample. It is performed by carefully interpreting the shape and the angle-dependent broadening of the diffraction peaks (Snyder et al., 1999). It is widely used in materials science to assess the residual stress and physical characteristics of industrial and engineering components, since the extracted parameters are directly related to the mechanical and reactivity properties of the materials.

One of the best examples of the application of microstructural analysis to geomaterials of importance in archaeology is the thorough investigation of Egyptian cosmetics carried out by the joint Louvre-CNRS-ESRF group (Martinetto et al., 2001; Ungár et al., 2002). The work was performed mainly using high-resolution X-ray powder diffraction data collected at ESRF (European Synchrotron Radiation Facility), and it analyzed in detail a number of Egyptian kohl samples used in antiquity as eye pigments. The investigation unambiguously showed that the careful mixing of black galena and white pigments (laurionite, hydrocerussite) could produce all shades represented by the observed colors. In addition, the grain size and stress analysis confirmed that galena (large grains, significant accumulated strain) was hand ground from natural sources of the mineral, whereas laurionite and hydrocerussite (small grains, no strain) were certainly produced by chemical precipitation, thus proving the very early production of synthetic cosmetics in ancient Egypt.

Diffraction analysis of bone apatite has also been a popular direction for research, since it has been demonstrated that diagenesis directly influences recrystallization of the mineral phosphate and that the crystallinity of apatite can be measured by XRPD (Hedges, 2002). However, the physicochemical transformations of bone hydroxylapatite during diagenesis are quite complex, involving chemical substitutions, thermal recrystallization, and crystal growth in solution. Therefore, in addition to diffraction measurements, an accurate interpretation of the diagenetic process would likely require complementary investigations, notably by chemical analysis, infrared and Raman spectroscopies, and transmission electron microscopy (see, e.g., Reiche et al., 2003; Piga et al., 2011).

Summary

Diffraction techniques represent a powerful archaeometric tool for investigating all kinds of geomaterials involved in archaeological issues and problems. By selecting the appropriate instrumental configuration and measurement strategies, it is possible to conduct fruitful investigations to characterize the natural materials forming archaeological sites, elucidate the microstratigraphy of layers formed by human activities, determine the sources of raw minerals and rocks employed in the building of architectural components (clays and sand for adobe and bricks, rocks for building stones, carbonates and pozzolanic sands from quarry and fire kilns for mortars and plasters, etc.), examine the properties and evolution of materials collected by humans and transformed by craftsmanship or industrial production into tools, such as flints and cherts into stone implements, ore minerals from mine to metals, clays for pottery and ceramics, etc., and finally investigate in detail archaeological objects in order to understand their nature, properties, and functions, while proposing effective conservation strategies.

X-RAY FLUORESCENCE (XRF) SPECTROMETRY IN GEOARCHAEOLOGY

M. Steven Shackley
Geoarchaeological XRF Laboratory, Department of Anthropology, University of California, Berkeley, CA, USA

Introduction

> X-ray fluorescence is now a well established method of analysis both in the laboratory and industry. The fact that the method is essentially non-destructive makes it particularly attractive for the analysis of archaeological and museum artifacts.... Due to certain fundamental characteristics of the technique it is not suitable for some projects which would seem at first sight to present no problems. (Hall, 1960)

Edward Hall's abstract for his 1960 paper entitled "X-ray fluorescent analysis applied to archaeology" in the journal *Archaeometry* is just as appropriate one-half century later. X-ray fluorescence (XRF) spectrometry may be more "well established" today, yet it is still "not suitable for some projects" even though it might seem so, and many archaeologists might wish that it would be so. This entry presents a brief discussion of the applicability of XRF analysis in archaeology. A number of recent published works on this subject delve into great depth and are highly recommended for further edification (e.g., Beckhoff et al., 2006; Potts and West, 2008; Shackley, 2011a; and the important Jenkins, 1999).

XRF has traditionally been conducted within a laboratory using desktop instrumentation, but currently, the market is flooded with many portable X-ray fluorescence (PXRF) instruments that can be taken directly to the field for immediate results. Do the portable devices really do all that their marketing suggests (see Shackley, 2011b; Speakman et al., 2011)? This question represents a watershed issue in the current practice of XRF spectrometry. The recent edited volume by Potts and West (2008) is devoted to the portable instrument and its applications in science and engineering, including archaeological stone and museum works of art, and more recently Ioannis Liritzis and Nikolaos Zacharias (2011) have provided a critical evaluation of PXRF in obsidian studies as well as other archaeological materials. The question for many excavators is whether there remains a need for the desktop laboratory EDXRF (energy-dispersive X-ray fluorescence spectrometer). Can the less expensive instrument that gives instant results in outside-laboratory settings serve just as well? It may be too soon for a definitive answer, but newer versions of PXRF instruments and software may be resolving some of these issues.

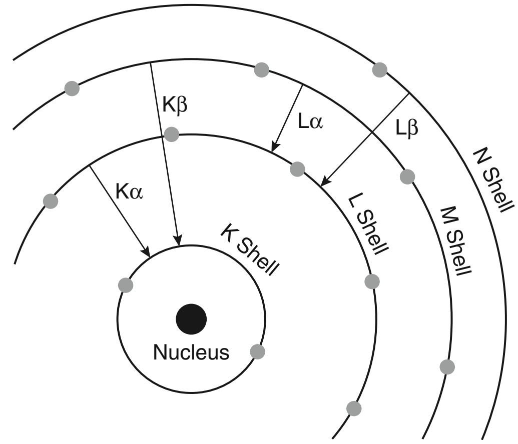
The vast majority of archaeological XRF worldwide is applied to inorganic materials, mainly volcanic rocks, and there are very good technical reasons (see Davis et al., 2011; Lundblad et al., 2011). This does not dismiss the potential value of analyzing ceramics or organics

(Speakman et al., 2011). Pottery is a mixture of rocks and clay sediments that lends itself to XRF analysis (Neff, 1992; Hall, 2001; Pollard and Heron, 2008). The difference is that volcanic rocks are formed at very high temperatures in the earth's mantle or crust, and they possess a geochemical uniformity within local rock bodies that helps match artifactual samples to their natural sources; ceramics show far greater variability in many ways, including composition and manufacture, which is a direct reflection of their human production, and thus sourcing pottery sherds, while commonly done, incorporates more complications.

Today provides a very different picture from Edward Hall's XRF world; archaeology as a discipline has changed markedly, both theoretically and methodologically, due in large part to the cultural insights and technologies that are available in the twenty-first century. Issues of social identity, equality, gender, national character, and native rights are all current and important concerns in archaeology today, but they are being addressed with the use of these new tools – XRF certainly among them (see Sillar and Tite, 2000; Pollard and Bray, 2007; Joyce, 2011; Mills et al., 2013). Scholars have argued that our twenty-first-century archaeological tools have offered broader and deeper perspectives on human behavior because the new data combined with evolving questions yields a process of inquiry much improved over previous decades (Shackley, 2005; see also Joyce, 2011). X-ray fluorescence spectrometry will continue to play an important role in illuminating the past. What XRF will look like in another 50 years is impossible to imagine, but the rise of the portables is perhaps a glimpse into that future.

History of XRF in archaeology

X-rays were discovered by the German physicist Wilhelm C. Röntgen (1845–1923), for which he won the Nobel Prize in 1901 (Röntgen, 1898). In 1909, Charles G. Barkla found a connection between X-rays radiating from a sample and the atomic weight of the sample. In 1913, Henry G. J. Moseley helped number the elements with the use of X-rays, by observing that the K line transitions – or primary transitions from one electron orbit to another – in an X-ray spectrum moved the same amount each time the atomic number increased by one, a primary theoretical precept in XRF physics (Moseley, 1913, 1914; see Figure 1 here). He is credited with revising the periodic tables, which were based on increasing atomic weight, to periodic tables based on atomic number. He later laid the foundation for identifying elements in X-ray spectroscopy by establishing a relationship between frequency (energy) and the atomic number, a fundamental basis of X-ray spectrometry. The potential of the technique was quickly realized, with half of the Nobel Prizes in physics awarded to developments in X-rays from 1914 to 1924.

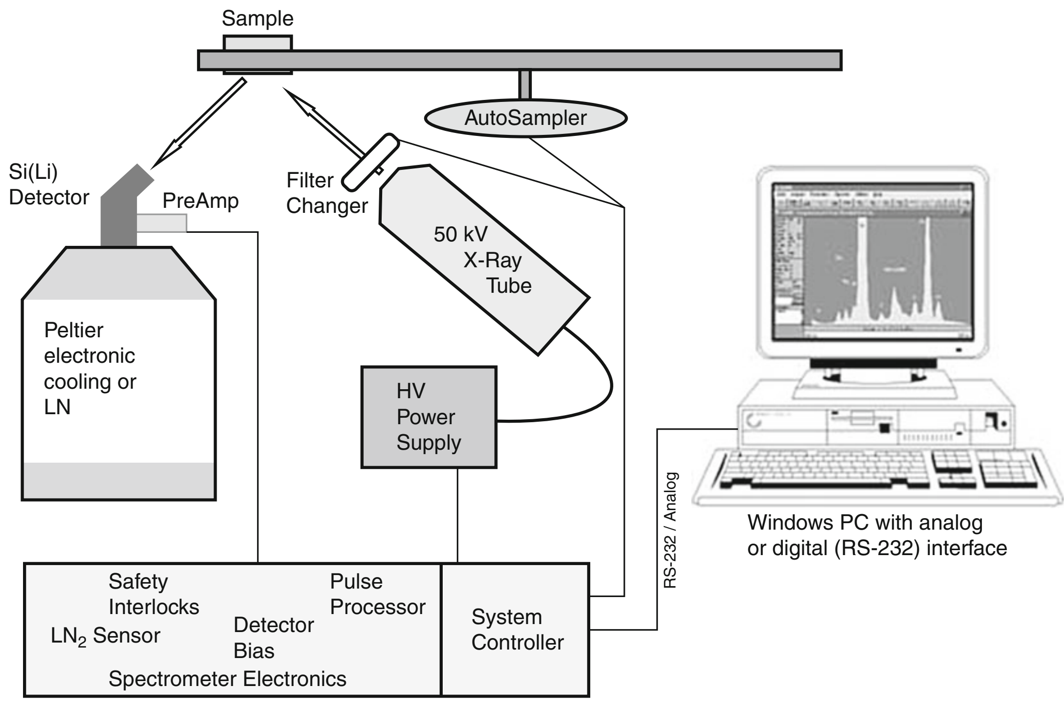


X-ray Fluorescence (XRF) Spectrometry in Geoarchaeology, Figure 1 Schematic view of orbital transitions due to X-ray fluorescence (From Shackley, 2011b: Figures 2-1). This graphic shows the orbital movement (transitions) of electrons subjected to high-energy X-rays in a typical sample. Electrons that are removed from their orbital position can move into other atoms, but when an electron returns to an orbital position, that X-ray energy creates an energy that is measured by the XRF system. The Kα transition is the most energetic and easily measured by today's XRF instruments. The Kα transition requires the greatest input energy to occur and thus creates the greatest energy (fluorescence) that is most easily measured by modern detectors.

A brief discussion of the principles of XRF

In EDXRF analysis, samples are irradiated with photons, usually from an X-ray tube or radioisotopic source. The primary X-ray beam excites electrons in the sample, causing the atoms in the sample to emit secondary X-rays, i.e., to *fluoresce*. The emitted X-rays occur at energies specific to elements in the sample, appearing as peaks over a given energy spectrum (Figure 1). The height or *intensity* of a given peak reflects, in part, the concentration of that element in the sample, and this amplitude may be converted to units of concentration, usually by comparison to a regression line or quadratic algorithm based on well-characterized standards (McCarthy and Schamber, 1981; Jenkins, 1999).

Traditional XRF analysis of geologic samples is destructive to the sample and requires rigorous and time-consuming sample preparation. Samples are ground to a fine powder and pressed into briquettes or, for analysis of major elements, prepared as fused glass disks, particularly for wavelength XRF (WXRF), where the relationship between the angle of the instrument and the object analyzed is crucial. However, with energy-dispersive XRF (EDXRF), the surface of the object is not as critical to success because the emitted energy is captured by the detector for all elements simultaneously, and through the detector and multichannel analyzer, that energy is converted to pulses that the software ultimately translates into elemental data (Davis et al., 2011; Figure 2 here). Figure 2 is



X-ray Fluorescence (XRF) Spectrometry in Geoarchaeology, Figure 2 Schematic drawing of a typical EDXRF instrument. Cooling can be either electronic Peltier or liquid nitrogen (LN), and many of the more recent instruments use more sensitive detectors than Si/Li (From Shackley, 2011b: Figures 1-9).

a schematic view of a typical EDXRF instrument, commonly used today, including many of the portable instruments, although the Si/Li detectors are now being replaced by detectors with greater sensitivity. Early EDXRF instruments did not yield the instrumental precision of WXRF, but neutron activation analysis (NAA), advances in detector electronics, and improved software have decreased the differences between these instruments. Miniaturization has ultimately heralded the portable XRF technology currently emerging (see Liritzis and Zacharias, 2011). A number of experiments (summarized in Davis et al., 2011) have shown that EDXRF is the most effective technique in the analysis of volcanic rocks when sample destruction is not possible (see also Lundblad et al., 2008).

The overarching assumption seems to be that XRF, and particularly energy-dispersive X-ray fluorescence (EDXRF) spectrometry, solves many of our problems in compositional analysis and geochemical sourcing. Glascock (2011) recently addressed this issue by directly comparing the results of NAA versus EDXRF for obsidian sources in central Mexico.

What's good about XRF?

The appeal of X-ray analysis of archaeological specimens lies in its remarkable combination of practical and economic advantages:

1. XRF is nondestructive. In the vast majority of cases, analyzed samples are not destroyed or changed by exposure to X-rays. They can thus be saved for future reference or used for other types of testing that may be destructive, such as obsidian hydration analysis.
2. There is minimal preparation. Many samples can be examined with little or no pretreatment, including almost all obsidian artifacts. While it is best to wash any sediments off archaeological specimens, it has been shown that if the dirt is minimal and the artifact has not been subjected to heat so high as to melt some sediment matrix onto the sample, vigorous cleaning is not necessary (Shackley and Dillian, 2002). This is mainly due to the penetration of X-rays in the mid-Z X-ray region – the region of the periodic table that contains elements from approximately $Z = 22$ (titanium) to $Z = 41$ (niobium) and generally does not require instrument chamber vacuum for analysis – beyond the surface, and while it does incorporate any contamination on the surface, it is generally not an issue if some soil remains in the flake scars. The analyzed volume is very large compared to any surface contamination. This is not the case with most metals, where patination and chemical weathering can radically change the composition at the surface and yield erroneous results (Hall, 1960).

3. XRF is fast. X-ray spectrometry enables chemical compositions to be determined in seconds. For an analysis of the elements Ti through Nb on the Berkeley Spectrace and Thermo desktop instruments, at 200 live seconds per sample, it takes about 5–6 min per sample depending on mass. More recent detectors can acquire these data even more rapidly.
4. XRF is easy to use. Modern instruments run under graphical interfacing software that easily handles measurement setup and results calculation. Tasks that once required the constant attention of a trained analyst can now be handled by skilled students and are fully automated after effective calibration and method compilation.
5. XRF is cost effective. Without the more involved sample preparation necessary in most WXRF and all destructive analyses, the cost is significantly lowered per sample.

While these advantages suggest that XRF will solve all our problems, it is not the panacea many would like it to be (Speakman et al., 2010).

What nondestructive EDXRF will not do

Sample size limits

Samples >10 mm in the smallest dimension and >2 mm thick are optimal for EDXRF analyses (see Lundblad et al., 2008; Davis et al., 2011). This is important because, as Shackley (1990) and more recently Eerkens et al. (2007) noted for hunter-gatherers in the North American West, high residential mobility often requires that stone sources, including obsidian, be conserved for long periods of time. As an example, an Archaic hunter will attempt to rejuvenate a dart point rather than make a new one whenever possible while moving through the landscape. The rejuvenation of that point creates debitage that is quite small, often smaller than 10 mm. With modern recovery techniques, these small fragments of debitage are retrieved much more often than they were in the past, and Eerkens et al. (2007) found that indeed these small obsidian flakes in North American Great Basin sites indicated not only greater distance to the original raw material used in toolmaking, but they indicated also a greater diversity of sources than was visible using only the analysis of larger flakes with EDXRF. So, while EDXRF can analyze much of the stone material left in prehistory, it may not solve all problems of interest to twenty-first-century archaeologists. To be fair, however, the procurement ranges that could be reconstructed were relatively accurate using samples above the 10 mm threshold in the Eerkens et al. (2007) study, and the smaller flakes were analyzed using NAA, which is essentially a destructive technique. Recently, however, newer digital EDXRF instrumentation and tube collimation have extended sample size ranges down to 2 mm with the Thermo Scientific Quant'X EDXRF at Berkeley.

Restricted elemental acquisition

As discussed below, nondestructive XRF is restricted generally to a subset of the mid-Z X-ray region, which is the best portion (including the Ti-Nb range) and contains excellent elements for the analysis of volcanic rocks (Shackley, 2005). While some rare-earth elements, those with low atomic numbers, or those possessing very low concentrations can be useful in discriminating sources, in most cases XRF cannot resolve their concentrations. This is discussed in detail in Glascock's (2011) comparison between XRF and NAA.

XRF cannot characterize small components

XRF like NAA is a mass analysis: every component in the irradiated substance is included in the analysis. It is possible to collimate the incoming x-rays from the tube and/or into the detector to focus on small components such as various minerals, but environmental scanning electron microscopy (ESEM), electron microprobe, or laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) is much better suited to this kind of analysis. However, the bulk analysis of volcanic rocks has been shown to be quite effective.

XRF will not solve all problems in archaeological provenance studies, but it is simply the best nondestructive analytical tool available at this time.

Is PXRF a revolution or just the latest development in XRF?

While portable XRF has both become very popular and highly criticized, this should be expected in a discipline that borrows much of its analytical technology (Liritzis and Zacharias, 2011; McAlister, 2011; Shackley, 2011a, b; Sheppard et al., 2011; Speakman and Shackley, 2013). What seems most problematic is that portable instruments were originally designed for mining and industrial applications and sought only qualitative results. Such methods and calibrations are neither necessary nor sufficient to address archaeological problems, where relatively precise quantitative data are required. Tied to this, most of the instruments, unlike lab/desktop EDXRF, have not allowed users to generate their own calibrations, and indeed, most relied solely on fundamental parameter routines that are often standardless and could not be modified beyond factory settings. The criticisms have had their effect, and many manufacturers are generating software that allows the user to employ linear calibrations by ratioing peaks/counts to the Compton scatter, a physical artifact of X-ray fluorescence, and thus eliminate the problem of differing sample sizes as earlier discussed by Davis et al. (2011) and Lundblad et al. (2008) for lab EDXRF instruments (for a detailed discussion of the Compton scatter, see Shackley, 2011b: 211). Given these important shifts in the ability of PXRF, it will be possible to take a sensitive instrument to field or museum settings and nondestructively analyze at least volcanic rocks with an instrumental precision and accuracy similar to those of lab XRF instruments. Most of the PXRF systems now available do not acquire the range of elements that laboratory systems do – i.e., sodium (Na) through uranium (U) – but the mid-Z (i.e., $Z = 22–41$) sensitivity seems to be very good. There may come a time in the near future when portable systems will acquire the typical sodium through uranium elements that laboratory instruments can today, but they are not here yet. This is likely in the future of XRF applications to archaeology. It is anticipated that archaeologists will evaluate it with dispassionate skepticism and use it in ways that yield useful information.

Definition

York (53°57′30″N; 1°4′49″W) is a city in northern England. It is situated on a well-drained east–west ridge (the "York Moraine") comprising deposits of the last Ice Age that crosses a low-lying NE-SE belt of land, the Vale of York, which was shaped by glaciers and surrounded by hills to the east and west. The moraine formed an easy route through the wet vale and became both a place for settlement and a defensive position for a succession of prehistoric and later invaders and occupants.

The region's landscape and water resources attracted prehistoric peoples, with Neolithic, Bronze, and Iron Age finds recorded from sites on the moraine, its lower slopes, and surrounding areas and peat bogs (Hall, 1996, 27; Neal and Roskams, 2012). Analysis of waterlogged organic-rich sediment dated to c. 1100 BC indicated that the land was then interspersed with shallow pools of water and that animal husbandry was practiced nearby (Hall, 1996, 66).

York itself was founded by the Romans in AD 71 on a relatively flat area of the moraine on a wedge of land between and to the north of the confluence of the major river (Ouse) and its tributary (Foss). They employed banks of earth and turf to build a 20-ha legionary timber fortress, which became the core of *Eboracum* [York] (Hall, 1996, 27–28). On the opposite side of the Ouse, the slope was significantly more pronounced, and when Roman civilian developments took place here in the late second century, the greater interventions for drainage and land stability this required had a stronger impact on the landscape. This is expressed archaeologically by layers of turf and clay-rich sediments forming terraces to counteract the natural slope, and by ditches dug in the second century (Hall, 1996, 31).

Lack of datable sediments from the fifth-century York makes interpretation of the post-Roman to early medieval periods uncertain. Thus, *dark earth* materials in York are rare: they were only observed below York Minster and in two areas of the ancient Roman *Colonia*, in the form of dark grayish-brown sediments postdating Roman deposits (Usai, 1999, 2001). Micromorphological characteristics of such deposits from the *Colonia* area included rare bone fragments, excrement features, and ash inclusions in only some of the examples, while all contexts contained charcoal fragments and were characterized by a low degree of mixing, with the rare traces of biological activity or postdepositional weathering suggesting the possibility of rapid burial at both sites (Usai, 1999, 2001). These deposits have been seen as having only limited similarities to stratigraphically analogous contexts elsewhere in Britain (Macphail, 1980, 1987).

Excavations in Coppergate, just to the south of the area of the Roman fortress, revealed an up to 8 m thick sequence of complex stratified deposits with a basal layer of yellow sandy clay cut by Roman features (Hall, 1996, 27–28). The latest Roman remains were covered by up to 85 cm of light gray loamy soil, representing the post-fifth-century period (and possibly spanning the period to the ninth century) with no trace of occupation. It was suggested that such soil was either brought in from elsewhere or formed by gradual accumulation of windblown silts (Kenward and Hall, 1995). The overlying deposits within the 8 m sequence enclosed vestiges of carefully planned properties with building plots and fence lines and a large accumulation of up to 3 m of exceptionally organic-rich sediments and debris, containing wood and bark fragments (including chips), from the building of

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

wooden structures and woodworking activities, along with the dumping of large quantities of dye-bath waste from textile working. Pit fills often largely consisted of human fecal matter, again with excellent preservation of delicate biological remains (Kenward and Hall, 1995). These highly organic deposits provided evidence for occupation that was resumed in the later ninth century by York's Viking occupants after 400 years with little activity (Hall, 1995; Kenward and Hall, 1995). The locally intense waterlogging conditions accounted for excellent organic preservation within the sediments, the material accumulating at a faster rate than it decayed, resulting in a rapid rising of the local ground level by up to 2 cm/year (Hall, 1996, 71). The sediments have been described as having compost-like consistence and "as 'water-retaining sponges' but not being usually saturated – yet often wet or merely damp" (Kenward and Hall, 2006). In particular, they preserved substantial remains of the ground plans of a series of timber buildings on four tenement plots. Investigation of plant and insect remains within the "sponge" materials yielded abundant evidence for living conditions, craft, and other activities in this area from the late ninth to late eleventh centuries while shedding light on the way the deposits had been formed (Kenward and Hall, 1995). Patches of the richly organic materials extended for 200 or 300 m laterally from the Coppergate area into the heart of the town, with areas of poorer preservation appearing to have resulted from recent decay (Kenward and Hall, 2000).

There are few geoarchaeological records for the late eleventh to early thirteenth centuries of Norman York. These consist mainly of sediments from a large pool of sluggish water (the King's Pool) generated by damming the River Foss. The works revealed no sedimentation within the pool during the late eleventh to thirteenth centuries, and this was attributed to regular cleaning of the pool for fish farming (Hall, 1996, 73).

Parts of York, along the gentler upper slopes of the Ouse and close to the Foss – particularly near the perimeter of the King's Pool and often overlying Roman deposits on river slopes – preserve layers of sediments exceptionally rich in organic material that act as "water-retaining sponges" (Kenward and Hall, 2006). The areas apparently formed from stable manure in the second- to third-century deposits, and more dramatically again in the Viking period (Allan Hall, pers. comm.). It has been suggested that standing walls, clay banks, and other archaeological features of Roman and later date may have acted as barriers to lateral water flow (Kenward and Hall, 2006).

The accumulation of organic-rich sediments becomes increasingly more restricted from the Norman to medieval period. In a sense, time is compressed in York's medieval stratification: very thin sediment layers close to the surface may represent several hundred years, whereas the same thickness of earlier deposits might represent decades (Hall, 1996, 79).

Many Roman and most Norman, medieval, and later stone buildings, including the city walls and Minster (cathedral), use the beautiful, easily worked, Permian magnesian limestone from outcrops to the southwest of the city (Buckland, 1977). The building stones of Roman York were mainly Carboniferous grit, sandstone, shale, and coal (Usai, 2005, 7); however, Jurassic sandstones and even Pleistocene volcanic erratics were employed for a minority of Roman and other buildings (Buckland, 1977).

Definition

Zhoukoudian, a small township located on the outskirts of present-day Beijing (China), is named for its 27 Pleistocene hominin and/or faunal fossil sites. These include Locality 1 cave where the *Homo erectus* fossils (aka Peking man) were recovered in 1929 and subsequent years. It is one of the UNESCO World Heritage sites of China inscribed in 1987.

Zhoukoudian is located in the Fangshan District, 55 km southwest of downtown Beijing. A hill called *Longgushan*, “Dragon Bone Hill,” was known by local farmers in the early twentieth century for quarrying of Ordovician limestone. Zhoukoudian was first visited by the Swedish geologist Johan Gunnar Andersson as a potential location for finding Quaternary mammalian fossils in 1918. The American paleontologist Walter Granger later identified fossils at Dragon Bone Hill in 1921. Austrian paleontologist Otto Zdansky then discovered three *Homo erectus* teeth from Locality 1 cave prior to 1926, the year Canadian anthropologist Davidson Black named the hominin teeth as a new species: *Sinanthropus pekinensis*. Black secured funding from the Rockefeller Foundation and started the official international collaboration with the Cenozoic Research Laboratory (today’s Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences) in 1927. Both Black and Chinese paleontologist Yang Zhongjian led excavations at the site, where the first skull of a Peking man was recovered by Chinese anthropologist Pei Wenzhong (aka W.C. Pei) in 1929. Since 1930, Zhoukoudian has become one of the most important paleoanthropology sites for the study of human evolution in the world.

Zhoukoudian includes 27 localities of hominins, faunal, and cultural remains, with the latest one – Tianyuandong Cave – identified in 2001. Four of these locations yielded significant hominin fossils of different species. From Locality 1 cave (the Peking man site), 203 fragments of *Homo erectus* belonging to more than 40 individuals were recovered. These included six nearly complete skulls, five of which were lost during WWII (Figure 1). The Peking man skulls are the most important study subjects for Asian *Homo erectus* and have been published extensively. A human premolar unearthed at Locality 4 in 1973 was unknown to the world; it probably belongs to Asian archaic *Homo sapiens*. Locality 26 (the Upper Cave) yielded 10 individual fossil remains belonging to modern human *Homo sapiens sapiens*, which are also well-studied specimens in paleoanthropology. The latest discovery of human fossils at Zhoukoudian was from the Tianyuandong Cave, where 34 fragments were found, including a mandible, teeth, and postcranial bones, which represent a nearly complete individual (Shang and Trinkaus, 2010). Direct AMS ^{14}C dating from a limb fragment produced the most reliable and earliest date for China’s *Homo sapiens sapiens* at Zhoukoudian, ranging from 42,000 to 38,500 years ago. Recent studies further identified evidence indicating that the Tianyuandong hominin might have worn shoes. Carbon and nitrogen isotope analysis of the samples suggest human consumption of freshwater fish at Zhoukoudian 40,000 years ago.

The most focused studies at Zhoukoudian have been dating, climatic context, lithic technology, and hominin and carnivore remains of Locality 1 cave. Recent dating

studies have changed the old perspectives about when Peking man lived, suggesting that he may have appeared at Zhoukoudian as early as 780,000 years ago (Shen et al., 2009), when the world was experiencing extreme cold and dry climates. With cultural material deposits measuring 40 m deep, it is possible to show the occupation of early hominins may have lasted half a million years at Zhoukoudian. Lithic artifacts were recovered from deposits of three cultural phases (early layers 8–10, middle layers 6–7 and QII, and late layers 3–5), accounting for more than 17,000 artifacts in total. These were cataloged into 10 classes with 40 types of stone tools, which suggest a gradual transition from simple use to a more complicated tool manufacturing process at the site (Zhang, 2004). The lithic artifacts from Locality 15 (dated to the late Middle Pleistocene and early Late Pleistocene periods) reveal evidence suggesting that lithic technology at the site was more developed than that of their predecessors at Locality 1. The Zhoukoudian Locality 15 hominin (most likely East Asian *Homo heidelbergensis* although no fossils have been recovered yet) effectively mastered sophisticated core reduction modes, represented by multidirectional flaking and alternate flaking, which were not evident at Locality 1.

Locality 13 was first excavated in 1933–1934 and re-excavated in 1956–1957. The stone tools recovered here were first considered to be within the East Asian "chopper-chopping tool" tradition in the original conceptualization of the Movius line, an apparent line proposed by Hallam Movius in 1948 that separated handaxe-using cultures of

western Eurasia from non-handaxe-using ones to the east. However, later studies suggest some of the chopper tools in early reports should be reclassified as cores instead. There is no chronometric date from the site, but comparative faunal dates and sediment stratigraphy suggest that this locality is possibly the earliest hominin occupation at Zhoukoudian.

One of the debated issues about Zhoukoudian's cultural contents surrounds the use of fire. Although there are no structurally defined hearths at the Locality 1 site, burnt ashes, charcoal, burnt bones, and even stone tools were often identified in situ. Whether or not these fire-related activities were the result of intentional human control and manipulation or due to natural causes and hydraulic transport is the subject of further studies. Since 2009, full-scale excavations at the Locality 1 site have been carried out by Chinese scientists and have revealed possible fire floors in layer 4 (Figure 2). An interdisciplinary research team is taking samples for all relevant scientific testing with the expectation that the results will advance our knowledge about the human use of fire in the Middle Pleistocene at Zhoukoudian.
