HARRIS MATRICES AND THE STRATIGRAPHIC RECORD

Edward Cecil Harris
National Museum of Bermuda, Sandys, Bermuda

Synonyms

Archaeological stratigraphy; Harris matrix; Stratigraphic excavation; Stratigraphic sequences

Definitions

Archaeological stratigraphy is the discipline that encompasses the study of all aspects of stratification on archaeological sites, including both human and geological formations. It is concerned with (1) the landscape components of stratification, i.e., surfaces embedded within the site, and with the contents of deposits, including artifacts and other contained remains, and (2) the sequential and chronological relationships between stratigraphic units. Stratigraphic studies lay the foundation for all later analyses of the surfaces and portable remains of archaeological sites; they are fundamental to any archaeological research involving excavation, which necessarily destroys stratigraphic evidence (but translates it into a stratigraphic archive) and removes samples of the remains found in deposits for analysis and preservation.

Stratigraphic excavation is the examination of archaeological sites (including geological components) using the principles of archaeological stratigraphy, wherein the latest units of stratification are removed before earlier ones, following the recording of "surfaces without deposits" and the "surfaces of deposits." It is axiomatic that the excavator follows and records the contours of surfaces as they are found and before excavation of underlying deposits, for that is the only way in which the landscape of the site can be reconstructed. It is also axiomatic that the reconstruction of archaeological sites is the reconstruction of the surfaces buried within the site, not the deposits lying above and below these surfaces, and that such a reconstruction is one of the principal goals of archaeological work on physical sites.

Stratigraphic sequences for archaeological sites are formed by the interpretation of the surfaces and deposits found during excavation and the placement of such universal stratigraphic units into a sequence in relative time. Such sequences represent the four dimensions of stratification, that is, the two dimensions of surfaces (area, length and width), the single dimension of deposits (depth or height), and, fourth, the relative time dimensions connecting the units of stratification on a site. Stratigraphic sequences form the testing pattern for much of the later analyses of the landscape and portable remains of a site. They are unique to each site, and that is their value to any form of archaeology that includes excavation, as well as for historical and anthropological studies. As stratigraphic sequences are all about time, and they form a unique "calendar," or "DNA" identifier for a site, they do not exist unless translated from the immaterial (surfaces) and material (deposits) evidence of stratification into a diagram. Since 1973, the Harris Matrix has provided the means for expressing such sequences in a diagrammatic form. Previously, "sections," or profiles, seen on a plane through a site, at one position or line only, were thought to fulfill that role. They cannot truly do so, as they represent only one dimension, that of depth, or height, on only one plane through a site.

Harris Matrices represent the stratigraphic sequences of archaeological sites in diagrams in which the oldest stratigraphic units are at the bottom, and later, or younger, stratigraphic units are at the top. Constructed on principles first delineated in the 1970s (Harris, 1975; Harris, 1977; Harris, 1979b), the Matrix, if assembled on an archaeological site during the excavation of stratigraphic units (archaeological and geological), will reflect in part the stratigraphic excavation of the site, with the sequence being built from the top, or latest stratigraphic units coming into place first, followed beneath by earlier units as excavation progresses. If assembled during the course of stratigraphic excavation, the Harris Matrix, or stratigraphic sequence, will be completed for a site, or part of a site, when excavation ceases. As the diagram is compiled without regard for the contained remains, but only in relation to the interpretation of the stratigraphic units, the Harris Matrix method is of universal application, since stratigraphic units are everywhere the same: a series of surfaces and deposits. With those methods in mind, any archaeologist, accountant-like, can audit the records of archaeological sites anywhere in the world and quickly ascertain if the "books" (the records) reflect that a site is being excavated and recorded by the principles of archaeological stratigraphy and that a valid and true stratigraphic sequence has been, or is being, compiled.

Introduction

In the historical development of the science of archaeology, where excavation of sites was a factor, it is fair to say that the process occurred in four phases. First, archaeologists dug up sites to find artifacts, for it was the portable remains, particularly those of intrinsic value, that were of paramount interest. Second, as the twentieth century progressed, architectural remains took on a value similar to that of portable artifacts, and many excavations consisted primarily of trenching to follow walls. Thus, the second historical phase came into being. Nonetheless, much early excavation was not conducted on stratigraphic principles, although one cannot often prove such an assertion; since the evidence was not often stratigraphically recorded, one cannot therefore match the recorded evidence of stratification with suppositions on excavation methods.

The third phase, wherein archaeologists became concerned with stratification and stratigraphic principles in detail, began after the profession had been in existence for over a century. This third phase began in earnest in the 1950s with the publication of Dame Kathleen Kenyon's *Beginning in Archaeology* (Kenyon, 1952) and Sir Mortimer Wheeler's *Archaeology from the Earth* (Wheeler, 1954), books that detailed new methods of stratigraphic excavation. The fourth phase began in the early 1970s, with the invention of the "Harris Matrix" in 1973, which was first published 2 years later in *World Archaeology* as "The stratigraphic sequence: a question of time" (Harris, 1975). A full description of the new methods in stratigraphic archaeology appeared in *Principles of Archaeological Stratigraphy* (Harris, 1979a; Harris, 1989). The title of the latter work suggested that an "archaeological stratigraphy" was inherent in the nature of stratification on archaeological sites and that principles of geology were not entirely apt for places formed primarily by human agency.

For a while, some scholars did not agree with that view. They thought that principles of geological stratigraphy were fundamental to archaeology (Gasche and Tunca, 1983; Farrand, 1984; Collcutt, 1987). Geology, however, had not provided archaeology with a method for compiling stratigraphic sequences. In the nineteenth century, archaeology took its stratigraphic principles primarily from the Law of Superposition, which generally asserts that if one deposit lies beneath another, the lower unit is older. An exception includes the case of consolidated, hard rock formations that have been overturned due to folding under pressure, thereby reversing the strata in places. In an archaeological context, where one must assume a "loose rock" analogy, any "overturning" results in the formation of new surfaces and deposits. Only the artifacts are "reversed" in sequence or displaced chronologically. The stratigraphic units in which they are found are newly formed due to the unconsolidated nature of most deposits on archaeological sites.

One of the components taken from geology that established the paradigm for archaeology until the 1970s was the section, or profile, cut vertically through a site. It was often recorded and presented as a "stratigraphic sequence," although that phrase was seldom used. The section as the supreme stratigraphic paradigm became enshrined in archaeological thought with the advent of the "Wheelerian Grid," in which a site would be excavated in square trenches with intervening "balks" that preserved the profiles. This approach inhibited a full understanding of the stratigraphic history of a site and the creation of true stratigraphic sequences, however. Within the boxlike excavation units, the details pertaining to embedded surfaces were largely destroyed by the excavation of the deposits, mostly without recording; and most excavators at the time did not understand that it is the surfaces, not the deposits, that hold the keys to complete comprehension of site stratification. Without a record of the surfaces, the stratigraphic sequence of a site cannot be compiled, as many archaeologists can attest after attempting to do so subsequent to the close of excavation. Surfaces, like time, do not exist unless recorded in a diagram. A strict focus on the digging process explains to some degree how earlier archaeologists thought of themselves as excavating the material (deposits) while they ignored the immaterial (surfaces.) They did not realize that, in stratigraphic interpretation, surfaces cover the entire site and are represented throughout the volume of its deposits, whereas a section and its associated stratigraphic sequence is true only along the plane through the site on which it appears as a vertical image, representing only the depth or height dimension of a site at that point.

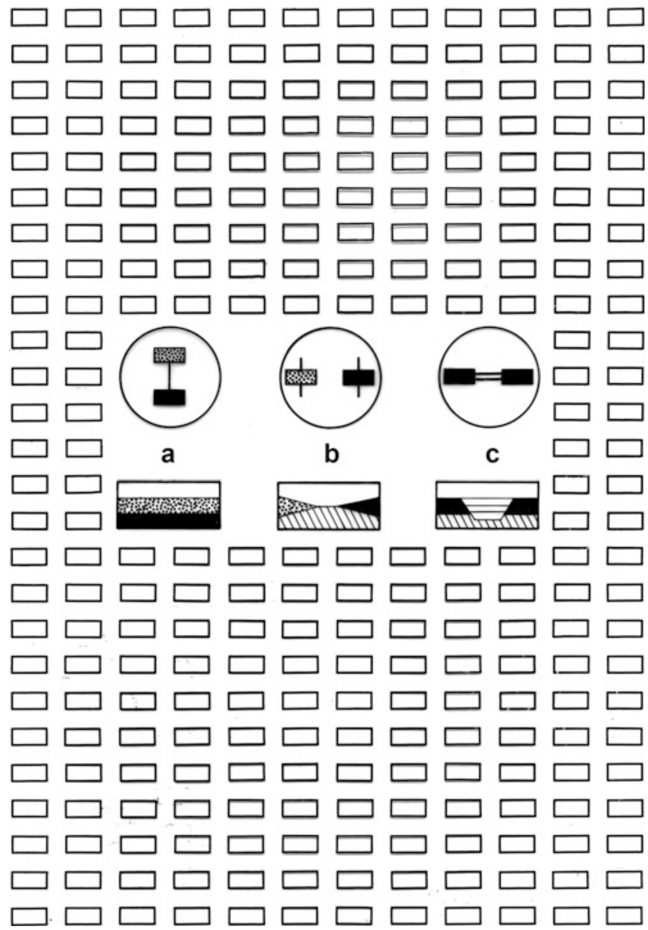
Some archaeologists in the late 1960s were aware that the section and Wheelerian Grid were detrimental to the understanding of sites, and that they were more an expression of a change in excavation methodology. Their new method, known as "open-area excavation," allowed for temporary balks and the ability to see the whole of a site without the interruptions of permanent balks (a surface, rather than section, approach). It did not translate into a full awareness of the central value of every surface in stratigraphic analysis, however, and most individual surfaces were not recorded. What transpired was the creation of "composite plans" that were thought to reflect major periods on a site, but in reality they often recorded only the "period of excavation." Given the overlap of surfaces and deposits, only parts of some surfaces were recorded, thus leaving a "data hole" where the unseen parts of those surfaces were lost because they were not recorded (Biddle and Kjølbye-Biddle, 1969; Barker, 1977). It is now known that if every surface is recorded, a phase or period plan can be reconstructed for the site at every turn, including when it was altered by the addition or destruction of stratigraphic units. Thus, a site with a thousand surfaces can have, if desired, a thousand phases or period plans, but such plans will depend upon the later analyses of contained remains, which will "move" surfaces up or down a string in relative time in a Harris Matrix, when coupled with a chronometric time scale on the side of the diagram. Hence, well into the mid-1970s, excavators were locked into the main tool of their trade – digging – and while stratigraphic excavation was continually refined, recording methods were stuck in the geological paradigm of the section.

After the invention of the Harris Matrix, it took several years to discern what archaeologists were not doing correctly, in terms of stratigraphic recording, so that true stratigraphic sequences could be compiled. The key, which was suggested by English archaeologist Laurence Keen, was the recording of each and every surface, in what were known as "single-layer," or later more correctly as "single-context" plans (since layers, or deposits, are not surfaces). For example, many surfaces are stand-alone stratigraphic units without an associated deposit, such as the surface of a trench cut into preexisting strata for the insertion of some installation like a water main. With Brian Hobley's assistance in 1974, single-context planning and the Harris Matrix system was used for the first time on a large excavation by the Museum of London with resounding success. Exploring a prehistoric ditch in Winchester, England, in 1975, Patrick Ottaway conducted the first experiment on an archaeological site to record each surface before it was excavated away (Harris and Ottaway, 1976). The experiment meant that the landscape of the site (the stratigraphic reality that people lived on or with, as people did not live in deposits) could be reconstructed simply by overlaying the plan of each surface unit, in stratigraphic order, beginning at the bottom of the ditch and working upwards to the modern surface that existed pre-excavation.

As an aside and a summary to this brief historical overview of archaeological stratigraphy, the "digger mindset" persisted for the first years of the Harris Matrix, as the diagrams were initially called "layer charts," layer being the then common name for deposits that can be dug up. It was only after a time that the understanding emerged that a Harris Matrix diagram was in fact the representation of the stratigraphic sequence of a site and, as such, could be compiled only if full attention were paid to the surfaces, their recording, and interpretation. The Harris Matrix has proved to be a valid method and has created a new stratigraphic paradigm for archaeology, prompting the statement that "For the first time, stratigraphy became truly *independent* of the section. . .it was quite a momentous occasion in the history of field archaeology in Britain" (Lucas, 2001, 57). The simple principles and methods of the Harris Matrix are explained below.

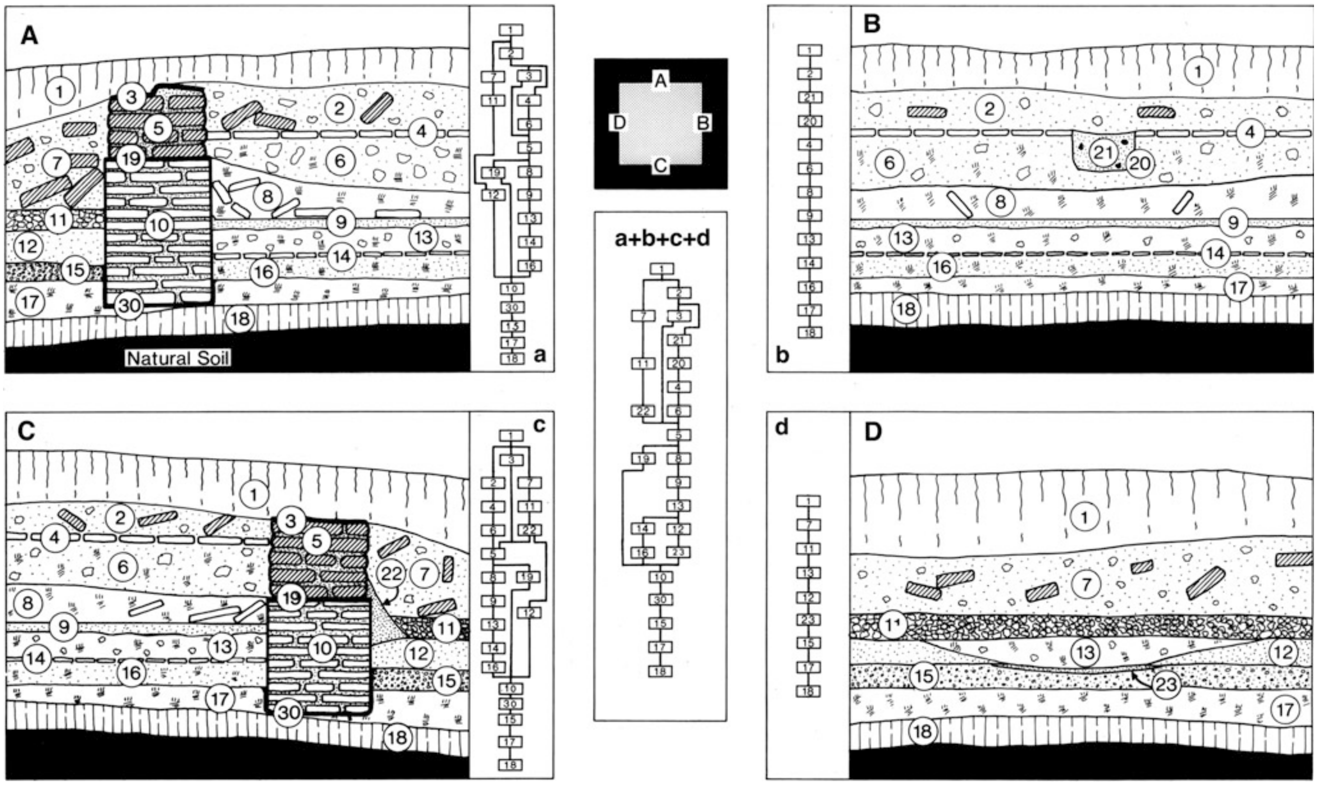
Principles of archaeological stratigraphy

Archaeological Stratigraphy is governed by a set of laws, elucidated by Harris (1979a, b). The reason for establishing such laws is that archaeological sites, which are made by people, do not generally conform to the laws of nature, as expressed in the tenets of geological stratigraphy. The laws borrowed by earlier archaeologists from geological sources ultimately proved inadequate to deal with the complexities of archaeological stratification, especially in intensely built-up sites. The Earth is now girdled with human stratification, some of it perhaps larger than any geological deposit; consider, for example, the Interstate Highway System of the United States, which stretches as a stratigraphic surface from coast to coast, and if joined with other highways, from Alaska to Patagonia. The Law of Superposition states generally that if a unit is below another, it is older. This relationship prevails unless surfaces without deposits are encountered. In such a case, applying the Law of Stratigraphical Succession resolves the issue. This law states that a unit takes its place in the stratigraphic sequence above the latest unit that the surface unit "cut" through. Thus, in a traditional section, a disused "tube" of the London Underground (a surface with no deposited fill) may appear below Roman deposits and give the impression of being earlier, but if traced in plan, the tube's surface reveals that it was cut down through overlying stratification. Therefore, the surface – and all of its contained units – emerges from its apparently contradictory physical situation and assumes its true position in relative time within the stratigraphic sequence: above (=historically after) units of the later Victorian period. The Law of Original Horizontality gives perspective on the nature of the layering of deposits, while the Law of Original Continuity is important, as it helps explain why stratigraphic units are interrupted, such as when a utility trench is dug through earlier surfaces and deposits. Those laws and methods of recording in archaeological stratigraphy provided the building blocks for the compilation of a Harris Matrix or stratigraphic sequence.



Harris Matrices and the Stratigraphic Record, Figure 1 A blank Harris Matrix sheet with inserts showing (*A*) two units that are in a superpositional relationship, (*B*) two units that are not in a superpositional relationship, and (*C*) two units that may be correlated (optional).

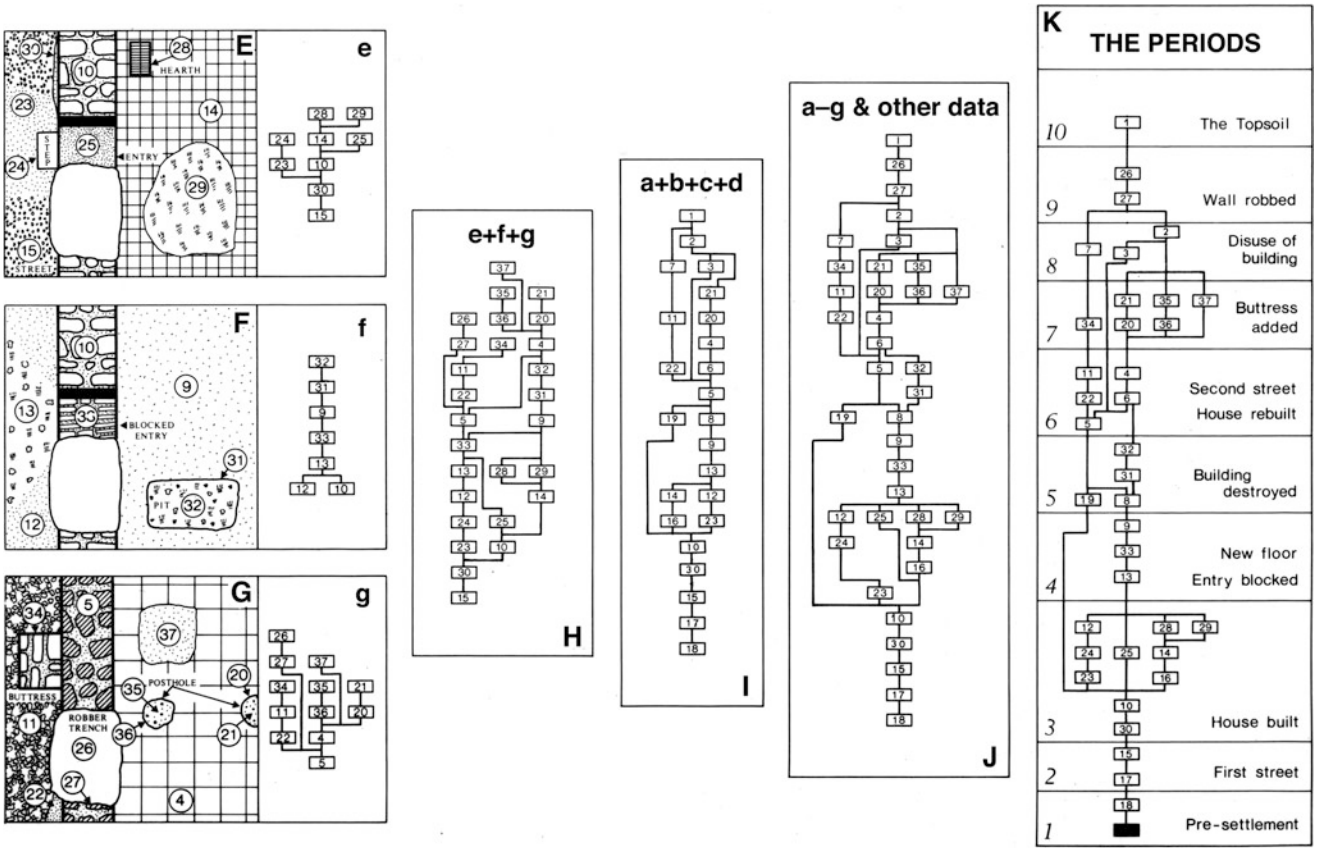
The compilation of a Harris Matrix, or stratigraphic sequence, is based on the question of relative time. To ask, "Which came first?" of any two stratigraphic units in superposition, one must determine which one, or which part of one, lies on top of the other unit, or part of it. The units are placed in the sequence with the lower one below and the later one above. A line emerging from the top of the box representing the lower unit and connecting to the bottom of the box representing the upper unit defines that stratigraphic relationship, and this relationship is fixed immutably at the time of observation and recording (Figure 1A). These relative time relationships cannot be broken, even if the progression of artifacts embedded within the vertical string of units suggests otherwise in terms of chronometric time. The presence of artifacts apparently out of sequence must be explained by other agencies (Harris and Reece, 1979), for the stratigraphic sequences reflect the order of deposition and creation of the stratigraphic units and must be compiled without



Harris Matrices and the Stratigraphic Record, Figure 2 A Harris Matrix is prepared for each section of an excavation unit, and then, as they are all actually one section, a single stratigraphic sequence is compiled by combining a+b+c+d and removing redundant lines (see Harris, 1989).

reference to any contained remains. To alter the stratigraphic sequence on the basis of contained remains is to alter the position of the associated surfaces, which cannot be moved into new positions in the sequence without potentially confounding and contradicting the physical buildup of the site over time. Contained remains are in effect locked into place by the position of the deposit that encloses them in the stratigraphic sequence. Therein lies part of the formidable and irreplaceable value of the Harris Matrix to all future analysis of the stratigraphic importance of a site's landscape history as well as the analysis of all contained remains and their significance in the site's cultural history. The other two relationships that are recognized are that two units of stratification need not be in superposition (Figure 1B) and that two parts of a once whole unit may be correlated with an = sign between two unit boxes (Figure 1C). The last is optional, while the first two are mandatory. The boxes of course carry their own unique identifier number for the individual stratigraphic units they represent; a deposit or unit that has been subdivided by later alterations to the site must be given separate numbers for each part, as each part is now a separate unit in the stratification.

Using the first two relationships only, the Harris Matrix can be built up, unit by unit, as excavation and recording proceed on the site; the third correlation relationship is optional. As each stand-alone surface or surface of a deposit is identified, numbered, and recorded in plan and in recording sheets, the unit can be added to the sequence. As excavation is generally done by hand, and only so many units can be excavated in one day, it should be easy to keep the diagram of the stratigraphic sequence updated each day. If one were dealing with a trench excavated by machine, so that the only stratigraphic evidence to record was that of profiles after the machine had exposed them, then each section would have its own sequence. If, however, the sections of a hole or trench were connected, the different section sequences would need to be joined together to form the single sequence representing the summary sequence of all the sections, as is demonstrated in Figure 2. That sequence would be further altered and elongated if surface data from within an excavation were available to be factored into the diagram to make the fullest possible stratigraphic sequence for the site (Figure 3). If one excavates the entire site stratigraphically, however, making surface plans and notations on superpositional relationships as work proceeds, the sequence is built up (down, during excavation), almost automatically, without the necessity of joining, say, several section sequences into a single one. That is to say that



Harris Matrices and the Stratigraphic Record, Figure 3 Harris Matrices are prepared for three plans, E, F, and G, and the sequences are combined as e+f+g with that of the sections in Figure 2 (a+b+c+d), and those two sequences are combined with other stratigraphic data not appearing in the plans or in the sections, to form the full stratigraphic sequence for the site in K, which can then be divided into periods based on contained artifacts.

some of the issues above apply only to sites which were not excavated while using the Harris Matrix to compile the stratigraphic sequence as work proceeds; this applies to many excavations worldwide that were conducted before, and since, the advent of the Matrix and its associated and necessary concepts on the principles of archaeological stratigraphy.

In the assigning of identifier numbers, it is axiomatic that all surfaces that do not have deposits, such as trenches and holes of whatever variety (postholes, ditches, wells, etc.), must be given a number following the Law of Stratigraphical Succession in determining the position of such "interfaces" in the stratigraphic sequence. If they are not numbered, the stratigraphic sequence then cannot be an accurate listing of the site formation progression. Surfaces that define the upper boundaries of deposits need not be numbered, although if they were, it would make more sense for the sequence and its periodization, since the surfaces and not the deposits mark the major "living" phases or periods on a site, and they often represent vastly greater time periods than the deposits which "support" such surfaces. That is, in the duality of stratification, its waxing and waning, its erosion and deposition, there are (a) periods of deposition (placing material into nonuse) and (b) periods of use, or nondeposition. For example, most surfaces of the Coliseum in Rome have been in use for a couple of thousand years, whereas the "supporting" stonework was "deposited," or put in place, only once. Presently, in most Harris Matrix diagrams, the surfaces of deposits are indirectly represented by the lines connecting the unit boxes, as they are not generally given unique identifiers. Perhaps they should be numbered as identifiers because they would then be tied into the plans of surfaces. Supporting deposits would appropriately have their own number, to which all contained remains would be tied.

Post-excavation analyses and reconstruction of sites

The Harris Matrix stands at the center between two pyramids of archaeological knowledge, the upper, or later, one resting atop the earlier one in an inverted position with the two points in contact. From the lower pyramid, all of the stratigraphic data from the site flow upward into the creation of the stratigraphic sequence at its apex. The upper, inverted pyramid represents all the later analyses, interpretations, artifact curation, and records archiving, most of which must take as its foundation the stratigraphic sequence, or be tested against it. The stratigraphic sequence is central to those two pyramids of data and knowledge, the lower one representing all the acquisition of new information from the physical site (stratification) and the sample collecting of the remains contained within the deposits – i.e., artifacts and ecofacts. The sum of all raw data steadily adds to our knowledge about the past when it is analyzed in the upper pyramid, which funnels upward and outward, for such analyses may go on for generations to come. Once analyses have taken place for various types of portable remains, the results of those studies are reconsidered in the light of the stratigraphic sequence, which can change shape (but not its fixed relationships) by elongation, in relation to a sidebar scale in calendar, or chronometric time. Such studies help to determine the position of "floating units" relative to other units with which they have no superpositional relationship in the sequence. Depending on the results of analysis, they can slide up or down on their separate strings relative to one another in the Harris Matrix diagram. This process invokes the permutations of stratigraphic sequences as originally raised in Dalland (1984), Harris (1984), and elaborated by Bibby (2002) and Roskams (2001); it is a major issue for archaeological interpretation. Subsequently, the final phase and period diagrams can be arranged for the site, based partly on the chronological input from the contained remains. Those images are represented in plan or map form for the periods of nondeposition (combined surfaces), and for the periods and phases of deposition, they are represented in section drawings, the latter showing the shape and volume of the stratification along a plane through the site. If individual surface plans are recorded with elevations, then on computers with GIS capabilities, sections can be constructed along any line through the site, an option that is impossible during excavation, as we must excavate stratigraphically from the top (surface), not from the side (section) of the stratified sequence. One of the main goals of excavation is to be able to reconstruct the site, which is to say, reconstruct its surfaces, its periods of usage. The recording of individual surfaces of each stratification unit is the only way to accomplish that reconstruction, for no matter the number of sections that may be recorded, there will never be enough to reconstruct the surfaces and therefore to allow for the full reconstruction of the site. That provable assertion should bring to an end the method known as "arbitrary excavation," whereby, in what appears to be a very precise and scientific method, a site is excavated entirely in predetermined levels. Such an excavation strategy results in the formation of false surfaces and the destruction of the original stratified surfaces before they are recorded. The original surfaces do not follow precise horizontal levels at uniform elevations on most sites. No site excavated in arbitrary levels can be reconstructed because its surface evidence is in reality a "sequence of excavation" levels, not a stratigraphic sequence compiled by following the contours of the original stratigraphic units.

Summary

While fundamental to the science of archaeology, the subject of archaeological stratigraphy received little elaboration of its basic principles for many decades. These principles had been borrowed from geology in the nineteenth century. A paradigm shift occurred in the 1950s when Kenyon and Wheeler brought attention to stratigraphic excavation, recording sections to include distinct lines for surfaces between deposits. They began to examine the methods of phasing (that is, the compilation of stratigraphic sequences in the first instance). In that phase, the section was seen as the stratigraphic sequence and surfaces not in the section were largely ignored. A subsequent paradigm shift added surfaces to the equation. Surfaces are, in effect, two major dimensions of stratification within archaeological sites, but the advent of "open-area excavation" by Philip Barker and others represented a shift largely in method of excavation and not a fundamental change in recording methods. In 1973, a fundamental paradigm shift occurred, which added a fourth dimension: time. This development brought not only the production of stratigraphic sequences in Harris Matrices, but also the acknowledgment and recording of surfaces lacking deposits, which are immaterial and can be seen only if recorded as a plan drawing The abiding importance of surfaces is that they represent the periods of time when the site was in use, i.e., when it was being lived on, and as such they usually reflect the passage of far more time than the deposits that were laid down, or constructed, to form those surfaces (Harris et al., 1993). As the eminent geologist, Charles Lyell, once wrote, stratification "is *undesignedly* commemorative of former events" (Lyell, 1875, I, 3), and thus, to add a modern corollary in archaeology, "stratigraphic sequences, being composed from the evidence of *undesigned* stratification, are unbiased testing patterns for archaeological sites." The Harris Matrix and associated methods are the only way to *see* such relative time sequences on archaeological sites, no matter the origins of the deposits or the cultural and ecological material remains contained within the deposits. Harris Matrices are of universal application and are thus becoming the "industry standard" in many countries around the world.

The Haua

Introduction

The Haua Fteah, in northeastern Libya (32°53′59″ N; 22°03′05″ E), is a large and imposing cave 1 km south of the Mediterranean coast at an elevation of 67 m asl. It was excavated in the 1950s by Charles McBurney (McBurney, 1967) and re-excavated between 2007 and 2012 by Graeme Barker and Tim Reynolds (Barker et al., 2007, 2008, 2009, 2010, 2012; Rabbett et al., 2013).

Geomorphology

The cave lies on the edge of a large doline, or sinkhole, one of several in the area. It most probably reached its present morphology when the doline intersected with a pre-existing cave of phreatic origin, with further modification by granular disintegration and episodic roof falls.

The cave fill

The filling of the cave is contiguous with, and interfingers with, the doline fill. The sequence contains 15.5 m of well-stratified sediments dating from late OIS 6 to the present. Most of the sequence consists of silty diamicts (poorly sorted deposits with different particle sizes) and silts deposited by mudflow and wash originating outside the cave and most probably reflecting rare extreme rainfall events and perhaps climatically disrupted vegetation. Pedogenic features and carbonate induration are episodically developed, reflecting phases with low rates of sedimentation and well-developed vegetation cover outside the cave (Inglis, 2012). Breccias ultimately derived from roof collapse and emplaced by debris avalanche are occasionally present, but they comprise the dominant lithofacies in late MIS 3 and MIS 2. Silts, silty diamicts, and breccias characterize the early mid-Holocene, with a facies shift to diamicts and stable-burning deposits caused by land use changes following the Greek invasion in 621 BC and a change in the use of the cave from residential to livestock penning. Gravels derived from alluvial fan deposits outside the cave were spread on top of the fill during military activity in the 1980s. Throughout the cave's history, sedimentation in the Haua Fteah was characterized by long periods of stillstand separated by extremely rapid and often catastrophic sedimentation events incorporating, on occasion, materials from older levels (Hunt et al., 2010, 2015). For example, the Holocene sequence appears to have accumulated as the result of only 24 significant sedimentation events.

Archaeology

The cave's archaeological record preserves a rich sequence featuring 'pre-Aurignacian' (elongate) Middle Stone Age (MSA), Levallo-Mousterian MSA, Dabban (Upper Paleolithic), Epipaleolithic, Neolithic, and Graeco-Roman artifacts plus a wide range of biological indicators including shell, bone, plant remains, pollen, and phytoliths. Human mandibles of early modern type were found near the base of the Levallo-Mousterian

MSA, provisionally dated to ca. 70,000 years ago (Douka et al., 2014). A Graeco-Roman temple was found near the top of the sequence.

HEARTHS AND COMBUSTION FEATURES

Susan M. Mentzer
Institute for Archaeological Sciences, University of Tübingen, Germany
School of Anthropology, University of Arizona, Tucson, AZ, USA

Definitions

Hearth. A structured and spatially discrete fire, typically of wood, built on the ground surface or a prepared substrate and intentionally lit by people.

Combustion feature. A concentrated deposit of burned materials in an archaeological site.

Introduction

Humans have interesting and complicated relationships with fire. The production and control of fire is a behavior that many believe increased the evolutionary fitness of our hominin ancestors and allowed our species to colonize and survive in the extreme northern and southern latitudes of our planet. Ethnographic and historical studies reveal many ways in which humans utilize fire as a technology for landscape modification; personal heating and heating of spaces; production of materials such as ashes or charcoal; transformation of materials from one state to another in the form of cooking, firing, smelting, or cremation; and the production of light and smoke. Humans also use fire in less tangible ways as a form of communication between each other and to other organisms. For example, fire offers protection not only against the cold but against carnivores and other people. Likewise fire can be used as a tool of physical destruction, ranging in scale from the disposal of domestic trash to the leveling of villages, as well as a tool of psychological destruction. Fires provide atmosphere and serve as foci for social activities that range from casual conversations to ritual and religious practice.

For archaeologists, identification of traces of burning in primary and secondary contexts can be informative about pyrotechnology as well as organization of space within a site. The places where humans produced or used fire are significant to archaeologists because these localities may have served many functions, both primary and secondary, such as cooking, social, and ritual spaces. Furthermore, identification of areas where burnt materials were deposited can be informative about peripheral zones within the site, intentional acts of curation, or postdepositional processes that served to redistribute anthropogenic materials.

The study of ancient fire use has in the past been accomplished by so-called archaeological generalists. Exceptions to this rule include the study of ancient pyrotechnologies such as ceramic production and metallurgy, which have been conducted by archaeological chemists. Lack of specialization in the study of fire use may be due to assumptions about the ease with which hearths and other types of combustion features can be identified and interpreted in the field. More recently, and driven in part by the true complexity of such identifications and interpretations as well as the need to evaluate critically the evidence for early controlled use of fire (e.g., Roebroeks and Villa, 2011), geoarchaeologists have begun to take a leading role in the identification of ancient fire.

Geoarchaeology provides an ideal approach to the study of combustion features principally because a majority of the analytical techniques used to identify burned materials are derived from the geosciences. These techniques include optical petrology, stable isotope geochemistry, and mineralogy (see below). In addition, combustion produces fine-grained materials that are typically classified by archaeologists as "sediment," and features composed of burned materials cannot be removed from the site and studied in the same way that one might study a stone tool or ceramic vessel. Geoarchaeologists have therefore developed analytical tools that facilitate integrative analyses of combustion features, including the collection of subsamples that can be studied in a laboratory setting. Furthermore, combustion features are impacted by taphonomic processes, and their study can easily fit within broader geoarchaeological research goals that include reconstruction of site formation processes. Following identification, the study of combustion features is ultimately best accomplished through collaboration between the geoarchaeologist(s) and specialists in architecture, ancient materials, and other areas. Nevertheless, it is entirely appropriate for a geoarchaeologist to be involved and actively engaged in the interpretation of combustion features in terms of individual human behavior and human social systems.

Types of combustion features

As deposits of burned materials in archaeological sites, combustion features are neutral with regard to human agency, that is, they can be produced by natural or anthropogenic causes. Combustion features consist of burned materials, including ashes, charcoal and other forms of charred plant material, heated stone, burned bones, glasses, and slags, with or without substrates and associated architectural elements that were directly exposed to heat. It is important to note that morphology and physical forms, including the spatial relationship between the heated materials and substrate, can vary according to, or independent of, function.

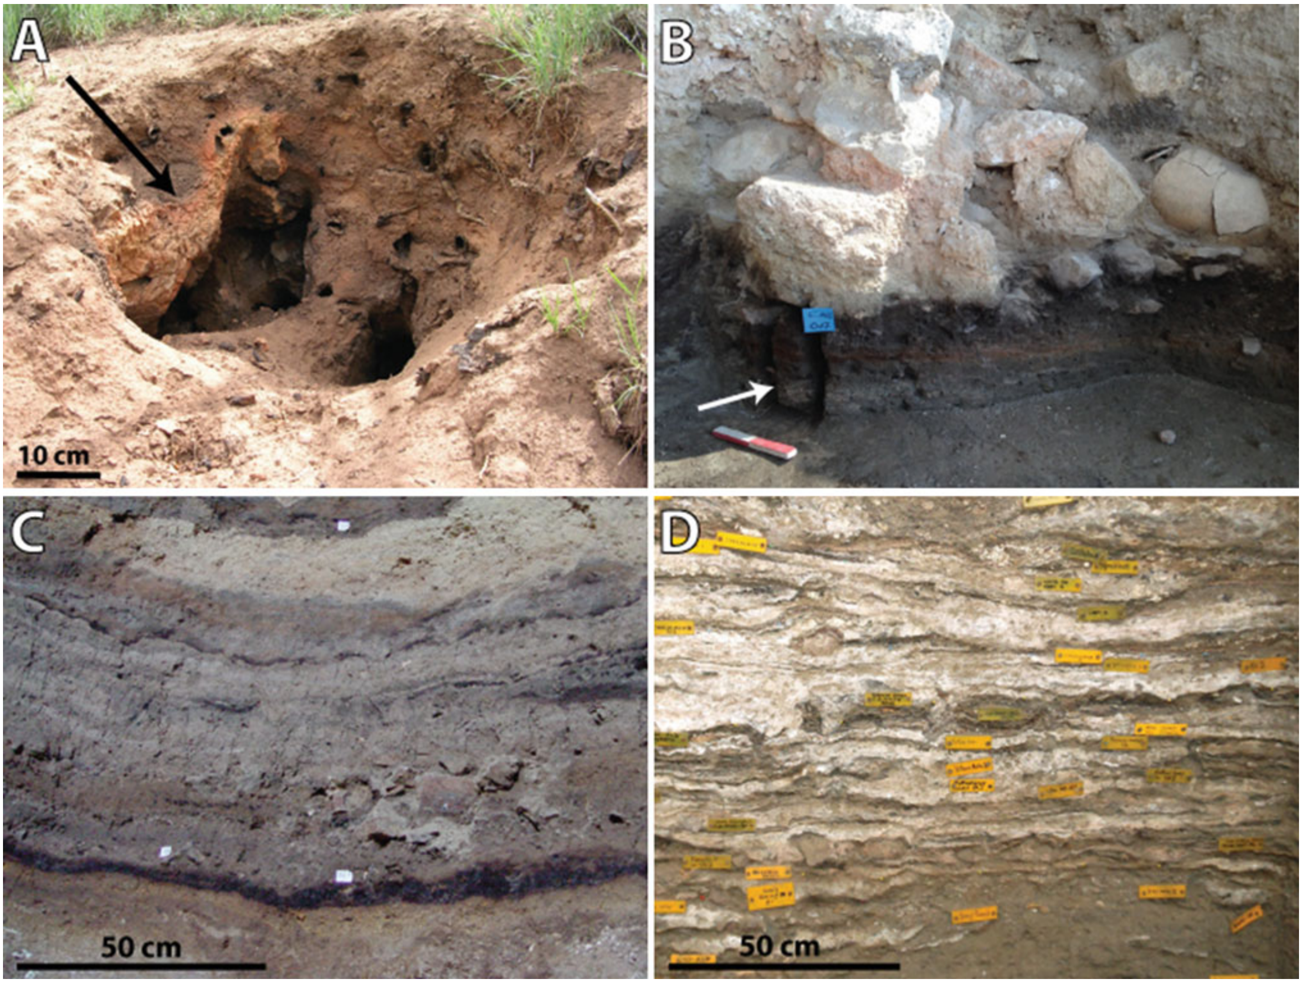
Primary or intact combustion features are located in the place where burning originally occurred, with complete or partial preservation of the original structure and internal spatial arrangement of components. An uncontained primary combustion feature (Figure 1) is a specific type of intact feature that lacks architectural elements and can result from natural processes as well as controlled and uncontrolled use of fire by humans. The lateral spread of burned materials in uncontained primary combustion features may be constrained by the initial distribution of fuel, and their wide extent can blur the boundary between what archaeologists may term features (spatially limited areas) and layers (deposits covering a wider area).

Uncontained primary features include non-anthropogenic fire deposits, such as the remnants of forest and brush fires (Figure 1a), burned materials derived from lightning strikes of trees or tree stumps, or spontaneous ignition of dung or guano. Although they are unrelated to human activity, each of these types of feature may be found in archaeological sites (Bellomo, 1993). Fire destruction layers (conflagrations) result from uncontained burning of single or multiple structures (Figure 1b), often in an urban setting (e.g., Shoval et al., 1989; Namdar et al., 2011). The ignition can be anthropogenic or non-anthropogenic, the former accidental or intentional.

Anthropogenic uncontained primary features can result from intentional ignition of combustible materials for the purposes of physical and psychological site maintenance, cleaning, or abandonment. *Fumier* (Fr.) is one type of uncontained primary feature that consists of one or more burned deposits of interbedded plant material, fodder, and dung that accumulate within animal pens and caves used as stables (Figure 1c; see also Brochier, 1996). Similar behaviors can produce burned bedding or other forms of prepared anthropogenic surfaces (Figure 1d; Goldberg et al., 2009). Finally, deposits associated with ritual closures of structures can include burned materials (e.g., Verhoeven, 2000; Rojo-Guerra et al., 2010; Van Keuren and Roos, 2013).

Contained intact combustion features (Figure 2) result from controlled burning activities in a spatially limited area. The lateral control of combustion, or containment, can be accomplished in a variety of ways ranging from simple placement of fuel to construction of architectural elements. Open hearths are the simplest forms of contained intact combustion features, consisting of unprepared or minimally prepared surfaces composed of the available substrate (Figure 2a). *Cuvettes* (from "en cuvette" Fr.) are a subtype formed on top of shallow depressions. Open hearths are constrained by the lateral distribution of fuel and may be found in association with perimeter lining of stones or banking against one or more preexisting walls.

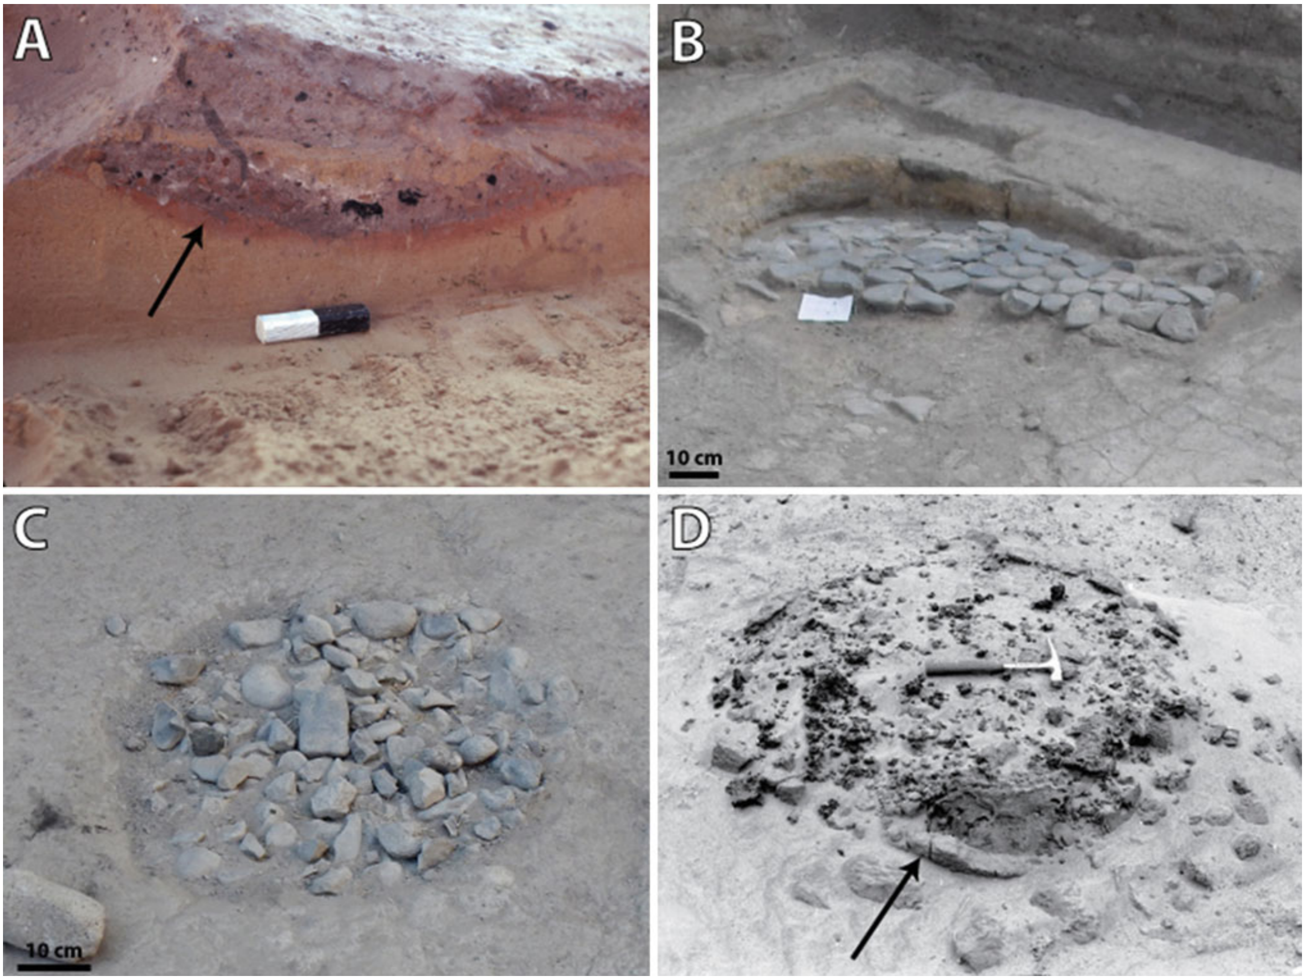
Prepared burning surfaces are a second type of contained intact combustion feature. These features exhibit anthropogenic substrates, such as nonlocal clay, pebbles, flat stones, or plaster (Figure 2b). The substrate may serve to reflect or retain heat, for example, in griddles or braziers. The substrate may also provide a visual focus for activity or serve in the broader construction of space, as in flat altars or platform hearths. A physically durable anthropogenic substrate may also aid in the reuse of the surface (Homsey and Capo, 2006), because removal of burned residues on natural substrates may over time change the morphology of the feature (Mallol et al., 2007).



Hearths and Combustion Features, Figure 1 Different types of intact uncontained combustion features: (**a**) A non-anthropogenic combustion feature formed from the complete burnout of a ponderosa pine snag during the 2002 Rodeo-Chediski Fire. The rubified sediment (*arrow*) is alluvial soil of Early to Mid-Holocene age. Mogollon Rim area of eastern Arizona, USA (Photograph credit: C. Roos in 2005). Non-anthropogenic combustion features located within archaeological sites can lead to issues of interpretation, including misattribution to human activity and misleading radiocarbon dates (Crombé et al., 2015). (**b**) Early tenth-century BCE destruction at Tel Megiddo, Israel. Section showing a burnt floor, an in situ vessel, and mudbrick collapse. Note the block of oriented sediment carved out for micromorphological analysis (*arrow*) (Courtesy of the Megiddo Expedition, Tel Aviv University). (**c**) *Fumier* layers formed during the Chalcolithic period as a result of periodic burning of layers of herbivore dung in a cave. Many of the layers have been subsequently altered by chemical diagenesis, as evidenced by the presence of phosphate minerals such as taranakite. Paltau Cave, Uzbekistan. (**d**) Burned bedding layers at the Middle Stone Age site of Sibudu, South Africa. These laterally extensive combustion features were identified using micromorphological analyses (Goldberg et al., 2009; Wadley et al., 2011).

Unlike open hearths and prepared burning surfaces, pit structures contain primary features that form when burning occurs below the ground surface (Figure 2c). In these features, the fire, or heated rocks, is contained in three dimensions using only locally available substrate and packing layers. Roasting pits, charcoal pits, earth ovens, and some types of simple kilns fall into this category.

Finally, the most complex types of contained intact combustion feature are fire installations (Figure 2d). These features consist of constructed containers located either above or below the ground surface. The containing elements may include prepared substrates and walls, a ceiling of some kind – either constructed or temporary due to the placement of a cooking pot or lid – and ventilation systems that can function actively or passively. Fire installations include fire places, constructed kilns, ovens, incinerators, and furnaces. Both pit structures and fire installations may reflect a desire on the part of their users to control the temperature, duration, or oxygenation conditions of a fire, and variations in their functional morphology have been investigated using ethnographic and experimental studies (Balkansky et al., 1997; Black and Thoms, 2014).

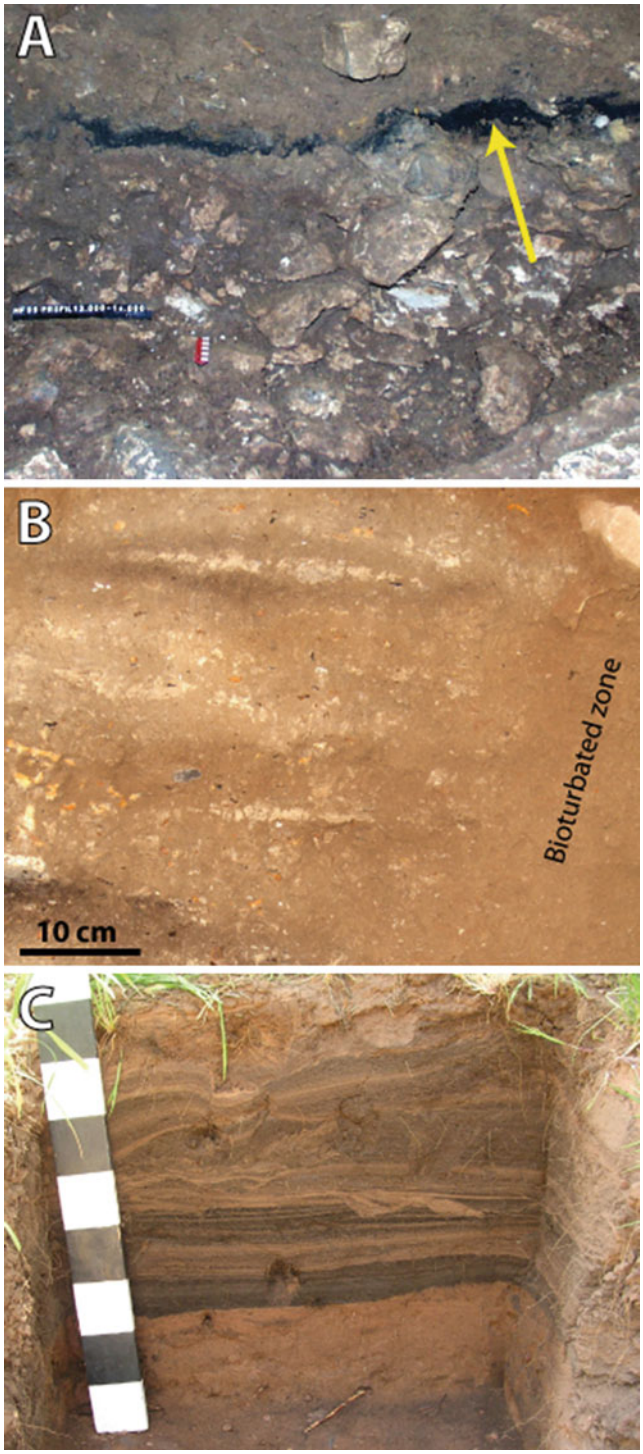


Hearths and Combustion Features, Figure 2 Different types of intact contained combustion features in archaeological sites: (**a**) An Epipaleolithic age open hearth in profile. The substrate is dune sand that has been rubified as a result of heating (*arrow*). The hearth contains visible charcoal and ashes. This stratigraphic sequence of heat-altered substrate overlain by ashes and charcoal is frequently encountered in sections of open hearths. Sinai, Israel (Photograph credit: P. Goldberg). (**b**) A prepared burning surface consisting of flat, rounded cobbles. This feature abuts against two walls of a structure. The surface of this burning surface and similar features was periodically cleaned following burning as evidenced by numerous ash and charcoal layers in middens throughout the site. Neolithic Aşıklı Höyük, Turkey. (**c**) A circular roasting pit filled with fire-cracked rocks and ashes exposed in excavation. Many roasting pits were disturbed in prehistoric times when the features were excavated in order to retrieve their contents following burning. Neolithic Aşıklı Höyük, Turkey. (**d**) A portion of a fire installation exposed by deflation. The feature is the remains of an iron smelting furnace that is filled with slag and fragments of the furnace shaft. Portions of the external walls are visible (*arrow*). The feature was intentionally broken in order to retrieve the bloom after smelting. Middle Senegal River Valley, Senegal (Photograph credit: D. Killick).

In secondary or reworked combustion features, the by-products of burning are not in their original place of combustion but are concentrated in such a way that archaeologists might still define them in the field as a feature. Reworking can result from human activity with the degree of intentionality ranging from trampling to active rake-out, fuel removal, sweeping, dumping (Figure 3a), secondary inhumation of cremations, or deliberate destruction of a feature. Reworking can also result from the feeding and nesting activities of other animals or insects. Bioturbation of burned materials physically moves components laterally or vertically and destroys the original structure and fabric of the feature (Figure 3b), while consumption of burned materials by mesofauna may chemically transform them. Finally, reworking can result from any number of surface processes such as transport by water, wind and gravity (Figure 3c), pedoturbation, and cryogenesis.

Methods

Methods for identification of combustion features and their microscopic components have been reviewed previously by Mentzer (2014). Here, the overview of



Hearths and Combustion Features, Figure 3 Reworked combustion features: (**a**) A Gravettian deposit comprising sand-sized fragments of burned bone in secondary context. The feature, which is expressed in the field as a black lens, is interpreted as a dump (Schiegl et al., 2003) (Photograph credit: M. Malina). (**b**) A sequence of partially bioturbated open hearths in the Middle Paleolithic site of Üçağızlı Cave II, Turkey. The ash layers visible on the *left side* of the photograph have been disturbed by tubular insect burrows. The sediment in between the ash layers contains general occupation debris. The sediment to the *right* is rich in burned materials, but is entirely homogenized by bioturbation. (**c**) Micro-charcoal in postfire erosion deposits that accumulated after the 1974 Day Burn in eastern Arizona, USA. The strongly laminated fabric is typical of deposition by water (Photograph credit: C. Roos).

methodological approaches is expanded to include field-based observations and techniques.

Field methods

Many combustion features and their components are first encountered visually in the field and documented using macroscale observations. Characteristics include the observation of by-products of combustion: concentrations of charcoal or charred plant material; gray, silty sediment; patches of sediment that are dark or rubified; and concentrations of other heated materials such as bone and slag. However, many researchers have noted that visual observations or identification of the by-products of combustion alone are not reliable on their own (e.g., Stahlschmidt et al., 2015). For example, it is possible to mistake humified plant tissues for charcoal under field observation conditions. Gray, silty sediment does not always derive its characteristics from the presence of calcareous ashes. Redoximorphic processes can produce patches of dark or rubified sediment, and sediment color changes with heating are highly variable (Canti and Linford, 2000). Finally, postdepositional staining can cause bone fragments to appear burned (Shahack-Gross et al., 1997). Therefore, all field-based documentation and identification of burned materials should be confirmed using laboratory analyses.

Other aspects of combustion features may also be identified visually. These include architectural elements of prepared burning surfaces and fire installations. In these cases, visual identification can be quite reliable in the field when the architectural features are distinctive (see Figure 2d). However, other types of feature can be more ambiguous. For example, simple rings of stones are not the best evidence for the former presence of a hearth, as humans produce concentrations of stones while conducting other activities.

Geoarchaeologists may conduct certain analyses while working in the field (Figure 4) directly on the combustion feature or on subsamples recovered during excavation or in profiles. Grain mount analysis (Figure 4a) is a simple petrographic method that can be used to distinguish calcareous wood ashes from other sources of gray, silty sediment at archaeological sites (see also Mentzer, 2014; Figure 2). This approach requires a portable petrographic microscope, as well as glass slides and a mounting medium. Grain mount analysis can also be used to identify or quantify other microscopic components of ashes that are indicative of fuel source, such as calcareous spherulites and phytoliths that derive from dung (Gur-Arieh et al., 2013).

On-site geochemical methods can also be used to identify specific types of burned materials. Hydrochloric acid produces carbon dioxide when exposed to calcareous minerals, some of which may be present in combustion features. The positive reaction of gray, silty sediment with hydrochloric acid can strengthen a working hypothesis that the purported combustion feature contains calcareous ashes. This approach must be used cautiously because the presence of other sources of silty calcareous materials (e.g., loess, dung spherulites) can result in a false-positive result.

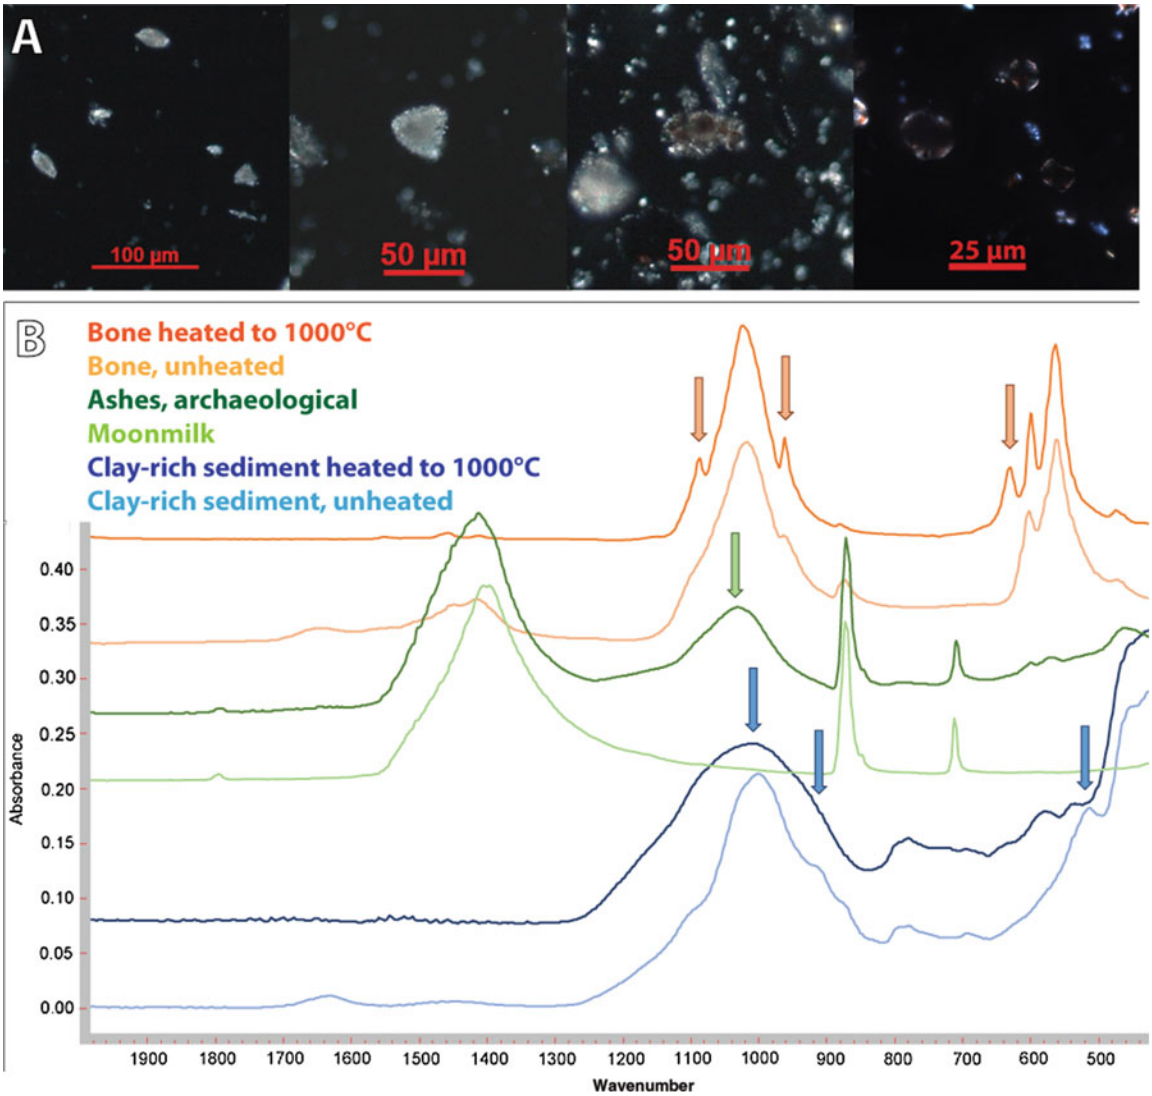
Another mineralogical method is Fourier transform infrared spectroscopy (FTIR) (Figure 4b). Analyses of loose subsamples of sediment can be conducted using a portable instrument in a field laboratory in order to study a variety of components, including calcite in suspected ashy sediment (Schiegl et al., 1996). Furthermore, the technique can be used to distinguish pyrogenic sources of calcite from geogenic and biogenic sources (Regev et al., 2010) and to identify burned bone and reconstruct burning temperatures (Thompson et al., 2013).

Certain types of magnetic methods can be conducted on site, prior to, or during excavation while others require specialized laboratory equipment (Bellomo, 1993). Magnetometry involves the use of on-site measurements of fluctuations in the local magnetic field to identify the presence of buried features that are enriched in ferromagnetic minerals and other substances. Magnetometry can also be used to identify localities where burning may have taken place or where heated materials have been redeposited and are apparent due to their acquired thermoremanent magnetism. Remnant magnetism is the measurement of the direction and strength of the local magnetic field at the last time that ferromagnetic minerals were cooled after heating within a combustion feature. This approach can be used to determine if materials were heated at any time in the past, with further parameters used for dating purposes or to reconstruct the local magnetic field (see below).

Magnetic susceptibility measurements of the abundance of magnetized grains in sediment can be conducted in the field or laboratory. Magnetic susceptibility can increase in sediments that have been exposed to heat due to the formation of ferromagnetic minerals, such as magnetite and maghemite, from weakly paramagnetic compounds that are initially present in most types of sediment (Jordanova et al., 2001). Because magnetic susceptibility can also increase due to soil-forming processes, integration with other methods or a careful study of the spatial distribution of susceptible sediments must be conducted (e.g., Herries and Fisher, 2010).

Laboratory methods

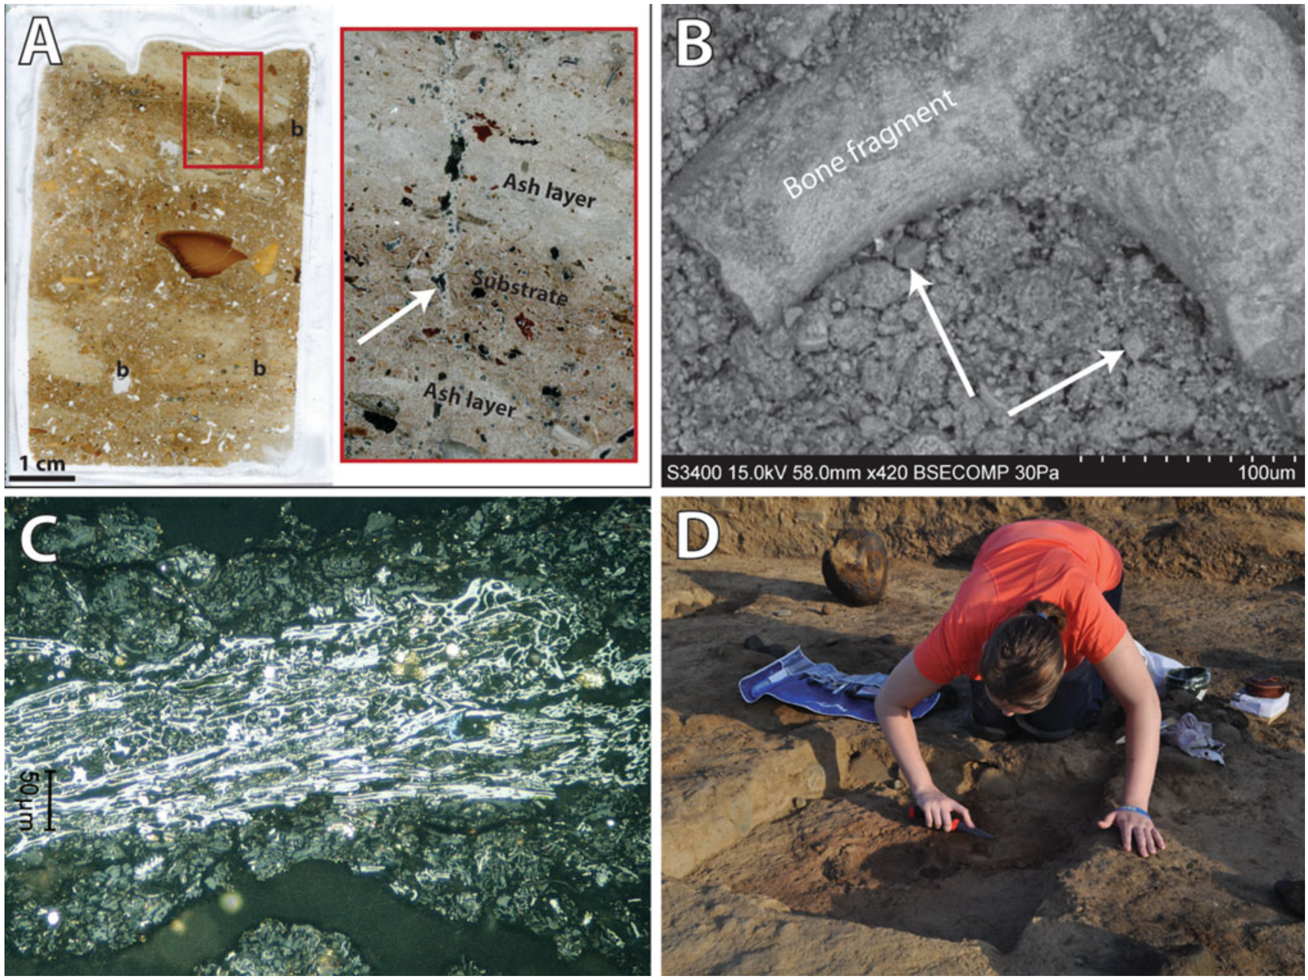
Field analyses of combustion features are typically followed by laboratory analyses of specific components (Figure 5). Micromorphology is a laboratory-based approach in which intact and oriented blocks of archaeological sediment are hardened with the aid of impregnation resin, sliced, and prepared into polished blocks and/or petrographic thin sections (Figure 5a). The prepared sections are then studied at magnification using a variety of instruments including, but not limited to, petrographic microscopes (Courty et al., 1989). This technique, which utilizes only a subsample of the larger feature, allows for the identification of anthropogenic, geogenic, and biogenic



Hearths and Combustion Features, Figure 4 Field analytical methods: (**a**) Examples of fuel residues identified using grain mounts under cross-polarized light. From *left* to *right*: experimental wood ashes produced from *Aesculus hippocastanum* (horse chestnut) burned for 4 h at 400 °C, archaeologically recovered wood ashes, experimentally heated dung spherulites burned for 1 h at 600 °C, archaeologically heated dung spherulites. Depending on available supplies, grain mounts or smear slides may be produced and analyzed quickly using glass slides and a mounting medium, with or without a cover slip. The experimental spherulite sample was prepared with Entellan new mounting medium and a cover slip. The remaining samples were prepared with paraffin lamp oil. The archaeological samples are from the combustion features in Figure 6a. (**b**) Fourier transform infrared spectroscopy-attenuated total reflectance (FTIR-ATR) spectra of typical components of combustion features compared to their unheated counterparts. The arrows indicate the positions of characteristic peaks that appear in heated materials. In the ash sample, the characteristic peak indicates the presence of silica from clay and phytoliths. These analyses can be conducted in the field using a portable spectrometer, and they can aid in the identification of fuel residues, heated materials, and feature substrates.

components using optical properties. Micromorphology is especially useful for the identification of burned materials, such as ashes (Canti, 2003; Shahack-Gross and Ayalon, 2013), bone, and shell (Villagran, 2014). The technique also facilitates description of the spatial distribution of components as well as documentation of internal structures and fabrics. These characteristics are critical for assessing whether features are primary or secondary and whether burned components have been impacted by physical and chemical taphonomic processes. In many cases, micromorphological analyses yield a wealth of information about human choices in fuel selection, construction and maintenance of the feature during its use, discard practices, and postdepositional alterations (Mentzer, 2014).

Other high-resolution laboratory analyses include scanning electron microscopy, which can yield information



Hearths and Combustion Features, Figure 5 Laboratory analytical methods: (**a**) Micromorphology is a common laboratory technique for the study of combustion features. Here, an incident light scan of a micromorphological thin section from the features illustrated in Figure 3b contains several open hearths. Insect burrows (**b**) are visible in the ash layer of a lower hearth. Two additional hearths are present at the *top* of the sample, and a higher magnification view under cross-polarized light (*inset*) reveals that the two ash layers are separated by a thin anthropogenic deposit that forms the substrate for the uppermost hearth. A crack void (*arrow*) is infilled with secondary carbonate. (**b**) Scanning electron microscopy can be used to image combustion feature components at very high magnification or measure elemental abundances. Wood ashes (*arrow*) and a sand-sized fragment of burned bone are visible in a loose sediment sample from the sacrificial ash at the altar to Zeus on Mt. Lykaion, Greece (see also Mentzer et al., 2015). This image of the particle morphology and surface topography was generated using the secondary electron detector. (**c**) Photomicrograph from an analysis of peat using organic petrology (oil immersion, reflected *white light*). The highly reflective material in the *center* of the image is fusinite in a fragment of charcoal derived from a natural fire and redeposited by wind or stream flow. The fusinite shows slight compression from compaction of the peat. The surrounding porous matrix is humified plant detritus which appears *dark gray*. Pleistocene peat level 13-II-3 from Schöningen, Germany (Photograph credit: D. Liguois). (**d**) Combustion features and their contents can be dated using a variety of methods, including radiocarbon, TL, OSL and archaeomagnetic dating. Here, a researcher collects a sample for archaeomagnetic analysis from the site of Pampas Gramalote, Peru. In this process, intact hearths are excavated to yield small, oriented blocks of sediment, which are secured inside a brass mold using clay and plaster. An azimuth is measured, and the exact location of the measurement is marked in the wet plaster. The molds prevent shifting of the sediment from its original position with respect to the measurement mark. In the laboratory, the researcher will measure the thermal remanent magnetism and calculate the magnetic declination at the time of burning. The results will be compared to a regional secular variation curve to obtain the age of the feature (Photograph credit: G. Prieto).

about the elemental composition of materials as well as morphological properties, such as observation of the presence of rhombic aggregates of microcrystalline carbonate that are characteristic of wood ashes (Figure 5b; see also Shahack-Gross and Ayalon, 2013). Organic petrology is an analytical approach that was developed for the study of coal, but that has applications in the study of combustion features. Reflectance measurements conducted on polished materials mounted in resin can be used to distinguish charcoal and charred plant material from humified plant material (Stahlschmidt et al., 2015). Similar measurements can also identify gels and fat-derived char that result from the heating of other materials (Figure 5c; also Goldberg et al., 2009).

Laboratory-based mineralogical methods include FTIR, which can be conducted on loose samples to address the same research questions as above. Additional applications of FTIR include reconstructing temperatures of heated sediment, which requires laboratory-based heating experiments using local sediment for calibration purposes (Berna et al., 2007; Forget et al., 2015). FTIR microspectroscopy entails the identification of heated materials in thin section or polished sediment block (Goldberg and Berna, 2010), and the approach combines the spatial information of a micromorphological analysis with molecular and optical identification of materials. Like FTIR, X-ray diffraction (XRD) can be used to identify calcite in purported ashes, as well as changes to the crystal structure of bone that result from heating (Rogers and Daniels, 2002).

Finally, other methods include elemental and isotopic geochemical analyses and luminescence measurements. Multielement mapping and analyses of the relative abundance of carbonates and plant-available phosphorus can be used to identify enrichments to archaeological sediments that result from burning (Wilson et al., 2008). Isotopic methods include measurements of the stable isotopes of oxygen and carbon in calcareous materials. This approach can yield ratios that are characteristic of calcareous ashes in various states of secondary cementation (Shahack-Gross et al., 2008; Shahack-Gross and Ayalon, 2013) when other properties of the materials, such as morphology, have been modified by postdepositional processes.

Luminescence methods include electron spin resonance (ESR), thermoluminescence (TL), and optically stimulated luminescence (OSL). ESR measurements can be conducted on bone and charred plant materials to determine the temperature of heating (Hillman et al., 1985; Hayes and Shurr, 2002). TL measurements can be taken on heated rocks (Richter, 2007), and OSL measurements can be conducted on rocks or quartz grains within architectural components using the quartz inclusion technique (Fleming, 1970; Murray and Mejdahl, 1999) or directly on the heated substrate (Rhodes et al., 2010). Both approaches depend upon the fact that heating empties electron traps within the target material. Following this reset, the radiation dose received over time excites additional electrons which accumulate within traps in the material and thereby provide a means to calculate the time of heating. Exploiting these techniques and applications of the radiocarbon method to charcoal and calcined bone, combustion features, and their contents can contribute to the dating of an archaeological site.

The choice of methods in the study of combustion features is determined by a number of factors, including access to on-site instrumentation, budget, ability to subsample and remove portions of the feature to a laboratory setting, and ultimate research questions. All methods are appropriate for identifying one or more by-products of combustion, but not all methods are appropriate for determining whether the features were generated by people. The strongest approaches are those that are integrative (Figure 6). The microcontextual approach (Goldberg and Berna, 2010) utilizes different types of petrographic analyses and microsampling within micromorphological sediment blocks. This approach can facilitate the direct comparison of the results of micromorphology, organic petrology, mineralogical analyses, and isotopic measurements (Figure 6a).

Approaches to the interpretation of combustion features

Geoarchaeological analyses of combustion features contribute to understanding the formation processes of features and archaeological sites. For example, a micromorphological study of a suspected hearth might reveal evidence for postdepositional processes, such as decalcification or bioturbation, that could have also impacted the preservation and distribution of other archaeological materials in the site. More importantly, geoarchaeological analyses of combustion features can provide a means to answer a wide variety of research questions about human activity in the past.

At the site scale, geoarchaeologists might ask:

- What is this feature?
- Was the burning a result of human activity?
- What types of fuels were used in domestic and nondomestic contexts?
- How were hearths, ovens, and kilns constructed with respect to other architectural elements?
- Where were wastes dumped at the site?

At larger scales, geoarchaeologists can help address questions, such as:

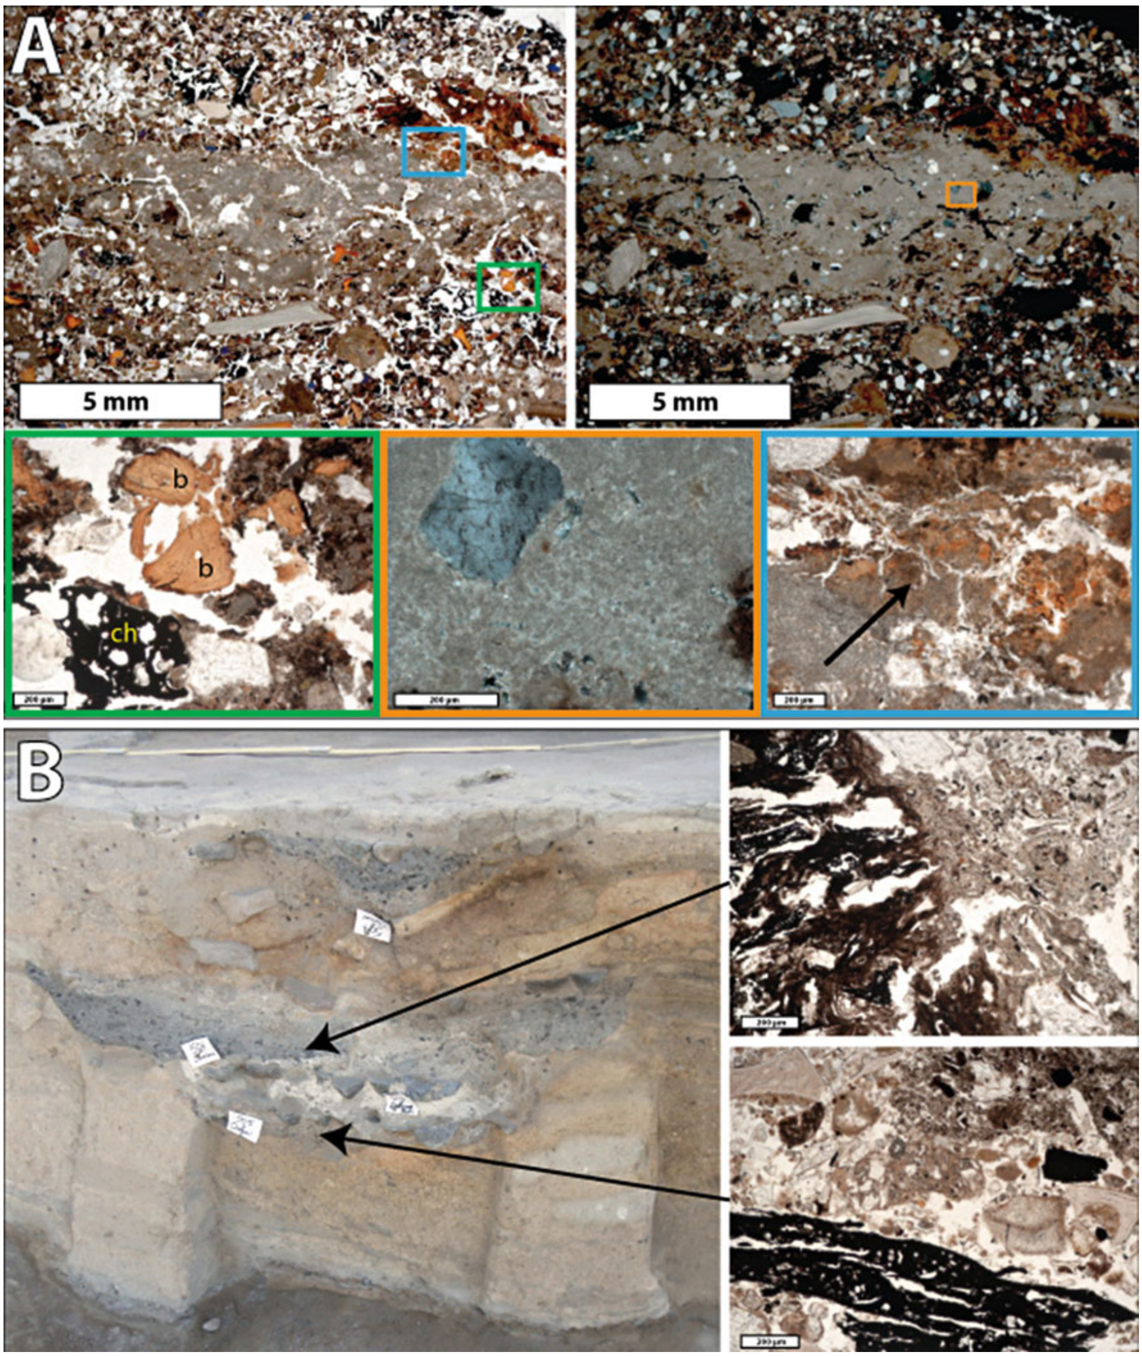
- Are there regional changes in intensity of site use?
- Did fuel availability change over time?
- How did humans use fire to manage their landscapes?
- Who had access to different types of pyrotechnology?
- Where did fire sacrifice originate and how did it spread throughout the region?

The following section provides an overview of some current research themes pertaining to fire and pyrotechnology and ways in which geoarchaeologists are contributing to their study.

Controlled use of fire

Fire use, habitual fire use, and controlled use of fire are considered by many to be key developments in hominin behavioral evolution. For example, fire use for cooking may have facilitated physical changes in hominin cognition (Wrangham et al., 1999). Fire use may have allowed hominins to colonize or exploit new environments, and some argue that regular access to fire was a trait that distinguished humans from Neanderthals (Sandgathe et al., 2011). As a first step toward testing these hypotheses, archaeologists must be able to identify definitely materials that have been burned. Furthermore, researchers such as James (1989) call for a critical evaluation of the evidence for hominin control of fire, noting that it is imperative that archaeologists distinguish between combustion features that formed as a result of hominin activity and those that may have formed from natural processes.

Most recently, Roebroeks and Villa (2011) reiterate that burned materials alone are not evidence for human agency in the presence of fire at an archaeological site. Instead, they argue that archaeologists must address the



Hearths and Combustion Features, Figure 6 (Continued) relationship between the burned materials and the broader archaeological context. In considering early evidence for fire in Europe, Roebroeks and Villa state that certain analytical methods are more reliable than others. In particular, they rank evidence for early fire at different sites using an "index of confidence" that is based on whether isolated burned materials or combustion features were identified and how the latter were studied. Sites that Roebroeks and Villa assign to the highest confidence index (i.e., a rank of 3) contain combustion features that were documented either using micromorphology or multiple geoarchaeological techniques. Applying similar criteria on a global scale, some claims for early fire at Lower Paleolithic sites such as Zhoukoudian and Swartkrans would not earn high indices. However, some cases for Lower Paleolithic fire are more robust (e.g., Gesher Benot Ya'aqov; see Alperson-Afil et al., 2007), and at the time of writing, geoarchaeologists working at Qesem Cave (Israel) have provided a convincing case for controlled and repeated use of fire in the Late Lower Paleolithic. Karkanas et al. (2007) and Shahack-Gross et al. (2014) integrate micromorphology of combustion features with isotopic and mineralogical analyses of the ashes contained therein.

Paleosurfaces versus palimpsests

Identification of combustion features can also contribute to debates regarding the distinction between so-called living floors and time-averaged accumulations of materials in archaeological sites (Dibble et al., 1997; Bailey, 2007; Malinsky-Buller et al., 2011). In sites lacking architecture, combustion features can mark the level of an ancient surface (Mentzer, 2014). Single burning events rarely last longer than days or weeks, and depending on their morphology, the resulting combustion features can provide information about the morphology and level of the ground during specific moments in time, or they may even protect underlying deposits from reworking due to human or animal activity (see Figures 1c and 3c). Geoarchaeological studies of multicomponent features, such as the stacked and reused hearth sequences at Kebara Cave or the destruction layer at Tel Dor (Berna et al., 2007), can also be used to provide information about rates of sedimentation within the site.

Organization and maintenance of space and local environment

In archaeological sites, the spatial relationship between combustion features and the physical traces of other activities can help researchers to understand the human organization of space. Geoarchaeological analyses of features can contribute to understanding whether spaces were areas of primary activity (e.g., hearths) or peripheral zones (e.g., middens) (e.g., Kebara Cave). The duration of use of these features can also yield clues to understanding social memory. Likewise, evidence for investment in the production of burning surfaces or installations can be informative about the intensity of occupation and residential permanence. In large sites, the morphology of combustion features and their locations with respect to traces of domestic and nondomestic activities can inform archaeologists about functional diversification of fire and ancient pyrotechnology.

The destructive properties of fire were harnessed by ancient people for both physical and psychological purposes. For example, the periodic burning of anthropogenic ground surface coverings (bedding) has been identified using micromorphology in sites as old as the Middle Stone Age (see Figure 1d; Goldberg et al., 2009). Wadley et al. (2011) postulate that this repeated maintenance behavior could indicate a desire by the inhabitants of the site of Sibudu to rid their domestic space of wastes and insects. In some pastoral sites, periodic burning of layers of dung and fodder was conducted on an annual or semiannual basis in order to rejuvenate stabling areas (see Figure 1c). Researchers postulate that this behavior served

Hearths and Combustion Features, Figure 6 Integrative methods in the study of combustion features: (**a**) The micro-contextual approach uses the micromorphological sample as the main unit of analysis (Goldberg and Berna, 2010). Geochemical analyses are conducted directly on the thin section, on the resin-impregnated sediment block, or on sediment drilled from the resin-impregnated block. In the open hearth pictured here (*right*, under plane polarized light; *left*, under cross-polarized light), three areas (***colored boxes***) will be targeted for geochemical analysis. First, organic petrology and micro-FTIR analyses will be conducted on the char (ch) and bone fragments (**b**) in order to identify their source and burning temperature (see Goldberg et al., 2009; Thompson et al., 2013). Second, isotopic analyses will be conducted on micro-drilled powders of the microcrystalline carbonate in order to confirm the petrographic identification of cemented ashes (see Shahack-Gross et al., 2008; Mentzer and Quade, 2013; Shahack-Gross and Ayalon, 2013). Finally, micro-FTIR analyses will be conducted on the *yellow* upper surface of the ash layer (*arrow*) to identify the presence of secondary phosphate minerals and reconstruct the postdepositional chemical alteration of the feature (see Schiegl et al., 1996). Klasies River Mouth, South Africa. (**b**) Radiocarbon dating may be coupled with micromorphological analyses of combustion features in order to provide context for the samples to be dated (see Toffolo et al., 2012). A sequence of up to eight combustion features are visible in the profile on the *left*. Their field identifications are based on the presence of visible charcoal fragments and sediment that appears ashy. Several of the features have prepared burning surfaces, while others are *en cuvette*. Two radiocarbon samples are matched with micromorphological analyses (*arrows*). The context for the upper sample is more secure. The fuel can be identified as dung, which is composed of short-lived plant parts, and the structure of the sample reveals little postdepositional disturbance. In contrast, the lower sample contains charcoal in a matrix of other anthropogenic materials, which raises the possibility that the burned materials could be in secondary context. Aşıklı Höyük, Turkey.

to reduce the volume of sediment in constrained spaces (e.g., caves) and also minimized insect populations. Redeposited ashes may have also served similar purposes, with their alkaline properties contributing to pest management or their symbolic purity serving to rejuvenate a space (Hakbijl, 2002). Destruction layers and ritual closure may likewise evidence the use of fire as a tool of psychological destruction. Finally, beyond the scale of the archaeological site, fire was used as a tool for managing landscapes (Conedera et al., 2009; Bowman et al., 2011). Geoarchaeological analyses of modern and experimental forest fire residues are currently contributing to the understanding of ancient land use practices (Rösch et al., 2002; Eckmeier et al., 2007; Roos, 2008).

Other uses of combustion features

Combustion features in archaeological sites possess significance beyond their relationships to past human activities, as they provide materials that are suitable for dating and paleoenvironmental reconstruction.

In sites that are younger than ~45,000 years, radiocarbon measurements can be conducted on charcoal and charred plant material. Less commonly, calcined bone fragments (Lanting et al., 2001) and ashes may also be dated, but their apparent ages relative to the burning event are complicated by the temperature of combustion as well as postdepositional processes (Regev et al., 2011). In radiocarbon dating, integrative approaches are increasingly being favored, such that sampling localities are documented at high-resolution and assessed for evidence of reworking or other taphonomic factors (Figure 6b; Toffolo et al., 2012). Combustion features can also provide materials suitable for dating using luminescence methods: either TL on heated rock (Richter, 2007) or OSL measurements on heated substrates or mineral inclusions within architectural features (Fleming, 1970; Rhodes et al., 2010). Finally, measurements of thermoremanent magnetism, or archaeomagnetic dating, can be used in conjunction with reconstructions of past magnetic fields to date the most recent burning event within a combustion feature (Figure 5d) (Eighmy and Sternberg, 1990). Sampling prioritizes portions of the feature associated with the substrate, such as rocks used in linings or as paving, or the floors of installations. In these cases, geoarchaeological techniques can be used to establish that heated materials have not moved since the last firing. Conversely, the fuels inside combustion features may be dated using radiometric methods, and measurements of thermal remnant magnetism conducted on the substrates may be used to identify and date fluctuations in the local magnetic field. Kapper et al. (2014) stress that these types of studies together with micromorphology can aid in identifying appropriate samples.

Combustion features can also provide materials that are useful for paleoenvironmental reconstruction. Botanical analysis of charcoal and other types of charred plant materials in combustion features can be identified as to plant part and sometimes to genus or species. Phytolith analyses may be conducted on the siliceous portion of plant ashes (see Figure 6b; also Albert et al., 2012). If geoarchaeological analyses support the interpretation that combustion features were produced by human activity, botanical and phytolith analyses can be used to reconstruct fuel choices in the past. Although fuel choice may be motivated by desired properties of the fire (Théry-Parisot, 2002), it can also reflect availability of plants in the local environment (Asouti and Austin, 2005).

Conclusions

As outlined above, geoarchaeological analyses are becoming essential tools for the identification and interpretation of combustion features in archaeological sites of all ages. This growing area of focus encourages integrative approaches, wherein geoarchaeologists employ a variety of field- and laboratory-based methods to identify the traces and composition of burned materials, as well as understand their relationship to past human activities. Combustion feature research can be conducted at many scales: from micromorphological analyses of individual burning events to landscape-scale records of forest clearance. Furthermore, in studying combustion features, geoarchaeologists are actively engaged in the research and interpretation of sediments as artifacts, an approach which requires us ultimately to ask and answer anthropological – as opposed to geological – questions.

HOHLE FELS

Christopher E. Miller
Geoarchaeology, Institute for Archaeological Sciences, Senckenberg Centre for Human Evolution and Paleoenvironment, University of Tübingen, Tübingen, Germany

Hohle Fels is a Paleolithic cave site located in the Swabian Jura region of southwestern Germany. It is well known for containing a cultural sequence spanning the Middle to Upper Paleolithic transition and for its evidence of Aurignacian portable art and musical instruments.

Hohle Fels, together with other well-known sites such as Geißenklösterle, Sirgenstein, and Brillenhöhle, is located in the Ach Valley, a tributary of the Danube River. The steeply sided valley was carved out by the Danube before avulsing into its modern drainage prior to the Riss glaciation. Hohle Fels and the other cave sites in the valley are remnant phreatic tubes formed within the Jurassic limestone of the region.

Bear teeth and reindeer bones were first collected in the cave in the 1830s, and the site was extensively excavated for its guano deposits in the 1840s. O. Fraas and T. Hartmann conducted the first scientific excavations at Hohle Fels in 1870–1871. R. R. Schmidt excavated there in 1906, and G. Riek and G. Matschak excavated in the cave between 1958 and 1960. During fieldwork at Geißenklösterle, J. Hahn conducted limited excavations at the site (1977–1979), returning in 1988 for more extensive investigations. Excavations at Hohle Fels are ongoing under the direction of N. J. Conard.

The site contains a cultural sequence spanning the Middle Paleolithic, Aurignacian, Gravettian, and Magdalenian. The Aurignacian at Hohle Fels, along with nearby Geißenklösterle, is famous for its figurative art, carved out of mammoth ivory and depicting a wide variety of animals (Conard, 2003). The site also contains one of the earliest representations of the human female form: the so-called Venus of Hohle Fels (Conard, 2009). In addition to figurative art, Hohle Fels and Geißenklösterle contain the remains of several bird-bone flutes.

Depositional processes at the site are complex and have been the subject of micromorphological study (Goldberg et al., 2003). The cave has a front entrance and a chimney in the back, both of which served as entry points for sediment. Loess, which accumulated on the plateau backing the cave, was washed into the chimney, forming a large sediment cone in the rear of the cave. Here, the calcareous loess was phosphatized in the presence of bat guano. The material moved downslope through colluvial processes and mixed with fresh loess which entered the cave through the front entrance. Following final deposition, the sediments were influenced by freeze-thaw processes, forming lenticular microstructures and rounded, cryoturbated coated aggregates.

Humans acted as significant depositional agents during the Upper Paleolithic occupations of Hohle Fels, as evidenced by the preservation of extensive combustion features. Notably, layer 3cf, dating to the Gravettian, extended across the entire area of excavation and was 5–15 cm thick. It was largely composed of sand-sized fragments of burnt and unburnt bone. Micromorphological analysis of this layer suggested that it formed when people, who were using bone as a fuel, cleaned their hearths and dumped the remains within the cave (Schiegl et al., 2003).

HOUSE PITS AND GRUBENHÄUSER

Richard I. Macphail
Institute of Archaeology, University College London, London, UK

Synonyms

Grophus (Swedish); Grubenhaus; Grubenhäuser (plural German); Le Cabane en Fosse (Swiss-French); Le fond de cabane (French); Pit house; Sunken feature building ("SFB"; UK term for undifferentiated pit house structures) (West, 1985, 14).

Definition

House pits (pit houses) and grubenhäuser are sunken feature buildings (SFB) where activities took place either (1) in the pit itself (in theory forming occupation floor deposits in the house pit) or (2) on an overlying planked surface laid atop the pit, which then functioned as an air space, or crawl space, in which case the archaeological remains would be mainly characterized as postdepositional fills (Tipper, 2004).

Introduction

House pits and grubenhäuser occur in a number of ancient cultures worldwide, but they were constructed and functioned differently within each culture. Some pit houses are clearly pit houses sensu stricto, with the base of the pit house acting as a floor surface, including a ramp or step-down (e.g., West Coast Native American, First Nation Canadians, and late prehistoric groups of Southwestern United States and northwestern Mexico, Jomon Period Japan, and Bronze Age Korea). In contrast, mainly during the Migration Period in Europe (~AD 400–800), the pit part of the structure was simply a wooden-supported, planked-over air space, and activities took place on this wooden floor (Gustavs, 1998; Tipper, 2004, 160 ff.). This is typical of France, Germany, England, and Scania (South Sweden), for example, although in Bulgaria, Poland, and Ukraine, "Slav" pit houses included a hearth in one corner and functioned as a pit house sensu stricto; some Swedish examples may also date to the Early Bronze Age (Kobylínski, 1989; Tesch, 1992; Tipper, 2004, 3; Henning, 2011, "personal communication"). Some twenty SFBs of Roman age (second century AD) are about 9 × 4.8 m in size and cut into chalk at Monkton, Isle of Thanet, Kent, UK, but though they can have stepped entrances, there were no occupation floor deposits; it is believed that a plank floor had been laid on the rammed chalk "floor" (Bennett, 1997). The exact origin of these structure types remains enigmatic, and they are so far unique in the UK. A further complication is that while pit houses in early and middle Saxon England functioned with an air space, Late Saxon (~AD 800–1050) pit houses could have a below-floor cellar and are therefore called cellared buildings. This is why the UK generic term "SFB" is often employed for such structures. Specialized subterranean features such as the "Kiva" of the Southwestern United States, crypts, and Mithraic temples of Roman Europe (e.g., Rentzel, 2011) may also have some aspects in common with pit house use and hypothetical trampled floor development.

In the Southwestern United States and northwestern Mexico, three types of habitations with some subterranean component were important constructions of the Early Agricultural period (AD 200–900) (Cordell and McBrinn, 2012, 158–161): (1) simple circular or oval structures built over shallow depressions, (2) houses-in-pits (where the pit floor extended out past the walls of the structure), and (3) true pit houses (where the walls of the structure incorporated the sites of the pit). The distinction between the latter two forms may be important because "domestic architecture is a conservative and functional technology, and the method of construction may be indicative of socialization and identity" (Herr and Young, 2012, 8). Little in the way of specific geoarchaeological data is available for these otherwise well-known structures of the North American archaeological record.

Sediment studies have been carried out mainly on pit houses in North America and on grubenhäuser across Europe (Simpson et al., 1999; Goldberg, 2000; Macphail et al., 2006). Some naturally formed subsoil features may contain artifacts but are not necessarily constructed dwellings sites (Newell, 1980), and thin sections have been employed to differentiate tree-throw subsoil hollows and pit features in general from pit houses sensu stricto (Macphail et al., 2008).

Occupation floor deposits and weathering in subterranean structures

In theory, the basal deposits of pit houses should record occupation activities and human traffic. As analogues, well-preserved microlaminated occupation floor deposits have been found that recorded floor constructions and supposed human traffic. One example is at a crypt in Guildford, UK, where heavy trampling bought in large amounts of fine-burned hearth and kitchen waste debris over a series of chalk floors (Figure 1). A second example is at the Biesheim Mithraeum, Alsace, France; here, only small traces of trampled-in anthropogenic material were recorded between mortar floor renewal layers, possibly because of the highly ritualized nature of the occupation (Rentzel, 2011). In Southwestern United States, mineralogical study of pit house floors using backscatter electron microscopy yielded evidence of increased weathering of

House Pits and Grubenhäuser, Figure 1 Guildford, UK; scan of thin section of medieval church crypt floor constructed of rammed chalk containing frequent coarse sand and fine gravel. Note layered beaten floor accumulation bringing in burned kitchen waste, rich in wood charcoal and burned bone, indicative of in situ trampling. Frame width is ~65 mm.

the house floor compared to the land surface around the habitation (Pope and Rubenstein, 1999). This was taken as evidence that more focused human habitation produced more intense weathering. It always has to be remembered, however, that any form of subsoil hollow will be more influenced by drainage effects compared to the surrounding soils (Veneman et al., 1984).

Hunter and gatherer house pit sites

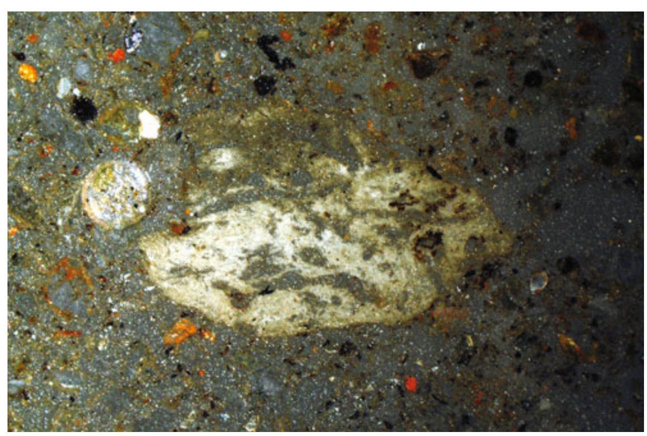
In contrast to these subterranean examples, pit house occupation deposits are less commonly well preserved because of a series of postdepositional processes active in earth and wood-based constructions. The hunters and gatherers of the First Nation Canadians settlement site at Keatley Creek (British Columbia, Canada), for example, has been under investigation since 1996 (e.g., Goldberg, 2000; Hayden, 2004; Villeneuve, 2009, "personal communication"). The first major house pits appear to have been constructed beginning at about 4800 BP, but the major period of occupation was during the Plateau (2400–1200 BP) and the early Kamloops (1200–1000 BP) horizons. The largest pit houses are 18–21 m in diameter (Figure 2), and pit houses have apparently homogeneous soil fills. Soil micromorphology studies by Goldberg (2000, and unpublished reports) and Macphail (unpublished reports) found that several processes often make it difficult to reconstruct these sites:

- Scavenging and digging (coprolitic traces) of canids and other essentially carnivorous animals (Figure 3)
- Structural collapse (pit sides and roof infills)
- Burrowing by insects (e.g., cicadas)
- Tree rooting and acid soil leaching

Floor layers have often been mixed, and ashes have commonly been dissolved by soil acidity. Nevertheless, studies of pit house floor layers, pit house rim deposits, pit fills, and plaza areas have yielded burned bone (including calcined bone), fish bone, charcoal evidence of hearths and kitchen waste, and phytolith concentrations representing possible grass roof or matting material. One exceptional floor sample was examined in 2009 (Goldberg, unpublished report). It comprised three floor sequences, where each sequence commenced at its base with a layer of moderately sorted silty sand (e.g., 1 and 2) or sand (e.g., 3), overlain by a finer layer of silty clay, commonly with remains of reddish brown organic material (matting?), and lastly, a layer of calcareous plaster (micrite, or microcrystalline calcite).

Finally, it can be noted that even the study of a Neolithic (2000–2500 BC) sunken long house site at Bjästamon, Ångermanland, North Central Sweden, employing ten thin sections, failed to identify intact floors, again because of intensive postdepositional bioworking under boreal coniferous woodland, with acid leaching and weak podzolization also occurring. Instead, the remains of Neolithic combustion zone (hearths) and midden waste occur as several concentrations of rare coarse (maximum 2.5 mm) and many fine charcoal fragments, burned mineral grains, rare coprolitic?/scat remains composed of very fine leached bone (upwards of 17 fragments, maximum 1.2 mm), and rare burned bone. These occur alongside trace amounts of possible burned shell (1–4 fragments up to 680 μm); this site would have been on the coast 4,000–4,500 years ago – it was affected by postglacial uplift. One coprolitic fragment included cereal material. These are useful traces that testify to the presence of kitchen waste and probably

House Pits and Grubenhäuser, Figure 2 Keatley Creek, British Columbia, Canada; field photo of First Nation Canadian multiperiod (~4800–1200 BP) pit house settlement; "footprint" of large pit house in foreground (Paul Goldberg as scale); numerous other pit houses can be seen in the background.



House Pits and Grubenhäuser, Figure 3 Keatley Creek, British Columbia, Canada; photomicrograph of thin section 07-2a, typically loose and bioworked pit house fill, here with whitish (canid?) coprolite fragments, and scattered fine charcoal. Fills were typically scavenged and dug up, then worked by mesofauna, intermediate soil organisms that feed on microorganisms and decaying materials. Oblique incident light (*OIL*), frame width is 2.38 mm.

the penecontemporaneous working of the deposits by scavenging canids (?), a situation clearly resembling that of Canadian pit houses. Another Swedish example is a late Mesolithic-Early Neolithic pit house at Vuollerim, Norrbotten, North Sweden, which has phosphate concentrations associated with bone debris concentrations (Linderholm, 2010).

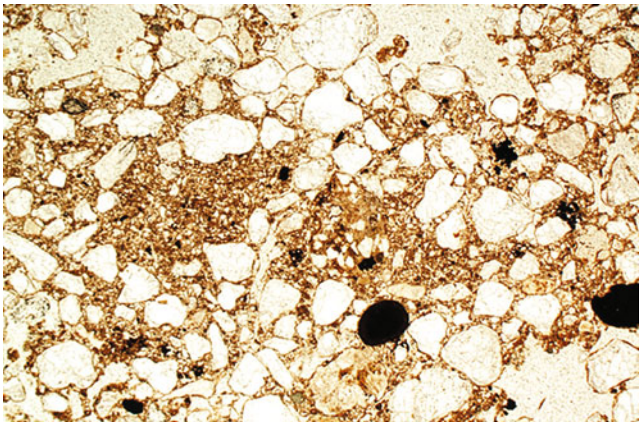
Grubenhäuser

Reviews and fieldwork show that when excavated, grubenhäuser can reveal subrectangular pits 4–6 m in length with depths of between 0.30 and 1.00 m. They may or may not have post holes, with some having 2 post holes, others 4–6 (Tipper, 2001, 2004; Macphail et al., 2006; Thomas, 2010) (see Figure 7). Sometimes, loom weights are found within their fills (see below), and this had led to the view that the grubenhäuser were weaving sheds. Their small size, however, generally makes this common interpretation debatable, except of course for the very long and large grubenhaus at the palace of Tilleda, Saxony-Anhalt, Germany, which is clearly reconstructed as a "weaving shed" (Grimm, 1968). Tipper (2004, 33ff.) reviewed grubenhäuser from Europe, including the major Anglo-Saxon sites of England in Mucking, Essex, West Stow, Suffolk, and West Heslerton, North Yorkshire, where 53, 69, and 90 grubenhäuser, respectively, have been excavated. In broad terms, these have either bipartite or tripartite fills (i.e., 2–3 layers), but none of these seemed to contain records suggesting use of the pit itself; they were deemed dominantly (post-abandonment) tertiary fills, rather than use or constructional fills. It should be noted that when settlements are excavated, these SFBs occur alongside larger and longer post-built halls, clearly indicating that pit houses were not the main dwelling structure.

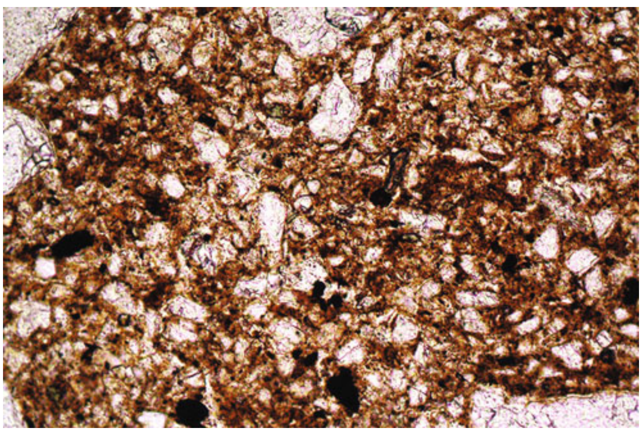
Fills can, however, include constructional residues, including extremely rare remains of planking – wood stains at Dahme-Spreewald, Germany (Gustavs, 1998); ferruginized wood at Lyminge, Kent (Macphail, 2011); burned planks from a suspended plank floor in SFB 15 at West Stow (West, 1985); and more commonly, turf fragments (possibly from load-bearing low walls). Chalky cob and chalky mortar have also been observed. Turf fragments provide useful proxy information on the local environment. In addition, ash and charcoal were found in the pit of a modern grubenhaus, built then razed at the reconstructed Anglo-Saxon village of West Stow, Suffolk, UK; this mixed burned debris occurs over the lowermost fill, which is composed of soil that had fallen down between the planks of the suspended plank floor (French and Milek, 2012).

Trampled pit "floor" deposits have never been observed in the very numerous UK grubenhäuser that have been studied. On the other hand, some lowermost fills may contain clues to function, and the presence of phytoliths and small amounts of cereal material have suggested a plausible grain store use. A storage function is the most favored interpretation by Tipper (2004, 185) because of the pit air space and benefits of airflow through a suspended plank floor. Most fills have been homogenized by biological activity attracted to the fills, but one Cambridgeshire example (Durnford Farm, Sawston, UK) had intact laminated use fills (Macphail and Crowther, 2011) (Figures 4, 5, and 6). This material, which presumably "silted" down through the spaces between the planks (see West Stow above), is composed of moderately poorly preserved alternating sands and silts, the latter particularly including humified fine organic matter and some fine charcoal. These laminae, however, simply record tracking-in of local decalcified topsoil, from a landscape probably managed by fire (perhaps pasture), with this grubenhaus likely being constructed at a "greenfield" site or at the edge of a settlement. Another rare case of preserved plank floor deposits was found at Lyminge, Kent (Thomas, 2010) (Figures 7, 8, and 9). Here, an AD 580/600–640/660 grubenhaus (SFB 1) was found with a 6 kg iron plow coulter at the bottom of the fill. This grubenhaus was 4.70 m by 3.60 m and 0.50 m deep, and it is present alongside 2 others in addition to a 12.8 × 4.6 m post-built hall. In SFB 1, iron salts from the coulter apparently ferruginized plank floor remains and sealed small amounts of occupation soil between it and the chalk substrate into which the grubenhaus pit had been cut. One 30 mm thick example showed that the chalky soil fill includes fine charcoal, an example of coprolitic waste, and amorphous organic

House Pits and Grubenhäuser, Figure 4 Sawston (Durnford Farm), Cambridgeshire, UK; field photo of Middle Saxon (~600–800 AD; SFB 2047) grubenhaus fill; sampling of primary fills from the balk, including rare discontinuous use secondary fills from occupation soil apparently falling through putative plank floor (*arrows*; fruit juice carton sample, Context 2049) (see Figures 5 and 6), and above that more obvious dark tertiary fill (sampled with Kubiena box M2, Context 2048) albeit with only 1.19 % LOI (loss on ignition), 1.55 mg g^{-1} P, and 2.35 % $\chi_{conv.}$, recording small amounts of anthropogenic inputs (burned mineral material, charcoal, ash, coprolitic material, etc.).



House Pits and Grubenhäuser, Figure 5 Sawston, Cambridgeshire, UK; photomicrograph of Context 2049, showing laminated sands and humic silts, of hypothetical plank floor silting origin, and recording actual use of the grubenhaus rather than tertiary infilling. Plane polarized light, frame width is ~4.62 mm.

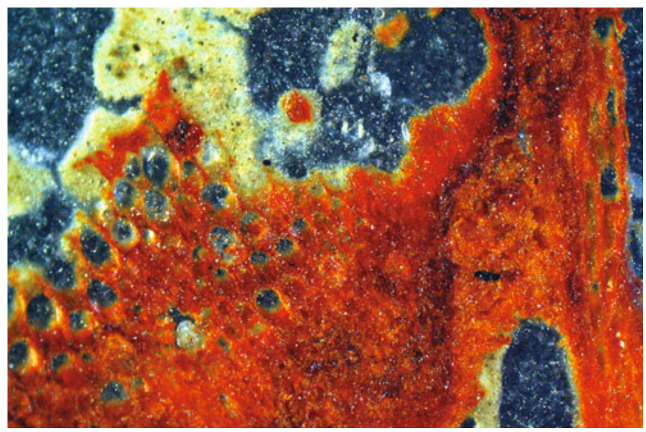


House Pits and Grubenhäuser, Figure 6 Sawston, Cambridgeshire, UK; photomicrograph of Context 2049, detail of humic silts, which include amorphous organic matter of possible dung origin (max 1.19 mg g^{-1} P); these silts suggest occupation of a rural soil environment that included animal management. Plane polarized light, frame width is ~0.90 mm.

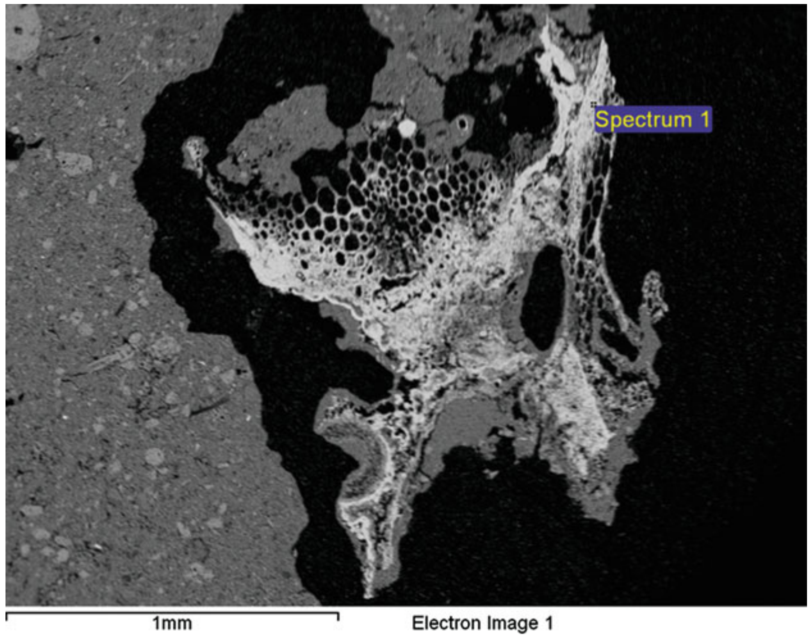
matter, which with the presence of fungal material may perhaps suggest a dung origin. This may record occupation silting through gaps in the putative plank floor. Probable earthworm burrows seem to include the "fossilized" remains of ferruginized and phosphate-enriched organic matter, again perhaps of dung origin – dung having been worked by these invertebrates. Like many SFBs, a rural settlement including animal management is not unexpected (after disuse or abandonment, chalky soil washed into this occupation fill.)

In fact, the fills of grubenhäuser often reflect the local environment of the settlement in which they were situated. For example, soil fragments from the cut of the pit provide soil data. It has been found in England and Scania (Sweden), for example, that fills occur as either of two contrasting types. These are essentially (1) archaeologically sterile fills reflecting the local (original) "greenfield" environment, with no relative phosphate enrichment and magnetic susceptibility

House Pits and Grubenhäuser, Figure 7 Lyminge, Kent, UK; field photo of typical Saxon grubenhaus (~560–660 AD; SFB 1), showing a pair of primary posts located on a longitudinal axis of the pit, both of which had been replaced during the lifetime of the structure, together with an additional six posts located at the corners and the midpoint of each of the longitudinal sides of the pit (photo courtesy of G. Thomas, University of Reading, UK). The iron plow coulter was found in a basal fill of the pit, some 30 mm above the chalk substrate exposed in the photo.



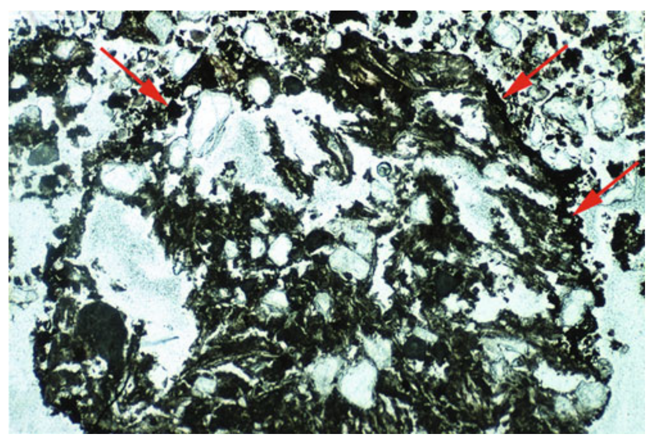
House Pits and Grubenhäuser, Figure 8 Lyminge, Kent, UK; photomicrograph of 1 mm thick iron pan formed under the iron plow coulter found in SFB 1. Here iron salts have pseudomorphically preserved wood comprising cells showing two lines of orientation, interpreted as knotwood that was relatively resistant to decay (see Figure 9). This is probably relict of a putative plank floor upon which the coulter was placed. Oblique incident light (OIL), frame width is ~0.90 mm.



House Pits and Grubenhäuser, Figure 9 Lyminge, Kent, UK; EDS (energy dispersive spectrometry) X-ray backscatter image of knotwood showing bright reflectance of iron impregnation (mean 65.6 % Fe). Mean 2.40 % P indicates that phosphate in the pit has also been concentrated into this iron pan-preserved wood. Spectrum 1 measured an example of this FeP concentration. Scale is 1 mm.

(MS) enhancement, or (2) fills that are strongly anthropogenic in character with clear phosphate enrichment and MS enhancement (data from 22 grubenhäuser; Macphail et al., 2006). The latter is a typical tertiary fill with dog and human coprolites, cess staining, and weakly to strongly burned microartifacts (e.g., bone, daub). It indicates local middening and accumulation of settlement waste ("cultural soils"). Dumped cess was also recorded in the Swiss Jura (Guélat and Federici-Schenardi, 1999), while in poorly draining sites, vivianite originating from secondary phosphate concentration occurs (Tempsford, Bedfordshire, UK). Unfired "clay" loom weights (e.g., composed of local silty clays on sandy soil sites) are often found, because they are preferentially preserved in these pit house fills. Dung residues also occur, e.g., probably from cattle in Scania and southern England and from sheep at West Heslerton (on edge of North Yorkshire Wolds; Figure 10); along with cereal processing waste, they testify to mixed farming activity.

Grubenhäuser can also include Late Saxon cellared buildings in England. One AD 875–1000 example at Whitefriars, Canterbury, UK, has an in situ pit floor lining/mud-plastered brick earth floor (brick earth = a Pleistocene loess-rich alluvium that was commonly employed to make bricks from Tudor times onwards). This has been subsequently partially mixed with much fine charcoal, rubefied mineral grains, and phytoliths,



House Pits and Grubenhäuser, Figure 10 West Heslerton, North Yorkshire, Yorkshire (chalk) Wolds, UK; Middle Saxon (~600–800 AD) grubenhaus fill (sample 140); secondary fill includes partially ashed ovi-caprid dung pellet associated with major sheep husbandry recorded at the settlement. Burned debris recording final fills of the grubenhäuser at West Heslerton includes "red ash," here as opaque material coating the burned dung pellet (*arrows*). Microprobe found: ashed dung pellet (e.g., 31.9 % Ca, 0.43 % Fe, 0.19 % P, 0.12 % S, 0.24 % K, 0.23 % Mn); anomalously iron-rich "red ash" (e.g., 0.62 % Ca, 11.7 % Fe, 0.23 % P, 0.04 % S, 0.0 % K, 0.84 % Mn); chalk (e.g., 27.5–38.7 % Ca). Plane polarized light, frame width is ~5.5 mm.

including articulated phytoliths. The site has been interpreted as the razed remains of a cereal processing/cereal storehouse (Macphail and Crowther, 2007). No trampled pit house floor was recognized, however. In contrast, the pit house fill of a ninth century AD cellared SFB at Place Street, Norwich, UK, recorded a 2 cm thick phosphate-enriched beaten floor over basal leveling deposits, testifying to use of this cellar (Macphail and Crowther, 2009). The structure burned down, and debris in the fill included chalk lime-rendered burned planks. In addition, burned thatch residues of siliceous slag also occur. These ashed and charred straw remains include vesicles relict of natural plant pores within the straw. Another example of structures with subsoil pit features is the Belgium Roman to medieval "postal" (Flemish/Dutch). For example, at Brecht Zoegweg in Belgium, locally collected turves were used to line the sunken animal byre, and they became enriched in urine and excrements of the stabled animals kept overnight or over winter (Mikkelsen et al., 2003). This fill material is then employed to manure fields, creating plaggen soils.

Summary

Pit house and grubenhäuser structures are described from the New and Old World. Pit house fills from Canada and Sweden were generally found to be very strongly worked by scavenging animals, soil mesofauna, and plant roots, while anthropogenic materials are highly dispersed. No intact pit floor trampled deposits were identified because of this postdepositional working; special sub-ground structures such as a Mithraic temple, however, had recorded floor trampling. Most European grubenhäuser of the Migration Period apparently had a suspended plank floor over the pit (apart from Slav pit houses). Most pit fills are of tertiary origin. Rare examples of sediments resulting from grubenhäuser use are provided.

INDUCTIVELY COUPLED PLASMA-MASS SPECTROMETRY (ICP-MS)

Hector Neff
Department of Anthropology and IIRMES, California State University Long Beach, Long Beach, CA, USA

Synonyms

Inductively coupled plasma mass spectrometry

Definition

A technique used for characterizing archaeological artifacts and sediments in terms of both elemental concentrations and isotope ratios.

Introduction

ICP-MS stands for inductively coupled plasma mass spectrometry. It is an analytical-chemistry technique that can measure even tiny (subpart per million) concentrations of most elements of the periodic table. In archaeology and geoarchaeology, elemental characterization by ICP-MS or other techniques is most commonly used for determining the sources of artifact raw materials. Other applications of elemental characterization include reconstructing technology and identifying and mapping activity areas on occupation floors. Some ICP-MS instruments can determine isotopic ratios with sufficient precision to be useful in human-population movement studies and uranium-thorium dating.

ICP-MS instruments

As indicated by its acronym, ICP-MS is a compound technique, consisting of an inductively coupled plasma connected to a mass spectrometer. Essentially, a sample is ionized initially within the plasma, and then the ions are separated and counted by the spectrometer. Plasma is a state of matter having no defining shape like a gas but consisting of atoms together with positively charged ions and free electrons. Its level of ionization allows it to respond to magnetic fields and conduct electricity. In ICP, an argon plasma is produced by seeding argon gas flowing through a quartz tube with electrons, which are accelerated with a radio-frequency generator. Collisions of some of the electrons with argon atoms yield more electrons, lost from argon atoms, and these electrons are themselves accelerated and then may collide with additional argon atoms, thus sustaining the plasma as long as the RF field is applied. The loss of electrons and their cyclical rejoining of other argon atoms in need of an electron repeat many times per second and generate extraordinary heat. Inductively coupled plasmas were first applied to atomic emission spectroscopy (AES) (Greenfield et al., 1964), the plasma being used to excite atoms in an injected sample, which then gave off light of characteristic wavelengths upon de-excitation. Not long after the advent of ICP-AES, it was recognized that argon plasmas, which produce temperatures in the 8,000–12,000° K range at their cores, are also excellent sources of positively charged ions. Once ionized, an atom can be identified as mass-to-charge ratio (m/e) by mass-spectrometric techniques.

In ICP-MS instruments, the ICP torch (which controls the flow of plasma) is oriented horizontally, and the stream of ions emerging from the torch is passed through an interface into a high vacuum environment conducive to measurement of mass-to-charge ratio. The interface usually consists of two nickel cones with small openings that allow passage of the ion beam from the torch while still maintaining a vacuum inside the mass spectrometer. Once under vacuum, ion optics focus the ion beam and remove stray photons and neutral species.

Measurement of ionic masses is usually accomplished by a device that filters the ion beam so that only particles

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

with specific mass-to-charge ratio pass through and hit the ion detector. By far the most common mass filters are quadrupoles, which consist of four metal rods to which radio frequency and direct current voltages are applied. The specific settings of the RF and DC voltages determine which *m*/*e* ratios are “resonant,” meaning that they will pass down the central channel of the quadrupole and interact with the ion detector. By varying the voltages on the quadrupole, signal intensities for the masses of interest can be measured. The voltages can be changed extremely rapidly, such that the entire mass spectrum can be scanned in seconds.

Specific *m*/*e* particles can also be selectively measured with what are called magnetic sector ICP-MS instruments. In these instruments, the ion beam is directed into electrostatic and magnetic fields, which bend the beam as it travels toward the ion detector. The trajectories of heavier particles will be less affected by the fields than lighter particles, and the detector can thus be positioned so that only specific *m*/*e* particles reach the detector. Magnetic sector instruments can be adjusted to yield much greater mass resolution than quadrupole instruments, thus eliminating many interferences (see below).

Magnetic sector ICP-MS instruments with multiple ion detectors are called multicollector (MC)-ICP-MS. Multicollector (MC)-ICP-MS instruments are sector devices that permit sampling of ions from the plasma simultaneously through a series of faraday cups and discrete dynode electron multipliers (typically 12–15 faraday cups and 1–3 electron multipliers). The detector array is configured so that a range of up to about 16 atomic masses can be monitored simultaneously. This configuration is essentially the same as that used in thermal ionization mass spectrometer (TIMS) instruments, which historically have been the workhorses for isotope ratio analysis. MC-ICP-MS instruments are capable of determining isotope ratios with precisions comparable to those of TIMS but with far less sample preparation, since both liquid digestion and laser ablation (see below) are generally far less time-consuming than sample preparation for TIMS.

Another mass-spectrometric technique used in ICP-MS is time of flight (TOF). Rather than selectively counting particles with specific mass-to-charge ratios, as in quadrupole or magnetic sector ICP-MS, TOF instruments accelerate packets of ions from the ion beam into a flight tube, where they are reflected by an ion mirror (or reflectron) back toward a detector. The flight tube and reflectron are configured so that, by the time the packet arrives at the detector, distinct *m*/*e* ratios are separated with greater than 1 atomic mass unit (u) resolution, so that the smallest *m*/*e* ratios arrive first and all of them arrive before the next *m*/*e*. In the most common commercially available TOF-ICP-MS, 30,000 ion “pushouts” per second can be integrated up to 50 times per second, thus making the TOF much more effective at analyzing highly transient signals, such as from laser ablation (see below).

Interferences

All ICP-MS analyses are affected by interferences on masses that would otherwise be the best choices for determining the concentrations of elements of interest. The three types of interferences are isobaric, polyatomic (or molecular), and doubly charged ions.

Isobaric interferences refer to cases in which different elements have isotopes with the same mass. For example, a very minor isotope of calcium, ^{48}Ca, creates an isobaric interference on the major stable isotope of titanium, ^{48}Ti. Even though the isotopic abundance of ^{48}Ca is only 0.187 % in nature, compared to 73.72 % for ^{48}Ti, the easily ionized calcium may contribute significantly to the mass 48 peak if (as is often the case) the abundance of calcium in the sample is an order of magnitude (or more) higher than titanium. In this case, as with most other isobaric interferences, the appropriate resolution would be to choose another isotope of titanium for analysis, such as ^{47}Ti, which is 7.44 % abundant but does not suffer from problems of interference.

Polyatomic interferences are created by recombination of plasma-gas ions and ions from the sample matrix in cooler regions of the plasma. Argon, being a plasma gas, is a major contributor to polyatomic interferences. Besides the major argon isotope at mass 40, there are minor isotopes at mass 38 and mass 36. Combinations with oxygen (isotopes at masses 16, 17, and 18) then create seven potential polyatomic interferences ranging from mass 52 to mass 58.

Doubly charged ions have a *m*/*e* that is half of the corresponding singly charged ion. One of the most common interferences from a doubly charged ion is Ba^{++}. Doubly charged ^{38}Ba, for instance, creates an interference at mass 69, which is a major isotope of gallium. In general, doubly charged ions are less important than isobaric or polyatomic interferences because the first ionization potential of Ar is lower than the second ionization potential of most elements.

Sample preparation and introduction

As typically configured, ICP-MS instruments require samples to be introduced to the plasma torch as liquids. A peristaltic pump moves a solution containing the sample to a nebulizer, where it mixes with argon gas and becomes an aerosol. The nebulized sample usually passes through a spray chamber, which removes large droplets before the aerosol flows into the ICP torch. Liquid sample introduction poses a problem for applications in archaeology and geoarchaeology, since characterization is usually sought for inorganic solids, such as metals, lithics, ceramics, soils, and sediments.

One way to solve the liquid-sampling problem is to digest samples using an appropriate mix of acids and/or heat and/or pressure. Most metals can be digested in nitric and/or hydrochloric acid (Young and Pollard, 2000). Silicates, such as obsidian, flint, ceramics, and sediments, require more aggressive treatment involving hydrofluoric acid and microwave heating inside of Teflon bombs (e.g., Kennett et al., 2002). Once digested, samples are usually diluted in some combination of nitric acid and deionized water prior to injection in order to bring the solutions into the optimal range of the ICP-MS. Liquid standards (see below) are also prepared using the same liquid matrix. Some studies (e.g., Kennett et al., 2002; Little et al., 2004) have reported satisfactory correlation between results from digestion-ICP-MS analysis of ceramics and neutron activation analysis of the same materials. Nonetheless, the added time, trouble, and potential danger of silicate digestion are significant. In addition, small variations in sample preparation procedures and reagent quality together with the potential for contamination of very small digested samples can introduce subtle random and systematic effects that compromise the quality of the analytical data.

An alternative sample introduction approach that has seen increasing use over the past decade is laser ablation-ICP-MS. A typical LA-ICP-MS setup has a 213-nm Nd-YAG solid-state laser with either argon or helium flowing through the sample chamber, coupled to one of the ICP-MS instruments described above. More recently, UV excimer (exciplex) lasers with a wavelength of 193 nm have become available commercially. Samples are placed in the ablation chamber together with reference standards, and the chamber is purged of ambient gases. Software controls x-y-z movement of the ablation chamber and projects a video image of the inside of the chamber. Ablation patterns (lines, rasters, spots, or lines of spots) are drawn on the samples, and the characteristics of the ablation (spot size, scan speed, laser power, repetition rate, number of passes, and dwell time) are specified. When the ablation starts, material vaporized from the sample and ejected from the site of ablation is entrained in the gas stream flowing through the chamber. If helium is the ablation gas, the ablated aerosol joins an argon gas stream from the ICP-MS before the mixture flows into the argon plasma of the ICP torch.

Standardization

The raw output of an ICP-MS analysis consists of ion counts per unit of time or "signal intensities." Although signal intensity for a particular element obviously correlates with the amount of that element present in the sample, the nature of the correlation depends on instrument tuning, other elements present in the sample, reagents used for digestion, and other variable conditions. Converting signal intensities into elemental concentrations entails use of standards – materials with known concentrations of the elements of interest – to develop standard curves for a given batch of analyses.

For analysis of digested liquids, standard solutions are prepared in a graded series of concentrations from commercially available multielement standards. Ideally the standard concentrations will overlap and bracket the concentrations expected in the unknown solutions. The standards and the unknowns are also spiked with a known amount of an "internal standard," i.e., an element assumed absent in the unknowns and standards; signal intensities are then normalized prior to calibration in order to compensate for instrumental drift during the analysis.

Standardization in LA-ICP-MS is trickier than in solution ICP-MS. Since project-specific preparation of solid standards is usually impractical, the usual approach is to obtain solid standards with known concentrations of particular elements from the National Institute of Standards and Technology (NIST) or other sources. For silicates, NIST Glass Standard Reference Material (SRM) 610, 612, and 614 are widely used. Homogeneous natural materials, the main example being obsidian, are also used. Copper, brass, and bronze standards are also available from NIST.

Given an appropriate set of calibration standards, an additional problem in LA-ICP-MS involves selection of an internal standard for normalization of signal intensities. The concentration of an internal standard can sometimes be assumed. Obsidian, for instance, is rhyolitic volcanic glass, in which silicon concentrations remain very close to 35 %. Thus, silicon, monitored at the minor isotope mass 30 because of the high concentrations, can be used as the internal standard, with 35 % as the assumed concentration. Another approach to internal standardization involves independent determination of the concentrations of an appropriate analyte, for example, by electron microprobe or x-ray fluorescence, which then serves as the internal standard.

A third approach to internal standardization in LA-ICP-MS is applicable both to homogeneous matrices and to individual components of heterogeneous matrices, such as individual temper grains within a ceramic fabric. The approach was first proposed by Gratuze (1999; Gratuze et al., 2001) and has been adopted by several other groups utilizing LA-ICP-MS (Speakman and Neff, 2005; Neff, 2012a). It assumes that elements in silicate matrices are present as oxides, and therefore, once converted to oxide concentrations, the major, minor, and trace elements measured by LA-ICP-MS should sum to 100 %. The advantage of this approach is that the internal standard concentrations need not be known, since the standardized concentrations (ratios to internal standards) must sum to 100 %. The algebra involved is straightforward and has been spelled out by Gratuze (1999) and Neff (2012a), among others.

Applications of ICP-MS elemental analysis

As a highly sensitive, precise technique for elemental characterization, ICP-MS has potential in all of the application areas to which neutron activation analysis (NAA), x-ray fluorescence (XRF) analysis, ICP-AES, and other elemental techniques can be applied. These application areas include provenance determination, activity-area analysis, constructing paleoenvironmental records, and investigation of ancient technologies. With laser ablation, additional applications become possible, such as the provenance investigation of micro-artifacts as well as slips and pigments on ceramics.

Digestion-ICP-MS can be used in a manner analogous to other bulk elemental techniques, such as NAA, to investigate sources of raw materials used by past craftspeople. The premise on which such studies are based is sometimes called the provenance postulate (Weigand et al., 1977). This postulate holds that source determination is possible "as long as some qualitative or quantitative chemical or mineralogical difference exists between natural sources that exceeds the qualitative or quantitative variation within each source" (Neff, 2000, 107–108). Although standard practice is to assume that compositional subgroups of artifacts represent distinct sources, a better approach is to treat the assumption as a hypothesis and to rule out other possible causes of subgrouping tendencies, such as diagenesis or technological variation (Neff et al., 2003; Neff, 2012b).

ICP-MS provenance studies began appearing in the late 1990s. Early examples include the work of Mallory-Greenough et al. (1998) on Egyptian pottery; a comparison by Kennett et al. (2002) of ICP-MS and INAA results for Virgin Branch Anasazi pottery; a study by Kennett et al. (2004) of Lapita pottery; a study of Song Dynasty porcelains (Li et al., 2005); a study by Thornton et al. (2002) of copper alloys from Tepe Yahya, Iran; and a study by Hall et al. (1998) of gold artifacts from a Late Sarmatian burial (Russia). Other artifact classes analyzed by digestion-ICP-MS for provenance determination include obsidian (Bellot-Gurlet et al., 2008), steatite (Jones et al., 2007), basalt (Ma et al., 2011), and flint (Olofsson and Rodushkin, 2011). This is far from an exhaustive list, and readers are advised to scan recent issues of the *Journal of Archaeological Science* and *Archaeometry* for other examples.

Due to ease of sample preparation and its sensitivity to a wide range of elements, LA-ICP-MS has recently seen a surge in popularity for provenance research. As a result, many materials that can be analyzed easily by NAA, XRF, digestion-ICP-MS, or other bulk techniques are now being analyzed routinely by LA-ICP-MS. These include chert and flint (Speakman et al., 2002; Stevenson et al., 2009); obsidian (Tabares et al., 2005; Carballo et al., 2007); jade (Kovacevich et al., 2005; Neff et al., 2010); turquoise (Zedeño et al., 2005); quartzite (Pitblado et al., 2008); rhyolite (Scharlotta, 2010); historic glass trade beads from various world regions (Popelka et al., 2005; Dussubieux et al., 2008a); copper and copper alloys (Dussubieux, 2007; Dussubieux et al., 2008b); Bronze Age glass from Egypt, Greece, and Mesopotamia (Walton et al., 2009); gold (Guerra et al., 1999; Brostoff et al., 2009); and Maya blue pigment (Arnold et al., 2007, 2012). Beyond these applications, which essentially duplicate what could be done with bulk characterization, the microprobe possibilities of LA-ICP-MS have been exploited to characterize ceramic slips and pigments (Speakman and Neff, 2002, 2005; Neff, 2003; Vaughn et al., 2005; Cecil and Neff, 2006; Duwe and Neff, 2007; Backes et al., 2012), individual nonplastic particles within ceramic pastes (Larson et al., 2005; Neff and Sheets, 2005), clay matrices in ceramic pastes (Larson et al., 2005; Cochrane and Neff, 2006; Fitzpatrick et al., 2006; Beck and Neff, 2007; Dussubieux et al., 2007; Sharratt et al., 2009; Stoner and Glascock, 2012), and obsidian micro-debitage (Scharlotta et al., 2011).

The microprobe capabilities of LA-ICP-MS can sometimes provide crucial complementary evidence that clarifies or extends results from bulk-characterization provenance studies. One example is a recently published study of the fugitive hematite pigment on Olmec carved-gray and incised pottery from Mesoamerica (Backes et al., 2012). An earlier NAA study of Olmec pottery detected high-volume export of Olmec pots from the Gulf Coast heartland but no other Early Formative ceramic exchange (Blomster et al., 2005; Neff et al., 2006a; Neff et al., 2006b). Backes et al. (2012) used LA-TOF-ICP-MS in time-scan mode to detect highly transient signals produced during the ablation of hematite patches on Olmec gray pottery from two well-sampled sites: San Lorenzo, Veracruz (in the Olmec heartland), and Cantón Corralito, a putative Olmec outpost in southern Chiapas. Also included in the study were raw pigments found in archaeological contexts at both San Lorenzo and Cantón Corralito and geological hematite from the vicinity of San Lorenzo. Because the iron signal from hematite overwhelmed other components, Backes et al. utilized ratios of other analytes to iron in a pattern recognition analysis. The results of analysis of pigments from the pottery group and the raw pigments showed that the raw pigments had been exported from San Lorenzo and that carved-gray pots at Cantón Corralito, imports from both San Lorenzo and local copies, had been decorated with San Lorenzo-derived hematite. Based on these results, the Olmec not only exported vessels decorated with their unique symbolic system but also exported the raw materials necessary to recreate that symbolic system outside the Gulf Olmec heartland.

As a microprobe, LA-ICP-MS has also been useful in testing hypotheses about the nature of compositional subgroups identified in ceramic provenance research. For instance, Golitko et al. (2012) analyzed ceramics from the Sepik Coast of New Guinea at the Field Museum and found some clear associations between find spot and chemical group. However, some of the distinctions were based on variation in barium, an element suspected to be susceptible to diagenetic enrichment (Neff et al., 2003). In order to test this possibility, microscale mapping of elemental concentrations in Sepik Coast sherds was undertaken with LA-TOF-ICP-MS. Since barium showed enrichment near surfaces in high-barium specimens but no cross-sectional trend in low-barium specimens, postdepositional enrichment of barium could not be ruled out as an explanation for certain high-barium compositions. Elements other than barium also showed no trends across sherd cross sections (Golitko et al., 2012).

ICP-MS, like other elemental characterization techniques, can also be used in the investigation of sediments that are of interest in archaeology. Eastwood et al. (1998), for instance, identified the Santorini tephra from the 3,300 BP eruption of the Aegean Island of Thera in sediments from a small intramontane lake in Anatolia. In another example, Neff et al. (2006c) analyzed sediments from a 6-m wetland core extracted in Pacific coastal Guatemala and argued that patterns of elemental variation are partly attributable to variation in the intensity of chemical weathering on adjacent low hills. The resulting climate archive bears some striking similarities to other neotropical archives.

Spatial variation in archaeological sediment composition is often used as an indication of variation in past activities both on small geographic scales (activity-area analysis) and on larger scales (land-use history). ICP-MS, with its sensitivity to such a wide range of elements, is perhaps ideally suited for such studies. Entwistle and Abrahams (1997; Entwistle et al., 1998) carried out exploratory work and demonstrated both the potential and some of the limitations of ICP-MS for land-use analysis, and Wilson et al. (2008) carried out additional investigations of the linkages between soil chemistry and past activities (also see Wilson et al., 2009). Recent archaeological examples of ICP-MS-based activity-area studies include documentation of mercury and gold enrichment on Classic Maya floors (Cook et al., 2006), an ethnoarchaeological study of fish-processing areas in Alaska (Knudson and Frink, 2010), and investigation of intra-site organization in the Aleutian Islands (Misarti et al., 2011).

The diversity of applications of ICP-MS elemental analysis extends beyond the major categories mentioned above. Other applications include a study by Cucina et al. (2011) that used trace elements in human tooth enamel to identify foreigners in an archaeological burial assemblage, with infant teeth used as the baseline "local" compositional profile. In another set of studies, LA-ICP-MS-based "dendrochemistry" identified elemental signatures of volcanic eruptions in tree rings (Pearson et al., 2005, 2009). These examples by no means cover the full range of applications of ICP-MS elemental analysis in archaeology and geoarchaeology, and the near future will certainly see continued rapid growth in the number and diversity of such studies.

Applications of MC-ICP-MS isotope ratio characterization

The potential of ICP-MS isotope ratio analysis has been recognized for some time (Angelini et al., 1993; Tykot and Young, 1996; Young et al., 1996; Pingitore et al., 1997). Unfortunately, the limited precision achievable for most isotopic systems with these instruments has restricted their use. Lead isotopes are the exception to this rule, as demonstrated by one methodological investigation (Dudgeon et al., 2007) and several provenance studies of lead-based glaze paint on ceramics (Habicht Mauche et al., 2000, 2002; Huntley et al., 2007). Multicollector ICP-MS instruments offer much greater potential, both for isotope-based provenance investigations and for uranium-series dating, and one can anticipate that their use will predominate in isotope ratio work over the coming decade.

In the past, high-precision isotope ratio applications in archaeology and archaeometry have usually employed thermal ionization mass spectrometers (TIMS). Multicollector ICP-MS instruments are replacing TIMS instruments because both liquid digestion and laser ablation are far less time-consuming than sample preparation for TIMS. In addition, several studies (Baker et al., 2006; Fenn et al., 2009) have demonstrated that solution MC-ICP-MS results compare favorably with TIMS results for lead isotope ratio determination in archaeological materials. An additional advantage of MC-ICP-MS over TIMS is that due to the efficiency of ionization in the plasma source, MC-ICP-MS can be used to study both "traditional" (e.g., Sr, Nd, Pb, Hf) and "nontraditional" (e.g., Li, B, Be, Fe, Cu, Zn, Cr, S, Hg, Mo) isotope systems (Albarède and Beard, 2004).

MC-ICP-MS isotope ratio analysis is beginning to answer provenance questions that have proven difficult or impossible to address with elemental characterization. An ironic example concerns the provenance of artifacts of turquoise, which occurs naturally in association with copper ore deposits throughout the US Southwest (Thibodeau et al., 2012). The irony is that the provenance postulate, which holds that sourcing is possible if between-source differences exceed within-source variation (see above), was first stated in the context of a trace-element study of turquoise (Weigand et al., 1977), yet trace-element characterization has consistently failed to identify source-specific turquoise elemental fingerprints. In contrast, the recent work by Thibodeau et al. (2012) convincingly demonstrates that $^{87}Sr/^{86}Sr$ together with the isotope ratios of lead (^{204}Pb, ^{206}Pb, and ^{208}Pb), determined in this case by MC-ICP-MS, easily discriminate southwestern turquoise mines.

Another application of MC-ICP-MS isotope ratio characterization has been in studies of hominin mobility patterns. Analogous to the abovementioned trace-element study of Cucina et al. (2011), these studies assume that $^{87}Sr/^{86}Sr$ ratios in tooth enamel depend on their values in the local geological environment and that these values are fixed when the tooth is formed, whereas bone values change during an organism's lifetime. In a methodological study, Horstwood et al. (2008) report determinations of strontium isotopes in archaeological tooth enamel by LA-MC-ICP-MS and point out the need for careful attention to interferences from the calcium phosphate matrix. In another study, Richards et al. (2008) detected evidence of Neanderthal mobility via LA-MC-ICP-MS characterization of strontium isotope ratios in tooth enamel. Enamel values from a Neanderthal molar recovered from a coastal limestone environment in Greece were found to be consistent with more radiogenic (older) rocks and, thus, suggested that the individual had spent his/her childhood at least 20 km away from the coastal location. Nowell and Horstwood (2009) criticize this study for inadequate attention to interferences within the mass range of strontium isotopes. These charges were rebutted by Richards et al. (2009).

Finally, uranium-series dating of carbonates in speleothems and corals is currently being done primarily by MC-ICP-MS. Goldstein and Stirling (2003) describe the analytical protocols for solution MC-ICP-MS determination of isotopes in the ^{238}U decay chain, which need to be measured in U-series dating (see Bourdon et al. (2003) for theory of U-series dating). Eggins et al. (2005) and Hoffman et al. (2009) discuss the potential of laser ablation-MC-ICP-MS for in situ U-series dating. Applications of uranium-series dating important to archaeology and geoarchaeology include dating of early human remains (Pike and Pettitt, 2003), dating of corals in paleoclimate studies (Eggins et al., 2005; Potter et al., 2005), dating of corals incorporated into human constructions in Polynesia (Kirch and Sharp, 2005; Weisler et al., 2006), and high-resolution dating of speleothems in paleoclimate studies (Lachniet et al., 2012).

Conclusion

Over the past decade and a half, ICP-MS has become a - well-established elemental characterization technique in archaeological and geoarchaeological research. Provenance studies still probably make up the bulk of applications, but activity-area and land-use studies, dendrochemistry, population-movement studies, uranium-series dating, and other applications not yet invented will also comprise major areas of application over the coming decade.

INUNDATED FRESHWATER SETTINGS

Jessi J. Halligan
Department of Anthropology, Florida State University, Tallahassee, FL, USA

Synonyms

Freshwater archaeology; Inundated terrestrial sites; Submerged prehistoric sites; Submerged terrestrial sites

Definitions

Base level: the imaginary line below which a river or stream can no longer erode. In coastal and near coastal areas, this is approximately sea level, but inland and in man-made reservoir systems, it can be quite different.

Karst: landscape formed by the dissolution of carbonates (limestones and dolomites, commonly) characterized by porous surface topography including sinkholes (more formally known as dolines), caves, and interrupted surface water flow with common underground stream flow.

Prehistoric: the generic archaeological term referring to the period before written records in a given area.

Submergence: the process by which a terrestrial site becomes inundated (or submerged), during which the site is most at danger for destruction.

Terrestrial: on land, especially in reference to sites that were created on dry land that are currently underwater.

Introduction

Prior to the Industrial Revolution, access to fresh drinking water was one of the most important considerations for human settlement. Unsurprisingly, the overwhelming majority of human habitation from the earliest hominin sites to modern cities was located very near water sources, which means a very large percentage of potential archaeological sites is likewise located near water sources, ancient and extant historical. This entry specifically deals with the geoarchaeology of submerged freshwater sites, as well as the site formation processes, preservation potential, and exploration of sites that can be found beneath freshwaters. Other entries on submerged continental shelves, coastal settings, and paleoshores discuss these matters for coastal environments or areas that became coastal environments, and the entry on alluvial settings discusses site formation processes in formerly wet areas that become desiccated and for settings adjacent to rivers.

Geological background: site formation processes and site preservation potential

Throughout the Pleistocene and Holocene, thousands of archaeological sites were submerged by oceans, rivers, and lakes. Most of these sites, however, were destroyed by scouring river channels with turbulent water flows, nearshore wave processes, and storm surge. In certain rare situations, some of these sites or portions of them have survived.

The world changed a great deal during the closing millennia of the Pleistocene and early Holocene, especially in the Northern Hemisphere. From approximately 18,000–5,000 radiocarbon years ago, global sea levels rose more than 120 m (Blum and Törnqvist, 2000; Balsillie and Donoghue, 2004; Peltier and Fairbanks, 2006; Milliken et al., 2008; Harris et al., 2013) due to massive influxes of glacial meltwater. As the glaciers melted, enormous channels were scoured by the meltwater, which created and reshaped many inland rivers such as the St. Lawrence, Mississippi, Missouri, Columbia, and Hudson drainage systems in North America. The North American Great Lakes were also created from larger glacial lakes. At the same time, the land surface itself was slowly rising because it was no longer being compressed by the weight of millions of tons of ice. This process, known as isostatic rebound, caused major topographic changes, which, in turn, caused dramatic changes in stream patterns and lake levels. Dramatic landform change also occurred due to the deposition of glacial loess (wind-borne sediment) in many northern latitudes.

As the meltwater began to refill the ocean basins, enormous swathes of land were submerged on the continental shelves, former rivers and streams were drowned, and the base level of all but the most interior rivers and streams rose in response. This rise in base level is especially significant to the discussion of freshwater site preservation, as many rivers dramatically changed shape in response. Specifically, many rivers concurrently began to infill former channels and switched from braided to meandering stream systems, especially on the coastal plains of the world (Leigh, 2008; Harris et al., 2013). This would have led to obliteration of some sites as terraces were destroyed by channel formation, yet there was deeply buried terrestrial preservation of some sites on abandoned terraces and, very rarely, preservation or partial preservation of other sites within river channels. Descriptions of flow types and processes that are found in meandering stream systems can be found in classic discussions of fluvial geomorphology (Wolman and Miller, 1960; Schumm, 1973).

The aforementioned rise in base level, increased surface water availability, and the generally warmer climate of the Holocene allowed thousands of lakes to form in the postglacial landscape. Many formed in features previously carved by glaciers or caused by glacial outwash in northern latitudes, but numerous lakes formed in non-glaciated areas as well. As a large percentage of the lakes increased in area throughout the Holocene, most sites created by people living on lakeshores late in the Pleistocene or early in the Holocene would have been inundated. Occasionally, these sites were preserved under the right conditions, generally when they were buried (especially in marshy deposits) before full submergence, or when they were transgressed quickly and then buried while newly submerged.

Talbot (2005) offers an excellent introductory discussion of the sedimentation processes within freshwater lakes. In general, sedimentation within lakes is strongly controlled by river inlets and outlets, and this means that the possibilities for buried sites will also usually be controlled by these rivers. Protected inlets where sediment can accumulate, rather than areas directly impacted by fluvial processes, are generally more likely to inundate in a way that would gently preserve sites. Sonnenburg et al. (2011), for instance, have discovered microdebitage in early Holocene peaty sediments in Rice Lake (Ontario) that were located in a shallow marshy lagoon adjacent to the main lake body. Mazurkevich and Dolbunova (2011) report numerous well-preserved mid-Holocene villages that were built on lakeside marshes and later inundated in northern Russia.

Man-made lakes also contain recently inundated freshwater sites. In the mid-twentieth century, thousands of dams were built for hydroelectric power, water reservoirs, and floodwater control all over the world (Graf, 2005). Many of these man-made reservoirs created large lakes out of former tiny streams. Over time, these artificial basins become infilled with sediment, as there is little to no flow through them, so sites on the former river terraces become flooded, then buried, which has led most likely to the destruction of the majority of them. A few sites preserved remarkably well. For instance, there are preserved towns under the waters of the St. Lawrence Seaway, Smith Mountain Lake, and the Oahe Reservoir, to name only a few, all regularly discussed on SCUBA diver fora. Though the prehistoric site potential of these reservoirs has been little explored, Hooge (2013) provides an excellent overview of the challenges and potentials through the study of Spring Lake in Texas. This untested potential is quite good in other reservoirs. Prior to dam construction, many prehistoric archaeological sites were partially excavated to salvage data. Some of these sites were well-preserved rock-shelters prior to flooding, such as Marmes Rockshelter in Washington state (Hicks, 2004). It is possible that the rapid flooding following dam closure would have allowed shelters to be rapidly submerged, infilling them with sediment, and preserving the site within, although this has not yet been tested.

In humid karstic environments, such as can be found in the Yucatan Peninsula, the Bahamas, and Florida, hydrology is a very complex process. Stream flow often abruptly disappears underground and reappears suddenly, and the terrestrial landscape and river bottoms alike are commonly pocked with sinkholes. This is due to the fractured and porous bedrock that causes very complex movements of groundwater. Karst settings have proven to be remarkable for preserving submerged archaeological sites of all kinds. In the Yucatan Peninsula, submerged karst features contain evidence of extinct fauna, many of the oldest human remains in the Americas, and the famous Mayan cenotes, which are not submerged sites in the traditional sense as people were deliberately depositing materials into the water (Leshikar-Denton and Luna Erreguerena, 2008; Chatters et al., 2014). In Florida, hundreds of Paleoindian artifacts dating to the late Pleistocene have been discovered within sinkholes in the bottom of karstic streams. Many of these artifacts are made of bone or ivory, some of which have been preserved well enough for direct dating, which is extremely rare for artifacts of this age (Hemmings, 1999; Balsillie et al., 2006; Webb, 2006; Dunbar, 2012). Many of these sinkholes have acted as sediment traps, containing equally well-preserved peats, soils, and sediments that contain excellent paleoenvironmental records from the late Pleistocene and Holocene. Some of the archaeological materials within these sinkhole deposits are associated with soils that formed during periods of terrestrial exposure and were thus available for people to utilize (Halligan, 2012).

In sum, very few archaeological sites probably survived inundation. The fluvial submergence process is not gentle. When rivers transgress new areas, flows are often turbulent, and much geomorphic work is likely to be done, destroying sites and redepositing their sediments along the way. Further, relatively few rivers maintain the same channel for long periods of time; as rivers meander through their floodplain, a site that is submerged in one century is likely to be exposed the next and possibly eroded in the following. In the case of freshwater lakes, shorelines are very often also quite turbulent and erosive, at least on a semiannual basis. This means that nearshore sediments are frequently reworked, so unless the site is submerged very rapidly and spends almost no time in the nearshore zone, artifacts are likely to be redeposited and features destroyed. Karstic systems and freshwater marshes have the best potential for long-term preservation due to relative landscape stability, but the discontinuous nature of streams in karst settings means that each portion of a karst river and each sink will have somewhat different preservation potential.

Freshwater shipwrecks may be exceptions to some or all of these general preservation rules. If a vessel sinks in cold deep water, it can preserve extraordinarily well if the water is fresh as it is below the reach of most geomorphic processes and is largely below biotic activity as well. There are a number of such vessels that have been recorded in the Great Lakes of North America (Crisman, 2014a) such as the *Hamilton* and *Scourge*, both of which had been preserved almost undamaged since 1812 until recent invasions by mussels. Vessels sunken in lakes may settle into bottom sediments for millennia (Wheeler et al., 2003), and wrecks in rivers may be submerged, buried, and re-exposed (Crisman, 2014b).

Inundated site preservation in all environments is most likely when sediment loads are relatively large and fine-grained so the site is buried before submergence and when the site is protected from the direct effects of turbulent flow even during major geomorphic events. Rapid burial, rapid inundation, and constant moisture all acting together increase organic preservation and the likelihood of in situ deposits as well. This confluence of geomorphic events is likely to be a relatively local process, which means site preservation would have been a local process as well, so fine-grained analyses are especially important when looking for inundated freshwater sites.

Location and excavation

Because site preservation will happen only in relatively rare exceptions, locating inundated freshwater sites requires either (1) precise modeling of broadscale geomorphic processes that are applied to rigorous models of human behavior to determine where people *may* have been or (2) sites must be located by chance. The corollary of site preservation is site visibility, which has two aspects: site complexity and site exposure. If a site was larger, more complex, and occupied for a long period of time, which are often related attributes, it is more likely to be at least partially preserved than a smaller site in the same setting. If it were to preserve, it also would be much more likely to be encountered by archaeologists for two main reasons. First, there is more of it, so testing strategies are more likely to encounter it. Second, complex, long-occupied sites are much easier to model on a landscape because the factors that made an area attractive for settlement are more predictable in this case. Site exposure (literally, site visibility) often means that a site is poorly preserved. Sites preserve best when they are buried in sediment before being inundated. If artifacts remain on the surface, they are very likely to become reworked into secondary contexts, just like surface artifacts on terrestrial sites. However, sometimes only a portion of a site has been exposed, which is how most underwater localities have been located. Sites that have been buried and protected may have excellent preservation, but they are almost impossible to find under ordinary circumstances unless a development project causes them to be exposed, such as occurred at the Windover site in Florida (Doran, 2002).

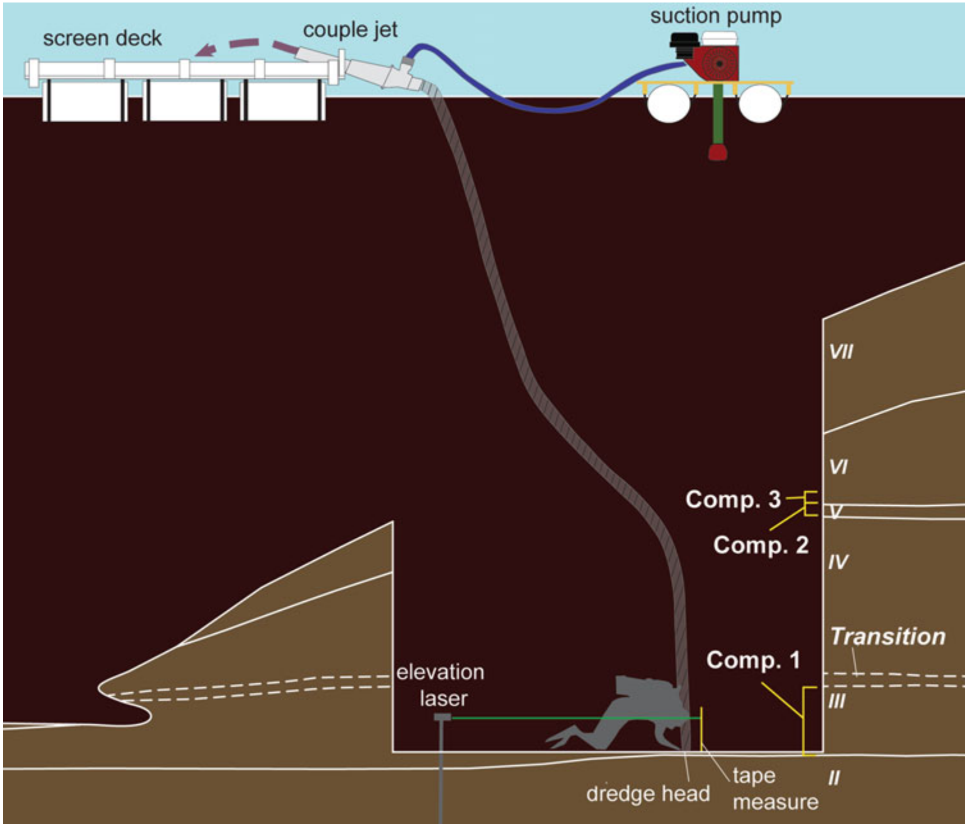
When looking for submerged sites, archaeologists often employ sonar surveys to locate areas of interest and gain an understanding of bottom topography. Everything from fishfinders to multibeam sonar systems has been utilized with some success to give the archaeologist a view of the bottom in two or three dimensions, while subbottom profilers give a profile view of the sediments directly below the machine. All of these types of remote sensing use sound waves of specific frequencies emitted at regular intervals. The machine emits the sounds and then "listens" for them to return after they bounce off a barrier or reflector of some kind. It keeps track of the travel time and performs complicated math to generate an "image" of the bottom that shows how far the wave traveled and how strongly it was reflected. See Chapter 13 of Bowens and Nautical Archaeology Society (2009) for an excellent summary of the main geophysical techniques utilized for site prospection.

When looking for shipwrecks or sites containing ferrous metals and built formal structures, side scanning sonar and magnetometers are the main survey equipment employed. Sonar systems do not usually have the resolution to see individual prehistoric artifacts or features (though see O'Shea et al., 2013). When looking for sites that predate the use of metals or are not associated with structures, archaeologists commonly look for landforms that would have attracted people, such as flat terraces adjacent to drowned streams or the edges of past waterholes. As buried sites are likely to be best preserved, they look at these localities more intensely for buried land surfaces. Thus, one must have some understanding of what the entire sediment column looked like. When feasible, subbottom profilers are used to give a sonar image of this. Many fishfinders now also have the ability to look through the top few meters of sediment, so they can be used as an inexpensive subbottom viewer to narrow down areas of interest.

Once target areas are defined, archaeologists next investigate them by a variety of more intensive means. At this point, a landform of interest has been defined, but no artifacts have been discovered, so it is not yet a definitive archaeological site. The archaeologist may then conduct visual surveys with SCUBA divers or underwater vehicles with cameras, swimming over the area looking for items of interest. If materials are likely to be buried, the archaeologists may use coring devices of various types. For instance, hand coring, vibrocoring, and Livingstone coring have been used in various seasons in Florida for soil prospection (Halligan, 2012). If logistics allow, test pits may be excavated with a dredge as well. During this phase, the researcher is looking for artifacts and/or incontrovertible evidence for submerged and preserved landforms, such as preserved buried soils in the cores or exposures of some cultural evidence. Soils form from the weathering of sediments in terrestrial contexts. Therefore, buried and inundated soils were surely exposed at some time in the past, and they could have been walked or lived upon by humans; they would therefore be worth further examination. Archaeologists will also look for places such as infilled sinkholes or ponds, places with exposed stone for flintknapping, and evidence of old shorelines, such as wave-cut notches, as these are all locations with resources that would have been attractive to people.

Underwater excavation is extremely expensive in comparison with terrestrial research (at least three to four times more expensive per day of research). Therefore, most underwater research is focused either entirely on survey and marking of areas of high potential or it is focused on excavation. If the latter, archaeologists will target only a few places with the highest probability of containing sites, which, in practice, usually means areas where erosion has exposed artifacts, allowing the researcher to spend less time on survey and more on excavation. Often, these sites have been revealed to the excavator by helpful local avocational archaeologists. This surface exposure, however, means that site context needs to be carefully examined, and artifacts must be discovered in situ in as yet undisturbed portions of the site in order to make any meaningful interpretations of human behavior in the past. Excavations on land and underwater must be carefully controlled so that artifact provenience can be carefully recorded.

The Page-Ladson site in Florida is a submerged sinkhole in the Aucilla River that contains some of the earliest archaeological material in North America. Research at this site was accomplished by excavating within 1x1 m grids that were laid in by tape and compasses from a datum placed underwater via Total Station. This is very similar to gridding a site on land. To control for elevations, archaeologists used a laser pointer specifically designed for underwater use that was mounted onto a level pole (Figure 1). The elevation of these poles was set from the datum point, and the laser was then an arbitrary line at a known height that would shoot across the unit, allowing excavators to take measurements below this line. Excavations were conducted by trowel to remove the sediments, with the backdirt sucked up to screens at the surface using a water dredge. Archaeologists on the surface maintained the air supply for divers and screened the sediments through nested 1/4″ and 1/16″ mesh in order to find even tiny artifacts and bones. Using this method, very accurate X, Y, and Z coordinates could be obtained for artifacts, sediment changes, and faunal remains 11 m below the river surface in water so tannin-stained that one could see only 1–2 m away even with a very bright light. Excavating with trowels and by hand allowed the archaeologists to tell instantly when digging was encountering a new stratum, and therefore, contextual associations could be recorded precisely.



Inundated Freshwater Settings, Figure 1 Generalized schematic of excavations at the Page-Ladson site, Florida, showing the excavation setup, the major stratigraphic units (in Roman numerals), and the three major cultural components found underwater (comp 1, comp 2, and comp 3).

Precise excavation is critical because artifact context is especially important for explicating site formation processes at underwater sites. The complicated logistics of working at these sites mean that only relatively small areas can be excavated in a field season, reducing the potential for finding cultural material in any given year's campaign; therefore, each artifact, feature, or ecofact is especially precious. Further, because few scientists have the training to visit the sites in person to draw their own conclusions about site formation, it is important to record the sites as thoroughly as possible. Finally, underwater sites often are more dynamic than their terrestrial counterparts, with excavation units filling in rapidly with leaves, sand, or other sediment, so dredging equipment is necessary, even just to see the site in many cases.

In the case of Page-Ladson, the disadvantage of dynamic change was mitigated by collecting numerous sediment samples for later lab analyses. To cross-check underwater interpretations of the stratigraphy, cores were collected using both vibrocoring equipment and a Livingstone-Bolivia corer, which were scanned for magnetic susceptibility and gamma density, photographed and described, and compared to the underwater unit descriptions. Paleoenvironmental samples were also extracted and analyzed for pollen, diatoms, phytoliths, and ancient DNA. The excellent preservation of the paleobotanicals represented one of the best sources of information, making this underwater site so significant to excavate even given its logistical difficulties. Inundated freshwater sites lack the salts that destroy organic remains in saline environments, so when the submerged burial environment is anaerobic, preservation can be remarkable. For example, 14,500-year-old grape skins were regularly noted in the sediments in the deepest levels of the site. Publication of these results is forthcoming.

Conservation and the benefits of excavating inundated terrestrial sites

Although underwater research can be costly, logistically intensive, and difficult, inundated freshwater sites can provide extremely important insights about past people because of the excellent preservation. For instance, at the Windover site (Doran, 2002), preservation of human burials was so good that brain tissue had survived for thousands of years in the underwater environment. The remains from this site helped to answer many questions about diet, mortality, and health in the early Holocene. The clothing and grave goods helped us understand how these early Americans crafted their material culture and presented themselves to others and gave some hints into their world view. Perhaps most importantly, archaeologists were forced to reconsider their own views about these early people due in large measure to the complementary artifactual assemblage encountered underwater. From more than 150 burials, there were fewer than 50 stone tools recovered. This is an especially significant reversal of expectation because stone artifacts are often the only material culture recovered from terrestrial sites of this age. The Windover site has reminded archaeologists about how little perishable material preserves on most terrestrial sites, and they have been forced to reassess the importance of stone tool technology to these forager societies because of what was *not* buried with the people discovered at Windover.

Inundated sites can reshape archaeological research based on the likelihood of finding a high degree of preservation, but they thus impose a higher level of responsibility. The rare gift of excellent preservation demands a more rigorous and costly commitment to logistics, time, and conservation for all the well-preserved organic materials. They afford extremely valuable insights about past people and past environments but only if properly conserved and curated. Thus, it is especially important to consider these factors, preferably in consultation with a trained conservator prior to data collection, although there are some useful references available for beginners (Pearson, 1987; Hamilton, 1999; Smith, 2003). As soon as organic materials are removed from the environment that has preserved them for so long, they will begin to degrade rapidly, and the potential information gained from them disappears. Thus, the decision to excavate these sites at all should be made with care and consideration for the cost of excavation and long-term conservation and curation.

Summary

In recent years, it has become increasingly apparent that many archaeological sites in freshwater settings have survived the inundation process and that these sites can be found and excavated with high levels of precision in some cases. Such freshwater sites often reveal extraordinary organic preservation, which allows for the recovery of artifact and ecofact types that are rarely found at coeval terrestrial sites, including DNA, microfossils, macrofossils, and organic tools. Recovery of these materials requires careful excavation, and conservation is a necessary part of the entire process if the delicate items are to survive for analyses. Discovery, excavation, conservation, and analysis of underwater sites in general are usually much more expensive and complex than their terrestrial counterparts, but the wealth of information recoverable from inundated freshwater sites can provide paradigm-changing insights about material culture and human behavior.

ISERNIA

Francesco G. Fedele
Formerly University of Naples 'Federico II', Naples, Torino, Italy

Definition

Isernia is a Lower Paleolithic open-air site in Molise, central Italy, with geographic coordinates of 41°35′27″ N, 14°14′29″ E. It lies at 455–460 m asl.

The archaeological site of La Pineta at Isernia, accidentally discovered during roadwork in 1978, is located on the western border of the Middle Pleistocene Isernia Basin, in the lower range of the Apennines. A stratified fluviolacustrine sequence including four cultural layers is documented, with several artifact- and bone-bearing levels interpreted as "living floors" (Fr. *sols d'habitat*) produced by repeated camping of hominins (Peretto et al., 1983; Peretto and Minelli, 2006). The closeness to a regularly flooding stream and the occurrence of volcanic events contributed to good preservation of the site, which was covered by silt and clay of riverine origin alternating with volcanic tuffs.

Showing a normal magnetic polarity, the whole sequence was deposited during the Brunhes Chron, i.e., in the Middle Pleistocene. Earlier age evaluations were contradictory, but the latest magnetostratigraphic and $^{39}Ar/^{40}Ar$ determinations have allowed the dating of the main archaeological level (t3a, a debris flow deposit) to 606 ± 2 ka (Coltorti et al., 2005), with ESR ages on bovid enamel in acceptable agreement (560 ± 84 ka; Bahain et al., 2007). Lithic artifacts include heavy-duty implements from locally available stones, mostly choppers, and flint and limestone flake tools (Peretto, 1994). Animal remains of cultural introduction are dominated by elephants (*Palaeoloxodon antiquus*), rhinoceri (*Stephanorhinus hundsheimensis*), and hippopotami (*Hippopotamus* cf. *antiquus*). Less frequent species include bears, wild boars, and Megaceros deer; occasional lion (*Panthera leo*) remains are among the earliest in Europe.

The sedimentary, palynological, and paleontological evidence suggests a persistent environmental mosaic in which large prairies alternated with marshes and low-mountain forests. In 2014, a deciduous hominin incisor attributed to *Homo heidelbergensis* was found on the surface of unit t3a. Interdisciplinary-oriented excavations are continuing, and an onsite museum has been created to allow the public a glimpse of Paleolithic archaeology and geoarchaeology in action.

ISOCHRON DATING

Jan D. Kramers
Department of Geology, University of Johannesburg, Auckland Park Kingsway Campus, Auckland Park, Johannesburg, South Africa

Definition

Isochron A term derived from Greek meaning "same time" that refers to a straight line given by the regression calculated for points plotted in X–Y space that represent isotope abundance ratios across a set of samples (minerals or rocks) of the same age; it is a graphical tool employed in radiometric age determination.

The isochron dating method is applicable to all radioactive decay systems used in geochronology. In archaeology and paleoanthropology, the uranium-lead variant has been applied since 2006 (Walker et al., 2006) for dating speleothems (stalagmites and flowstones) older than the ca. 500,000 year age limit for U-series dating.

Essentially, the isochron diagram describes isotopic changes since the formation of a rock. At crystallization (whether from a magma or from drip water in a cave), the parent radioisotope (P) and its stable daughter product (D) within the newly formed rock or mineral would present an initial ratio of D_0/P_0 and register an age of zero based on the absence of accumulated daughter product. Over time, decay of the parent would lead to a decrease in its quantity and an equal increase in the stable daughter isotope. Using a different stable isotope of the daughter (S) as a reference, and plotting the ratios of D/S against P/S for several samples collected from the same rock layer (and representing the same age of formation), the plotted points would form a straight line, and the slope of the regression should increase with the age of the sample. This is possible only if the production of new daughter product D occurred within a closed system with no outside disturbances and all samples analyzed possessed the same initial D_0/S_0 ratio.

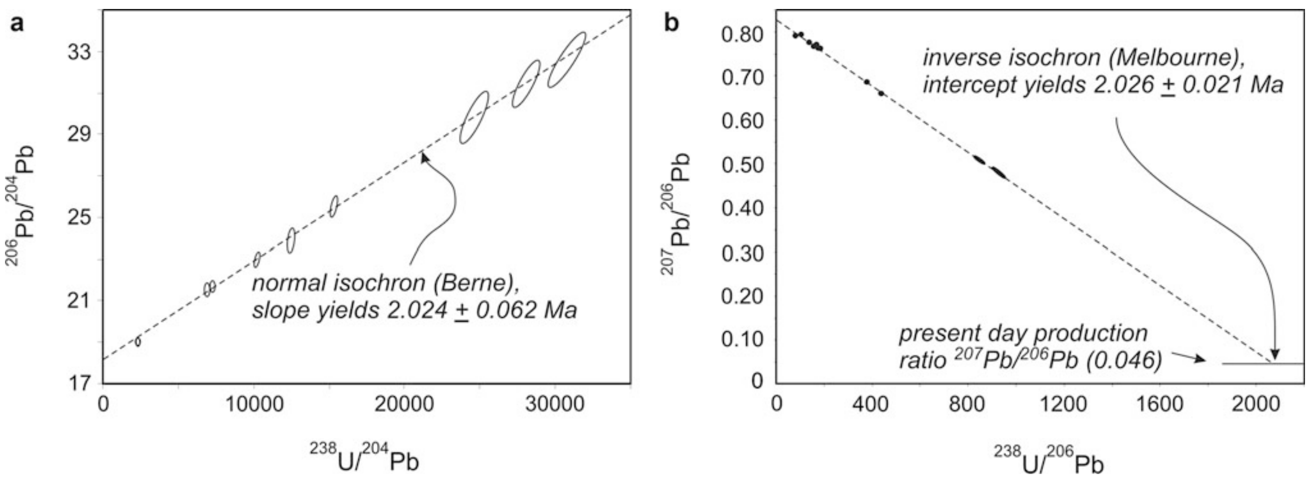
In the most commonly used (normal) isochron diagram applicable to speleothems, the abundance of a long-lived radioactive isotope P (e.g., ^{238}U) and its stable daughter isotope D (e.g., ^{206}Pb) are plotted. Both abundances are given relative to the same stable reference isotope of the daughter element S (e.g., ^{204}Pb). Simply stated, the isotope ratios ^{238}U/^{204}Pb (i.e., P/S) and ^{206}Pb/^{204}Pb (i.e., D/S) are determined for several samples and plotted on an isochron graph (Figure 1a). If P/S is displayed on the abscissa (x-axis) and D/S on the ordinate (y-axis), then the positive slope of the isochron (D/P) yields the age of the samples: Age = $\ln(D/P + 1)/\lambda$. Here, λ is the decay constant of ^{238}U, which is 1.55125×10^{-10} year^{-1}.

Another value that can be of importance for geochemical interpretation is the initial isotope ratio. This is the D/S ratio (e.g., ^{206}Pb/^{204}Pb) that the samples defining an isochron had at the time they were formed. It is indicated by the intersection of the normal isochron with the y-axis.

Somewhat analogous to its usage in ^{40}Ar/^{39}Ar dating, an inverse isochron is frequently applied in U-Pb dating of Neogene samples (dating between 23 and 3 Ma ago). This can be seen in the regression line with negative slope for a plot of ^{207}Pb/^{206}Pb versus ^{238}U/^{206}Pb (Figure 1b). It is in fact a mixing line between the initial ^{207}Pb/^{206}Pb ratio of the samples indicated at the Y-intercept and pure radiogenic ^{206}Pb (derived from the decay of ^{238}U) represented by the intersection of the isochron with the horizontal line giving the present-day ^{207}Pb/^{206}Pb production ratio (0.046) from the decay of ^{235}U and ^{238}U, respectively. The age is derived as above from the D/P ratio: 1/(^{238}U/^{206}Pb) at this intersection. The inverse isochron method plots the ratio of parent/daughter along the x-axis unlike the normal method, which separates parent and daughter on the x-axis and y-axis; it also does not require measurement of the minor stable isotope ^{204}Pb and is therefore more precise (compare Figure 1a, b). It does, however, rely on the assumption that the initial ^{207}Pb/^{206}Pb ratio was uniform among the samples.

U-Pb isochrons yield the correct ages for the samples only if the intermediate nuclides in the ^{238}U decay chain existed in secular equilibrium at the time the dated minerals or rocks (e.g., speleothems) were formed. ^{230}Th is normally absent in speleothems when they form, necessitating an upward correction of the apparent isochron age by about 80,000 years. On the other hand, ^{234}U is frequently present in excess, and this requires a downward correction which can be as great as 700,000 years. In samples younger than about three million years, a residual excess of ^{234}U can in many cases still be detected, which allows the correction to be made (Walker et al., 2006). In older samples, ^{234}U and ^{238}U are, within the uncertainty limits of measurements, in secular equilibrium. It must then be accepted that the true age may be up to 700,000 years younger than the value yielded by an isochron.

For example, following the discovery of fossils of the new hominin species *Australopithecus sediba* in 2008 at the Malapa site, Gauteng, South Africa (Berger et al., 2010), a flowstone horizon underlying the fossiliferous clastic cave sediments was independently dated by university laboratories in Berne, Switzerland, and Melbourne,



Isochron Dating, Figure 1 Normal (**a**) and inverse (**b**) uranium-lead isochrons obtained on flowstone layers with ca. 1 ppm U at the Malapa fossil site, Gauteng, South Africa. Age results quoted, and error ellipses in (**a**) are at the 95 % confidence level. Error ellipses in (**b**) are mostly smaller than symbols (Modified from Dirks et al., 2010).

Australia, using the normal and inverse isochron methods, respectively (Dirks et al., 2010; Figure 1). Later, the combination of these results with those from a flowstone overlying the fossils as well as paleomagnetic data yielded a precise age of 1.977 ± 0.002 million years (Ma) for the fossils (Pickering et al., 2011).

J

JAVA (INDONESIA)

O. Frank Huffman
Department of Anthropology, University of Texas at Austin, Bastrop, TX, USA

Java is a Southeast Asian island with special geoarchaeological significance. Since 1890, geological studies in its eastern part have supported the discovery and interpretation of >100 skeletal fossils of *Homo erectus*, an extinct human ancestor (Theunissen et al., 1990; Zaim, 2010). There have been no confirmed finds of Homo erectus in other areas of Southeast Asia or Australia.

When Eugene Dubois chose Java in 1890 to search for fossil connections between *Homo sapiens* and apes, he focused his attention on cave deposits and volcanic-rich sedimentary rocks that were known to contain mammalian bones. He soon found what he called the skeletal "missing link" – *Homo erectus* (initially named *Pithecanthropus erectus*) – in excavations at Trinil along the Solo River (Shipman, 2001). The bone bed contain the Homo erectus fossil was a conglomeratic sandstone lens, <1 m thick, that was part of the local bedrock. The lens produced many thousands of teeth and strongly fossilized bones representing deer, cattle, *Stegodon* (a large late Cenozoic to Quaternary proboscidean), and other terrestrial animals, mixed with the remains of hippopotamus, crocodile, freshwater mollusks, and trees. Evidence of shellfish consumption and shell engraving has recently been found (Joordens et al., 2015).

In 1931–1933, geologists excavated 12 partial *Homo erectus* calvaria (skullcaps including parts of the frontal, parietal, and occipital bones) and two long bones from another thin bone bed (Huffman et al., 2010). The new discoveries came from river terrace deposits at Ngandong, 10 km from Trinil. Several years later, the fossilized braincase of an infant was unearthed from fossil-rich gravelly sandstone, ~3.3 m thick, deposited in a channel of an ancient marine delta, 125 km east of Trinil. Like earlier finds, this specimen was embedded in sediment eroded from episodically active stratovolcanoes, which are numerous in Java. Over subsequent decades, *Homo erectus* discoveries have been most numerous 60 km west of Trinil at Sangiran Dome, where the fossils were contained within fluvial and lacustrine deposits together with a few artifacts and cut-marked bones. No *Homo erectus* fossils are known from the many karstic caves of eastern Java, but Song Terus cavern, 100 km south of Trinil, contains artifacts attributable to the species (Sémah et al., 2002).

Eastern Java was favorable for *Homo erectus* occupation and fossilization during roughly a million years of the Pleistocene. Dietary resources of aquatic, forest, and large mammal origin present along rivers draining stratovolcanoes evidently sustained recurring or continuous *Homo erectus* inhabitation, while rapid volcaniclastic deposition, sometimes following debris flows in the highlands, served to preserve skeletal remains (Huffman et al., 2012). Additional geoarchaeological research on Java *Homo erectus* is needed, especially on chronometric dating of occupations and determining coeval paleoenvironmental conditions.

K

KEBARA CAVE

Paul Goldberg
Department of Archaeology, Emeritus at Boston University, Boston, MA, USA

The site of Kebara, located along the western side of Mt. Carmel, ~30 km south of Haifa, Israel, is formed in a Cretaceous limestone reef complex at an elevation of ca. 60 m asl (Figure 1) (Bar-Yosef et al., 1992, 1996; Bar-Yosef and Meignen, 2007). Initial excavations by Turville-Petre (1932) exposed deposits with Natufian, Kebaran, and Upper Paleolithic implements; later excavations explored Upper and Middle Paleolithic deposits (Schick and Stekelis, 1977).

The sediments are geogenic and anthropogenic, with the latter especially apparent in the Middle Paleolithic (Goldberg et al., 2007). Geological processes include the following:

(a) Deposition of basal sands is associated with preoccupation phreatic water flow.
(b) Red colluvial silty clays occurring at the entrance to the cave are terra rossa soils reworked from Mt. Carmel above the cave (some were also washed in through a chimney at the rear of the cave).
(c) The deposits of (b) and older ones at the entrance were also reworked by sheet wash, particularly during the Upper Paleolithic under wetter conditions.
(d) Collapse of meter-sized limestone blocks from the cliff above the cave entrance during the Upper Paleolithic.
(e) Weak aeolian inputs of silt and sand.

Anthropogenic processes are signified by numerous lenticular and tabular combustion features and their remains (e.g., charcoal and ashes) (Meignen et al., 2007). These features prevail in the Middle Paleolithic layers but are rare in the Upper Paleolithic and later sediments. Micromorphological analysis shows that the Middle Paleolithic (Mousterian) features also include ash dumps and hearth cleanouts as well as in situ burning events.

Postdepositional effects include phosphate diagenesis (Schiegl et al., 1996), which results in extensive dissolution of bones. Calcite precipitation occurs in areas adjacent to the bedrock walls. Physical modifications include localized slumping and faulting; a major slumping event took place at the end of the Middle Paleolithic, producing >2 m of relief from front to back. Bioturbation (mammal and insect) is local but widespread.

Thermoluminescence (TL) dates on burnt Mousterian flints range between 48000 and 60000 BP (Valladas et al., 1987). Several radiocarbon dates place the transition from Middle to Upper Paleolithic between 49/48 and 47/46 k radiocarbon calibrated years before present (years cal BP) (Bar-Yosef et al., 1996; Rebollo et al., 2011).

KENNEWICK MAN

Gary Huckleberry
Department of Geosciences, University of Arizona, Tucson, AZ, USA

Definition

Kennewick Man is a ∼9,200-year-old skeleton that became the focus of a legal battle over interpretation of US law regarding disposition of ancient human remains.

Human skeletal remains discovered in 1996 along the shore of Lake Wallula (Columbia River) in Kennewick, Washington, yielded a $\delta^{13}C$-corrected radiocarbon age of 8,410 ± 60 years BP, making it one of the oldest, well-preserved skeletons from the Pacific Northwest (Chatters, 2000). Preliminary analysis indicated that the skull morphology did not match modern Native Americans, generating considerable public and scientific debate. Several Northwestern Native American tribes requested that the skeletal remains be immediately repatriated, citing the 1990 Native American Graves Protection and Repatriation Act (NAGPRA). The federal government announced its intention to give the skeleton to representatives of local tribes for reburial, but a group of scientists filed suit (Bonnichsen et al. vs. US Government) and argued that the skeleton should be retained for scientific study.

In order to gain contextual information on the skeleton, a preliminary geological study of the discovery site was conducted in 1997 (Wakeley et al., 1998; Chatters, 2000). The shore of Lake Wallula exposes a Holocene alluvial terrace of the Columbia River. Contained within the alluvium was a volcanic ash layer identified as the 7,600-year-old Mazama tephra. A soil that had developed within the terrace beneath the Mazama tephra contained secondary carbonate nodules similar to those that were described as adhering to the skeleton. The preliminary interpretation was that the skeleton had eroded out of alluvial deposits located stratigraphically beneath the Mazama tephra, but that more detailed analysis of the site and skeleton were needed to test this hypothesis. The site was buried by the Army Corps of Engineers (ACE) in 1998 before the study could be completed.

In 1999, the US Department of the Interior (DOI) selected a team of scientists not included in the lawsuit to perform a series of tests to help determine the applicability of NAGPRA to Kennewick Man (www.nps.gov/archeology/kennewick/). Although the discovery site had been covered by the ACE, it was possible to analyze sediments adhering to the skeleton and compare them with stratigraphic information obtained during the site investigation. Granulometric, mineralogical, and chemical analyses were conducted on sediments that were removed from the exterior of several postcranial elements and that had been collected from the site during the initial investigation. In addition, micromorphological analysis was performed on an intact aggregate of sediment from within the skull. Results of this forensic geoarchaeological study reaffirmed that Kennewick Man originated from pre-Mazama alluvium and was quickly buried by ancient sediments after death (Huckleberry et al., 2003).

Further radiocarbon testing on bone confirmed that the skeleton was ∼9,200 years old. The case eventually went to trial, and a federal court decision was rendered in 2002 stating that cultural affiliation could not be determined for such an ancient skeleton and that plaintiff scientists could study the skeleton. Results of biometric, chronometric, isotopic, and taphonomic analyses conducted by plaintiff scientists and colleagues are detailed in Owsley and Jantz (2014). Meanwhile, Kennewick Man remains locked in a vault in the Burke Museum, University of Washington, Seattle. For different perspectives regarding Kennewick Man and NAGPRA, see Thomas (2000), Bruning (2006), Burke et al. (2008), and Weiss (2008); also see Friends of America's Past (www.friendsofpast.org).

KOSTENKI, RUSSIA

Vance T. Holliday[1] and John F. Hoffecker[2]
[1]Anthropology and Departments Geosciences, University of Arizona, Tucson, AZ, USA
[2]INSTAAR (Institute of Arctic and Alpine Research), University of Colorado, Boulder, CO, USA

The Kostenki-Borshchevo localities include 26 Upper Paleolithic open-air sites in well-stratified contexts along the Don River, ~40 km southwest of the Russian city of Voronezh on the East European Plain (Holliday et al., 2007). The well-expressed and relatively uniform stratigraphy among these sites has long been recognized by field investigators (e.g., Lazukov, 1957; Velichko, 1961; Grishchenko, 1976; Sinitsyn et al., 1997; Kholmovoi and Nesterova, 2001) and has been a primary means of correlating the many occupation sequences (e.g., Praslov and Rogachev, 1982). Prior to the development of numerical dating methods, stratigraphy was the only means of establishing the relative chronology (Rogachev, 1957).

Study of the Kostenki-Borshchevo sites had a significant impact on Paleolithic archaeology in Eastern Europe (Klein, 1969, 26–31; Hoffecker, 2002, 148–151). The initial discovery of stone artifacts and mammoth bones at Kostenki 1 in 1879 helped document the presence of Paleolithic people in Russia, and since that time, many prominent Soviet and Russian archaeologists have worked at these sites (Praslov, 1982). Much of the investigation prior to World War II was focused on the spectacular feature complex and associated remains in the uppermost layer at Kostenki 1 (Efimenko, 1958). The emphasis on broad horizontal excavations and mapping of former dwellings and other features (termed the "Kostenki School") promoted the analysis of Paleolithic social and economic patterns many years before this became a focus of research in Western Europe. After World War II, A. N. Rogachev and several geologist colleagues expanded the study of earlier Upper Paleolithic remains and their stratigraphic context (Lazukov, 1957; Rogachev, 1957), and in recent years, it has become clear that the primary importance of the Kostenki sites lies in their early Upper Paleolithic record, which contains evidence of Upper Paleolithic occupation of the East European Plain before 40,000 years ago (e.g., Anikovich et al., 2007).

Most of the Kostenki-Borshchevo sites are on the first and second terraces along the west bank of the Don River. Recent geoarchaeological research (e.g., Holliday et al., 2007) focused on the sites of Kostenki 1, 12, and 14, with more limited work at Kostenki 8, 11, 16, and 17, and Borshchevo 5. The strata are grouped into three units, described here from the bottom up. Unit 1, >50 cal ka, consists of coarse alluvium (representing upper terrace 2 deposits) and colluvium, overlain by fine-grained sediments. Unit 2 includes archaeological horizons sealed within two sets of thin lenses of silt, carbonate, chalk fragments, and organic-rich soils (termed *lower humic bed* and *upper humic bed*) dating 50–30 cal ka. Several horizons buried in the lower part of Unit 2 contain Upper Paleolithic assemblages. Separating the humic beds is a volcanic ash lens identified as the Campanian Ignimbrite Y5 tephra, dated elsewhere by Ar/Ar to ca. 40 cal ka (Pyle et al., 2006; Giaccio et al., 2008). The humic beds appear to result from the complex interplay of soil formation, spring deposition, slope action, and other processes. The springs and seeps, which are present in the area today, emanated from the bedrock valley wall. Their presence may account for the unusually high concentration of Upper Paleolithic sites in this part of the central East European Plain. Unit 3, <30 cal ka, contains redeposited loess with a buried soil (*Gmelin soil*) overlain by a primary full-glacial loess with an associated Chernozem (Mollisol), forming the surface of the second terrace.

KOSTER SITE, ILLINOIS

Edwin R. Hajic
GeoArc Research, Inc., Santa Fe, NM, USA

Koster site

Koster (11GE4) is an archaeological site located at the foot of the eastern bluff line of the lower Illinois River Valley in west central Illinois, USA (Brown and Vierra, 1983). It contains at least 23 stratigraphically distinct Early Archaic to Mississippian cultural deposits buried to depths in excess of 10 m. The site provides a nearly continuous Holocene record of deposition, soil formation, and human occupation, and between 1969 and 1978, it became the cornerstone of pioneering interdisciplinary research conducted by the Foundation for Illinois Archeology, Northwestern University, and the Center for American Archeology. Recognizing the significance of buried pristine cultural deposits rich in plant and animal remains with a cumulative record that spanned more than eight millennia at a single location, Stuart Struever and James Brown focused their research on identifying cultural adaptations (e.g., social, economic, technological) and exploring their links to changing Holocene climate and valley environments. In the process, cultural phases of the then little known Archaic period were defined.

Within this cultural framework, major advances applicable to the midcontinent and beyond – all based on the Koster artifact and feature record and local and regional paleoenvironments – were made in understanding cultural adaptations that culminated in the more complex later woodland cultures. Evidence for what at the time were the earliest Midwest house floors, along with thick middens and diverse artifact assemblages, changed ideas about Archaic sedentism and settlement patterns. Not only did archaeobotanical remains reveal the earliest origins of regional cultivation, but they provided evidence for the rise of broad-spectrum subsistence patterns in hunter-gatherer lifeways, with attendant behavioral strategies and patterns for environmental exploitation. Evidence from skeletal remains was used to examine human responses to environmental stresses and changes in social status (Buikstra, 1981).

Koster also is significant in being one of the earliest experiments in a large-scale interdisciplinary archaeological undertaking aimed at understanding cultural adaptations to changing climate and landscape at different scales (Struever and Holton, 1979). Along with archaeologists, the research team included specialists in archaeobotany, malacology, palynology, geology, and computers. Struever also actively engaged the public through field schools and other educational programs, using the high-profile Koster site to draw attention to regional interdisciplinary research at numerous sites in the Lower Illinois Valley.

In addition to its contributions to the interpretation of the archaeological record, Koster provided ideas to advance deep site excavation techniques and design, including deep macroblock excavations. Dewatering wells were installed to draw down the water table and make excavation possible at depth. Conveyor systems and bulldozers were utilized to remove backdirt. Flotation sample collection and processing techniques were improved and then systematically and uniformly applied during years of excavation. Piece-plotting of all artifacts and debris was employed as a large-scale experiment.

Cultural deposits at Koster are buried and preserved within a southeast-facing prism of valley margin colluvium, situated within the mouth of a small bedrock valley occupied by Koster Creek, and an associated alluvial fan. Colluvial and fan deposits consist almost entirely of silt derived from loess eroded from surrounding uplands by raindrop and sheetflood processes and deposited by sheetflood sedimentation. The entire alluvial fan and part of the colluvial wedge aggraded on a late Pleistocene terrace of the Illinois River valley. Koster Creek drains into a paleochannel lake basin on a second, younger pre-Holocene terrace beyond fan limits. Thus, evolution of the entire Holocene Koster slope/fan depositional system, while open, was independent of, and isolated from, Holocene geomorphic fluvial change in the Illinois Valley.

Forty-four radiocarbon ages from macroblock excavations primarily in colluvium document moderate sedimentation rates for the early Holocene, with a pattern of initially rapid but overall declining sedimentation rates from about 8450 ^{14}C yr BP through the remainder of the Holocene. Superimposed upon this is a series of at least seven sediment-soil cycles, individually characterized by continuous sedimentation at progressively decreasing rates (Hajic, 1990). Most cycles culminate in cumulic A horizons built up over a period on the order of several hundred years, as sedimentation never actually ceased. The oldest and two youngest cycles culminate in soils with structural B horizons that developed on the order of 500–1500 years under a regime of limited sediment accumulation. Most of the younger buried soils are truncated by sheetflood erosion, accompanied by gullying and development of stone lines of cultural debris. All buried soils have associated distinct cultural deposits, but a greater number of distinct cultural deposits are not associated with soil sola (i.e., A and B horizons that were created by the same soil-forming processes; singular = solum). Anthropogenic enrichment of buried soil A horizons is common.

The character of the sediment sequence at Koster is the result of a combination of extrinsic and intrinsic factors operating at different time scales (Hajic, 1990). Overall decreasing sedimentation rate throughout most of the Holocene is attributed largely to changing geometric relationships between eroding loessial slopes and the colluvial slope, although changes to and from more open vegetation on hillslopes with less than a 4° degree slope at the onset and end of the middle Holocene, respectively, are a contributing factor. The timing of individual sediment soil cycles at Koster corresponds with other colluvial records in the lower Illinois Valley region and broadly with alluvial fan records as far west as western Iowa (Wiant et al., 1983). Regional patterning in colluvial sedimentation during the Holocene compared to independent regional paleoenvironmental records suggests there is a biogeomorphic response to a shift toward more arid conditions that improves the effectiveness of raindrop and sheetflood erosion, thus initiating an increase in soil erosion of upland slopes and colluvial slope sedimentation that marks the beginning of each cycle. Slowing sedimentation rates culminating in soil formation reflects a gradual shift back toward relatively wetter conditions. Late Holocene erosional episodes that truncate soils and some cultural deposits are an intrinsic response to the eclipse of a threshold colluvial slope angle between 7° and 9°.

LA MICOQUE

Christopher E. Miller
Institute for Archaeological Sciences, Senckenberg Centre for Human Evolution and Paleoenvironment, University of Tübingen, Tübingen, Germany

La Micoque is a Paleolithic site located in the Dordogne region of southwestern France. The site is well known for its Acheulian and particularly its Middle Paleolithic artifacts. The site lends its name to the Micoquian industry of stone tools.

Situated along the left bank of the Manaurie valley, 500 m from its confluence with the Vézère River, La Micoque sits below a cliff of Coniacian limestone (Late Cretaceous). The site was first discovered in 1895 by the landowner and subsequently excavated by Chauvet and Rivière in 1896, Capitan in 1896, Harlé in 1897, Peyrony in 1898 and 1929–1932, Coutil in 1903–1905, Cartailhac in 1905, and Hauser in 1906–1907. Bordes excavated the site in 1956, and it was most recently investigated by Debénath and Rigaud between 1983 and 1996.

The lowest cultural layers contain the transition from Acheulian to Mousterian industries (the so-called Tayacian), which has been dated by Electron Spin Resonance (ESR) on horse teeth to between 241 ± 15 and 288 ± 10 ka (Schwarcz and Grün, 1988). The site also contains small, elongated, bifacially worked hand axes, known as Micoquian-type hand axes, in addition to scrapers with quina retouch and Mousterian points.

Capitan and Hauser were the first excavators to describe the stratigraphy (Capitan, 1896); however, the stratigraphic system of Peyrony, first established in 1933, has become the standard for the site (Peyrony, 1938). He defined several horizontal layers, starting with A at the base and finishing with M at the top. He identified layers with angular limestone clasts as *éboulis* (rock scree or talus) and layers with rounded cobbles as having a fluvial origin. Breuil (1938) criticized Peyrony's interpretation of the rounded cobbles and suggested that their rounding was a result of cryoclastism related to cryoturbation and solifluction. Bordes, Laville, and Rigaud adopted this interpretation and suggested that the deposits formed within a rock-shelter, whose roof no longer exists (Laville, 1973, 197–226). La Micoque became a key site for the development of Laville's climatostratigraphic synthesis of cave and rock-shelter sequences in southwestern France. At La Micoque and other sites, he interpreted the *éboulis* layers as representing cold, glacial periods and the reddish sandy-clay layers as representing in situ formation of soils during interstadials and interglacials.

Texier, in a recent reassessment of site formation processes at La Micoque (2009), questions most of the previous interpretations. Like Peyrony, he argues, based on sedimentological data, that the majority of the site was formed by fluvial action, as indicated by rounded grains and cobbles, graded bedding, and cross-stratification. Some diamictic layers, formed by colluvation, originated from the limestone cliff backing the site. Taken together, the geoarchaeological evidence strongly suggests that La Micoque is not a former rock-shelter, but rather the remnant of a former fluvial terrace of the Manaurie River, now a small stream.

LAKE MUNGO AND WILLANDRA

Jim Bowler
Earth Sciences, University of Melbourne, Parkville Campus, VIC, Australia

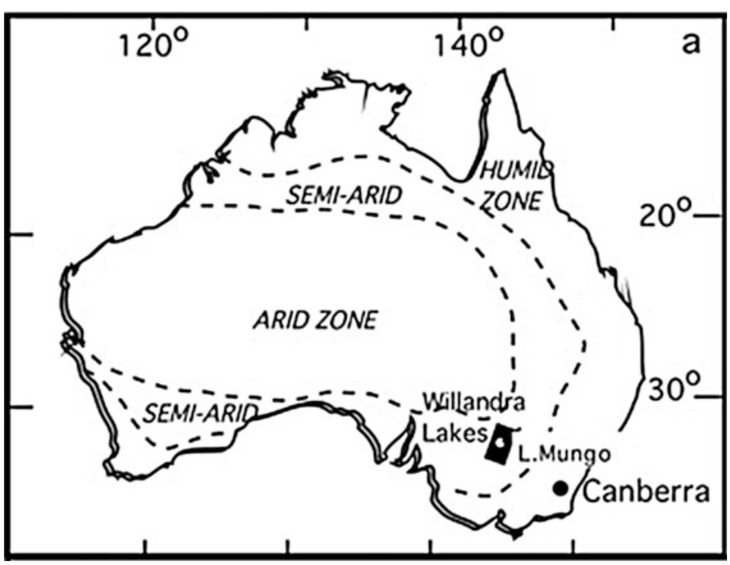
Definition and introduction

Lake Mungo is located in western New South Wales, Australia (Figure 1), and represents a dry lake bed that forms part of the Willandra Lakes Region, a series of 19 relict lake basins which was named in 1981 a World Heritage Site for both natural and cultural value. At Lake Mungo, early evidence of human occupation has been found within the large and presently eroding dune, or lunette, that lies along the eastern shore of the former lake. Also at Lake Mungo, geoarchaeology has played a major role in helping to establish the date and ancient environment within which the early inhabitants lived.

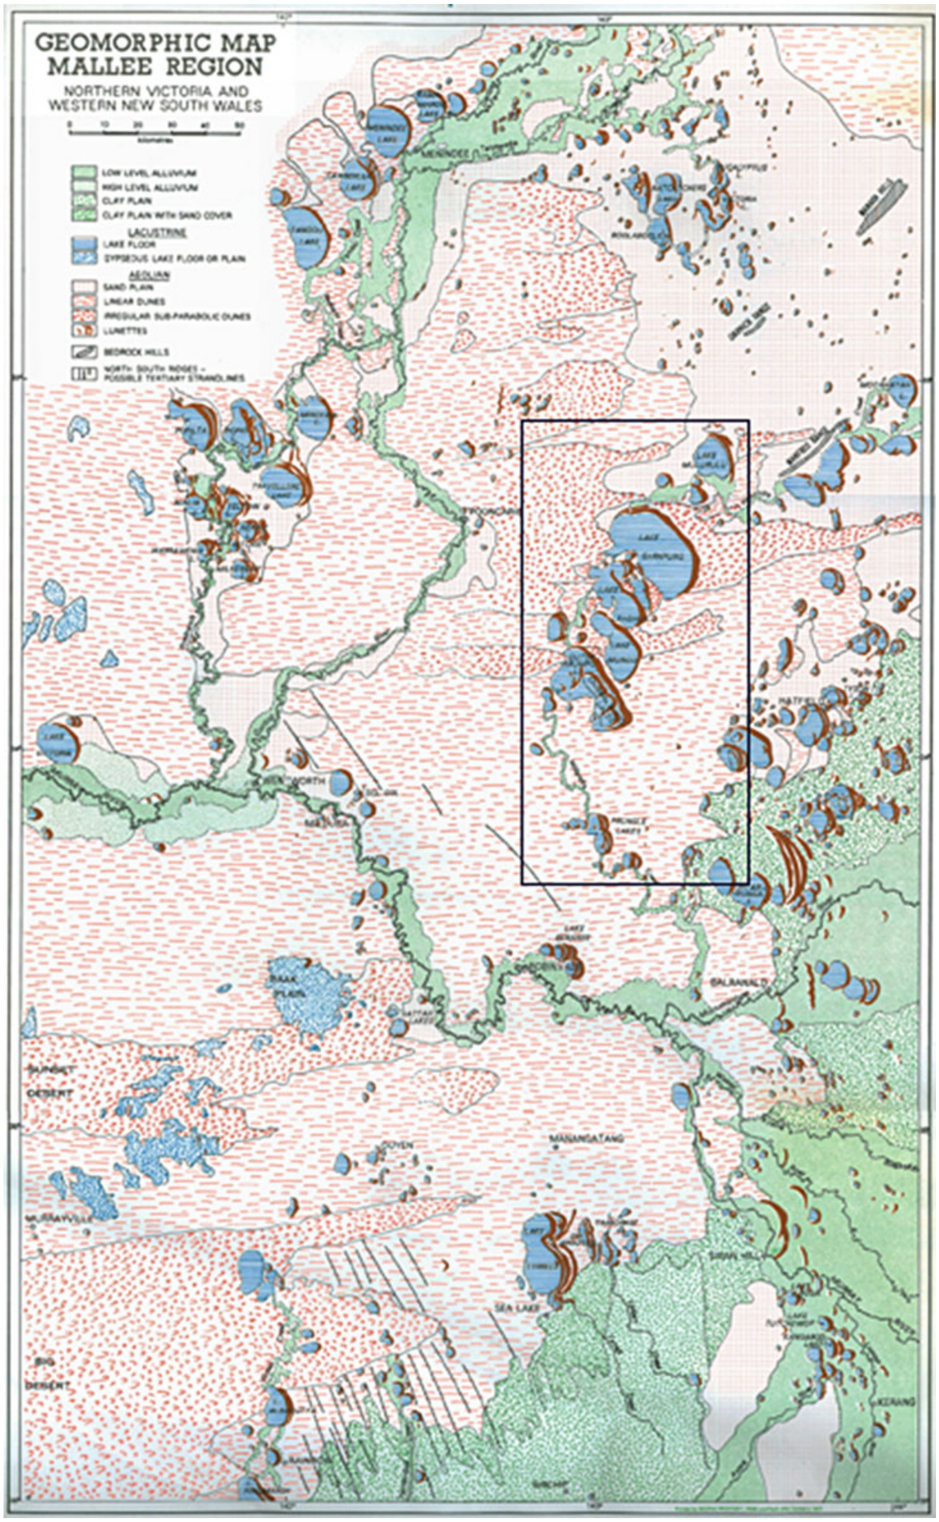
Lake Mungo and the Willandra Lakes Region in which it lies are in some ways analogous to the African Rift Valley sites. Both are open, vast in expanse, and deep in time scale. Both require expansive geomorphic mapping as well as detailed stratigraphic analyses. At Lake Mungo, joint teamwork in geology and archaeology has been highly successful in reconstructing habitation in early Australia.

The Willandra Lakes landscape preserves a series of dry basins formerly supplied by the Lachlan River, which derived its waters from catchments in the southeastern highlands near Canberra (Figure 2). These lake basins were mapped and named in the course of a paleoclimatic study of lakes and dunes of the last glacial cycle (Bowler, 1971). The incipient stages in the growth of the Mungo lunette date from 150,000 years ago (Bowler and Price, 1998), when the large crescent-shaped dune along the eastern lake margin began to form from the blowing of sand off the lakeshore (Figures 3 and 4). Understanding of these lakes was made possible by the definition of lunette formation processes (Bowler, 1973). Lunette landforms are of special relevance, as they (1) record hydrologic change in their internal alternation of sand layers deposited during moist periods and clay layers laid down during dry phases and (2) the alkalinity of their sediments that has proved favorable to the preservation of archaeological remains.

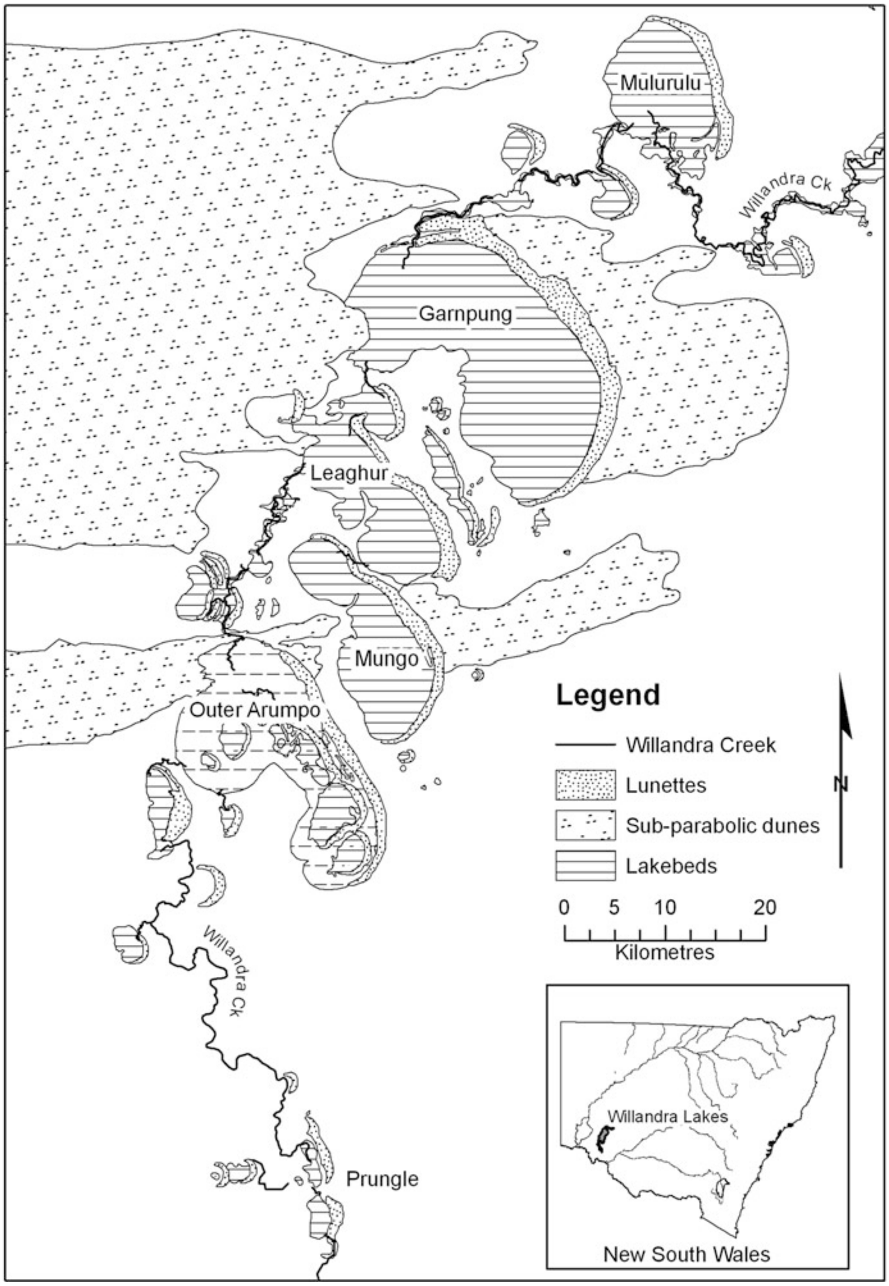
The Golgol layer in which the lunette began was followed by the Mungo layer (50–25 ka), which saw the arrival of human groups that settled along the lake margins



Lake Mungo and Willandra, Figure 1 Map showing the location of the Willandra World Heritage Region in semiarid southeastern Australia.

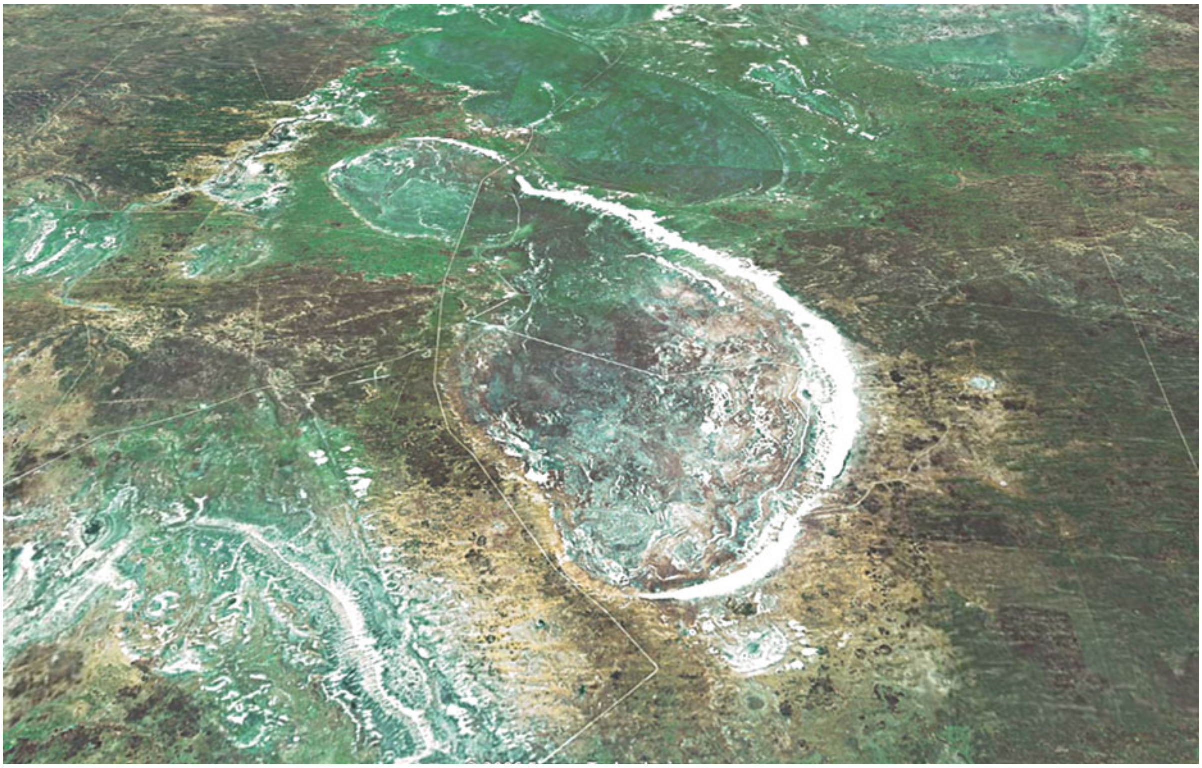


Lake Mungo and Willandra, Figure 2 Geomorphic map of the Mallee dunefields and lunette-lake basins in southeastern Australia. Lying northeast of the Darling and Murray River confluence, the Willandra lakes were fed by a former Lachlan River channel.

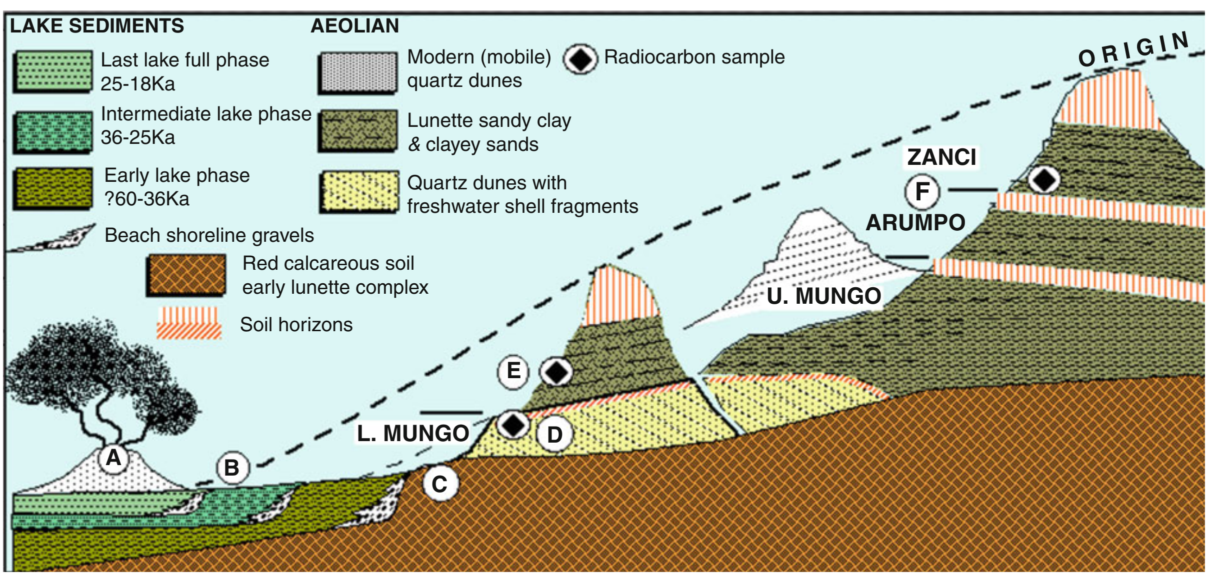


Lake Mungo and Willandra, Figure 3 The Willandra chain of lakes forms a linking overflow system set within fossil dunefields. Lunettes on the eastern sides preserve a 50,000-year record of human occupation in the context of Ice Age environmental change.

within the growing lunette. The Mungo layer is the most archaeologically significant, as its evidence for human colonization is the earliest known to date in Australia. The slopes of the dunes remained mostly stable with vegetation cover over long periods, but draining and drying of the lake starting at the Last Glacial Maximum, ca. 20–18 ka (Bowler, 1998), exposed the slopes to winds that began mobilizing the dunes and eroding them severely, so that the buried remains continuously become exposed and, as in the African Rift Valley, visible to archaeologists (Figure 5). Presently, erosion by high-intensity storms provides both positive and negative opportunities: positive in the sense that huge areas of sediments are constantly worn down presenting new surfaces for inspection, but negative in the sense that cultural materials, once exposed, are rapidly destroyed by later storm events unless they are found, evaluated, and where necessary preserved or collected.



Lake Mungo and Willandra, Figure 4 Oblique satellite view looking north over Lake Mungo. The lunette extends 25 km along the eastern lakeside and is subject to intensive erosion, which continuously reveals a rich tapestry of geological and archaeological information. The location of the main burial sites lies near the southern termination of the lunette. Image from Google Earth.



Lake Mungo and Willandra, Figure 5 Diagrammatic cross section through the eastern side of the Lake Mungo lunette. Layered lunette sentiments deflated from the lake floor lie downwind of the lakeshore beach and gravel facies. Episodic changes spanning the last 60,000 years (Mungo to Zanci age units) are inset into the older Golgol unit dating to the previous glacial cycle.

In 1969, the partially cremated remains of a young woman – Mungo Lady – were found deep within the lakeshore lunette, and this discovery opened the door to a new phase of Australia's archaeological history (Bowler et al., 1970). Soon after, in 1974, an articulated and ochre-anointed male burial was uncovered nearby – Mungo Man – and this new find brought increased attention and significance to the site. Both burials indicated ritual behavior, and they were dated to 41,000 years ago (Bowler et al., 1972, 2003; Gillespie, 1998).

In 2003, the discovery of a complex of human footprints (Webb et al., 2006) preserved in saline muds of the Zanci layer just south of the Lake Garnpung basin and dated to around 21 ka by OSL added a new component of international interest. The hardpan into which the footprints were impressed comprises layers of silty clay cemented by an unusual mineral, hydromagnesite. Erosion had exposed 89 of the 123 human footprints at the moment of discovery, most of which form eight different tracks. The substrate on which the humans walked must have been unconsolidated and intermittently wet as it took mostly excellent impressions of feet belonging to a range of individuals that included adults and children.

Summary

The Willandra basins and Lake Mungo constitute a widespread and open archaeological region containing dry lands undergoing active erosion; this erosion provides almost continuous surface exposures. The remains uncovered are of high archaeological value and provide unique opportunities to bring together both natural and cultural history to elucidate patterns of past human-land interaction, which are among the earliest known in Australia. In addition to its science, the region has immense social value in building reconciliation bridges between modern white communities and today's Aboriginal Australians.

LANDSCAPE ARCHAEOLOGY

Tim Denham
Archaeological Science Programs, School of Archaeology and Anthropology, The Australian National University, Canberra, ACT, Australia

Definition

Landscape archaeology refers to the understanding of archaeological remains (artifacts, sites, and site complexes) in terms of the wider spatial realms (both physical and meaningful) of past human experience.

Introducing landscape

"Landscape" is an integrated term that encapsulates the environmental and human aspects of a bounded area of land. The environmental aspects include the combined effects of climate, hydrology, landforms, vegetation, and fauna. The human imprint reflects the cumulative effects of cultural processes that have occurred through time, including: the histories of vegetation disturbance, clearance, and planting; earthmoving; settlement; pollution; and so on. In addition to the physical aspects of past landscapes – in terms of both environmental and human processes – a landscape is explicitly or implicitly associated with layers of human meaning and value.

A landscape represents an amalgam of different processes operating over disparate timescales. For instance, landforms and the rocks that comprise a landscape may have formed over million- or billion-year timescales, whereas vegetation and buildings may reflect processes over much shorter annual to centennial timescales.

The boundary (physical) and boundedness (cultural) of a landscape are usually poorly defined and diffuse, both in the abstract and with respect to a particular landscape in the present or the past. Namely, it is often impossible to demarcate clearly a boundary for a landscape on a map, and it is usually impossible for someone standing within a landscape to indicate clearly where one landscape ends and another begins. Despite this ambiguity, the landscape represents an intermediate spatial scale; it is larger than a site or site complex but smaller than a region. In many ways, the landscape represents a human scale of lived experience. Most people, whether they live in a postindustrial, industrial, or traditional society, spend most of their lives within a bounded area, which could be referred to as the landscape of everyday experience.

In sum, a landscape reflects a combination of environmental and human processes that have operated through time and across space. Today, no landscapes are free from the direct or indirect effects of human-induced modification, although the degree and nature of these influences vary greatly. Landscapes are also imbued with layers of cultural meaning that have accrued to the present.

A brief history of landscape archaeology

David and Thomas (2008a, 38) have suggested "landscape archaeology is . . . concerned with the things that locate human existence." Although conceptually appropriate, such a scope is too broad to be methodologically useful or applicable. In many ways, and for most of history, the landscape represented a "human scale" of past lived experience (Denham, 2008). Indeed, the term "landscape" implies a meaningful place for the inhabitants, visitors, or viewers. People lived, and continue to live, in landscapes, even though the physical scale and the degree of mobility within and between landscapes have changed through time. Consequently, landscape archaeology can be considered to be the study of artifacts, features, sites, and site complexes within the broader spatial realms – both physical and meaningful – of past human experience.

Landscape archaeology has undergone considerable transformation and augmentation since it was first coined and applied in the mid-1970s (Aston and Rowley, 1974; David and Thomas, 2008a). Although archaeological concerns with "landscape" are much older, Aston and Rowley's text marks the emergence of "landscape archaeology" as a subdiscipline. From the 1970s onward, various incarnations of landscape archaeology have reflected to a large degree the general trends in archaeological theory within the discipline as a whole. Rather than sequentially replacing each preceding trend, subsequent perspectives have tended to augment the purview of landscape archaeology, resulting in a broad array of conceptual and methodological approaches (Ashmore and Knapp, 1999; David and Thomas, 2008b).

Initially, landscape archaeology was associated with various streams of archaeological science, environmental archaeology, and spatial analysis, reflecting the dominance of processual thought or New Archaeology. These types of approach have tended to focus upon the distributions of artifacts and sites across an area, primarily with respect to environmental features such as landforms, hydrology, soils, and vegetation (e.g., Torrence, 2002). They have also tended to incorporate perspectives from environmental archaeology or geoarchaeology (e.g., Denham, 2008). Explanatory models have prioritized environmental, ecological, economic, and social interpretations to understand observed distributions.

To exemplify, changing human use of the lunette (sand dunes of the eastern shore) at Lake Mungo in rural New South Wales, Australia, has been articulated in terms of fluctuating climates and ensuing lake levels from ca. 50,000 to 46,000 years ago (Bowler et al., 2003). Interpretations of archaeological remains, including human burials, have necessitated a spatial understanding of lunette formation through time. Ongoing investigations are now focusing upon detailed histories of landscape formation and human subsistence for sections of the lunette (pers. comm., Nicola Stern, 2012).

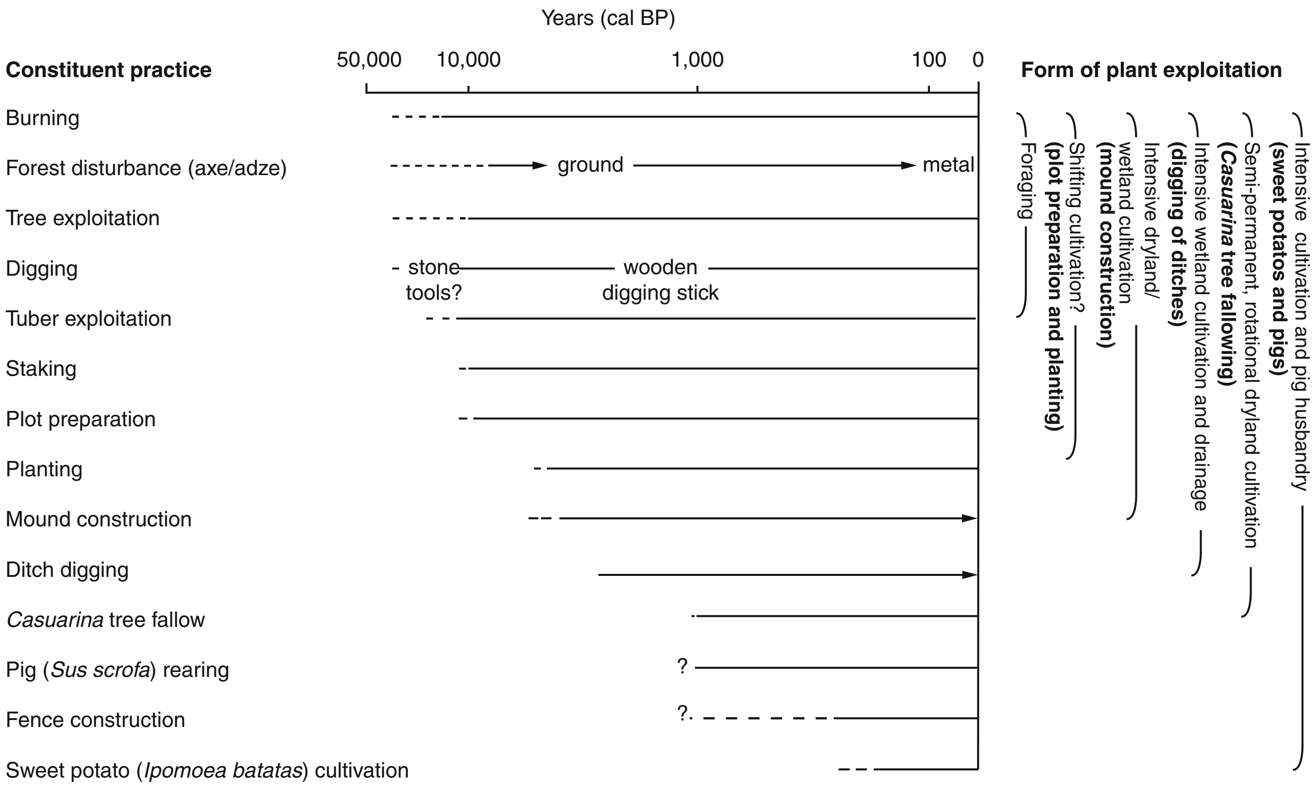
In recent decades, landscape archaeology has broadened to include an array of emergent perspectives including ethnoarchaeology (Ballard, 1994); humanistic, phenomenological, and symbolic interpretations (Tilley, 1994; Bradley, 2000); and political and indigenous critiques (Bender, 1993). These perspectives draw on diverse intellectual traditions to prioritize the meanings attributed to places, including the distribution of archaeological finds within the landscape. Although sometimes criticized, these approaches to landscape archaeology usually represent serious attempts to convey a sense of the ways people were connected to places in the past.

Following the above, landscape archaeology can be viewed as having two main streams: (1) the empirical aspects of human-environment interactions within a bounded area in the past and (2) the ways in which archaeologists today consider landscapes to have been meaningful to the people who inhabited them in the past. A third minor theme, not dwelt upon here, is the study of landscapes and landscape depictions as historical, political, symbolic, or colonial representations; this is a relatively recent development within archaeology that can trace its intellectual roots to geography (Cosgrove and Daniels, 1988; Cosgrove, 1998).

Landscape as a product of human-environment interactions

Landscape archaeology is primarily concerned with the environmental context of human activities in the past. Here, landscape is taken in terms of its physicality. Consequently, aspects of landscape archaeology mirror those of environmental archaeology and geoarchaeology in seeking to characterize how past environments structured, and have in turn been structured by, past human behavior. Accordingly, landscape archaeology is concerned with the recursive and mutually determining nature of human-environment interactions in the past.

In terms of a differentiating characteristic, landscape archaeology takes as its object of study how past human activities occurred and were structured *across* space within a bounded area, rather than at the scale of individual sites or at the scale of interregional and intercontinental comparison. In this way, landscape archaeology



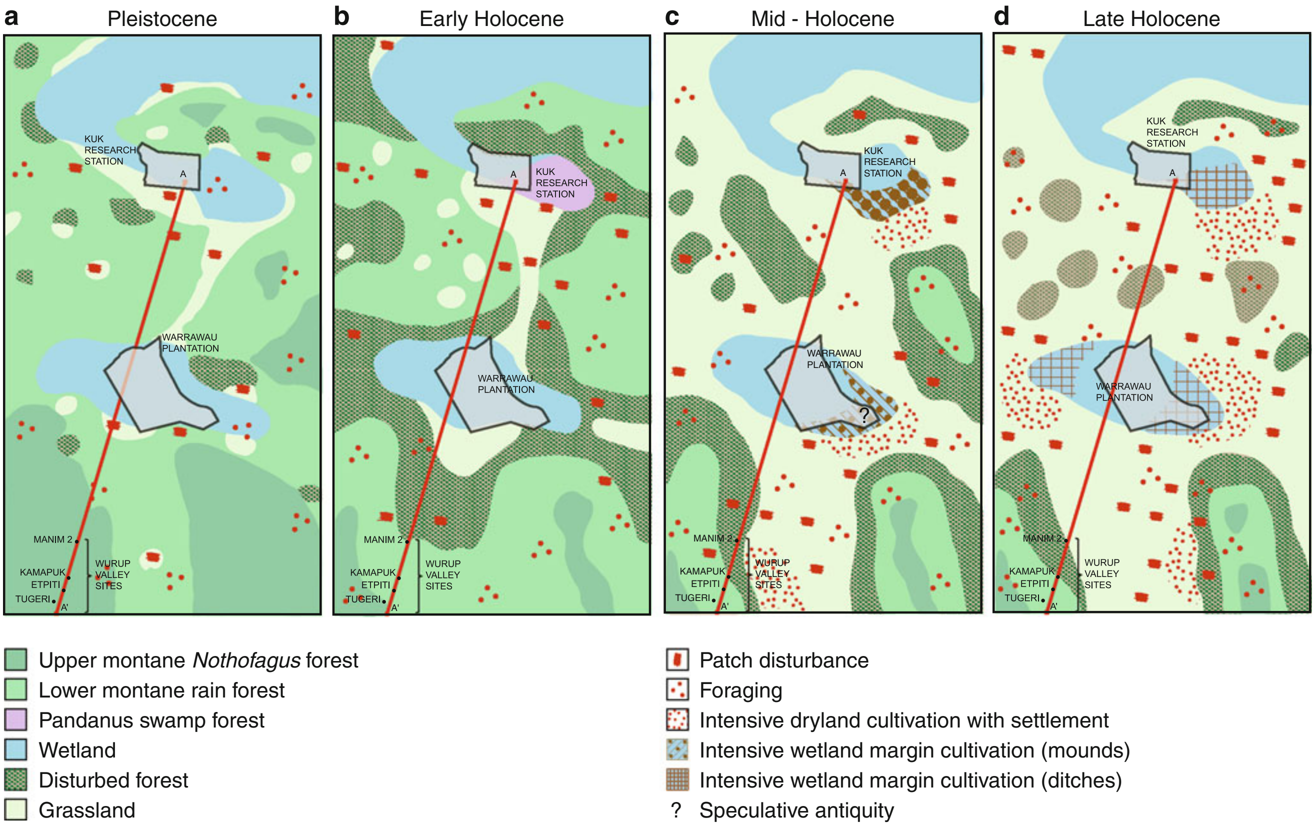
Landscape Archaeology, Figure 1 Chronology of practices and forms of plant exploitation reconstructed for the Upper Wahgi Valley, Papua New Guinea, using multidisciplinary lines of evidence.

provides a middle scale of analysis linking finds and formation processes at individual sites to larger-scale trends. Landscape archaeology is not just an intermediate spatial scale of analysis; it also provides a methodological bridge comparable to, but different from, intermediate conceptual formulations such as middle-range theory (Raab and Goodyear, 1984) and contextual or reflexive archaeology (Hodder, 1999).

A useful methodological tool to unravel the complexities of how people lived in a landscape is the concept of "practice" (Bourdieu, 1990; Barrett, 1994; Denham, 2008; Jusseret, 2010). In archaeology, practices represent human actions in the past, including habitual modes of behavior and dispositions, as well as individual idiosyncrasies. Practices become inscribed in the landscape through time, providing sequential evidence of human-environment interactions in the past. The concept of practice is a useful way to overcome various dualisms, or binary divisions, that permeate the study of human-environment interactions in the past and present, because practices represent the nexus of these interactions (Denham, 2008).

Evidence of practices can be derived from multiple disciplines, each with its own methodological limitations. For example, archaeological and geophysical surveys provide information on the distribution of archaeological materials across the surface and subsurface, respectively, of a landscape. Archaeological excavations provide chronologically specific site-based information, although in some cases, large expanses of a landscape can be exposed and excavated simultaneously. In contrast, paleoecology provides a conflated record of vegetation history and burning for a local and extra-local area that can be used to infer what people were doing in the past but with varying degrees of chronological and geographical specificity. Taken together, archaeological and paleoecological records can provide robust reconstructions of how people lived in and changed landscapes through time.

To exemplify, multidisciplinary evidence at several occupation and wetland archaeological sites in the Upper Wahgi Valley of the Papua New Guinea highlands has enabled a chronology of practices to be reconstructed (Figure 1; Denham and Haberle, 2008; Denham, 2009). Different disciplines provide evidence of different types of practice in the past; for example, paleoecological records indicate burning in the Late Pleistocene; archaeological excavations show evidence for numerous practices, including digging, planting, and fencing; and residue analysis indicates the exploitation of tuberous plants in the early Holocene. Individual practices can be bundled together to show how agriculture emerged and was transformed in the Upper Wahgi Valley through time.



Landscape Archaeology, Figure 2 Landscape reconstructions for multiple time slices in the Upper Wahgi Valley landscape: (**a**) terminal Pleistocene, ca. 12,000 cal BP; (**b**) early Holocene, ca. 9,000 cal BP; (**c**) mid-Holocene, ca. 6,500 cal BP; and (**d**) late Holocene, ca. 2,500 cal BP (Denham and Haberle, 2008: Figure 6). The *red line* is 17 km long, and several archaeological sites along this transect are named. Note the different land use practices across the landscape, ranging from localized patch disturbance to intensive cultivation, and the resultant transformations of vegetation, ranging from disturbed montane rainforest in the Pleistocene to extensive grasslands from the mid-Holocene.

The same multidisciplinary evidence can be represented spatially to illustrate how people lived across the landscape at specific times in the past (Figure 2). Although creative, these synchronic reconstructions, or time slices, rely upon relatively high-resolution records from several archaeological sites, including rock-shelters and wetland sites, as well as paleoecological records from multiple sites. The multidisciplinary records shed light on the types of practice occurring in, as well as the effects of those practices upon, different parts of the landscape. These reconstructions provide readily interpretable impressions of how people lived in landscapes in the past.

The meanings of landscape

Landscape archaeology has increasingly become concerned with the ways in which past landscapes, or the places people inhabited, were meaningful to the people who lived there. Here, the landscape is not conceived in terms of its physicality, but as a meaningful realm of past human experience (following Relph, 1976). Such perspectives invariably shift the emphasis from physical remains of past human activities to more conceptual and interpretative concerns. They should still be reliant, however, on the spatial distribution of archaeological remains together with any associated paleoenvironmental data to infer how people meaningfully conceived, lived in, and used that landscape.

The interpretation of the human dimension within landscape archaeology leads away from an empirical basis to more interpretative concerns in order to infer the ways in which people made their world meaningful. In these types of phenomenologically-informed archaeological discourses, the term "world" does not refer to the realm of entities and things as they physically occur in time and space, namely, the empirical world; rather, it refers to realms of meaning, namely, as things and entities are made meaningful and understood by people. Phenomenologically informed landscape archaeologies are diverse and draw on a range of different concepts, including embodiment, temporality, place, sensory experience, and poetics (Tilley, 2008).

To exemplify, renewed excavations at Stonehenge and other monuments of the early Wessex landscape in southern England have employed ethnographic analogies to infer how the landscape was meaningful to people in the past (Parker Pearson et al., 2006). Different monuments and landforms have been mapped and archaeologically investigated to infer the ways in which people of the mid-third millennium BC conceived domains of the living and domains of the dead within the landscape. From this perspective, the stone structures at Stonehenge are associated with the dead, whereas comparable timber structures at Durrington Walls, Britain's largest henge monument, are associated with ceremonies for the living.

Although most clearly articulated in post-processual debates, the adoption of perspectives to understand or rationalize past human behaviors has, either explicitly or implicitly, always been part of archaeological interpretation. Earlier debates tended to focus on the economic and ecological determinants of human behaviors, such as resource exploitation, whereas more recent decades have witnessed considerable diversification in interpretative frameworks. Phenomenologically-informed perspectives have been at the forefront of conceptual developments within landscape archaeology.

Summary: bridging the divide

Although the two main streams of landscape archaeology appear to be very different, they are complementary and should be considered to represent different emphases. Any historical understanding of landscapes in their physicality, namely, as empirical phenomena, necessitates an interpretation of how they formed or how they came to be; namely, there is always a desire to understand "how" and "why" people engaged in certain types of activity in the past. Similarly, any interpretation of how landscapes may have been meaningful to past inhabitants should be structured by knowledge about changing human-environment interactions within those landscapes in the past. Both approaches to landscape archaeology are predicated on empirically derived knowledge of past human-environment interactions, as well as upon interpretations that seek to understand human behavior in the past, that is, how past landscapes were meaningful to the inhabitants.

LEAD ISOTOPES

A. Mark Pollard
Research Laboratory for Archaeology and the History of Art, School of Archaeology, University of Oxford, Oxford, UK

Definition

Lead isotopes. The four stable isotopes of lead are ^{204}Pb, ^{206}Pb, ^{207}Pb, and ^{208}Pb. In geochemistry, the isotopes are usually measured and discussed as the ratios to the ^{204}Pb value, but in archaeology, the ratios of ^{206}Pb/^{204}Pb, ^{206}Pb/^{207}Pb, and ^{208}Pb/^{207}Pb are used.

Provenance. For a metal object, the term refers to the metalliferous ore source from which the metal is derived.

Cupellation. The process by which silver is extracted from argentiferous galena or naturally occurring lead sulfide (PbS).

Fractionation. A process by which the isotopic ratio is altered.

LIA. Lead isotope analysis.

TIMS. Thermal ionization mass spectrometry.

HR-ICP-MS. High-resolution inductively coupled plasma mass spectrometry.

Origins of variation in lead isotope ratios

Most elements exist in nature as different isotopes, which are atoms of the same proton number that possess the same chemical characteristics but vary in the number of neutrons, thereby giving rise to atoms of different atomic weights. Lead is unusual in that it has a wide range of natural isotopic variation, due to the fact that three of its four stable isotopes (^{206}Pb, ^{207}Pb, and ^{208}Pb) lie at the end of major radioactive decay chains. The chains with their half-life are as follows:

$^{238}\mathrm{U} \rightarrow {}^{206}\mathrm{Pb}\ T_{1/2} = 4.468 \times 10^9$ years
$^{235}\mathrm{U} \rightarrow {}^{207}\mathrm{Pb}\ T_{1/2} = 0.7038 \times 10^9$ years
$^{232}\mathrm{Th} \rightarrow {}^{208}\mathrm{Pb}\ T_{1/2} = 14.01 \times 10^9$ years

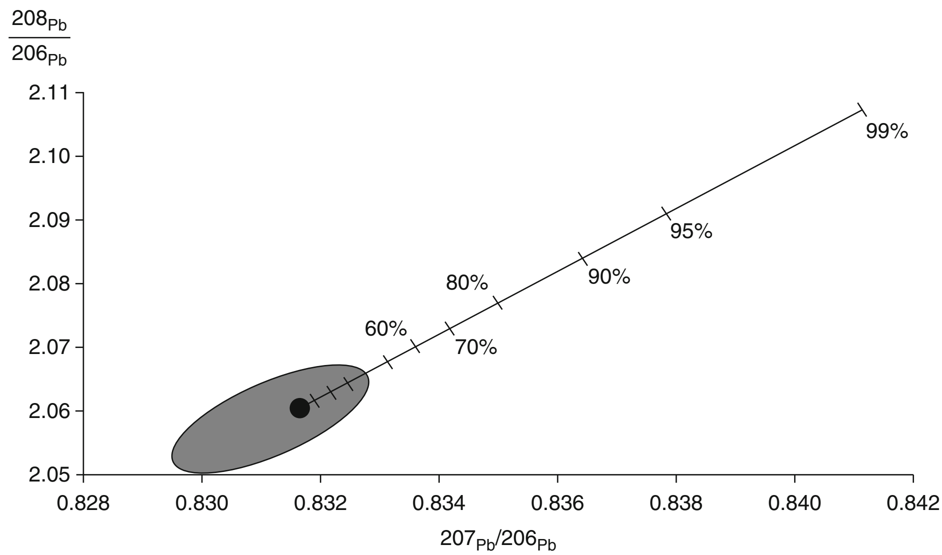
The fourth stable isotope, ^{204}Pb, is not produced by radioactive decay but is residual from the formation of the universe; it is therefore termed *primeval*. By convention, the isotopic composition of lead is discussed in terms of ratios. Geochemists use ^{206}Pb/^{204}Pb, ^{207}Pb/^{204}Pb, and ^{208}Pb/^{204}Pb, since ^{204}Pb is non-radiogenic. These ratios occur in the equations for the isotopic evolution of ore bodies, but there is also a practical reason for using ratios, since ratios can be measured more precisely than the individual abundances using either thermal ionization mass spectrometry (TIMS) or inductively coupled plasma mass spectrometry (ICP-MS).

The lead isotopic composition of an ore body is controlled by the original isotopic composition of the lead at the time of emplacement, the original amount of uranium and thorium in the deposit, and the geological age of the deposit, which means that the isotopic composition of an ore body can be used to indicate the time elapsed since the formation of that body. A number of models exist that can predict the isotopic composition of the ore body, given the starting composition and the age – although many deposits exist for which these models do not give good predictions (Pollard and Heron, 2008, 316). Geologists have been quick to exploit this tool, first to obtain an estimate of the age of the Earth, and subsequently to estimate the geological age of the various metalliferous deposits.

Lead isotope ratio measurements in archaeology

The use of "chemical fingerprinting" to trace metal objects back to their ore source has been one of the main goals of archaeological chemistry since at least the 1930s. Achieving this by chemical analysis is difficult, however, because of the use of high temperature processes causing selective volatilization and the potential effects of mixing and recycling (Bray and Pollard, 2012; Pollard et al., 2014). Brill and Wampler (1967) showed that by using measurements of the lead isotope ratios, it was possible to differentiate lead coming from Laurion in Greece from that obtained from England and Spain. They did note that an ore sample from northeastern Turkey fell into the same "isotope space" as that occupied by three ores from England, thus presaging some of the subsequent interpretational difficulties. The scope of this method was vastly increased when researchers realized that it could be applied not only to metallic lead artifacts (archaeologically rare) but also to the traces of lead left in silver objects extracted from argentiferous lead ores by cupellation (Barnes et al., 1974) and also to the traces of lead in copper objects smelted from impure copper ores (Gale and Stos-Gale, 1982).

The potential issue of lead isotope fractionation during anthropogenic processing was not ignored by the pioneers of the method, since, if it did occur, it might have invalidated the method by changing the isotopic ratios through some separation mechanism. As a test, Barnes et al. (1978) compared the lead isotope ratios of galena (PbS, lead sulfide) with those of (1) the lead smelted from it, (2) litharge (PbO) prepared from the smelted lead, and (3) a K_2O-PbO-SiO_2 glass and a yellow pigment ($Pb_2Sb_2O_7$) prepared from the same lead. They reported no difference in any of the measured ratios, within the precision then available. Hindsight, however, suggests that these experiments may not have been those expected to give the most significant fractionation. Scaife (1993) suggested that non-equilibrium evaporation from a liquid could have a significant effect on the isotopic ratio of lead, providing that the non-equilibrium losses are sufficiently large. He showed (Figure 1) that 40 % non-equilibrium losses would be sufficient to move a sample from the center to the edge of the published lead isotope field for Laurion, and above 60 % would remove it completely



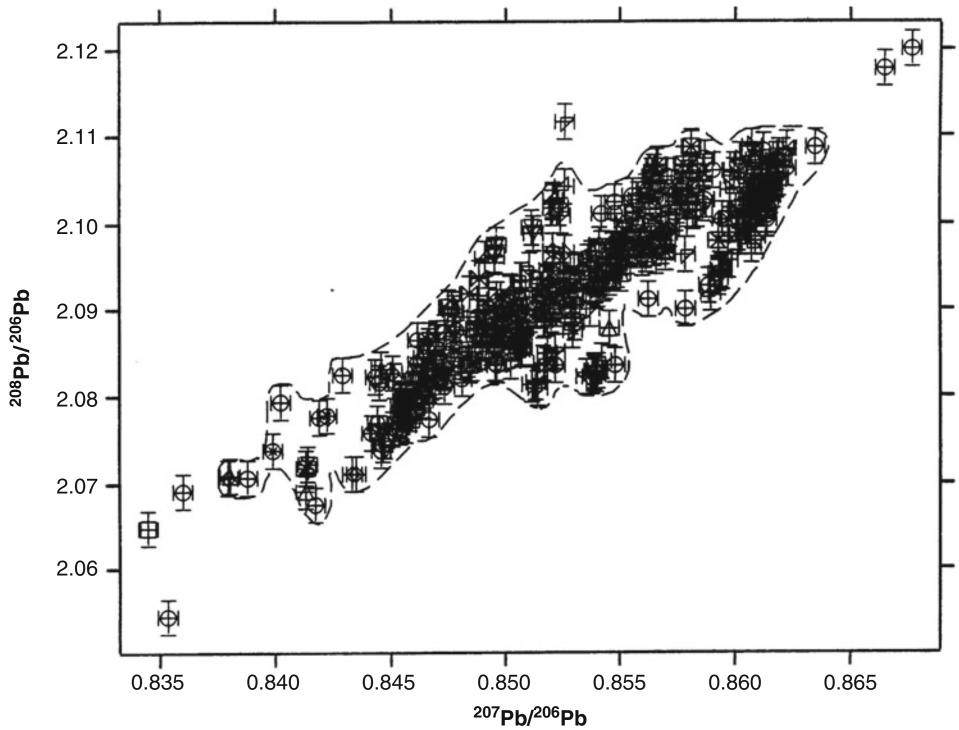
Lead Isotopes, Figure 1 The theoretical effect of non-equilibrium evaporation on the lead isotope ratios of an ore sample from the Laurion field (from Scaife, 1993, Figure 9.3).

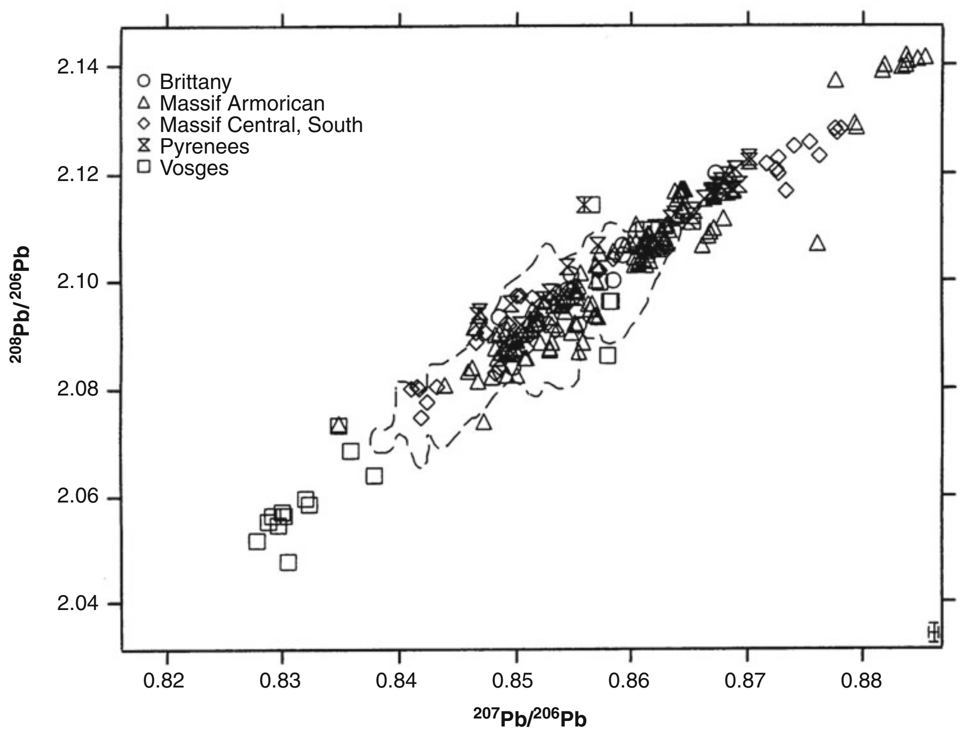
from the field (Pollard and Heron, 2008, 324). The shaded ellipse in Figure 1 represents the typical range of the Laurion field ores for the ratios of the coordinate axes, and the diagonal line indicates progressive deviation as the non-equilibrium loss increases beyond 40 %. In the experiments reported by Barnes et al. (1978), the losses were much lower than this; hence, it is not surprising that no measurable fractionation was observed. Experiments by Pernicka and Bachmann (1983) on the cupellation of silver from Laurion galenas revealed that the process did not result in any fractionation. In the 1990s, a series of simulated laboratory metallurgical processes were carried out, and despite occasionally achieving significant lead losses, isotopic measurements showed no significant change (Budd et al., 1995). More recently, however, Cui and Wu (2011) measured such fractionation using high-resolution ICP-MS but concluded that the magnitude is unlikely to influence provenance studies. Subsequent application of the theory of non-equilibrium evaporation to other metallic systems of archaeological interest, particularly brass (copper-zinc), suggested that the non-equilibrium evaporation model may be appropriate to this system (Budd et al., 1999).

The application of lead isotope measurements in archaeology

The discovery that the isotope ratios of lead vary measurably from metal deposit to metal deposit and are unaffected by anthropogenic processing was naturally hailed as a major breakthrough in the scientific study of archaeological metals. It has been widely applied in studies of ancient metallurgy, particularly in Late Bronze Age metal production in Anatolia and the Eastern Mediterranean. Early enthusiasm soon became tempered by reservations that focused on issues such as the statistical definition of an "ore field" (i.e., how consistent must a set of isotope ratios be to indicate a single metalliferous source) and, given that lead isotope ratio data are not normally distributed, the identification and treatment of "outliers" (Pollard, 2009). A particular case study indicates the degree of caution necessary when trying to use lead isotopes to identify the source of a metal object. In their work on the British sources of copper in the Bronze Age, Rohl and Needham (1998) showed that despite the fact that nonferrous mineralization in the British Isles occurs in four different geological environments, their isotope data revealed no systematic differences among them (Figure 2). In fact, these authors presented the data from all British and Welsh ore sources as EWLIO – the "English and Welsh Lead Isotope Outline." They also explored the relationship between the EWLIO sources and neighboring Scottish, Irish, French, and German ones; in all cases, the data from the neighboring sources overlapped those of the EWLIO, although they often did extend beyond. Particular attributions can sometimes be made (e.g., certain parts of Cornwall have high uranium, which gives a very distinctive lead isotope signature), but it seems clear that, in this case, isotope data are insufficient to characterize uniquely the source of the material. This is an important finding, confirming the generic problem of field overlap first identified by Brill and Wampler (1967). Not all geographically discrete ore fields are isotopically distinct, and therefore, no amount of statistical manipulation can separate groups which fundamentally overlap in the measured parameters.

This difficulty need not be a complete impasse. The "unguided" technique of measuring isotope ratios in an archaeological object and then comparing them to





Lead Isotopes, Figure 2 Scatter plots of lead isotopes ($^{208}Pb/^{206}Pb$ vs. $^{207}Pb/^{206}Pb$): (**a**) "EWLIO" galenas from all English and Welsh lead sources (Rohl and Needham, 1998, 37); (**b**) isotopes from French lead minerals superimposed against EWLIO, showing substantial overlap (Rohl and Needham, 1998, 71) (From Rohl and Needham (1998), with permission. © The Trustees of the British Museum).

a database of potential ore source values in the hope of finding a "match" is largely discredited. This approach would normally be difficult to pursue in any case because much of the raw data on source values remains unpublished. But there is still tremendous value in the technique as a carefully constructed discriminatory test. It is, after all, an axiom of the provenance hypothesis (Wilson and Pollard, 2001) that chemical or isotopic measurements can never *prove* an association with a particular ore source, but they can *disprove* such an association, thereby subjecting an hypothesis to possible rejection. There is thus an increasing tendency to use lead isotope measurements as one of a set of tools (including other isotope systems or elemental analysis) which, when combined with good quality archaeological data, can be used to distinguish between a set of hypotheses relating to human behavior (Pollard and Bray in press).

Advances in analytical instrumentation, and specifically the high-throughput capacity, multi-element sensitivity, and isotopic resolution of the new generation of high-resolution inductively coupled plasma mass spectrometers, mean that capacity is no longer limited by analytical constraints. In particular, with sensitivities for isotopic ratios such as lead comparable to (if not better) that of conventional TIMS instrumentation (Halliday et al., 1998), the widespread use of HR-ICP-MS machines has heralded a new age of relatively rapid and cheap isotopic and chemical studies of archaeological materials. This is happening not only with lead isotopes but also with isotopes of copper (Gale et al., 1999) and tin (Clayton et al., 2002). Recent lead isotope studies of archaeological metals have tended to focus on less well-known areas of the world (archaeometallurgically speaking), such as South Asian metal icons (Srinivasan, 1999), Islamic copper objects (Al-Saad, 2000), bronze Punic coins from Sardinia (Attanasio et al., 2001), Southeast Asian copper sources (Pryce et al., 2011), and also iron artifacts (Degryse et al., 2007). Moreover, lead isotopes have also been used on nonmetallic archaeological materials, such as pottery (Renson et al., 2011), glazed pottery from China (Cui et al., 2010), and painted pottery from New Mexico (Huntley et al., 2007). Nor is the technique limited to inorganic materials. Lead isotopes measured in dental enamel, usually combined with other indicators such as strontium and oxygen isotopes, are now being widely used to "provenance humans" – i.e., to determine where a particular individual was living when her or his dental enamel was being formed (depending on the tooth examined). This offers the potential to reconstruct individual mobility, but also larger archaeological issues such as the migration of groups of people, and also the cultural identity of groups within populations (e.g., Valentine et al., 2008).

Summary

The use of lead isotopes in archaeology, initially as a technique to identify the source of the metal (primarily silver and copper) used for artifacts, but lately on a wider range of material and even human dental enamel, has gone through a typical cycle of enthusiastic adoption followed by a slower reevaluation of the best ways in which to deploy the technique. It is best used in combination with other techniques, and it always requires a careful appraisal of the geological context of the data. It is, together with all scientific applications in archaeology, most effective when used to answer specific, well-constructed archaeological questions rather than as an unguided tool. With the recent developments in essentially nondestructive analysis by laser ablation coupled with ICP-MS, one should look forward to an ever-increasing portfolio of applications.

Definition

Meaning "cool cave" in the local Manggarai dialect, this infamous large limestone cave, 7 km northwest of Ruteng in Western Flores, Indonesia, is renowned for its deeply stratified deposits (17+ m) containing stone artifacts and faunal remains (Morwood et al., 2004), and the discovery of an almost complete skeleton (and parts belonging to several others) of a new species of diminutive human named *Homo floresiensis* (Brown et al., 2004). Flores falls within the area called Wallacea, which represents islands that have never been connected to mainland Southeast Asia on the west and Australia on the east due to the presence of deep trenches that have limited major biotic migrations even during intervals of low Pleistocene sea level.

The large cathedral-like cave of Liang Bua (Figures 1 and 2) is decorated by a dense array of stalactites. It was first excavated by the Dutch priest Father Theodor Verhoeven (1950–1965) revealing a wealth of Neolithic burials with grave goods (Verhoeven, 1953). More extensive excavations followed by R. P. Soejono from 1978 to 1989 (Soejono, 1980, 1985). The full extent of the cave's potential was not revealed until a joint Australian-Indonesian team led by Mike Morwood (2001–2004) extended the west wall excavations using an innovative method of shoring to guard against collapse as lower levels of the cave were explored. These deeper pits exposed the skeletal remains of a mature female of diminutive stature (Morwood et al., 2004, 2005) that was affectionately nicknamed "Hobbit" by the team members. This skeleton represented a species of humans that had a tiny brain and stood only a meter tall with ape-like limb proportions.

Liang Bua formed as a stacked cave system in a tropical karst landscape that evolved rapidly due to the availability of water for solution of the rock and the rapid uplift caused by subduction in a tectonically active region. It was originally formed as a connected, subterranean solution chamber ~600 ka and was later exposed by river downcutting and cave collapse that were fueled by the uplift (Westaway et al., 2009a). Presently, the site is situated at the same elevation as the highest of three alluvial terraces (510 m amsl), which were deposited by the Wae Racang River in a wide Miocene limestone valley. The subaerial exposure of Liang Bua by the downcutting river left its mark at the rear of the cave with a high-energy conglomerate deposit that fines upwards (Westaway et al., 2007). This exposure event, dated at 190 ka, created the first opportunity for human occupation, and since then, the

Liang Bua, Figure 1 Photograph looking to the northwest at the front of Liang Bua. The excavations are visible in the *bottom right* with the large spoil heap in the background. Note the profusion of stalactites on the cave roof that feed the large stalagmite block in the *center* and the extensive flowstones that coat the west wall. The *Homo floresiensis* skeleton was discovered in Sector VII in the *bottom right* of the photograph. The cave was formed when the rear rounded chamber coalesced with the domed front chamber from 600 ka and was later exposed ~190 ka.

cave has accumulated a wealth of archaeological material during an ~100 ka occupation period. The ages of the three alluvial terraces, dated by red TL techniques, at 118 ± 48, 18 ± 4, and 5 ± 2 ka (Westaway et al., 2009a) illustrate when the river occupied that elevation and thus provide a proxy for alluvial downcutting. The combined rate of 305 mm/ka is much faster than the rate of cave development (113 mm/ka) (Westaway et al., 2010) estimated using assumptions of karstification rates (the height of the highest cave above sea level and the age of the limestone), but both are slower than the rate of uplift (500 mm/ka) according to the elevated marine terraces in nearby Sumba Island (Bard et al., 1996). This suggests that the landscape evolution in this region displays some lag effects when responding to uplift but that the fluvial system, despite having a large proportion of its water volume channeled underground, responds much quicker than cave development (Westaway et al., 2010). This information provides a useful context for the formation and sedimentary context of the site.

From 600 ka to the present, a series of geomorphic events influenced the structure of the cave and deposits, creating a complex stratigraphy containing stone artifacts, plant and animal remains, pottery, metal items, and human skeletal remains. Within these deposits, nine main sedimentary units have been identified, and the stratigraphic relationships between these units provide the evidence needed to reconstruct the geomorphic history of the cave. This history was dominated by water action, including slope wash processes, channel formation, pooling of water, and flowstone precipitation, which created waterfalls, cut-and-fill stratigraphy, large pools of water, and extensive flowstone cappings. The sequence of geomorphological events – exposure of cave and high-energy deposition, suspension in a pool, creation of higher ground, channel erosion, cut and fill, bank and pool deposition, volcanic events, and sheetwash – restricted occupation to certain zones. Continuous occupation of the cave may not have been possible until after ~100 ka, when the accumulated water had drained from the front chamber. The next ~89 ka were dominated by flowing water creating waterfalls, cut-and-fill by channels, periodic pooling of water, occasional volcanic events, and the creation of a dominant zone of occupation – established ~74–61 ka in the center of the cave. This evidence was protected from sheetwash and channel processes by an extensive flowstone that caps this occupation zone (Westaway et al., 2009b).

Since 2004, the new species interpretation has been criticized by claims that the fossils represent modern

Liang Bua, Figure 2 Photograph of the rear of Liang Bua taken from the northwest corner looking southeast. The height of the cave and shape of the domed front chamber are apparent, along with the conglomerate deposit on the *right* that represents the river's first violent exposure of the once subterranean chamber. Excavations have been conducted mostly on the flat *front* section of the cave where the evidence for occupation was concentrated.

humans with pathological abnormalities (e.g., Jacob et al., 2006; Henneberg and Schofield, 2008). However, the team argues that the fossils were securely discovered within the unbroken 100 kyr record of sediments within the cave, and that they were associated with a stone tool technology (Moore et al., 2009), complex faunal assemblages that reveal cut marks (van den Bergh et al., 2009), living floors with sharp stone tools and hearths (van den Bergh et al., 2009), and an often harsh environment both inside and outside the cave (Westaway et al., 2009a, c) that influenced their pattern of occupation (Westaway et al., 2009c). The skeletal material can be dated within the interval of 95–18 ka, and stone tools are as old as 190 ka (although age ranges are currently being revised). This evidence, which also informs about paleoclimate changes, insular evolutionary processes, human dispersal, and the arrival of new peoples, animals, and technologies, suggests that there is more to learn about Liang Bua than merely the presence of *H. floresiensis* (Morwood et al., 2009). This context was reconstructed using a barrage of dating techniques: radiocarbon, luminescence (OSL and red TL), U-series, and ESR (Roberts et al., 2009).

The cave has not yet revealed all of it secrets. The current Liang Bua excavations started in 2001 by Mike Morwood are ongoing by his team, with 28 large pits now excavated to 11+ m. This new evidence is providing a better understanding of the complex stratigraphy and its association with the archaeological material so that a more detailed chronological framework has been established that will form the basis of publications in the near future.

Definition

Lithics. Stone used and modified in prehistory. The analytical tools and methods used to understand lithics in the past.

Introduction

Lithics is the term used to describe stone implements of the past and their study. It includes analysis of archaeologically recovered tools as well as the processes used to manufacture them based on empirical examination of residual evidence, experimentation, and analogy to modern and historic toolmaking societies. Lithic technologists work directly with the stone artifacts themselves and are concerned with the above goals. In contrast, this entry deals with the geoarchaeological aspects of lithic analysis, i.e., the information obtained by earth science techniques such as petrology, that further help refine our understanding of tool-using behavior. The entry will also examine some of the history and advances made in geoarchaeological approaches, with special emphasis on the directions that twenty-first century geoarchaeology and archaeometry are currently taking toward an understanding of the composition of stone artifacts. From chipped stone to sculptural stone, using both optical methods (petrography) and analytical chemistry, the quantity and quality of research have been increasing exponentially. No attempt will be made here to describe chronometric techniques applied to stone. The present entry reexamines to some extent two previous reviews (Shackley, 1998a, 2008), but the subject is covered by a huge literature that is well beyond the focus of the limited treatment here—for example, see Delage (2003) for chert and Shackley (2008) for an extensive bibliography.

In 1983, D. R. C. Kempe and Anthony Harvey published an edited volume entitled *The Petrology of Archaeological Artefacts*. This book was the first attempt to compile the ever-increasing work on the geoarchaeological analysis of stone in all its forms, from chipped to sculptural stone, and it included chapters on ceramics and metals. This landmark study received very little attention by lithic technologists, particularly in the Americas, yet lithic technologists have much to gain from instrumental analyses of stone, and many have recently come to see the value of a geoarchaeological perspective

(Shackley, 1998a, 2008 Odell, 2003; Högberg and Olausson, 2007; Hughes et al., 2012).

The goal of this entry is to address some of the important recent advances as well as the continuing problems that affect geochemical studies of archaeologically recovered stone implements; this is done with the archaeologist in mind rather than the trained geochemist. Important new and experimental techniques in archaeometry, both in the field and lab, are being applied to stone tools and structural stone studies in archaeology. Not all emerging possibilities can be covered – for example, isotope studies through ICP-MS (Speakman and Neff, 2005) – an emphasis will be placed on problems of chert and obsidian characterization.

The chemical characterization of stone

The writer has written frequently about a "sourcing myth" in archaeometry (Shackley, 1998a, 2005). Archaeometrists involved in chemical characterization know very well the physical and geochemical foundations of the varied techniques that have been used to identify elemental composition in many kinds of stone artifact: x-ray fluorescence (XRF), neutron activation analysis (NAA), proton-induced x-ray emission/proton-induced gamma ray emission spectrometry (PIXE/PIGME), mass spectrometry (MS), inductively coupled plasma-mass spectrometry (ICP-MS), and others (see Speakman and Shackley, 2012). Archaeologists are not always so familiar with these methods, and they are not always aware of issues involving statistical probability and its role in assigning an artifact to a source (see Baxter, 1994; Neff and Glascock, 1995; Shackley, 1998b). The success of any attempt to use geochemical composition to locate the raw materials employed in artifact manufacture will depend heavily upon unimpeded communication between the scientist and archaeologist, a situation that should, but does not always, occur. Furthermore, the conclusions of an archaeometrist can rarely be directly checked by the archaeologist, who must therefore trust the results. This places much weight on the accuracy of the science, but it also suggests that archaeologists should not use such data alone to support their conclusions. The geochemical data should be one part of a search for multiple lines of evidence. This review will survey problems in the chemical characterization of two very important substances used throughout prehistory and which have become a focus for much archaeometric research in the last three decades: (1) secondary siliceous sediments, here collectively called chert, and (2) volcanic glass, both silicic and mafic. The issues raised are typical of the analysis of other stone materials, particularly those that are heterogeneous.

Returning to the "sourcing myth," the term "sourcing" has become one of the most misused terms in archaeometry. Archaeologists and geoarchaeologists use it often, and most understand the word to mean that specimens submitted for analysis will return with a certified provenance that is not probabilistic at all, but confidently determined. In truth, nothing is ever really "sourced." The best outcome is a chemical characterization and a probable fit of the artifact's resultant profile to similar profiles obtained from raw material obtained at a known source. The key word here is *known*. Many regions of the world are poorly covered with respect to source data, and matches can be obtained only when source materials that might have been used for artifact production have been analyzed and their spectra already archived. Thus, one can never really be sure using geochemical data alone that an artifact's material came from a particular source, even beyond the scientific process of orderly refutation of alternatives (Ward, 1977; Luedtke, 1992; Hughes and Smith, 1993; Williams-Thorpe, 1995; Cauvin and Balkan-Atlı, 1996; Gratuze, 1999; Kuzmin et al., 2002; Shackley, 2005).

Chert and characterization

Attempts to determine the provenance of chert through chemical characterization have proven to be difficult and vexing to archaeologists and archaeometrists for decades (Luedtke and Myers, 1984; Matiskainen et al., 1989; Luedtke, 1992; Warashina, 1992; Church, 1995; Hoard et al., 1995; Roll et al., 2005; Högberg and Olausson, 2007; Hughes et al., 2012). This is due mainly to the processes of chert formation, which involve precipitation from a parent material at ambient temperatures where only certain elements and compounds can be removed from the original matrix to become part of the chert body. Additionally, sources of chert, particularly Phanerozoic marine cherts, are by their very nature often broadly distributed, covering large geographic expanses; the extent of their uniformity and wide dispersion decreases the possibility of discriminating local varieties and therefore diminishes their utility as a means to derive inferences for exchange, interaction, or procurement processes. Most of the techniques that have proven helpful in deriving useful chemical data for cherts are destructive and expensive, further limiting their attractiveness for routine analysis, especially where conservation of objects is an issue (see Roll et al., 2005). Barbara Luedtke's (1992) treatment of the subject for archaeologists is an excellent summary. Among many useful ideas, Luedtke suggests a four-step process for determining the probable source of cherts (1992: Appendix A). Her steps have been modified here by the addition of a few more based on this writer's experience. In general, these steps are appropriate for most stone provenance studies.

1. Several similar chemical profiles indicating unknown sources may be detected in stone artifacts from various archaeological contexts. Often these will cluster into groups that compare favorably to raw material from various geologic regions.
2. One should consult the regional geologic literature to ascertain the location of the nearest and most likely rock bodies. (In the case of obsidian, however, volcanic

glass is rarely mentioned in association with mapped rhyolite bodies in the geologic literature.)

3. Frequently, local residents, archaeologists, rock hounds (amateur geologists), rock hound guides, and generally word-of-mouth can provide excellent information when searching for natural sources of obsidian and chert. Nearly all of the obsidian and chert sources "discovered" in the North American Southwest were first found by nonscientists (Shackley, 2005).
4. It is often necessary to begin the search downstream from a probable source area. Many sources formed during the Tertiary Period and earlier have been highly eroded, releasing many nodules and fragments into the sediment load to be carried hundreds of kilometers downstream from their origin (Shackley, 1998c, 2005, 2013).
5. In the field, when a source is discovered, the extent and density of the natural distribution of raw material, its general geologic setting, and the variability of human lithic production in the region should be recorded. Pedestrian transects across the source area should lead to collection of specimens from various sample strata. These specimens will form the basis for optical and/or instrumental analysis, insuring as representative a sample as possible.
6. Determine which techniques or procedures are optimal. For museum specimens, it is often unacceptable to cut thin sections for petrographic analysis or subject them to destructive NAA; in these situations, nondestructive methods like XRF may be acceptable (see Hughes et al., 2012). Each method has its advantages and limitations, and the results of a given technique may not be specifically valid in certain situations (see Goffer, 1980; Neff and Glascock, 1995; Green, 1998; Shackley, 1998a; Roll et al., 2005; Speakman and Neff, 2005).
7. Matching artifactual profiles to those of the sources is the final step. The literature contains many examples of incorrect applications at this stage of the analysis. Multivariate statistical techniques are often sought after, but archaeologists often don't have the quantitative background to evaluate these results. Simple bivariate plots and central tendency statistics that compare the artifacts and geologic data are often sufficient to link artifacts to sources (Hughes, 1984a; Shackley, 1988, 2005; Baxter, 1992; Baxter, 1994; Neff and Glascock, 1995; Glascock et al., 1998).
8. Source descriptions should include exact locations, preferably UTM geographical coordinates, a description of the geologic context, megascopic attributes of the raw stone (cortical and interior variation, nodule size, color, fabric, opacity), distribution of secondary deposits, density and character of lithic reduction (tool production waste, or debitage) at the source, and relevant published sources.

Within the last two decades, archaeometrists and archaeologists have together begun to focus on the problems of chert characterization and source assignment (Church, 1995; Hoard et al., 1995; Roll et al., 2005; Hughes et al., 2012). As archaeologists gain a better understanding of the instrumental techniques involved and the assumptions archaeometrists often must make, they are following appropriate sampling design and presentation of results. Sampling is an important matter, illustrated by the exchange between Church and Hoard et al. cited above. Church rightly questioned whether sampling reduction debris at the source was sufficient and necessary to capture sufficient variability within the raw material. Hoard et al. noted that while some geologic samples were gathered during their work, much of the characterization conducted by their project was based on secondhand collections. Without a firm knowledge of potential chert sources in a region, errors of misassignment will occur, as the level of macroscopic and chemical variability inherent in secondary siliceous sediments can be high. In this case, the potential for sampling error, due mainly to retooling at the source, was great—and potentially unknown to the archaeologist or the archaeometrist (Thomas, 1986, pp. 213–217; Bernard, 2006). Given all these caveats, however, chert characterization and source assignment provide a significant tool in archaeology for understanding lithic production and use. Despite the difficulties of source heterogeneity and the general need to apply destructive or partially destructive techniques, confocal microscopy tied to optical petrography, in addition to the instrumental techniques mentioned here, promises to reveal new data about chert exploitation in the past.

Obsidian characterization and the "Sourcing Myth"

Many of the points outlined for chert studies are equally relevant for obsidian studies in archaeology, but because these homogeneous, disordered, silicic glasses can be so precisely characterized, the potential abuses are much greater. Since it is a common aspect of archaeological practice and a good example for other data sets, a few words will be directed toward some of the problems in the chemical characterization of silicic glasses that directly impact the resolution of archaeological problems.

Obsidian studies in archaeology are a relatively recent aspect of archaeological research (Boyer and Robinson, 1956; Green, 1962; Cann and Renfrew, 1964; Jack and Heizer, 1968; Jack and Carmichael, 1969; Williams-Thorpe, 1995; Green, 1998; Shackley, 2005). Early studies relied on naked eye observation, density measures, and mass spectrometry in an attempt to define source groups and correlate artifacts to sources. The results were mixed. In the late 1960s and early 1970s, with the evolution of relatively inexpensive x-ray fluorescence spectrometers and increasing use of NAA, obsidian studies in archaeology began to be applied in the exploration of exchange and interaction (Glascock, 1994; Shackley, 1998b, 2005; Glascock et al., 2007; Glascock, 2011). Archaeologists working in the Mediterranean, the New

World, and Oceania were particularly keen to exploit these new methods, mainly since the instruments were available at most university campuses (Hughes, 1984b; Nelson, 1984; Shackley, 1988; Tykot, 1992; Shackley, 1995, 2005; Williams-Thorpe, 1995; Green, 1998; Glascock, 2011). By the 1980s, archaeologists in every part of the world where obsidian was naturally present were engaged in obsidian provenance studies. Now thousands, if not tens of thousands, of pieces of archaeological obsidian are analyzed yearly by x-ray fluorescence spectrometry (XRF), neutron activation analysis (NAA or INAA), inductively coupled plasma-mass spectrometry (ICP-MS), and proton-induced x-ray emission-proton-induced gamma ray emission (PIXE/PIGME), and much of this analysis is performed by archaeologists rather than physical scientists (Shackley, 2002). The expanding investigation is a welcome sign, but as discussed above, there is still some concern that many factors affecting accurate source assignment (such as quality of the instrumental results and extent of data from potential sources) will be downplayed in favor of easily derived quantitative estimates.

The obsidian hydration controversy

Obsidian hydration dating has fascinated and frustrated archaeologists for decades (Layton, 1973; Ericson and Kimberlin, 1977; Michels et al., 1983; Stevenson et al., 1987, 1989; Liritzis, 2006). The technique involves measuring the thickness of a veneer of hydration caused when a freshly exposed surface of obsidian absorbs water from the environment. This rim or rind can be seen in thin section, and its thickness has been associated with the length of time since the exposure (due to purposeful flaking in the process of toolmaking) occurred. Obsidian hydration dating hasn't played a major role in Old World chronology building for a number of reasons, and European scholars have not dealt with the controversy in a major way. It is employed mostly in the New World, principally in parts of North America (California, the Great Basin) and Oceania (particularly New Zealand). The historical reasons for this include primarily the dominance of obsidian in those regions and the absence of other datable materials. Currently, many feel it is fraught with too many issues to function as a reliable member of the chronometric tool kit (Shackley, 2005).

Beginning with Friedman and Smith (1960) on dating using obsidian hydration, scholars have moved into two camps: those who believe fervently in the utility and validity of the method (Jackson, 1984; Hall and Jackson, 1989; Hull, 2001; Hull, 2002) and those who find the recurring problems simply too difficult to overcome (Ridings, 1996; Stevenson et al., 1998; Anovitz et al., 1999; Loyd, 2002). Even those who are dubious about the use of obsidian hydration as a direct dating method still work toward the resolution of the problems. Factors that frustrate attempts to use hydration as a direct chronometric method include (1) variances in atmospheric heat and humidity through time; (2) the inability to control for the burial history of the artifact; (3) resetting of the hydration rim after postdepositional burning; (4) seemingly exponential, nonlinear shifts in the absorption of water over time; and (5) inter-observer measurement error. More recently, Hull (2001) has argued that such critiques have emerged simply because researchers focus on the method as a direct rather than relative technique, although Hull seems to use it as the former in her own work (Hull, 2002). A recent symposium exploring the effects of fire on obsidian hydration in California found through empirical observation and experimentation that hydration rims can be reset during forest fire conditions, thereby dealing a lethal blow to the chronometric dimension, at least for the nonbelievers (Deal, 2002; Loyd, 2002; Loyd et al., 2002; Skinner, 2002). Some western federal archaeologists in North America will no longer pay for obsidian hydration analyses through federal funds (Skinner, 2002, and personal communication). Parenthetically, it has been determined through experimentation and field studies that there is no statistically significant change in trace element chemistry when obsidians are heated to high temperatures (Skinner et al., 1997; Shackley and Dillian, 2002; Steffen, 2002).

So, what should archaeologists do? Hull suggests that obsidian hydration should not be seen as a direct chronometric dating method like dendrochronology, but as a relative dating tool to be used within single site contexts where the depositional history and environment are similar from one area to another (2001, p. 1026). In recent, historic period sites, Hull was able to obtain interesting relative dates (with substantial error rates due to the vagaries of hydration) where ^{14}C dating is useless given the inherent uncertainty of the calibration curve in near "modern" periods (see also Ambrose, 1998; Hull, 2002). Though Ridings (1996) and Anovitz et al. (1999) seem willing to claim obsidian hydration a failure, some, including Anovitz, are willing to continue experimentation with the goal of resolving the issues (Friedman et al., 1997; Stevenson et al., 1998).

Instrumentation: which instrument is best?

A frequently asked question concerns which instrument is the best for analyzing stone objects. The answer depends upon the problem design of a given project and the level of precision needed to address that design. Ten years ago, the question was easier to address (Shackley, 1998b), but with the general improvements in technology, instrumental applications in archaeological geochemistry have similarly improved. Almost all instrumental and empirical techniques have been used, including density, magnetism, atomic absorption, PIXE-PIGME, ICP (for obsidian, see Tykot and Young, 1995; Speakman and Neff, 2005; Shackley, 2005), megascopic criteria, and others. Today, three major instrumental methods dominate the field: (1) neutron activation analysis (NAA or INAA), (2) wavelength and energy-dispersive x-ray fluorescence (XRF) including portable XRF (PXRF), and

(3) increasingly, laser ablation inductively coupled plasma-mass spectrometry (LA-ICP-MS) (Neff and Glascock, 1995; Glascock et al., 2005; Shackley, 2005; Speakman and Neff, 2005; Glascock, 2011). All of these methods have benefited from the revolution in microprocessors and the attendant software improvements and are now easier to use (and hence misuse). For archaeologists, Goffer (1980) and, to a certain extent, Harbottle (1982) detail some of the intricacies of each method for an earlier period. Glascock (1991, 2011) presents a good, though technical, treatment of NAA (see also Neff and Glascock, 1995; and see Speakman and Glascock, 2007, which represents a special issue on NAA in *Archaeometry*), and XRF and PIXE-PIGME are explained in some detail in (Shackley, 1998b; Shackley, 2011; see also What Is XRF? http://www.swxrflab.net/xrfinstrument.htm). The present entry will address the relative merits of the three most commonly used analytical techniques – NAA, EDXRF, and PIXE-PIGME—given the real situations encountered by archaeologists.

A level of mythology has also grown regarding the optimal analytic instrument for geochemical studies of stone. The prevailing ideal seems to be that NAA offers the "best" technique if funding is available. For most elements, NAA is precise, and it can detect more elements than the other two methods (Glascock, 1991; Neff and Glascock, 1995; Speakman and Glascock, 2007; Glascock, 2011). Neutron activation analysis, however, has two primary shortcomings. First, it is in essence a destructive technique; while the material is not literally destroyed, depending on the specimen's original size, it may be broken into relatively small pieces, and the analyzed material can remain radioactive for decades. Second, NAA is not readily available, partly due to its elevated cost and partly due to the public fear of nuclear energy. Also, when applied to obsidian characterization, NAA cannot analyze for Sr, Y, Zr, and Ba as accurately as the other two methods (see Shackley, 2005; Craig et al., 2007; Glascock, 2011). These are important incompatible elements in silicic melts and can be extremely valuable in separating sources or dealing with intra-source issues (Hildreth, 1981; Mahood and Hildreth, 1983; MacDonald et al., 1987; Hughes and Smith, 1993). Neutron activation can, however, quite accurately analyze for other incompatibles and rare earth elements that are outside the range of XRF.

For museum specimens and artifacts that are subject to repatriation, NAA is not an appropriate choice. If precision and accuracy are necessary, which can be an issue in intra-source studies and in situations where long-distance exchange is probable, then NAA will always provide the most efficient alternative. Additionally, if the sample is extremely small (<2–5 mm as the largest diameter), NAA or LA-ICP-MS may be the best analytical method. Other methods may require a minimum sample size for optimal results (Davis et al., 2011).

Recently, Michael Glascock compared the results of both NAA and EDXRF analyses of central Mexican obsidian (2011). He concluded: "In most cases, XRF should be sufficient to determine the provenance of the artifacts. However, if the artifacts come from a source that overlap on elements measured by XRF, then short-NAA and long-NAA are a possible way of obtaining the data critical to sourcing these difficult artifacts" (Glascock, 2011, p. 191).

What this means for an archaeologist is that any laboratory employing EDXRF, WDXRF, NAA, PIXE-PIGME, or ICP-MS will provide valid and comparable results, given a sufficient sample size, particularly for obsidian. The constraints for the particular project determine the main criteria for the selection of analytical methods. A more critical factor is likely to be the accuracy and inclusiveness of source data: if the region of interest has not received the level of geoprospection necessary for accurate source assignment, the precision of the instrument employed will not overcome this deficit.

Sampling: how much is enough?

Sampling is not new to archaeology. Over 20 years ago, the US Department of the Interior spent a considerable sum investigating the subject both for confidence in predictive modeling and regional and intra-site sampling (Judge and Sebastian, 1988). Throughout this work, and many other investigations like it, lies the basic tenet of probability theory regarding the simple law of large numbers: as sample size increases, the probability of obtaining a representative sample increases. Given that funding constrains archaeology in all its forms, the law of large numbers is an ever-present demon since collecting an optimal sample is invariably costly. Sampling still deserves consideration at all levels of archaeometric analysis, both in the field and the laboratory; while most projects may not be able to support extensive sampling based on these precepts, the risks inherent in such decisions must be recognized in formulating conclusions. When sampling raw material at source localities as well as artifacts from an archaeological assemblage, there appears to be a minimum number of samples necessary to derive a confident conclusion. The following examples at both the source and artifact assemblage levels are illustrative.

The Mule Creek regional source: "Real" chemical source variability

A 1988 study of the Mule Creek source in western New Mexico sampled 15 obsidian source standards from a population of 200 gathered at five localities. Two chemical "outliers" were noted among the analyzed specimens that showed significantly higher rubidium concentration values (Shackley, 1988, p. 767). These outliers have now been identified as a distinct chemical group, often mixed together with three other chemical groups in the regional Gila Conglomerate (see Shackley, 1995, 2005). The eruptive geology in the area is complex and has been studied by Ratté and others—see Ratté (2004) for a summary of research. For three of these chemical groups, primary in situ localities have been found with natural exposures of perlite (hydrated obsidian) and remnant marekanites (rounded nodules of obsidian eroded from their perlite matrix).

At least four discrete chemical groups were evident, distinguished by their Rb, Y, Nb, and Ba, and to a lesser extent Sr and Zr concentration values; each was named after the localities where marekanites have been found in perlitic lava: Antelope Creek, Mule Mountains, and Mule Creek/North Sawmill Creek, all in New Mexico (Shackley, 1998c, 2005). During the 1994 field season, a fourth subgroup was discovered in Quaternary secondary deposits in the San Francisco River alluvium near Clifton, Arizona. While in situ nodules (marekanites) have not yet been found, they are certainly located somewhere west of the Blue River and north and west of the San Francisco River since none of this "low zirconium" subgroup was discovered in alluvium upstream from the juncture of the Blue and San Francisco Rivers. The genetic relationship is apparent in bivariate and trivariate data plots (Shackley, 2005), signifying that Mule Creek silicic geology possesses a very complex nature that further complicates the subsequent depositional mixing in the Gila River conglomerate. The original random sample of 15 marekanite nodules merely indicated that some variability existed, and only after extensive transect survey and sampling, and the discovery of three localities with marekanites did it become apparent that there was significant chemical variability inherent in the "source." The most important point of this case study is that without the knowledge of these other sub-sources, analysis of archaeologically recovered obsidian artifacts from the region could have promulgated the existence of a new and unknown source.

So, how much should be sampled? It depends on many factors. Often, laboratory analysis will detect variability in archaeological specimens despite the fact that source standards have not demonstrated such variability (Hughes, 1994; Glascock et al., 1998). In some cases, even ten samples sent to an analyst might not be sufficient to define with confidence the high elemental variability of a source. The following source sampling strategy can serve as a guide. It has been compiled based upon research in the American Southwest (Shackley, 1988, 1995, 2005), in Mesoamerica (Glascock, 1994, 2011, Glascock et al., 1998), in the American Northwest (Skinner, 1983), in California and the Great Basin (Hughes, 1984b, 1994; Jackson, 1986, 1989; Hughes and Smith, 1993), in Oceania (Torrence, 1992; Green, 1998; Summerhayes et al., 1998), and in the Mediterranean and the Near East (Williams-Thorpe, 1995; Tykot, 1998; Carter et al. 2006).

1. On-the-ground sample surveys must incorporate the entire primary and secondary extent of the source. This often requires days or weeks of field reconnaissance and extensive discussions with geologists and local inhabitants of the source area.
2. In order to determine the probable location of primary sources, it is often useful to conduct extensive sampling of the secondary distribution; this can isolate probable areas for further study. The San Francisco River alluvial samples were delimited in this way (see above).
3. Mark the location of all samples geographically at least to the section, square kilometer, UTM, or other appropriate global positioning system (GPS) coordinates.
4. Divide the total survey area into sample strata based on the field localities that were collected, and analyze preferably at least five or more samples from *each locality*. "Five or more" does not constitute a magic number that will be appropriate to the variability of every source area.

In some instances, particularly with Quaternary sources, erosion and secondary deposition of primary obsidian may not be an issue since there has been little geologic time for the glass to weather and disperse into the environment; also, large-scale pyroclastic eruptive events may not have occurred during such a short interval (see Shackley, 2005). While this minimizes the problems of secondary deposition, it does not mitigate the challenges of possible intra-source chemical variability.

Archaeometry and the inference of tool use

Most of the history of prehistoric lithic technology studies have been dominated by direct observation, experiment, and opinion—and it has also been subject to polarized dialectic surrounding which particular paradigm was correct, or even "politically correct" (Grace, 1996). Many of these arguments have been based on opinions about methods and the validity of the assumed analogy between modern experiments and prehistoric knappers and tool users (Keeley, 1980; Odell and Odell-Vereecken, 1980; Gendel and Pirnay, 1982; Unrath et al., 1986; Lewenstein, 1987; Bamforth et al., 1990; Young and Bamforth, 1990). The problems of inferring use from marginal damage on stone tools, particularly utilized flakes, have produced a high level of consternation among lithic technologists and paramount frustration among contract archaeologists who are most pressed for time in determining site function and therefore site significance in management decisions—see Grace's (1996) review of the literature in *Archaeometry*.

One of the most commonly practiced techniques, and one of the most empirically frustrating, is inferring use-wear and therefore function from unmodified flakes. Studies that rely on readily available microscopic techniques are exceptions rather than the rule. Most archaeologists rely on macroscopic examination of flake margins, deriving inferences of prior use based on these gross morphological indications. Blind tests conducted with various researchers who examined experimentally produced specimens macroscopically have indicated that few archaeologists agree on the character of the damage and hence the implied function of the tool (Bamforth et al., 1990;

Young and Bamforth, 1990; Christensen and Walter, 1992; Christensen et al., 1992). The more "experienced" observers more often identified the use-wear correctly, but some did not. This finding serves as a warning since *the* most common flaked lithic tool found in prehistoric contexts is often the utilized flake. Young and Bamforth argue that "some degree of experimental experience should be required of all archaeologists who intend to include such tools in their research, simply to ensure that they observe their collections accurately" (1990, p. 408). Gaining some experience with archaeometric methods should carry equal importance (see Burroni et al., 2002). Young and Bamforth may be overoptimistic about the effectiveness of experience in diagnosing use-wear, and the error rate using macroscopic criteria is probably too high.

So what can archaeometry and analytical chemistry offer to solve the dilemma? Some studies by Marianne Christensen, Phillipe Walter, and others in France using environmental scanning electron microscopy (ESEM) may have far-reaching implications for use-wear research, and more recent studies using a variety of techniques have refined these efforts (Christensen et al., 1998; Evans and Donahue, 2005). Generally, even if one can determine the scraping, cutting, or rotary-wear utilization with some degree of confidence, it is rarely possible to determine the actual material upon which the tool was used beyond that it was a "hard or soft substance." Bone and wood are often lumped together as one material, but there are often important behavioral differences between stone tool use on one as opposed to the other.

Christensen et al. (1992; see also Christensen and Walter, 1992; and Menu and Walter, 1992) have explored margin polish (also referred to as "corn gloss" and "sickle sheen") on various stone tools by replicating experimental implements, using them, and employing ESEM with an EDXRF probe to yield qualitative elemental data that can be paired with the various substances against which the implements were used. The results were cross-checked using RBS (Rutherford backscattering spectrometry) and PIXE (proton-induced x-ray emission spectrometry). Another aspect of their research that cannot be treated in depth here is the empirical evidence for "melting silica," where the polish is essentially a combination of loss of lepispheric quartz (spherical aggregates of platy cristobalite or tridymite crystallites) from the chalcedony matrix of chert *and* an accumulation of material, in this case bone (see also Witthoft, 1967; Christensen et al., 1992, p. 491).

The importance of this work is that the material upon which a tool was used can be empirically defined. Quite similar and reliable data were also obtained with ESEM/EDXRF. The pilot study of Christensen et al. (1992) was applied to 13,000-year-old Magdalenian burins recovered from the important site of Étiolles in the Paris Basin that was thought to be a lithic production area. Their study indicated that some of the burins were used to modify "chalky matter," suggesting that the burins could have removed the chalk cortex of chert in the early stages of reduction (Christensen et al., 1992, pp. 492–493). Perhaps more illuminating was the analysis of Pre-dynastic Egyptian fish-tail knives and ripple-flaked knives that have often been considered uniquely for ritual purposes in contrast to household or other utilitarian functions. Using this technique, Christensen et al. concluded that the fish-tail knife was used to cut meat, and the ripple-flaked knife was used in plant cutting (1992; Menu: personal communication 1993). Most importantly, these several-thousand-year-old tools were museum pieces and handled by many people throughout their 100 + years of curation, and the technique is completely nondestructive when using the ESEM. While still experimental, the technique is readily available to most archaeologists worldwide and promises to solve some important issues that cannot be achieved with macroscopic and low-power microscopic techniques.

This study has been replicated and refined more recently using LA-ICP-MS by Evans and Donahue (2005). The authors not only used LA-ICP-MS to great effect, but they used even harsher cleaning techniques than the Christensen group a decade earlier and found that there was still not significant removal of the organic material (cf. Burroni et al., 2002). While ESEM and RBS are useful in determining the kind of material worked by tool users in prehistory, LA-ICP-MS is more efficient and, given that the instrumentation is becoming readily available at many universities, promises to revolutionize lithic use-wear studies in the twenty-first century.

Summary

Geoarchaeological petrology is steadily improving in its ability to assist the practice of lithic studies. Few archaeologists now think that a single analytical method is sufficient to characterize any stone material. Even obsidian, which is by definition completely disordered with no crystalline structure, has often been shown to exhibit source heterogeneity. While XRF is a good nondestructive tool for characterizing obsidian sources and artifacts, it may not always include enough elements to produce a distinctive characterization. Many regions in the world, including northern Mexico, Eurasia, and even parts of the USA and Canada, possess "unknown" sources that are still insufficiently studied to be useful in determining origins for stone objects recovered from the archaeological record. In contrast, many chert sources, particularly the Phanerozoic marine sediments that cover large regions (e.g., the Precambrian Ouachita Transition of the Edwards Plateau of Texas and the region of central France), reveal such substantial elemental and isotopic variability that it may be a long time until chert characterization studies approach the effectiveness of obsidian.

The most important general conclusion is that source assignment of any rock based on examination by eye alone is risky at best and simply does not work in many cases (Shackley, 2005, p. 101–105). Many of the techniques used to characterize rocks, most of them discussed here, are relatively inexpensive, and therefore, today's research should keep up with the latest improvements in direct measurement and analytical instrumentation.

Introduction

When people spend a period of time in one spot on the earth's surface, a signature of that occupation is often recorded in the place at which they stopped. Such surfaces are referred to as *living surfaces*, and evidence they contain indicates a human presence. Information on human behavior, such as subsistence strategies, tool making, and other activities, as well as length of occupation and population size, may be gleaned from living surfaces preserved in the archaeological record. Generally, such living surfaces occur as discrete units that reflect a particular occupation or activity at a particular point in time (Dibble et al., 1997). Living surfaces are often defined by their chemical and physical characteristics, though the spatial distribution of artifacts and features is also critical for understanding human behavior at an archaeological site.

Living surfaces are formed in various ways. When humans discard artifacts on the surface, introduce organic matter into soil or sediment, or disturb a surface by other actions, they leave signatures that can be detected using a number of techniques. Living surfaces may be visible to the naked eye, appearing as dark stains in the soil or sediment, or they may be marked by the presence of artifacts, charcoal, and/or burned earth. In other cases, living surfaces may be identified only through geochemical analyses. The combination of all three methods may be the most effective way to identify the presence or absence of a living surface.

Geoarchaeology has become an important component in the investigation of living surfaces. Specifically, geoarchaeologists often play critical roles in identifying and tracing living surfaces (i.e., archaeological prospection) and assessing the vertical and horizontal integrity of cultural deposits associated with such surfaces. Also, by using geochemical prospection and micromorphological analysis, they contribute to the identification of specific activity areas on living surfaces.

Formation of living surfaces

All archaeological sites consist of at least one living surface, though such a surface may in reality represent a palimpsest of multiple unrelated occupations succeeding each other over time. The characteristics of living surfaces vary depending on the length of occupation and the types of activities performed at the site. A thick, dark, organic-rich soil may be indicative of a long-term occupation where cooking and other activities resulted in the deposition of charcoal, ash, and other organic waste. To produce such a deposit, people might have disposed of food remains, charcoal, and other organic matter into the soil over an extended period of time, creating a distinct horizon that is visible in the stratigraphy. These horizons would also have a strong and distinctive geochemical signature compared to the natural stratigraphy. *Terra preta*, a type of Amazonian Dark Earth of South America, provides a good example of this kind of living surface (see the entry on Anthrosols in this volume). Though there are several hypotheses concerning how they were formed, it is generally accepted that *terra preta* represents an anthropogenic or anthropic soil, created as people continuously occupied an area for decades, adding organic matter to the soil from cooking, eating, and living (Eden et al., 1984; Woods and McCann, 1999; McCann et al., 2001; Neves et al., 2003; Glaser and Woods, 2004). In Europe, degradation of construction materials and occupation deposits associated with Roman and Classical period urban sites also forms dark earths that mark former living surfaces (Macphail and Courty, 1985; Yule, 1990; Goldberg and Macphail, 2006, pp. 271–272, 274–275, Tables 13.1 and 13.2). Thick, dark layers that often appear to be homogenous are characteristic of European Dark Earths (Borderie et al., 2015); however, micromorphological and geochemical analyses have revealed that the layers are typically anything but homogeneous and often display internal bedding (Macphail, 2002).

On the opposite end of the spectrum from a long-term occupation and associated, well-established living surface, the presence of a few artifacts in an otherwise unremarkable soil horizon may represent short-term site use. A scatter of stone artifacts that is not associated with a hearth or structure may be evidence of a site where a person or small group passed through the area but did not stay long. At these sites, a few artifacts may be the only visible evidence that a human or humans occupied the space. For example, in the open grasslands of south-central and southwestern South Dakota, bison migrated between the open prairie and the forested Black Hills. As such, many archaeological sites in the badland and grassland areas are small lithic scatters, possibly left behind as people followed the large game. The badland area also contains excellent raw material quarries. Sites near the quarries tend to consist of tested cobbles, flakes, and hammerstones (Hannus et al., 2003; Dempsey, 2014). At these sites, people picked up the raw material, determined if it was workable, took what they needed, and then moved on. These living surfaces do not have the thickness or organic content of the *terra preta* or European Dark Earths, but they constitute an important kind of living surface that helps archaeologists interpret the record of past human behavior.

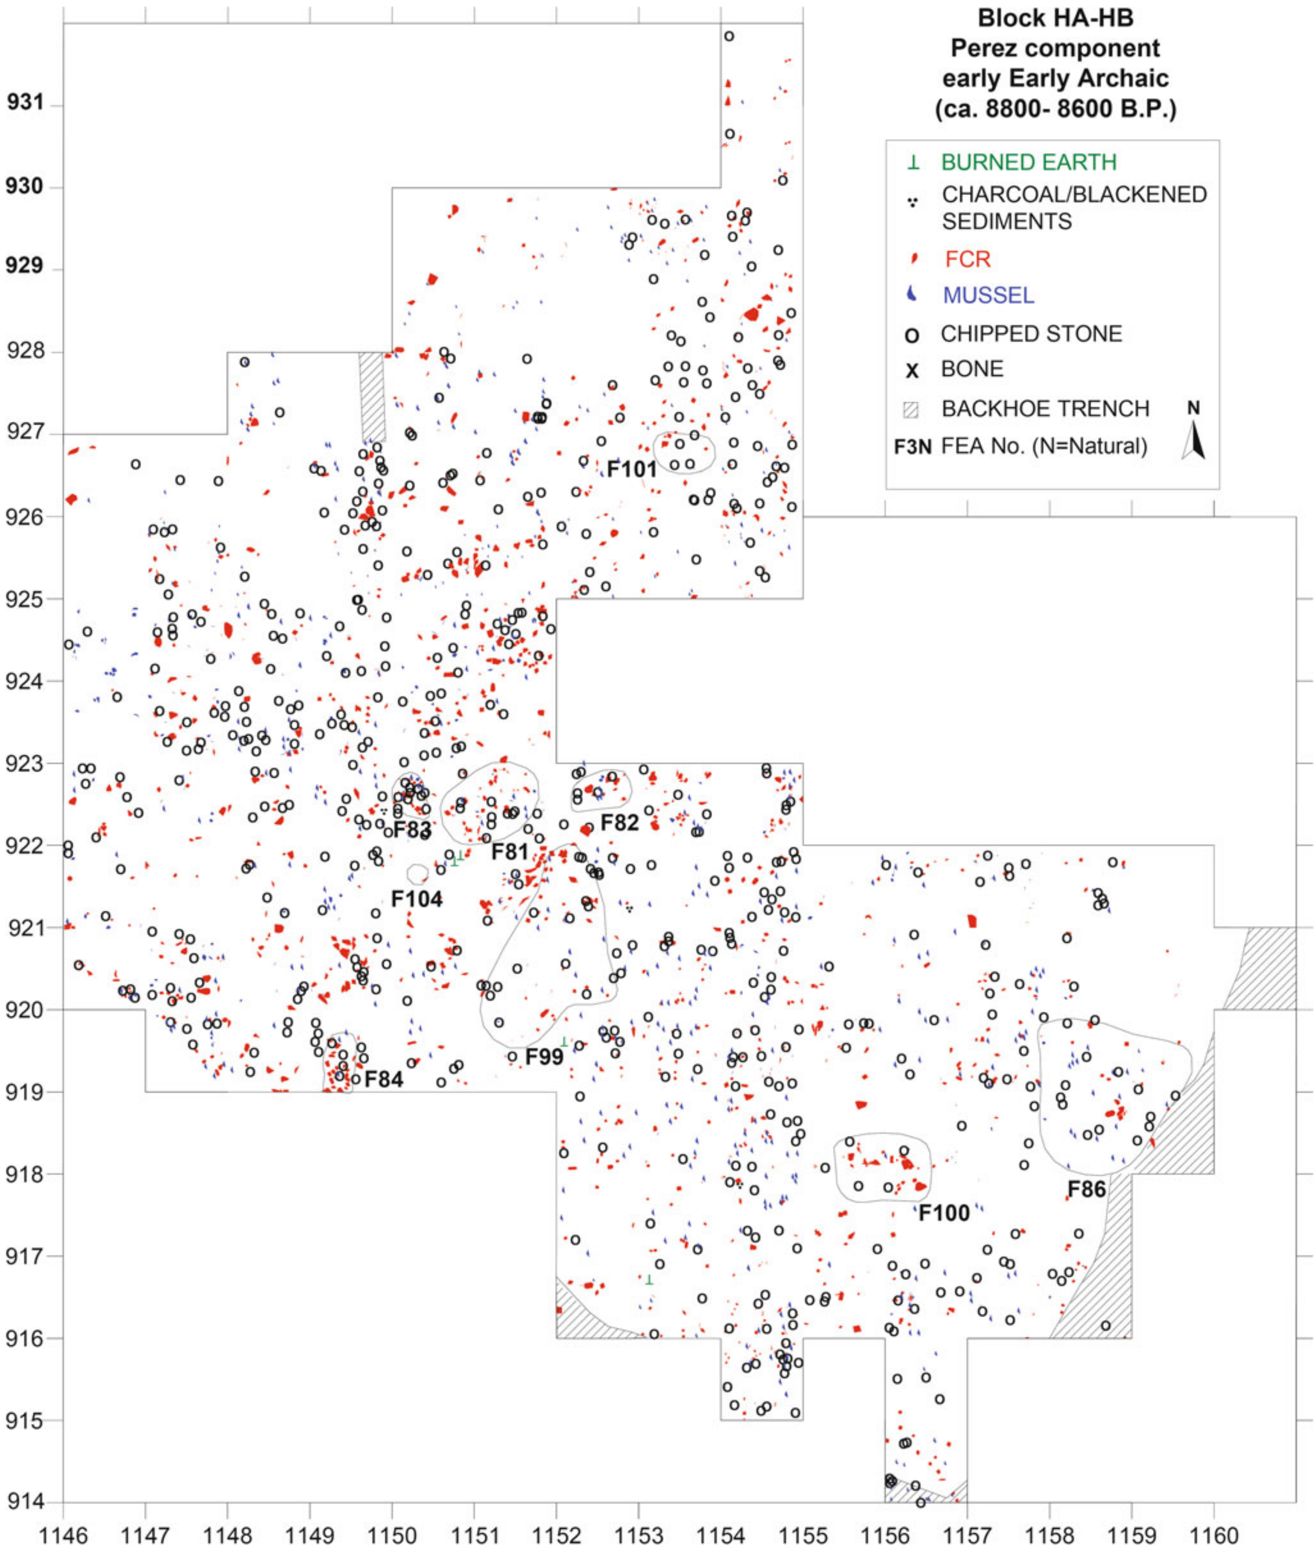
Many recorded prehistoric open-air archaeological sites fall somewhere between a long- and short-term occupation, and the associated living surfaces often have fairly dense concentrations of artifacts, but there is little or no evidence of soil *melanization* (i.e., darkening from the accumulation of organic matter). For example, at the Richard Beene site in south-central Texas, at least 20 discrete living surfaces spanning the past ca. 10,000 years were recorded in the upper 12 m of alluvial fill beneath a terrace of the Medina River (Thoms and Mandel, 2007). Nearly all of the living surfaces were represented by dense concentrations of artifacts (mostly chipped stone and fire-cracked rock) that were products of decades of occupation by hunter-gatherers on a former floodplain. Despite the abundance of cultural deposits (Figs. 1 and 2), none of the buried soils with living surfaces at Richard Beene are melanized (Mandel et al., 2007).

In caves and rock-shelters, combustion features are often associated with living surfaces, and in some cases, most of the cultural deposits in these protected settings consist of charcoal and ash (Goldberg and Mandel, 2008). For example, one of the striking characteristics of the deposits at Kebara Cave in Israel is the abundance of ashy combustion features associated with Middle Paleolithic living surfaces (Figure 3) (Meignen et al., 1989, 2001; Goldberg and Macphail, 2006, pp. 180–185). Large, prominent combustion features indicative of Paleolithic living surfaces have been recorded in other caves in the Middle East, including Tabun and Hayonim (Goldberg and Bar-Yosef, 1998), as well as in Middle Stone Age caves in South Africa, such as Klasies River Mouth, Die Kelders, and Blombos (Singer and Wymer, 1982; Marean et al., 2000).

It is important to note that living surfaces are preserved in a variety of environmental and geomorphic contexts. Caves, rock-shelters, pond or lake margins, springs, and wetlands often contain excellent examples of living surfaces for two reasons: (1) they are settings that attract humans and their prey, and/or (2) they are areas of good archaeological preservation (Ashley, 2001; Farrand, 2001; Feibel, 2001; Mandel et al., 2014). At sites in these contexts, living surfaces and other strata are often rapidly buried by sediment, and therefore lengthy exposure of such surfaces to the elements is limited. Open-air sites that occur on hilltops or along streambanks, though often equally as attractive as the localities listed above, may be less amenable to preservation because of dynamism in the taphonomic processes occurring at an elevated or fluvial site that experiences frequent or continual episodes of erosion. Living surfaces may be differentially preserved in these locations depending on the history of climate change, the density of vegetative cover, the erodibility of the sediment or bedrock, and other factors.

Identifying living surfaces

Living surfaces may be identified through several methods including visual identification of physical characteristics, geochemical analyses of soils and sediments, and geophysical techniques. A visual reconnaissance is likely the first technique the archaeologist uses to identify a living surface, the physical characteristics of which vary depending on how the surface formed. Visible differences



Living Surfaces, Figure 1 Plan view showing the distribution of deeply buried cultural materials on the Early Archaic (ca. 8800–8600 BP) living surface in Block HA-HB at the Richard Beene site, south-central Texas (From Clabaugh and Thoms, 2007, Figure 13.28).

Living Surfaces, Figure 2 A concentration of fire-cracked rock and chipped stone artifacts (red tape) marks the deeply buried Angostura (Late Paleo-Indian/Early Archaic) living surface at the Richard Beene site (Photograph by Rolfe Mandel).

in soil color, hardness or compaction of sediment or soil, and the presence of artifacts may be primary indicators that a living surface has been preserved. The distribution of artifacts and features across a living surface is an important component of interpreting behavior and formation processes at the site. Activity areas may be identified based on the distribution of cultural material. Though activity-specific remains may not occur as discrete units, analysis of microartifacts, microstratigraphy, and careful site mapping may reveal significant patterns of site use. Often, though, living surfaces are not recognizable through a visual inspection. In those cases, chemical prospecting is useful.

With geochemical prospecting, the basic premise is that certain chemical compounds are deposited in soils and sediments as a result of particular human activities (Wells and Terry, 2007; Luzzadder-Beach et al., 2011). For example, phosphorus, an element (and its compounds) that has been analyzed in archaeological research and geochemical prospection for a long time (Linderholm, 2007), is often associated with the preparation and consumption of foods and beverages. Also, sodium and potassium compounds are by-products of wood ash in hearths and kilns, and iron oxide and mercuric sulfide accumulate in soils as a result of certain pigments, such as hematite and cinnabar, commonly used in ceremonial settings such as burials and caches (Wells and Terry, 2007). These chemical compounds, especially those of phosphorus, are rapidly fixed to the mineral surfaces of sediments and tend to remain stable and immobile for long periods in most soil systems (Tiessen, 1995); hence, they are good proxies for various human activities on living surfaces.

Geochemical prospection has been used to locate and delimit site boundaries (e.g., Aston et al., 1998; Schlezinger and Howes, 2000; Haslam and Tibbett, 2004), and it also frequently serves to detect and analyze ancient living surfaces and associated activity areas (Sánchez Vizcaíno and Cañabate, 1999; Fernández et al., 2002; Hutson et al., 2009). The application of geochemical prospection has been especially critical to the evolution of Mesoamerican archaeological research (Dunning et al., 2015). For example, at Piedras Negras, Guatemala, Parnell et al. (2002) found phosphorus to be the most useful indicator of human activities, especially those involving food processing and disposal. At the rapidly abandoned site of Aguateca, Guatemala, Terry et al. (2004) demonstrated a strong relationship between phosphorus and artifact assemblages indicative of food processing and consumption. Cook et al. (2006) used inductively coupled plasma mass spectrometry (ICP-MS) analysis to test for 60 major, minor, and rare earth elements collected from living surfaces at the ancient site of Cancuen, Guatemala, with 30 elements showing enrichment compared to control areas. The most notable concentrations were of mercury and gold, which are by-products of the processing of cinnabar as a pigment and jade for ornamentation, respectively. Testing of a portable X-ray fluorescence scanner (pXRF) at the Colonial era Hacienda Telchaquillo in Yucatan indicates that this unit is useful in detecting trace metals on living surfaces, but not for detecting the presence of phosphorus (Coronel et al., 2014).

Geophysical techniques also may help identify living surfaces, particularly those that are buried. For decades, subsurface remote sensing techniques, such as magnetometry, ground-penetrating radar, resistivity, and electrical conductivity, have been used to identify buried living surfaces (e.g., Kvamme, 2001; Banning, 2002; Gaffney and Gater, 2003; Conyers, 2004, p. 146; Venter et al., 2006; Arciniega-Ceballos et al., 2009). These methods are adept at identifying near-surface cultural deposits and developing focused research programs for their study. Geophysical methods are particularly useful for understanding the distribution of living surfaces across a site, as well as differences in construction methods and variability in cultural and natural site processes (Thompson et al., 2011).

Merging different field methods and laboratory analyses has proven effective in detecting and tracing buried

Living Surfaces, Figure 3 (**a**) A sequence of combustion features and anthropogenic deposits associated with Middle Paleolithic living surfaces at Kebara Cave, Israel. The whitish zones were originally calcareous ash accumulations, which have been subsequently altered by diagenesis to apatite (calcium phosphate) or other phosphate minerals. The photo scale is 50 cm long. (**b**) Macrophotograph of the sequence of thin combustion zones from the Middle Paleolithic living surfaces at Kebara Cave shown in (**a**). Note the dark charcoal-rich layers overlain by lighter ash. The length of the macrophotograph is 75 mm (From Goldberg and Mandel, 2008, Figure 6).

living surfaces at archaeological sites. For example, Dirix et al. (2013) combined geochemical prospection and coring with geophysical techniques to detect buried living surfaces at a site in Sagalassos, Turkey. At the McNeal Alluvial Fan (site 13MC15) in Eastern Iowa, Mandel et al. (2006) combined deep coring and soil micromorphological analysis to locate and trace buried archaic living surfaces marked by concentrations of charcoal and micro-debitage. Similarly, Hajic et al. (2007) used cores and soil micromorphology to determine the spatial limits of deeply buried Paleo-Indian living surfaces at the Big Eddy Site in southwestern Missouri.

LOESSIC PALEOLITHIC, TAJIKISTAN

Richard S. Davis[1] and Vance T. Holliday[2]
[1]Department of Anthropology, Bryn Mawr College, Bryn Mawr, PA, USA
[2]Anthropology and Departments Geosciences, University of Arizona, Tucson, AZ, USA

The thick, extensive loess deposits of Europe and Asia contain buried evidence of Paleolithic occupations, and the relative ubiquity of archaeological remains spanning hundreds of thousands of years, within the loess of China, Tajikistan, Ukraine, the Czech Republic, and Germany, gave rise to the term "Loessic Paleolithic" (Ranov, 1995). The southern Tajik loess has the longest and most complete archaeological sequence; it is 100–200 m in thickness and contains multiple, well-expressed buried soils (Table 1) (Dodonov, 1991; Dodonov and Baiguzina, 1995; Dodonov, 2002). Artifacts are almost exclusively associated with the buried soils, which may have developed due to prolonged landscape stability, more hospitable interglacial climatic conditions, or some combination. The cycles of loess sedimentation and stability/soil formation provide insights into paleoenvironmental conditions and changes. Correlating buried soils between archaeological sites is key for establishing a cultural chronology.

Beginning in the 1970s, more than 40 archaeological discoveries have been made in the southern Tajik loess deposits. Virtually all the finds come from the buried soil pedocomplexes (PCs) that are correlated with the relatively warm, humid climates characteristic of interglacial periods. Principal artifact horizons are from the 12th, 11th, 6th, 5th, 4th, and 2nd PCs (lower to upper) (Table 1). Kul'dara, Karatau, Lakhuti, Obi-Mazar, and Khonako III are the chief localities where excavations have taken place and substantial collections recovered (Dodonov et al., 1992; Davis and Ranov, 1999; Dodonov, 2002). Kul'dara features a diminutive pebble flake industry located in the 11th and 12th PC, which lie below the Brunhes/Matuyama paleomagnetic boundary (~780,000 years B.P.) and are estimated to be ~800,000 years old (Table 1). Somewhat more discrete concentrations of artifacts were found within the 6th PC at Karatau I (~200,000 years ago based on thermoluminescence) and in the 5th PC at Lakhuti I (~130,000 years based on thermoluminescence) (Lomov and Ranov, 1984, 1985; Dodonov, 1991; Ranov, 1995). The TL ages may be underestimated according to Frechen and Dodonov (1998). Recent analysis has focused on correlating the PCs with marine ^{18}O stages, which would put Lakhuti and Karatau between 400 and 600 ka (Shackleton et al., 1995; Akhmetyev et al., 2005). The assemblages from both Karatau and Lakhuti also represent pebble tool industries, but they include choppers and large flake tools. The Khonako III site contains a blade industry identified as Middle Paleolithic with an estimated date of 200,000–240,000 years ago.

With the exception of Khonako III, the artifacts at all of the sites were not in concentrated horizons or clear occupational layers. They were instead distributed as if in a "suspension" (Ranov and Schäfer, 2000). At Kul'dara, for example, the density of lithic artifacts averaged less than 3 per cubic meter, and they were distributed vertically over a depth of 1.8 m (Davis and Ranov, 1999, p. 188). This highlights a problematic aspect of the "Loessic

[b]Soil type listed by Ranov (1995:Table 1) is indicated, plus likely Soil Taxonomy equivalent in parentheses.

Paleolithic" archaeology in Tajikistan and elsewhere. The pedocomplexes are 2–4 m thick, and archaeological features such as hearths, pits, or activity areas are absent. Only occasional faunal fragments have been found. The zones of maximum artifact concentration are in association with the zones of maximum pedogenic expression, but no discrete occupation levels are apparent. One interpretation is that there was repeated occupation of the sites during slow aggradation of the soils (Lomov and Ranov, 1984, 1985). This could well be the case on a loess landscape, as described in the model of soil upbuilding (Kemp, 2001). Turbation cannot be discounted as a cause, however. In comparing the vertical distribution of artifacts at Lakhuti, Karatau, and Kul'dara, the youngest site (Lakhuti) has the most discrete concentration, while the oldest site (Kul'dara) has the least discrete concentration (see Lomov and Ranov, 1985, Figures 30–77; or Holliday, 2004, Figure 6.19).

The Tajik loess finds are highly significant discoveries. They were the first Lower and Middle Pleistocene Paleolithic sites found in good stratigraphic context, and they documented an adaptation of early populations to a semiarid interglacial environment within Central Asia.

LUMINESCENCE DATING OF POTTERY AND BRICKS

Ian K. Bailiff
Department of Archaeology, University of Durham, Durham, UK

Definition

The luminescence dating of ceramic materials, including pottery and bricks, is an experimental method for determining the time elapsed in years since the ceramic material was produced by firing in a kiln.

Introduction

Luminescence techniques for dating ceramic artifacts have been described in detail by Aitken (1985, 1998), and guidelines produced by English Heritage (Duller, 2008) provide a concise overview of applying the method. Although the dating of sedimentary deposits currently forms the main focus of application for luminescence dating in general, the dating of ceramics is discussed here and in a number of review papers (Feathers, 2003; Preusser et al., 2008; Wintle, 2008; Liritzis et al., 2013), and also by Wagner (1998).

Historical perspective

When thermoluminescence (TL) dating was proposed as a new scientific dating method in the 1960s (Aitken, 1985; Wintle, 2008), its viability was demonstrated using pottery from archaeological contexts, objects that had been heated in the course of their production. Application to other types of ceramic artifacts, such as curated works of art (Fleming, 1979), and ceramic building materials (CBMs) soon followed. During the 1980s the development of optically stimulated luminescence (OSL) techniques led to a focusing of research effort on the dating of processes associated with sedimentary deposits that had not been heated above ambient temperatures, and this type of application now dominates the field. Both TL and OSL measurement techniques can be applied to date ceramic materials, but the use of OSL tends to be preferred by dating laboratories.

Although testing of the earliest pottery of Late Pleistocene origin is within the chronological range of the method (Kuzmin et al., 2001), its adoption for dating pottery was muted, despite the common occurrence of pottery on many sites from the Neolithic onwards (Orton et al., 1993). For general application, the specialist advice needed for sampling made its deployment less convenient compared with radiocarbon testing, and, moreover, the levels of uncertainty in luminescence dates were considered too high to improve upon pottery chronologies developed on the basis of typology and fabric analysis. Since the dating of many sites of late prehistory has relied on the use of typologies and other visual characteristics, there is an interest in testing the robustness of such pottery chronologies by applying absolute dating methods. In cases where the application of radiocarbon is not appropriate, either because of poor temporal resolution arising from calibration issues or where no suitable organic samples are available, there is consequently a potential role for luminescence to serve in the testing of pottery chronologies. In addition, the dating of brick in standing buildings and monuments lacking diagnostic features has, after years of dormancy, become an active area of research.

Technical issues

The clock mechanism that forms the basis of luminescence dating employs the buildup of electric charges (e.g., electrons) stored in "traps" that are associated with imperfections within the structure of crystalline grains of luminescent minerals (e.g., quartz and feldspars). Ionizing radiation emitted by naturally occurring radioactive sources present within ceramic and environmental materials (e.g., soils forming the burial medium) penetrates the mineral grains, causing the generation of free electric charges within the grains. Some of the electrons removed from their orbitals by the radiation are captured and stored in the traps, and over time, the energy absorbed by the grains during this process is defined as the "absorbed dose." The population of trapped charges increases with time until it is released by heat stimulation of the grains in the laboratory, producing luminescence. In simple terms, the intensity of the luminescence emitted is proportional to the time elapsed since a "zeroing" process. For ceramic materials, heating to firing temperatures represents that zeroing because it removes all previously stored charges, resetting the clock mechanism, and, upon cooling to ambient temperatures, the accumulation of trapped charges resumes. The (steady) rate at which the population of stored charges increases with time is proportional to the dose rate, which is related to the concentration of radioactive sources within the ceramic and in the surrounding burial medium. These concentrations vary according to the geological source of the material.

The luminescence age equation (Aitken, 1985, 1998), expressed in its most compact form,

$$\text{Age} = \text{Paleodose/Dose Rate},$$

is used to calculate the time elapsed since the zeroing process. The age, given in years before the year of testing, is accompanied by an overall uncertainty, given at the 68 % level of confidence (1σ), that is, typically between ±5 % and ±10 % of the age. The paleodose, determined by applying luminescence techniques (these are discussed in Duller, 2008) to grains extracted from the dating sample, corresponds to the cumulative absorbed dose (in units of gray, Gy) received by the grains following a zeroing process, such as a kiln firing in the case of a ceramic. Since resetting can be achieved at temperatures as low as ca. 400 °C (i.e., baked or burnt clay), most well-fired archaeological pottery will have met this condition. Within the relatively short lifetime of a cooking pot, the effect of reheating on a fire has a negligible effect on the luminescence age, but if sherds were redeposited onto a ground surface long after burial and subjected to prolonged heating during a conflagration to temperatures in excess of those indicated above, resetting would occur and a date for the destruction event obtained, not the original kiln firing. The value of paleodose inserted into the age equation is obtained by calculating the average of the results obtained from many individual samples of grains, making the experimental work a lengthy process. The dose rate is usually determined by measuring the concentration of radionuclides present in the sample and the surrounding burial medium and then applying conversion factors (Aitken, 1985, 1998).

Paleodose

Most ceramic materials contain grains of luminescent minerals, such as quartz and feldspar, within the fine (e.g., <20 μm diameter) or coarse (e.g., 100–300 μm diameter) fractions of clays and temper, respectively. Such grains can be extracted in the laboratory by mechanical crushing and sieving and the application of acid treatments. Typically, a minimum of 25 g of ceramic is sufficient for dating measurements, although for some applications this can be reduced significantly by drilling (Fleming, 1979). There are important differences in the luminescence properties of the two commonly present mineral types, quartz and feldspar, and this affects their use for dating measurements. In particular, trapped charge, which forms the basis of the chronometer mechanism, is retained without significant loss in quartz over archaeological timescales, whereas for most feldspars, there is a small but continuous loss due to a physical effect referred to as anomalous fading that causes the age to be underestimated. Although a correction can be applied for the loss, this increases the uncertainty in the luminescence age, and each sample must be tested to establish the extent of fading, since the rate of loss varies according to the geological source of the feldspar (Lamothe, 2004). Hence, coarse quartz grains are usually preferred when testing ceramic materials, providing they are present in the fabric. Where this is not the case, extraction of the "fine-grain" fraction that usually contains both quartz and feldspar provides an alternative approach. Although feldspars can be selectively removed using acid treatment, the fine-grain technique for paleodose determination tends to be applied routinely without such additional treatment unless part of a methodological study.

Dose rate

There are two physical volumes of interest when assessing the dose rate to grains extracted from a sample to be dated: (a) the ceramic sample itself and (b) its immediate environment. The latter comprises the burial medium (to a distance of about 50 cm; Aitken, 1985) which contains radionuclides emitting gamma rays contributing ca. 25–45 % of the dose rate, where the proportion depends on the grain size selected for paleodose measurements. Hence an assessment of the radionuclide content of both the ceramic artifact and the immediate environment is required. The assessment of the dose rate is more complex for samples adjacent to layers of media with differing radionuclide composition or within deposits near the ground surface, for example, and for this reason the longstanding advice given (Aitken, 1985) in the case of excavated pottery has been to select samples located within a uniform burial medium. Given that much of the burial medium of interest may have been removed during excavation, this technically sound sampling advice has persisted (Duller, 2008). For more complex situations, such as shallow or surface contexts, laboratories may use the fine-grain fraction for paleodose determination because a higher proportion (ca. 75 %) of the dose rate is due to radioactive sources located within the pottery, and this demonstrates that the composition of the burial medium and the extent of overburden exert somewhat less influence on the luminescence age. In the case of a brick within the external wall of a standing building, the immediate environment, as referred to above, includes the surrounding bricks and the ground adjacent to the wall (e.g., soil); in this instance, a sample location having the simplest environment is usually preferred.

A further factor that has a bearing on sampling is the moisture content of both ceramic and the burial medium because water has a moderating effect on the dose rate. An average value for the moisture content during the burial period is estimated by the laboratory, and a conservative allowance is usually made for the uncertainty (typically ± 20 %) in the value adopted. Although the maximum moisture uptake of the ceramic, which is controlled by the porosity of the fabric, can be measured in the laboratory, it is desirable to obtain samples of both pottery and soil and store them so as to retain the moisture content representative of contemporary conditions within the burial environment. The overall precision in the luminescence age increases (i.e., the uncertainty is lower) in regions where there has been long-term aridity, but it decreases where the pottery is porous and the moisture content relatively high.

Luminescence age

There is no internationally agreed specification for the presentation of luminescence dating results, but a listing of technical parameters related to the evaluation of the paleodose and the dose rate normally accompany the luminescence age in publications and formal reports. The Ancient TL Date List, although no longer actively compiled, provided a systematic compilation of dating results, and the last two issues produced included listings of luminescence dates for pottery from Britain (Barnett, 1999) and the Southwest of North America (Feathers, 2000); more recent guidance concerning aspects of date quotation is included in Duller (2008).

Pottery

Applications of the method to dating pottery can be broadly grouped into those that (a) establish the date of deposition for a layer or feature from which the pottery was recovered, (b) test chronologies developed through pottery typologies, and (c) examine methodological issues, such as the feasibility of dating a previously untested type of pottery. There are several published large-scale dating studies, where the term "large scale" applied here refers to several tens of determinations rather than the several hundreds that could be envisaged with radiocarbon.

The accuracy of luminescence has been tested against independent dating evidence with pottery recovered from sealed contexts where its use before deposition was judged to be short-lived. From a statistical analysis of the results for 24 sherds of diagnostic pottery of the British Iron Age (first millennium BC), an average difference of $\sim$100 years was obtained between the luminescence dates and the midpoint of the assigned age range in each case (Barnett, 2000). Similarly, comparisons of luminescence dates for pottery from short-lived Navajo sites of ca. AD 1700 in North America with independent dating evidence provided by dendrochronology produced a favorable outcome (Feathers, 2000, 2003).

On many sites, pottery is frequently undiagnostic and found scattered both spatially and temporally within the stratigraphy. Following fragmentation and discard, sherds may be redeposited in the filling of large features such as ditches, pits, and middens. Luminescence dating of pottery from sites in Britain and North America has confirmed that indiscriminate testing of redeposited pottery in large features will produce misleading results when the processes of manufacture and deposition are significantly displaced in time. However, luminescence has a constructive role to play by providing a means of testing chronologies for the onset and persistence of particular fabric types. The luminescence dates obtained in several studies on pottery from sites in Britain (Barnett, 2000; Cramp, 2006) and North America (Feathers, 2009) have challenged aspects of previously established fabric chronologies. In one region of Britain (Northampton), the incorporation of fine or coarse shell fragments in temper had been used to distinguish Early and Late Iron Age manufacture, corresponding to a separation of several hundred years, yet the luminescence dates showed that each type of temper was not confined to one of these periods and that the two groups strongly overlapped. In related work, the luminescence dates obtained for sherds of scored ware thought to have been introduced during the fourth century BC suggest much earlier introduction, in the ninth century BC. Comparable issues have been raised by the testing of shell-tempered pottery from North American native sites in the Lower Mississippi Valley (Feathers, 2009) and also sand-tempered fabrics from sites in southern Florida (Feathers, 2003). While the majority of luminescence dates obtained for shell-tempered pottery from two mound sites were consistent with the assigned date range in the early eleventh century AD on the basis of the cultural assemblage and radiocarbon dates, luminescence dates of up to nearly a millennium earlier were obtained for several sherds from each site. These early dates, although considered enigmatic, flagged the possibility that relict pottery may have been brought to the sites by migrants. AMS radiocarbon dating applied to the carbonate temper to cross-check the reliability of the luminescence dates has since indicated that further work is required to evaluate the extent of a reservoir offset correction to the radiocarbon ages (Peacock and Feathers, 2009). Resolution of this issue represents an important test of the capability of luminescence to provide a reliable tool for investigating the full temporal ranges of pottery chronologies. While this aspect is being more actively investigated for North American pottery, work has also progressed sporadically on various sites across Eurasia and East Asia.

Due to the nature of the native North American mound sites, pottery is sampled from contexts that are very shallow or within erosional surfaces. As indicated earlier, the fine-grain technique can be applied in such cases to reduce the uncertainty in the dose rate, albeit with the attendant issue of anomalous fading to deal with if the feldspar minerals are not removed. The further development of such work has wider methodological implications for sites in other parts of the world where pottery surface scatters form a key component of the surviving archaeological evidence (Dunnell and Feathers, 1994; Sampson et al., 1997) and where the testing of organic matter by radiocarbon is highly problematic because of postdepositional disturbance.

Ceramic building materials

The dating of ceramic building materials (CBM) is a natural extension of the dating of pottery in terms of the experimental techniques applied. Fired brick has been used extensively in the construction of buildings during the last two millennia, and although the literature is currently limited, examples of dating applications can be found for individual buildings and structures in Europe (e.g., the Czech Republic, Denmark, England, Finland, France, Germany, Italy, and Poland), in Asia (e.g., Cambodia, India, Sri Lanka, Thailand, and Uzbekistan), and in South America (Brazil). While precise dating of high-status buildings of the last millennium can be obtained to within a couple of decades or better, lower-status "vernacular" buildings of the Late Medieval and early modern periods in Europe are problematic; dating the construction and phasing of structural changes to better than 50–100 years are often difficult to achieve. In these circumstances, there is the opportunity for luminescence to make a contribution to the dating of brick buildings where an overall uncertainty in the date of ca. ± 5 % of the age (± 25 years for a 500-year old sample) can be approached. When applied to four buildings with reliable documentary and stylistic dating evidence in England, luminescence dating of brick produced extremely encouraging agreement (Bailiff, 2007): for six samples taken from these dating control buildings (within the range of ca. AD 1400–1720), the mean difference between the central values of luminescence and assigned ages was 5 ± 10 years (s.d., $n = 6$).

The value of applying an absolute dating method is illustrated by studies that address wider research questions of chronology that are not bound by regional typologies and also extend beyond application to a single building. For the period following the Roman withdrawal from northwestern Europe during the early fifth century AD, in particular from Britain and Gaul, there has been a longstanding uncertainty regarding when the manufacture of CBMs was resumed. Recent work with bricks from a group of ecclesiastical buildings in northwestern France (Blain et al., 2007) and England (Bailiff et al., 2010) indicates that, while in France the practice of brickmaking was maintained during the Early Medieval period, it did not resume until the eleventh century AD in England. The testing of brick from Late Medieval buildings in England has also provided an initially unexpected outcome. Whereas it had been assumed that new bricks were produced for a specific building, the dates obtained for multiple bricks from a single building suggest that recycling was practiced by late medieval builders. This is of particular interest to building historians when assessing changes to, and loss of, buildings in urban and rural landscapes. However, the possibility of recycling CBM also provides a note of caution when sampling: in addition to a structural examination of the phasing of a building, the brickwork requires careful inspection for the use of recycled brick. In response to this issue, the possibility of dating the emplacement, rather than manufacture, of bricks using OSL has been explored by testing luminescent grains located within either the surface of a brick (Vieillevigne et al., 2006) or incorporated in lime mortar (Goedicke, 2011), as long as the grains were sufficiently exposed to sunlight before use in construction and subsequently stored under dark conditions until tested in the laboratory.

Summary

After a prolonged period of gestation, two main methodological roles for the application of luminescence dating to archaeological ceramic materials have emerged: the building and testing of pottery fabric chronologies and dating the manufacture of ceramic building materials. When luminescence dates for pottery and brick have been compared against independent dating evidence in well-designed studies, the performance of the method has been found to be reliable and accurate within the estimated experimental uncertainties.

Magnetic prospecting

Definition

Magnetometry. Application of magnetometers to detect and trace archaeological features and structures that lie beneath the ground

Field magnetometers. Instrumentation adapted for magnetic prospection of near-surface structures in archaeology

Soil magnetism. Applying mineral magnetic analysis and methods of measuring rock magnetism to the characterization of the magnetic properties of soils

Introduction

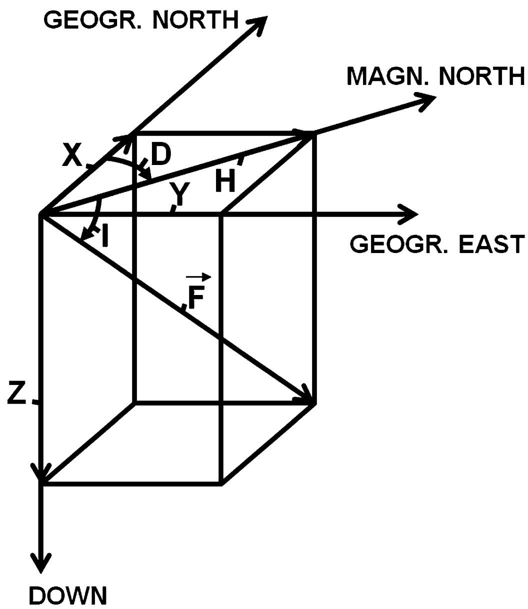
Magnetic prospection was applied for the first time to archaeology in 1956 (Belshé, 1957; Aitken, 1958), and over the years since then, it has become one of the most important archaeological methods for the detection and mapping of buried remains at large archaeological sites (Aitken, 1974; Scollar et al., 1990; Clark, 1996; Neubauer et al., 1998–1999; Benech, 2005; David et al., 2008). Magnetic detection methods are extremely sensitive in the characterization and analysis of iron oxides, much more so than any other form of chemical analysis. Therefore, given a full understanding of the nature of magnetic properties, many details of soil layers and buried archaeological structures can be discovered, visualized, and interpreted only by the "magnetic eye" (Schleifer et al., 2003; Fröhlich et al., 2003; Schleifer, 2004). A complete archaeological interpretation prior to excavation must consider all available archaeological background information as well as surface findings; however, many more crucial details can be derived through a comprehensive soil magnetic analysis, and many new archaeological questions arise from such geophysical prospecting results. For a long time, archaeologists held the firm conviction that geophysical prospecting results on their own would be only of limited use in the resolution of archaeological problems. Today, it has become commonplace that the initiation of a modern archaeological excavation must be preceded by some kind of geophysical prospecting (Schmidt, 2002; Fassbinder, 2007; Aspinal et al., 2008; Fassbinder, 2015a).

The great success of magnetic prospection in general is due to the fact that almost all soils of the world show an enhancement of magnetic minerals such as maghemite or magnetite in the topsoil (Le Borgne, 1955, 1960). Except for very rare situations, mostly on sites with dammed-up water and consistent soil wetness, there exist no limiting geological factors precluding the application of magnetic prospecting. Enrichment of these minerals in archaeological soil layers – especially in fireplaces, but also in ditches, pits, or postholes – is caused by the formation of these minerals either by natural or anthropogenic fires, varied pedogenic processes (Taylor et al., 1987), or magnetotactic soil bacteria (Fassbinder et al., 1990; Stanjek et al., 1994). The use of fire, however, plays the major role in the enhancement of magnetic minerals in soils, since this occurs on nearly all sites from the Paleolithic to modern times.

The magnetometer

There exists a wide range of suitable but very different instruments for the measurement of the Earth's magnetic

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,



Magnetometry for Archaeology, Figure 1 Common coordinate system representing the Earth's magnetic field. The declination angle between geographic (true) north and magnetic north is the declination (D). The inclination (I) is the magnetic dip, an angle that varies from place to place because the lines of force of the Earth's magnetic field do not generally run parallel to the ground surface. The intensity (F) of the field is proportional to the force it exerts on a magnet. Another common representation uses x- (north), y- (east), and z- (down) coordinates.

field (Lenz, 1990); however, for the special application of archaeological prospection, a robust but also sensitive instrument that can be operated easily and quickly in the field is required (Becker, 1995, 1997; Gaffney et al., 2000).

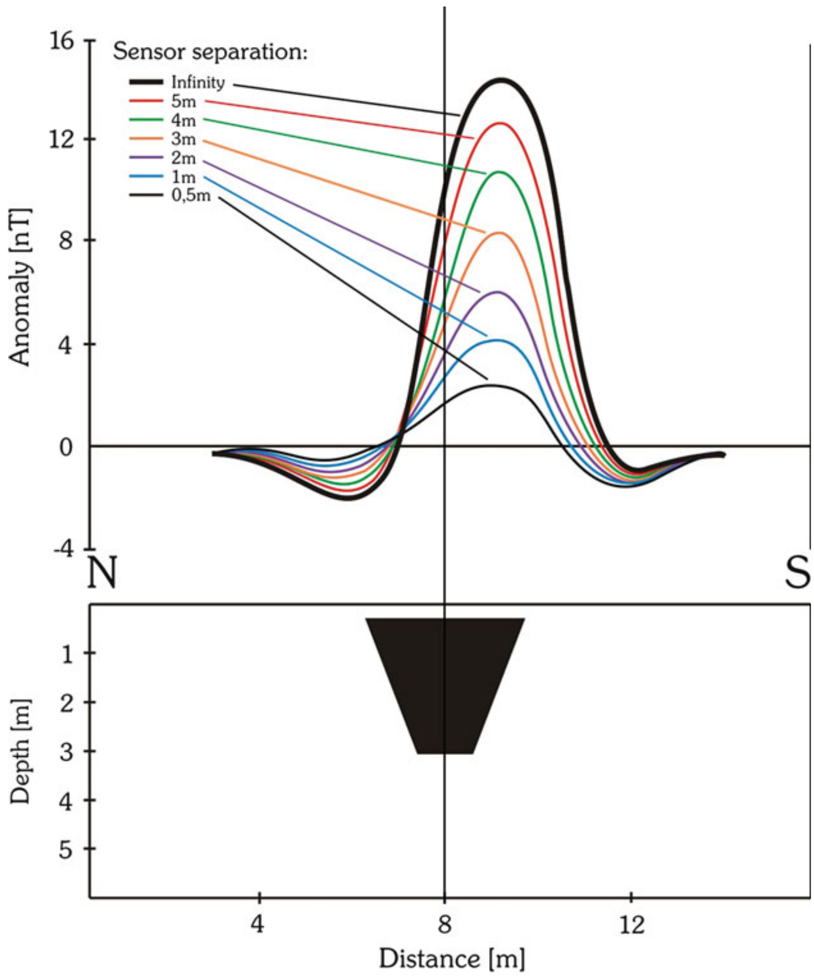
The survey procedure involves marking out the area to be surveyed as a grid of 20 × 20 m, 40 × 40 m, or other dimensions and then conducting the survey by measuring the magnetic field at discrete intervals, such as distances of 25 × 25 cm or 25 × 50 cm. Surveying on a grid requires walking along the guidelines to mark the profiles. The magnetometer probe can be carried by hand or mounted on a wheeled device ca. 30 cm above the ground. With the use of an integrated GPS, it is possible to eliminate the need to walk along the guidelines, but the survey still requires walking perfectly straight lines with a clipping radius of 25 cm to guarantee sufficient accuracy.

In general, one has to differentiate between *vector* and *scalar* magnetometers. While the vector magnetometer measures only the intensity of one direction (the x-, y-, or z-component) of the Earth's magnetic field, the scalar magnetometer measures the total intensity, F, of the Earth's magnetic field more or less independently of the orientation of the probe (see Figure 1).

The diurnal variations of the Earth's magnetic field are sometimes in the same range as those of the magnetic anomalies caused by buried archaeological remains. These diurnal disturbances are removed automatically with vector magnetometers since they are designed as gradiometers and can be operated in the field in a gradiometer mode only – where the device measures the gradient z-component of the Earth's magnetic field (determined by two fluxgate sensors that are mechanically fixed within a single device). In theory, and in the laboratory, one could design such a device with any arbitrary intersensor distance, but in practice it is difficult to design such a mechanically stable instrument with a nonmagnetic distance. Commercial fluxgate magnetometers are available with gradients of 50–100 cm. Scalar magnetometers are more or less tolerant of tilting sensors and can be applied as a differential or as a variometer system – where the device measures the difference in magnetic field between two places at the surface using adjacent sensors and thus with gradients greater than 5 m. Otherwise, the resulting data need complex treatment in order to remove the effects of these daily variations.

The decision to use a particular magnetometer system should be carefully balanced between the advantages and disadvantages of each system, and this will depend very much on the situation and the specific aim of the survey. Vector magnetometers that are designed for the measurement of the z-component (vertical) are quite independent of disturbances in the x-y horizontal components. Hence, these instruments can be more easily operated in the vicinity of a magnetic vehicle or nearby technical installations (e.g., metal structures, brick buildings, etc.) that would interfere with the measurement of subsurface variations. On the other hand, instrument sensitivity is limited by other factors, namely, the need to use a gradiometer system. Although SQUID magnetometers (superconducting quantum interference devices with sensitivity of the tensor component ±1 femtotesla or 10^{-15} T) are physically the most sensitive instruments, in practice (like other vector magnetometers), they can operate only in a gradiometer mode (Chwala et al., 2001; Schultze et al., 2007). While fluxgate magnetometers operate with a separation of 50–100 cm, SQUIDs are restricted by other physical reasons to a sensor separation of 4 cm.

Modern total field instruments like the proton magnetometer, the Overhauser magnetometer, or the optically pumped alkali-vapor magnetometer such as cesium magnetometers have a sensitivity of ±0.1 picotesla (10^{-12} T), but they can be operated in a "variometer" or "duo-sensor" configuration and therefore reach an overall sensitivity that is in the same range as the SQUIDs (Lenz, 1990; Becker, 1995, 1997). In this differential configuration, the reference probe is set virtually to infinity, and therefore all magnetic anomalies will be detected with their maximum intensity (Figure 2). The advantage is that the resulting image gives more information at greater depths (ca. 1–3 m), while fluxgate gradiometer results



Magnetometry for Archaeology, Figure 2 Dependence of the intensity of a magnetic anomaly above a V-shaped ditch (about 2.75 m deep and 3.5 m wide at the top) on the sensor/probe configuration of a magnetometer calculated for an inclination of the Earth's magnetic field of 60° in the northern hemisphere.

show archaeological structures more sharply, since they may be limited to the first meter beneath the surface by their gradient configuration of 50–60 cm. On the other hand, it is "disturbed" by geological features and very much by narrow technical installations and/or small amounts of modern metal waste.

Digital image processing

Digital image processing of geophysical data represented a milestone in the field of archaeological prospecting and a crucial step in making survey results intelligible to both geophysicists and archaeologists. The potential for digital image processing of geophysical data compared to the isoline display ("contour" lines joining areas with the same magnetic intensity values) was recognized and applied very early in the history of archaeological prospecting (Scollar and Krückeberg, 1966). Meanwhile, sophisticated programs are available that enable one to treat the data with a multitude of correcting and processing tools appropriate for the requirements of the different instruments used in archaeological prospection (Schmidt, 2002; David et al., 2008).

A survey area should be measured by a sampling interval of at least 25 × 50 cm or even better 25 × 25 cm. The magnetometer data (the relative intensity versus x-y-position) is then converted to a gray-shaded image, displayed on the computer screen, and then exported and stored as a tif file. The reason for the display as a gray-shaded image is twofold: (1) the intensity of the magnetic field is a single-parameter data set, so the only physically sensible display of such data is using a single-parameter scale and (2) the human eye is capable of discriminating up to 60 grayscales. Hence, the display of magnetometer data as a grayscale plot of 256 gray shades (from white to black) is a crucial tool for the success of this prospection method. The popular term for the resulting image of the magnetometer data is "magnetogram," although this term is also used in geomagnetism to describe the variation of the Earth's magnetic field with time.

Soil magnetism

Small-scale or local deviations in the intensity and/or direction of the Earth's normal magnetic field are caused simply by the magnetic contrast between buried archaeological features and the adjacent soils and sediments; these variations enable magnetometers to detect archaeological sites beneath the ground. The enhancement of ferrimagnetic minerals in the topsoil is a common property of almost all soils worldwide (Le Borgne, 1955; Mullins, 1977; Fassbinder and Stanjek, 1993). It has been observed even in very magnetic soils of volcanic origin (Tucker, 1952; Fassbinder et al., 2009).

Enrichment and separation of these heavy ferrimagnetic minerals to form magnetic patterns can occur mechanically by wind or water (Fassbinder et al., 2005) as well as by pedogenic processes in soils, but it is produced most commonly by the heating of soils during natural fires and, more intensively, by the use of fire concentrated in limited spaces by people. Once produced in the topsoil, these minerals end up in ditches, pits, palisades, or postholes, and they will generate a magnetic anomaly that can be sensed by instrumentation above the ground.

Formation of magnetic minerals in soils

Enrichment of ferrimagnetic minerals in topsoils was recognized and described by Le Borgne (1955, 1960) and initially ascribed to the widespread use of fire during forest clearance or other anthropogenic activities. But it soon became clear that many archaeological features previously detected by magnetometers as positive anomalies (the feature in question shows stronger magnetic signals than surrounding soils or the Earth's field in general) were never exposed to fire (Fassbinder, 1994). Tite and Linington (1975) showed that climate also has a huge influence on magnetic susceptibility due to the formation of magnetic minerals (magnetite and maghemite) in soils (magnetic susceptibility is the ratio of the magnetization M of a material to the magnetic field H inducing it). The distinction between magnetite and maghemite as well as other magnetic sources is of great importance (Tables 1 and 2). The presence of one of them may provide valuable information about the history of an archaeological site since it allows one to discriminate between modern metallic waste, burned features such as kilns and fireplaces, and pure organic waste pits, cesspits, or bogholes – e.g., in horse stables of Roman camps (Fassbinder 2010a).

Le Borgne (1955, 1960) ascribed the formation of maghemite either to:

Magnetometry for Archaeology, Table 1 Occurrence and origin of magnetic iron oxides and sulfides in soils and archaeological layers and objects

Phase	Origin		
	Pedogenic	Lithogenic	Anthropogenic
Magnetite	SP, SD	SD, PSD, MD	Industrial dust
Maghemite	From Gt, Lp by fire	Oxidized Mgt	Oxidized Mgt, industrial dust, ceramics
Greigite	SP, SD	??	No
Hematite	Yes	Yes	Fire, industrial dust, ceramics
Goethite	Yes	Yes	No
Ti-Mgt, Ti-Mgh	No	Yes	Ceramics

SP, super paramagnetic; PSD, pseudo-single domain; SD, single domain*; MD, multi-domain; Gt, goethite; Lp, lepidocrocite; Mgt, magnetite

*Single-domain grains are too small to accommodate a domain wall and hence exhibit only one magnetic direction. They must change their magnetization by rotation. They exhibit a unique thermoremanent magnetism (TRM, see below) blocking temperature, while the TRM of larger multi-domain grains is complicated by the mobility of the domain walls (Dunlop and Özdemir, 1997)

Magnetometry for Archaeology, Table 2 List of the specific magnetic susceptibility (nondimensional SI units) of natural magnetic minerals and ferrous iron

Remanence-carrying minerals	Specific susceptibility (SI units)
Ferrous iron	2×10^7
Magnetite (Fe_3O_4)	5×10^4
Maghemite ($\gamma - Fe_2O_3$)	4×10^4
Pyrrhotite (Fe_2S_8)	5×10^3
Ilmenite ($FeTiO_3$)	200
Lepidocrocite (FeOOH)	70
Goethite ($\alpha - FeOOH$)	70
Hematite (Fe_2O_3)	60

1. Fermentation, with reduction by the decomposition of organic materials in anaerobic soils, followed by reoxidation to maghemite during dry weather periods under aerobic conditions
2. Natural and anthropogenic fire:

$\propto - Fe_2O_3$ hematite	reduction	Fe_3O_4 magnetite	oxidation	$\gamma - Fe_2O_3$ maghemite

Both processes start with hematite, have magnetite as an intermediate phase, and should finally yield maghemite. Synthesis experiments and observations in nature, however, indicate that the processes forming maghemite are different and more complex. Four precursors are known for maghemite:

1. Magnetite inherited from a parent rock or sediment oxidizes (partially) to maghemite. These maghemites usually have grain sizes in the range of millimeters. This process has been observed, e.g., for titanomagnetites (Fitzpatrick and Le Roux, 1976).
2. Depending on the particle size, lepidocrocite (γ – FeOOH) dehydrates between 260 °C and 300 °C to maghemite (Scheffer et al., 1959; Schwertmann and Taylor, 1979).
3. In the presence of organic matter, goethite is transformed to maghemite during bushfires (Schwertmann and Fechter, 1984; Anand and Gilkes, 1987; Stanjek, 1987).
4. Siderite ($FeCO_3$) oxidizes readily to maghemite when it is gently heated (Van der Marel, 1951; Schwertmann and Heinemann, 1959).

Hematite, however, has not yet been observed acting as a precursor for maghemite or magnetite. Apart from the fact that hematite is not always present in soils in which maghemite is found, it has not been conclusively shown that hematite can be reduced to magnetite under natural soil conditions. Mineral assemblages (Anand and Gilkes, 1987; Stanjek, 1987) as well as calculations (Scotter, 1979) suggest that the maximum temperatures reached in topsoils during natural episodes of burning are about 300–400 °C, and at these temperatures, a reduction of hematite by reducing agents such as organic carbon is unlikely.

The formation of magnetite in soils and sediments is still debated with some controversy in the literature (cf. Oldfield, 1992; Dearing et al., 1997). Two pathways for its pedogenic formation have been proposed:

1. Inorganic: in synthesis experiments, the controlled oxidation of ferrous iron yields magnetite (David and Welch, 1956). This inorganic formation may also take place in soils (Maher and Taylor, 1988).
2. Biologically: the biologically controlled formation of magnetite (BCM) by soil bacteria has been observed by Fassbinder et al. (1990). The intracellular magnetite crystals formed in this way may be arranged in chains and have similar size and shape to magnetite that was extracted from soils. Furthermore, dissimilatory iron-reducing bacteria such as GS-15 (Lovley et al., 1987) may form magnetite extracellularly (referred to as biologically induced formation of magnetite or BIM) in soil.

The formation of greigite (Fe_3S_4) in soil can occur by two pathways:

1. Inorganic: it has been shown in synthesis experiments under controlled conditions that greigite can be produced by combining aluminum ferrous sulfate with sodium sulfide, autoclaving, and quenching (Uda, 1965).
2. Biologically controlled: evidence of magnetotactic greigite bacteria was found by Mann et al. (1990). Evidence of biologically unidentified soil bacteria was reported by Stanjek et al. (1994) and Fassbinder and Stanjek (1994). Both greigite and magnetite magnetotactic bacteria are reported to precipitate either magnetite or greigite. The crystals form within a membrane and are arranged into chains. They can be preserved as magnetofossils in archaeological layers, soils, and sediments and in the geological record (Petersen et al., 1986).

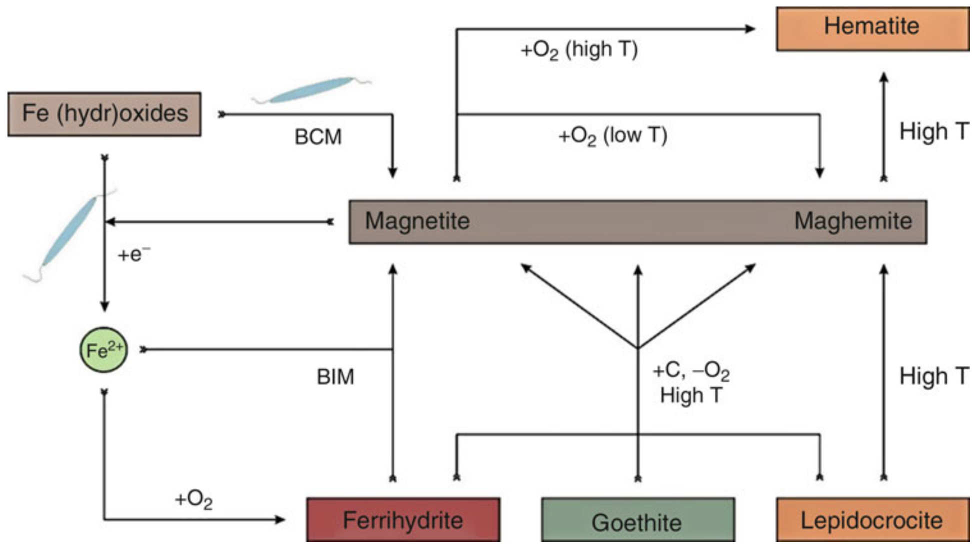
The formation and transformation process of iron oxides in soils is a complex interrelation between geochemistry, temperature, temporary weather conditions, and climate (Schwertmann, 1988). A simplified chart illustrating the different pathways in the formation and transformation processes for magnetite and maghemite that may occur in natural soils and sediments is shown in Figure 3.

Induced magnetization

If a ferromagnetic sample is exposed to a magnetic field, a magnetization J_i will be induced in the sample. Magnetometer measurements in an applied field (in the range of the Earth's magnetic field) provide information on the nature and quantity of the magnetic minerals and can therefore monitor changes that occur in a sample as a result of heating. Examples of archaeological sites where the resulting magnetic anomalies can be explained by the induced magnetization of the features come from archaeological sites in the Nile Delta (Becker and Fassbinder, 1999) and from a kiln site near Regensburg, Bavaria (Fassbinder et al., 2011) (see below, Figures 5 and 9). Knowledge of the origin and formation of iron oxides in soils and the specific magnetic susceptibility values of these minerals and of ferrous iron (Tables 1 and 2) allow improved specification and analysis, and thus a better and more detailed interpretation, of the intensity of a magnetic anomaly.

Along with induced magnetization due to the formation and enrichment of fine-grained magnetic particles, the remanent magnetization of archaeological features and objects also plays a significant role in generating magnetic anomalies (see below).

The exact connection between an anomaly and the buried archaeological structure (body) is not always clear – usually because the material causing the anomaly is not knowable without an archaeological excavation. The interpretation of an anomaly depends on whether the magnetization is induced by the present Earth's magnetic field only (and is therefore parallel to the present field direction) or is mainly remanent (permanent) and aligned with an ancient field, for example, the ancient magnetization may deviate at some angle from that of the present field direction if the buried structure was magnetized in situ by a burning or heating event (i.e., TRM or thermoremanent magnetization). The Koenigsberger ratio (Qn) of remanent to induced magnetization is therefore an



Magnetometry for Archaeology, Figure 3 Flowchart showing the possible formation pathways of maghemite and magnetite in soils (After Stanjek, 1999, pers. communication; and Schwertmann, 1988). Transformations depend on high or low temperatures (T), presence or absence of carbon and oxygen, and magnetotactic bacteria (BCM, biologically controlled formation of magnetite; BIM, biologically induced formation of magnetite).

important parameter that may help with the archaeological interpretation of the results. While the remanent versus induced magnetization for archaeological soils is in the range of Qn $\sim$ 1, in burned bricks and heated soils, it can reach values of >10 (depending very much on the grain size of the magnetic minerals); in places struck by lightning, Qn can reach values of up to 500–700 (see below Figure 8).

The remanent magnetization in archaeological structures

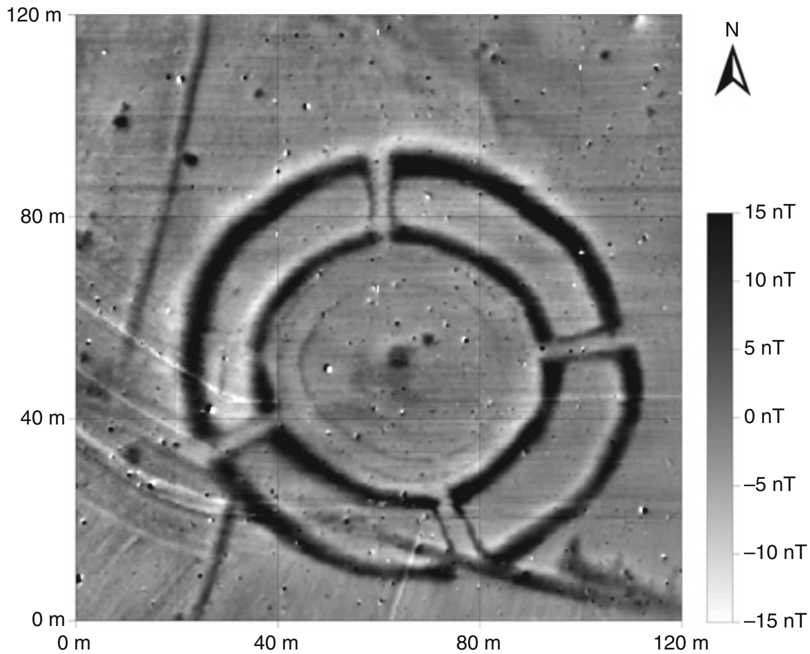
Nearly every rock, sediment, and fossil or archaeological soil has a remanent magnetization (Fassbinder, 1994; Dunlop and Özdemir, 1997). A primary natural remanent magnetization (NRM) can be acquired by four basic processes: thermoremanent, detrital remanent, chemical remanent, and lightning-induced remanent magnetization.

Thermoremanent Magnetization (TRM)

If rocks, sediments, or soils are exposed to high temperatures, they become initially magnetized by a thermoremanent magnetization (TRM). When the constituent magnetic minerals cool through their curie (or blocking temperature) in the ambient geomagnetic field, the direction of their magnetization will be "blocked," aligned along the Earth's magnetic field direction at that time. Additional ferrimagnetic minerals such as maghemite will be created by the transformation of antiferromagnetic minerals such as goethite and lepidocrocite (see Figure 3). The high magnetic intensities caused by archaeological pottery kilns, fireplaces, and metal production sites originate from TRM, and they can be easily identified in the magnetogram (see also Figure 9 below). The thermoremanent magnetization occurs at the moment of last cooling, so the magnetic field recorded will be the one in existence at the most recent time of heating, which may be significantly different from the field of today.

Detrital Remanent Magnetization (DRM)

As an archaeological soil containing permanently magnetized oxide grains is deposited in water (e.g., in a pit, in a ditch, or in ground depressions), the grains tend to orient themselves in a position of minimum energy, i.e., with their magnetic axis aligned along or parallel to the ambient magnetic field direction. Although there is usually still some disorientation among many grains, a statistical alignment along the field direction in existence at the time remains; this is called DRM. If there are some grains that are sufficiently small relative to interstitial volumes, they will continue to align with the ambient field as they are buoyed somewhat by pore water trapped within the interstices of the soils. Such tiny grains can swing into alignment without being impinged by the surrounding sediments even after deposition. This is referred to as a postdepositional remanent magnetization (PDRM). Although such remanences are quite weak, they can result in a detectable magnetic anomaly if they remain in situ. Mixing of these sediments through various disturbances such as excavation and backfilling of the material into a ditch or pit so that magnetic minerals and their domains are randomized results in a "mechanical demagnetization" (Fassbinder and Becker, 2003; Fassbinder and Gorka, 2009b; Fassbinder, 2010b).



Magnetometry for Archaeology, Figure 4 Steinbrunn, Austria. Magnetogram of the Neolithic ring ditch enclosure. The ditch is filled by topsoil, but the palisades and a pit in the center of the enclosure also show up as a normal positive (*black*) anomaly. Magnetometer survey, CS-2 Scintrex magnetometer, sensitivity ±1 picotesla, in variometer (duo-sensor) configuration, 40 × 40 m grid, spatial resolution 12.5 × 50 cm, interpolated to 25 × 25 cm, total Earth's magnetic field at the site 48,090 ± 20 nT, date May 1997, angle of dip +65°, *gray-shaded* plot in 256 grayscales from positive (*black*) to negative (*white*).

Chemical Remanent Magnetization (CRM)

At normal Earth-surface temperatures and for sufficiently small magnetic particles, thermal fluctuations dominate and the alignment of particles is randomized. But if the particle volume grows through a critical value, magnetostatic forces overcome the thermal fluctuations and produce a chemical or crystallization remanent magnetization.

Lightning-Induced Remanence (LIRM)

A lightning strike can produce a magnetization in the area immediately surrounding the impacted location, including rocks, sediments, and soils. Such a lightning strike magnetization is easy to recognize by its anomalously high Koenigsberger ratio (Qn), its magnetic intensity (>200 nanoteslas), but with respect to magnetic prospecting also by its typical star-shaped structures (see below Figure 8) (Maki, 2005; Fassbinder and Gorka, 2009a).

The interpretation of the magnetometer data and of the magnetogram image

In a simple form, the magnetogram offers a readily recognizable distribution of the structures beneath the soil. Knowledge of soil magnetic properties combined with the descriptive and comparative methods of archaeological interpretation forms the basis for obtaining optimal results using this approach (Neubauer and Eder-Hinterleitner, 1997; Fassbinder and Irlinger, 1999).

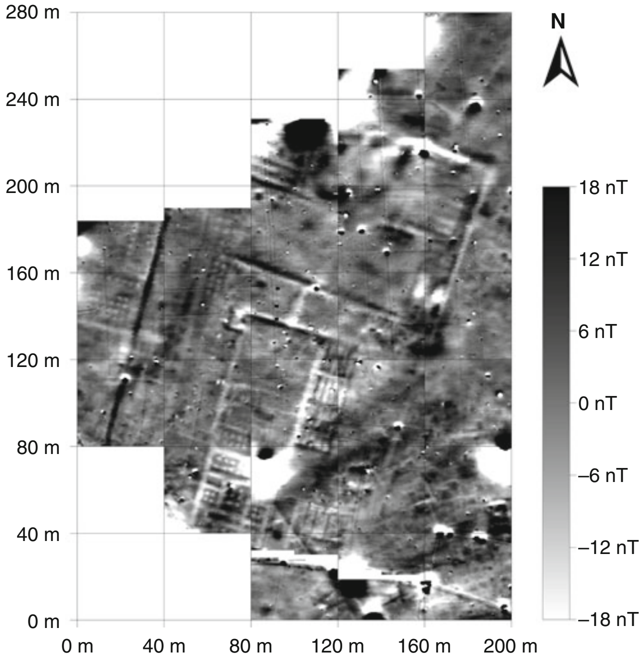
Positive magnetic anomalies on archaeological sites

The most common situation on nearly all soils of the world is an enhanced magnetization and magnetically enriched topsoil. Hence, any pit, ditch, or wooden posthole refilled by topsoil will generate a positive magnetic anomaly. If such a structure is refilled by homogeneous topsoil, the intensity and the shape of the anomaly is proportional to the size and volume of the archaeological feature. Any concentration of pottery, ash or burned material, and solid rocks or other materials will cause a deviation and thus will determine the intensity and the shape of the magnetic anomaly. The Neolithic ring ditch from Steinbrunn (northeastern Austria) gives an ideal example of this situation (Figure 4).

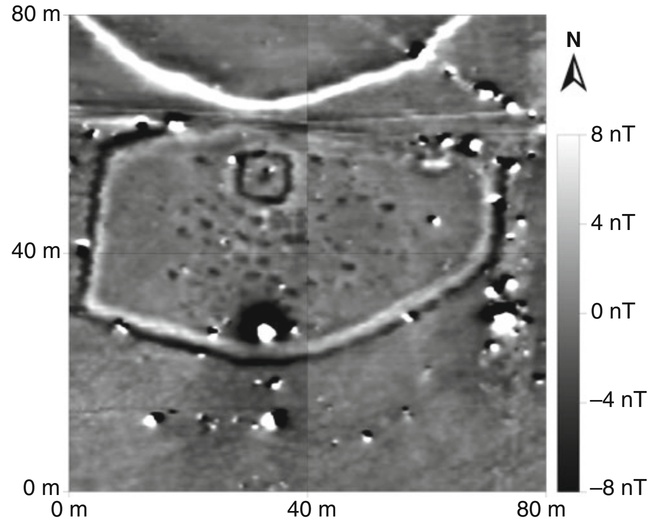
Negative magnetic anomalies on archaeological sites

Negative Magnetic Anomalies May Have Numerous Causes

1. The material of the archaeological structure possesses a lower magnetic susceptibility than the adjacent topsoil. For example, this will be the case if there are foundations of weakly magnetic limestone or sandstone in the ambient magnetic soil but also when mud bricks



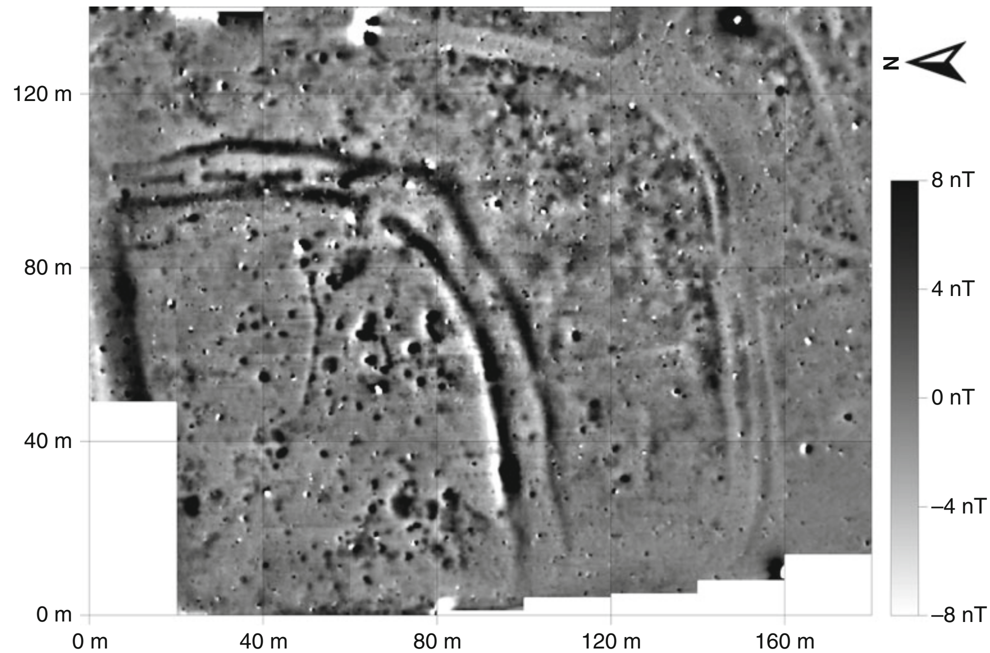
Magnetometry for Archaeology, Figure 5 Qantir, Egypt. A palace of Ramses II. The mudbrick walls are made using materials of different magnetic susceptibilities. This explains why they show up in some areas as a positive (black) anomaly but in other areas as a negative (*white*) anomaly. However, the bases of stone columns were made of sand and limestone, so they always show a negative (*white*) anomaly. Magnetometer survey with SmartMag SM4G special cesium magnetometer, sensitivity ±10 picotesla, variometer (duo-sensor) configuration, 40 × 40 m grid, spatial resolution 12.5 × 50 cm, interpolated to 25 × 25 cm, intensity of total Earth's magnetic field at the site 43,280 ± 20 nT, date October 1998, angle of dip +45°, *gray-shaded* plot in 256 grayscales from positive (*black*) to negative (*white*).



Magnetometry for Archaeology, Figure 6 Bajkara, Kazakhstan. Magnetogram of the Islamic cemetery adjacent to a Scythian kurgan. Magnetometer survey with SmartMag SM4G special cesium magnetometer, sensitivity ±10 picotesla, variometer (duo-sensor) configuration, 40 × 40 m grid, spatial resolution 12.5 × 50 cm, interpolated to 25 × 25 cm, intensity of total Earth's magnetic field at the site 56,230 ± 30 nT, date June 1999, angle of dip +70°. Note that the gray-shaded image was *inverted* and shows negative anomalies in black; the single graves, inside the oval, show up as negative (*black*) anomalies.

are made from more sandy material than the surrounding mud or the debris of ceramic, pottery, and burned materials. The ground plan of a palace of Ramses II in Egypt shows up as a negative magnetic anomaly for extensive parts of the wall, but in some areas, it also appears as a positive one depending on the magnetic susceptibility of the mud bricks (Figure 5). The bases of the columns, however, were always visible as a negative anomaly because of their limestone and/or sandstone foundations. In situ measurements of the magnetic susceptibility of mud bricks confirmed this hypothesis (Fassbinder, 2015b).

2. A negative magnetic anomaly may also occur whenever there was an excavated pit that was immediately refilled by the same material. The resulting magnetic field intensity, which is due to the induced plus the remanent magnetization, is diminished by the remanent part of the soil; in other words, whatever remanence the soil previously had is now randomized by the reburial process and hence nullified. Hence, the resulting magnetogram will show a negative anomaly compared to the adjacent intensity within intact soil areas. Similar case histories of magnetic anomalies, which could most likely be explained this way, are reported, albeit rarely (Fassbinder and Irlinger, 1998b; Fassbinder, 2010b). A comprehensive example of such a case was found in the steppes of northeastern Kazakhstan (Figure 6). Adjacent to a Scythian kurgan, there was an Islamic cemetery of the seventeenth century. The site consists of an oval ditch that is still 40 cm deep and visible at the ground surface. Inside the oval, there is a small memorial square place also enclosed by a small ditch. In the remaining area, although there is nothing else visible in the topography, roughly 40 negative (white) anomalies were detected, ca. 1 × 2 m in size; these can very probably be ascribed to the pits of a burial yard. These pits were excavated to a depth of ca. 1.8–2 m for the funeral interments and then immediately refilled with the same loess sediment that was removed to create the grave pits (Fassbinder and Becker, 2003).
3. A geochemical process such as the partial dissolution of ferrimagnetic particles and the precipitation of iron oxides as goethite, ferrihydrite, and lepidocrocite is another basic cause for the occurrence of a negative magnetic anomaly. In soils where there is stagnant moisture in combination with a changing groundwater table, an originally positive anomaly can be



Magnetometry for Archaeology, Figure 7 Riekofen, Bavaria. The Neolithic site is enclosed by four concentric ditches; the two inner circles show up as a positive trace (*black*) and the two outer ditches as negative (*white*). Magnetometer survey with CS-2 Scintrex magnetometer in variometer (duo-sensor) configuration, sensitivity ± 1 picotesla, 40×40 m grid, spatial resolution 12.5×50 cm, interpolated to 25×25 cm, intensity of total Earth's magnetic field at the site $47{,}920 \pm 20$ nT, date April 1997, angle of dip $+65°$, *gray-shaded plot* in 256 grayscales from positive (*black*) to negative (*white*).

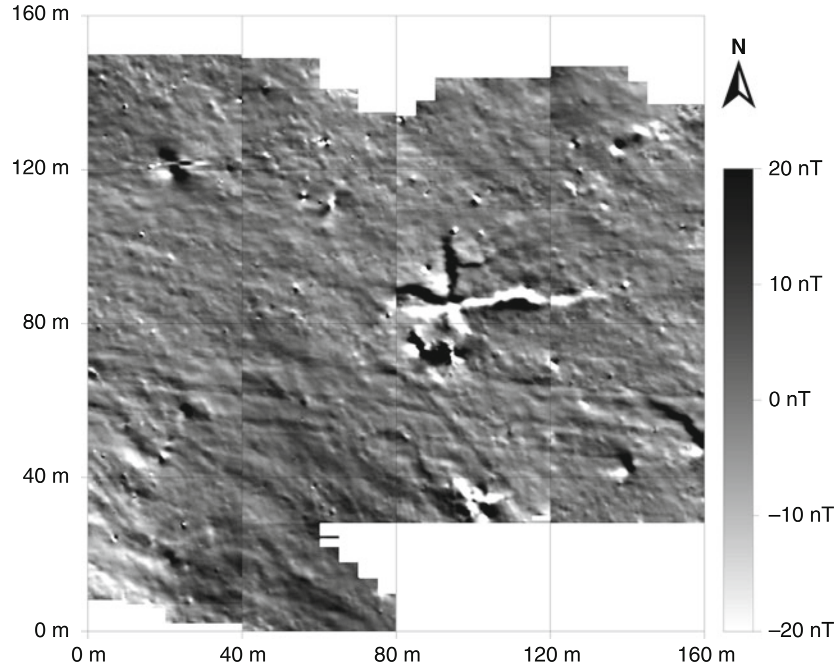
transformed into a negative one. A former ditch of an earthwork that was originally filled with topsoil and organic material of high magnetic susceptibility can eventually show up as a negative anomaly. A good example for this is the Neolithic earthwork of Riekofen in Bavaria. The central settlement lies on a slight hill only 1.5 m above a small river. The inner ditch shows a normal positive magnetization, whereas the outer one was partly flooded by water and shows a "negative" trace (Figure 7) (Fassbinder and Irlinger, 1998a; Schleifer et al., 2003). Temporary soil wetness is also one of the main reasons why the large ditches of Celtic square enclosures become magnetically "invisible" despite the fact that they were clearly detected by air photos and aerial prospecting (Fassbinder, 2005; Berghausen, 2015).

Lightning-induced remanence-based features

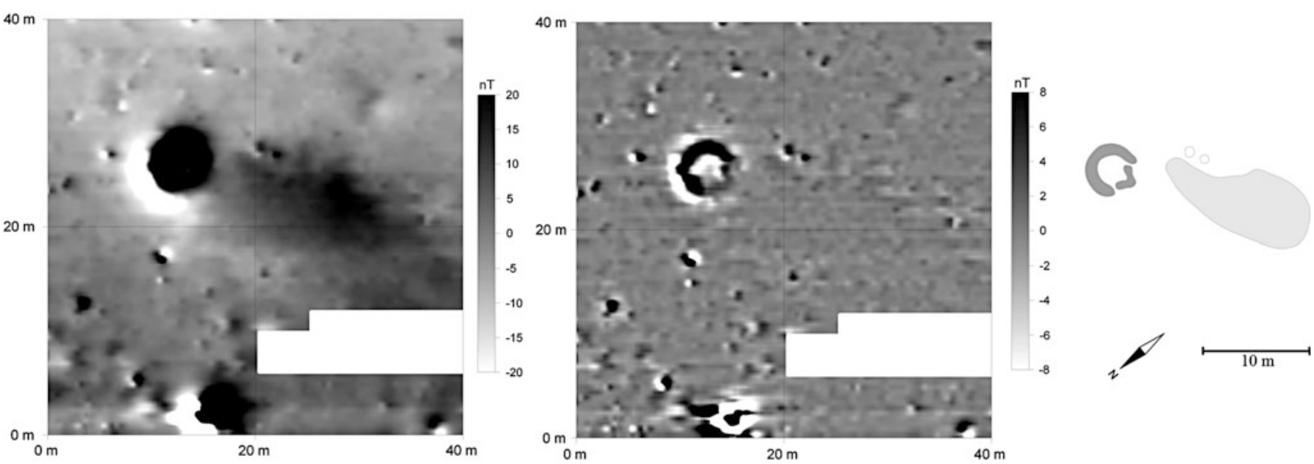
A wide range of examples can be offered of lightning-induced magnetic anomalies in archaeological sites. In early surveys, such anomalies were often misunderstood and erroneously interpreted. Lightning-induced anomalies are typically star shaped and characterized by the varying directions of their remanence. While thermoremanent magnetization of archaeological features reveals anomalies that are more or less parallel to the Earth's magnetic field at the time of heating, lightning-induced remanence has erratic directions, which follow the traces of the electric current in the soil. The highest density of lightning-induced anomalies was found associated with the famous geoglyphs of Nazca, Peru (Figure 8). Although they are located in one of the driest areas on Earth (average precipitation of less than 5 mm per year), these sites are situated on the borderline between the desert and fertile land, and they were exposed extensively to lightning strikes in the past (Eitel pers. comm.; Eitel et al., 2005). On a measured area of ca. 100 ha (five trapezoidal geoglyphs around Palpa, Peru), evidence for a total of 50 lightning strikes was found (Fassbinder and Gorka, 2009a).

Thermoremanent magnetic anomaly

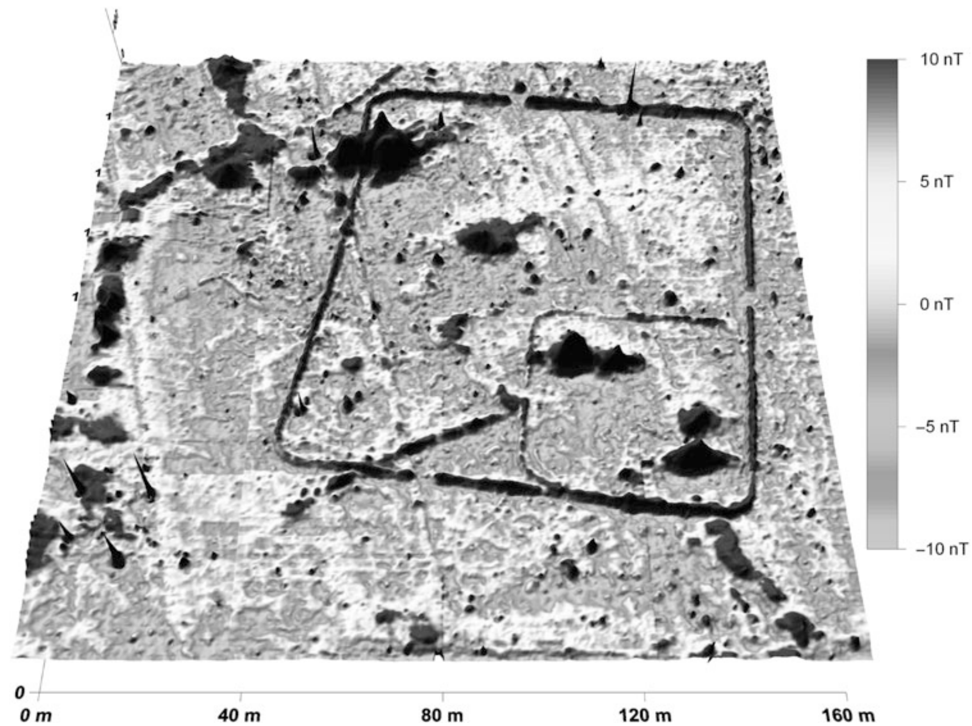
The example of a kiln, which was discovered by magnetic prospecting near the Roman fort of Großprüfening (city of Regensburg), is shown in Figure 9. The normalized magnetic anomaly of the total field measurement possesses a large positive (black) round shape (ca. ± 20 nT) with an oval-shaped area adjacent to it; these indications were due to an enrichment of fine-grained magnetic minerals in the topsoil (± 8 nT). Applying a high-pass filter to the data set enables us to visualize the round shape and the ground plan of the furnace in all its details, including the opening of the kiln. The magnetic traces of the ash deposits, located beyond the opening, were removed by the high-pass filter (Fassbinder et al., 2011).



Magnetometry for Archaeology, Figure 8 Reloj Solar, Peru. A typical star-shaped magnetic anomaly of a lightning strike on a trapezoidal geoglyph. Magnetometer survey with SmartMag SM4G special cesium magnetometer, sensitivity ± 10 picotesla, variometer (duo-sensor) configuration, 40×40 m grid, spatial resolution 12.5×50 cm, interpolated to 25×25 cm, intensity of total Earth's magnetic field at the site $25{,}350 \pm 20$ nT, date August 2005, angle of dip $= -5°$, gray-shaded plot in 256 grayscales from positive (*black*) to negative (*white*).



Magnetometry for Archaeology, Figure 9 Großprüfening (Bavaria). Typical magnetic anomaly of a huge pottery kiln, with traces of ash layers that are visible only in the total field mode (*left image*). Magnetometer survey with SmartMag SM4G special cesium magnetometer, sensitivity ± 10 picotesla, variometer (duo-sensor) configuration, 40×40 m grid, spatial resolution 12.5×50 cm, interpolated to 25×25 cm, intensity of total Earth's magnetic field at the site $48{,}330 \pm 20$ nT, date November 2010, angle of dip $= +65°$, *gray-shaded* plot in 256 grayscales from positive (*black*) to negative (*white*). Images from *left* to *right*: total field measurement; after application of a high-pass filter; archaeological interpretation.



Magnetometry for Archaeology, Figure 10 Burgsalach, Bavaria. The magnetometer image processed as a pseudo-3D image of a Roman camp revealed very clearly two archaeological phases of the fortification. Magnetometer survey with SmartMag SM4G special cesium magnetometer, sensitivity ± 10 picotesla, variometer (duo-sensor) configuration, 40×40 m grid, spatial resolution 12.5×50 cm, interpolated to 25×25 cm, intensity of total Earth's magnetic field at the site 48,220 $\pm$ 20 nT, date April 2008, angle of dip $= 65°$, *gray-shaded* plot in 256 grayscales from positive (*black*) to negative (*white*).

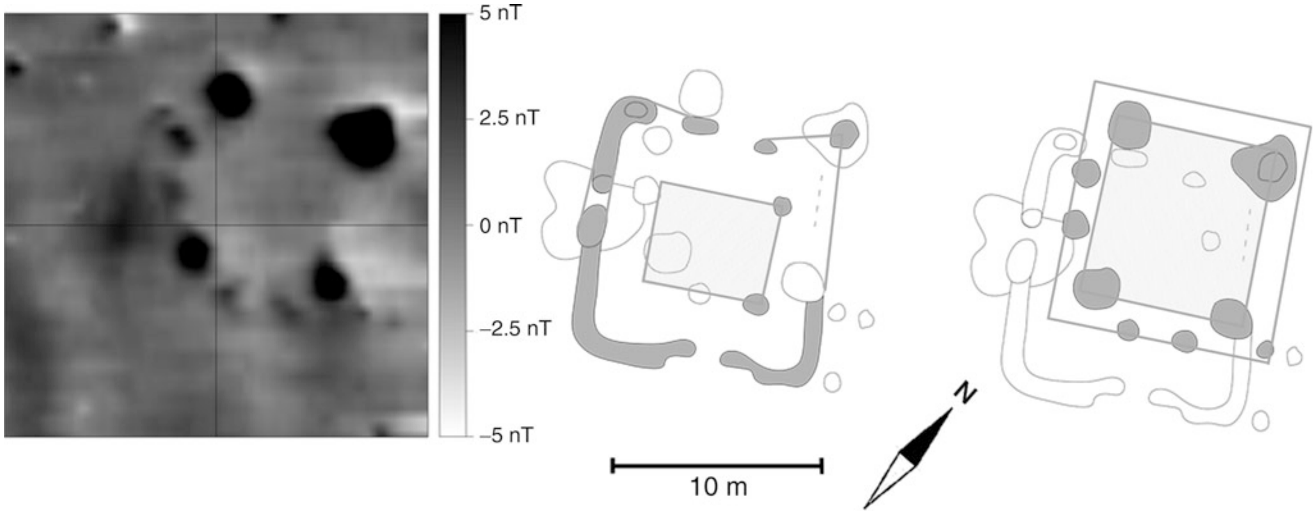
Magnetic prospection of archaeological stratigraphy

Magnetic prospecting is not very suitable for detecting archaeological layers and discriminating them from each other. Nevertheless, there are some case studies that demonstrate the possibility of distinguishing at least two phases of a stratigraphic archaeological sequence (Fassbinder and Irlinger, 1999). The Roman camp of Burgsalach (Figure 10) provides one such example. The small Roman camp, ca. 40×40 m in size, was fortified by a palisade (visible as a small, narrow ditch), and then in a second phase, it was overbuilt and enlarged to a camp of ca. 100×120 m. The older trace of the palisade was enclosed by the new one, and it became visible to the magnetometer at the junction of both constructions. This geophysical interpretation is supported by archaeological interpretations based on the ground plan of the site. The symmetry and the entrances of the later camp are based on the remains of the smaller and older camp (Fassbinder and Gorka, 2009b).

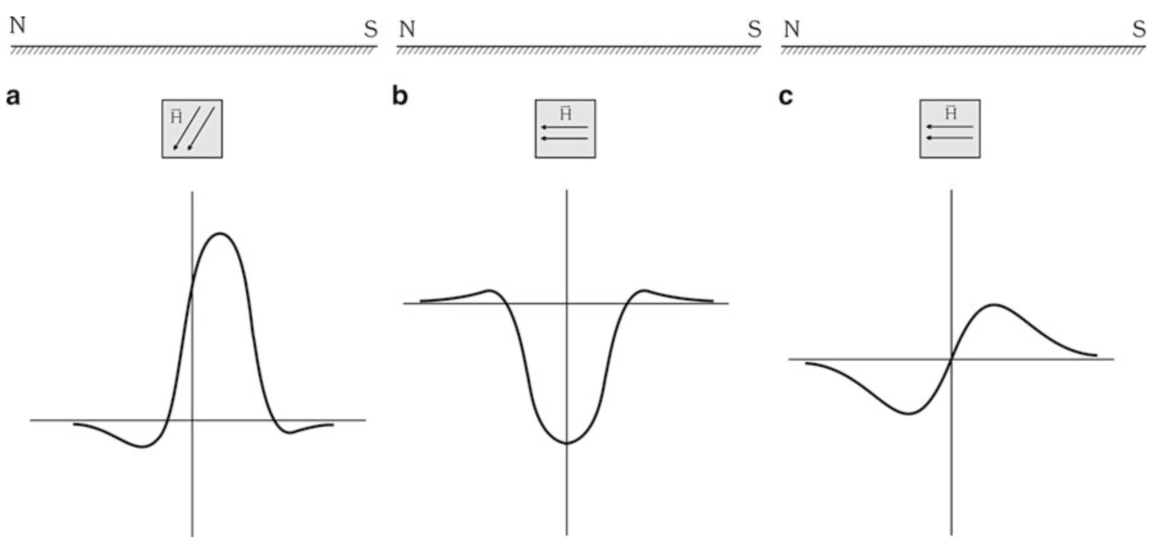
Celtic square enclosures are typical earthwork constructions abundant in southern Bavaria, in Baden-Württemberg, as well as in France. Magnetic prospecting of nearly 40 sites in Bavaria has revealed the main characteristics of these monuments (Fassbinder, 2005). Almost all consisted of an earth wall that was enclosed by a ditch, which was partly filled by water. Some of these ditches contained stagnant water, and thus they could hardly be recognized in the resulting magnetogram. Despite their large size (from 1 to 5 ha), only a few buildings could be found inside. Many of these buildings were destroyed by fire, and the resulting magnetogram of these buildings shows a high intensity. With the help of "archaeological knowledge" and the excavation report of a similar type of building with two phases (Möslein, 2002), it was possible to interpret the magnetogram (Figure 11).

Magnetic prospection near the geomagnetic equator

Although there are numerous case studies of magnetic prospection for archaeological sites in the northern hemisphere, only rare papers report on sites located near the geomagnetic equator (Tite, 1966; Fassbinder and Becker, 1999; Magnavita and Schleifer, 2004; Schmidt et al., 2009; Fassbinder and Gorka, 2011). There are probably two reasons for this. First, geophysics is well established as a prospecting method for archaeological fieldwork in Europe, Russia, and North America, as well as in China and Japan, but it is poorly established in the countries at the equatorial latitudes. Second, the results of magnetometer surveys near the geomagnetic equator are complex



Magnetometry for Archaeology, Figure 11 Itzling, Bavaria. The ground plan of a typical pile dwelling that was found inside a square enclosure revealed two archaeological phases. By comparing the magnetometer data with archaeological excavations from other sites, it was possible to infer two archaeological phases. Magnetometer survey with SmartMag SM4G special cesium magnetometer, sensitivity $\pm$10 picotesla, variometer (duo-sensor) configuration, 40 $\times$ 40 m grid, spatial resolution 12.5 $\times$ 50 cm, interpolated to 25 $\times$ 25 cm, intensity of total Earth's magnetic field at the site 48,180 $\pm$ 20 nT, date September 2011, angle of dip = +65°, gray-shaded plot in 256 grayscales from positive (*black*) to negative (*white*).



Magnetometry for Archaeology, Figure 12 Idealized shape of the magnetic anomaly of a cubic body measured by a total field magnetometer (**a**) at a latitude of 50° north, angle of dip ca. 70°; (**b**) at the geomagnetic equator, angle of dip = 0°; (**c**) measured with a fluxgate system (vertical sensor) at the geomagnetic equator.

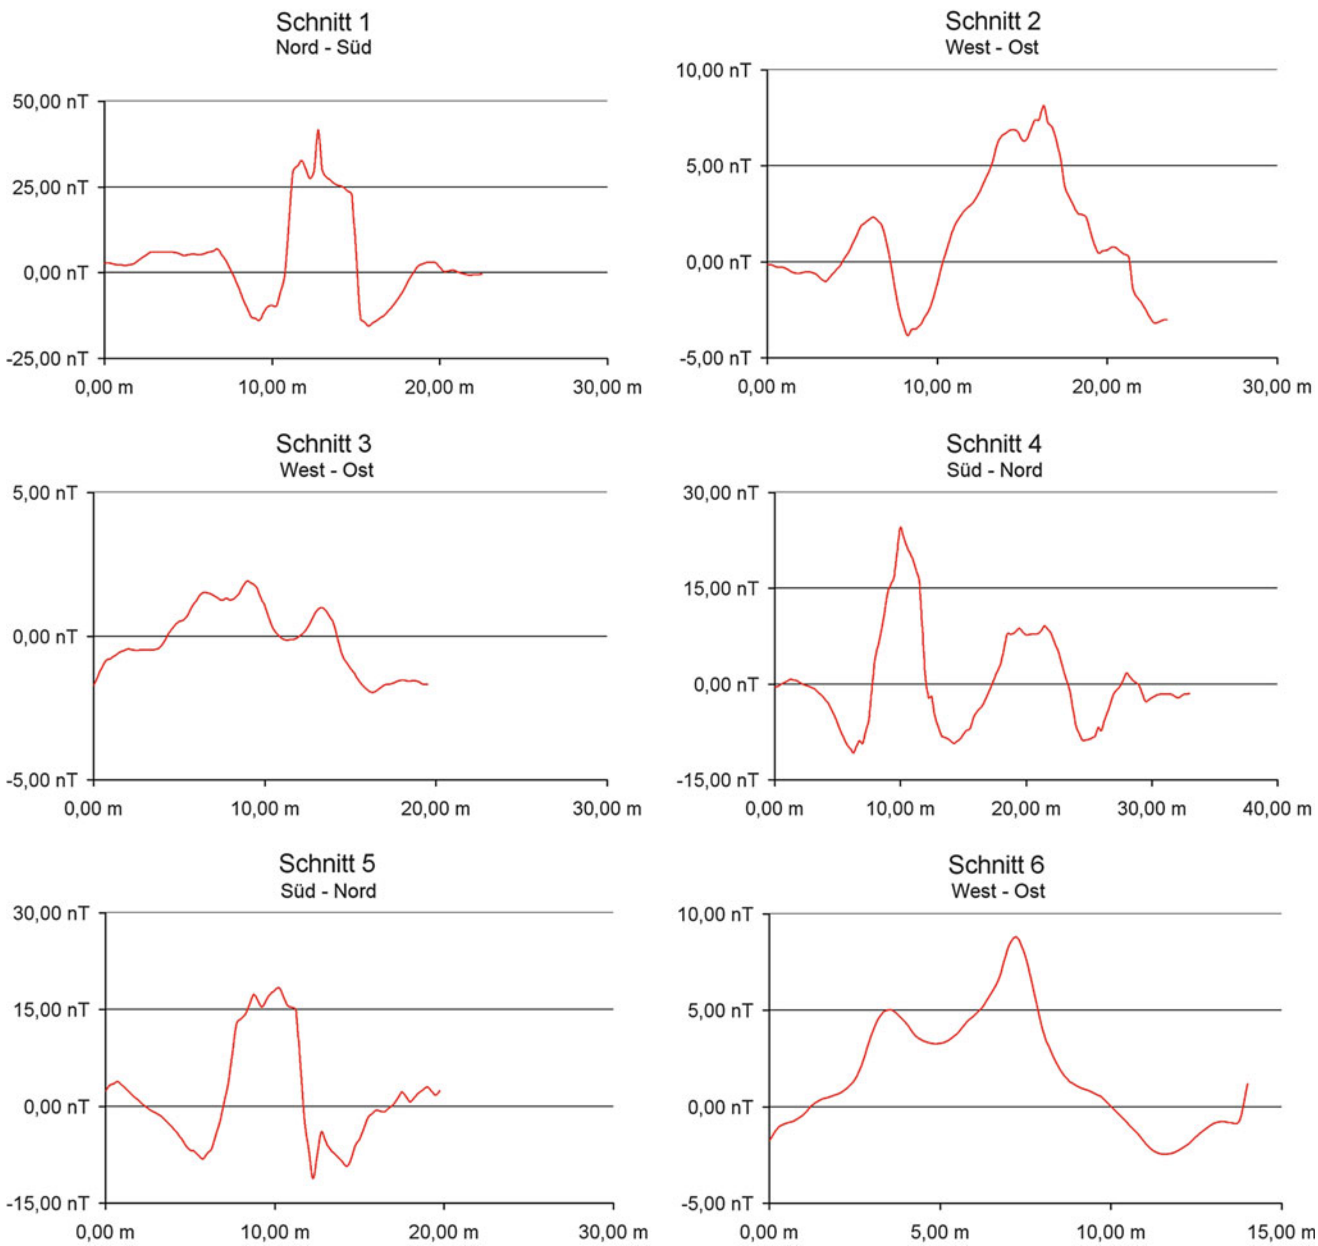
and require special knowledge for proper archaeological interpretation. The shape of the magnetic anomaly of the same feature varies dramatically depending upon latitude as well as the type of magnetometer used (see Figure 12).

A case study undertaken in Bolivia demonstrates the difficulties. The pre-Hispanic archaeological sites and ring ditches near Bella Vista in the lowlands of the Llanos de Moxos (northern Bolivia) were discovered after a large forest clearing in 1999. Initial excavations by archaeologists of the German Archaeological Institute revealed the occurrence of single burials inside the ditches, but no further structures or traces of settlements were discovered. The magnetogram (Figure 13) reveals clearly all the problems involved in the interpretation of magnetograms near the geomagnetic equator. Although there is a full ring, this ditch is clearly visible only in the northern and southern parts. This result compares quite well with the theoretical prediction and the shape of magnetic anomalies at the Equator (see Figure 12).

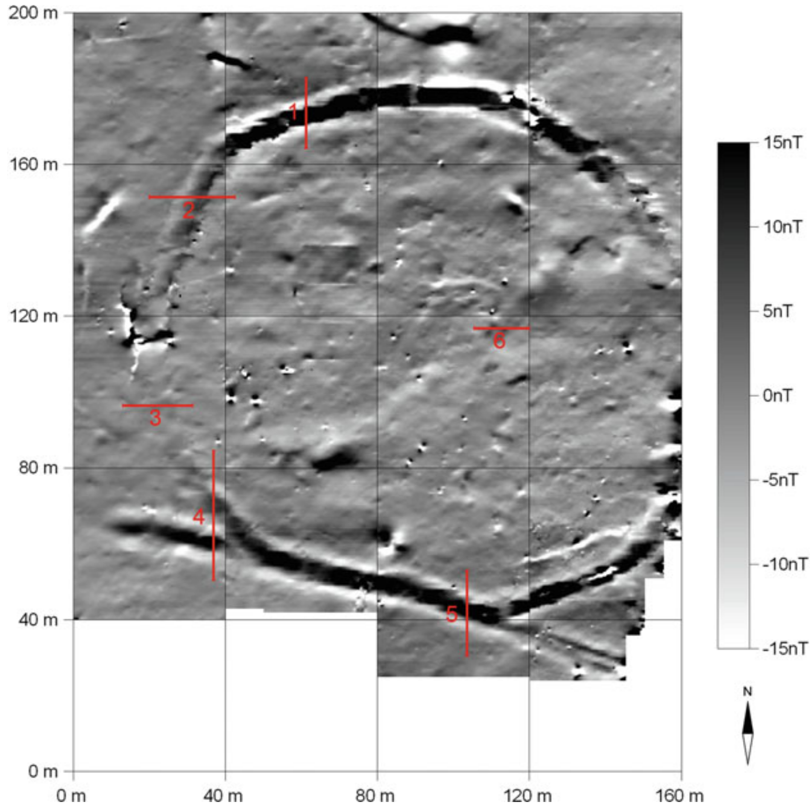
Summary

Without magnetic prospecting, many details of an archaeological site would probably remain overlooked and unexplored in the subsequent excavation phase. However, magnetic prospection can be successful only on sites where there is a magnetic contrast between the archaeological structures and the adjacent undisturbed soil layers. Until today, no simple correlation between the variety of different geochemical conditions and soil magnetic properties has been identified. At the present time, there is no way to forecast soil magnetic properties and hence whether magnetic prospecting will be successful or not.

Magnetic prospecting can provide detailed maps of ancient settlements and even entire ancient cities, as well as monumental buildings from different time periods. In particular, the prospecting of a multiplicity of sites from



Magnetometry for Archaeology, Figure 13 (Continued)



Magnetometry for Archaeology, Figure 13 Bella Vista (Bolivia). *Left*: selected profiles across archaeological structures. *Right*: magnetogram of a typical ring ditch of pre-Hispanic cultures. The northern and southern parts of the ring ditch are clearly visible, while the eastern and western parts of the ring are nearly faded out. Magnetometer survey with SmartMag SM4G special cesium magnetometer, sensitivity ±10 picotesla, variometer (duo-sensor) configuration, 40×40 m grid, spatial resolution 12.5×50 cm, interpolated to 25×25 cm, intensity of total Earth's magnetic field at the site $24{,}000 \pm 20$ nT, date August 2010, angle of dip $= -5°$, *gray-shaded* plot in 256 grayscales from positive (*black*) to negative (*white*).

the same category and/or archaeological period yields valuable information for archaeological and geophysical research as well as for cultural heritage protection (Fassbinder, 2005, 2010a; Berghausen, 2015). With an understanding of mineral and rock magnetic science and knowledge of their formation processes, the specific magnetic susceptibility of minerals (Tables 1 and 2), and the different types of remanent magnetization, it becomes possible to explain a significant number of details about buried archaeological features. The contribution of geophysics depends upon the magnetic anomaly, which is determined by the intensity and direction of the magnetization. Further analysis can discriminate between induced and remanent magnetization, and it may also yield information on different archaeological phases. The contribution of archaeology allows the possibility of roughly dating buried features by comparing the layout of structures to other findings already known from other excavations.

The methodology, instrumental measurement, sensitivity, and image processing for magnetic prospection will continue to improve, but already the results of magnetometer surveys are comparable to the maps of an archaeological excavation. Specific structures and the shape of the features allow a rough dating of a site, without any destructive removal of soil to expose the remains. Magnetometer surveys will never substitute for or replace an archaeological excavation, but they should precede every archaeological field project, in order to maximize the efficiency and minimize the physical destruction of an archaeological heritage.

MASS MOVEMENT

John F. Shroder[1] and Brandon J. Weihs[2]
[1]Department of Geography and Geology, University of Nebraska at Omaha, Omaha, NE, USA
[2]Department of Geography, Kansas State University, Manhattan, KS, USA

Definition and introduction

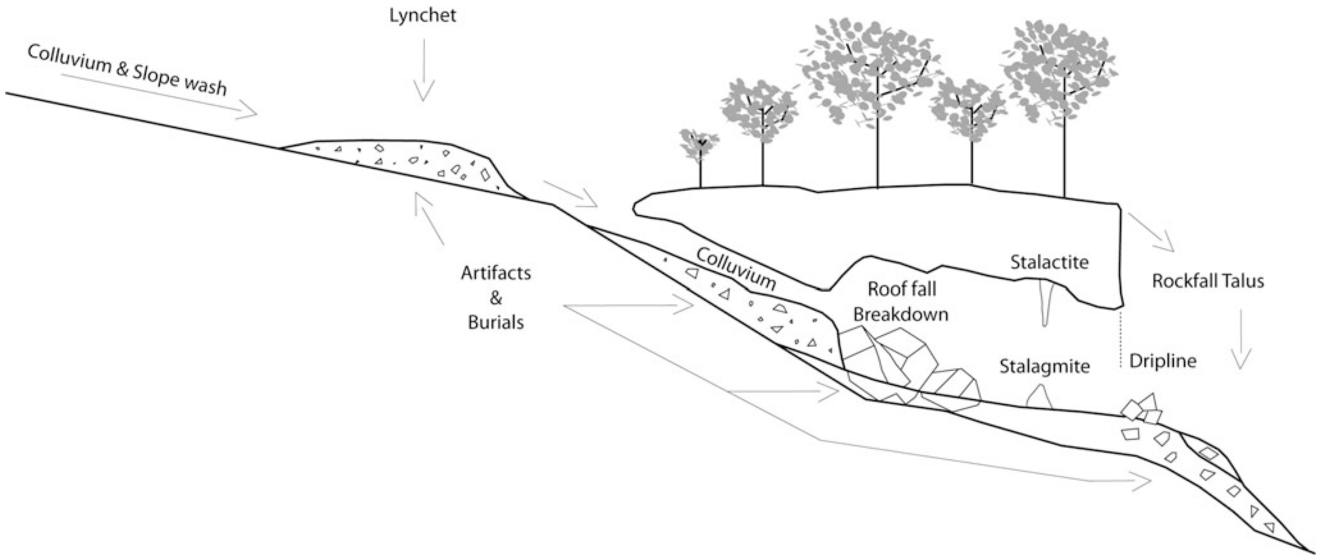
In the context of geoarchaeology, mass movement can be significant on several levels, including both site preservation and site disturbance. In some cases, catastrophic mass-movement events have altered local conditions, favorably or unfavorably, forcing ancient humans to change their land use patterns and thereby alter the archaeological record in important ways (Schruth and Pike, 2006; Pike, 2008). Mass movements and the forces that cause them can be complicated, but the diversity of physical processes involved must be understood by archaeologists at least on a fundamental level to enable better and more inclusive site interpretations. Furthermore, the future preservation of sites that have been newly exposed by excavation may be placed at risk by instabilities created by the digging itself or by the inherent nature of sites situated in vulnerable locations. In all such cases, improved understanding of mass-movement hazards at excavation sites may become necessary to preserve the site for posterity.

Mass movement is erosion, transportation, and deposition of earth and rock materials primarily as the result of gravity only, but it may include various admixtures of water, ice, and water vapor in the natural initial state. The term *mass wasting* is used by some; however, this term is considered somewhat outmoded by many, and it is ambiguous, leading to connotations that may erroneously include some aqueous slope wash. The more precise terminology of mass movement is much preferred. Human-made materials may be incorporated on, within, or beneath mass-movement deposits by various pre-, syn-, and post-event processes as well. Fluids are generally involved only minimally in mass-movement processes, and therefore sorting of particle sizes tends not to occur as it does with deposits laid down by water and wind. The result is that mass-movement events characteristically produce chaotic masses of mixed-up grain sizes and fragments, all of which can be considered collectively as colluvium. Most archaeological sites are similarly characterized by seemingly chaotic mixtures of different sizes of materials left by humans, who sort materials only when they are constructing things or depositing them consciously or not in spatially patterned ways. Otherwise the seeming chaos of most archaeological overburden may result from the relatively random combination of artificial and natural accumulations that cover sites slowly or quickly. Differentiating between small mass movements at a site and those produced directly by human activities may be difficult in some places. Scale-dependent process and product differentiation may be possible with attention to the details of mass-movement mechanics, especially where the mass movement was spatially large enough and temporally isolated to make its boundaries more easily recognizable.

Gravitative processes of mass movement are almost ubiquitous in many landscapes, and humanity has interacted with such environments repeatedly, leaving extensive records of such associations (James and Lecce, 2013). In some cases, mass movement established landforms that later provided shelter for humans, such as slope niches, overhangs, caves, and harbors. Both slow and more rapid processes of mass movement can affect the archaeological record in both preservative and destructive ways. For example, at the bottom of most slopes, various minor and slow gravitative movements of rocks and sediments – including slope wash or precipitation-induced sheet wash of fine sediment and frost-induced solifluction or gelifluction – may contribute thin layers of colluvium that build up successively to cover sites and artifacts (Figure 1). Older artifacts originally contained within sediments resting on slopes may be weathered out and moved downslope by these mass-movement processes and incorporated into newer colluvium, thus confusing and inverting the normal superposition of progressively younger layers covering older ones. An understanding of these fast or slow mass-movement mechanics will help the archaeologist interpret the original context of the archaeological site.

Archaeologically relevant mass-movement types

Mass movement is generally classified scientifically first by the type of material moved and second by the type of movement to which the material was subjected. The classification of mass-movement materials is simple in that only three categories are used: (1) rock and rock fragments that lie at one extreme, (2) fine-grained sediments (including sand, silt, and clay that collectively constitute "earth") that lie at the other, and (3) debris, which are composed of mixtures of both coarse rock fragments and fine clastics. The most rapid movements are falls, topples, slides, and the wetter, more fluid kinds of flow (mudflow, debris flow, volcano-sourced lahar flows). Slower forms of mass movement are subsidence, creep, solifluction (gelifluction), and earth flows. Talus is the one-by-one accumulation of rock fragments from isolated minor rock falls and slides that accumulate at the angle of repose in steep cones at the bases of cliffs and other steep slopes. All types of fast and slow mass movements can transport large quantities of sediment, moving artifacts, producing natural geofacts that resemble human-made artifacts, or burying archaeological sites. Colluvium is the general term for any kind of sediment emplaced by these gravitatively driven, mass-movement processes.



Mass Movement, Figure 1 Cross section through colluvia associated with surficial slope deposits and underground cave accumulations. Colluvium may accumulate downslope through long-term slope movements, slope wash, and ancient agriculture to constitute a positive or depositional lynchet, whereas the erosional area upslope that provides the material to build the positive feature may be the negative lynchet. Such lynchet terminology is characteristic of some European sites, but not necessarily elsewhere. Cave sites may accumulate colluvium carried in from outside through cracks and fissures, as well as from roof falls inside the cave or outside as a result of cliff collapse into a rockfall talus. Artifacts and burials can occur beneath the colluvium if the cultural activities occurred prior to mass movement or later as a secondary occupation or burial within the colluvium itself.

Creep

Creep is an imperceptible, slow, downhill movement of soil materials that generates plentiful colluvium in many archaeological sites. It includes the results of animals and humans trampling materials downward on slopes, as well as various downhill movements caused by the caving in of burrows created by fossorial animals, and plant-root expansion or collapses of plant-root decay cavities. In addition, creep can be produced by the ratcheting processes relating to phases of heating, wetting, and freezing of slope materials that cause an expansion outward and perpendicular to the hillslope gradient, followed by contraction phases brought on by cooling, drying, and thawing, all of which tend to result in net downward movement with gravity after each expansion-contraction cycle. Soil creep can have an important influence on the spatial distribution of artifacts by differentially transporting heavier or denser ones farther downslope than others, and if artifacts were originally deposited at the base of a slope, they can be buried by soil creep from upslope.

Colluviation and colluvium

All mass-movement processes can produce variable amounts of sediment known as colluvium, although the thinner varieties due mainly to creep at hillslope bottoms or footslopes are more commonly recognized in a geoarchaeological context. Typical hillslope cross sections consist of an upper stable interfluve of minimal declivity that passes outward and downslope into a zone of erosion with convex-upward seepage and creep slopes to a lower concave-upward transportational midslope. The lowermost zone of deposition is also concave upward in cross section and is characterized first by the colluvial footslope and the alluvial toeslope at the valley bottom. (See the nine-unit land-surface erosion model in the entry on colluvial settings.)

Colluvium from mass movement thus commonly forms hummocky topography or smooth fan-shaped deposits at the bases of mountains and hillslopes; they resemble, and may be intermixed with, alluvial-fan deposits that are predominantly caused by running water or sheet wash. Many colluvial soils can have an associated fragipan zone: brittle subsoil layers typically high in clay components. Such fragipans may result from the smearing of soils during the colluvial process wherein clays seal the surface between the moving fragipan and the stationary soil on which it slides. Archaeological sites can be buried and preserved beneath colluvium if changes in the landscape, e.g., deforestation or more extensive agriculture, lead to extensive downward movement of soil materials.

Identification of colluvial materials at archaeological sites can be problematic for the nonspecialist, and so checklists of features have been developed by the Soil Analysis Support System for Archaeology at the University of Stirling, UK (SASSA, 2009), that can be used in the field to determine the likelihood that a deposit could be considered to be colluvium:

- Landscape location of colluvium on footslopes, terraces, benches, floodplain edges, and valley-floor margins, or anywhere a break in slope occurs.
- Deposit matrix of colluvium can be slightly more silty and better sorted than deposits upslope, depending upon the processes by which the colluvium formed.
- Stones, potsherds, and charcoal in colluvium can have a weak tendency to align in the downslope direction.
- Softer potsherds and charcoal in colluvium may be worn and abraded.
- Common origin of colluvium from eroded topsoils can impart an organo-mineral composition and a brownish color.
- Colluvium should have a composition and stone lithology similar to soils upslope.
- Colluvial deposits should thin upslope and thicken toward the base of the slope.
- Colluvium may have less well-developed granular soil structures than non-disturbed topsoil materials, although periods of stability can allow reformation of granularity.
- Internal stratification and stone lines can form in colluvium.
- Lower boundaries of colluvium can be sharp or abrupt if not bioturbated by living organisms or heavily rooted.
- Clay coatings can occur in void spaces and on walls built of rock and sediment aggregations in colluvial materials.

Solifluction

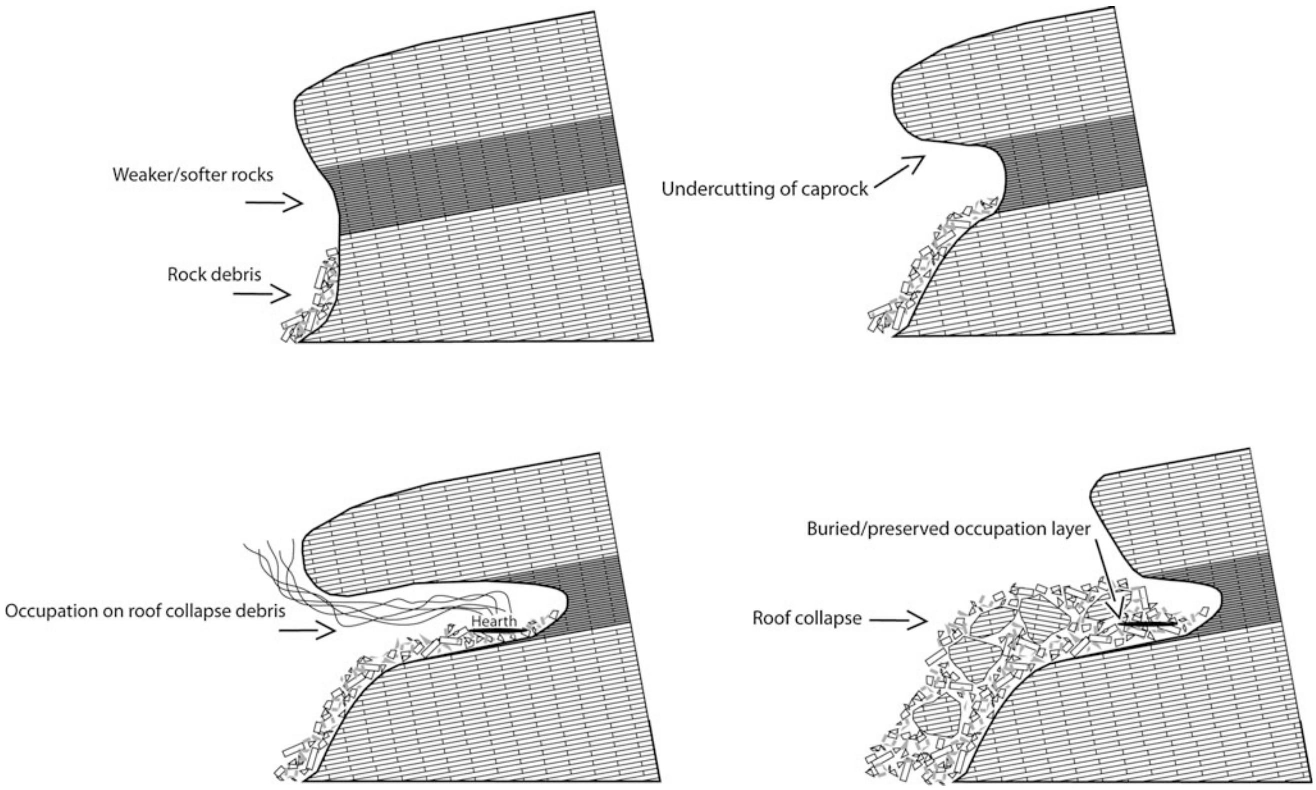
Solifluction results from strong freeze and thaw on slopes, commonly during the summer melt season. It describes masses of water-saturated debris moving downslope, commonly but not necessarily above permanently frozen deeper soils (Butzer, 1964; Goldberg and Macphail, 2006). Gelifluction, which is also understood as a form of solifluction, is the downslope movement of water-saturated sediments and soils that are generally associated with periglacial conditions in the seasonally thawed active layer above permafrost. Under these conditions of solifluction or gelifluction, major deformation of archaeological stratigraphic sequences can occur. Solifluction lobes can move downhill like the front end of bulldozer treads, creating a situation in which younger artifacts on the surface move forward across the top, past the advancing edge, and down the front as the lobe rolls over them on its way down the slope. Any stratigraphic sequence in the original soil is thereby reversed or inverted and no longer reflects the normal order of superposition with younger objects generally lying above older ones.

Early humans possessed a rich archaeological history in the Pleistocene Ice Age of Europe, and thus, their remains are commonly associated with extensive solifluction and related mass-movement deposits produced by high freeze and thaw. Deposits of unsorted and sorted rock rubble and sorted talus are the *éboulis ordonées* and *grèze litées* that are characteristic slope deposits in that region (Butzer, 1964). Such sorted rubble and talus slopes are caused by frost shattering on rocky slopes and cliffs, with subsequent downhill sliding of the resulting clastic sediment down slopes as shallow as 17 % (10°) and as steep as 60 % (35°). The fundamental mechanisms for the production of such bedded mass-movement deposits seem to be that first freezing in the spring breaks the rock debris and produces coarse beds of fragments that are well stratified and contain little or no interstitial material because the fragments slide over still-frozen soil. Thereafter, solifluction transports and deposits fines over the coarser materials, leaving multiple layers or stratifying the mass-movement beds.

Caves and overhangs

Early humans commonly sought shelter beneath overhanging rock-wall niches and in caves, and such locations therefore became living sites containing well-preserved archaeological remains (Figure 2). Many overhangs and caves include the deeper, dark interiors that were exploited for artistic and ritualistic activities, but most cultural material is located at the better illuminated cave mouths. Where archaeological material was deposited, however, it was always subject to burial and concealment by cave-roof falls of varying sizes (sometimes referred to as *éboulis* or rubble). The front edge or brow of the overhanging roof can produce a dripline, perceptible on the cave floor as a line representing the direct impact of precipitation falling from the top of the entrance. This location is the area of most active deadfall, where rock materials can also come down from slopes above. Talus and colluvium will accumulate downslope below the cave or rock-shelter entrance, and it is within this mass-movement material that cultural artifacts and other refuses (primary, secondary, de facto) from inside the cave will accumulate, including human burials in many cases (Figure 1).

Archaeological investigations of cave sites must take into account the likelihood that dramatic changes have occurred over time in which successive roof falls and retreat of the cave brow may have exposed ever deeper areas of the shelter to the forces of natural conditions outside the cave. The mouth of the cave may have been completely eliminated through roof collapses in the form of incremental mass-movement events. This can be documented by the series of driplines formed as the cave mouth receded (Figure 2). Many external fluvial, lacustrine, and aeolian processes can intercalate and intermix with the mass-movement sediments as well. In calcareous cave environments, the precipitation of dissolved calcium carbonate as layers of travertine flowstone (i.e., speleothems) can seal underlying cave sediments and artifacts. In some cases, unstable accumulations of cave bat and bird guano have themselves been remobilized to flow deeper into caves, forming additional mass-movement deposits (Dykes, 2007). In all cases of archaeologically significant cave stratigraphy, the stratification of sediments can be quite complex, and the elucidation of



Mass Movement, Figure 2 Four steps (*top left* to *lower right*) in the evolution of a typical shelter in limestone or other rocks where cave-roof collapse can preserve cultural materials and archaeological remains of the occupation layer beneath a cover of colluvium (in part after Rapp and Hill, 2006).

sequences containing intermixed materials deriving from a combination of gradual and mass-movement processes must be done carefully.

Special mass-movement erosion and deposition sites

In special cases, mass movements may figure importantly in the interpretation of archaeological sites, as when particular mass-movement actions effect landscape changes that offer advantageous settlement conditions for humans or where mass movements abruptly cover and seal important cultural remains. For example, in northern Israel, the gorge of the Jordan River north of the Sea of Galilee is geologically unstable. The Tuba I slope failure (>20,500 years ago) was perhaps generated by a strong earthquake (Shroder et al., 1999), and the large mass movement dammed the river, producing a lake that backed up within the gorge for many kilometers. As is common with most landslide dams across rivers, the impounded water eventually overtopped the dam causing a breakout flood that poured coarse gravels down upon the delta of the Jordan River at its entry into the northern end of the Sea of Galilee. This event established an irregular series of protected embayments composed of mass-movement gravels that were reworked by the breakout flood. It was here that ancient humans found a favorable setting to establish a coastal village over 5,000 years ago. This coastal fishing village grew over the ensuing millennia to become the important Biblical city of Bethsaida, a quiet-water port in which fine-grained low-energy muds accumulated directly at its edge. About 1,800 years ago, another landslide, the Tuba II slope failure, occurred within the Jordan River gorge and dammed the river once again. The ensuing re-impoundment of the Jordan River and failure of this second dam then brought coarse gravels from the landslide deposit via another breakout flood to the city and port of Bethsaida. This second mass-movement event proved to be a disaster in human terms, as it destroyed the protected anchorage, advanced the shoreline southward several kilometers, and eliminated the commercial value of the harbor to exploit the resources of the lake. With its chief fishing livelihood cut off, Bethsaida was ultimately deserted, and its exact location became lost until it was rediscovered in the late twentieth century (Arav et al., 2000).

Another example of mass movement having an archaeological impact occurs on the northern tip of the Olympic Peninsula in the state of Washington, USA. An ancient whaling village was established on the coast at Cape Alva by the Makah Native American people about 2,400 years ago with occupation lasting up to its final abandonment in the early twentieth century (Kirk, 1986; Samuels et al., 1991; Kirk and Daugherty, 2007). Radiocarbon dates of the oldest deposits recovered within archaeological exploration trenches dug below the long houses at the site indicated the great antiquity of the ancient village. Called the Ozette Site after a nearby lake of that name, the location was apparently overwhelmed by a mudslide that knocked the village flat and buried everything in deep, wet, preservative mud. The slope failure may have occurred about 300–500 years ago, and some think the date might be precisely on 26 January 1700 when a recorded earthquake occurred in the region. A substantial part of five large long houses from the village and all their contents were flattened and buried by the resulting mudslide or mudflow. The ten-foot-thick mass movement of wet clay pushed an airtight cover over the site and set up an anaerobic or oxygen-free environment that prevented the decay of all sorts of delicate organic materials that are rarely ever preserved in other burial environments. Delicate artifacts included harpoons, boats, kayaks, whistles, combs, gambling pieces, carvings, baskets, and artistic and/or ritualistic objects. Whale bones were recovered throughout the deposit, indicating the importance of the hunting of marine mammals to the ancient people.

Volcanic mass movements

Volcanoes and volcanic events preserve archaeological sites through ashfalls and other ejecta that may have nothing to do with mass movement. Lava flows, for example, commonly burn, crush, or pulverize and completely destroy most human-made structures before covering them with what becomes solid rock once everything cools. On the other hand, the common association of crater lakes and glaciers on high volcanic mountains provides plentiful water that can initiate rapid, wet volcanic mudflows, or lahars, from mobilized pyroclastic ash and other debris (Plunket and Uruñuela, 2008). The loose pyroclastic ash and cinders that accumulate in abundance on the flanks of most volcanic cones generally come to rest at steep angles of repose, and thus they are inherently unstable. During explosive eruptions, torrential rains can be unleashed by the atmospheric disturbance of the ash column above the volcano, and as the pyroclastic materials become saturated by the downpour, they can collapse producing enormous flows of muddy lahar material. The size and speed of such flows can be quite rapid, perhaps 40 m per second down the flanks of the volcano itself and perhaps 5–15 m per second as far as 50 km away. Most lahar masses are as destructive as lava flows because they resemble churning wet concrete as they sweep downslope, destroying everything in their path. Such material, once it dewaters and "sets up" after emplacement, can become quite indurated and hard, especially if it was once fairly hot as well. In rare cases, the result will be a thick, wet cover of hummocky volcanic debris that can quickly bury sites and preserve them for later archaeological excavation.

Scholars once thought that the ancient town of Herculaneum near Mt. Vesuvius had been buried by volcanic lahars rather than the loose tephra that buried Pompeii. This was because the material that covered Herculaneum had become almost rock hard, as mud would do over time. Present-day consensus, however, is that although a number of lahars did occur in the region, this volcanic mass-movement type was not the process that killed so many ancient Roman subjects and preserved their towns so well (Zeilinga de Boer and Sanders, 2002). Thus, only in a few places are lahars known to have been preservative of cultural remains. An example would be the rare exception of an old Native American settlement near volcanic Mt. Rainer, where the Osceola "mudflow" lahar overran the site to preserve numerous projectile points, scrapers, and other tools, as well as charcoal that gave a date of about 5,600 years ago (Harris, 1999). Many centuries elapsed before the native peoples reoccupied the site in a new settlement; their legends even allude to the tremendous lahar event (Stein, 2003).

Lahars do not always occur during volcanic eruptions; they can be set off at any time when torrential rains mobilize deposits of ash and loose rock. It is therefore difficult to make accurate predictions of lahar events, although general warnings are commonly issued. Volcanic eruptions demonstrate some predictability, as they are usually accompanied by precursory hints such as earthquakes, vents of steam and ash, and changes in the local water tables or in the height of the ground, but lahars can be triggered by a single day of heavy rain, which makes them a real danger in populated areas. Throughout history, lahars have destroyed many settlements, potentially rendering a few of them into deeply interred archaeological sites.

Mass-movement damage to archaeological sites

Mass movements of various kinds have negatively affected many archaeological sites in the past. They have occurred either as natural processes wherein sites established in unstable locations were partially destroyed (Stanley et al., 2006; Hartvich et al., 2007) or where the archaeological excavation itself resulted in the instability. In some cases, the very nature of the site is problematic, and special steps must be taken to preserve it from mass-movement damage – e.g., Machu Picchu, the Incan site in the Andes built atop steep cliffs (Vilimek et al., 2007). At Machu Picchu, a multidisciplinary approach has tried to discriminate between pre-habitation slope movements and those that occurred later up to the present time, as well as to evaluate landslide risk to existing structures. Elsewhere, Incan sites prone to landslide damage in Ecuador have been assessed using the techniques of satellite image analysis and geographic information system (GIS) analysis, including 3D visualizations and ortho-photo analyses to map site-specific hazards (Yugsi et al., 2006).

Another example of archaeological impact is Stutfall Castle, which represents the remains of a coastal Roman fort constructed about 270 CE near Lympne in extreme southeastern England. The fort was built on unstable Weald clay, and sometime following its construction, it was damaged by landsliding. The mass-movement event might have led to collapse of the fortress wall and therefore forced its abandonment. At present, all parts of the fort have been moved (at different times) from their original location, and the intact timber foundation piles beneath the rock walls have been bent and sheared off. Mapping of three main slope failure movements suggests that most of the slippage occurred after abandonment of the fort in the fourth century. A radiocarbon date of about 570 CE has dated the main slide mass that affected the site.

Similarly at the Celtic fortification site of Obři Hrad in the Šumava Mountains of Bohemia, in the Czech Republic, multigenerational slope deformation has disrupted the ancient site, probably multiple times in the past, and this has added to the complexity of site interpretation (Hartvich et al., 2007). Possibly, the ancient Celts established their fortifications purposefully in close proximity to the gods that were disrupting the ground, but in any case, the instability has eliminated parts of the site, the remains of which have been swept downslope ultimately to complete removal by the Losenice River below.

Conclusions

Mass-movement events can play integral roles in the preservation or destruction of archaeological evidence. Their wide spatiotemporal range and the physical properties and processes that govern their genesis and development have forced geoarchaeologists to consider the possibility of mass movement in almost any site setting, especially since its effects are so prevalent (in some cases disruptive and in others formative). Careful consideration of mass-movement processes will provide better explanations of site formation and use, and it will also help to preserve already excavated sites from damage by future movements.

METALS

Vincent Serneels
Department Geosciences, University Fribourg, Fribourg, Switzerland

Metals, metal-bearing minerals, and ores

Metals are elements that are suitable conductors of heat and electricity. Most of them are malleable and shiny, but all other physical and chemical properties are highly variable. From the 98 elements naturally occurring on Earth, 73 are metals. An alloy has properties similar to a metal, but it is made of more than one element. Prior to the nineteenth century, only a limited number of alloys were in use, related to only six metals: gold, silver, copper, tin, lead, and iron. Other elements played a significant but specific role in ancient metallurgy: zinc, antimony, arsenic, platinum, nickel, and mercury. With the Industrial Revolution, new metals were introduced: magnesium, aluminum, titanium, manganese, chromium, nickel, cobalt, molybdenum, and tungsten.

The natural average abundance of metals within the continental crust of the Earth is quite variable (Rudnick and Gao, 2004). Aluminum and iron are major components, possessing an average of 8 % and 5 % by weight, respectively. The others are rarer: copper, zinc, and lead are in the range of 0.01–0.001 % (by weight); tin, silver, and gold are at 0.0001 % or even lower.

In rare cases, metals occur in the native form as solid metallic particles in nature. More often, metallic elements are trapped within minerals, e.g., oxides, sulfides, and carbonates (Klein and Dutrow, 2008), which necessitates a metallurgical treatment subsequent to mining in order to extract the metal (Higgins, 1993).

An ore is a natural rock containing a useful substance (element or mineral) that can be technically and economically exploited. The geological classification of ores is based on their formation processes (Guilbert and Park, 1986). The nature and grade of suitable ores are variable through time and space as technical and economical contexts evolve. An important parameter for the suitability of an ore is the concentration of valuable minerals within it, i.e., the ore grade. Simple processes like crushing, washing, and handpicking can sufficiently enrich the ore grade so that a crude ore coming out the mine contains more of the desired material when the concentrate is loaded into the furnace. In modern times, the tonnage of a deposit is as important as the ore grade itself to make an investment profitable, but this aspect was not that relevant during ancient times. Ores are nonrenewable resources, and their deposits are not equally distributed on Earth due to their tendencies to form in specific, well-defined geologic settings. With simple prospection methods, it is much easier to explore for ore deposits in mountainous areas and deserts, where the topography and the absence of soil provide a better chance to observe the outcropping ore.

Whatever the metal being worked, metallurgy can be presented as a production line (“chaîne opératoire”) involving raw materials (ore, fuel, refractories), means of production (manpower, energy, tools, and devices), skills and knowledge (practical and symbolic), and behavioral aspects. From a point of view restricted to technology, it is always a complex sequence with five main steps: extraction of the ore (mining), beneficiation of the ore (ore dressing), primary production of the metal (smelting), improving the metal quality (purification, alloying, etc.), and finally shaping of the functional object (casting, hammering). In addition, numerous techniques of decoration can be applied to metals, from simple engraving and punching to complex gilding. Metallurgy is a complex technology at the cutting edge of human knowledge.

History of metallurgical technology

From a worldwide perspective, the story of metallurgy is quite complex (Tylecote, 1992; Craddock, 1995). The first metals to be used were the ones naturally occurring as solid metal in the native state, i.e., copper, gold, and iron (Patterson, 1971). Lumps taken from sizable masses of native copper allowed the first metallurgists to experiment with the fundamental properties of metals: plastic deformation under hammering and melting at high temperature. The key role of native copper at the very beginning of metallurgy has been stressed (Wayman, 1989). Copper can be shaped by cold hammering and annealing at low temperature. It can also be melted in a crucible and afterwards poured into an open mold. The melting point is 1,083 °C, a temperature easily reached in a simple hearth by using a blowpipe or a bellows.

Searching for native copper opened the door to the discovery of ore smelting, i.e., the transformation of metal-bearing minerals into metal by the application of high temperature. Indeed, native copper occurs along with copper carbonates and oxides, which are easy to smelt.

Subsequently, smelting of mixed ores containing arsenic or antimony-bearing minerals led to the production of "natural" alloys that possessed more suitable physical properties than pure copper alone.

The cradle of metallurgy

In the Middle East, small objects made of native copper were already in use before 7000 BC. A few of them have been found at early Neolithic sites, like Çatalhöyük in Turkey, or Çayönü Tepesi, which lies farther east near the mines of Ergani (Maddin et al., 1991). It remains difficult to identify the oldest object made of smelted copper, but the process seems to have emerged around 6500 BC (Hauptmann and Weisgerber, 1996; Bourgarit, 2007).

Alloyed coppers are much harder than pure copper, and thus, they are more suitable for tools and weapons. Arsenic- and antimony-containing copper alloys were probably first produced by smelting naturally mixed ores containing those elements (Northover, 1989). The generalization of bronzes, the alloys of tin and copper, was a significant step leading to the Bronze Age ca. 3300–1200 BC. Except for a few deposits hosting the rare mixed mineral stannite, tin and copper minerals are not found together. Bronzes were deliberately obtained by mixing the two components. Tin is quite rare, especially in the Middle East (Yener, 2008; Yener et al., 2015). Thus, the search for tin became a strong motive for trading and long-distance exchanges (Penhallurick, 1986; Nezafati et al., 2006).

Gold and silver entered the archaeological record in significant fashion during the Bronze Age, with, for example, the magnificent treasure of Ur in Iraq at about 2600 BC (Bachmann, 2006), but earlier finds from cemetery remains in the Levant during the fourth millennium BC (circlets of gold and electrum, an alloy of gold and silver; see Gopher and Tsuk, 1996) and in Varna, Bulgaria, during the mid-fifth millennium BC (gold jewelry and other adornments from high-status Eneolithic burials; see Ivanov, 1978; Renfrew, 1978). Some of the oldest iron objects are nickel-rich, a typical chemical signature for meteorites (Waldbaum, 1980). Smelting of iron started at around 1400 BC by the Hittites in Anatolia (present-day Turkey).

Out of the cradle?

Recent archaeological work has modified our perception of the spread of metallurgy through the world. Traditionally, a diffusionist model has been favored, presenting the Middle East as the unique source area for metallurgical inventions in the Old World; however, the story is more complicated. Although the Middle East was an early and active spot for metallurgical works, inventions and improvements took place in many other areas, too. How these different places influenced each other is still a matter of debate.

The world's oldest gold objects have been found in the tombs of Varna, Bulgaria, which date to an age before 4000 BC (Kuleff, 2009). In this context, gold was already used as a prestige good with evident high social status significance (Renfrew, 1978). Excavations in Serbia indicate that the smelting of copper started at about 5000 BC in the northern Balkans without any obvious hints of influence from the Middle East (Radivojevic et al., 2010). In southern Spain, copper smelting started at around 3000 BC, but with a very primitive and non-slagging technology (Hook et al., 1991). At the same time, the technology of copper smelting was already much more evolved in the eastern parts of Europe (Strahm, 1994). It seems improbable that an already outdated technology had been imported. Some form of separate, Western reinvention process is more likely to have occurred. In Sweden, the earliest objects made of smelted iron are dated to 1200 BC (Hjärthner-Holdar, 2008). It is, therefore, difficult to merge these findings with the diffusionist model centered on Anatolia. The situation is probably similar regarding iron metallurgy in sub-Saharan Africa, although the early dates proposed (before 800 AD) still have to be confirmed (Alpern, 2005; Killick, 2009). No Bronze Age can be identified in most of the African archaeological record.

There is no doubt that metallurgy was invented independently in the Andean area (Peru and Bolivia). There, the use of gold started at about 2000 BC and spread after 1000 BC, giving rise to a range of peculiar gold alloys. There is evidence for copper ore smelting in the Moche culture on the coast of northern Peru (200 BC–600 AD) and later all over the Cordillera, even up to Western Mexico (Hosler, 1988; Shimada and Merkel, 1991). At about 850 AD, bronze alloys were produced in Bolivia, a region with deposits of tin ores. Iron smelting never appeared in pre-Columbian societies. In North America, the huge deposit of native copper on the Keweenaw Peninsula (Michigan, USA) provided metallic raw material to the native people from 3000 BC onwards (Childs, 1994). In this area, no ore smelting metallurgy is attested before contact with Europeans.

Some other significant steps in the development of metallurgy

About 2,000 years ago, only the fundamental metals (i.e., gold, silver, copper alloys, and iron) were part of the material culture of Europe and most of Asia and Africa. This situation changed dramatically with the onset of the Industrial Revolution. During the nineteenth century, the range of metals and alloys increased dramatically (Gille, 1978), and the tonnage of all kinds of metal production increased by several orders of magnitude. The industrial production of aluminum started during the twentieth century.

During the two millennia prior to the Industrial Revolution, many metallurgical improvements took place: low-grade sulfide copper ores were worked using the matte process, the production of brass by the cementation process was mastered, the difficult extraction of silver out of copper ores was solved by liquation with metallic lead, the use of mercury amalgam improved the recovery of gold, and so on (Tylecote, 1992).

The production of iron in the liquid state was a significant improvement. For more than 2,000 years, iron was obtained by the bloomery process in the solid state at low temperature and at low reduction rate (Rostoker and Bronson, 1990; Pleiner, 2000). The blast furnace producing molten cast iron was developed in the Rhineland during the Middle Ages, around 1300 AD. Cast iron is breakable and must be decarburized to obtain wrought iron (finery process). A further advance took place with the invention of the converter introduced by Bessemer (1850 AD), allowing the production of liquid steel. However, it should be noted that cast iron had been produced in China since 300 BC, much earlier than in Europe (Wagner, 2008). In general, the story about the development of metallurgy in India and China is quite different from that of the Western world. For example, the production of metallic zinc occurred much earlier in India, as it is attested in written sources from the first century BC and by archaeological evidence at Zawar from the twelfth century AD (Craddock, 1998).

The impacts of metals on human societies

The economic impact of metals on human societies is substantial. The need for utilitarian metals or the desire for precious ones is more intense in highly populated areas, i.e., areas suitable for agricultural production and human settlement. On the other hand, mountain belts or infertile deserts are the easiest places to find the ore deposits. Thus, the search for metals became a very strong factor in establishing exchange networks and contacts among different cultures. This process started during the Bronze Age but remained a trend throughout history. The Spanish conquest of the Americas and various gold rushes represent additional examples. There are numerous stories of booming cities directly related to mining, like Potosi (Bolivia), Goslar (Germany), and Jachymov (the Czech Republic).

Hard metals, mainly bronzes and steels, are the most suitable materials for the production of efficient weapons and tools. Primitive agricultural production based on slash-and-burn was much improved by the replacement of the Neolithic polished stone axe with one composed of bronze. Digging up the soil to introduce fresh nutrients by using a hoe or an ard significantly improved the production of food when iron cultivating implements became available for farmers. The introduction of more efficient iron plows during the Middle Ages in Europe brought similar consequences.

Efficient weapons ensure security and enhance military power. Good tools significantly improve the productivity of labor. Metal tools (chisels, axes, etc.) are the most efficient with which to work hard raw materials like metal, stone, or wood. The development of metallic machines during the Industrial Revolution greatly increased productivity again. In the modern world, metals become essential for machines, buildings, and transportation. The use of electricity is made possible by copper wires.

Precious metals, predominantly gold and silver, are not suitable for practical uses, but they gained a symbolic value and were used as prestige goods. Later, metallic coinage became the normal means for the payment of goods and services, increasing the demand for gold and silver. The search for precious metals is a quasi-universal and permanent driving force in human societies.

The impact of metals is not limited to the economy; there are also important social and cultural aspects. The production of metals, from the mine to the finished object, is a complex and sophisticated sequence of technical actions, with infinite variations depending upon the kind of ore, the technology, and the final product. The skills and knowledge required for a successful metal production line have to be highly developed, and they typically require a long apprenticeship. It has been argued that the development of metallurgy stimulated the process of specialization within prehistoric societies. In several cases, metallurgy became a prerogative of specialized social groups like the various endogamic groups of smiths in Africa (Tamari, 1997).

Metallurgy was efficiently practiced long before it was properly understood in the nineteenth century. The nature of metals had always been a matter of wonder and questioning for curious minds. The medieval alchemists are a good example of this intellectual endeavor, but there were classical Greek and Islamic predecessors, as well as the Chinese and Indian traditions. *De Re Metallica* ("On the Nature of Metals") written by Georgius Agricola (1556) is one of the most famous technical books of the Renaissance. Metallurgy is a strategic activity, always tentatively controlled by the social authorities and rulers via direct control, taxation, etc. Laws and regulation texts were already promulgated in early times.

Archaeometallurgy

Archaeometallurgy deals with all questions related to the production and use of metals during the past (Rehren and Pernicka, 2008; Killick and Fenn, 2012). For prehistoric periods, the archaeological record is the only source of information (Ottaway, 1994), but for the later, historic periods, illustrated, written, or even oral sources are available. Experimental archaeology – the modern replication of ancient technical processes under controlled conditions (Coles, 1979; Tylecote and Merkel, 1985) – and ethnological comparisons (Killick, 1991) also provide important information.

How, when, how much, and why metals have been produced and used are the basic questions addressed by archaeometallurgy. A wide range of methods has been developed to investigate these questions. The focus here will only be on the archaeological approaches and the contributions of natural sciences.

A first challenge for archaeometallurgical studies is the reconstruction of ancient technologies. There are always a number of ways to achieve a certain goal. To do things in a given way is a cultural choice influenced by technological constraints (Rehren et al., 2007), and therefore, the study of technologies is part of the study of cultures. In the pursuit of archaeometallurgical information, the archaeological record can be used to make detailed descriptions of production lines. Field data on the relevant archaeological remains (furnace design, site organization, etc.) must be combined with laboratory work (characterization of raw materials, waste, and products, estimates of temperature ranges, etc.). In this manner, it is possible to decipher the history of technology.

A second classical approach is the provenancing of metals. Much effort has been focused on developing methods to link a metal artifact to the geologic deposit from which its ore was originally mined, in the sense of geochemical sourcing. This knowledge can contribute significantly to a description of exchange networks and commercial contacts in the past. A third question is the location of major production centers in time and space and the quantification of production. Provenancing and quantification both contribute to the development of economic history.

Finally, archaeometallurgy aims to understand the impact of metals on societies and the environment.

The metallic objects

A first major source of information is the morphology of the metallic object itself. Typological and stylistic studies have always been performed, at least for well-preserved artifacts. More recently, small and degraded objects have also been analyzed. Beyond the interest in the object itself, however, the archaeological contexts of metallic finds are of crucial importance for understanding the way metals were used and discarded in the past.

With the development of metallography and other techniques for the chemical and physical characterization of metals during the late nineteenth century, specialists started to investigate the ancient materials themselves. A piece of metal can basically be characterized in two ways: by its chemical composition and by its physical structure.

Many methods can be used to measure the elementary chemical composition of a piece of metal using both bulk (XRF, AAS, PIXE, NAA, ICP-MS) and point (LA-ICP-MS, SEM, EPMA) analyses. Many of these methods are explained in other parts of this volume. There always is a risk in investigating small samples taken from large objects, as a representative result is not guaranteed. For metals, surface analyses are not recommended owing to possible corrosion. Measurements of the main elements are useful in specifying the type of alloy, but the minor and trace elements can provide information about the ores and metallurgical treatments. The elementary chemical composition of a metal is dependent upon the nature of the raw materials used, but it is dramatically affected by the metallurgical treatment. A copper object must have been made primarily from a copper ore, but all other elements initially present in the ore could have been removed totally or in part during the metallurgical treatment, while all the other elements present in the finished metal could have been introduced during the treatment. The interpretation of compositional data always requires good contextual knowledge. Despite those limitations, elementary chemical compositions provide fundamental information for the understanding of metallic objects. Trace elements are of particular interest for the study of copper-based alloys, both regarding their variability in ores and their influence on the metallurgical treatment (Junghans et al., 1968; Pernicka, 1998; Rapp et al., 2000). Current research focuses on nonmetallic micro-inclusions (slag) in bloomery iron for provenancing (Dillmann and L'Héritier, 2006; Schwab et al., 2006).

Much progress has been made in the measurement of isotopic chemical ratios in archaeological metals by means of mass spectrometry. Isotopic ratios that were present in the ore are not affected by metallurgical treatments, so they can be used for provenancing artifacts by comparing them to ratios found in the varied ores being tested. The main limitation of this technique arises when metalworkers in antiquity mixed metals, a quite frequent practice during recycling, which affects the isotopic ratios directly because objects from different sources may be combined. Nevertheless, the inherent variation of lead isotope ratios in ores is quite important and has been investigated in detail for many ore districts. Several successful studies based on isotopic ratios have been performed on lead, silver, and copper objects (Gale et al., 1980; Gale and Stos-Gale, 1982). A comprehensive example is a study of Bronze Age copper oxhide ingots found in the eastern Mediterranean Basin (Stos-Gale et al., 1997). The isotopic data pinpointed their origin on the island of Cyprus, mainly from the mine of Apliki. Copper, tin, and osmium isotopes are also used in provenance studies (Junk and Pernicka, 2003).

The physical structure of metal greatly influences the physical properties of an artifact. At the scale of the object, any defect such as a crack, a hole, or a deficient joint will likely be directly responsible for local weakness and breaking. At a microscopic scale, the size, shape, and distribution of crystals or grains will significantly affect physical properties, including hardness and ductility. The craftsman can control the microstructure during the production process: cold-working (hammering) decreases the grain size and increases hardness, while annealing (heating) increases the grain size. Characterization of the internal structure of a metal artifact can be done using X-ray radiography or tomography, but these techniques complement the more traditional optical observations, which involve metallographic reflected light microscopy and chemical etching on polished sections (Scott, 1991). These techniques are often accompanied by hardness measurements, scanning electron microscopy (SEM), or microprobe (EMPA) investigations.

Direct dating of metal artifacts remains very difficult. The presence of carbon from the fuel in steel and cast iron allows the use of the ^{14}C dating method (van der Merwe, 1969; Enami et al., 2004).

The production sites and their remains

Mining and metallurgical production remains and sites are the second type of evidence for archaeometallurgy. For a long time, these were overlooked by most archaeologists. In Europe, many ancient production sites of major importance were severely damaged during the intensification of mining activity in ore-bearing areas at the end of the nineteenth century, as recorded by several mining engineers of the period. The scientific archaeology of mining and metallurgy was established only during the 1950s. Archaeological field work, such as remote sensing surveys, excavation, and description of remains deliver much valuable information about dating, technology, size, and organization of metal production. Laboratory studies on wastes and debris, especially slag, supplement these field approaches.

Mining sites

During the nineteenth century, old galleries and ancient surface workings were observable in many active mines. A typical example is the Laurion district near Athens, Greece, where hundreds of pits and impressive slag heaps were observed (Ardaillon, 1897). These localities were involved in the extraction of silver during the classical period. For several decades, it was assumed that modern mining had destroyed everything (Davies, 1935), but during the last 30 years, this assumption has been completely reversed by new surface surveys and underground explorations conducted on ancient mines.

Several ores (gold, tin, iron) are present as particles or pebbles in superficial unconsolidated sediments. In the past, these placer deposits were attractive to miners because the ores are easy to recover. Extended fields covered by extraction holes 1–10 m in size are known for many periods and places. For example, at Vert-Saint-Denis, near Paris, France, more than 2,500 small pits for the extraction of iron ore were recorded during a rescue excavation (Daveau and Goustard, 2000). More intensive extraction can be managed with the help of running water within channels. Extensive surveys and archaeological work on the Iberian Peninsula revealed the large-scale development of superficial washing works of Roman and pre-Roman age at the square kilometer scale (Domergue, 1990). At the famous site of Las Medulas, Spain, a thick accumulation of poorly consolidated sediments containing low-grade gold was exploited by the so-called *ruina montium* technique described by Pliny the Elder, in his *Naturalis Historia* (N.H. 33, 66). First, shafts and tunnels were dug into the sediments. Afterwards, water, which had previously accumulated in large water tanks, was forced into the galleries to disaggregate the sediment. The volume of excavated material is estimated to have been up to 0.1 km^3.

Underground mining had already developed during prehistory, initially for flint but subsequently for metals. Bronze Age underground copper mines have recently been studied in Wales (Timberlake, 2003), Ireland (O'Brien, 2004), the Middle East at Timna, Israel (Conrad and Rothenberg, 1980), and at Faynan, Jordan (Hauptmann, 2007). Greek mining for silver at Laurion, Greece (Conophagos, 1980); Roman mining for silver and copper at Aljustrel, Portugal (Domergue, 1990); and medieval works for silver at Sainte-Marie-aux-Mines, France (Ancel and Fluck, 1988), are further examples of well-studied historical mining districts. Various marks on gallery walls help to discriminate formerly used techniques and tools, e.g., stone hammers, metal picks, or chisels, and use of fire. Water management is the most complex aspect of underground mining and a limiting factor in many cases.

The recent development of underground archaeological excavations brought exceptional finds to light, like in the Roman gold mines of Rosia Montana, Romania (Cauuet, 2008). Waterlogged galleries provide exceptional preservation conditions for supporting wood and machines.

Disposal of wasted rock outside of the mine entrance at the surface produces sizeable heaps. A mining landscape reveals not only varying amounts of extraction debris but also track ways, accesses, waste disposal areas, water channels and tanks, as well as additional settlements and buildings. In recent decades, the cultural importance of historical mining landscapes has been recognized, and several sites are now protected and valued as natural and cultural heritage. Some of them are on the UNESCO list of World Heritage Sites, such as the Roman gold mining field of La Medulas in Spain, the Engelsberg Ironworks in Sweden, the Rammelsberg mines in Germany, and the Blaenavon Industrial Landscape in the United Kingdom.

Solid knowledge of ore geology is of great importance in mining archaeology. For example, the variation of the ore grade at the scale of a meter can explain the complexity of the shape of old galleries. A detailed understanding of ore composition is required for the development of successful provenance studies. In many cases, the ancient exploitation started in the upper part of an ore deposit where the primary ore is usually transformed by supergene alteration and often appears at the surface as a highly oxidized staining of the local rocks by residual iron oxides (called gossan or eisenhut) after the main ore bodies have weathered. The upper-level ore minerals or rocks are very different from those mined deeper within the lode, as later operations at the same locality would discover. For example, during Roman times, the main ore at the Rio Tinto deposit in Spain was the silver-bearing jarosite, an uncommon sulfate mineral formed during the alteration process (Rothenberg and Blanco-Fereijeiro, 1981), but during the nineteenth century, Rio Tinto was the world's largest copper mine.

Ore dressing plants, in general, are located close to the mines. During ancient periods, the treatment of the ore was a combination of simple techniques based on crushing, washing, and handpicking. Flotation, lixiviation (leaching the desired solute from an ore using a solvent), and other chemical processes developed only recently. Some treatments can be performed with simple tools like a hammer, sieve, and bucket. More sophisticated equipment and machines were already in use during the classical periods, like the helicoidal washing plants of Laurion in Greece (Conophagos, 1980) and the rotary mills of Les Martys in France (Domergue, 1993). A complete medieval production line is illustrated by the drawings made by Heinrich Gross in 1529 at La Croix-aux-Mines in France (Brugerolles et al., 1992). Water channels and tank systems, heaps of crushed gangue (waste) rocks, and accumulations of fine-layered sediments are the typical remains of ore dressing plants (Bailly-Maître, 2010).

Remains of the extractive metallurgy

Slag heaps and furnace ruins are the characteristic indications of primary extractive metallurgy. Smelting sites in general are located close to the mines to minimize transportation of heavy loads of ore. Large quantities of fuel are also needed, and the location can be influenced by the proximity of wood or other burnable resources. In Europe, from medieval times onwards, water power has been used to run the bellows of large furnaces, and thus, plants have been built on riverbanks. In a few cases, metallurgists built their furnaces in specific locations to take advantage of particular conditions. For example, the iron furnaces driven by the monsoon winds in Sri Lanka are built just below the crest of hills where the wind is steady (Juleff, 1996). As a general rule, large smelting operations took place on specialized sites outside of settlements. The pattern of the distribution of the smelting sites illustrates the organization of production. Small-scale units can be scattered all over an extensive territory, or the activity can be centralized at a single large site with shared facilities. The distribution of production sites regarding the roads, waterways, farming estates, grouped settlements, and fortifications offers significant clues about the social system (Cleere, 1974; Jockenhövel and Willms, 2005; Rippon et al., 2009).

Early iron smelting sites called bloomeries are the most abundant and widespread for three main reasons. First, iron ores are abundant and widespread. Second, iron has been produced to a much higher scale than any other metal. Finally, the bloomery process produces large amounts of slag, and such slag heaps averaging 100,000 tons are known from the Roman period all over the Empire (Cleere, 1974; Domergue, 1993, 2008; Cech, 2008). Most of them were damaged or even totally recycled during the late nineteenth century when fayalite slag was fed into blast furnaces (Goudard, 1936; Pistolesi, 2006). Very large iron smelting sites are still preserved in many parts of the Sahel area in Africa (de Barros, 1986; Robion-Brunner, 2010; Serneels et al., 2012). Much smaller sites weighing in with a few tons of slag are quite numerous. Large slag heaps are the result of the dumping of wastes from furnaces that were reused many times, but single-use furnaces were also common, especially in northeastern Europe (Pleiner, 2000). The slag block formed inside such a furnace was left in the ground, and a new furnace was built adjacent to the first. Extended sites with hundreds of slag blocks have been investigated in the Holy Cross Mountain area of Poland (Bielenin, 1992).

There are spectacular remains of copper smelting, e.g., Faynan in Jordan (Hauptmann, 2007) and Cyprus (Kassianidou, 2000). Much work has also been done in the Alps (France, Italy, Austria) where significant Bronze Age production is evident (Cierny, 2008).

Sites and remains related to transformation metallurgy

For the production of metallic objects, the craftsman needs specific installations, including at the most basic level a hearth or furnace and a working bench or anvil. Many other features can be found at production sites, such as polishing facilities, water tanks, and fuel storage, and such workshops can be either simple and unspecific or highly specialized with sophisticated equipment. The metallurgical wastes, including slag, are characteristic of the type of work being conducted, and the quantities are always significantly less than the ones encountered at locations of extractive metallurgy. Areas where craft activities were performed are frequently found within large settlements, as such places permitted craftsmen to interact with consumers. Production of artifacts with new metal was only a part of the repertory of activities; recycling, repairing, and maintenance were also of major importance. Workshops were frequently grouped to form specialized districts within towns, and the metallurgical wastes produced in urban workshops were frequently used as embankment fill outside the working area.

From the Iron Age onwards, iron blacksmith workshops were common in the archaeological records of settlements. The normal range of smithing wastes from a single workshop is between a few kilograms and a few metric tons (Ottaway, 1992; Anderson et al., 2003). Many workshops for the production of nonferrous objects are known from historical periods (Chardron-Picault and Pernot, 1999), and as an example, a gold processing workshop found at Sardis in Turkey has been investigated in detail (Ramage and Craddock, 2000).

Common laboratory methods for the study of metallurgical wastes

There are not many precisely defined words that differentiate the types of waste produced during metallurgical activities (Bayley et al., 2008). Slag is a term that can refer to all kinds of waste that underwent at least partial melting. Another type of debris includes the ceramic materials involved in the metallurgical process, like furnace walls, air pipes (tuyères), molds, crucibles, cupels (for refining noble metals like silver through cupellation), and other vessels. Pieces of metal, at various stages of work, can usually be recovered at such sites. Hammerscales are small iron oxide particles formed at the surface of the hot metal in contact with the atmosphere; they are broken and scattered under the impact of hammer blows during smithing (Dungworth and Wilkes, 2007) and can be found within site sediments. Pieces of ore, additives or fluxes (limestone), and fuel (charcoal) can also be present. When the ancient smith operated with a well-mastered process, the nature of the waste tends to be constant, as the routines were automatic and repetitive. On the other hand, a poorly mastered process will yield variable wastes. In general, a single process will not give rise to one single type of waste but instead an assemblage of different wastes in more or less constant proportions.

All kinds of production waste can be investigated with the goal of material characterization (Bachmann, 1982; Serneels, 1993; Kronz, 1998; Fluzin et al., 2000; Bayley et al., 2008), and the methods listed for elemental or isotopic analysis of metals apply to slag and other wastes (see section on metallic objects above). In many cases, metallurgical wastes are found to be very heterogeneous. It is then important to investigate the structure and variability of the materials. Careful examination of the morphology and geometry of the waste is frequently key to understanding its significance and explaining the original metallurgical processes. In general, the structure of the slag at a grain-size scale reflects the cooling rate. The mineralogical composition can also give an estimate of the range of temperatures. Iron oxide, silica, and alumina are the most frequent chemical components; the most frequent minerals are fayalite (iron silicate), wüstite (iron oxide), and hercynite (iron aluminum oxide) (Bachmann, 1982, Serneels, 1993, Hauptmann, 2007).

For smelting slag, the chemical composition reflects the charge introduced into the furnace. The ore, constituting metallic minerals and unseparated gangue minerals, is always a predominant component of the charge, but fluxes and additives can be present. In many cases, high temperatures cause the partial melting of the furnace walls or the tuyères, and the resulting slags are contaminated. Finally, the fuel adds a significant amount of mineral matter into the furnace itself, predominantly calcium and potassium as ash.

It is a common approach to use phase diagrams to present chemical and mineralogical data on slag. Those diagrams are drawn from systems that reach a thermodynamic equilibrium, so they cannot be applied without caution to ancient metallurgical systems, which can be very far from equilibrium (Allibert and VDEh, 1995). In spite of this limitation, phase diagrams can help to assess the melting temperature and explain the relations between the ore, slag, and other components.

The composition of the gaseous atmosphere in the furnace is a key factor that affects the metallurgical treatments. The combustion of the fuel, mainly charcoal, controls the quantities of free oxygen, carbon monoxide, and carbon dioxide. The presence of more or less oxidized minerals in the slag is a useful indicator of the reduction rate, especially in the iron-oxygen system – metallic iron (Fe), wüstite (FeO), magnetite (Fe_3O_4), and hematite (Fe_2O_3).

There is no well-established method for the direct dating of fayalitic slag, and associated materials can be more suitable. Radiocarbon dating (^{14}C) is widely used on charcoal. In addition, thermoluminescence (TL) or even optically stimulated luminescence (OSL) can be applied to heated quartz grains embedded within industrial installations, such as the ceramic materials in furnace walls and tuyères, etc. Archaeomagnetic measurements can also be conducted on furnace and other heated clay structures found in situ.

Quantitative approach to metallurgical production

The qualitative approach to metallurgical remains aims to characterize the technology used and to define the different steps of the production line at a given archaeological site. A quantitative approach differs in that it attempts to evaluate the importance of the various past activities. Metallurgical remains are, with some restrictions, suitable for a quantitative approach, and as a general rule, there is a quantitative relation between the masses of slag, the amounts of ore processed, and the weight of metal produced.

In this respect, the simplest process is smelting: for a given amount of ore, a smelting operation will produce specific amounts of slag and metal (Eschenlohr and Serneels, 1991; Kronz, 2003; Crew and Charlton, 2007). The chemical data on ore, slag, and metal allow calculation of the ratio (mass balance calculation). The measure of the mass of slag allows an estimation of the masses of ore and metal involved. Hypotheses can then be formulated about the quantities of fuel and labor involved. The chemical composition of slag can be directly measured; however, it remains complex to define the composition of the ore. Sometimes, it is possible to sample the ore used from its geological position in the mine if such is known, but in most cases the crude ore underwent a process of beneficiation during production. A detailed topographic mapping can be used to evaluate the total volume of slag in remaining heaps (Decombeix et al., 1998). The mass of slag by unit of volume is directly weighed during trial excavation.

In many cases, quantification is difficult. If the metallurgical process was variable (including variability of the ore and the efficiency or quality of the product), no average calculation would be meaningful. Serneels and Perret (2003) present an example of a complex quantitative approach to a case of blacksmithing slag. An experimental approach is an alternative possibility to derive figures useful in comparison to quantification of archaeometallurgical sites (Crew, 1991), and ethnographical records offer a further option for obtaining similar comparative data (Bellamy, 1904).

Environmental approaches

Fuel studies

Fuel is involved in most metallurgical activities, as it is necessary for the production of heat. Carbon monoxide plays an active role in the reduction process. In most cases, the working temperatures are high (above 1,000 °C), and an efficient fuel is required (Rehder, 2000). Charcoal performs better than wood, and dense wood (hard) is better than lightwood (soft). High-quality coal is even better than charcoal. Before the Industrial Revolution, coal did not play a significant role in Europe. For the production of cast iron, the presence of sulfur in natural coals has long been a reason for rejection. The introduction of desulfurized coke obtained by distillation of coal by A. Darby at the beginning of the eighteenth century was an important advance during the Industrial Revolution. Other fuels, like turf or cow dung, have been of very limited use.

Species characterization of charcoal recovered from metallurgical sites and wood remains from mines offer interesting information about the natural environment of the sites, but they can also reveal practices of wood management, or even shortages (Py, 2006; Eichhorn et al., 2013). Dendrochronological approaches can provide significant data on seasonality or intensity of the labor (Pichler et al., 2013). Occasionally, wood or straw imprints on slag have yielded species identifications (Mikkelsen, 2003; Iles, 2009).

Paleopollution in soils, in sediments, and in ice cores

Metallurgical activities, with their high-temperature pyrotechnics, release significant quantities of dust and fine particles as an aerosol into the atmosphere. Geochemical anomalies of heavy metals, mainly lead, have been detected in ice cores drilled into the Greenland ice sheet. They are interpreted as an archive of ancient metallurgy at the global scale (Hong et al., 1994; Hong et al. 1996). Similar anomalies have been studied in peat deposits and lake sediments, mainly in the northern countries of Europe or in mountainous areas (Mighall et al., 2002; Shotyk, 2002). In the best cases, this type of record could reflect in detail the timing and the intensity of metallurgical activity. The data remain difficult to interpret, as the record is influenced by the superimposition of global and local signals and can be perturbed in many ways. Lead isotope measurements from aerosol particles can help to define the origin of the paleopollution (Dunlap et al., 1999).

Slag in stream sediments can be an interesting proxy leading to an understanding of the recent behavior of rivers and land use (Stolz and Grunert, 2008). Geochemical anomalies in archaeological sediments can reveal undetected metallurgical activity, and therefore, geochemical or geophysical measurements conducted during the excavation of workshop areas can provide significant information about the organization of local industrial activities. Several studies on smithing workshops pointed out the presence of hammerscale to identify the location of an anvil (Veldhuizen and Rehren, 2007). In the future, sedimentological methods, including micromorphology, could be applied successfully to ore dressing plant wastes and to soils of metallurgical workshops.

Summary

Metals are essential to human societies. For the production of tools and weapons, iron and copper-based alloys are the most efficient materials. Gold and silver were always used for prestige goods and later on for coinage. The oldest metal objects can be traced back before 7000 BC, but production at a significant scale started with the Bronze Age about 3300 BC and subsequently increased progressively. A peak in antiquity was reached around 100 BC in Europe, India, and China. The Industrial Revolution introduced several innovations, and production increased further during the nineteenth century.

Archaeometallurgy aims to reconstruct ancient technologies, past production patterns, and economies. This includes the study in the field of old mining works, large heaps of slag, furnace ruins, and archaeological traces of workshops, but it includes also the investigation of metallurgical wastes and artifacts in the laboratory. Historical period mining and metallurgy has had a significant impact on the environment (landscape change, pressure on fuel/wood resources, early pollution), but the use of metals has brought major advances to human societies, including the improvement of agricultural productivity, the development of craft specialization, and the accumulation of prestige goods.

Definition

The study of sedimentary deposits at the mm to cm scale.

Introduction

A concept of major importance to both the earth sciences and archaeology is that of stratigraphy. Stratigraphy has many "*definitions*," and a typical one can be expressed as simply: "[the] scientific discipline concerned with the description of rock successions and their interpretation in terms of a general time scale" (Encyclopædia Britannica online, 2012). A more informative and broader *characterization*, which is suitable to a geoarchaeological audience, might be: the geometrical, spatial, and temporal arrangement of rocks, deposits, soils, and archaeological features (e.g., architecture, hearths). For predominantly historical reasons, geologists have erected a variety of operationally and conceptually independent stratigraphic strategies within the realm of stratigraphy; these include lithostratigraphy, biostratigraphy, magnetostratigraphy, chronostratigraphy, and soil stratigraphy (e.g., Gilbertson, 1995). Such approaches are needed in order to correlate (i.e., demonstrate physical or temporal equivalence) different objects and deposits encountered in a geoarchaeological context.

Typically, stratigraphy is intellectualized at a variety of scales, including that of geological landscapes (e.g., the state of New York), an exposure in a single area (e.g., within the Grand Canyon), or an outcrop. In archaeology, stratigraphy is normally envisioned at the site scale, be it a Middle Eastern tell or that exposed in excavation of a Neanderthal encampment in France. Geoarchaeologists need to be conformable about working at several scales, which commonly overlap: conducting a regional search for rocks involved in sourcing raw materials or attempting to understand the nature and origin of a "mousey brown" layer exposed in the corner of an excavated building.

Related to the idea of stratigraphy is that of facies, which can be considered as the "physical, chemical, and biological aspects of a sedimentary bed and the lateral change within sequences of beds of the same geologic age" (Encyclopædia Britannica online, 2012). Thus, within a deltaic deposit, we can observe various lithologies depending on the location (e.g., beach, channel, swamp, distal bar). Facies is an important concept because it allows us to monitor different, spatially contiguous and contemporaneous lithologies that represent subenvironments of the same depositional system.

In geology, the notion of facies has been extended to the study of deposits at a finer, mm to cm scale. Microfacies, "…the total of all sedimentological and paleontological data which can be described and classified from thin sections, peels, polished slabs or rock samples" (Flügel, 2004, 1), is an invaluable tool for conceptualizing and examining stratigraphy at a fine scale, i.e., microstratigraphy. Microstratigraphy, then, is no different in principle from stratigraphy as employed on a geological scale, except that the primary focus is lithostratigraphy, which describes packets of deposits based on similar lithological criteria such as color, texture, grain size, structure, and consistence. In addition, microstratigraphy may be delineated on the basis of different microfossils (e.g., diatoms and foraminifer) in marine and coastal environments, or pollen in waterlogged terrestrial environments. In geoarchaeology, microartifacts recovered by sieving, or identified and counted in thin section, also contribute to understanding microfacies (Rosen, 1993; Sherwood et al., 1995).

Methods used in microstratigraphy

Microstratigraphy is studied both in the field and in the laboratory. Field approaches entail detailed observations of the microstratigraphy, including vertical and lateral facies changes. At the same time, the stratigraphic units are documented by careful drawings and detailed photographs of the deposits; flash photography is particularly useful as the flash can enhance contrast and make subtle stratigraphic units much more visible. In addition, archives of the deposits can be produced by employing sediment peels (Goldberg, 1975), a technique borrowed from geology.

Once microstratigraphic units have been identified and characterized, they can be sampled for subsequent work in the laboratory. The most appropriate sampling strategy at the outset is to collect undisturbed blocks for micromorphological analysis (Goldberg and Macphail, 2003) (see entry on Soil Micromorphology). At the same time, bulk samples from individual microstratigraphic units can be taken, carefully noting their relationship to the block sample and the overall microstratigraphic sequence. Such "microbulk" samples are very useful undertaking bulk analyses on loose sediments, such as grain size, bulk chemistry, magnetic susceptibility, etc.

In the laboratory, block samples are dried and impregnated with resin (polyester or epoxy) and processed into petrographic thin sections and observed under the polarizing light microscope (Courty et al., 1989). Although micromorphological analysis provides a very effective means of characterizing the deposits (e.g., composition, texture, and their three-dimensional arrangement: fabric) and revealing the interplay between depositional and postdepositional geogenic and anthropogenic processes, it has its limitations in identifying the nature of inorganic and organic small (say, fine silt and smaller) particles, including mineralogy, organic composition, and degree of heating of a material. Thus, additional "microstratigraphic" techniques are required to yield such information (Artioli, 2010; Weiner, 2010). These techniques can include Fourier transform infrared spectrometry (FTIR; and micro-FTIR, which enables identification of materials contextualized within the thin section itself (Goldberg and Berna, 2010); see entry), x-ray diffraction (see entry on X-ray Diffraction (XRD)), Raman spectroscopy, and scanning electron microscopy (SEM) or microprobe, both of which can provide microelemental analyses (see Figures 7 and 8). In addition, bulk chemical analyses (e.g., Parnell and Terry, 2002; Barba, 2007) and magnetic susceptibility (Crowther, 2003) can be performed on the microbulk samples that were collected at the same time as the undisturbed micromorphology blocks.

Application of microstratigraphy to geoarchaeology

Unlike geological microstratigraphy, archaeological microstratigraphy takes into consideration the artifacts of humans and site formation processes brought about by them. Context units and subunits can therefore be partially or wholly the product of human activity. In many readily understood and well-studied Quaternary sites, natural physical and chemical effects often predominate, but in anthropogenic deposits and occupation surface formations, especially within settlements of complex societies, sedimentary processes may well be totally anthropogenic. In the case of the French Middle Paleolithic site of Pech de l'Azé IV, for example (see entries on "Rockshelter settings" and "Site Formation Processes"), natural cave sediments are intercalated with combustion zone deposits, as well as lithic and faunal remains (Figures 1 and 2). Natural cave sediment formation processes often play a secondary role in such contexts and in this example include localized phosphatization. In other Paleolithic cave and rock-shelter deposits in France, for example, geogenic deposits can be more prominent (e.g., Laville et al., 1980; Texier et al., 2004)

The Upper Paleolithic site of Chongokni, Hantan River, Republic of Korea, in the Imjin River Basin, is characterized by Acheulean-like hand axes, with new charcoal dates, which suggest that some 10 m of alluvium accumulated over 30 kyr (Seonbok Yi, Seoul National University, pers. comm.). Such rapid sedimentation makes it very difficult to differentiate alluvial site formation

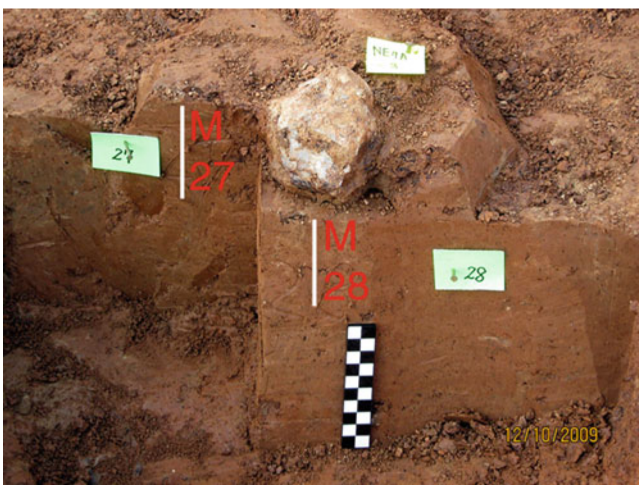
Microstratigraphy, Figure 1 Layer 8 from the French Middle Paleolithic site of Pech de l'Azé IV, showing the remains of both intact combustion features with ashes (*white band*) and those that have been modified by trampling and rake-out (redistribution of combusted material in cleaning and preparation for new fires).

"noise" from information associated with paleoenvironmental reconstruction of the land surface associated with the presence of hominid activities. This challenge was mitigated by sampling beneath and next to the artifacts (Figure 3). Large artifacts such as hand axes and quartzite cores protected sediment that is immediately beneath them. At one example, the microstratigraphy is composed of bedded microlaminated wet season alluvium; here silts occur with eroded clasts of clayey soil (Figures 4 and 5, "Bsed"). Immediately below the quartzite core, the alluvium becomes worked by soil fauna and rooting plants (Figure 6). Thus, in theory, a thin homogenized entisol (a young soil) had briefly formed during the dry season, and it was during this season that hominids traveled this landscape and at this location discarded a quartzite core. It can also be noted that within this microstratigraphic sequence it was important to recognize the hierarchy of the features, notably that:

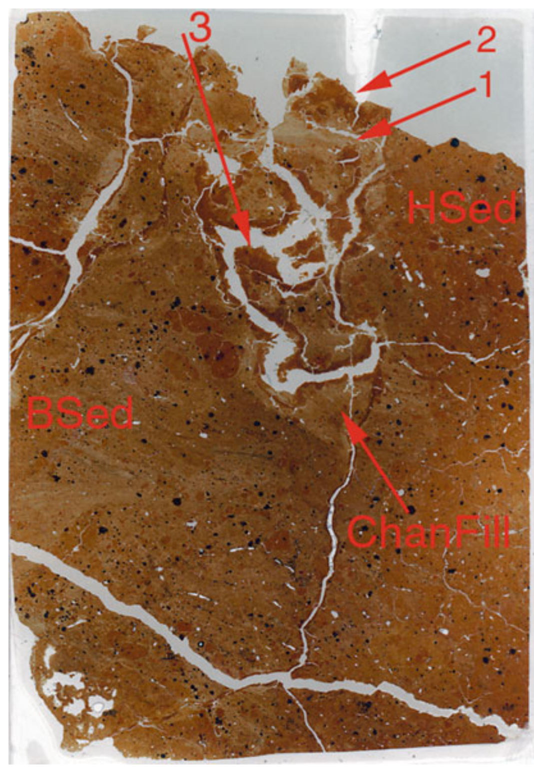
1. Bedded alluvium came first ("Bsed").
2. Followed by surface soil homogenization (Hsed).
3. The quartzite core was discarded (Figure 3).
4. Finally, renewed alluviation led to inwash of clay ("ChanFill").

As suggested above, the microstratigraphy of deposits in complex societies can be much more complicated, as they form mostly through human activities, such as dumping, sweeping, and trampling. Thus, they can reflect different activities through space and time and not different natural environments. They still produce diverse types of microfacies, however, that can be interpreted in terms of activities and use of space (Courty, 2001). A major site

Microstratigraphy, Figure 2 Microstratigraphic sequence from Middle Paleolithic deposits at Roc de Marsal, France. Some of the stratigraphic units are depicted here with *green* numbers. (*1*) Reddish silty clay formed in pockets above the bedrock. (*2*) Dispersed remains of combustion feature, locally phosphatized. (*3*) Band of intact and reworked combustion features; *yellow arrow* points to erosional contact with unit 4. (*4*) Stony clayey silt rich in bones. (*5*) Partial remains of combustion features with sharp, erosional contact with the overlying layer 6 (*yellow arrow*). (*6*) Similar to layer 4 but occurs as lens with upper, erosional contact with layer 7 (*red arrow*). (*7*) Stony clayey silt with charcoal and organic matter.



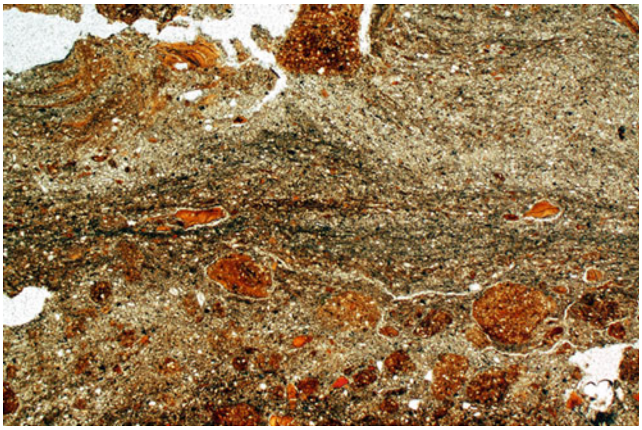
Microstratigraphy, Figure 3 Upper Paleolithic Chongokni, Hantan River, Republic of Korea; quartzite core sample, core-buried protected soil sample M28, and unburied soil surrounding quartzite core sample M27 (NE 07A) (Courtesy of Seonbok Yi, Seoul National University).



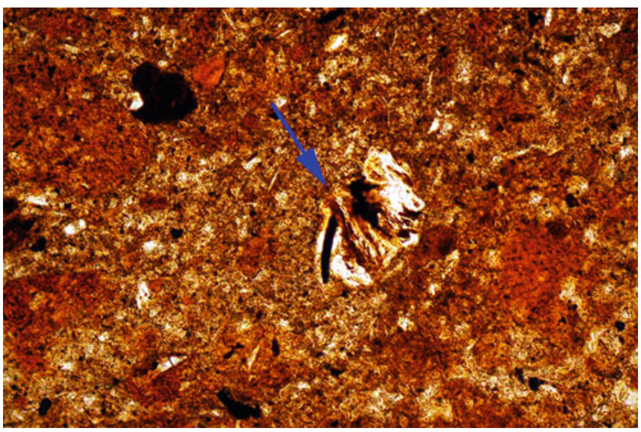
Microstratigraphy, Figure 4 As Figure 3; scan of M28, showing pre-quartzite core-bedded fluvial sediments (Bsed) and the biologically homogenized soil-sediments (Hsed) that had developed in them (also 2). This alluvial entisol probably formed during the post-wet season period and just before the cobble was deposited. The next wet season's rainfall led to subsurface (sub-core) channeling or "tunneling." The channel then became infilled (ChanFill) with silts (see also 1). Finally low-energy alluvial clay-infilled cracks in the fill (3). Frame width is ~50 mm.

formation model proposed by Gé et al. (1993) attempted to characterize a specific type of anthropogenic sediment related to occupation "floors" and their origin. Passive, active, and reactive zones were identified in accordance with their original constituents and the physical effects of trampling on the floor surfaces. Additional aspects considered were open-air sites, roofed sites, and how different material and moisture contents affected the character of the sediment at these complex sites (Courty et al., 1994, Table 1).

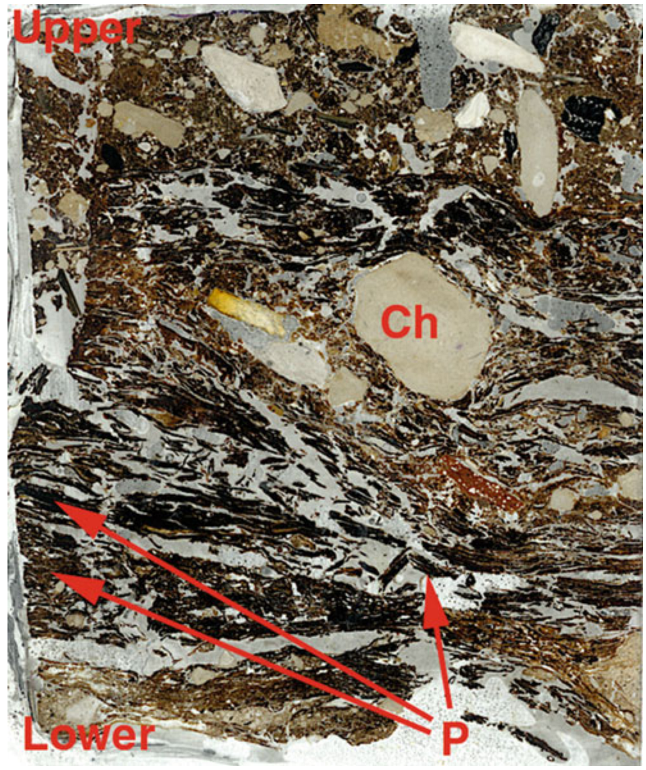
More recently, additional analytical approaches have been developed to help characterize occupation deposits.



Microstratigraphy, Figure 5 As Figure 4, photomicrograph of "Bsed," laminated alluvial silts and eroded clay clasts, the surface of which became biologically homogenized probably over one season (see Figure 6) before the quartzite core was discarded (?). Plane-polarized light (*PPL*), frame width is ~4.62 mm.



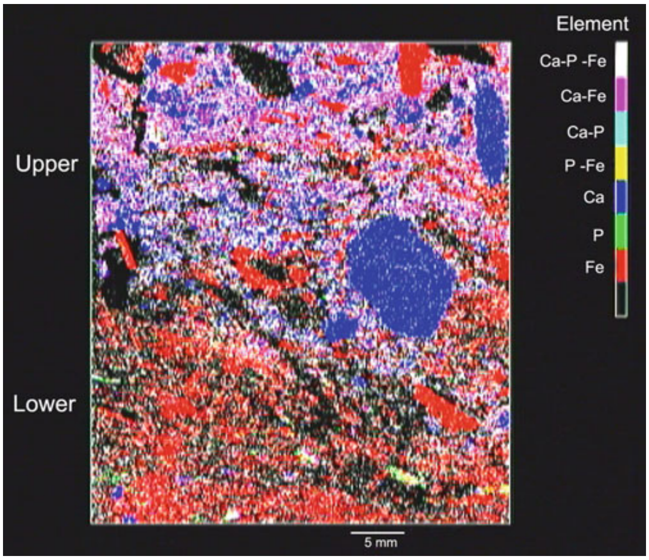
Microstratigraphy, Figure 6 Photomicrograph of pre-core homogenized "entisol" (Hsed) formed in possibly months after fluvial deposition of bedded silty clay (Bsed) and before core was "dropped" (see layer 2, Figure 4). Note ferruginized root section (*arrow*, *center*) and fragments of hematite-iron clay (XRD). PPL, frame width is ~0.9 mm.



Microstratigraphy, Figure 7 Pilgrims' School, in the environs of Winchester Cathedral, UK (Courtesy of Oxford Archaeology South). Scan of M309B (14th C Context 309); anomalously humic (34.4 % LOI), enriched in both phosphate (3.92 mg g-1 P) and lead (736 μg g-1 Pb), with very rich pollen content of cereals, grasses, and herbs. Frame width is ~50 mm.

One approach includes the measurement of magnetic susceptibility (χ). For example, a constructed floor may have an enhanced χ because its composition includes burned mineral material, and/or because it was heated in situ, as in a hearth or near-hearth location. Equally, phosphate may be high, but again this may be due to included fragments of bone and coprolites or to secondary phosphate migration. The same applies to heavy metal contamination. In all these cases, different methodologies need to be used – including soil micromorphology, bulk soil analyses of the microstratigraphic units and ultimately EDS and microprobe, FTIR, and XRF – in order to be able to fully understand the formation of a sediment at the microscale.

The above shows how important it is to study intact samples along with bulk samples and how crucial it is to have flawless contextual correlation among the samples. For many years Neolithic Mediterranean cave sediments were simply associated with stabling of domestic animals, mainly sheep and goats, because of the presumed mineral remains of dung (composed of calcite dung spherulites and phytoliths) that were commonly found in bulk samples. When these cave sediments were studied systematically through soil micromorphology (as well as through EDS and macrofossil analysis of plant remains present in thin sections), a more sophisticated understanding of cave use was realized. For example, domestic space – and periods when domestic occupation dominated – was clearly differentiated from stabling areas and episodes. Moreover, microstratigraphic analysis revealed that stabling produced repeated sediment sequences from seasonal overwintering of stock and that animals were fed on a leaf hay fodder (e.g., *Quercus ilex*), which produces very few phytoliths (Macphail et al., 1997); in contrast to domestic use sediments these stabling deposits were



Microstratigraphy, Figure 8 Microprobe map of M309B (Figure 7), showing distribution of Ca (chalk, calcite ashes, etc.), Fe (e.g., iron-stained organic matter), and P (phosphate-stained organic matter – typical of stabling waste). Here, domestic constructional debris and ash residues were dumped over organic stabling debris. Ashes appear associated with lead concentrations (0.09 % Pb). Scale =5 mm.

then also burned in situ. Faunal remains supported the identification of overwintering of stock in sediments showing these cycles of stabling.

When human activities are added to the mix, the interpretation of microstratigraphy becomes increasingly difficult. This has been mitigated by the analysis of microfacies types produced during experiments and ethnoarchaeological analogues. Examples include complementing micromorphology with image analysis to study a Bedouin camp and adding pollen, bulk, and microchemistry to microfacies analysis of domestic and stabling floor investigations at the experimental Iron Age farm at Butser, Hampshire, UK (Goldberg and Whitbread, 1993; Macphail et al., 2004). In the latter case, in situ stabling deposits and intact dumped stabling refuse were shown to have typical a multidisciplinary signature. This yardstick has permitted the identification of well-preserved byre (cowshed) waste dumps, as, for example, in the fourteenth-century environs of Winchester Cathedral, by the River Itchen (Figures 7 and 8). The stabling waste is composed of microlaminated long plant stems of grasses and cereals that are part cemented with phosphate, as typical of stable floor crusts; the pollen analysis revealed a typical fodder plant composition. This layer is overlain by chalky floor construction dumps and ash residues, which are themselves enriched in lead (Pb).

Conclusions

It can be seen that by employing the geological concept of microstratigraphy, geoarchaeologists can greatly improve the characterization of stratigraphy on archaeological sites. Moreover, microstratigraphy is best observed and studied in thin section, which then can be further analyzed using small bulk samples for chemistry, magnetic susceptibility, and microfossils; macrofossil, EDS, FTIR, and reflected light (char) analyses can be carried out directly on the thin section in some cases. Overall, consensus interpretations of both vertical sequences and lateral differences in use of space can all be recognized and interpreted.

MINNESOTA MESSENIA EXPEDITION (MME)

George Rip Rapp
Department of Geological Sciences, University of Minnesota, Duluth, MN, USA

The Minnesota Messenia Expedition (MME) was the first major multidisciplinary archaeological expedition in Greece. Its focus was the Bronze Age and involved surface survey, large-scale excavation, with many integrated studies focusing on paleoenvironmental reconstruction, archaeological science, cultural history, and social anthropology (McDonald and Rapp, 1972; Rapp and Aschenbrenner, 1978; McDonald et al., 1983; McDonald and Wilkie, 1992). Although this project was not organized formally until 1962, survey work began in 1958 after Carl Blegen had suggested to William McDonald the critical need for such a survey. Regular surface survey initially was conducted by McDonald and Richard Hope Simpson. During the 1960s, McDonald realized the need for associated scientific studies and engaged H. E. Wright, Jr. (paleoecology), William Loy (geography), Jesse Fant (civil engineering), and others to conduct them. This culminated in 1966 with the addition of geoarchaeologist George (Rip) Rapp being named associate director. He expanded the scope of the scientific investigations into other specialties, such as archaeometallurgy and coastal change, and assisted McDonald in securing the permit to excavate the site of Nichoria.

Based on the years of archaeological survey, which located hundreds of sites, seven sites were identified as most worthy for excavation. The "lower town" of the Pylos Palace was the highest priority, with Nichoria second. Having excavated the palace, Blegen controlled the permit for the palace area. He suggested that another site be selected, so Nichoria was picked and the permit was secured. With McDonald as director and Rapp as associate director, excavations began in 1969; they continued through 1975. Based on the Linear B tablets found at the palace, it was believed that there was a subsidiary capital of a "further province" in the Pylean Kingdom. Nichoria was considered to be the best candidate for this. It was located on a ridge with a commanding view of both land and sea.

Excavation began in 1969 with a so-called trial trench season. Subsequent years of excavation exposed well-preserved deposits ranging from the Middle and Late Helladic (Bronze Age), through the Dark Age (Early Iron Age) to the Byzantine (Medieval). As in the survey, the excavation staff was composed of scholars representing a wide range of disciplines. To facilitate their studies, a large "dig house" was constructed with specialized areas and facilities (see Rapp and Aschenbrenner, 1978: Plates 1–2 through 1–16). Space and equipment was available for ethnobotany, sedimentology, petrography, osteology, color and black and white film processing, as well as the standard ceramic and lithic studies. For the recovery of small-scale remains, a screening and gravity concentration unit was constructed near the excavation house.

MME's geoarchaeological studies were published in McDonald and Rapp (1972) and in Rapp and Aschenbrenner (1978). The relevant chapters in the 1972 volume were The Physical Setting, Soil Studies, Metallurgical and Geochemical Studies, and Geophysical Exploration. The geoarchaeological chapters in the 1978 volume were Introduction, The Holocene Environmental History of the Nichoria Region, The Physiographic Setting, Soil Formation, Lithological Studies, and Archaeological Geology of the Site.

MME is likely to be remembered for its pioneering role in multidisciplinary survey and excavation. It should be noted that the MME survey was a reconnaissance survey, not an intensive survey. Many years later part of the region covered by MME received the needed intensive survey, led by Jack Davis (Davis and Alcock, 1998).

Field Survey

MONTE CIRCEO CAVES

Francesco G. Fedele
Formerly University of Naples 'Federico II', Naples, Torino, Italy

Definition

Cape Circeo is an isolated point of high relief, 541 m in elevation, presently configured as a cape on the Latium coast in central Italy (41°14′ N, 13°05′ E). It was a landmark to early Greek sailors and named after Circe, the mythical enchantress thought to live in its woods (Homer's *Odyssey*, Book 10).

Archaeological study of the caves in the limestone units of Monte Circeo began in 1939 when a Neanderthal skull, reportedly within a circle of stones, was found inside a newly discovered cave exposed by construction work. The cave, later named Grotta Guattari (20 m asl), had been sealed by rock debris at about 50 ka and contained a preserved floor or "archaeosurface" with underlying stratification. Contrary to past interpretations of the bone remains from the floor as evidence for Paleolithic ritual behavior, both taphonomic and zooarchaeological studies reveal that the aggregates, hominin cranial fossils included, are the product of denning by spotted hyenas (Stiner, 1991; White and Toth, 1991; Bietti and Manzi, 1992). In fact, large carnivores, including cave hyena (*Hyaena spelaea*) and leopard (*Panthera pardus*), appear to have used the Circeo cavities regularly as dens during the last glacial period.

At Guattari, the strata below the cave surface reproduce the general stratigraphy of Monte Circeo's sea level cave belt, which reveals from the base upward: (1) Marine Isotope Stage (MIS) 5 aggradational beach deposits with the marine gastropod *Strombus bubonius* (ca. 100–75 ka), (2) continental sands and concretions containing "Pontinian" Mousterian assemblages made from beach pebbles and associated faunas (early last glacial), and (3) partly indurated, thermoclastic cave sediments containing Mousterian industry and culturally derived faunas, often suggesting opportunistic procurement of red deer and aurochs. Contemporary, mid-last glacial breccia formation occurs in the outer part of several caves.

During the glacial low sea stand, Monte Circeo dominated on three sides an extensive coastal plain. Other important archaeological caves include Grotta Breuil and Grotta del Fossellone, both presently at sea level. Breuil provided a well-studied instance of later Mousterian adaptations, land-use strategies, and cave space organization (Spinapolice, 2006). At Fossellone, an impressive 14-m-thick fill spanning the whole Late Pleistocene contains Mousterian and Upper Paleolithic occupations, the latter amounting to tens of Aurignacian and Epigravettian levels. From the Aurignacian layers, two pendants made from rare steatite and imitating red deer canines are known (Mussi, 1988–89). Both caves have produced several more Neanderthal remains (Alciati et al., 2005).

MONTE VERDE

Tom D. Dillehay
Department of Anthropology, Vanderbilt University, Nashville, TN, USA

Definition

Monte Verde is located in south-central Chile (Dillehay, 1997). The site is an open-air campsite on the banks of a small stream, surrounded by sandy knolls, small bogs, and damp forests that have been there since 15,000 bp.

The bog later developed in the stream basin, covering the abandoned site under a layer of peat. Because the lack of oxygen in the bog inhibited bacterial decay, and because the constant saturation prevented drying for thousands of years, various types of organic materials that normally disappear from archaeological sites through decay processes have been preserved. An interdisciplinary research team of more than 60 scientists studied the remains excavated from two areas at the site, called Monte Verde I and Monte Verde II.

Monte Verde II exhibits the remains of a long tentlike structure made of wood and animal hides. Several pieces of cordage and string made of reed wrapped around wooden posts and stakes, recovered among the architectural remains, show that the people planned a lengthy stay. The tent's dirt floor was embedded with hundreds of microscopic flecks of hide tissue, suggesting that it was covered with animal skins. On the floor of the tent were brazier pits lined with clay and surrounded by stone tools and the remains of edible seeds, nuts, and berries. Outside the tent were two large communal hearths, a store of firewood, wooden mortars with their grinding stones, and three human footprints near one of the large hearths. All these remains indicate tasks, primarily food preparation and consumption, tool production and maintenance, and the construction of shelters.

A second structure was wishbone-shaped in ground plan and made of wooden uprights set into a foundation of sand and gravel. Parts of gomphothere (*Cuvieronius* sp.) and paleo-llama (*Paleollama llama*) carcasses were butchered, hides were prepared, and stone and wood tools were manufactured in and around the structure. Eighteen probable medicinal plant species were found inside the structure as well. The remains of a wide variety of local and nonlocal edible plants also were recovered from the hearths, living floors, and small pits. The presence of exotic foods, including seaweed, and other items at the site shows that distant coastal habitats provided important resources to the Monte Verde economy. Three different stone tool technologies also exist at the site, including bifacial tools, unifacial implements and waste debris, and grinding stones.

The distinct living structures, features, and concentrations of specific materials at the site suggest that occupation was continuous and that portions of the site were used more intensively than others. Different kinds of artifacts give evidence of a wide variety of activities. A long sequence of radiocarbon dates on different materials from the site place the Monte Verde II occupation at about 12,500 BP.

Buried in a different area of Monte Verde is a possibly earlier occupation, Monte Verde I, with twenty-six stone tools and three burned clay features. Radiocarbon dates placed this possible occupation around 33,000 years ago.

MOUNT CARMEL

Claudio Vita-Finzi
Natural History Museum, London, NW, UK

Definition

In archaeological contexts, the name Mount Carmel usually denotes four caves 20 km south of Haifa on Wadi el Mughara – es-Skhul, et-Tabun, el-Wad, and el-Jamal – although the area is now known to include at least 283 prehistoric sites (Olami, 1984).

Background

The caves were first excavated by British prehistorian Dorothy Garrod and her colleagues in 1929–1934 (Garrod and Bate, 1937). More recent excavations have been carried out at Tabun by A. J. Jelinek in 1969–1971 and then by A. Ronen from 1975 and at Wad by F. R. Valla and O. Bar-Yosef in 1980–1981 and by M. Weinstein-Evron since 1988. In 2012, Mount Carmel was named a UNESCO World Heritage Site.

The caves are about 45 m above sea level and a little over 3 km from the present Mediterranean coast from which they are separated by a range of fossil calcareous sand dunes (*kurkar*), with intervening sediments representing former swamps some of which were drained by channels cut through the *kurkar* in Roman times. Drilling on the coastal plain has yielded evidence of a number of marine transgressions and regressions dating from the Pleistocene.

The stratigraphy of the four caves as delineated by Garrod and Bate (1937) was based mainly on artifact typology, and it was linked on that basis to the sequence of Pleistocene pluvials identified in the Jordan Valley (Picard, 1937) and the raised shorelines of Lebanon and other parts of the Mediterranean and thus to the fourfold Alpine glacial sequence then in favor (Zeuner, 1945). Components of the stratigraphy, sedimentology, and faunal remains of the caves later received attention (e.g., Coles and Higgs, 1969; Jelinek et al., 1973; Tsatskin 2000), and ESR, TL, $^{10}Be/^{26}Al$, and U/Th techniques, especially in the context of paleoanthropology, have shown that most of the radiocarbon dates obtained in the 1960s represent minimum ages. For example, it is now known that the Tabun sequence spans over 400,000 years rather than 50,000 (Grün and Stringer, 2000; Mercier and Valladas, 2003; Rink et al., 2003).

Es-Skhul

Four major stratigraphic units are generally recognized within the cave. Starting from the bottom, layer C overlies sterile sand and contains abraded artifacts cemented into a breccia; layers B2 and B1 contain a Levalloiso-Mousterian lithic industry with some resemblance to material in Tabun; layer A contains a mixture of Natufian, late Paleolithic, and Levalloiso-Mousterian material and pottery from later periods. Marine mollusks from pre-Natufian levels include the saltwater clam *Acanthocardia deshayesi* (Payraudeau, 1826), the cockle *Laevicardium crassum* (Gmelin, 1791), the scallop *Pecten jacobaeus* (L), and the sea snail *Nassarius gibbosulus* (Linnaeus, 1758), the last from layer B and including specimens artificially perforated and presumably brought in by humans. Layer B also yielded remains of a bovid, pig, rhinoceros, and hippopotamus, but their ecological significance is disputed (Coles and Higgs, 1969). Abrasion of the layer C material was ascribed to spring action within the cave (Garrod and Bate, 1937).

At least ten individuals – seven adults and three juveniles – were uncovered, some of whom appear to have been intentionally buried. Bearing a close similarity to hominins recovered from Qafzeh Cave in the Galilee to the north, they have been dated by mass-spectrometric U-series, TL, and ESR analyses and appear to have lived at some time between 100 and 135 ka (Grün et al., 2005).

Et-Tabun

At Tabun Cave, the basal layer (G) contains a Tayacian lithic industry; layer F yields final Acheulean; layers Ed, Ec, and Ea Yabrudian, layer Eb Amudian; layers D, C, and B Levalloiso-Mousterian; and layer A Bronze Age to recent. The mammalian fauna of layer F consisted largely of extinct species (McCown and Keith, 1939), but it included a high percentage of fallow deer (*Dama mesopotamica*). Hippopotamus and rhinoceros persist in layers C and D, together with substantial gazelle content, but high values of *Dama* return in layer B. The relative proportions of deer and gazelle once inspired a graph reflecting the alternation of dry/wet conditions over time, but the scheme is now considered too simplistic. Layers E and F are dominated by windblown material (Jelinek et al., 1973). Layer F contains the marine dwarf oyster *Ostreola stentina*, given as *Ostrea crenulifera* (Sowerby, 1871) in Garrod and Bate (1937).

Tabun layer B has yielded an archaic *H. sapiens* female skeleton (named Tabun C1 but probably from layer B) and a separate mandible. U-series and ESR dating give C1 a combined age of about 143 ± 37 ka (Grün and Stringer, 2000), and a tooth from layer Ed has given a combined ESR/U-series age of 387 ± 40 ka (Rink et al., 2003). A TL determination on a burnt flint from Tabun G gave an age of ~415 ka (Mercier et al., 2000).

El-Wad

The basal layer (G) at el-Wad contains Mousterian and Emiran ("Advanced Paleolithic") material; layers F to C contain Advanced Paleolithic, with the artifacts in C equated with the Atlitian; layers B1 and B2 contain Natufian and have yielded more than 100 burials dated to 15–13 cal ka (Weinstein-Evron et al., 2012). Charcoal from the Natufian levels, including *Tamarix* sp., *Quercus calliprinos* Webb, *Q. ithaburensis* Decne, and *Cupressus sempervirens* L., reflect a Mediterranean climate similar to that of the present (Lev-Yadun and Weinstein-Evron, 1994).

Part of layer F, forming a sublayer some 10 cm thick in the cave, contains abraded and heavily rolled Levalloiso-Mousterian artifacts free from matrix. The underlying deposit G here is 4.3 m thick and consists of hardened gray grit lacking in artifacts or faunal material (Garrod and Bate, 1937). The elevation of this section corresponds with the upper part of layer C in Skhul, which, as noted above, also contained abraded artifacts. The abrasion has been ascribed to spring action in both Wad and Skhul.

El Jamal

Long considered to be almost empty, Jamal Cave has yielded Acheulo-Yabrudian material, together with two Levallois-style flakes, embedded within cemented sediments with a maximum thickness of 1.5 m that betray redeposition (Weinstein-Evron and Tsatskin, 1994). The presence of Levallois material in the Upper Acheulean of the Levant is considered commonplace. A sample of flowstone overlying the archaeological layer gave a $^{230}Th/^{234}U$ age of 220–223 ka (Zaidner et al., 2005). The absence of later industries contrasts with the long record of the other Mount Carmel caves.

The abrasion on pebbles and artifacts in layer F and G of Wad Cave and in layer C of Skhul Cave that was first ascribed to spring action is consistent with shoreline deposition about 120,000 years ago, when sea level was 5–6 m above its present datum. This would therefore indicate subsequent uplift by 40 m of Mount Carmel, which is bordered on the west by fossil beaches up to 125 m high and on the east by the active Carmel fault (Vita-Finzi and Stringer, 2007; but see Galili et al., 2007; Zvieli et al., 2009).

The faunal remains and artifact assemblages in the caves point to a range of economic strategies, including the seasonal exploitation by hunters of deer and other herds at times of low sea level (Vita-Finzi and Higgs, 1970; Marín-Arroyo, 2013). Local environmental history thus overrides the coarser narrative of alternating glacial and interglacial times derived from the climatic record of glaciated areas in high altitudes and latitudes. What is more, the caves lie "on a great highway of migration" between Africa and Asia (McCown and Keith, 1939, 226) so that seemingly parochial changes in topography and resources must at times have acted as barriers or bridges between those two realms.

INAA (Instrumental Neutron Activation Analysis); NAA

Definition

Neutron activation analysis is a highly sensitive and precise technique of elemental analysis using nuclear properties

Neutron activation analysis

Neutron activation analysis (NAA) is a well-established chemical analytical technique for the accurate identification and highly precise quantification of elemental constituents in a wide variety of matrices (de Soete and Hoste, 1972; Harbottle, 1976; Neff, 2000). It is based on properties of samples that involve induced radioactivity within the nucleus of atoms rather than the chemical and physical form in which the samples exist. This technique requires the exposure of the sample to a source of neutrons, most frequently in a nuclear reactor, and it has been widely applied in studies of environmental, biological, geological, and archaeological specimens. The method most frequently used takes an instrumental approach (INAA) that entails no postirradiation radiochemical separations. INAA is known for its great sensitivity in the detection and quantification of elemental constituents, including those present in trace and ultra trace concentrations, and its capability for simultaneous multielemental determinations that are largely free of matrix effects or interferences. Because neutrons penetrate most materials in a uniform manner, analysis can be carried out on small solid samples, thereby greatly reducing the sample preparation time required by most other instrumental analytical techniques and, with moderate laboratory care, lowering the risks of contamination. Over more than half century during which INAA has been used the generation of reliable results has made it the standard against which newer techniques of multielement analysis are compared.

A nuclide is an atom characterized by the number of protons and neutrons, *i.e., an atom with a specific nuclear composition*. The number of protons determines the *atomic number* of the atom, while the sum of the protons and neutrons determines the *mass number*. The nuclei of atoms of the same chemical element have the same atomic number, but need not have the same mass number. When the nucleus of an atom has the same atomic number but differs in the number of neutrons, it is said to be an *isotope* of that atom. Many, but not all, naturally occurring *elements* are mixtures of isotopes of varying abundance. Some combinations of protons and neutrons are unstable, *or radioactive, and these radionuclides* decay by various means to stable combinations at rates, *or half-lives, that are* specific to the *radionuclide*.

When a neutron is absorbed by a target nucleus, several physical effects can take place, but the primary reaction of interest involves the "capture" of a neutron by a nucleus. This process forms an intermediate or compound nucleus that is in a highly energetic state. De-excitation of the nucleus occurs in different ways, including the release of particles (alpha or beta) and gamma rays of discrete energies. Gamma rays are photons of electromagnetic radiation, similar to light but much more energetic. The release of gamma rays by an excited nucleus may occur as the nucleus captures a neutron, and these emissions are termed "prompt" gamma rays. With the appropriate instrumentation, the prompt gamma emissions may be detected, sorted as to energy, and counted. This is referred

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

to as prompt gamma neutron activation analysis or PGNAA (Lindstrom and Yonezawa, 1995). More typically, however, INAA utilizes delayed gamma rays (DGNAA) that are emitted as the radionuclide decays according to the half-life of the radioactive isotopes that have been formed. The important properties of these gamma ray emissions lie in their having energies and intensities that are characteristic of specific isotopes, which lend themselves to the identification and quantification of a sample's elemental constituents.

This process can be illustrated using the element cobalt. All cobalt occurs in nature as a single stable isotope with an atomic number of 27 and a mass number of 59 (i.e., 27 protons and 32 neutrons in the nucleus), and the element is represented symbolically as Co-59. Under conditions of neutron bombardment, the nucleus can capture an incident neutron forming the radioactive isotope, cobalt-60. The radioisotope decays with a half-life of 5.27 years, forming the stable isotope Ni-60 through the emission of a beta particle and two energetic gamma rays of 1.17 MeV and 1.33 MeV. Like that of Co-60, the decay schemes for most radionuclides elements are well determined, as are the energies of gamma emissions that are characteristic of isotopes of that element. Since the gamma emissions of the radioactive isotopes of all elements in a multi-element sample are going on simultaneously, a spectrum of energies and intensities is created. When the irradiated sample is placed in front of a gamma ray detector, (usually a high purity or lithium-drifted germanium detector), and its associated electronics, a percentage of the incident gamma ray photons emitted from decaying sample atoms interacts with the detector material to produce a photoelectric discharge of electrons proportional in energy to the incident gamma ray. These reactions are sorted according to energy and quantified to constitute an isotopic pattern for the analyzed sample.

Some commonly determined elements have isotopic half-lives (the time it takes for one-half of the radioactivity to decay) of only a few minutes (Al, Ti, V), others a few hours (e.g., Mn, Na, K, La), days (e.g., Ca, Sc, Cr, Fe, Zn, As, Br, Rb, Sr, Zr, Sb, Ba, Ce, Nd, Sm, Tb, Yb, Lu, Hf, Ta, Th, U), or years (e.g., Co, Cs, Eu). The detection and counting of emissions are carried out at specific intervals following the end of irradiation(s) in order to measure isotopes with half-lives of different lengths. Which isotopes are detected depends upon several factors including (1) the abundance of the target nuclei, (2) the likelihood that an incident neutron will react with a target nucleus (thermal neutron cross section), (3) the density and duration of the neutron bombardment, (4) size of the sample being irradiated, (5) the decay period, and (6) the specifics of the counting environment. The high sensitivity of INAA for detecting elements occurring at very low concentrations permits some 70 elements to be identified. However, using routine procedures of delayed gamma spectroscopy, it is more likely that 30-40 elemental concentrations can be determined. If this is supplemented through the use of PGNAA, another 5-6 elements (Al, Ca, Cl, Dy, Ti and V) can be added to the list (Glascock, 1994). The elements tend to be spread across the periodic table and include alkali metals, the alkaline earths, transition elements, halides, and the lanthanide and actinide series. This means that the resulting data can be searched for information pertaining not only to elemental abundance but also for patterns of elemental association and chemical behavior (e.g., fractionation among the rare earth elements).

At the end of sample irradiation, the activity of the radioisotopes is proportional to the number of target nuclei in the sample. Quantification of elemental abundance can be carried out by comparing the unknown sample to a standard reference material of known elemental concentrations that has been treated under the same irradiation conditions. Appropriate corrections must be made for differences in weight, radioactivity, and time elapsed since the end of irradiation. Comparator standards include the certified reference materials available from the National Institute of Standards and Technology (e.g., Coal Fly Ash 1633c, Brick Clay 679, Marine Sediment 2702), and may be supplemented by a "check standard" such as the commercially available air-floated, Redart, 200-mesh Ohio Red Clay (Djingova et al., 1990). The use of a comparator standard does introduce additional error, however, as the abundances in the reference material are certified to varying degrees of certainty. Alternatively, the data can be quantified through a K_0 method using gold as the single comparator (De Corte, 1987; Kennedy and St-Pierre, 1999), but this requires detailed knowledge of the neutron spectrum and flux.

Not all elemental concentrations can be determined by NAA. Some elements do not form radioactive nuclei, some may have severe spectral interferences, and some or cannot be reliably determined without expending excessive analytical time that would reduce the number of samples that could be analyzed. Each determined elemental concentration has some magnitude of error associated it, and these errors may arise from analytical factors, such as counting statistics, geometry, gamma peak shape and location, interferences and peak integration, and comparator reference standards, among others. Despite these sources of variation, many of which can be reduced to an acceptable level, many elemental concentrations can be determined with high analytical precision (1-2 % error), others with 5-10 % uncertainties and a few with greater uncertainties (e.g., As, Ba, Nd, Sr, and Zr).

Archaeological use of neutron activation data, which is really just a description of variably quantified elemental constituents, requires more than just careful analysis: it requires attention to sample design and reasoned data analysis (Harbottle 1976; Bishop et al., 1982; Neff 2000; Bishop, 2003). No matter how specifically the initial archaeological question is focused, most applications of

INAA in archaeology are regional in scope. They represent attempts to understand chemical variation in archaeological materials in a manner that permits social, economic, or political interpretations pertaining to the acquisition, use, and discard of cultural material, and such a perspective can be obtained most effectively by broad spatial or temporal sample comparisons. Most situations are complex and it is not surprising therefore that some of the most successful applications of INAA in archaeology have been in the attribution of obsidian artifacts to source. Obsidian is a volcanic glass formed from a rapidly cooled molten magma that was exploited culturally to produce useful shapes without changing its composition. The application of INAA has allowed the source of obsidian artifacts to be determined, occasionally to specific obsidian flows.

Another class of archaeological material that has been the subject of intensive analysis by neutron activation is pottery. Data obtained from ceramic analyses are more complex than those of obsidian as they reflect the interaction of several factors that can be categorized as (1) variation in natural materials combined within the ceramic object and (2) potting human practices involved in the creation of the pottery (Bishop et al. 1982; see also IAEA, 2003). Ceramics are combinations of naturally occurring raw clays and silts, often with variably sorted coarser materials that may have been mixed in some customary manner, and these combinations can change spatially and over time. Preparation of the ceramic paste can involve the removal of some fraction of the naturally occurring material or the addition of other materials to "temper" the working properties of the malleable mixture so that a vessel can be formed and fired successfully. Added tempering materials can include clay of a different plasticity than the base clay, crushed fired clay, crushed pottery (grog), weathered limestone, quartz sand volcanic glass, grass and manure among others. Each material, added in variable proportions, modifies the original composition of the base clay matrix in some manner. Thus tracing the analyzed pottery back to a specific source, such as a particular clay deposit or highly delimited location along a river, may not be possible due to the effects of mixing multiple ingredients within a highly composite final product. In most cases, archaeological sourcing of pottery relies on identifying groups of ceramics that are sufficiently similar in chemical composition. These groups are used to infer a source of manufacture that is spatially and/or temporally delimited and discrete by comparison to other groups of similarly analyzed ceramics. The location of manufacture can be determined by matching the chemical composition of unsourced ceramic groups to the waster products recovered from archaeological potting workshops, but such sites are relatively rare. If the pottery being analyzed reveals a discontinuous spatial distribution, an inference may be made that it is most likely to have originated in the geographical location where it is most abundantly recovered. Exceptions, however, may occur.

There are two major considerations that follow from the preceding statement. The first one is the need to analyze reasonably large numbers of samples representing the pottery of interest; depending upon the specific problem, or question to answer sample sizes for archaeological uses may be in the low hundreds (Bishop and Blackman, 2002). Second the size of a resulting data matrix, in addition to the natural, cultural and analytical sources of variation that are represented within it, requires well-considered steps to mine the data for patterns that are meaningful for archaeological interpretation. Since data sets normally consist of several dozen to several hundred analyzed specimens, multivariate procedures are used to assess degree of resemblance among individual chemical profiles according to some chosen definition of similarity (Bishop and Neff, 1989; Neff 2002). Analytical approaches may involve the use of several pattern extraction methods involving cluster analysis, outlier identification, and group evaluation, in addition to techniques that display aspects of variation in the data (e.g., the well-known technique of principal components analysis). These techniques should be chosen based upon properties of the data are being explored and evaluated, not so much by arbitrary statistical results but with attention to how the chemical patterns covary with archaeological attributes of form, decoration, time, association, etc.

In addition to obsidian and pottery, INAA has been applied with varying degrees of success to other types of archaeological materials including unfired clay, limestone, marble, chert, turquoise, jade, native copper, steatite, and shell, among others. With all of these materials, given an adequate elemental abundance in the target material and appropriate irradiation and counting conditions, INAA is capable of producing high-quality data. Recalling that one of the great strengths of INAA is its ability to analyze a solid or bulk sample, interpretive difficulties may nevertheless arise with such bulk samples because it is difficult to know exactly what is being analyzed.

Since the 1980s, the scientific community has had to respond to economic and political pressures for greater emphasis on applied research, including research carried out with the aid of nuclear reactors (e.g., Byrne, 2001, 83). Many of the large reactor facilities that undertook neutron activation of archaeological materials (e.g., Brookhaven National Laboratory, Lawrence Berkeley National Laboratory, Hebrew University, the Slowpoke Reactor-Toronto) have now ceased to operate, and with only a few notable exceptions, archaeological reliance is slowly moving to the use of newer analytical techniques (such as inductively coupled mass spectrometry) that involve skills and knowledge in chemical analysis that are beyond the level of archaeologists. The few remaining INAA facilities capable of undertaking archaeological research (e.g., Missouri Research Reactor, National Centre of Scientific Research "Demokritos" [Greece], Oregon State University, Smithsonian-NIST facility [Gaithersburg, MD]) continue to run at full capacity, contributing to existing legacy databases that remain to be more fully mined for existing patterns that inform about the past.

The Great Cave of Niah

Introduction

Niah Cave, more properly known as the Great Cave of Niah, in Sarawak, Malaysian Borneo, lies in the northern side of the Gunong Subis massif 11 km inland from the shore of the South China Sea. The cave was dug in the 1950s and 1960s by Tom and Barbara Harrisson, in the 1980s by Zuriana Majid, and between 2000 and 2004 by Graeme Barker and Tim Reynolds, with geoarchaeological work coordinated by David Gilbertson.

Geomorphology

The cave is one of several enormous, highly complex and extremely ancient caves in the Gunong Subis, a tower karst massif developed in Miocene patch reef limestones. This elevated area stands in coastal lowlands which are underlain by turbiditic mudrocks also of Miocene age. The cave displays morphological evidence for phreatic development (formation beneath the water table) followed by a long and complex history of vadose modification (above the water table).

The cave fill

The cave sediments are highly complex (Gilbertson et al., 2005, 2013; Stephens et al., 2005) and best known from the archaeological excavations and reconnaissance in the West Mouth and other entrances to the cave (Gilbertson et al., 2005, 2013). The longest sequence is in the West Mouth, where ancient, complex, highly weathered basal diamicts (poorly sorted sediments with different particle sizes), referred to as Unit (1) are overlain by clayey diamicts, sands, and silts of Unit (2C) and (2) dating from ~55,000 to ~38,000 BP and containing abundant archaeological materials including lithic artifacts, bone, shell, and charcoal. These deposits were cut and partially disrupted by a major mudflow event (Dykes, 2007) which gave rise to thick diamicts now characterized by "spots" of white secondary gypsum (Unit 3). From about 35,000 BP, silty diamicts with abundant occupation debris (Unit 4) were laid down in a basin formed by partial collapse of older deposits. Unit 4 continued to accumulate episodically until late Holocene times. From ~35,000 BP, people cut deep pits into the cave sediments. Some of these seem to have been used for detoxifying the poisonous nuts of *Pangium edule* (Malay "kepayang") since these are found in great quantities. During the latest Pleistocene and particularly the Holocene, the cave was used as a burial site.

Archaeology

The Great Cave first came to prominence in 1958 with the finding by Barbara Harrisson of the so-called Deep Skull, for many years the oldest morphologically modern human skeletal material in the world. Recent re-evaluation and U-series dating suggests that the "Deep Skull" is ~35,000 years old and may have been part of a secondary burial (Barker et al., 2007; Hunt and Barker, 2014), but the earliest human activity in the cave is estimated to be around 52,000 BP (Hunt et al., 2012). The cave was used as a habitation site during the Late Pleistocene, and the cave fill contains abundant evidence of the skill of the inhabitants in exploiting the complex, difficult, and rapidly changing ecosystems of the period, with animal bones, shell, macro-plant remains, pollen, phytoliths, and starch all very well preserved (Barker et al., 2007; Barton et al., 2009; Piper and Rabett, 2009; Barker, 2013). The cave was also used for ritual activity using human remains from ca. 45,000 BP (Hunt and Barker, 2014), and exploitation as a place of interment became its main use during the Holocene. So far, 258 burials have been investigated with excellent preservation of organic materials including hair, skin, basketry, and wood (Lloyd-Smith, 2012).

OLDUVAI

Gail M. Ashley
Department of Earth and Planetary Sciences, Rutgers University, Piscataway, NJ, USA

Synonyms

Oldupai (wild sisal plant); Olduvai (Maasai language); Olduvai Gorge

Olduvai Gorge is a valley incised into the Serengeti Plain in northern Tanzania. The main tributary of the Olduvai River flows 46 km eastward from lakes Masek and Ndutu to a depression, Olbalbal, at the foot of the Ngorongoro Volcanic Highland (Hay, 1976). The gorge is ~100 m deep and cuts across the Olduvai basin, exposing a two million-year-long sequence of volcaniclastic sediments interbedded with numerous tuffs that have been dated with $^{40}Ar/^{39}Ar$ radiometric dating.

Olduvai sediments contain a rich faunal and cultural record of early hominins – *Paranthropus boisei*, *Homo habilis*, and *Homo erectus* (Leakey, 1971). There are over 50 archaeological sites; the two sites with the densest concentration of stone tools, bones, and human modified bones are FLK Zinj, dating to ~1.84 Ma (Domínguez-Rodrigo et al., 2007; Ashley et al., 2010a) and BK, dating to >1.2 Ma (Domínguez-Rodrigo et al., 2009).

Paleoenvironmental studies have indicated that most of the archaeological sites are located near the margin of ancient Lake Olduvai. It was originally assumed that the lake was used by hominins as a water source (Leakey, 1971; Hay, 1976), but it is now known that the lake was saline-alkaline (toxic) and that it was a playa that fluctuated frequently in level and dried up periodically (Hay, 1976; Ashley, 2007). Recent studies show that freshwater springs were associated with many of the archaeological sites and that these springs likely attracted hominins and other vertebrates to the area of Olduvai (Ashley et al., 2010b).

OPTICALLY STIMULATED LUMINESCENCE (OSL) DATING

Zenobia Jacobs
School of Environmental and Earth Sciences, University of Wollongong, Wollongong, NSW, Australia

Synonyms

Green-light stimulated luminescence (GLSL); Infrared stimulated luminescence (IRSL); Optical dating; Photon-stimulated luminescence (PSL); Photonic dating

Definition

Optical: Relating to the use of visible or near-visible light

Stimulated: To excite with a stimulus (light or heat)

Luminescence: The emission of light

Optically stimulated luminescence: The emission of light from crystalline materials when stimulated by light following previous absorption of energy from radiation

Introduction

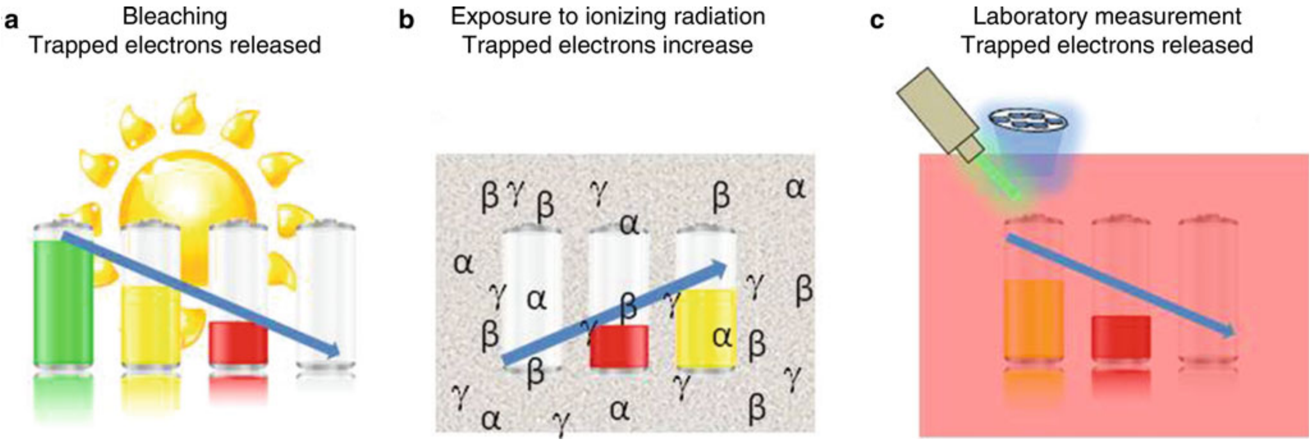
Luminescence dating consists of a family of analytical methods, most of which are used in archaeological research. They can be applied to samples ranging in age from just a few years to several hundreds of thousands of years (beyond the range of radiocarbon dating), and they are, therefore, able to cover a time interval that includes important turning points in the evolution of humans. The choice of luminescence method depends on the availability of appropriate minerals, the time period of interest, and the nature of the target event. When one technique is not suitable to a particular situation, another technique often is. The basic principles of all the different luminescence dating techniques, and also electron spin resonance (ESR) dating, are the same: each relies on the effects of radiation exposure. Ages are obtained by measuring the cumulative effect of ionizing radiation on the crystal structure of certain minerals. The longer the duration since first exposure to radiation, the greater the amount of energy absorbed, and consequently, the greater the luminescent signal obtained, which is indicative of an older age for the material being investigated. The physical basis has been discussed in detail for the nonspecialist by Feathers (1996) and Wintle (2008) and for the specialist by Aitken (1985, 1998) and Bøtter-Jensen et al. (2003). Recent advances in luminescence dating of sediments and applications in the earth and archaeological sciences have been described by Feathers (2003), Duller (2004), Lian and Roberts (2006), Lian (2007), Jacobs and Roberts (2007), and Roberts et al. (2015). The impact of luminescence dating in archaeology was demonstrated in two comprehensive review papers by Roberts (1997) and Wintle (2008). The former covered early work on sites in Africa, Western Europe, East Asia, Siberia, Australia, and the Americas, whereas the latter reviewed the more recent applications as part of a history of the last 50 years of luminescence dating in archaeology.

OSL

Optically stimulated luminescence (OSL) dating of sedimentary quartz grains and thermoluminescence (TL) dating of burnt stones are the methods most commonly applied in archaeological contexts, and the former is the subject of this entry. The use of OSL dating was first proposed by Huntley et al. (1985). OSL dating of sediments yields an estimate of the time since mineral grains, such as quartz or feldspars, were last exposed to sunlight. In this instance, the duration of burial in the absence of sunlight can provide ages for site occupation, the manufacture of artifacts, and the accumulation of faunal remains, all inferred from the depositional age of the associated surrounding sediments being dated. The first archaeological application was published by Rhodes (1988), who used the method to analyze quartz grains from three archaeological sites (Chaperon Rouge, Skhirat, and Tahadart) in Morocco. OSL dating can also be applied to heated materials, such as burnt stones and pottery, but TL dating remains the method of choice for such materials. Bøtter-Jensen and Duller (1992) were the first to date heated materials by OSL when they dated quartz grains extracted from burnt stone at a Viking Age site in Sweden.

Age determination

The OSL dating technique is based on the fact that natural minerals (such as quartz and feldspar) are not perfectly formed but contain defects in their crystal lattices that are able to trap negatively charged electrons within positively charged vacancies (“holes”). These mineral grains can be likened to rechargeable batteries (Figure 1). While buried, the mineral grains are exposed to a low-level flux of naturally occurring ionizing radiation resulting from the nuclear decay of potassium (^{40}K), rubidium (^{87}Rb), uranium (^{238}U and ^{235}U and their decay products), and thorium (^{232}Th and its decay products) from within the sample and also external to the sample in the surrounding soil. Cosmic radiation also contributes a small amount. While buried in the ground and hidden from sunlight, these “batteries” trap and store electrons as particles emitted from unstable radioactive atoms move them out of their normal orbital locations. In this way, the trapped electrons become more numerous and accumulate energy at a predictable rate over time (Figure 1b). If the sediment is transported by wind or water and the “batteries” are exposed to sunlight, they lose their charge in a matter of seconds (Godfrey-Smith et al., 1988), thereby emptying the battery; the luminescence “clock” is thus set to zero (Figure 1a), and once the sediments are again buried, they “recharge” by the same process. Likewise, the same would happen if the sediments were heated to high temperatures (>400 °C). When these sediments are subsequently



Optically Stimulated Luminescence (OSL) Dating, Figure 1 A rechargeable battery serves as a useful analogy for how mineral grains behave as natural dosimeters in OSL dating. When mineral grains are exposed to sunlight (**a**) or heat, trapped electrons are released, a process called bleaching that resets the luminescence "clock." Once the mineral grains are buried and hidden from sunlight again, the grains are reexposed to natural ionizing radiation (alpha, beta, gamma, and cosmic in origin) and become recharged (**b**). Once the sediment sample has been collected and taken back to the laboratory, the mineral grains can be stimulated with a green laser or blue light-emitting diode, which will release the trapped electrons in the form of light emission (*OSL*) that can then be measured (**c**).

cooled and deposited within accumulating sediments, e.g., within a cave, they once again become hidden from sunlight, and the "batteries" begin to recharge (Figure 1b). In other words, natural radiation sources in the immediate vicinity of the grains will result in the movement of new electrons out of their orbitals and into traps, with the rate of filling being determined by the level of natural radiation.

To determine an OSL age, the following equation is used:

$$\text{Age estimate}(ka) = \frac{\text{Equivalent dose } (D_e)(Gy)}{\text{Estimated environmental dose rate}(Gy/ka)}$$

where D_e (equivalent dose) corresponds to the radiation dose absorbed by the mineral grains since they were last exposed to sunlight or heat, Gy (or gray) is a unit of radiation absorption equal to 1 J of radiation per kg of sample, and ka is 1,000 years. The environmental dose rate refers to the rate of supply of ionizing radiation to the mineral grains from environmental sources. Further details about how these two parameters are estimated are discussed below.

Sample collection and preparation

To estimate the D_e of a sample, the sediments must be collected in the dark. This prevents exposure of the grains to light, a process known as bleaching, which would lead to the light-sensitive OSL traps being emptied and the OSL "clock" being reset. There are many ways of collecting OSL samples. The most typical would be to hammer opaque plastic or metal tubes into a cleaned section wall; the sediment at both ends of the tube will then be discarded in the lab, and the inner light-safe portion will be used for the measurement of the OSL signal. Alternatively, samples can be collected by scraping sediment into black light-tight bags while covered by a black tarpaulin to keep light out; a red-light torch can be used for illumination since red wavelengths do not affect the electron traps. Or samples can be collected at night also with the aid of a red-light torch.

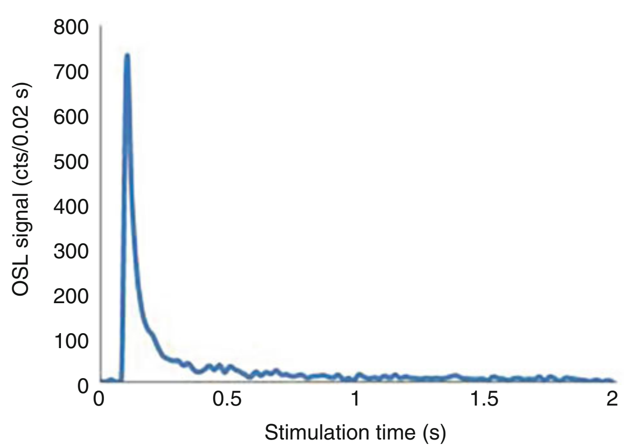
The samples are then transported to a suitable luminescence laboratory where the OSL measurements are made on mineral grains extracted from the bulk sediment sample. The lighting level in the luminescence laboratory is low and usually red, similar to the conditions in a photographic darkroom. The grains, 90–300 μm in diameter (sand sized), are usually extracted from the bulk sediment sample by wet or dry sieving and are then chemically treated with hydrochloric (HCl) acid to remove carbonates and hydrogen peroxide (H_2O_2) solution to digest any organic matter. The mineral grains are then suspended in heavy liquids, such as sodium polytungstate, at specific densities to remove heavy minerals, such as zircons, and to separate quartz and potassium feldspars. In addition, the sand-sized grains are chemically etched in hydrofluoric (HF) acid to remove the outer surface of each grain. The grains are then sieved again to provide a narrow range of sizes (e.g., 180–212 μm diameter) and mounted in a monolayer on a 9.8 mm diameter stainless steel or aluminum disk, which has been pre-sprayed with silicone oil so that the grains stay adhered during the measurement procedure. In the case of single-grain dating, each grain is placed in an individual hole drilled into the surface of an aluminum disk, each disk designed to hold 100 single grains. Selection of specific grain sizes is important as this allows calculation of the relative contributions of alpha and beta radiation to the grains in their natural environment.

Equivalent dose (D_e) determination

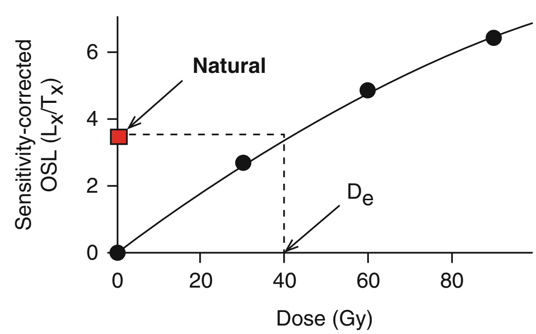
Once in the laboratory, the trapped electrons can be released by stimulating the quartz grains with blue or green light (or infrared radiation if the mineral is potassium-rich feldspar) (Figure 1c). This release, and the subsequent physical processes inside the crystal, results in the emission of OSL, which decreases in intensity during the stimulation time as the light-sensitive traps are quickly and progressively emptied. The resulting plot of the OSL signal decrease versus stimulation time is known as an OSL decay curve (Figure 2). The OSL signal from the as-collected (natural) sample is related to the number of electrons that have populated the light-sensitive traps since they were last emptied; it is, therefore, related to the time elapsed since the grains were last exposed to sunlight. The D_e is the radiation dose required in the laboratory to produce an OSL signal of the same intensity as the natural OSL. It is estimated by comparing the natural OSL signal just obtained with those obtained from the same now bleached sample after it receives a series of calibrated radiation doses in the laboratory using a $^{90}Sr/^{90}Y$ beta source or, less commonly, a gamma- or X-ray source. These subsequent laboratory exposures to radiation are regenerative doses designed to find the dose that delivers an equivalent natural OSL signal. The resulting plot of OSL intensity versus laboratory dose is known as a dose-response curve, or growth curve (Figure 3). The D_e is estimated by projecting the natural OSL signal onto this curve, and the intercept – the D_e – is expressed in Gy, which is the SI unit for absorbed radiation dose.

To obtain useful information regarding the burial time of quartz grains, the OSL signal must be converted into a reliable estimate of the D_e. Over the last decade, methodological and technological developments have shifted the emphasis from using multiple-aliquot procedures to determine the D_e (Feathers, 1996; Lian and Roberts, 2006) to measuring the D_e for individual aliquots composed, typically, of tens, hundreds, or thousands of grains. An aliquot is the sample of grains mounted on a disk; the size of the aliquot can be changed, and an extreme case of single-aliquot dating is when each aliquot consists of just one grain (Duller, 2008). Multiple-aliquot methods require the use of many aliquots (e.g., 24 or more) to produce a single estimate of the sample D_e, whereas single-aliquot and, hence, single-grain measurements require only one aliquot or one grain, to yield an estimate of D_e. In other words, the entire dose-response curve shown in Figure 3 is constructed on the basis of one grain or aliquot, whereas at least five different aliquots would be needed to construct the same curve using the multiple-aliquot approach. A key benefit of the single-aliquot approach is that replicate measurements of D_e can be generated for the same sample. It is typical to measure 24 or more multigrain single aliquots or many hundreds of single grains. These provide an internal check on the reproducibility of results, thereby facilitating the recognition of sample contamination and other problems that may need to be addressed before final age determination. For sediments that have been exposed only briefly to sunlight before burial or that have suffered from postdepositional disturbance, the most accurate OSL ages will be obtained by using single-aliquot and single-grain methods along with appropriate statistical procedures (e.g., Galbraith et al., 1999; Roberts et al., 2000; Jacobs and Roberts, 2007).

Two principal methods have been proposed for measuring the D_e using single aliquots or single grains of quartz:



Optically Stimulated Luminescence (OSL) Dating, Figure 2 An OSL decay curve observed from the luminescence emitted by an individual quartz grain upon stimulation by a green laser beam. The OSL signal drops rapidly as a function of time as electron traps empty when exposed to laser light.



Optically Stimulated Luminescence (OSL) Dating, Figure 3 An OSL dose-response curve, or growth curve, constructed for an individual quartz grain using the single-aliquot regenerative-dose (*SAR*) procedure to estimate the D_e. The natural OSL signal is denoted by the *red square* on the y-axis, and the *black circles* are the signals induced by repeated and varying laboratory doses, to which the dose-response curve has been fitted using a saturating exponential.

the single-aliquot additive dose protocol (Murray et al., 1997) and the single-aliquot regenerative-dose (SAR) procedure (Murray and Roberts, 1998; Murray and Wintle, 2000; Wintle and Murray, 2006). The latter procedure is currently the preferred approach because the D_e is obtained by interpolation rather than by extrapolation of the dose-response curve. This results in more accurate and precise estimates. The SAR procedure also has several other attractive features. It takes account of sensitivity changes that commonly occur during laboratory heating procedures and that may have occurred during the burial period. It also contains various internal checks that allow routine testing of the performance of the SAR protocol for any specific sample and the rejection of aliquots or grains that fail these checks (Wintle and Murray, 2006; Jacobs et al., 2006). Tests can also be made to confirm the suitability of the experimental conditions applied to the dated grains, such as the ability of the SAR protocol to recover the correct dose from grains that have been deliberately bleached and then given a known laboratory dose (Roberts et al., 1999) and to minimize the complicating effect of other luminescence minerals such as feldspars (Duller, 2003). Application of the SAR protocol to individual grains, in particular, enables a statistically significant number of D_e values to be generated. By examining the structure of the resulting D_e distributions, insights can be obtained about potential complications, such as incomplete bleaching and sediment mixing, so that a high degree of confidence can be placed in the final OSL age determinations (e.g., Jacobs and Roberts, 2007).

Dose rate determination

The dose rate is usually expressed in units of grays per thousand years (Gy/ka). The total dose rate represents the sum of the contributions from uranium and thorium and their decay products together with potassium, rubidium, and a minor contribution from cosmic rays. These radioactive elements are present at low concentrations in most sediment, and their radioactive decay gives rise to alpha and beta particles and gamma rays. The distance of influence of alpha particles is very short (less than 0.02 mm), whereas beta particles can travel 2–3 mm through most sediments, gamma rays can penetrate up to 30 cm, and cosmic rays many tens of meters (Aitken, 1985, 1998). For purposes of dating, the internal dose rate of quartz or potassium-rich feldspar grains should be estimated together with the external dose rate that consists of the alpha, beta, and gamma radiation emitted by the materials surrounding the dated grains, as well as the cosmic-ray dose rate. Uranium and thorium are commonly present at low concentrations inside quartz grains, typically giving rise to an internal dose rate of 0.02–0.05 Gy/ka, whereas potassium-rich feldspar grains have a significant internal contribution from potassium, amounting to ~0.6–0.9 Gy/ka, depending on the size of the grain. These internal dose rates are most often assumed, rather than measured for each sample. The external alpha contributions are typically removed from consideration when dating sand-sized grains by etching away their outer 0.02 mm rinds using HF acid.

The cosmic dose rate is estimated using an equation provided by Prescott and Hutton (1994) that incorporates positional information on the geomagnetic latitude, altitude, and depth and density of sediment, rock, and water overburden averaged over the burial period of the sample. The remaining external dose rates from beta and gamma radiation can be measured in either of two ways: chemical or emission counting methods. Chemical methods such as neutron activation analysis (NAA), X-ray fluorescence (XRF), atomic absorption spectroscopy (AAS), and inductively coupled plasma-mass spectrometry (ICP-MS) can be used. These methods typically measure the parent radionuclide at the top of the decay series of ^{238}U and ^{232}Th. Very little (<2 %) of the gamma dose rate and <40 % of the beta dose rate delivered to the grains are derived from the parent nuclide in the uranium series. Relying on measurement of the parent concentration to obtain accurate estimates of the dose rate would be viable only if one can demonstrate that there is no disequilibrium in the uranium and thorium decay chains. Disequilibria occur when the parent and daughter radionuclides are not present in equal activities, and this can arise because the parent and several of the daughter products in the ^{238}U chain, in particular, are prone to migrate under certain geochemical conditions (Ivanovich and Harmon, 1992). Disequilibria in the uranium series are commonplace in the surficial environment, and some situations have resulted in the dose rate changing over time, which requires corrections to be made to the measured (modern-day) dose rate (Olley et al., 1996, 1997). The impact of such time-dependent changes can be minimized by using (1) emission counting techniques that can measure the parent and daughter nuclides individually, such as high-resolution gamma spectrometry and alpha spectrometry, and (2) techniques that can measure the daughter nuclides lower down the decay chain in the case of the gamma dose rate using, for example, in situ gamma spectrometry, or (3) by measuring the total radioactivity emitted by the parent and daughter products in the case of the beta dose rate, using techniques such as beta counting and thick source alpha counting.

There are also spatial variations in the beta and gamma dose rates that require consideration in some situations. For example, limestone caves may contain occasional blocks and clasts of roof spall scattered among the archaeological sediments. Lumps of limestone are comparatively free of radioactivity, so it is necessary to account for their lower gamma-ray contribution to the total dose rate; this is achieved most commonly by in situ measurement of the gamma dose rate either using TLD (thermoluminescence dosimetry) capsules or a field gamma spectrometer. The same caution, and solution, applies to samples collected less than 30 cm from the boundaries of sediment units that have markedly different dose rates.

The beta-, gamma-, and cosmic-ray dose rates also require adjustment for the long-term water content of the sample, which can be estimated from its present-day moisture content and water-holding capacity, as well as probable moisture fluctuations over the period of sample burial. A 1 % decrease in water content results in ≈1 % increase in dose rate and ≈1 % decrease in age for many quartz-containing sediments. It is usually possible to accommodate all likely long-term variations in the uncertainty term attached to the water content estimate. This uncertainty is reflected in the total uncertainty assigned to the OSL age. Uncertainties on OSL ages are typically reported at 1σ (standard error) and are calculated by combining in quadrature the total uncertainties on the D_e and dose rate estimates, each of which includes not only random but systematic errors too, unlike many other dating methods.

Applications

OSL dating is now applied routinely in archaeology (Roberts, 1997; Feathers, 2003; Wintle, 2008; Roberts and Lian, 2015) and has had a major impact on archaeology, particularly for the period beyond the limit of ^{14}C dating. It has also proven useful for deposits that lack suitable materials for ^{14}C dating. Some examples include OSL dating of possible early evidence for the exodus of modern humans out of Africa (Petraglia et al., 2007; Armitage et al., 2011; Rose et al., 2011), OSL dating of the earliest known evidence for modern human behavior (Henshilwood et al., 2002, 2011; Bouzouggar et al., 2007; Marean et al., 2007), the calculation of start and end dates and duration of two important Middle Stone Age industries – the Howiesons Poort and Still Bay – across Southern Africa (Jacobs et al., 2008), the age and duration of the Aterian of the Maghreb (Barton et al., 2009; Schwenninger et al., 2010; Jacobs et al., 2011, 2012), and the oldest artifacts and human remains discovered in Australia (Roberts et al., 1994; Bowler et al., 2003).

ORGANIC RESIDUES

Michael W. Gregg
Department of Anthropology, St. Francis Xavier University, Antigonish, NS, Canada

Definitions

Organic residues are carbon-based substances of biological origin that may survive in a broad range of archaeological contexts, including the fabric of pottery vessels, food preparation and floor surfaces, midden or latrine deposits, and archaeological sediments themselves.

Biomarkers are unique molecular compounds or distributions of compounds surviving in archaeological materials that can be matched with those of modern plant and animal species or hydrocarbons from known geological sources.

Introduction

The recovery and characterization of organic residues surviving at archaeological sites is becoming an increasingly effective means of identifying economic activities and subsistence practices associated with different prehistoric and historic cultural and technological traditions. Organic residues provide not only direct evidence of procurement and utilization of resources, but they also hold the promise of answering myriad questions that have long puzzled archaeologists using more conventional methods of inquiry (Jones, 2001; Pollard et al., 2007; Pollard and Heron, 2008; Evershed, 2008; Gregg, 2010). Yet, the possibility of gaining new insights into long-standing archaeological questions through chemical analysis of organic residues is dependent upon the limitations of current recovery protocols and instrumental analytical techniques as well as the diagnostic potential of the materials being examined.

Researchers have been interested in investigating the chemical properties of materials recovered from archaeological sites for more than 150 years, with early studies initially seeking to identify the chemical elements of pottery fabrics and clay sources (Brongniart, 1844; Richards, 1895) and later ones attempting to isolate the organic compounds that may have once have been contained within ceramic vessels (Berthelot, 1906). Overviews of these early wet-chemistry investigations can be found in Caley (1951, 1967), Rice (1987), Pollard et al. (2007), and Pollard and Heron (2008), but three of these initial studies are worth mentioning specifically because the principles used in separating the component molecules in archaeological residues from one another were established in the early twentieth century.

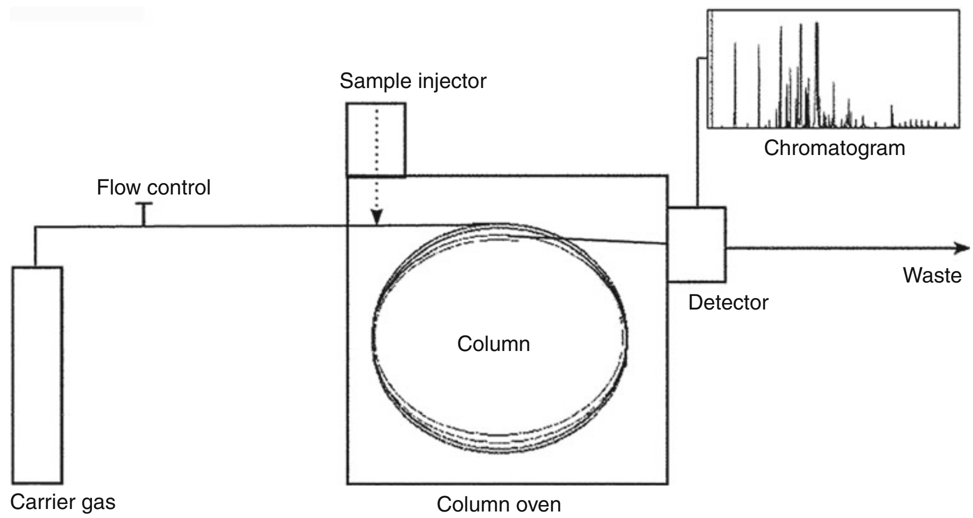
French chemist Marcellin Berthelot (1906) was the first researcher to attempt to characterize fatty acids surviving in the dregs of two Gallo-Roman vessels through the application of an alkali and organic solvent protocol to residues and subsequent separation of the solid and liquid portions through blotting paper filtration. Berthelot (1906, 128–129) claimed to have matched the proportions of palmitic ($C_{16:0}$), stearic ($C_{18:0}$), and oleic ($C_{18:1}$) free fatty acids surviving in the residue to those of olive oil. (The number of carbon atoms and type of bonds holding long chains of carbon atoms together in saturated and unsaturated fatty acids are designated with subscript notations following the symbol for carbon, such that a saturated fatty acid such as $C_{18:0}$ has 18 carbon atoms and no double bonds, whereas an unsaturated fatty acid such as $C_{18:1}$ contains a single double bond in the middle of the carbon chain.) The methods Berthelot used in his recovery and quantification remain unclear, however, and we now know these compounds can serve as evidence for the presence of both degraded animal fats and plant oils.

Later, Sir Leonard Woolley sought the assistance of petroleum chemists in identifying bitumen residues at the ancient city of Ur in southern Mesopotamia. In their sequential application of different organic solvents to solid amorphous lumps and rings found at Ur, Hackford et al. (1931) and Forbes (1936) were able to separate organic petrocarbon compounds from the asphaltene mineral fraction and imbedded reeds and rushes and measure the different components by weight and volume.

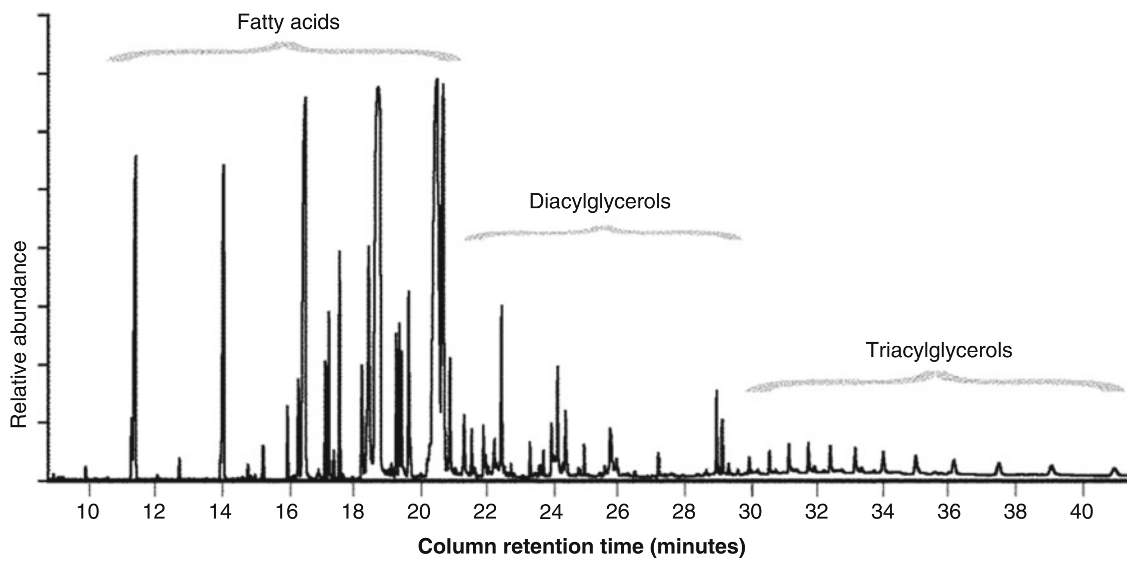
Many different laboratory-based recovery protocols and wet-chemistry and instrumental analytical techniques have been used in subsequent attempts to identify the diverse range of fats, oils, proteins, starches, alcohols, resins, waxes, and pigments that may survive in archaeological materials – many with ambiguous or misleading results (Jones, 2001; Pollard et al., 2007; Evershed, 2008; Gregg, 2010). Advances in computer technology and analytical instrumentation in the late 1970s have resulted in a more systematic approach to the classification of organic compounds in many disciplines within the natural sciences. An overview of the basic tenets of analytical chemistry and a comprehensive examination of the major recovery protocols and instrumental analytical techniques and their application to archaeology can be found in Pollard et al. (2007). Brief summaries of the principal methods used in examining different classes of organic matter are provided here, but due to the preferential survival of lipids in ceramics recovered from many archaeological contexts and limited availability of space in this entry, greater emphasis will be placed on explanation of those recovery protocols and instrumental analytical techniques that have proven highly successful in the identification of animal fats, vegetable oils, plant resins, waxes, and bitumen from pottery. The summary of the principal techniques used in gas chromatography and mass spectrometry provided below will inform the subsequent discussion on the degradation processes affecting the differential preservation of lipids at archaeological sites, in addition to later sections dealing with the survival of residues of sugars, starches, proteins, amino acids, and DNA at archaeological sites.

Principles of gas chromatography and mass spectrometry

Gas chromatography (GC) separates and measures the molecules in a compound on the basis of their physical behavior. Gases, liquids, and solids can all be separated on a GC column, but before organic residues from archaeological sites can be analyzed, these preserved compounds must be released from the matrix of materials within which they are bound. This can accomplished through a variety of recovery protocols that will be discussed below. All compounds are introduced into the GC column dissolved in an organic solvent solution (such as hexane or dichloromethane) that is vaporized as it is injected into a carrier gas (such as hydrogen or helium); this is known as the mobile phase (Figure 1). The carrier gas then passes the components of the vaporized solution into a long, coiled, silica-lined, narrow-diameter, metal column inside a temperature-controlled oven where organic compounds 'stick' in what is known as the stationary phase. Temperatures are programmed to rise in the oven at very controlled rates, and compounds are released, or eluted, into the carrier gas again as temperatures rise and their volatility increases. The retention times, elution orders, and relative abundances of the different molecules in the compound are then measured and recorded as they are released and combusted in a device known as a flame ionization detector. Components with lower molecular weights sharing electrons between atoms equally elute before those with higher weights sharing electrons unequally, and thus they are retained in the column for longer periods (Pollard et al., 2007). The retention times, elution orders, and



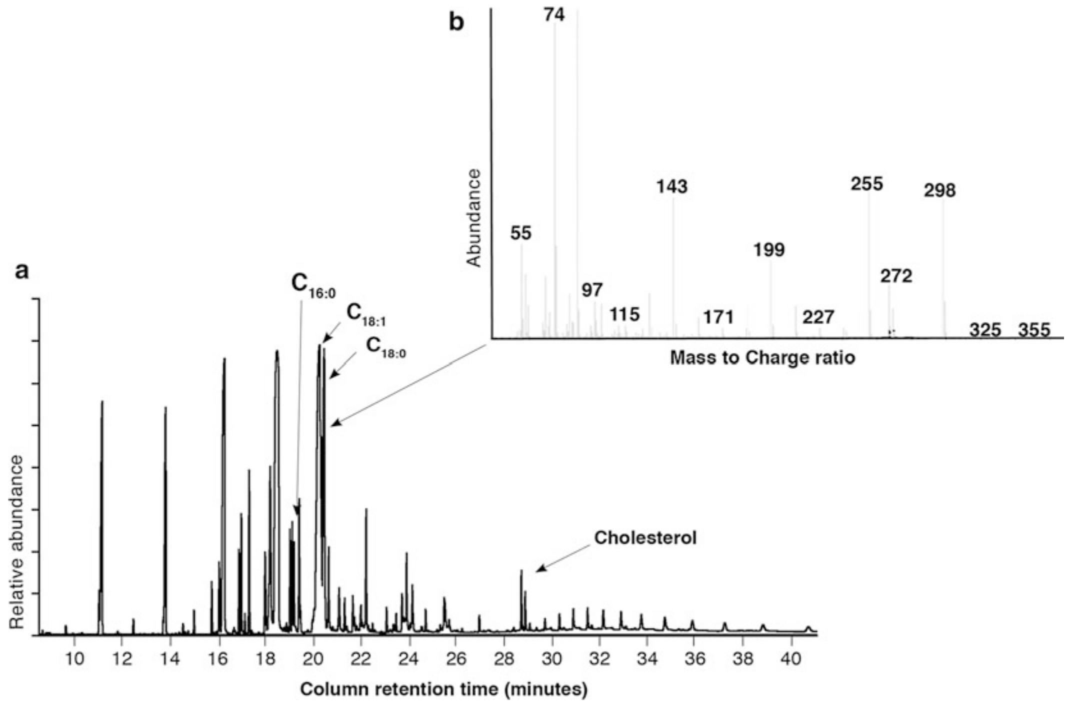
Organic Residues, Figure 1 Schematic diagram of a gas chromatography column.



Organic Residues, Figure 2 A chromatogram of the molecular components of a modern butter fat sample. The retention times, elution orders, and relative abundances of different molecular components in an unknown archaeological sample can be matched to those of known modern organic substances. Molecular components are released in a predictable sequence by the GC column based on their individual boiling points, with shorter carbon chain fatty acids eluting before diacylglycerols and triacylglycerols.

relative abundances of molecules in the unknown samples are then compared to those of known compounds, generally through the use of a chromatogram, which is a graphic representation of the measured values of molecular components in the separated organic compound (Figure 2).

A mass spectrometer is often coupled to the output port of a GC in order to match the molecular weights and ion fragments of the components in a compound. As molecules are released from the gas chromatography column, the mass spectrometer generates a shower of high-energy electrons that removes an electron from each molecule, and creates a stream of charged particles that is subsequently bent by a powerful magnetic or electrical field. The positive molecular ions in the stream of charged particles are separated from one another on the basis of their atomic masses (Pollard et al., 2007), with lighter ion fragments bending more readily than ions having heavier masses. The ion fragments of individual molecular components of a potsherd extract can then be statistically



Organic Residues, Figure 3 Molecular weights and ion fragments of individual molecular components in organic substances recovered from archaeological sites can be measured and matched to those of known compounds through the use of a computer database attached to a mass spectrometer. (**a**) Gas chromatogram of all lipids making up a modern butter fat sample. (**b**) Mass spectra of a singular molecular component ($C_{18:0}$ saturated fatty acid) that has been isolated from all other components of the modern butter fat sample.

matched to those of known organic and inorganic compounds through an attached computer database (Figure 3). Different compounds often share many similar molecular components that vary only to a small degree, and therefore, mass spectrometry provides corroboration for the identification of compounds by gas chromatography, and it offers increased efficiency and reliability in the identification of complex mixtures.

Molecular characterization of animal fats, vegetable oils, plant resins, waxes, and bitumen using gas chromatography (GC) and mass spectrometry (MS)

Two pioneering examinations of archaeological residues using gas chromatography and mass spectrometry were conducted on substances surviving in Gallo-Roman pottery (Condamin et al., 1976; Rottländer and Hartke, 1982), but much like the earlier work of Berthelot, results of these studies were ambiguous because they relied solely on fatty acid distributions for the classification of residues and their assignment to specific plant and animal species. Concentrations of $C_{16:0}$ and $C_{18:0}$ saturated fatty acids can, in fact, be useful in distinguishing whether archaeological residues are of plant or animal origin, but these are of little diagnostic value by themselves in differentiating major classes of mammalian fats or plant species (Heron and Evershed, 1995, 260). Working with a "resinous adhesive material" that had been recovered from a third century BCE Carthaginian shipwreck off the coast of Sicily, National Gallery of Britain conservators John Mills and Raymond White were the first researchers to identify an archaeologically retrieved organic substance with certainty by matching chromatographic elution orders and abundances of a unique molecular biomarker (diterpenoid methyl esters) found in pine tree resins (Mills and White, 1977).

A number of research studies conducted in the early 1990s by Richard Evershed, Carl Heron and colleagues in the Department of Chemistry at the University of Liverpool set the agenda for methods used in recovery and analysis of lipids from archaeological materials up until the present day (Evershed et al., 1990, 1992; Heron et al., 1991, 1994). Evershed and Heron developed a protocol for the extraction of residues from the clay matrix of archaeological pottery fragments in which a fine ceramic powder was removed from the interior surface with a high-speed modeling drill and collected on sterile sheets of household aluminum foil under controlled laboratory conditions. Lipids were subsequently extracted from the ceramic powder through repeated applications of a solution of chloroform and methanol solvents in a glass vial while being subjected to high frequency sound waves to free organic compounds bound within the ceramic matrix. Solvent solutions were then concentrated and the major classes of lipids (saturated and unsaturated fatty acids, monoacylglycerols, diacylglycerols, and triacylglycerols) separated from one another through gas chromatography (GC) as outlined above. The relative abundances, elution orders, and retention times of these specific lipid classes were then measured and compared with modern reference samples (Evershed et al., 1990, 1992; Heron et al., 1991, 1994). This research group successfully identified molecular compounds surviving in pottery from three very different archaeological contexts in Great Britain: (1) small amounts of cholesterol confirmed the presence of animal fats in vessels recovered from a Roman villa (Heron et al., 1991); (2) lipids known from leafy vegetables indicated the cooking of cabbage at a medieval Saxon hamlet (Evershed et al., 1991); and (3) other long-chain carbon compounds from beeswax attested to the collection of honey (if not the keeping of bees) during the late Neolithic period in northern Europe (Heron et al., 1994).

Since the early 1990s, many researchers throughout the world have built on Evershed's and Heron's early work (including members of their respective research groups at the University of Bristol and the University of Bradford) to develop yet further protocols that could maximize the recovery of lipids from both pottery and archaeological sediments. Comparisons of methods using a range of different organic solvents as well as acidification and saponification techniques can be found in Stern et al. (2000) and Gregg (2010).

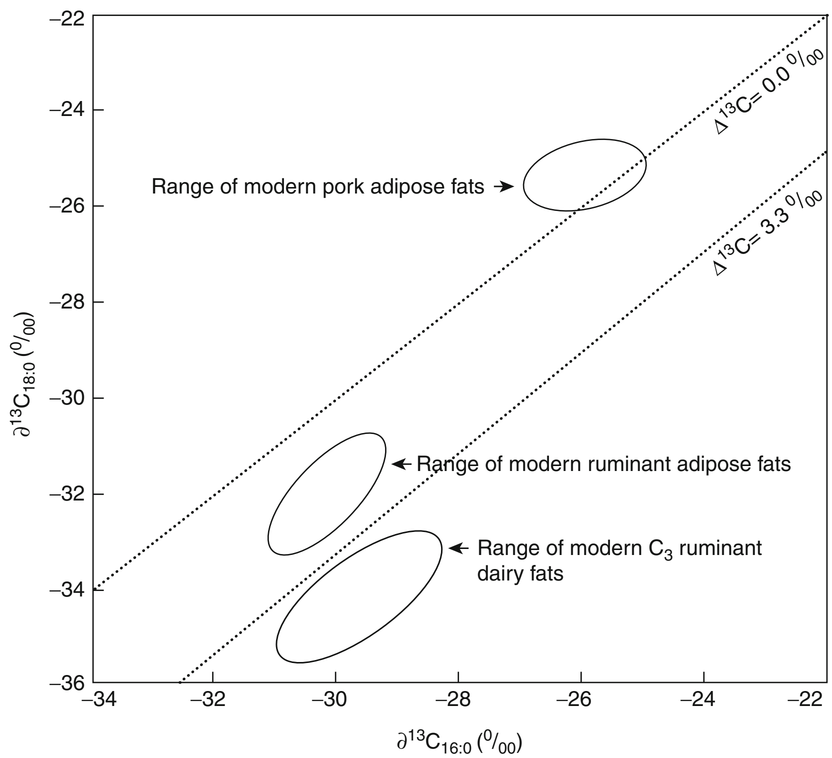
Although many of these techniques have proven successful in the recovery and identification of organic residues from different archaeological contexts in many regions, 20 years of intensive research have shown that unique molecular biomarkers or diagnostic distributions of longer carbon chain compounds are rarely preserved at archaeological sites for more than 2 or 3,000 years (Heron et al., 1994; Boëda et al., 1996; Connan et al., 2004; Mirabaud et al., 2007; Gregg et al., 2007). It is suspected that the delayed decomposition of lipids within archaeological pottery is due to their being absorbed into the clay fabric of vessels (Evershed et al., 1990; Heron et al., 1991), but diagnostic long carbon chain molecules survive only under exceptional circumstances, such as the anaerobic conditions at the submerged fourth millennium BCE site at Clairvaux XIV in the French Jura (Mirabaud et al., 2007) or the continuously desiccated 18th dynasty Egyptian capital at Amarna (Stern et al., 2000). Bitumen appears to be the one notable exception, with extant molecular signatures having been identified in pottery vessels from 8th millennium BCE sites in southern Mesopotamia (Connan et al., 2004; Gregg et al., 2007) and on the surface of 40,000-year-old Middle Paleolithic tools from northern Syria (Boëda et al., 1996).

Robert White's *Principles and Practice of Soil Science* (2006) provides a useful guide to the physical and chemical process involved in biodegradation of organic compounds under different soil and climatic conditions. Colonizing insects, arthropods, annelids, fungi, and bacteria can all affect the survival of buried organic matter, but microbial degradation is accelerated in most depositional environments through increases in temperature, moisture, and hydrolysis resulting from the acidic or alkaline conditions of the soil (White, 2006; Pollard et al., 2007). However, it is the differences in the physical characteristics of the molecular components in a substance that results in the preferential preservation of some lipids more so than others (Eglinton and Logan, 1991; Pollard et al., 2007). Hydrophobic classes of lipids that share electrons between atoms symmetrically, such as nonpolar $C_{16:0}$ and $C_{18:0}$ saturated fatty acids in animal fats and vegetable oils and long carbon chain compounds in bitumen, waxes, and tree resins, are much more likely to survive microbial degradation during burial for prolonged periods of time than water-soluble lipid species that share electrons between atoms asymmetrically (Eglinton and Logan, 1991; Heron et al., 1994; Heron and Evershed, 1995; Connan, 1999).

Isotopic characterization of $C_{16:0}$ and $C_{18:0}$ fatty acids from remnant animal fats and vegetable oils

As a result of poor preservation of distinctive molecular biomarkers in the overwhelming majority of pottery fragments from Iron Age, Bronze Age, and Neolithic sites in Europe, a group led by Evershed established new criteria for identification of animal fats by specifically targeting saturated fatty acids that were preserved in archaeological ceramics (Evershed et al., 1997). Employing gas chromatography and combustion isotope ratio mass spectrometry (GC-C-IRMS) as analytical techniques, Evershed and his colleagues measured the stable carbon composition ($^{13}C/^{12}C$) of modern animal fats and observed that $\delta^{13}C$ values of $C_{16:0}$ and $C_{18:0}$ fatty acids from ruminant animals (sheep, goats, and cattle), pigs, and dairy foods fell into discrete ranges that could be used to categorize the biological origins of residues from archaeological materials. The basis for identification of fatty acids recovered from archaeological pottery is illustrated in Figure 4. Ratios of $\delta^{13}C$ values plotting below the $\Delta^{13}C = -3.3$ line are categorized as dairy fats; values plotting between the $\Delta^{13}C = -3.3$ and $\Delta^{13}C = 0$ lines are categorized as ruminant carcass fats; and values plotting above $\Delta^{13}C = 0$ line are categorized as pig fats. By convention, the lower case letter delta in the Greek alphabet (δ) is used to denote small – parts per thousand (per mil or ‰) – differences in isotopic composition of carbon ($^{13}C/^{12}C$) in the fatty acids, while the uppercase letter delta in the Greek alphabet (Δ) is used to denote subsequent comparison of δ values of individual fatty acids to one another.

These advances have opened new windows for investigation of subsistence practices associated with different prehistoric cultural traditions. A number of notable studies have used these criteria as evidence for the processing or consumption of dairy products at Medieval to Neolithic



Organic Residues, Figure 4 Ratios of δ^{13}C values of $C_{16:0}$ and $C_{18:0}$ fatty acids used to categorize dairy fats, ruminant carcass fats, and pig fats.

period sites (Dudd and Evershed, 1998; Copley et al., 2003; Craig et al., 2005; Spangenberg et al., 2006; Gregg et al., 2009; Dunne et al., 2012; Salque et al., 2013), with the earliest date for milk use currently linked to cattle herding in the Near East and southeastern Europe (Evershed et al., 2008). Other studies have characterized the isotopic composition of additional modern reference materials and used this technique to identify fatty acids from a wide range of archaeological contexts, including plant oils and animal fats used as fuel in ceramic lamps in Bronze Age Egypt (Copley et al., 2005), marine mammal blubber in slab-lined pits in prehistoric Norway (Heron et al., 2009), and the milking of horses into pottery vessels shortly after their initial domestication on the steppes of Central Asia (Outram et al., 2009). However, there also remains the potential for the reporting of false or ambiguous results given our current state of knowledge of modern biological processes and diagenetic factors affecting the isotopic composition of remnant plant oils and animal fats (Gregg et al., 2009; Gregg and Slater, 2010; Steele et al., 2010). Studies by a number of research groups (Spangenberg et al., 2006; Gregg et al., 2009; Gregg and Slater, 2010; Steele et al., 2010) have shown that there is greater diversity in the fractionation of carbon isotopes (the division of carbon into relative amounts of ^{13}C and ^{12}C) than previously reported using the criteria established by Evershed et al. (1997).

Variations in the fractionation of carbon isotopes in plants having different photosynthetic pathways produce a shift in the δ^{13}C values of fatty acids in animals that consume them (O'Leary, 1981; Lee-Thorp 2008), thus reinforcing the fact that you are what you eat. Animals that exclusively consume δ^{13}C grasses or cereals in regions with temperate climates, such as Europe, have more negative δ^{13}C values than animals consuming large quantities of C_4 plants, such as corn, sorghum, and millet, or tropical grasses or chenopods that are abundant in many other parts of the world (O'Leary, 1981). Researchers in the Evershed group had initially suggested that isotopic values falling between the discrete modern ranges in Figure 4 could be attributed to the mixing of animal fats in antiquity (Dudd and Evershed, 1998, 1480), but more recent observations of the isotopic composition of modern olive oils by Steele et al. (2010, 3484) demonstrate that interpretations of δ^{13}C values falling between these ranges as mixtures of animal fats "can no longer be considered valid." Isotopic values of modern carcass fats and dairy foods from central Europe (Spangenberg et al., 2006) and the Middle East (Gregg et al., 2009; Gregg and Slater, 2010) have also been observed to plot outside the currently applied ranges that were generated based on modern samples from the United Kingdom (Dudd and Evershed, 1998; Copley et al., 2003). Given the complexities of differentiating the isotopic values of plant oils from animal fats, it is essential not only to determine the extent to which stable carbon values of animal fats and dairy foods are affected by the photosynthetic pathway of vegetation that animals are consuming, but also to compare the isotopic composition of ancient residues with the full suite of plant and animal species that may have been consumed within the region or ancient period of interest (Gregg, 2010; Greenfield, 2010).

Sugars and starches

Sugars are simple carbohydrates (monosaccharides and disaccharides) found in an extensive range of foodstuffs, whereas starches are the semicrystalline structures (polysaccharides) that hold large numbers of sugars together to act as the main energy store in green plants. Both sugars and starches are highly polar organic substances with molecular bonds that are readily dissolved in water (McMurry, 2004; Pollard et al., 2007). Researchers have long been interested in differentiating the physical characteristics of starches by genera and species (Reichert, 1913), and many studies have used microscopic examination of the morphological attributes of starch grains recovered from archaeological sediments as evidence for subsistence practices of prehistoric populations (Samuel, 1996; Piperno and Holst, 1998; Piperno et al., 2000; Piperno et al., 2004; Henry and Piperno, 2008; Mercader et al., 2008; Hardy et al., 2009; Piperno et al., 2009). However, many other researchers have also questioned whether these complex carbohydrates are able to survive burial for prolonged periods as discrete entities while still retaining their diagnostic potential in reconstructing ancient human diets (Atchinson and Fullagar, 1998; Perry, 2001; Haslam, 2004; Reber and Evershed, 2004a; Evershed, 2008), with Wilson et al. (2010, 594) recently noting that "how variations in [starch granule] shape occur, the effects of local geographical and environmental effects on granule shape and the diagenetic effects of aging are not fully understood or explained."

Attempts to identify fruit sugars and starchy grains from archaeological contexts through chemical analysis also have not proven to be particularly successful (Reber and Evershed, 2004a; Evershed, 2008). Michael Haslam points out that "once a component such as starch has entered the soil and begun to be broken down, it is rarely possible to determine just how much was present, owing to biochemical similarities in the make-up of all living things" (Haslam, 2004, 1720). The poor preservation of complex carbohydrates under most soil conditions is further aggravated by the lack of any known species-specific lipid biomarkers for starch grains (Reber and Evershed, 2004a), and the masking of starch lipids by those from other foods such as meat, milk, fish, and oily seeds (Reber and Evershed, 2004a). Reber and Evershed (2004a, 400) note that this masking often "leads to the underestimation of starchy staple lipids present in a residue," making it difficult, if not impossible, to confirm evidence of starchy grains through molecular criteria alone. However, Reber and Evershed (2004b) have been able to demonstrate a chronological progression of the processing of maize in pottery vessels during the early Mississippian period in southern North America, ca. 800–1,100 cal AD. Through the adaptation of the GC-MS and GC-IRMS instrumental analytical techniques described above, Reber and Evershed (2004b) characterized the isotopic values of long-chain carbon compounds surviving in potsherds recovered from precontact sites along the Mississippi Valley. Isotopic analysis revealed a change in $\delta^{13}C$ values of these molecular compounds coinciding with botanical evidence for the introduction of maize, a C_4 plant, into the American Bottom region from the Lower Mississippi Valley between 1,000 and 1,100 cal AD (Reber and Evershed, 2004b).

Patrick McGovern of the University of Pennsylvania's Museum of Archaeology and Anthropology has directed projects specifically targeting trace elements in pottery vessels associated with the conversion of sugars and starches to alcohol; the presence of these elements can then be used as evidence of winemaking and brewing during prehistoric periods and regions. McGovern and his colleagues have reported finding direct chemical evidence of the manufacture or storage of alcoholic beverages in pottery vessels from the Middle East, China, and Central America (Michel et al., 1992, 1993; McGovern et al., 1996, 1997, 2004; Cavalieri et al., 2003; Henderson et al., 2007). A number of researchers have questioned the reliability of the Fourier transform infrared spectroscopy (FTIR) and wet chemistry "spot tests" used in the studies from the ancient Middle East (Boulton and Heron, 2000; Guasch-Jané et al., 2004; Pollard et al., 2007; Stern et al., 2008) and identification of trace amounts of beeswax associated with honey in "mixed fermented beverage" from the Early Neolithic period in China (Evershed, 2008). There also remains uncertainty as to whether the biomarkers calcium oxalate and tartaric acid recovered from potsherd extracts in McGovern's studies can be, respectively, interpreted as unambiguous evidence that the vessels ever contained beer or wine rather than other plant foods or fruit-based beverages (Hornsey, 2003; Stern et al., 2008; Evershed, 2008; Gregg, 2010). In a recent study attempting to uncover chemical evidence for wine production in the ancient Near East, Hans Barnard and colleagues (2011) built on McGovern's pioneering work and identified the presence of malvidin (a plant pigment that provides both pomegranates and grapes with their red color) in two Late Chalcolithic period potsherds from the Areni-1 cave complex in Armenia. Barnard et al. (2011) conservatively note that the presence of malvidin is not necessarily associated with ancient wine production but can only be used as evidence of the presence of grapes or pomegranates, both species native to the region.

Proteins, amino acids, and DNA

The overwhelming majority of studies examining extant organic residues have focused on the identification of molecular and isotopic biomarkers of lipids rather than proteins, due to the apparent preferential survival of animal fats and vegetable oils in most archaeological contexts. However, when proteins are preserved, they can provide species-specific identification of organic residues through the use of a wide range of immunological testing methods (Smith and Wilson, 1992, 2001; Newman et al., 1993; Barnard and Eerkens, 2007; Stevens et al., 2010). But many researchers have questioned the merit of attempting to characterize proteins that may survive in organic residues. The peptide bonds holding long chains of amino acids together break down rapidly under highly acidic or alkaline soil conditions, and concentrations are often below the detectable limits of conventional chromatography biomarker techniques (Evershed and Tuross, 1996).

Uncertainties concerning the diagnostic potential of proteins in archaeological materials have been aggravated by the controversy surrounding the detection of blood residues on the surfaces of prehistoric stone tools and alleged identification of species (Loy, 1983; Loy and Wood, 1989; Loy and Hardy, 1992). Material scientists, biochemists, immunologists, and archaeologists (Custer et al., 1988; Gurfinkel and Franklin, 1988; Smith and Wilson, 1992, 2001; Manning, 1994; Downs and Lowenstein, 1995; Gernaey et al., 2001; Pollard et al., 2007; Heaton et al., 2009) have all questioned the validity of the discovery of hemoglobin on stone tools based on the use of chemical test strips for the detection of hemoglobin in urine (Loy, 1983; Loy and Wood, 1989) or the visual recognition of crystalline structure of salts allegedly formed through the precipitation of proteins from a solution in which the tools were soaked (Loy, 1983; Loy and Wood, 1989; Loy and Hardy, 1992). The selectivity of chemical test strips is limited to hemoglobin, with consistent false-positive results produced through the presence of many organic compounds present in archaeological soils (Custer et al., 1988; Manning, 1994; Downs and Lowenstein, 1995). Researchers have also not been able to replicate the crystalline structures allegedly attesting to the presence of hemoglobin using the methods described by Loy and colleagues (Smith and Wilson, 2001).

Despite the improbabilities associated with the identification of proteins in archaeological residues, University of Newcastle researchers Matthew Collins and Oliver Craig did have some initial success in identifying bovine aS1-casein from cow's milk in storage vessels from an Iron Age site in the Hebrides through the use of a hydrofluoric acid digestion-and-capture immunoassay (DACIA) method (Craig and Collins, 2000; Craig et al., 2000). However, these researchers were unable to replicate their results in examination of pottery fragments of much greater antiquity from three Neolithic sites in the Danube basin (Craig et al., 2005), and subsequently they abandoned the DACIA process and adopted the lipid recovery protocols and GC-C-IRMS techniques outlined above.

Recent innovations in electrospray ionization mass spectrometry (ESI-MS) may allow archaeological researchers to resolve molecular structures of both fats and proteins preserved in archaeological residues that have not thus far been possible to characterize through conventional gas chromatography and mass spectrometry techniques (Mirabaud et al., 2007; Solazzo et al., 2008; Stevens et al., 2010). In electrospray ionization mass spectrometry, a small amount of the substances being analyzed is dissolved in a volatile mixture of solvents and introduced into a chamber where a charged field at the tip of a hypodermic needle disperses the mixture into a fine spray of charged droplets (Fenn et al., 1990; Pramanik et al., 2002). The volatile solvents rapidly evaporate through a sequence of small Coulomb explosions, with individual ions from the substance being released into the ambient gas of the chamber before being sent to a mass analyzer (Fenn et al., 1990). Electrospray instrumental methods are particularly well suited to the analysis of fats and proteins because they compensate for the tendency of macromolecules such as diagnostic triacylglycerides in animal fats and amino acids in proteins to fractionate when they are ionized (Pramanik et al., 2002).

Mirabaud et al. (2007) used ESI-MS to obtain higher resolution in molecular distributions of triacylglycerides from carcass fats and dairy foods of modern ruminant animals than had been previously possible through conventional GC-MS techniques. Triacylglyceride distributions of ruminant carcass fats and dairy foods become indistinguishable from one another following burial for prolonged periods of time (Heron and Evershed, 1995), but Mirabaud et al. (2007) were able to match triacylglyceride distributions of milk fats from modern European cattle to those of potsherd extracts from a long submerged Neolithic settlement at Clairvaux XIV in France. French and American researchers also used ESI-MS to identify protein peptide sequences of seal muscle and whale blubber in the clay matrix of an 800-year-old Inupiat potsherd from Point Barrow in northern Alaska through comparison with modern reference samples using a protein-matching database (Solazzo et al., 2008). While electrospray ionization mass spectrometry could prove useful in identifying organic compounds in archaeological residues recovered from anaerobic burial environments or those that have remained frozen for prolonged periods, this instrumental technique may have little applicability in characterizing organic residues from the vast majority of archaeological sites. Much like mammoths from northern Siberia (Michel, 1998), the "Iceman" from the Italian Alps (Gostner and Egarter Vigl, 2002), or "bog bodies" from the northern Europe (Stankiewicz et al., 1997), frigid or anaerobic conditions have likely protected molecular structures of fats and proteins from the kinds of biodegradation processes that prevail at archaeological sites throughout of the rest of the world.

This is also much the same case with ancient DNA. The underlying mechanisms of DNA degradation are becoming increasingly well understood (Collins et al., 2002; Götherström et al., 2002; Schwarz et al., 2009; Adler et al., 2011), and reviews of the physiological and diagenetic processes affecting the survival and recovery of DNA from teeth and bone can be found in Collins et al. (2002) and Adler et al. (2011). The external sugar-phosphate backbones of DNA molecules are made up of water-soluble ribose sugars and phosphates that are highly susceptible to biodegradation processes, whereas the internal nitrogenous bases making up the genetic replication sequences in DNA (adenine, guanine, thymine, and cytosine) are water resistant and therefore more likely to survive. Götherström et al. (2002) have shown that DNA is absorbed into the crystalline structure of the mineral portion of bone and stabilized by hydroxyapatite in calcified tissue and collagen. However, only a limited number of studies inform our understanding of the factors affecting its preservation in organic residues from archaeological sites (Hansson and Foley, 2008; Foley et al., 2012). Maria Hansson and Brendan Foley (2008) have extracted fragmentary strands of olive, oregano, and *Pistacia lentiscus* DNA from scrapings of the interior surfaces of two amphorae from a 2,400 year-old shipwreck off the Greek island of Chios using polymerase amplification techniques and existing criteria established for authenticating ancient DNA. The survival of DNA shows that a wide range of foodstuffs were shipped in these vessels, and it allowed these researchers to question long-standing assumptions about the use of amphorae as exclusively wine and olive oil transport containers in ancient Greece (Foley et al., 2012). However, the low water solubility of olive oil, which is suspected to have been shipped in these vessels on multiple occasions, and the relatively anaerobic conditions of the deepwater location from which they were recovered would both have aided in the preservation of the DNA of other substances shipped in the same containers (Hansson and Foley, 2008).

Summary

Chemical analysis of organic residues is becoming an increasingly useful tool in identifying economic activities and subsistence practices associated with different cultural traditions or archaeological time periods in both the Old and the New Worlds. Due to variable rates of degradation in individual components of organic compounds, however, unambiguous identification of amorphous or invisible residues surviving at archaeological sites is not always a straightforward task. Interpretations of chemical data must be evaluated in the context of complementary or contradictory lines of evidence that inform the researchers' understanding of the problems they are hoping to clarify. It might not be practicable for archaeologists to extract residues and conduct analyses themselves, but both archaeologists and the natural scientists with whom they collaborate need to be aware of all of the constraints placed on classification of organic substances by degradation processes at archaeological sites. And both sides must be confident that molecular or isotopic biomarkers are unique to a specific organism or physiological process before being used as evidence of past human activity.

Ötzi, the Tyrolean Iceman

ÖTZI, THE TYROLEAN ICEMAN

James H. Dickson
Dickson Laboratory for Bioarchaeology,
York Archaeological Trust, Glasgow, UK

Sometimes called the Tyrolean Iceman and often given the humanizing nickname Ötzi, the body of this late Neolithic (Chalcolithic or Copper Age) male was found in September of 1991 and became famous instantly. Mummified by freezing, his body is very well preserved, though shriveled and damaged by the rough recovery. There were several items of clothing and varied personal equipment, some poorly preserved. The items of gear were found up to 5 m from the body, but all are usually assumed to have been his possessions.

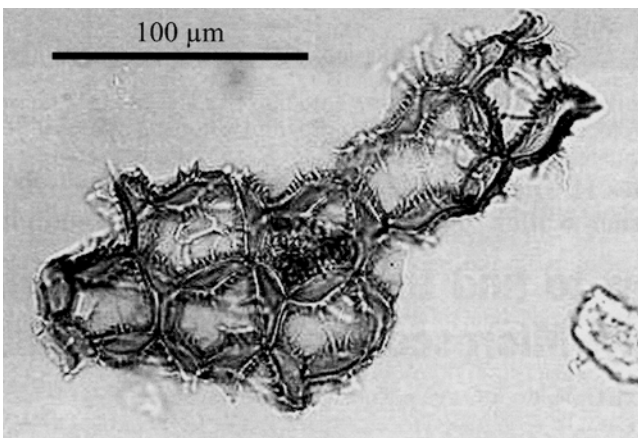
Especially important are a complete copper-headed ax, an unfinished longbow with a quiver containing 14 arrows, incomplete or broken, and a belted pouch containing a fire-making kit with true tinder fungus, flints and pyrites, and a retouching tool. The grass cape, fur cap, well-crafted shoes, and all other items of clothing are unparalleled finds from the European Neolithic. This mummy of a man some 46 years of age with many of his garments and objects is unique and totally unexpected. Its discovery is of great archaeological importance because it preserves body soft tissues and other organic materials that do not normally survive so long into the present.

On the basis of many radiocarbon dates, Ötzi lived 5,200–5,300 years ago. The numerous radiocarbon dates were obtained from body tissues, the equipment, leather, hair, charcoal, bast fibers of the tree *Tilia* (used for bindings), and low altitude grasses from the clothes; they all produce a perfectly homogeneous series. That his body was preserved by freezing so quickly is taken as evidence of increasing cold with advancing glaciers in the Alps around 5,000 years ago – the Neoglaciation. In the late twentieth century, the corpse finally melted out of ice at 3,210 m a.s.l. on the main divide of the Alps about 92 m inside Südtirol, Italy. Topographically, the site is at the very uppermost part of the Ötztal, within the drainage that flows through Austria to the Danube and the Black Sea.

Housed in the Iceman Museum in Bolzano, Südtirol, the corpse is not a typical glacier mummy. Bodies melted out from glaciers have usually been broken into pieces by the downhill movement of the ice. This mummy was trapped within a -boulder-strewn, rock-cut hollow, which was overridden crosswise by the ice (Figure 1). Any movement of the body was a matter of a few meters, and it was likely caused by melt water during some period or periods of milder climate.

Many interpretations of the Iceman, especially his lifestyle and death, are controversial. What we can know with some confidence is that Ötzi had died quickly by an arrow shot into his back under the left shoulder, probably in the immediate vicinity in which his body was found. The death occurred while food from his last meal remained in the stomach sensu stricto. The arrow had pierced the scapula, ruptured the subclavicular artery, and led to

Oxygen Isotopes, Figure 1 Ötzi was discovered within a protected, ice-covered hollow that lay directly beneath the standing men (Photograph looking southeast taken in late summer of 2000 by James H. Dickson).



Oxygen Isotopes, Figure 2 The tiny leaf fragment of the bog moss *Sphagnum imbricatum* sensu lato, a low altitude species, recovered from Ötzi's colon Botanical Institute, Innsbruck.

profuse blood loss. He had been very active during the last hours of his life, having descended from a high to a low elevation, then having ascended back to a higher location. This journey was deduced from the presence of pollen (crucially that of *Ostrya carpinifolia*) and submicroscopic plant remains, including mosses, extracted from the stomach, ileum, colon, and rectum. During his complex final travels, his right palm was badly and deeply cut down to the bone between the thumb and index finger. The wound may have been staunched by bog moss (*Sphagnum*), of which a tiny leaf fragment was found in the colon (Figure 2). The archaeobotanical evidence from the alimentary tract for spring/early summer as the season of death has not convinced everyone.

The location of the site in the towering mountainous topography is such that Ötzi's last journey was either southwards or northwards, not eastwards or westwards. That it was northwards is strongly indicated by the archaeology, and particularly the science, including notably the remains of plants such as the small tree *Ostrya carpinifolia* and the moss *Neckera complanata*. The likely route was from the Vinschgau (or Val Venosta) up the Schnalstal (or Val Senales), eventually to about 3 km northwest of the mountain Similaun where the body was later found.

Though the media promulgated the story that the Iceman died in "battle," such an interpretation is without any scientific justification, there being no peer-reviewed data ever having been published to sustain such an argument. What Ötzi's social role had been and the significance of his copper-bladed ax are especially controversial matters, difficult to resolve. The notion that Ötzi had been a herdsman, strongly espoused by Konrad Spindler, is very unlikely to be true. That he had apparently carried an unfinished bow and quiver with 14 useless arrows is enigmatic. A recent claim that the corpse had been buried on a "platform" at the very edge of the site has been rebutted by nine leading investigators.

The uniqueness of the discovery, the detailed nature of the diverse analyses, and the new and often dramatic findings over 20 years have led repeatedly to much untrammeled speculation in the media and on the web. There are numerous books, some of them trashy, that make scientifically unsupported claims, including one that labels the whole matter a hoax and another devoted to the "Curse of Ötzi."

OXYGEN ISOTOPES

Lori E. Wright
Department of Anthropology, Texas A&M University, College Station, TX, USA

Definition

Stable oxygen isotope ratios are widely measured in archaeologically and paleontologically recovered bones and teeth as measures of climate change, geographic provenance, migration, and cultural behavior.

Oxygen isotope species

Stable isotopes are variants of atoms that differ in mass but do not decay over time, that is, they are not radioactive. The element oxygen (O) is found in three naturally occurring stable isotopes, ^{18}O, ^{17}O, and ^{16}O. The nucleus of each of these oxygen isotopes contains eight protons and either eight, nine, or ten neutrons, respectively. Of these stable isotopes, ^{16}O is the most abundant on earth, accounting for 99.757 % of atoms, while ^{17}O (0.038 %) and ^{18}O (0.205 %) occur in far smaller concentrations worldwide. Although some 17 unstable isotopes (which decay radioactively) are also known for oxygen, 14 of which are radiogenic (produced by the decay of other atoms), each of these isotopes has a half-life of 2 min or less, and therefore they do not factor appreciably into studies of oxygen isotope systematics in nature. The stable isotopes of oxygen behave equivalently in chemical reactions because they each have eight electrons in the reactive shell around the nucleus. Because they differ in mass, however, the rate at which these various isotopes of oxygen (or the isotopes of other elements for that matter) complete chemical reactions also differs, leading to uneven natural distributions of the isotopes. A difference in the isotopic ratio between the reactants and the product of a chemical reaction or physical state change is known as the *fractionation* of the isotopes (Fry, 2006).

Delta notation and standards

Stable isotope ratio mass spectrometers measure the content of various masses of a sample gas, such as carbon dioxide (CO_2), and compare those to a standard reference gas of known composition, alternating between the sample and standard gas to obtain a precise measurement. These ratios are then corrected to international standards to ensure interlaboratory comparability. $\delta^{18}O$ ratios can be calibrated either to the Vienna PeeDee Belemnite (vPDB) standard when measured on CO_2 or to the Vienna Standard Mean Ocean Water (vSMOW). Standards are defined by the International Atomic Energy Agency (IAEA). The ratio between the stable isotopes of oxygen is reported as a delta value, calculated as follows:

$$\delta^{18}O = [(R_{SAMPLE}/R_{STANDARD} - 1)] * 1000$$

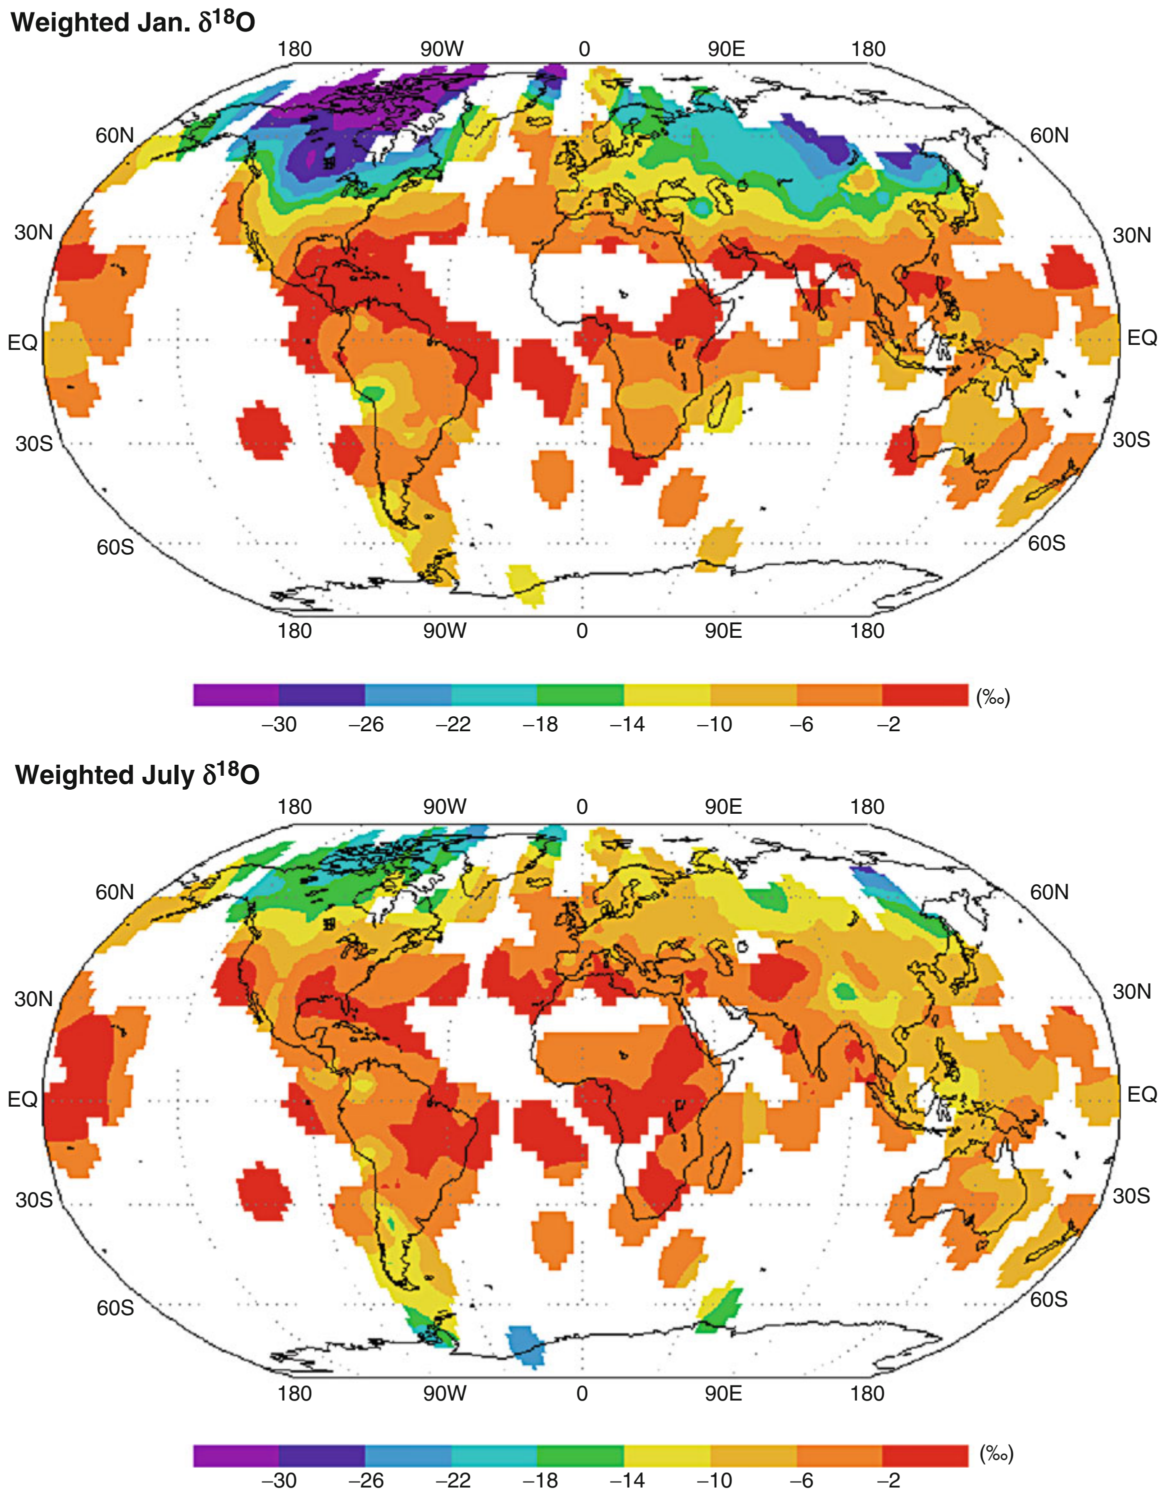
where $R = {}^{18}O/{}^{16}O$. This delta notation has the advantage of making small variations in the abundance of ^{18}O into larger, more manageable numbers. When measuring CO_2, which possesses one carbon and two oxygen atoms, a mass spectrometer has detectors set to measure the masses 44, 45, and 46, corresponding to the masses of $^{12}C^{16}O^{16}O$, $^{13}C^{16}O^{16}O$ or $^{12}C^{18}O^{16}O$, and $^{13}C^{18}O^{16}O$, which covers all the combinations of atomic weight in the stable CO_2 molecule. From these measurements, the abundances of the isotopes in the sample are calculated by comparison with their known abundance in a reference gas (Fry, 2006).

Oxygen isotopes in the global environment

Oxygen is found in most natural compounds, and it is ubiquitous in the tissues of living organisms as a result of its being the primary constituent of water, H_2O, though it is also found in most organic molecules. The isotopic ratios of natural systems are thus driven initially by global variation in the stable isotopic composition of water.

Global rainfall largely originates from oceanic water evaporated in the tropics. The "lighter" $H_2{}^{16}O$ (where the oxygen atom is ^{16}O) evaporates more quickly than the "heavier" $H_2{}^{18}O$, so the $\delta^{18}O$ of water in clouds and precipitation is low, i.e., negative on the vSMOW scale. As rain clouds travel over land, and as they move from warmer to cooler regions, the oxygen isotopic ratio of water held in the clouds declines further due to disproportionate condensation and precipitation of $H_2{}^{18}O$. As clouds move farther from their evaporative source, the remaining water is progressively depleted in ^{18}O. Subsequent evaporation of water from the earth's surface at higher latitudes also contributes to an increasingly "light" precipitation in temperate and polar regions, a process known as Rayleigh distillation. Thus, the isotopic ratio of rain that falls in latitudes far from the tropics contains proportionately less ^{18}O than rain in coastal tropical areas. Comparing the difference numerically, rain falling in coastal tropical regions has a $\delta^{18}O$ of approximately -5 ‰$_{SMOW}$, while this value declines with increasing latitude to as low as -30 ‰ in the Arctic. The $\delta^{18}O$ of rain also varies seasonally in accordance with changing temperature. Tropical air masses laden with ^{18}O condense when they encounter cooler air in temperate zones (Rozanski et al., 1993). Accordingly, the seasonal maps for global variation in the $\delta^{18}O$ of meteoric water differ considerably, as shown in Figure 1, which shows the global patterning in rainfall $\delta^{18}O$ (IAEA, 2006).

Terrestrial surface waters (rivers and lakes) derive from meteoric water; however, their isotopic composition is partly determined by mixing with other surface waters. For instance, lakes accumulate water over multiple seasons or years during which rainfall may differ in composition. Lakes and rivers also contribute water to the atmosphere through preferential evaporation of ^{16}O, which in turn leaves the remaining water in the reservoir further enriched in ^{18}O. When there is a pronounced dry season, such evaporative enrichment may lead to significantly higher $\delta^{18}O$ in lakes than in meteoric water. The effect of seasonal fluctuation in rain $\delta^{18}O$ on surface waters depends upon the proportional contribution of rain to the ground reservoirs throughout the year. In tropical areas, for example, most of the rain may fall during a short rainy season, while the limited dry season rainfall contributes little volume to surface reservoirs available to animals and plants (Lachniet and Patterson, 2009). In mountainous regions, $\delta^{18}O$ varies



Oxygen Isotopes, Figure 1 Amount-weighted monthly stable oxygen isotope ratio averages for global precipitation show a gradient from tropical to polar regions. The degree of this isotope change with latitude is seasonal: above = January, below = July (Data from the Global Network of Isotopes in Precipitation (IAEA, 2006)).

with elevation: higher altitudes receive rain of lower $\delta^{18}O$ than the adjacent lowlands, and the leeward side of mountain ranges may show isotopic rain shadows in accord with the path of prevailing climate systems. In piedmont areas, rivers may contain water that originated as rainfall at high elevation on nearby mountains, and thus they may contain lower $\delta^{18}O$ than local meteoric water. Such factors influence the $\delta^{18}O$ of water available to plants and animals in local habitats, contributing to considerable diversity in $\delta^{18}O$ ratios across a landscape.

Water in the body and skeleton

The $\delta^{18}O$ of body tissues in all living organisms roughly follows the same global patterning in isotope ratios that is fundamentally shaped by rainfall $\delta^{18}O$ patterns. In this way, $\delta^{18}O$ can serve as a natural tracer (Schwarcz and Schoeninger, 1991). Although food contributes a small amount of oxygen to body tissues, imbibed water is the largest contributor to the body water pool (Longinelli, 1984; Luz et al., 1990; Bryant and Froelich, 1995; Kohn, 1996). In humans, as in other mammals, body water is typically enriched in the ^{18}O isotope, relative to imbibed water (presumably derived from rainfall), due to the disproportionately greater loss of ^{16}O in CO_2 from respiration as well as urine and sweat.

Skeletal tissues, such as bones and teeth, contain oxygen as components of both collagen and bone mineral. Skeletal hard tissues are precipitated in equilibrium with bicarbonate ions in the body water pool. The $\delta^{18}O$ of apatite precipitated in skeletal mineral is typically enriched in ^{18}O relative to the body water $\delta^{18}O$. This offset is species specific, since the magnitude of the fractionation that occurs in mineral precipitation is dependent on body temperature (Urey, 1947; Lécuyer et al., 2010), which varies among animal species. Bone mineral is composed of a poorly crystalline carbonated hydroxyapatite, $Ca_5(PO_4)_3(OH)$. Oxygen can be readily acquired for analysis from carbonate (CO_3) groups that substitute for the hydroxyl or phosphate groups within the hydroxyapatite or are adsorbed onto crystal surfaces. Bone phosphate $\delta^{18}O$ values are typically positive on the vSMOW scale, although bone carbonate contains proportionately less ^{18}O than the vPDB standard and thus shows mostly negative values on that scale.

For carbonate samples, carbon dioxide gas is typically collected by reacting powdered bone mineral with 100 % orthophosphoric acid under vacuum in a sealed reaction system (an Isocarb or Kiel peripheral) attached to a mass spectrometer. Oxygen bound within phosphate (PO_4) groups of hydroxyapatite is more difficult to prepare, often by reaction with bromine to produce silver orthophosphate, which is needed to separate it from the carbonate ions in hydroxyapatite (Stuart-Williams and Schwarcz, 1995). Newer methods using a thermal conversion elemental analyzer (TCEA) with continuous flow mass spectrometry may soon facilitate greater accuracy with smaller phosphate samples (Wiedemann-Bidlack et al., 2008; LaPorte et al., 2009). $\delta^{18}O$ measurements may also be collected through laser ablation of tooth surfaces (Cerling and Sharp, 1996), although it is not clear whether these data are derived from oxygen in carbonate alone or also from phosphate oxygen. A new instrument, the sensitive high-resolution ion microprobe (SHRIMP), is a secondary ion mass spectrometer that probes tiny and invisible spots on the surface of samples such as teeth (Aubert et al., 2012). Presumably, carbonates are the primary source of these ions, as with laser ablation. Although carbonate and phosphate $\delta^{18}O$ are highly correlated in paired samples (Iacumin et al., 1996), it is possible that carbonate signals attenuate a longer period of enamel maturation, since they appear to show slightly less seasonal fluctuation in $\delta^{18}O$ than does phosphate (Pellegrini et al., 2011).

Bone is subject to considerable postdepositional chemical transformation, or diagenesis, because of its porosity and high collagen content. Thus, archaeological applications of $\delta^{18}O$ analyses need to consider the biological integrity of the isotope ratios measured. The addition of exogenous ions and recrystallization of original bone mineral (with fractionation) can be detected by a variety of methods, such as looking at the crystallinity of the sample using Fourier transform infrared spectroscopy (FTIR) (Wright and Schwarcz, 1996; Kohn et al., 1999; Sponheimer and Lee-Thorp, 1999a; Lee-Thorp and Sponheimer, 2003). More recent work has emphasized tooth enamel as a sample material because of its greater resistance to diagenetic exchange than bone (Sponheimer and Lee-Thorp, 1999b), with both carbonate and phosphate frequently studied.

Climate

Oxygen isotope measurements from ocean sediment cores provide a record of climate change in the past. Oceanic sediments contain the carbonate skeletons of Foraminifera that fall to the ocean floor after the death of the organism, as well as pollen and other organic particles. Because the fractionation of $\delta^{18}O$ is temperature dependent (Urey, 1947), the measured $\delta^{18}O$ serves as a proxy for ancient oceanic temperature. Data from such cores has been used to reconstruct climate change during the Quaternary period, and it shows oscillating periods of warmer and cooler seawater (Emiliani, 1957). These periods are known as oxygen, or marine, isotope stages (OIS or MIS). Sediments with higher $\delta^{18}O$ identify stages that correspond to glaciations, while sediments with lower $\delta^{18}O$ were deposited during warmer interglacial intervals. The fluctuating $\delta^{18}O$ values of seawater are not directly related to temperature. They are now understood to be the result of changes in volume of the glacial ice sheets, which preferentially removes ^{16}O from the ocean. The climate fluctuation documented in these sea cores, and confirmed in core data from glaciers, is understood to be a result of fluctuating warming by the sun caused by changes in the tilt of the earth's rotational axis, known as Milankovitch cycles (Imbrie et al., 1984).

In archaeology, climate change has also been explored through stable oxygen isotopic analysis of prehistoric fauna (Longinelli, 1984; Luz and Kolodny, 1989). This kind of paleontological analysis is a growing field, with research underway on local climate sequences around the world. Many studies explore ancient climate variability through the analysis of archaeologically dated mollusks (Kennett and Voorhies, 1995), herbivore teeth (Bryant et al., 1994; Fabre et al., 2011), and other archaeological materials.

Migration in human history

Soon after the first studies conducted on animals, research began using human bone as the sample material to distinguish the skeletons of immigrants who were buried far from their lands of origin (Schwarcz et al., 1991; Stuart-Williams et al., 1996; White et al., 1997). In this approach, stable oxygen isotopes are measured in a number of skeletons. Depending on the nature of the skeletal sample analyzed, a local skeletal δ^{18}O ratio is determined, either from the variability of the δ^{18}O data collected or by comparison with data from other nearby sites. If human samples are numerous enough, and if there is reason to believe that most of the skeletons were local residents (e.g., burials from a typical cemetery or settlement), a statistical approach to the identification of outliers may be practical (Wright, 2012). Skeletons with δ^{18}O ratios that differ from the local value can be interpreted as immigrants or foreigners. In contrast to strontium isotopes, which are also used for tracking migration in the ancient past, δ^{18}O ratios from animal remains do not provide a comparable local environmental proxy for humans living in the same area because animal body temperatures vary by species, and fractionation of δ^{18}O during bone formation is temperature dependent. Moreover, both wild and domestic fauna may not have access to water of the same isotopic ratio as the humans who consume them and leave their bones to be recovered within ancient sites. Estimating local bone δ^{18}O values from modern surface water data turns out to be surprisingly complicated (Bell et al., 2009, 2010; Millard and Schroeder, 2010), perhaps due in part to varied contributions to bone isotope ratios from food (Daux et al., 2008). Additionally, error in estimating the δ^{18}O of drinking water from human bone values is considerable, raising doubt about the specificity of this approach (Pollard et al., 2011). Many researchers wrestle with the difficulty of defining a local value for human δ^{18}O due to variability in the water sources potentially exploited by humans. In the Andes, for example, rivers bring highland water to the piedmont and coast (Knudson, 2009; Turner et al., 2009). Direct comparison to human skeletal data from potential homelands is perhaps the most reliable approach.

Stable oxygen isotopes have been used to document migration in varied parts of the world. In Mesoamerica, oxygen isotopes have revealed complex patterns of military recruitment and long distance warfare at the state of Teotihuacan (White et al., 1997, 2002; Spence et al., 2004). In highland Guatemala, most nonlocal skeletons in elite tombs appear to be from the lowland Maya area, rather than central Mexico (Wright et al., 2010), as was suggested by archaeologists. Studies of large urban communities such as Rome (Prowse et al., 2007), Roman Winchester (Eckardt et al., 2009), Tombos in Egypt (Buzon and Bowen, 2010), and Tikal (Wright, 2012) have identified a considerable proportion of migrants, suggesting that immigration contributed to population growth of these states.

Oxygen isotope values are not unique to individual sites, and numerous locales may share equivalent values. Therefore, stable oxygen isotope analysis is most useful in identifying migrants from very distant environmental contexts that differ substantially in climate. For instance, recent studies have sought to identify African slaves (migrants) in Mexico (Price et al., 2012), Vikings in Ireland (Knudson et al., 2012b), etc. The strength of these interpretations is greatly improved by combining several isotopic methods, including stable strontium, carbon, nitrogen, lead, and sulfur isotopes (see, e.g., Turner et al., 2009; Oelze et al., 2012; Laffoon et al., 2013).

Breastfeeding and cultural practices

Teeth also provide the advantage of registering body water isotopic composition for a limited span of development, unlike bone, which is continually reworked by remodeling systems with osteoclast cells that tunnel through bone and osteoblast cells that rebuild it. While bone isotopes are biased in reflecting the ages of late adolescence when the skeleton reaches its maximal size (Hedges et al., 2007), bones also incorporate food and water consumed throughout life. Tooth enamel is not remodeled after it is deposited, and it retains the isotopic composition of childhood water intake, when it mineralized. Body water is enriched in ^{18}O when compared to drinking water; thus nursing infants show higher body water δ^{18}O than their mothers (Roberts et al., 1988). This principle explains the higher δ^{18}O signature of teeth that form early in postnatal life when infants are nursing, such as permanent first molars, as compared to teeth that form during older childhood (Wright and Schwarcz, 1998).

Because the duration of nursing is highly variable, both within and among cultures, as are the complementary feeding practices for older infants (Dettwyler and Fishman, 1992), δ^{18}O analyses of teeth provide a means to explore nursing duration in the past. Among the Maya, $\delta^{18}O$ differences among teeth suggest that children may have nursed to more than 5 years of age (Wright and Schwarcz, 1998). Oxygen isotopes have also been used to study nursing in Roman skeletons (Dupras and Tocheri, 2007). This nursing effect should also be kept in mind when selecting teeth as samples for migration studies, since $\delta^{18}O$ may even vary within a single tooth crown due to a change in nursing behavior (Wright, 2013).

Beyond breastfeeding, little research has yet been done on the effect of other cultural practices on $\delta^{18}O$ in humans. Daux et al. (2008) have shown that $\delta^{18}O$ of cooked food is higher than that of local drinking water due to evaporative enrichment. Social variability in access to water sources and water storage methods might introduce some variability in $\delta^{18}O$, especially in complex societies, where restricted access to certain water reservoirs or socially distinct culinary practices might distinguish status groups.

Because the teeth of many mammals grow for extended periods of time, they contain a record of seasonal changes in animal body water $\delta^{18}O$. This has been exploited to investigate seasonal hunting and fishing practices (Hufthammer et al., 2010), as well as the management of domestic sheep herds (Henton et al., 2010; Blaise and Balasse, 2011). Where pastoralists were involved in long distance trade, $\delta^{18}O$ may shed light on the geographic origin of mobile animals, as in the case of Andean camelids (Knudson et al., 2012a).

The rate of research on $\delta^{18}O$ in both human and faunal samples from archaeological sites has increased exponentially over the last decade. New analytic methods and applications make this an exciting and very promising field of study.

Definition

Paleodemography refers to the description and explanation of biological adaptations, mortality, fertility, and migratory patterns of prehistoric populations, within the explanatory framework of evolutionary theory. Traditionally, paleodemography relied on morphological studies of bioarchaeological (bone material) evidence, although in recent years it has also been based on DNA and stable isotope evidence as well.

Introduction

Paleodemography is concerned with the impact of cultural and environmental change on the lives of past peoples. Once the preserve of paleontologists, anthropologists, and archaeologists, it now attracts biologists, geneticists, bioinformaticians, and chemists with fresh methods and perspectives that have made this field an exciting multidisciplinary endeavor. Knowledge of past human populations traditionally came from studying human osteological remains from archaeological contexts. The primary concern was the description and characterization of biological differences, and where temporal differences in skeletal morphology were found, these were interpreted in terms of migration and replacement. For example, the indigenous people of Tierra del Fuego (at the southern tip of South America) show a robust morphology, substantially different from the gracile morphology of other Amerindians. While this was initially interpreted as the result of the Fuegians belonging to an earlier migration into the continent (Lahr, 1995), other studies suggested that their morphology may reflect local adaptation to hard diets and extreme climate or long-term population isolation (Bernal et al., 2006). Further studies involving genetic analyses have now concluded that Fuegians and Amerindians share a common ancestry and come from the same migration that populated the rest of the Southern Cone (Perez et al., 2007, Perez et al., 2009). This example highlights how modern disciplines and new methodologies, such as genetics, can inform and change traditional paradigms in paleodemographic studies.

The first part of this review highlights the general methodological issues linked to paleodemographic studies (including the contribution of modern approaches such as genetics and isotope analyses); the second part discusses some of paleodemography's current topics.

Methods in paleodemography: issues and current advances

Sources of paleodemographic data: bioarchaeological material and preservation issues.

Our ability to reconstruct the life and lifestyle of past populations depends largely on the quantity and quality of the recovered archaeological finds. Biological material of paleodemographic interest is often not well preserved in archaeological sites. Hard tissue (primarily bone) is most commonly recovered, but, occasionally, soft (mummified) tissue can also be preserved, providing further opportunities for analysis. Other valuable sources in paleodemographic studies include hair and coprolites (fossilized feces). The information obtained from these different sources at the macroscopic, microscopic, and molecular levels provides alternative, and often

complementary, insights into the mobility, diet, social organization, environmental interactions, and biological adaptations of past people.

Skeletal material

Bone is the main source of biological material that is found within archaeological sites, as it has better chances of preservation than soft tissue. The amount and type of information that can be retrieved from the skeleton directly correlates with the sample's state of preservation. It is essential, therefore, to understand the chemical, physical, or biological changes that affect skeletal material in a burial context because they can introduce biases into the archaeological record that impact upon the analysis and interpretation of the data.

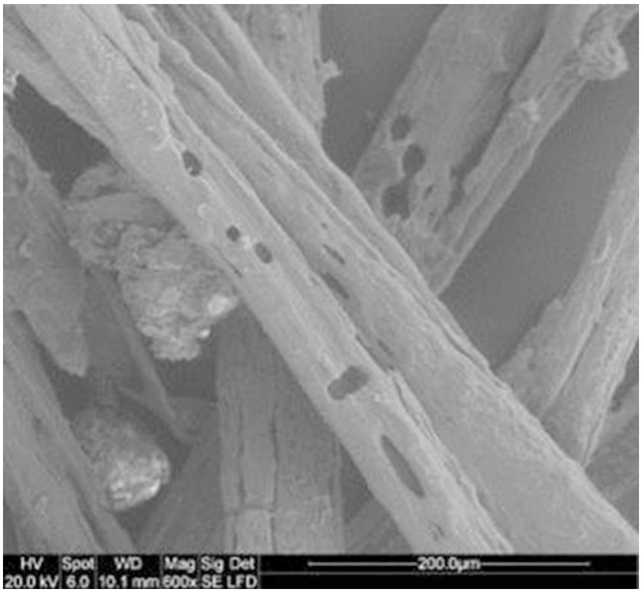
Bone (Figure 1) is a composite of mineral (mostly hydroxyapatite, a calcium phosphate complex) and protein (mostly collagen). Bone deteriorates through one or more of the following processes: (1) bacterial and fungal decay, (2) chemical loss of collagen, and (3) dissolution of the mineral phase. Bacterial decay is the most common and probably occurs early, when initial bone demineralization (due to soil pH, temperature, exposure to water, etc.) allows bacteria to access the collagen and initiate focal destruction (Collins et al., 2002). Bacterial degradation significantly affects bone preservation, increasing bone porosity and accelerating the demineralization process, thereby reducing the chances of collagen preservation and increasing the risk of contamination with exogenous biomolecules (Jans et al., 2004). Collagen loss occurs by hydrolysis or microbial attack (Hedges, 2002); the rate of degradation is time, pH, and temperature dependent (Collins et al., 2002). Broadly speaking, high temperatures and extreme pH accelerate collagen loss, and this alone can explain preservation differences among different archaeological sites (Hedges, 2002). Exposure to water plays an important role in the dissolution of the hydroxyapatite, which then exposes the collagen to bacterial degradation and hydrolysis, thus increasing crystallization and accelerating the fossilization process (Collins et al., 2002). Bones lying near water will also be more susceptible to solute uptake from the soil (e.g., uranium, carbon, and strontium), which greatly affects radiocarbon and isotopic analyses.

Hair

Hair is the most robust nonskeletal material of archaeological interest. Its strong molecular structure comes from high levels of keratin, a protein that constitutes the bulk of the fiber and is highly resistant to enzymatic attack, except by some specialized microorganisms (Kunert, 1989). The keratin coating also renders the hair insoluble in water and resistant to acids and alkali (Taylor et al., 1995). However, despite its relative robustness, hair can deteriorate rapidly. Although the process by which deterioration takes place is poorly understood, the main factor appears to be bacterial attack (Wilson et al., 2007, Wilson et al., 2010), though certain fungi can also degrade keratin, leaving characteristic tunnel-shaped lesions (DeGaetano et al., 1992) (Figure 2).

Coprolites

Coprolites are desiccated or mineralized feces, usually preserved in arid and temperate regions, which contain a variety of macroscopic and microscopic remains such as fibers, plant and animal residues, phytoliths, intestinal parasites, and pathogens, thereby providing information about health and lifestyle. Coprolites have not been extensively used in archaeological research, mainly due to the apparent lack of consensus in the way data are reported, making comparative analyses difficult (Bryant and Dean, 2006). Other limitations with its use are the usually small sample size, dependency on context, difficulties in associating particular coprolites with a species, and the risk of contamination through leaching. Moreover, coprolites are easily repositioned, making their stratigraphic context



Paleodemography: Methods and Recent Advances, Figure 2 Electron microscopy image (600× magnification) of hair shaft showing damage by fungal tunneling (Reproduced from (Bengtsson et al., 2011)).

less reliable. Even when animal or plant residues are detected, dietary extrapolations are complicated by issues of seasonality, quantity of food consumed, or eating patterns (Bryant and Dean, 2006). Macroscopic or microscopic inspection is often insufficient to distinguish human from nonhuman coprolites, but DNA recovered from coprolites can help with species identification (Reinhard and Bryant, 1992; Goldberg et al., 2009). However, leaching and contamination with DNA from other sources remains a major consideration; a recent study claiming to have recovered DNA from a human coprolite predating the Clovis occupation of the Americas acknowledged the possibility that the DNA could have come from later human populations and leached into a nonhuman coprolite (Gilbert et al., 2008).

Paleodemographic information at three levels of analysis: morphological, microscopic, and molecular.

Bioarchaeological material can provide invaluable information about past human populations, but issues of preservation and contamination must be considered carefully. Analyzing the samples at three levels reduces risk and provides complementary data.

Morphological analysis

Quantitative morphometric analyses have been the conventional approach to the study of bioarchaeological samples, providing information about sex, ancestry, health, diet, and adaptations. Traditional morphometry consists in applying multivariate statistical procedures to datasets of two-dimensional distances, angles, or distance ratios of anatomical structures. More recently, three-dimensional geometric morphometric methods using Cartesian coordinates have provided more robust results, as they preserve spatial information (Slice, 2007). Sometimes, morphometrics is the only way to analyze skeletal material – particularly when the sample's age or preservation precludes molecular studies – and it is used in determining paleodemographic parameters such as sex and age. Sexing relies on measurements of sexually dimorphic skeletal elements, typically the pelvis and skull (Scheuer, 2002), although long bones can also be highly informative (Özer and Katayama, 2008). Sexual dimorphism results from differential growth rates during adolescence and is largely genetic, though the effect of the environment (e.g., malnutrition and illness) is also considerable. Consequently, sexing a skeleton solely on size measures is often problematic (Meindl and Russell, 1998). Determining age at death relies on the skeleton's developmental characteristics (dentition patterns, bone size, shape, and degree of ossification), which are more accurately determined in the still-growing juvenile skeleton, while in the adult skeleton, age determination relies on measures of bone degeneration, though these can be affected by health and lifestyle factors (Franklin, 2010).

Morphological traits display a high degree of population variation, which represents a significant confounding factor when determining the age and sex of a skeleton. However, this variation has traditionally been used to determine ancestry, prehistoric migrations, and population continuity, particularly of extinct populations where DNA analysis is not possible. Regional differences of cranial and dental morphology have been used to understand the relationship between the Paleolithic inhabitants of Japan (the Jomon), the Neolithic farmers (the Yayoi), and the present-day Japanese (Ishida et al., 2009), whereas limb proportions have been used to understand the extent of climatic adaptations in the same populations (Temple et al., 2008), as interpopulation variation in the skeleton is also heavily influenced by the environment (Katzmarzyk and Leonard, 1998). Tooth morphology is closely linked to genetic background and geographical origins, and population affinities can therefore be tracked using dental anthropology. For example, differences of incidence of root and canal number in human populations have been suggested, with higher incidences of teeth with additional canals and roots occurring in Chinese, Australian, and sub-Saharan African populations and the lowest incidence in Western Eurasian, Japanese, and American Arctic populations (Cleghorn et al., 2007). Moreover, a recent study analyzing nine crown morphology traits in four contemporary Kenyan populations has suggested a strong correlation between dental morphology and genetic structure (Hubbard et al., 2015). In this study, the closest genetic and dental affinities were observed between population samples within each ethnic group and the greater divergence among samples from the different ethnic groups.

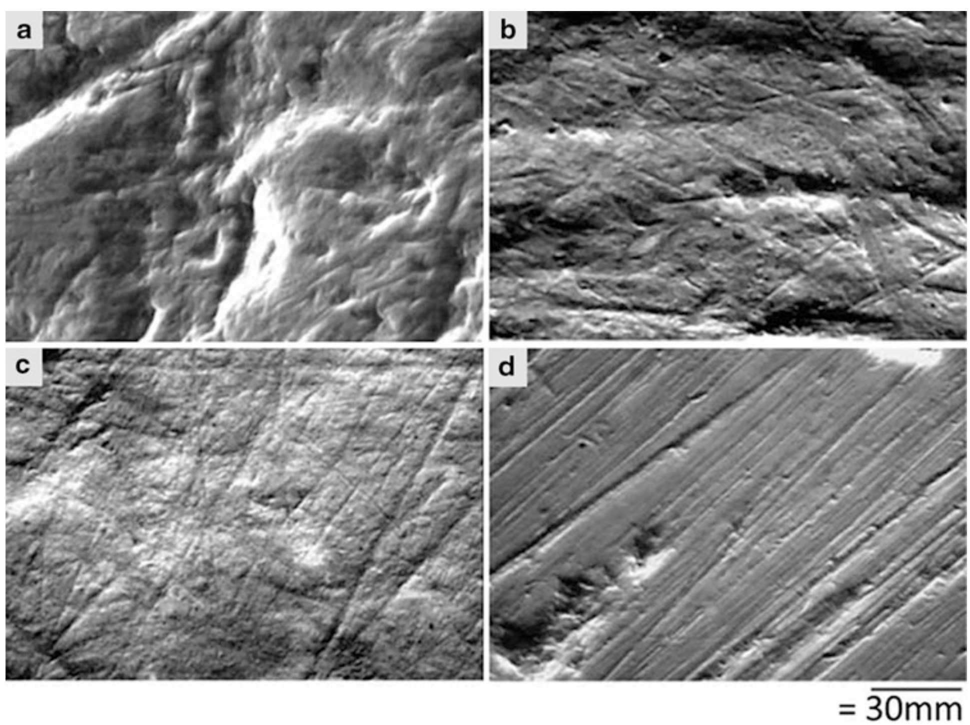
Microscopic analysis

Microscopic analysis of bone and dental structures, coprolites, and hair is routinely used alongside morphometric and other techniques to provide complementary information about diet, age, paleopathology, etc. For example, while macroscopic inspection of tooth size, allometry, and enamel thickness can indicate the mechanical properties and kind of foods a species is capable of eating, microwear patterns can reveal actual food preferences and/or consumption. Species that consume hard, brittle foods tend to show more pitting in their teeth, while those whose diet comprises hard leaves tend to present more striations (Figure 3). In fact, dental microwear in early *Homo* suggests that *H. erectus* may have consumed more hard and brittle foods than *H. habilis* (Ungar et al., 2006). An understanding of food preference in these early species has obvious implications for understanding the evolution of the genus *Homo*, including *H. sapiens*, which traditionally has been tied to changes in diet and environment.

Pathological conditions from archaeological bones are usually determined microscopically, though this is far from straightforward. In the case of tuberculosis (TB), a major infectious disease, determination relies on the presence of characteristic microscopic bone lesions, particularly in the vertebrae. However, only 5 % of TB sufferers develop bone tissue destruction, making this diagnostic marker unreliable, particularly given that in the pre-antibiotic era, infectious diseases such as TB were probably endemic (Donoghue et al., 2009). Parasitic remains provide direct evidence of diseases, animal and human migrations, diet, sanitation habits, etc. (Dittmar, 2009). These are also hard to determine microscopically because they are rarely preserved (particularly endoparasites). Parasites are more commonly found in feces or hair, and nowadays their presence and composition are more effectively determined by DNA analyses.

Molecular analysis

Emerging molecular methodologies provide powerful new tools, successfully used across the various subfields of paleodemographic research. These are not infallible; on the contrary, their high power of discrimination can be their main setback, because the sensitivity of the techniques can amplify any contamination. Nevertheless, molecular methods promise to fill important gaps in paleodemographic studies. This review considers only two of the current molecular approaches, isotope and DNA analysis of ancient human remains (ancient DNA or aDNA), which are the most widely used molecular techniques in bioarchaeology.



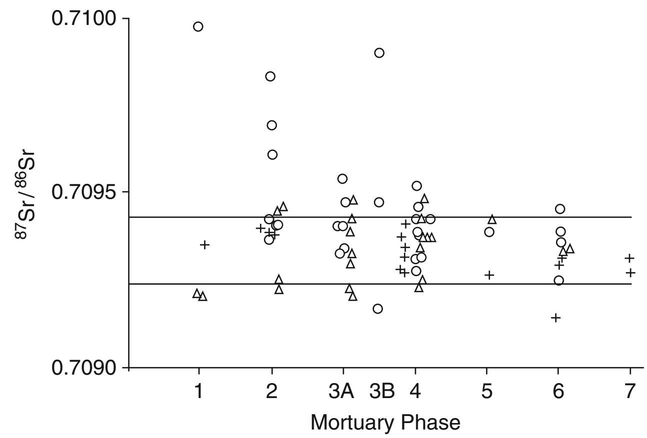
Paleodemography: Methods and Recent Advances, Figure 3 A comparison of dental microwear. (**a**) Gray-cheeked mangabey (*Lophocebus albigena*) of Central Africa; (**b**) *H. erectus*; (**c**) *H. habilis*; (**d**) *Gorilla gorilla*. Note the size and number of pits in these four species. Larger pits (as in **a** and **b**) are indicative of a diet composed predominantly of hard but brittle foods, while smaller pits and more striations (as in **c** and **d**) are suggestive of a diet comprising mostly tough leaves or stems (Reproduced from (Ungar et al., 2006)).

Isotope analysis

Many common elements (such as carbon, hydrogen, strontium) occur with different atomic masses, and these variants are called isotopes. For example, carbon (C) has three naturally occurring forms, ^{12}C, ^{13}C, and ^{14}C, whereas nitrogen (N) has two, ^{14}N and ^{15}N. Isotopic signatures are the ratio of stable isotopes in a particular material. Signatures of light isotopes, such as C and N, are mainly influenced by reaction rates (the speed at which isotopes form and break chemical bonds), whereas that of heavy isotopes, such as strontium (Sr), are primarily influenced by the substrate (the source of the isotope, e.g., foods or minerals in the water consumed by the organism) (Schoeninger, 1995). Isotopic signatures can be studied in a variety of archaeological material such as bone and dentine collagen, bone mineral and enamel, hair, nails, organic residues in artifacts (pottery, stone tools, etc.), and coprolites, providing information about different processes. For example, enamel and dentine are formed in childhood and adolescence and do not remodel during adulthood; thus their isotopic signatures reflect these early periods and can determine where people may have been born and spent most of their childhood. Conversely, bone has a regular turnover, and isotopic signatures reflect a -long-term average that can inform deductions about diet and behavior. Hair has a very rapid turnover, and so its isotope signatures may reflect the environment at the time of death, whereas isotopes in coprolites can provide evidence of foods consumed in a particular season.

The largest source of carbon isotope variability occurs in plants and primary consumers (herbivores). Land plants fix atmospheric ^{12}C with differing efficiency depending on the enzymatic pathway used for carboxylation, thus resulting in different $^{13}C/^{12}C$ ratios. These ratios are then reflected in the tissues of the consumers (animals and humans) and are therefore indicative of food consumption (Lee-Thorpe, 2008). The main source of $^{13}C/^{12}C$ in archaeological material is bone collagen and enamel, with the former used primarily for dietary determinations. $^{13}C/^{12}C$ signatures have been particularly useful in understanding patterns of resource utilization in hominin species, likely associated with adaptations for a more versatile subsistence strategy that gave them an advantage during climatic changes and habitat diversification in the late Pliocene (Lee-Thorpe, 2008).

Nitrogen enters the food chain either through bacterial degradation of organic material in the soil or through nitrogen-fixing bacteria in root nodules (e.g., legumes). These plants have higher relative content of ^{15}N. There is a stepwise enrichment of ^{15}N in each trophic level, probably due to inefficient excretion of ^{15}N (Schoeninger, 1995). Therefore, the higher an organism is in the food chain, the higher their $^{15}N/^{14}N$ ratio, with carnivores (secondary and tertiary consumers) presenting the highest values. Marine organisms have higher ^{15}N content than terrestrial organisms, which can be reflected in the isotopic signatures of individuals with a predominantly marine diet.



Paleodemography: Methods and Recent Advances, Figure 4 Sr signatures from remains of seven mortuary phases spanning 500 years at the archaeological site of Khok Phanom Di (Thailand). *Horizontal lines* delimit the local Sr values, which lie between 0.7092 and 0.7094. Note that the early phases are characterized by overrepresentation of nonlocal women (*circles*), who show ratios well above 0.7095, whereas men (*triangles*) and *crosses* (infants) are mostly local, suggesting a pattern of patrilocality at this site (Redrawn from (Bentley et al., 2007)).

Strontium differs from nitrogen and carbon in that it is a highly stable heavy isotope, with a signature that reflects its source. Different rocks contain different levels of ^{87}Sr which enters the food chain through the water and rock minerals absorbed by plants. There is no stepwise enrichment of ^{87}Sr; hence the relative $^{87}Sr/^{86}Sr$ ratios in the skeleton primarily reflect the geographic environment from which the organism has taken the Sr (groundwater and/or local vegetation), therefore making it useful for geographic provenancing. As skeletal tissue remodels through life, $^{87}Sr/^{86}Sr$ signatures reflect a lifetime average of the individual's geographic residence (Figure 4). Tooth enamel, which forms during infancy, does not remodel; hence $^{87}Sr/^{86}Sr$ values reflect the geographic environment during childhood.

aDNA analysis

Methodological advances in the last decades have enabled the successful recovery of DNA from preserved skeletal remains, plants and animals, mummified tissue, coprolites, hair, and even sediments and permafrost. The extraction of aDNA (or ancient DNA) from bioarchaeological material involves the use of invasive techniques, so careful cost-benefit analysis must always be conducted to avoid the unnecessary destruction of unique material. It is generally accepted that DNA preservation is considerably poorer in temperate environments compared with very cold regions; thus, the chances of successfully obtaining DNA sequences from specimens from these regions are considerably reduced and would require more extensive destruction, as a larger sample would be needed to achieve successful DNA extraction.

The advent of next-generation sequencing (NGS) has contributed further, enabling us to overcome some of the early limitations of aDNA research, namely, the small amount of DNA surviving in bioarchaeological material, but it has also brought fresh difficulties (e.g., the high potential for contamination with DNA from modern sources). Contamination with modern DNA has led to some spectacular claims, famously the multiregional origin of modern humans based on putatively aDNA sequences from the 50,000-year-old skeleton from Lake Mungo, Australia (Adcock et al., 2001) and, more recently, the claim that up to 30 % of the human genome is shared with Neanderthals, thus supporting the view that modern humans and Neanderthals interbred (Green et al., 2006). Nowadays, stringent protocols to avoid contamination are in place and, in most cases, are a prerequisite for publication (Gilbert et al., 2005).

Despite the issues of preservation and contamination, aDNA has extraordinary potential to elucidate past population history, probably more than any other methodology. The distribution of human genetic variation shows a striking geographic structure at the continental level, and provided that sufficient DNA variants are tested, it is possible to infer ancestry and ethnic relatedness with a high degree of accuracy. However, this is less true at the microgeographic scale, as migrations and admixture at the local level tend to blur genetic signatures. Therefore, genetic analyses of human remains can be valuable for inferring broad patterns of migrations.

aDNA analysis is often the only way to elucidate phylogenetic relationships between extant and extinct groups, particularly when osteological material is insufficient for morphological studies. Two genetic studies conducted on a phalanx from an unknown female hominin group discovered at the Denisova Cave in Southern Siberia revealed that the bone belonged to a new hominin group that shares a common ancestor with modern humans and Neanderthals and diverged about 1 million years ago, thus suggesting a migration out of Africa different from that of the ancestors of modern humans and Neanderthals (Krause et al., 2010; Reich et al., 2010). The finger bone had been found in a stratum containing both Middle and Upper Paleolithic elements and had been radiocarbon dated to approximately 41,000 years ago, but both the morphology and the stratigraphy were difficult to interpret.

Some current topics in paleodemography

The peopling of the Americas

America is one of the last frontiers of human dispersal out of Africa, but the details of the initial settlement are poorly understood. Competing hypotheses regarding the routes and times of human dispersals throughout the continent have been discussed, each with broad implications for the evolution of human diversity over the last 15,000 years.

Early archaeological evidence from a number of sites in North America pointed to the Clovis culture as the first inhabitants of the continent, approximately 11,000 years ago (or 11 ka) (Waters and Stafford, 2007). Several sites in South America consistently yield radiocarbon dates just prior to 11 ka, proving the presence of humans in the Southern Cone before the first North American Clovis sites (Steele and Politis, 2009). Evidence of pre-Clovis settlement is not limited to South America; radiocarbon dating and DNA evidence from a human coprolite in the USA also suggested human presence in North America before 12 ka (Gilbert et al., 2008). The expansion of the Clovis culture, therefore, was probably the result of a second migration that may have erased the signature of the first dispersal from the archaeological record (Fiedel, 2000). This two-wave scenario is now supported by genetic data (Fagundes et al., 2008; Hellenthal et al., 2008; Perego et al., 2009), analyses of human cranial morphology (Hubbe et al., 2010), and radiocarbon dating of charcoal and cut-marked animal bones (Steele and Politis, 2009).

The last glacial period exposed a land bridge between Northeast Asia and Alaska (Beringia), allowing the first Americans to move eastward from Asia. The dispersal may have halted in Beringia, where the gene pool accumulated American-specific DNA mutations (Tamm et al., 2007). The Beringian incubation occurred around 23–19 ka (Fagundes et al., 2008) or 21–18 ka (Achilli et al., 2008).

After the glacial maximum (18 ka), only two routes from Beringia to the Americas appear possible: (1) an early coastal route along the Pacific coast or (2) a later inland corridor between continental glaciers. Mitochondrial DNA (mtDNA) evidence indicates a first migration along the coast approximately 18–15 ka (Fagundes et al., 2008) and a later migration through the newly opened ice-free corridor. The Pacific coastal route hypothesis remained controversial due to a lack of archaeological evidence until the discovery of several drowned archaeological sites just below the Pacific shoreline, radiocarbon dated to 13–9.5 ka (Fedje and Christensen, 1999).

Neolithic expansions and the beginnings of agriculture

The beginning of the Holocene was marked by profound climatic changes leading to the spread of plants and animals, sea level rise, reshaping of landmasses, etc., that provided new opportunities for human adaptation. The human response to ecological change was probably the transition from nomadism to sedentism and the development of farming. This then allowed population growth and expansion, both demic and cultural.

It has long been debated whether the spread of agriculture to Europe from its center of origin in Southwest Asia was merely a cultural process or was mediated by significant migrations. Early studies suggested a clinal distribution of human blood group frequencies, explained in terms of demic diffusion from the Near East (Ammerman and Cavalli-Sforza, 1984), whereas studies of extant European mtDNA lineages (reflecting their maternal ancestry) suggested a predominant Paleolithic component in the gene pool of Europeans, thus dismissing any significant contribution from Neolithic migrations (Richards et al., 2000; Richards and Macaulay, 2000). Later studies of mtDNA from ancient remains showed different lineage frequencies between Neolithic and modern Europeans, supporting the idea of a limited contribution of Neolithic farmers to the genetic pool of extant Europeans. However, a recent study on craniometric diversity suggested that Mesolithic and Neolithic populations are substantially differentiated and skull variation best fits a model of continuous dispersal from Southwest Asia (Pinhasi and von Cramon-Taubadel, 2009). Studies of European Y chromosomes (reflecting the paternal ancestry) have also suggested a significant contribution of Near Eastern lineages and stressed the unique role of male-mediated migrations during the Neolithic transition (Balaresque et al., 2010). Moreover, Sr isotopic signatures paint a more complex picture of patrilocality and indigenous adoption of agriculture following a single Neolithic colonization (Bentley et al., 2002). These studies illustrate both the complexity of European paleodemography and the benefits of an integrated multidisciplinary approach in gaining a fuller picture of the past.

Summary

Few fields of enquiry match the recent expansion and progress of paleodemographic studies, made possible by methodological advances and the contribution of emergent disciplines, such as aDNA, that have turned the field into a truly multidisciplinary endeavor. Despite the inherent limitations of preservation and contamination, bioarchaeological material is more than ever open to enquiry, and there is a growing sense that in years to come, new breakthroughs will fill important gaps in the understanding of our human past.

PALEODIET

Judith Sealy
Department of Archaeology, University of Cape Town, Rondebosch, Cape Town, South Africa

Synonyms

Paleonutrition

Definition

Ancient foodways reconstructed using various avenues of archaeological evidence, including artifacts, anatomical features, and the chemical composition of remains.

Introduction

In recent decades, studies of human and animal paleodiet have become increasingly important across a timescale ranging from the recent past (forensics and historical archaeology) to deep time (paleontology). This entry will summarize biogeochemical approaches to reconstructing paleodiet. Other approaches include studies of tooth shape, size, structure, and wear (e.g., Ungar, 2011, and references therein) and identification of food refuse from living sites, especially in archaeology. The best understanding of paleodiet usually comes from combining as many different types of evidence as possible.

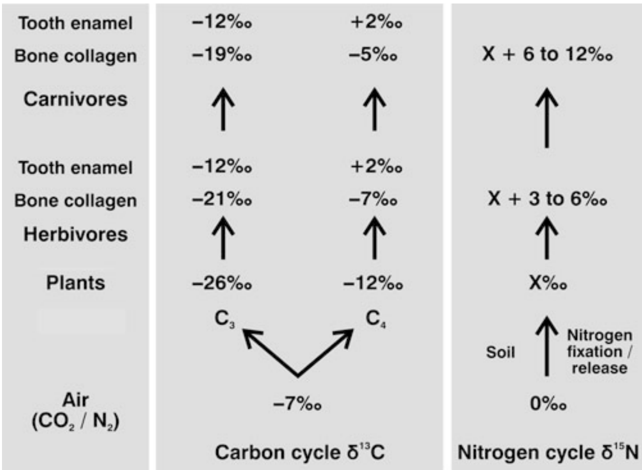
Basic principles

Biogeochemical studies of paleodiet involve stable isotope and/or trace element measurements of preserved tissues in order to reconstruct diet during life. Stable isotope approaches are based on the ratio of the (less common) heavier isotope to the (more common) lighter isotope, for example, $^{13}C/^{12}C$. While the amount of carbon and its structural position within any living tissue is tightly controlled, the ratio of ^{13}C to ^{12}C varies according to the diet consumed in life. For successful biogeochemical studies, there are two necessary preconditions: (i) the isotopes or trace elements in question must be differentially distributed across different categories of foods in ways that we understand, and (ii) the tissues being analyzed must retain their original composition. The first criterion is relatively well met for stable carbon isotopes ($^{13}C/^{12}C$), rather less so for $^{15}N/^{14}N$, $^{18}O/^{16}O$ (in paleodiet studies), $^{34}S/^{32}S$, and $^{2}H/^{1}H$. Trace element distributions in nature are very variable; for paleodietary purposes, the most useful are probably Sr and Ba, which may substitute for Ca in the mineral lattices of calcified tissues such as bones and teeth (Brown, 1974; Schoeninger, 1979; Sillen and Kavanagh, 1982; Burton et al., 1999).

Stable isotope ratios are reported as δ values relative to an internationally accepted standard: $\delta^{H}X = (R_{sample}/R_{reference} - 1) \times 1000$ where H is the mass of the heavier isotope, X may be the elements C, N, O, H, S, etc., and R is the ratio $^{13}C/^{12}C$, $^{15}N/^{14}N$, $^{18}O/^{16}O$, $^{2}H/^{1}H$ (also referred to as D/H, or deuterium/hydrogen), or $^{34}S/^{32}S$. The units are parts per thousand or per mille (‰). The standard material for carbon isotopes is the marine limestone PDB – or the Pee Dee Belemnite, a Cretaceous deposit in South Carolina composed largely of the fossil cephalopod *Belemnitella americana*. For oxygen and hydrogen isotopes, the standard may be PDB or Standard Mean Ocean Water (SMOW). For nitrogen isotopes, the international standard is atmospheric nitrogen, or Ambient Inhalable Reservoir (AIR), and for sulfur isotopes it is the iron sulfide troilite of the Canyon Diablo meteorites (CDT), which are fragments of the meteor that created the Barringer Crater in Arizona. Negative values show that the sample contains less of the heavy isotope than does the standard, while positive values indicate more of the heavy isotope (Sharp, 2007; Hoefs, 2009).

Isotopic discrimination during photosynthesis forms the basis of variation in the proportions of carbon isotopes in living organisms. Atmospheric carbon dioxide contains mostly $^{12}CO_2$, with approximately 1 % $^{13}CO_2$. $\delta^{13}C_{atmosphere}$ in preindustrial times was approximately −6.5 ‰; it is currently around −8 ‰ and becoming more negative due to the combustion of fossil fuels (Friedli et al., 1986; Trudinger et al., 2002). $^{12}CO_2$ molecules dissolve more readily in moisture on the surfaces of leaves and diffuse more easily through plant stomata than larger, heavier $^{13}CO_2$. In addition, the photosynthetic enzyme RUBISCO strongly favors $^{12}CO_2$, leading to the formation of plant tissue that has more ^{12}C and less ^{13}C than atmospheric carbon dioxide; such a shift in isotope ratio is called "fractionation." Plants that photosynthesize using the C_3 or Calvin-Benson pathway have $\delta^{13}C$ values of about −27 ‰, those using the C_4 or Hatch-Slack pathway have values around −13 ‰ (O'Leary, 1988; Cerling et al., 1997). Most C_4 plants are tropical grasses, so low-latitude grasslands are C_4-dominated ecosystems. The economically important tropical grasses maize, sugarcane, sorghum, and millet are also C_4, and when introduced as crop plants into areas that are otherwise C_3, their contribution to the food chain can readily be identified (Vogel and van der Merwe, 1977; van der Merwe and Vogel, 1978; Buikstra and Milner, 1991). Plants in temperate regions and high-altitude environments are C_3, as are wheat, barley, oats, rice, nearly all trees and shrubs, and fruits and vegetables. (There are a few exceptions, particularly succulent plants such as prickly pears and pineapples, but these are sufficiently unusual that they need not receive detailed discussion here.)

The isotopic composition of animals and humans derives from the food they have eaten. There is some further partitioning of isotopes within the body, for example, much ingested ^{12}C is respired as CO_2 while a relatively greater proportion of ^{13}C is used to synthesize muscle, bones, and teeth. Figure 1 shows some average values as one moves along a food chain. Note that different body tissues have different $\delta^{13}C$ values: the two tissues most frequently used in paleodietary studies are bone collagen and tooth enamel.



Paleodiet, Figure 1 Approximate values for $\delta^{13}C$ and $\delta^{15}N$ in typical food chains. Note that the concentration and isotope ratio of atmospheric CO_2 depends upon the global carbon cycle. Values at the Last Glacial Maximum (about 26.5 to 19 ka) differed from those of the Holocene (Leuenberger et al., 1992) with more substantial shifts in deeper time (Zachos et al., 2001). Adapted from Figure 3 in Lee-Thorp and Sponheimer (2006), using a value of +14‰ for the isotopic spacing between diet and herbivore tooth enamel (Cerling and Harris, 1999; Passey et al., 2005). $\delta^{15}N$ values of plants are very variable (depending on nitrogen in the soil), and hence they are represented by X.

The same basic principles apply to other stable isotopes: in most chemical reactions the lighter isotope is preferred for energetic reasons, leading to isotopic fractionation. The degree of fractionation is the highest for $^2H/^1H$, where the mass difference between the isotope pair is greatest. $\delta^{15}N$ increases by 3–6‰ in consumers compared with their food, making it useful as a trophic level indicator (Schoeninger et al., 1983; Hedges and Reynard, 2007). $\delta^{34}S$ shows little stepwise fractionation along food chains, but there are significant differences between marine and most terrestrial and/or freshwater environments. Hoefs (2009) and Sharp (2007) provide excellent overviews of the distributions of stable isotopes in various geochemical reservoirs. Fry (2006) and chapters in Michener and Lajtha (2007), especially Koch (2007), discuss stable isotopes in life sciences and ecology.

Issues to keep in mind

Much early paleodietary work (in the 1970s and 1980s) attempted to use trace element concentrations in bones and teeth to reconstruct foods consumed in life. Researchers came to realize, however, that the distribution of many trace elements is not as predictable as was initially thought, and that metabolic control over which components of food are incorporated into body tissues frequently makes it difficult or impossible to identify meaningful paleodietary signals in trace element profiles of calcified tissues. Postdepositional contamination or "diagenesis" is also a serious problem, especially in bone and dentin. Tooth enamel, which is a much denser material, is less affected by postdepositional processes. In certain situations, diagenetic trace element signals can contribute valuable information, for example, to distinguish components of mixed ex situ fossil assemblages with different taphonomic histories.

Diagenesis can be a problem in stable isotope studies, too. In relatively well-preserved material, the analytical tissue of choice is usually collagen, the major structural protein of bone. Collagen contains carbon and nitrogen, enabling measurement of $\delta^{13}C$ and $\delta^{15}N$, also $\delta^{34}S$, $\delta^{18}O$, and $\delta^{2}H$ (although the last three have been much less studied). Collagen extraction has been extensively researched in relation to radiocarbon dating, which is much more sensitive to contamination than stable isotope analysis. Collagen molecules consist of three protein chains wound together in a triple helix; if this structure is preserved, isotopic integrity is likely to have been maintained (van Klinken, 1999). In old or poorly preserved materials, especially those from tropical environments, collagen may have decayed. It is possible to measure $\delta^{13}C$ and $\delta^{18}O$ in the small amounts of carbonate incorporated into bone apatite, but diagenesis in bone apatite can be difficult to detect and mitigate. In the absence of collagen, most researchers now prefer to analyze tooth enamel (composed mostly of apatite), which can preserve its original ("biogenic") composition over millions of years (Ayliffe et al., 1994; Wang and Cerling, 1994; Koch et al., 1997; Lee-Thorp, 2002, 2008).

Collagen is a protein, and carbon atoms in collagen tend to derive mainly from protein foods in the diet. $\delta^{13}C_{collagen}$ therefore tracks primarily protein foods, while dietary fats and carbohydrates are under-represented (Ambrose and Norr, 1993; Tieszen and Fagre, 1993; Howland et al., 2003; Jim et al., 2004). Carbonate in apatite, on the other hand, is formed from blood bicarbonate. Since most ingested carbon is converted into blood bicarbonate, $\delta^{13}C_{bone\ apatite}$ is a better indicator of total diet than $\delta^{13}C_{collagen}$, as long as the diagenetic issues mentioned above can be dealt with. Analysis of both $\delta^{13}C_{collagen}$ and $\delta^{13}C_{bone\ apatite}$ can reveal added dimensions of foods consumed, especially if diets were isotopically heterogeneous. Ambrose et al. (1997) showed that in human skeletons from the Marianas, $\delta^{13}C_{bone\ apatite}$ reflected consumption of sugarcane that was invisible in $\delta^{13}C_{collagen}$. Bone apatite and tooth enamel both derive from blood bicarbonate, and until recently, most studies have assumed that $\delta^{13}C_{bone\ apatite}$ and $\delta^{13}C_{tooth\ enamel}$ are equivalent. We now know that this is not the case (Warinner and Tuross, 2009; Loftus and Sealy, 2012), but the reasons are not obvious. The problem is most acute for $\delta^{13}C$ since carbon may originate from different nutrients, whereas in higher organisms, nitrogen is incorporated mostly from protein. Researchers have not yet begun to consider this issue for other isotopes.

One of the original goals of isotopic and trace element studies of diet was to achieve precise quantitative reconstructions of foods eaten. Ecologists use mixing models for this purpose, whereby n isotopic indicators in the tissues of a consumer are used to calculate proportions of n + 1 isotopically different food sources (Phillips, 2001; Phillips and Koch, 2002; Phillips et al., 2005). For example, measurement of $\delta^{13}C$ and $\delta^{15}N$ in bone collagen can enable three categories of foods to be distinguished. This approach assumes that all foods contribute equally to the tissues being analyzed: an assumption that we know is not valid for carbon. In some situations, this may not matter much; in others (e.g., Ambrose et al., 1997), it renders this approach invalid.

It should be remembered that the isotopic and trace element composition of a tissue reflect diet during the period over which that tissue was laid down. Tooth enamel forms early in life, and once formed, it is metabolically inert. Bone, on the other hand, continues to grow and remodel throughout life. Analyses of tooth enamel and bone therefore track diet at different stages of life, a phenomenon that can be put to work to trace dietary life histories of individuals (Sealy et al., 1995; Cox et al., 2001; Price et al., 2001, 2006). Serial analyses of tooth enamel record life events during the period of formation of that tooth (Wright and Schwarcz, 1998; Balasse, 2002; Sponheimer et al., 2006). If soft tissues are also preserved, even more detailed reconstructions are possible (Müller et al., 2003; Richards et al., 2007; Meier-Augenstein and Fraser, 2008; see also Stott et al., 1999).

Some applications

Analysis of carbon isotopes in paleosols and in the tooth enamel of fossil grazers has enabled some elegant reconstructions of past ecosystems, including the demonstration that the C_4 grasslands that today dominate many low-latitude regions of the world developed only in the late Miocene, ca. 8–6 mya (Cerling et al., 1993; Wang et al., 1994). We do not yet fully understand the reasons for this major worldwide ecological transformation, but these are likely to have been complex, involving geological, ecological, and phylogenetic aspects (Edwards et al., 2010). In Australia, Miller et al. (2005) found that $\delta^{13}C$ values of ancient eggshells indicated major environmental change between 50 and 45 ka. These authors suggest that the first humans in Australia burned the landscape, changing the vegetation from a patchwork of different plant communities, including significant quantities of C_4 grasses, to fire-adapted scrub like that of today.

Stable isotope analyses of fossil tooth enamel have been used to reconstruct the diets of extinct species, including fossil human ancestors (Sponheimer et al., 2006; Lee-Thorp and Sponheimer, 2006; Lee-Thorp, 2008; Cerling et al., 2011; Ungar and Sponheimer, 2011). This work has significantly changed our understanding of hominin dietary ecology, with implications for models of human evolution. $\delta^{13}C$ measurements of australopithecines show substantial dietary variation between, and in some cases, within species. The most startling comparison is between East and South African species of robust australopithecines. Both had exceptionally robust dental architecture and thick tooth enamel, and were formerly thought to have been specialized feeders who consumed hard foods such as seeds and nuts. More recently, studies of dental microwear have ruled out large quantities of hard foods such as grass seeds (Ungar, 2011). Isotope analyses show that the two ate very different diets: the East African *Paranthropus boisei* consumed mostly C_4-based foods (van der Merwe et al., 2008; Cerling et al., 2011), while the South African *Paranthropus robustus* ate a more mixed diet incorporating both C_3 and C_4 items. Quite what form the diet of *P. boisei* took is not yet clear; it may have focused on plants such as sedges. This work clearly shows that morphology alone does not provide an adequate basis for reconstructing dietary paleoecology.

The question of carnivory and/or herbivory in ancient diets recurs in different contexts, including the diets of extinct animals (Bocherens et al., 1994; Lee-Thorp et al., 2000) and Neanderthals. Neanderthal bones from central and eastern Europe have been shown to have very positive $\delta^{15}N$ (Bocherens, 2011, and references therein). There is stepwise fractionation of nitrogen isotopes with increasing trophic level, as mentioned above, so these individuals certainly ate large quantities of animal food. The amount of fractionation in a consumer compared with its food may, however, vary depending on diet (Sponheimer et al., 2003), and there have been changes in the carbon and nitrogen cycles since Neanderthal times (Bocherens et al., 2005; Stevens et al., 2008), making it difficult to ascertain the precise extent of carnivory.

A major application of stable carbon and nitrogen isotope analysis has been in distinguishing marine/terrestrial inputs into the diets of consumers. A few studies have focused on animals (Clementz et al., 2003; Chamberlain et al., 2005), but most have addressed the issue with archaeological humans. Dozens of papers have been published on this topic from many different parts of the world (e.g., Chisholm et al., 1982; Schoeninger et al., 1983; Sealy and van der Merwe, 1985; Yesner et al., 2003; Sealy, 2006; Quinn et al., 2008; Byers et al., 2011). One high-profile debate has been the extent to which the Mesolithic/Neolithic transition in Europe involved a shift away from marine foods toward a terrestrially oriented diet (Richards and Hedges, 1999; Richards et al., 2003; Milner et al., 2004, 2006; Richards and Schulting, 2006; Fischer et al., 2007).

Current research in paleodiet is extending the range of isotope methods. Isotopic analysis of individual chemical compounds enables much more specific tracing of foodstuffs, and greater resolution of complex mixtures of foods (Evershed et al., 2007). Less well-known isotopes ($^{2}H/^{1}H$, $^{44}Ca/^{40}Ca$) hold promise, as do studies of intra-individual variation to investigate seasonal differences in diet, migration, or age at weaning. Paleodietary studies can focus on single individuals or whole ecosystems, over time scales ranging from days or weeks to many millions of years. There will no doubt be an even greater range of applications in the future.

PALEOENVIRONMENTAL RECONSTRUCTION

Rolfe D. Mandel[1] and Vance T. Holliday[2]
[1]Department of Anthropology, University of Kansas, Lawrence, KS, USA

Introduction

A major component of geoarchaeology is the reconstruction of paleoenvironments at archaeological sites or within a region. Paleoenvironmental information can be essential for understanding the environment before, during, and after site occupation, and it may provide insights into environmental changes that influenced technology, social structure, human subsistence, and settlement strategies. According to Rapp and Hill (2006, 187), "The impact of the earth's environmental and climatic patterns on human physical and behavioral development, and the effect of prehistoric human behavior on changing environmental landscapes, can be pursued by means of a geoarchaeological approach as part of a broader geoecological perspective."

Karl Butzer was the first geoarchaeologist to place a strong emphasis on paleoenvironmental reconstruction, a theme echoed in his 1964 and 1971 books, *Environment and Archaeology* (Butzer, 1964; Butzer, 1971). Over the past 50 years, geoarchaeologists have become more engaged in paleoenvironmental reconstruction, and it is now quite common for archaeologists to engage in paleoecological research with the collaboration of geologists, geographers, soil scientists, paleobotanists, and paleontologists.

The significance of environmental change on the evolution of humans has long been acknowledged, and according to Blockley et al. (2012), those changes "underpin many of the proposed mechanisms behind models of human evolution, including population movement, isolation, specific adaptations and speciation." For example, environmental change has been identified as one of the key factors behind the migration of the first hominins out of Africa. At Dmanisi in the Republic of Georgia, where the earliest evidence of *Homo erectus* outside Africa has been found, paleoenvironmental evidence suggests the existence of sparse vegetation and a semiarid landscape at the time of occupation (ca. 1.8 Ma BP) (Gabunia et al., 2000). This may have been an ideal environment for a species considered to be an arid-adapted hominin. Similarly, in Indonesia, glacial climatic episodes after ca. 1.8 Ma BP may have promoted the development of open woodland and grassland mosaic environments for Javan *H. erectus* to exploit (Bettis et al., 2009).

In the context of paleoenvironmental reconstruction, a distinction must be drawn between "environment" (a more general term) and "climate" (a more specific term). *Environment* "encompasses all the physical and biological elements and relationships that impinge upon a living being" (Dincauze, 2000, 3), including the climate, plants (flora), animals (fauna), and landscape setting. *Climate*, in contrast, refers to the regional, long-term characteristics of weather patterns such as average precipitation, average temperatures, and seasonal fluctuations, i.e., "the atmospheric conditions typical of the location" (Aguado and Burt, 1999, 381). By looking at proxy indicators of climate, the intent is usually to gain access to relatively specific kinds of information about temperature or precipitation. The reconstruction of environments, however, can be much more general, but also very localized, such as the reconstruction of poorly drained, bog-like conditions, which can be fairly restricted in area.

The reconstruction of paleoenvironments typically involves the analysis of abiotic and/or biotic evidence. Abiotic evidence includes geomorphic, sedimentologic, and stratigraphic attributes, and biotic evidence consists of plant and animal remains as well as evidence of other living things. In addition, there are geochemical indicators of paleoenvironments, primarily the stable isotope composition of sediments, soil organic matter, soil nodules, and carbonates. With the exception of geochemical indicators, which are addressed elsewhere in this encyclopedia, the *primary* sources of paleoenvironmental information used in geoarchaeolgical studies are briefly described below. Also presented are examples of the application of paleoenvironmental data in geoarchaeological investigations.

Abiotic evidence

Geomorphic, sedimentologic, and stratigraphic indicators

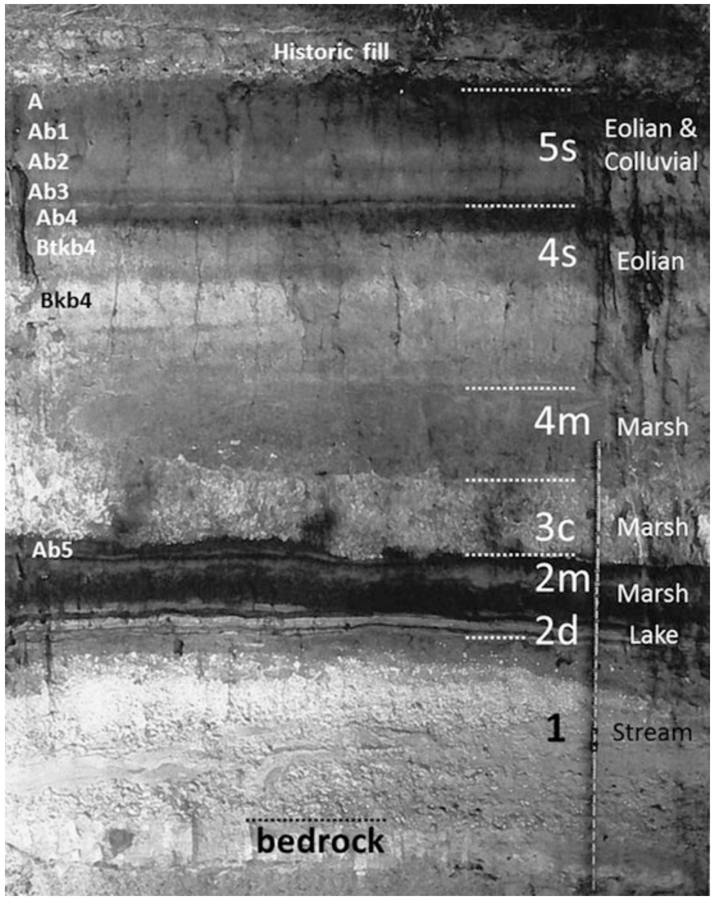
Descriptions and analysis of landforms, sediments, and stratigraphic sequences at and near archaeological sites provide a way to identify depositional processes and past environments (also see the entries on "Sedimentology" and "Stratigraphy" in this volume). As discussed in the entry on "Site Formation Processes" (also in this volume), various depositional processes and depositional settings produce characteristic sedimentologic and stratigraphic assemblages. Paleoenvironmental interpretations are based on comparisons of the attributes of prior landforms together with their associated sediments and stratigraphic sequences with the characteristics of modern landscapes and depositional environments. In short, understanding the processes that form landscapes and deliver sediments at and near archaeological sites is crucial in any attempt to reconstruct environments that existed before, during, and after a site or region was occupied.

Geomorphology was used as an indicator of paleoenvironments in a geoarchaeological investigation near Kharga in the Western Desert of Egypt (Mandel and Simmons, 2001). That study recorded many small playas, or pans, on the Libyan Plateau, overlooking the Kharga Depression. Dense concentrations of artifacts were recorded on the edges of the pans (Figure 1), indicating that these geomorphic features were focal points for human occupation, presumably when they held water. For the area that was surveyed, Middle Paleolithic, Terminal Paleolithic, and Neolithic occupations are strongly tied to pans. Unlike the spring-fed lakes in the Nubian Desert, the pans on the Plateau received all of their water from local rainfall; they were never influenced by precipitation farther south that recharged the regional aquifer, which in turn supplied water to spring-fed lakes in the Kharga Depression. Hence, the relationship between the temporally diagnostic artifact assemblages and pans supports the hypothesis that monsoonal summer rains of central Africa periodically penetrated at least as far north as Kharga at various times during late-Quaternary wet phases (pluvials) (Mandel and Simmons, 2001).

Geoarchaeological investigations in the dry valleys, or draws, of the Southern High Plains in northwestern Texas and eastern New Mexico demonstrated how sedimentology could be used to infer late-Quaternary environmental change (Holliday, 1985; Holliday, 1995; Holliday, 1997) (see the entry on "Great Plains Geoarchaeology"). Much of the paleoenvironmental information was gleaned from stratigraphic sequences at two sites: Lubbock Lake in Yellowhouse Draw (Figures 2 and 3) and Clovis in Blackwater Draw (Figure 4). From the terminal Pleistocene to the early Holocene, there was a hydrologic shift from flowing water (based on the accumulation of alluvium and spring sands) to standing water (indicated by the accumulation of diatomaceous and palustrine muds), then to the almost complete disappearance of surface water and the deposition of eolian sands. These environmental changes resulted from a decrease in effective regional precipitation from the late Pleistocene to the middle Holocene (Holliday, 1995).

Paleoenvironmental Reconstruction, Figure 1 View of fire-cracked rocks and Terminal Paleolithic artifacts along a 75-m-long shoreline of a shallow basin, or pan, on a portion of the Libyan Plateau in the hyper-arid Western Desert of Egypt. The pan, which apparently held water during the terminal Pleistocene, is a good example of geomorphic evidence of a former wetter climate in the region (Photograph from Mandel and Simmons (2001: Figure 5)).

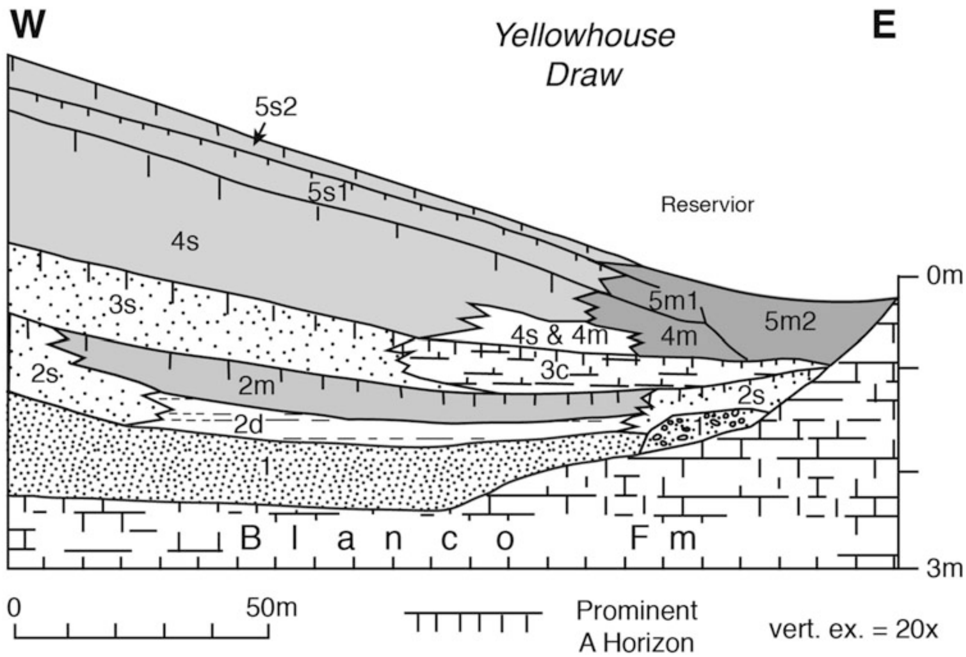
At the Winger site on the High Plains of southwestern Kansas, local and regional environmental changes spanning most of the Holocene were inferred from the



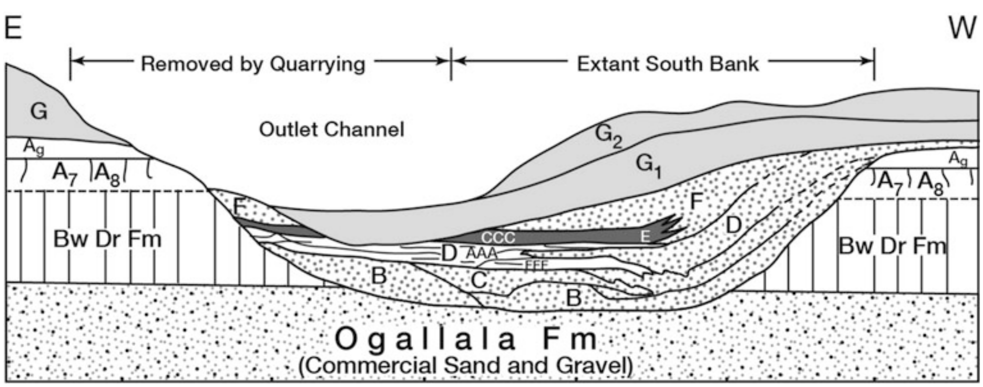
Paleoenvironmental Reconstruction, Figure 2 Photograph of a stratigraphic section at the Lubbock Lake archaeological site in northwest Texas. The section was exposed along the valley axis of Yellowhouse Draw (see also Figure 3). The lithostratigraphy (1–5; m = marsh muds, d = diatomite, and s = sandy eolian facies) and depositional environments are indicated to the *right*. A simplified soil stratigraphy is shown on the *left*. The rod is 3 m long (Photo from the Museum of Texas Tech University and labeled by V. T. Holliday).

geomorphology, stratigraphy, and sedimentology of the site. A deeply buried bone bed representing a Late Paleoindian bison kill at Winger occurs in a former playa basin (Mandel and Hofman, 2003). The bone bed dates to ca. 9100 ^{14}C yr BP and is in a buried soil developed in clayey, organic-rich basin fill overlain by early Holocene alluvium (arroyo fill) (Figure 5). Recent alluvium overlies a truncated soil developed in the early Holocene alluvium, and modern deposits of eolian sand 2 m to 35 cm thick mantle the site area. Based on the stratigraphic context of the bone bed, the playa fill was aggrading at the time of the bison kill. The bison bones were quickly buried in lacustrine sediments, followed by an episode of landscape stability and concomitant soil formation in the playa. There was a major change in the sedimentary environment soon after ca. 9100 ^{14}C yr BP, with Bear Creek breaching the margin of the playa basin and depositing alluvium on top of the lacustrine sediments. Alluviation during the early Holocene was followed by a period of soil formation around 8500 ^{14}C yr BP, then net erosion during the middle Holocene. The episode of mid-Holocene erosion in western Kansas is attributed to aridity and reduced vegetative cover (Mandel, 2006). A brief episode of late-Holocene alluviation at Winger was followed by accumulation of eolian sands during the Historic period as dunes buried the site.

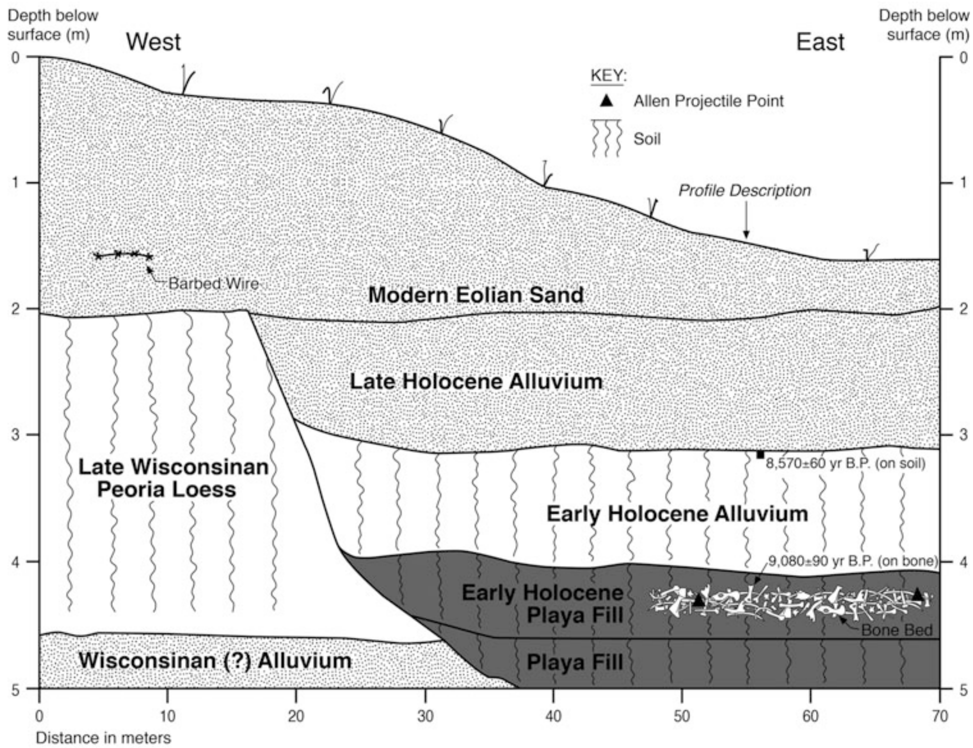
Detailed analyses of sediments and microstratigraphy were used to reconstruct terminal Pleistocene and early Holocene paleoenvironments at the Wasden site in Idaho (Moody and Dort, 1990). Those analyses revealed that the sediments contained within the Coyote Cave depression, a part of the Wasden site, were derived from various materials on the Snake River Plain and deposited by alluvial and eolian processes. Moody and Dort (1990, 367) noted that the physical properties of the sediment, especially grain-size distribution, provided "information about environmental conditions both at the Wasden site itself and in the surrounding area during and between times of



Paleoenvironmental Reconstruction, Figure 3 Stratigraphic cross-section across Yellowhouse Draw at the Lubbock Lake site (see also Figure 2). The bedrock is the Blanco Formation (Pliocene) and was incised in the late Pleistocene. Stratum 1 is gravel, sand, and clay alluvium deposited ≥11,000 ^{14}C yr BP. It contains Clovis-age fauna and archaeological remains. Stratum 2 includes diatomite beds (2d) and Folsom occupation debris deposited in a lake and lake margin settings ~11,000 to ~10,000 ^{14}C yr BP. Stratum 2d evolved into marsh muds (2 m) that persisted from ~10,000 ^{14}C yr BP until ~6500 ^{14}C yr BP, with stability and soil formation. Both 2d and 2 s strata have valley margin sandy eolian facies (2 s). Late Paleoindian features are common in stratum 2 m, but Early Archaic remains are rare. From ~6500 to ~5500 ^{14}C yr BP, marl (Stratum 3c) accumulated in a hardwater marsh along the valley axis. Brief incision and localized deposition of marsh muds (stratum 4 m) were followed by widespread deposition of sandy eolian sediments (stratum 4 s) from ~5500 to ~4500 ^{14}C yr BP. Middle Archaic occupations are rare but present in stratum 4 s. Stability with concomitant pedogenesis ensued for most of the rest of the Holocene. Late Archaic and late prehistoric archaeology is locally common in the soil. Starting ~1000 ^{14}C yr BP, episodic deposition of eolian and colluvial sediments (stratum 5 s with soils) locally buried stratum 4. The stratum 5 sequence includes Late Prehistoric, Proto-historic, and Historic Native American features and Historic European occupations (Diagram from Holliday (1995: Figure 28B)).



Paleoenvironmental Reconstruction, Figure 4 Generalized east–west geologic cross-section of the south end of the Clovis site paleobasin. The basin fill is inset into the Ogallala Formation and Blackwater Draw Formation (Bw Dr Fm and A_7, A_8 and A_9). The oldest basin fill is spring-laid sand divided into Unit B (13,000–11,500 ^{14}C yr BP) and Unit C (11,500–11,000 ^{14}C yr BP) and separated by an unconformity. The Unit B and C sands have yielded Clovis artifacts. Units D and E consist of diatomaceous earth (pond deposit) and an organic-rich sandy mud (marsh deposit), respectively. Most of the Paleoindian features were found in units D and E. Eolian sands comprise units F and G. Also shown are the stratigraphic relationships of the Paleoindian archaeological components (FFF = Folsom, AAA = Agate Basin, and CCC = Cody/Firstview) to the basin fill (Diagram from Holliday (1997: Figure 3.10) as modified from Haynes (1995: Figure 7)).



Paleoenvironmental Reconstruction, Figure 5 Stratigraphic cross-section of the exposure at the Winger site, a Late Paleoindian bison kill in southwestern Kansas. From the early Holocene to Historic period, there was a hydrologic shift from standing water (accumulation of lacustrine sediments) to flowing water (accumulation of alluvium), then accumulation of eolian sands. Erosion during the middle Holocene and the development of sand dunes during the Historic period are attributed to a decrease in effective regional precipitation (Diagram from Mandel and Hofman (2003: Figure 6)).

occupation of the cave." For example, alternating beds of very fine sandy loam and silt loam underlying the ramp in front of Coyote Cave were attributed to episodes of local dune activity and regional loess deposition, respectively, and the loess was considered the product of a relatively dry eolian climatic regime.

Soils

Soils are intimately related to the environment because soil development is directly linked to local environmental conditions. The nature of past environments has long been a fundamental question in archaeology, and therefore many attempts have been made to use soils from archaeological contexts to provide paleoenvironmental reconstructions. Such attempts have met with mixed success, however, because the relationship between soil genesis and environmental conditions is very complex. Moreover, using a specific soil or soil characteristic to reconstruct paleoenvironmental specifics, such as past climate conditions, can be difficult.

As previously noted, it is important to distinguish between "environment" and "climate" for the purposes of paleoenvironmental reconstruction. Soils are better suited for environmental reconstructions, though the discussion below will explain that, under some circumstances, a degree of climatic or even vegetation specificity can be involved.

Climate influences pedogenesis most directly through precipitation and temperature, and indirectly through flora and fauna. The most direct impacts produced by biota probably come from (1) the addition of a wide range of chemical compounds, (2) bioturbation, and (3) rooting. Using soils to reconstruct past climatic and biotic conditions, however, has proven to be very difficult for a number of reasons. Plant and animal communities are closely linked to one another and to climate, and consequently, it is difficult to sort out the varied influences in the factorial approach (Jenny, 1941, 197–199; Birkeland, 1984, 165, 260; Birkeland, 1999, 268). Further, soils are not sufficiently sensitive in responding to discrete climate changes that may be culturally significant. Such changes can be more readily detected using plant or animal remains, particularly in a high-resolution, microstratigraphic context. However, as is the case with many environmental proxies, the microclimate and local vegetation can influence local soil forming processes in a dominant way, thus obscuring the regional climatic and vegetation

Paleoenvironmental Reconstruction, Table 1 Paleoenvironmental Indicators from soils (From Holliday, 2004: chapter 8).

Soil characteristic		Environmental characteristic
Color	Dark color[a]	High soil organic-matter production under relatively wet conditions; can include the surface horizon of grassland and forest soils and also thicker peats and bog-related soils.
	Red color	Red or reddish-brown colors generally indicate well-drained conditions; a deep, reddish-brown, "coffee" color can indicate iron translocation under intense "podzolic" leaching conditions (see below).
	Gray, greenish-gray, bluish-gray, or gley colors[b]	Reducing conditions promoting either reduction (usually high water table) and reprecipitation of Fe or Mn, or leaching of Fe or Mn out of the soil.
Zones of $CaCO_3$ accumulation	Bk, Bkm, and K horizon (calcic or petrocalcic horizon)	These zones form when calcium and bicarbonate ions are available in the soil solution and evaporation exceeds precipitation; they are ubiquitous pedogenic characteristics in arid and semi-arid environments. A wide variety of factors, in addition to precipitation and evapotranspiration, have a significant impact on the morphology and depth of these horizons.
E horizon and podzolic characteristics	E horizon	Formation of an E horizon represents leaching (eluviation) of clay, iron, aluminum, organic matter, or a combination of these constituents, leaving a lighter colored zone with a concentration of sand-sized or silt-sized quartz just below the A horizon and above the B; usually takes place under humid, forested settings.
	Podzolization	A particularly intense form of leaching and translocation of iron, aluminum, or organic matter out of the E horizon and precipitation within the B horizon. The result is a strongly expressed E or albic horizon and Bh, Bs, or Bhs spodic horizon. Key environmental ingredients in podzolization are coarse parent material (enhancing rapid, deep leaching), abundant water, and vegetation that produces a thick, acidic litter, such as coniferous forests, heather, or lichen-heath in the tundra. An E horizon, therefore, is broadly indicative of the pedogenic environment – in particular, humid, forested conditions.
Cryogenic characteristics[c]	Solifluction	Contorted beds and soils.
	Gelifluction	A type of solifluction; slow down-slope movement of water-saturated soil above permafrost.
	Micromorphology	Disruption of clay films lining voids, formed in earlier temperate periods and incorporated into the soil matrix (as "papules"); silty cappings on sand particles, platy structure; rounded granules of illuvial silt; accumulation of soil or sand in fissures or coarse pores, and large rounded pores or vesicles produced by air bubbles during thawing of ground-ice.

[a]Low chromas and values in the Munsell soil color system.
[b]Chroma typically <2.
[c]Formed by *cryoturbation*, which refers to soil mixing due to freezing and thawing of the ground.

conditions that may be of interest. In addition, climate changes in the Holocene, the time period with which most North American archaeologists work, were often of insufficient magnitude to be detectable in the pedological record.

The properties of soils that seem to be the best indicators of the climatic conditions during which soil formation occurred include organic matter content, the depth of leaching (which determines the presence or absence of $CaCO_3$ and more soluble salts), depth to the top of the zone of accumulation of the carbonate or salts, and overall profile morphology (Table 1).

There is only a limited amount of information that helps to identify the pedological features most closely related to past plant and animal communities. Further, as noted above, the distribution of plants and animals is so intimately linked to climate that sorting out the effects of each is often difficult. The soil characteristics that seem to be most directly indicative of vegetation and that also persist in buried soils over long intervals are the E horizon and related podzolic characteristics, and some overall profile morphologies.

A significant environmental characteristic of soils is that they are largely the products of immediate, localized conditions. The physical, chemical, and biological characteristics of a soil profile were determined by the parent material at that site, by the flora and fauna living at that site, and by the meteorological conditions (such as precipitation and temperature) that operated on the site over time. This is in contrast to other proxy environmental indicators (e.g., sediment characteristics, pollen) that are affected by both regional and local conditions.

In using soils to reconstruct environmental conditions, therefore, the key is selecting those pedogenic characteristics that are indicative of relatively specific conditions such as drainage, topographic setting, rainfall, or plant communities. The best results in using soils as paleoenvironmental indicators seem to be obtained for local environmental reconstructions. Soils are particularly useful in assessing local drainage conditions and paleotopographic settings because pedogenesis is sensitive to both surface and subsurface water movement and because the topographic setting affects water movement.

The localized nature of pedogenesis also raises a cautionary issue. The reconstruction of regional environments using soils should not be based on one or a few soils from an archaeological site because local pedogenic conditions may not necessarily reflect regional environmental conditions. The reasons why an archaeological site is located where it is may be due to unusual characteristics, such as access to water or other resources – characteristics that may have a profound impact on local pedogenesis but may not be expressed in the regional soils of the same age and stratigraphic position. Springs, for example, are key locations of hominin and animal activity and as such have been the focus of archaeological research. However, spring localities are microenvironments and, therefore, are not necessarily representative of regional environmental conditions. On the contrary, the very conditions that make springs attractive to people (water along with availability of floral and faunal resources) may be because of the absence of such conditions elsewhere in the region (e.g., Haynes and Agogino, 1966; Haynes, 1975; Holliday, 1985; Haynes, 1995; Holliday, 1995; Ashley, 2001; Holliday et al., 2007; Ashley et al., 2009; Haynes and Warnica, 2012).

Equifinality is also an issue in the paleoenvironmental interpretation of soils. In particular, long periods of soil formation apparently can produce some pedological characteristics similar to those produced under particular climatic conditions. As a corollary to equifinality, relatively few specific soil features or types of surface or buried soils are related to unique or easily circumscribed environments of formation. For example, argillic horizons occur in modern surface soils in a wide variety of environments throughout North America.

The polygenetic nature of soils can also confound their paleoenvironmental signal: the very characteristics that make soils useful as indicators of the passage of time compromise their utility as paleoenvironmental proxies. As soils form through time they may be subjected to a succession of environments. The longer the duration of pedogenesis, the more changes a soil will likely experience, i.e., the more polygenetic it will be. At best, therefore, soils represent some sort of "averaging" or mixing of whatever morphological and chemical characteristics may be linked to the environment. Broadly speaking, soils that formed over relatively short periods and did not experience many environmental changes are more useful for reconstructing the environmental conditions at the time of pedogenesis than are soils that formed over a longer interval and were subjected to a variety of environments (or at least much more effort is required to reconstruct the environmental history of polygenetic soils). The problem with pedological features that develop relatively quickly, however, is that they tend not to persist in buried soils (Yaalon, 1971).

Finally, a stratigraphic sequence with a buried soil, though suggestive of changes in landscape stability, is not necessarily indicative of environmental changes. Certainly this is the case with multiple weakly expressed A-C soils buried in floodplain deposits. The cycles of sedimentation and stability are simply part of the natural evolution of a floodplain, relating to variability in precipitation and runoff from year to year (Ferring, 1986; Brown, 1997, 96–103; Ferring, 2001). Soils can also be buried due to human activities such as construction (e.g., Leighton, 1933; Bettis, 1988; Sandor, 1992; Cremeens, 1995; Alexandrovskiy, 2000) or human-induced soil erosion (e.g., Overstreet and Grolier, 1988; de Maigret et al., 1989; Fedele, 1990; Wilkinson, 1997).

There have been many studies in which soils were used for paleoenvironmental reconstruction at archaeological sites. For example, Reider (1980, 1982a, 1982b, 1990) noted that soils at terminal Pleistocene archaeological sites in Wyoming and eastern Colorado are mostly Aquolls and Argialbolls with properties indicative of a generally cool, humid environment. By contrast, calcareous or alkaline soils (Calciustolls and Natrargids) at sites dating to the middle Holocene thermal maximum, the Altithermal (ca. 8000–4000 BP), were interpreted as evidence of significant climatic drying. Reider (1990) suggested that weak development in post-Altithermal soils probably reflects general landscape instability associated with fluctuating Neoglacial climates in the region.

Soils also have provided clues to the paleoenvironmental context of hominin sites in Olduvai Gorge, Tanzania. Ashley and Driese (2000) identified a buried paleocatena in proximity to wetlands and dated it to ~1.75 Ma. The buried soils were then used to reconstruct the evolution of the local paleohydrology. The paleocatena was identified within a "cumulative red paleosol" formed in volcaniclastic parent material, and it was differentiated into an upslope and a downslope facies (over a distance of about 1 km). Compared to the downslope facies, the upslope facies was characterized by less evidence for plant rooting, greater clay translocation, and greater zeolitization (i.e., greater weathering of the volcaniclastic parent material). The downslope soil exhibited strong redoximorphic mottling, which was attributed to its proximity to an ancient lake. Also, the downslope soil exhibited evidence for two generations of redoximorphic features, separated by a phase of clay translocation, indicative of a shift from poorer drainage to better drainage and back to poor drainage. The changing drainage characteristics were attributed to fluctuations in lake level, among other factors (Ashley and Driese, 2000). By contrast, the upslope soil was oxidized and lacked redoximorphic features. Hence, the upslope setting was probably a drier and better-drained site than the downslope one.

Buried organic-rich or formerly organic-rich soils have figured importantly in environmental reconstructions for archaeological sites in the middle latitudes of North America. A common association of soil colors and horizons in many buried situations is a black or very dark gray A horizon, sometimes cumulic and relatively high in soil organic matter (SOM) content, over a fully reduced or mottled C or Bw horizon – Cgb or Bgb (see the entry on "Soils" in this volume). This relationship is indicative of a high water table producing the reduced zone and also promoting high rates of SOM production in the A horizon. This sort of soil profile has been reported from a wide variety of paleotopographic lows in now well-drained settings at sites throughout the central and western United States dating to the late Pleistocene and early Holocene. These buried organic-rich zones are most widely known as "black mats," but they have been referred to by other names as well – see Quade et al. (1998) and Haynes (2008) for a review of the terminology. They are not always described as soils, but they clearly represent some form of pedogenesis (accumulation of SOM on a stable land surface along with postdepositional alteration of parent material below the surface). The black mats are also clearly indicative of local environmental conditions (perhaps a "wet meadow" or bog) and may be tied to climate if a direct relationship can be shown between the local groundwater conditions and climate.

A recent study of organic-rich cumulic soils representing buried Paleoindian landscapes in the US Central Plains linked soil development to paleoclimate (Mandel, 2008). According to that study, very slow alluviation occurred between ca. 13,000 and 9000 ^{14}C yr BP because strong zonal airflow at the surface restricted the northward penetration of moist Gulf air masses into the Central Plains at that time. Weak Pacific storms depleted of Gulf moisture may have generated enough rainfall and associated runoff to promote alluviation in streams, but at a slow rate, thereby allowing organic-rich cumulative soils to develop on floodplains and alluvial fans.

Biotic evidence

As previously noted, biotic evidence consists of plant and animal remains. The most common types of plant fossils recovered as part of a geoarchaeological investigation are pollen and phytoliths. Diatoms are unicellular forms of algae, sometimes aggregated into filamentous colonies, that many classify among the Protista. They have also provided evidence for understanding environmental change in geoarchaeological studies. The animal fossil groups that are used to infer past environmental conditions consist of vertebrates (e.g., mammals, reptiles, amphibians, fish, and birds) and invertebrates (e.g., insects, mollusks, and ostracods).

Pollen

Under certain conditions, pollen and spores from plants can be preserved in sediments and soils and may be used to reconstruct paleoenvironments at and near archaeological sites (e.g., Troels-Smith, 1960; Martin, 1963; Dimbleby, 1963; Leroi-Gouran, 1965; Short, 1978; Dimbleby, 1985; Tsukada et al., 1986; Bryant and Holloway, 1996; Bakels, 2000; Roy et al., 2012). Rapp and Hill (2006, 169) noted that, "Except for certain macrofossils, pollen has probably contributed more to archaeological interpretation [of paleoenvironments] than any other plant remains."

Various objectives related to paleoenvironmental reconstruction have driven the application of palynology (the study of pollen) in archaeological investigations. In some cases, pollen analysis provided a way to determine whether certain plant resources were available within the former landscape for people to use in the past. For example, archaeological investigations at the Inuit winter settlement sites of Oakes Bay 1 in north-central Labrador included pollen and macrofossil analyses to determine if terrestrial resources such as peat and wood were available for fuel and house construction, respectively, during the Little Ice Age (AD 1500–1870) (Roy et al., 2012). Based on the pollen record, following a 2000-year period of cold and dry conditions that characterized the Neoglacial climatic episode (post Altithermal, that is, beginning around 4000 BP), the reappearance of moist-habitat plant species and the establishment of larch at ca. 1000 cal yr BP provide evidence of a return to more humid conditions that in turn triggered the onset of paludification and the formation of peat that persisted well into the Little Ice Age. Hence, Roy et al. (2012) concluded that natural resources such as trees and peat were readily available and certainly more abundant during the Little Ice Age compared to the Neoglacial.

Pollen analysis also has been used to identify episodes of regional bioclimatic change that may have (1) favored or deterred human occupation at an archaeological site or (2) brought about cultural transitions. For example, the pollen record preserved in a fen at the L'Anse Aux Meadows site in Newfoundland was used to determine whether there were significant environmental changes over the past 6000 years that may have caused episodic human occupation and abandonment of the site (Davis et al., 1988). Although the relationships between regional environmental changes (inferred from the pollen spectra) and the human response are indistinct, a cool interval soon after 2500 BP coincides with a 1000-year hiatus in occupation at the site.

In a similar study, Verkhovskaya et al. (1994) analyzed pollen in sediments at three stratified archaeological sites in the Iman River basin of eastern Russia. The pollen record spanned the past 5000 years and indicated that during the transition from the Bronze Age to the Early Iron Age, which occurred around 2500 years ago, mixed coniferous and broad-leaved trees replaced a thinning birch forest surrounding the sites. Also, the pollen data indicated that the transition was marked by a dramatic increase in moisture. Verkhovskaya et al. (1994) suggested that the environmental change occurring at ca. 2500 BP strongly influenced the changing cultural traditions in eastern Russia.

Pollen data also can serve to reconstruct changes in depositional environments at archaeological sites. A good example of this application is a study of late Holocene environmental change at the ancient Yeanri burial mound on the Gimhae fluvial plain in southern Korea (Yi and Saito, 2003). Detailed studies of palynomorphs (microscopic organic fossils that include pollen, spores, and other biotic forms) recovered from cores collected near the burial mound revealed two local pollen zones: a lower Pollen Zone I, dominated by a *Pinus-Quercus* assemblage, and an upper Pollen Zone II, dominated by a *Pinus-Quercus-Gramineae* assemblage. The pollen data, combined with an analysis of the mollusk assemblages, indicate that the depositional environments changed from a lower intertidal flat of a shallow bay environment to an upper intertidal flat in a shallow bay shortly before ca. 1300 ^{14}C BP, and then finally to a fluvial plain similar to that of today. This environmental change may have resulted from uplift along the Yangsan Fault. Later, the exposed area was modified by human activities, as indicated by a sudden increase in grassland herbaceous pollen grains. According to Yi and Saito (2003), the loss of this bay probably had a dramatic effect on the Golden Crown Gaya State (third–seventh centuries AD), which used it as a major port for regional trade; the disappearance of the bay environment may explain why it eventually merged with the Shilla State.

Phytoliths

Phytoliths, or "plant stones," are rigid, microscopic silica bodies deposited in the cell walls, cell interiors, and intracellular spaces of many plants (Piperno, 2006). Phytoliths provide structural support (increased rigidity and strength) and protection from herbivores and pathogens. Although species of many plant families produce phytoliths (Piperno, 1989), in the temperate regions of North America and Eurasia, only a few families are responsible for over 95 % of all phytoliths (Piperno, 2006). These include Poaceae (grasses), Cyperaceae, Asteraceae (Lanning and Eleuterius, 1989; Piperno, 2006), ferns, horsetails, conifers (Klein and Geis, 1978), and some deciduous trees (Geis, 1973; Bozarth, 1992). Although dicot forbs produce few diagnostic shapes of silica (Morris et al., 2009), they contribute some amorphous biogenic silica to the soils. A few families common in the temperate regions do not appear to accumulate silica (e.g., Fabaceae and Brassicaceae) and are therefore "silent" in the soil phytolith record (Blinnikov et al., 2013).

The advantages offered to geoarchaeology by phytoliths include (1) their abundance in grasses, (2) the fact that they are deposited directly into the soil, (3) their siliceous skeletons that are resistant to decay, and (4) the morphological differences they exhibit between the dominant C_3 and C_4 grass subfamilies (i.e., Chloridoideae, Panicoideae, and Pooideae). Soil phytolith assemblages have provided paleobotanical data going back hundreds to millions of years (Rovner, 1988), and as a result, phytoliths can be important paleoenvironmental proxies, especially at archaeological sites where pollen is not preserved.

Changes in phytolith assemblages throughout a soil profile may indicate shifts in local environment from warm/dry to warm/moist or cool/moist. Chloridoids are C_4 shortgrasses such as grama grass (*Bouteloua* spp.) and buffalo grass (*Buchloë dactyloides*). Chloridoids are adapted to warm/dry climates and have a diagnostic "saddle" shape, short-cell phytolith. Panicoids are C_4 tallgrasses such as switchgrass (*Panicum*), Indian grass (*Sorghastrum nutans*), big bluestem (*Andropogon gerardii*), and little bluestem (*Schizachyrium scoparium*) that are adapted to warm/moist climates. Panicoid short-cell morphotypes include cross-shapes and bilobates. Pooids are C_3 cool-season grasses that include a variety of genera such as bluegrass (*Poa*), wheatgrass (*Agropyron*), wild rye (*Elymus*), and needlegrass (*Stipa*). Pooids produce a variety of unique morphotypes that are classified as trapeziforms (Madella et al., 2005), including the *Stipa*-type lobate trapeziform identified by Fredlund and Tieszen (1994). In most cases, C_3 trees and shrubs are under-represented in the phytolith record (Fredlund and Tieszen, 1997; Piperno, 2006).

Phytolith preservation in soils and sediments is affected by bioturbation, translocation, presence of iron and aluminum oxides, erosion, fire, wind, herbivory, anthropogenic activity, soil texture and pH, rates of deposition, and exposure to water (Fredlund and Tieszen, 1997; Grave and Kealhofer, 1999; Piperno, 2006; Murphy, 2008). Also, while grasses actively collect soluble silica, other plants, such as C_3 trees and shrubs, do so passively and may produce phytoliths irregularly depending on local climate and soil conditions (Bozarth, 1992).

Combining phytolith data with stable carbon isotope values determined on pedogenic carbon (see the "Stable Carbon Isotopes in Soils" entry in this volume) can be very effective in reconstructing paleoenvironments at archaeological sites. Changes in the relative proportions of C_3 versus C_4 species inferred from the $\delta^{13}C$ values can be compared to the phytolith data, and inferences can be made about the input of carbon from C_3 trees and shrubs that are under-represented in the phytolith record (Fredlund and Tieszen, 1997; Piperno, 2006). In addition, phytolith differentiation among the major grass subfamilies allows a more refined assessment of the stable carbon isotope ($\delta^{13}C$) data. Because warm/moist and warm/dry C_4 grasses as well as cool/moist and cool/dry C_3 grasses can be differentiated based on phytolith morphotypes, more precise paleoenvironmental assessments can be made compared to using only the broad trends in stable carbon isotope values. For example, at the Beacon Island site, an Agate Basin (Paleoindian) bison kill in northwestern North Dakota, the results of phytolith analysis provided information about precipitation trends for the period of record that could not be gleaned from the $\delta^{13}C$ values determined on soil organic matter alone (Mandel et al., 2014). Based on the combined phytolith and $\delta^{13}C$ data, cool-season C_3 prairie species that prefer moist habitats dominated the site at ca. 10,300 ^{14}C yr BP, the time of the bison kill. Slight warming and drying occurred soon after ca. 10,300 ^{14}C yr BP, indicated by relatively higher $\delta^{13}C$ values determined on soil organic matter and a significant increase in phytoliths from drought-resistant *Stipa*, respectively. Phytolith and isotope data also point to a warmer and probably drier climate after ca. 8000 ^{14}C yr BP, indicated by higher $\delta^{13}C$ values and the appearance of warm-season C_4 chloridoids at the site. Hence, the Agate Basin occupation at the Beacon Island site coincided with the coolest and wettest climatic episode recorded in the sampled deposits (Mandel et al., 2014).

Phytolith analysis was combined with other proxies, including stable carbon isotopes ($\delta^{13}C$) and microscopic charcoal, to help reconstruct the vegetative history at the Kanorado locality, a cluster of three Early Paleoindian sites in northwestern Kansas (Cordova et al., 2011). Phytolith and $\delta^{13}C$ data for site 14SN106 at Kanorado show a gradual shift from C_3 plant to C_4 grass dominance, beginning with open woodland containing C_3 grasses around 14,200 cal yr BP to the modern C_4 shortgrass-dominated prairie soon after ca. 10,400 cal yr BP.

Diatoms

Diatoms are unicellular algae that occur in moist or aquatic settings and are among the most common types of phytoplankton (Battarbee, 1988). Like phytoliths, diatoms have siliceous cell walls resistant to decay and can be preserved as microfossils in sedimentary sequences. Distinct shapes provide a way to identify different species of diatoms, and the various species have specific habitat tolerances. Because diatoms are sensitive indicators of water conditions (e.g., chemistry, depth, flow, temperature, and turbidity), they are valuable paleoenvironmental proxies in certain settings.

Diatoms have been recovered from both lake and marine sediments and are especially useful in documenting environmental changes that reflect fluctuations in water levels. Diatoms can help document sea-level changes because some species are very sensitive to changes in salinity and are consequently indicators of transgression and regression sequences (Rapp and Hill, 2006, 175). Particular species are associated with freshwater, brackish, or marine conditions, and therefore, studies of diatoms can help reconstruct paleoenvironmental settings connected to coastal archaeological sites. For example, along the Baltic coast, the interaction of isostatic uplift and eustatic sea-level rise has produced a complex pattern of transgressions and regressions, all reflected in the diatom record (Smol and Stoermer, 2010), and altitudinal zonation of ancient shorelines and archaeological sites. In the area of Stockholm, Sweden, diatom analysis at Mesolithic to Medieval-age archaeological sites revealed a pattern of site abandonment and reoccupation related to oscillations of the Baltic Sea strandline (Miller and Robertsson, 1981).

Diatoms are also useful in paleoenvironmental analyses of archaeological sites associated with modern and former lakes or ponds because (1) diatoms tend to be the best preserved algal fossils in freshwater sediments and (2) the most complete preservation of whole diatom communities tends to occur in Quaternary lake and pond sediments, where 90 % or more of the assemblage survives burial and can be sampled (Round, 1981). A good example of using the diatom record to reconstruct paleoenvironments at sites in nonmarine settings is from North America's Southern High Plains. A series of deeply entrenched ephemeral streams, or draws, in that region contain a rich archaeological record spanning the past 13,000 years. Complex stratigraphic sequences consisting of alluvium, lacustrine deposits, and eolian sands occur in many of the draws (see discussion below on sedimentology of the draws). Diatom analysis was originally used to reconstruct local depositional environments at and near individual archaeological sites, including the Clovis site on Blackwater Draw (Lohman, 1935; Patrick, 1938). More recently, Winsborough (1995) conducted diatom analysis at 10 archaeological sites on the Southern High Plains, all in draws. Results of her work show that the draws experienced similar changes during the late Pleistocene and the Holocene. In particular, the diatom assemblages indicate that there was great similarity in the lacustrine and palustrine habitats in the draws during the terminal Pleistocene and early Holocene, with conditions that fluctuated between slightly brackish to much fresher water. These conditions were consistent with regional climatic changes that affected precipitation, which in turn caused fluctuating spring flow and water levels in ponds and marshes (Winsborough, 1995).

Animal remains

When using fossil vertebrate remains to reconstruct paleoenvironments, there are several factors to consider. Specifically, most large mammals have broad habitat tolerances, and consequently, they are less reliable indicators of environmental conditions. By contrast, small mammals, such as rodents, are more ecologically restricted and therefore usually more valuable for environmental reconstruction (Yalden, 2001). For example, at the Beacon Island bison-kill site in northwestern North Dakota (Mandel et al., 2014), the micromammal remains from the Agate Basin (Paleoindian) component reflect the presence of a marsh or bog-like environment. According to Falk and Semken (2012), the "Dark Faunule" micromammal assemblage, mostly consisting of voles, indicates cool, moist conditions with a high water table and a grassy substrate (either a meadow or a bog). Also, two taxa in the Dark Faunule, the red-backed vole (*Myodes* sp.) and

Ungava vole (*Phenacomys ungava*), require low shrubby vegetation; dwarf birch is preferred by both taxa. In addition, the remains of two large rodents, the American beaver (*Castor canadensis*) and common muskrat (*Ondatra zibethicus*), indicate the presence of standing water at or near the Beacon Island site (Falk and Semken, 2012). Hence, the remains of small mammals indicate that, at the time of the bison kill (ca. 10,300 ^{14}C BP), there was water in the kettle basin, which probably attracted bison to the locality.

Among invertebrates, insects are ideal for paleoenvironmental reconstruction. They comprise more than half the faunal and floral species known today, and their remains are common in many depositional contexts, including ponds, bogs, lakes (often near the margins), floodplains, caves, rockshelters, and pack-rat middens (Elias, 1994). Over the past several decades, the common occurrence of well-preserved insect fossils in many archaeological settings has been demonstrated (Elias, 1994; Elias, 1996).

Prior to 1980, insect fossil studies were applied to archaeological sites mainly in Europe, especially Great Britain (Elias, 1996). From the 1980s onward, however, many interdisciplinary North American archaeological projects included insect fossil analyses in order to reconstruct paleoenvironments – e.g., Lubbock Lake site, Texas (Elias and Johnson, 1988); Lamb Spring site, Colorado (Elias, 1986); and False Cougar Cave, Montana (Elias, 1990). Although insect fossils recovered from soils and sediments at archaeological sites have yielded useful paleoenvironmental information, insect assemblages from natural deposits adjacent to archaeological sites (pond and lake sediments, peat bogs, etc.) have helped reconstruct environmental conditions for the periods of human occupation (Elias, 1994; Elias, 1996).

Mollusks, like insects, are one of the most common types of invertebrate remains associated with archaeological sites (Preece, 2001). Mollusks include gastropods (snails) and bivalves (including clams and mussels) and occur in a variety of depositional settings, including loess; caves and rockshelters; stream, lake, and spring sediments; and marine environments. Rapp and Hill (2006, 178) stressed that several factors must be considered in reconstructing paleoenvironments from assemblages of fossil mollusks, including taphonomic processes of deposition and preservation (including the potential for mixing), the relative abundance of various types of mollusks, sampling, and identification.

An excellent example of how fossil snails can be used to reconstruct paleoenvironments is the recent geoarchaeological study by May et al. (2008) at the stratified Clary Ranch site (Late Paleonidian) in Ash Hollow valley, southwestern Nebraska. This study included a detailed analysis of the composition of deeply buried fossil snail assemblages preserved in alluvium. Between ca. 9900 and 9600 ^{14}C yr BP, aquatic snails were at their highest densities, and terrestrial snails present at that time required moist substrates in protected settings. From 9500 to 9400 ^{14}C yr BP, aquatic snails disappeared and land snails became rare, indicating that standing water was no longer present. Between ca. 9300 and 9100 ^{14}C yr BP, some species of terrestrial snails returned, and they indicate the presence of dense prairie. At the end of this last interval, many snails show evidence of burning, indicating a fire in the drainage basin. Following Late Paleoindian occupation of the Clary Ranch site at ca. 9000 ^{14}C yr BP, both snail diversity and density declined, indicating a changing regional climate toward drier conditions (May et al., 2008).

In a regional study, Rollins et al. (1987) developed criteria for the recognition of ancient El Niños using mollusks from archaeological sites along coastal South America. A combination of growth increment and stable isotope analyses indicated that elevated sea surface temperatures during large-scale El Niños leave a record decodable from the growth patterns of selected bivalve shells. They concluded that these methods can be used to recognize some of the major culturally disruptive El Niño events in the geoarchaeological record, especially if ancillary information, such as faunal distribution patterns, is also considered. They also note that chances of discovery of major El Niño perturbations in the geoarchaeological record of shell middens is enhanced by the catastrophic nature of such events, and by the indication that major El Niños have a high probability of being closely spaced in time.

Definition

Ferromagnetic minerals. Minerals that give rise to a magnetic field in the absence of an applied field.

Magnetostratigraphy or *magnetic stratigraphy*. The pattern of polarity zones in stratigraphic sequences.

Paleomagnetism. History of the Earth's magnetic field as recorded in rocky materials.

Relaxation time. The time (τ) over which magnetic remanence will decay to 1/e of its initial value.

Virtual geomagnetic pole. The geographic point where the axis of the Earth's magnetic dipole intersects the surface of the Earth.

Introduction

More than 400 years ago, William Gilbert concluded "magnus magnes ipse est globus terrestris," meaning that the Earth itself is a giant magnet. Several centuries of studies on geomagnetism, followed by investigations into paleomagnetism, have led to present-day knowledge of the geomagnetic field's behavior and the properties and intricacies of remanent, or fossil, magnetism in rocky materials. In addition, by studying the paleomagnetic record, it has been possible not only to improve our understanding of the long-term structure and temporal change of the geomagnetic field but also to develop the geomagnetic polarity time scale, or GPTS (e.g., Cande and Kent, 1995), archaeomagnetic curves (Tanguy et al., 2003; Pavón-Carrasco et al., 2009, 2010; Hagstrum and Blinman, 2010), relative paleointensity curves (Guyodo and Valet, 1999; Valet et al., 2005; Channell et al., 2009), and geomagnetic excursion records (e.g., Channell et al., 2002, 2012; Thouveny et al., 2004; Laj and Channell, 2007) in order to construct better chronological sequences.

The fundamental assumptions of paleomagnetism are as follows. (1) Rocky materials record the Earth's magnetic field, i.e., they become magnetized during their formation (primary magnetization) or at a subsequent time (secondary magnetization). (2) The time-averaged paleomagnetic field is produced by a geocentric axial dipole (GAD), so the calculated paleomagnetic pole coincides with the paleogeographic axis over a few thousand years.

Rocks, sediments, soil, and the majority of archaeological artifacts contain traces of ferromagnetic minerals that possess a magnetization aligned with the Earth's magnetic field. They therefore act as fossil compasses that record the Earth's magnetic field of the past. The most common ferromagnetic minerals include magnetite (Fe_3O_4), hematite (Fe_2O_3), goethite (α-FeOOH), and some iron sulfides (e.g., greigite, Fe_3S_4). A number of experiments and observations have proved that igneous and sedimentary rocks acquire an initial or primary magnetization during or shortly after formation, which is statistically aligned with the Earth's field direction. The geomagnetic field keeps changing over time, both in intensity or strength and in polarity (wherein the field reverses itself, and magnetic north reestablishes itself toward the southern geographic pole). It is possible to use such changes to assign an age to rocks, sediments, or archaeological artifacts, by comparing the observations to reference curves.

Mechanisms of natural remanence acquisition

Thermal remanent magnetization (TRM)

When a rock or object of pottery is heated above the Curie temperature (temperature at which ferromagnetism is lost) of its constituent ferromagnetic minerals – e.g., magnetite (578 °C) or hematite (680 °C) – thermal energy dominates the system. As the temperature in the system continues to cool, the thermal energy will decrease until the magnetic energy becomes large enough to block, or fix, the magnetization in the direction of the ambient field at that time.

At this stage, the magnetization M is effectively blocked so that the rock or artifact acquires a thermal remanent magnetization (TRM), and the relaxation time – the time (τ) for the remanence to decay to 1/e of its initial value – increases dramatically. The two-part corollary is that (a) an assemblage of grains with TRM will display a remanence which is parallel to the orientation of the Earth's magnetic field, and (b) the magnitude of the TRM should be proportional to the intensity of the Earth's magnetic field that was present during the moment of cooling.

Detrital remanent magnetization (DRM)

Numerous studies (see Tauxe and Kent, 1984) have examined the behavior of magnetic particles being deposited in water. As opposed to the thermal remanent magnetization mechanism, detrital grains in sedimentary environments are already magnetized, and during deposition, such magnetic particles can become physically aligned with the ambient magnetic field of the Earth. In reality, however, there are other forces besides the Earth's magnetic field competing to orient the grains, including turbulent motions of the water, viscous drag, gravitational effects when the grain strikes the bottom of the water body, and others, so that only a fraction of the grains align with the direction of the prevailing field. Processes such as consolidation, bioturbation, compaction, etc. occur following initial deposition, and these can also affect the final grain orientation. As a result, the process of magnetic acquisition in sedimentary environments should be viewed as a continuum which includes depositional and postdepositional influences (Tauxe, 2010).

Chemical remanent magnetization (CRM)

Grains in sediments can acquire a chemical remanent magnetization (CRM) by growth from zero initial volume (authigenesis) or by diagenetic alteration of preexisting minerals (e.g., weathering). Either way, during growth, grains acquire a stable remanent magnetization at a given *blocking volume*, that is, the volume at which a given magnetic grain experiences a dramatic increase in relaxation time (τ) and thus records the environmental magnetic field, just as with TRM. CRM is a very important acquisition mechanism in sediments because magnetic minerals can grow during diagenesis. If CRM is acquired long after sediment deposition, it is then a secondary remanence.

Viscous remanent magnetization (VRM)

Rocky materials very often contain "unstable" grains, i.e., they can realign to a new magnetic field after a geologically short time. The time period in which such realignment occurs is related to the relaxation time (τ). Grains with shorter τ can acquire a VRM, which is a form of secondary magnetization. The magnitude of VRM can be significant compared to the primary magnetization, and it has been detected in a vast number of materials.

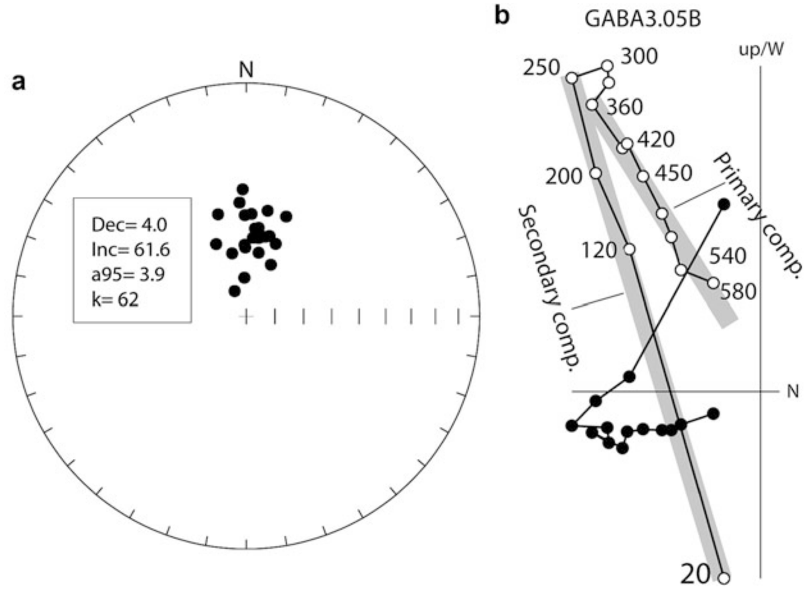
The effect of viscous magnetization can be removed by thermal demagnetization and often by alternating field demagnetization, but it can sometimes mask the primary magnetization. VRM in rocks is typically parallel to the present-day field, which can be a useful clue in its identification.

Sampling procedures

The sampling scheme in paleomagnetism varies depending on whether the study is for magnetostratigraphy (relatively spaced sampling), secular variation (narrow sampling in order to observe short-scale variations of the paleomagnetic field), or paleointensity. In magnetostratigraphic studies, the goal is to characterize the record of the Earth's magnetic field at different stratigraphic intervals through time, and sampling is designed to eliminate secular variation effects, to average errors involved in the sampling and measuring processes, and to assess the reliability of the recording medium (e.g., rock, soil, pottery). Consequently, the desired sampling resolution for magnetostratigraphy is established by the estimated sedimentation rate, and three independently oriented *samples* (N) are generally taken at each *site* (= horizon or stratum), so that the polarity can be characterized unambiguously and site statistics determined. Note that in magnetostratigraphy, sampling is broadly applied to avoid the variability from "paleomagnetic noise," whereas in secular variation studies, this is precisely the goal, and more samples per site are taken than would be the case for magnetostratigraphy to maximize the capture of detailed variations in the paleomagnetic record (e.g., Lanos, 2004; Kovacheva et al., 2009). Generally, eight specimens are considered minimally adequate (e.g., Eighmy and Sternberg, 1990), as only very small increases in precision are achieved beyond ten specimens (Tarling, 1971).

When sampling, it is often necessary to excavate a pit to obtain unweathered material using a pick mattock, spade, or similar tool, and then a vertical face can be fashioned in firmly consolidated sediment using a scraper or hacksaw blade to yield a fist-sized sample. Soft, non-cohesive clay and silty deposits can be sampled by hammering a brass tube with a reinforced stainless steel tip into the cleaned outcrop surface at a given angle. Alternatively, block samples carved from an outcrop can be obtained in the field. When dealing with soft sediments, it is useful to impregnate with a solution of sodium or ethyl silicate and water (1:1) for solidification. In cohesive, hard materials, a portable drilling machine, equipped with a -water-cooled diamond nonmagnetic drill bit, is typically used.

In all cases, samples need to be carefully oriented in the field with the help of a magnetic compass (or sun compass for strongly magnetic rocks, i.e., basalts) and a level.



Paleomagnetism, Figure 1 (**a**) Equal-area projection of the characteristic remanent magnetization (*ChRM*) directions. Each *dot* on the stereographic projection corresponds to an individual sample. Symbols are projections onto the lower hemisphere and thus correspond to samples with normal polarity (Data from the northern hemisphere). Particulars of the mean paleomagnetic directions are shown (*Dec* declination, *Inc* inclination, $\alpha_{95} = 95$ % confidence circle radius, k = precision (Fisher) parameter). (**b**) Example of an orthogonal projection diagram, also known as Zijderveld diagram. Solid (*open*) data points represent vector end points projected onto the *horizontal* (*vertical*) plane. Numbers adjacent to data points are demagnetization levels (Celsius degrees in this example). *Thick lines* show the primary (*ChRM*) and secondary magnetization directions identified in the sample.

Primary and secondary magnetizations: demagnetization procedures

In addition to their primary magnetization (TRM, DRM, CRM), rocky materials can acquire secondary magnetizations, which result from natural processes such as weathering, heating for an extended time, diagenesis, etc. In addition, materials can be artificially magnetized by proximity to strong magnetic fields during sampling, drilling, transportation, etc. One of the major tasks in paleomagnetism involves resolving the natural remanent magnetization (NRM) – i.e., the sum of all magnetizations carried by a rock – into its components, primary and secondary.

Alternating field demagnetization

In order to isolate and retrieve the primary remanence, specimens are subjected to *progressive demagnetization* or magnetic cleaning in the laboratory. The underlying principle is that minerals carrying a secondary magnetization are magnetically "softer," or put in different words, they have shorter relaxation times. Several methods are routinely used to clean or demagnetize the samples. *Coercivity* can be defined as the critical field strength to realign the magnetization of a grain. The so-called alternating field (AF) demagnetization is based on an oscillating field (the demagnetizing field) which is smoothly reduced to zero in the absence of any external field. Because of the alternating nature of the demagnetizing field, and the application of progressively increasing peak demagnetizing fields, grains with coercivities lower than the peak field will realign their remanence back and forth and will be frozen half along one direction and half along the opposite. As a result, the net contribution to the remanence will be zero. In practice, the demagnetizing field – typically a peak field of around 200 mT (milliteslas) – is applied along several orthogonal directions, or else the specimen is "tumbled" relative to the AF field.

Thermal demagnetization

The time required for the magnetization of a grain to decay in a field-free space (lacking a magnetic field) is a function of temperature. The temperature at which the magnetization of a grain becomes unlocked is called the unblocking temperature. In contrast, when an igneous rock is cooled from a melt and temperature falls below the Curie point, the remanence becomes blocked and any ambient field orientation is fixed. *Thermal demagnetization* is based on a similar principle: samples are heated to progressively higher temperatures and then allowed to cool in a field-free space. As temperature is increased stepwise, the magnetization of grains with blocking temperatures lower than that reached will be randomized. The precise unblocking temperature of grains will depend on volume, domain state (single domain or multidomain), and composition, and commonly it is a few tens of degrees below the Curie temperature.

Adequate analysis of the NRM components usually requires progressive demagnetization at a minimum of eight levels (temperature or AF peak field). The laboratory routine involves measuring the NRM and then subjecting the sample to increasingly higher demagnetization steps. The remanent magnetization is measured after each step until the most stable magnetization component is isolated; this is known as characteristic remanent magnetization (ChRM).

Display of NRM

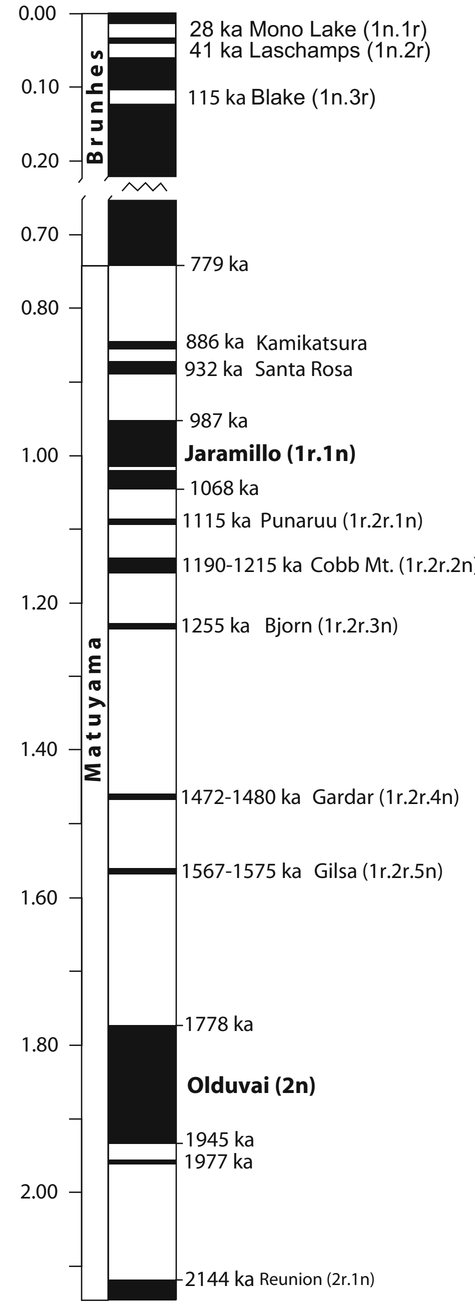
The magnetization of a rock sample is given by three values: the angles of declination (Dec) and inclination (Inc) and the intensity (J). Declination is an angle measured in the horizontal plane and ranging from 0 to 360°, and inclination is the angle in the vertical plane between the magnetic direction and the horizontal. Stereographic, lower-hemisphere equal-area projections are typically used to display NRM directions and mean ChRM directions (Figure 1a). Statistics are normally based on a probability density function (Fisher statistics), which provides the mean direction (Dec, Inc) for a given site (group of samples), the associate angle α_{95} between the unit vector and the true direction, and *k*, a precision parameter (for details and related software, see Tauxe, 2010).

Progressive demagnetization graphical display is usually done with the help of orthogonal projection diagrams, originally introduced by As and Zijderveld (1958). Such diagrams, commonly called "Zijderveld diagrams," have the power of displaying directional and intensity information on a single diagram by projecting the vector onto two orthogonal planes (also see Butler, 1992) (Figure 1b).

Magnetic reversal stratigraphy

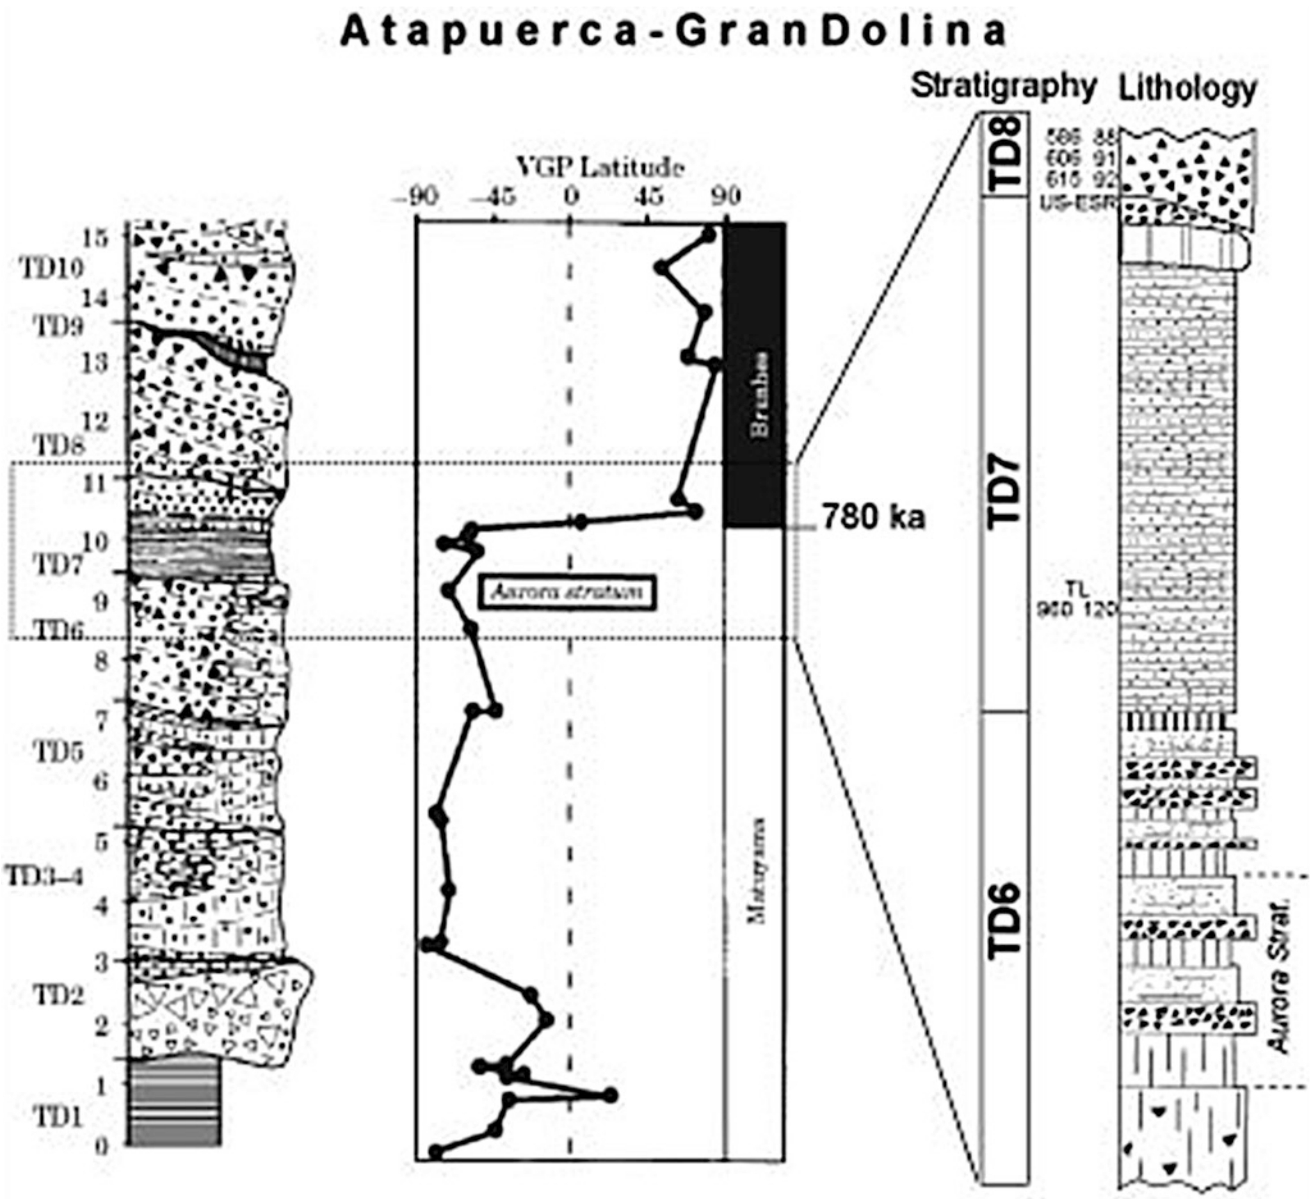
One of the most extended applications of paleomagnetism to geoarchaeology is the use of magnetic reversals to constrain the age of deposits. It is generally accepted that a reversal of the Earth's magnetic field is a global, 180° change in the geocentric axial dipole field averaged over a few thousand years (e.g., Merrill et al., 1996). The polarity (normal or reverse) of the field in a given record is therefore provided by the VGP (virtual geomagnetic pole) position, which represents a snapshot in time. A VGP can then be regarded as the paleomagnetic analog of the present-day geomagnetic pole. For a given stratigraphic profile, the variation in VGP is expressed as VGP latitude as a function of depth or stratigraphic height, where values close to +90 denote normal polarity and close to −90 denote reverse polarity. It is customary to represent the polarity as black (normal) and white (reverse) bar diagrams (see Opdyke and Channell, 1996).

In "old" archaeological contexts (Middle Pleistocene and earlier), magnetic reversal stratigraphy is very often the preferred initial means of age dating. For example, the Lower-Middle Pleistocene boundary, as marked by the Matuyama-Brunhes boundary at 780 ka, has been used in a number of archaeological sites (e.g., Parés and Pérez-



Paleomagnetism, Figure 2 Geomagnetic polarity time scale (*GPTS*) for the past ~2 Ma (Data from Cande and Kent, 1995; Channell et al., 2002, 2012).

González, 1995; Verosub et al., 1998; Oms et al., 2000; Parés et al., 2006, 2010). Magnetostratigraphy has provided major advancements in the chronology of East African localities (e.g., Tamrat et al., 1996; Lepre and Kent, 2010). In addition to the major reversals, a plethora of short polarity intervals (SPI) and some geomagnetic excursions (often regional departures of the geomagnetic



Paleomagnetism, Figure 3 Summary of the magnetostratigraphy and chronology for TD6 through the lower TD8 stratigraphic layers at Gran Dolina, Atapuerca. *Left* side of the figure shows the existing paleomagnetic and stratigraphic data (Modified from Parés and Pérez-González, 1999), and to the *right* is an enlargement (Lithology is modified from Bermúdez de Castro et al., 2008). US-ESR ages from Falguères et al. (1999) and TL ages from Berger et al. (2008).

pole and/or changes in geomagnetic intensity with durations limited to tens of thousands of years or less) have been described in the upper part of the Matuyama and Brunhes Chrons (Channell et al., 2002, 2012) (Figure 2), which also have potential for age determination.

The TD6 level at Atapuerca Gran Dolina (northern Spain) provides an excellent example of magnetostratigraphic dating of an archaeological horizon with applications for hominin paleoanthropology. The infilling sediments at Gran Dolina cave, more than 15 m thick, were originally studied for paleomagnetism by Parés and Pérez-Gonzalez (1995, 1999), and reversed magnetization provided a minimum age of 780 ka for the human-bearing sedimentary layer. A change in magnetic polarity, from reverse to normal (up section), was detected in the uppermost part of the TD7 stratigraphic layer, which overlies the fossiliferous level TD6. This geomagnetic reversal is interpreted as the Matuyama-Brunhes boundary

(780 ka), as suggested by biostratigraphy (Cuenca-Bescós and García, 2007; Cuenca-Bescos et al., 2010) and combined U-series/ESR analyses (Falguères et al., 1999; Parés et al., 2013). The latter was performed on three teeth from TD8, about 1.5 m above the Aurora Stratum, and yielded a mean age of 0.60 ± 0.05 Ma (Falguères et al., 1999). More recently, Arnold and Demuro (2015) reported a TT-OSL age of 851 ± 46 ka for horizon TD6-3 (Figure 3).

Summary

Paleomagnetism, including magnetostratigraphy and archaeomagnetism, is a useful tool for geoarchaeologists and is habitually the first method chosen for age dating in very early periods. It gives data on remanent magnetization recorded in rocks, sediments, and artifacts, which may help in establishing chronologies by age equivalence. If polarity zones of a magnetic stratigraphy profile can be unambiguously correlated to the GPTS, they provide a precise temporal framework for sedimentary sequences.

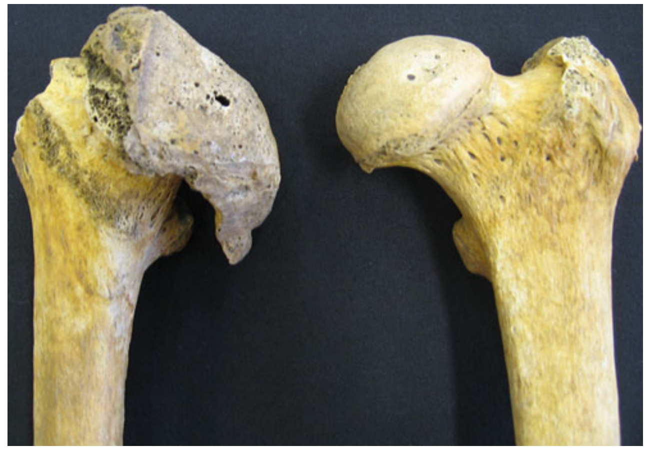
PALEOPATHOLOGY

Charlotte A. Roberts
Department of Archaeology, Durham University, Durham, UK

Definition and history of study

Paleopathology is defined as the scientific study of the evidence of disease in human and non human remains from archaeological sites (Tombs) and was first described as such by Marc Armand Ruffer in the early twentieth century (Ruffer, 1910). Human remains are the primary source of evidence for past disease (Roberts and Manchester, 2005). Other forms of evidence are provided in historical documents and art (e.g., Rawcliffe, 2006 on leprosy in medieval England), but these data can prove difficult to interpret. Whilst evidence for disease in human remains can be challenging to diagnose and interpret, artists and authors may be biased in their representations of the range of diseases from which people suffered, and signs and symptoms illustrated and written about can often be very difficult to associate with specific diseases. Furthermore, it was often the more dramatic diseases that were considered, while the more commonplace ones were ignored. However, documentary and art evidence for disease can help to reveal those conditions that affected only the soft tissues such as those common in childhood.



Paleopathology, Figure 1 Normal femur head on the *right* and diseased head of femur on the *left* side of the picture (diseased femur head is abnormally flattened and has signs of osteoarthritis: new bone formation on the underside of the head and "holes" in the head).

Paleopathology is a subdiscipline of physical anthropology (the study of humans from past to present – Jurmain et al., 2008) and bioarchaeology (the study of human remains within their archaeological context – Buikstra and Beck, 2006). Most people working in the field are those with an archaeological or anthropological training, although there are important and invaluable contributions from medical doctors, anatomists, and dentists. To be able to work within the discipline, it is necessary to have an excellent familiarity with the normal appearance of the skeleton and its associated soft tissues in order to be able to recognize the abnormal diseased state (Figure 1); this is in addition to being able to identify often fragmentary and poorly preserved human remains, including those that have been cremated, and distinguish between human and non human bones and teeth (Figure 2).

Most of the time, the remains studied are skeletons because those are the most common remains to be excavated (Figure 3), but in areas of the world where there are specific environmental conditions, whole bodies may be excavated, thus providing potential evidence of disease

Paleopathology, Figure 2 Horse femur on the *left* and human femur on the *right side* (the bones have similar features but the proportions and size of features differ).

Paleopathology, Figure 3 7th-8th century AD skeleton buried at the Bowl Hole cemetery, Bamburgh Castle, Northumberland, England (Courtesy of Sarah Groves and Graeme Young).

affecting the soft tissues of the body (Aufderheide, 2000; Lynnerup, 2007). Paleopathology has had a long history stretching back into the seventeenth century in Switzerland (Buikstra and Roberts, 2012), which initially was concentrated on archaeological animal remains (e.g., see Figure 4, and more recent work in Davies et al., 2005), later being transferred to those of humans. Most early work on human remains considered individual skeletons or mummies (Ruffer, 1913), often without considering the remains within their cultural context, and it was not until around the early twentieth century that larger groups of skeletons were studied, thus providing a population-based approach to understanding health (Aufderheide and Rodríguez-Martín, 1998). However, this approach did not become common until much later, and in some parts of the world even today, "case studies" are the norm for reporting disease in the past.

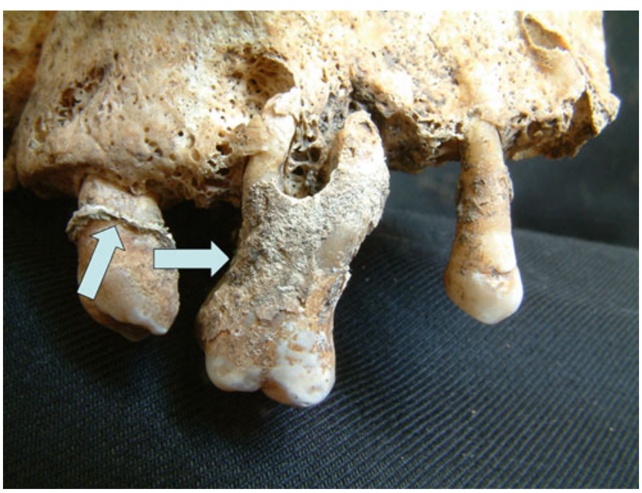
Methods of study

Paleopathology is studied by observing abnormal alterations to the body tissues as evidenced in human remains excavated from archaeological sites. While soft tissues can be studied when they are preserved, a focus here is taken on observations of skeletal remains (bones and teeth). The two key bone changes that can represent disease are bone formation and bone destruction or a combination of the two (Figure 5). In the teeth, disease is represented by loss of dental tissue such as enamel and addition of plaque or tartar in the form of calculus (Figure 6); the bones of the jaws can also be involved, for example, when an abscess affects the person (Figure 7). Bone formation may appear as active woven bone (porous and additional to the original bone cortex) or as healed lamellar bone (chronic and incorporated into the original cortex, indicating healing). Likewise, destruction of bone may be active (unhealed edges to lesions) or healed (edges are rounded). If lesions indicate "activity" then the disease process is deemed active at the time of death. In the case of teeth, destruction of dental tissue is permanent and does not heal. Standard methods have been developed that scholars are encouraged to use (Buikstra and Ubelaker, 1994; Grauer, 2008), and there are many texts that provide useful data for diagnosis and interpretation (Ortner, 2003).

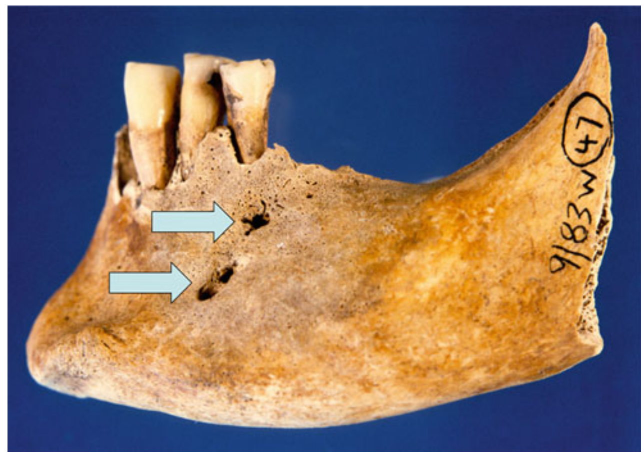
The initial recording of the remains to identify pathological lesions is done by making comparisons between the bones and teeth being observed and normal bones and teeth so that the abnormalities can be recognized. However, there are abnormalities of the bones and teeth that are considered normal variants and are not

Paleopathology, Figure 4 Diseased bone of a sheep on the *left side* compared to a normal one on the *left* (Courtesy of Julie Bond).

Paleopathology, Figure 5 Bone formation and bone destruction on ribs, late Medieval Ireland (Courtesy of Eileen Murphy); *arrows* show examples of the bone destruction (blue) and formation (red).



Paleopathology, Figure 6 Dental calculus (plaque) on teeth, nineteenth century England (Courtesy of Anwen Caffell); *arrows* show the deposits of calculus.



Paleopathology, Figure 7 Dental abscess affecting a lower jawbone, fourth century AD England; *arrows* show the holes (bone destruction) of the abscess where pus drained out into the soft tissues of the jaw.

Paleopathology, Figure 8 Cervical (neck) vertebrae: normal on *right* (one hole) and abnormal on *left* (two holes).

pathologically induced. These are termed non metric traits, some of which can be inherited through families (Tyrrell, 2000; Scott, 2008) – Figure 8. Once the pathological lesions have been noted, making sure that postmortem damage is not mistaken for a disease process, and using detailed descriptions, their distribution pattern is then recorded. This is important for considering possible (differential) diagnoses. It is only possible for the skeleton to react in a limited number of ways to the impact of disease, and therefore similar bone changes can occur in different bone diseases. For example, there are many different diseases that affect the joints, but different joints can be affected in different diseases. It is therefore important to consider all diseases that could have created the bone changes. Similarly, it is vital that the distribution patterns of lesions are examined because, in archaeological contexts skeletons can be fragmentary, and it is often not possible to be certain of a specific disease diagnosis. The distribution pattern of lesions is then compared with what is known in the clinical medical record about how diseases affect the skeleton; this does however assume that reactions to disease in the skeleton have not changed over time. Diagnosis is challenging as there are limited methods available (Waldron, 1994). Diseases that may be recognized in skeletal remains are those affecting the teeth (e.g., caries), joints (e.g., osteoarthritis), the endocrine glands (e.g., hypothyroidism), and metabolism (e.g., scurvy), along with infections (e.g., tuberculosis), congenital conditions (e.g., spina bifida) and tumors, not forgetting the effects of accidents and interpersonal violence in the form of traumatic lesions such as fractures.

Once the pathological data have been collected from the skeletons or mummies, they are analyzed to produce frequency rates for diseases observed according to age and sex (Paleodemography), although this will underestimate the absolute frequency of disease (see below for Limitations). It may also be possible to look at disease in relation to status if the burial record provides evidence of different statuses, for example, in grave good inclusions (Jankauskas, 1999). Following on from analysis of the data, the frequency of disease is then interpreted with reference to what is known about the lives of the people under study. For example, if dental diseases are noted, the diet (Paleodiet) needs to be known because a diet high in carbohydrates would, for example, lead to dental caries. Knowledge of what diet people were eating may be gained from evidence of plant and animal remains at an associated contemporary settlement site along with evidence for economic practices (e.g., agriculture) and food-processing artifacts such as querns used to grind grain (Figure 9). Additionally, stable isotope analyses of carbon and nitrogen levels in bone provide an indication of the general type of diet eaten (Muldner and Richards, 2007). This is termed the "bioarchaeological" or "biocultural" approach; disease data should always be interpreted with reference to the context of the remains studied.

Most scholars record the evidence visually, sometimes with low-power magnification (magnifying glass or binocular microscope). However, radiography, a non destructive analytical method, has also been used regularly to aid diagnosis because the internal structure of bones can be altered by disease (Mays et al., 2006) – Figure 10. Without radiography, these changes would not be visible (Grauer and Roberts, 1996). Routine "plain film" radiographs are the norm, but in recent years, more sophisticated imaging methods have been applied.

Paleopathology, Figure 9 Quernstone, and shells indicating seafood was eaten, at the multiperiod site of Jarlshof, Shetland Islands, Scotland (Bronze Age to the 16th century AD).

Paleopathology, Figure 10 Radiograph showing healed fracture of a fibula, early Medieval England (arrow shows fracture line).

These have included computed tomography (CT) and micro-CT, where "slices" of bones and teeth can be viewed; this has proved particularly valuable for mummified remains (Pernter et al., 2007 – Oetzi). Paleopathologists have also used destructive techniques to diagnose disease, and these have included histological analysis (Schultz, 2001) and more recently biomolecular analysis (Brown and Brown, 2011). The latter has particularly enabled diagnoses of diseases that only affect the skeleton, for example, malaria (Taylor et al., 1997), but the method is still developing along side with methods in biomolecular science.

Limitations of study

Paleopathology is not without challenges, succinctly stated by Wood et al. (1992). It should be remembered that the preservation of a skeleton or a mummy will affect the survival, observation and recording of pathological lesions, so poorly preserved remains will reveal less evidence, and it will be harder to make more specific diagnoses. There is also an assumption that how diseases affect the skeleton has not changed over thousands of years. The focus is on using clinical data on skeletal changes due to disease in people who have not had access to any treatment, for example before antibiotics were used for infections. It should therefore be emphasized that in more recent times, the way in which a disease affects the skeleton could have changed if a person had treatments such as drug therapy, and it is much more likely that treatment would ultimately prevent progression of the disease into the skeleton anyway. This has implications for using disease (along with a suite of other characteristics) as a way of identifying victims of crime in forensic anthropology (Thompson and Black, 2006).

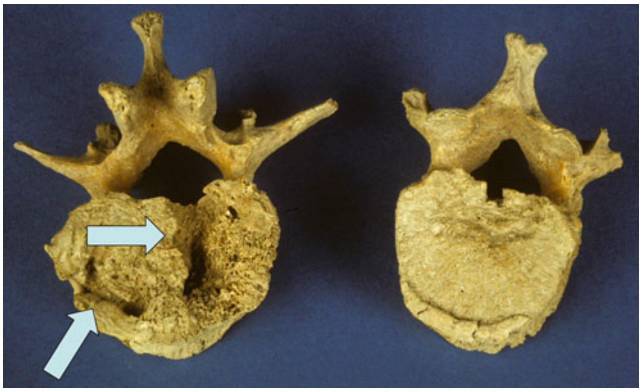
As discussed above, when dealing with skeletons, it is only the diseases that can potentially affect bones and teeth that are identified, although, despite debates about authenticity, ancient DNA analysis of pathogens such as bacteria that cause infections are now being done, but not without controversy (Raoult et al., 2000; Gilbert et al., 2004). Another problem is that for many diseases, only a few percent of (untreated) people will be affected; for example, the infectious disease of leprosy will only affect the skeleton in 3–5 % of people, dependent on their immune response to the bacteria. A person with a high resistance to the bacteria may not develop bone changes, but one who has not. Most evidence is chronic in nature and is interpreted as representing a "healthy" person, with that evidence considered a sign that the person survived the acute stages of the disease. Those without any bone changes of course died of some disease or injury, but it may have killed them quickly, leaving no chance for the disease to make its mark on the skeleton (or the cause of death was a soft tissue disease). When producing frequency rates for disease, those rates will not represent reality for many reasons, including the preceding problems, but also because it is usually not known how representative the dead are of the living population being analyzed. Furthermore, it is not usually possible to detect increases and decreases in disease in cemetery populations because it is usually impossible to divide the skeletons of any one cemetery into smaller time ranges beyond a time range of several hundred years for the whole cemetery's lifespan (see Waldron, 1994).

"Case studies" versus "population" studies in paleopathology

Early on in its history, paleopathology was focused on "case studies" documenting diseases in individual skeletons or mummies at a specific place and time. Often, these studies were devoid of context, commonly reflecting lack of archaeological or anthropological training for those working in the field. While these studies continue to be useful to the discipline, there has been increasing emphasis over the years on population-based work (e.g., see Mays, 2010, 2012). Scholars now regularly focus their studies on testing a generated hypothesis and using specific questions to direct their studies, on the basis of their collected and analyzed data, the hypothesis proposed will be supported or rejected. For example, a number of studies have hypothesized that urban living created more health problems in the medieval period, a hypothesis often upheld. For example, Roberts (2007) discusses facial sinus inflammation in relation to poor air quality, especially in urban Medieval Europe. However, there can be exceptions to poor health in urban environments (e.g., see Judd and Roberts, 1999 where rural medieval people had more fractures than urban people).

Knowledge gained and benefits to archaeology and society today

Over its long history, paleopathology has contributed much to our understanding of the health challenges people faced in the past. The data in general suggest that health has declined as time has gone by and societies have become more complex in how they live, eat and work (e.g., see Steckel and Rose, 2002 on the Americas; Roberts and Cox, 2003 on Britain; Cohen and Crane-Kramer, 2007 for a global view). There are, of course, exceptions, but this seems to be the general trend; living as a hunter–gatherer was healthier than being in a permanent settlement where agriculture was practiced, or living in an urban or industrialized setting. Of course, this is based on studying skeletal remains, and therefore, the broad range of health problems people experienced in the past cannot be seen. This overall view of a decline in health has been developed not only by synthetic work but also through studies of human remains from individual archaeological sites throughout the world, although the amount of study varies depending on availability of training and the absolute number of scholars working in those areas. For example, the USA. and Europe have produced more data than some parts of the world, but times are changing. There are also more focused studies on specific diseases that have informed us about when and where diseases originated and how they have developed over time (e.g., see Roberts and Buikstra, 2003; Powell and Cook, 2005). For example, the earliest evidence for the bacterial infection tuberculosis comes from a number of European



Paleopathology, Figure 11 Destructive lesions (*arrows*) in a vertebra, probably tuberculosis, early Medieval England.

countries and is several thousands years old, but the disease did not become common until Medieval urban living impacted the lives of those people (Figure 11). Paleopathology in more recent times has developed considerably and is now producing data using more sophisticated methods of analysis (e.g., pathogen aDNA analysis and imaging techniques, see above) than has ever been possible before.

How does this work help archaeology and indeed society today? For archaeology as a discipline, one has to remember that without humans, there would be no archaeological evidence. People built settlements and burial monuments, domesticated animals and plants, and made pottery and other artifacts. Knowledge about their health therefore is imperative to understand the past and how society functioned. If a large proportion of people in a population was sick (as we might see today), life could not proceed as normal, and ultimately the socio-economic basis for survival could be threatened, as seen in the Medieval Black Death that killed a large part of Europe's population (Park, 1993). As for society today, paleopathology provides the time depth to the history of disease that allows us to visualize the peaks and troughs in diseases over thousands of years, something that is simply not possible to do when studying disease in the living. It allows us to consider what factors were important for disease to flourish and decline. Intrinsic (age at death, sex, ethnicity) and extrinsic (e.g., diet, living conditions, hygiene levels, occupation) factors create situations where diseases may take advantage and establish and maintain themselves. Paleopathology provides some indication of how to plan for the future, and scholars in the discipline are starting much more to focus on contemporary health problems. Paleopathology is also contributing to the newly emerging discipline of evolutionary medicine (e.g., see Nesse and Williams, 1994) "Evolutionary ways of thinking and doing research may lead to new ways of treating and preventing diseases and disorders, potentially saving lives, or at the very least, improving the quality of life for those whose conditions compromise health or lead to early death" (Trevathan et al., 2008, p. 10).

Future developments

There are an ever-increasing number of scholars working in paleopathology, even in remoter parts of the world that until recently had produced little data on the history of disease in human remains; this is undoubtedly because training has become more widespread, people from other countries are working on human remains in those places, or scholars are being trained elsewhere and returning home to work on human remains with newly developed skills. Countries seeing this trend emerge will naturally be slower in producing the much needed population-based studies in paleopathology more common in the United States and Europe, but in time these will come. Without a doubt, as methods develop, there will be increasingly more attention paid to using biomolecular analysis to diagnose disease in human remains (e.g., see Bouwman et al. 2012), notwithstanding some of the limitations identified (e.g., see Roberts and Ingham, 2008; Wilbur et al., 2009). Paleopathology has a promising future in helping the world plan for the health of its population.

Summary

Paleopathology is the study of ancient disease seen in animal and human remains excavated from archaeological sites. It has had a long history of study and helps us to understand how disease has shaped human populations today. It is based in clinical medicine, practiced mainly by people with archaeological and anthropological backgrounds, and it emphasizes contextualization of data collected to understand patterns seen. It provides a deep time perspective on health, contributes to evolutionary medicine and utilizes a range of methods of analysis.

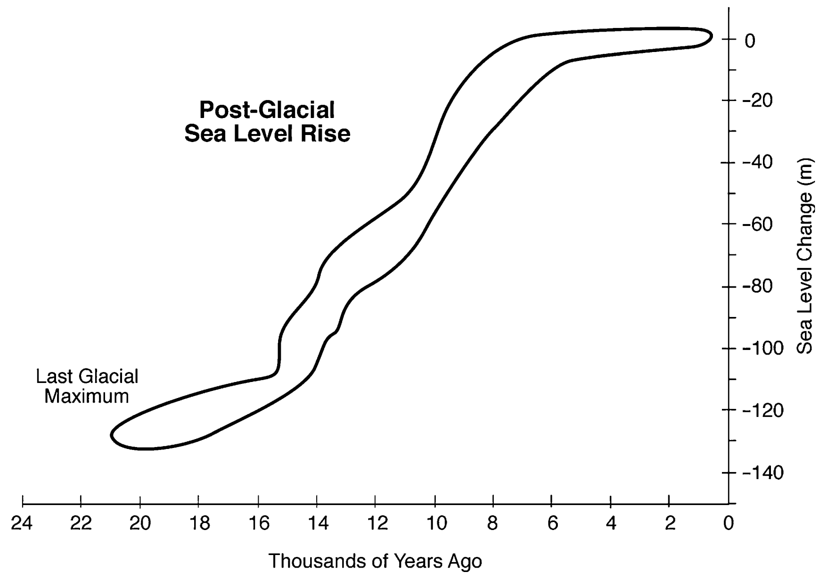
Introduction: traces on the Rhodian shore?

In his seminal book looking at nature and culture in western thinking, Glacken (1967) stated that geography, particularly geoarchaeology, poses the question of possibilism, the idea that the environment sets certain constraints and



Paleoshores (Lakes and Sea), Figure 1 Sea-level changes since 18,000 years BP (Adapted from Fleming et al., 1998). The outlined area subsumes the variability in sea level spatially and temporally (tides, oceanic circulation, etc.).

that humans can act as geomorphic agents. In this sense, shorelines are an archetypal interface to look at rapidly changing terrestrial and aquatic environments.

More than a century ago, the American geomorphologist John Wesley Powell introduced the term "base level" to define the elevation below which a stream cannot downcut deeper into its valley. Fluvial processes cease where a river flows into a large lake or the ocean because the hydraulic gradient is reduced to zero at the origin of sedimentary deposition (Chorley et al., 1964). Since the time of Powell's pioneering work, the ocean has been regarded as a reference base level even though sea level varies in space and time, and it is paramount in driving shoreline changes and human settlement geographies. One of the key advantages of living in coastal areas is access to marine resources, including mollusks, mammals, and birds, all of which provide potentially rich sources of energy and protein.

Geological evidence for relative sea-level changes and local crustal movements is critical to understanding the archaeological record in coastal areas. Gaps in the record increasingly point to the need for underwater exploration of submerged shorelines, and a growing body of evidence shows that archaeological sites are prevalent in submerged landscapes. Two major forcing factors explain shoreline deformations: (1) relative sea-level (RSL) changes and (2) modifications in sedimentary budgets at various spatiotemporal scales.

Geoarchaeology of paleoshorelines and Quaternary RSL changes

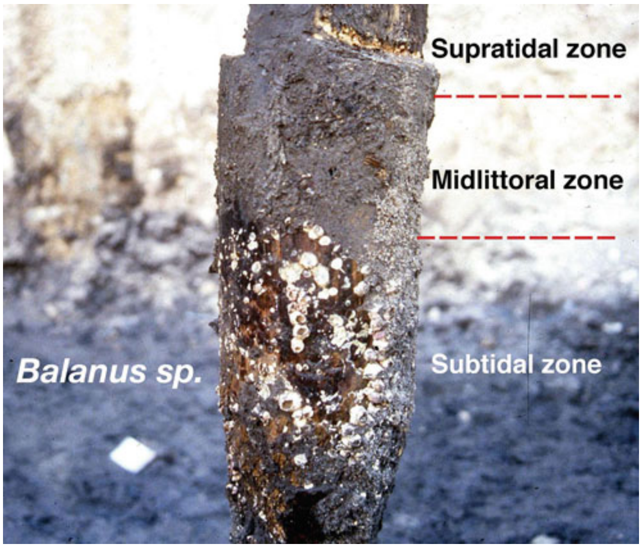
Past sea-level changes have been driven by eustatic and crustal factors, e.g., isostasy, tectonics, geoidal changes, and the effects of changes in the Earth's rotation. Over the past 20,000 years, these forcing agents have interacted at various spatial and temporal scales (references and synthesis in Church et al., 2010).

During the interval prior to ca. 6000 years BP, most sea-level curves are characterized by a general rise in the water level corresponding to the eustatic signature of melting continental-based ice caps. Once the last of the large ice caps had melted (around 6000 years BP), glacio-eustatism ended (e.g., Pirazzoli, 1991; Mörner, 1996; Lambeck and Bard, 2000) (Figure 1). Since this date, relative sea-level records have been dominated by crustal mobility and the irregular redistribution of water masses over the globe, primarily driven by variations in ocean and atmospheric circulation systems (marine currents, evaporation/precipitation budgets). Since the Neolithic, a plethora of archaeological indicators can be used to estimate RSL changes.

Archaeological and biological markers of RSL changes

Since 6000 years BP, ancient societies have left different types of coastal evidence indicating RSL changes, including town structures, anchorages, and ports. Submerged artifacts can provide interesting details to reconstruct ancient shoreline changes. The use of archaeological RSL markers draws upon the close interaction between archaeologists, geomorphologists, and biologists (Pirazzoli, 1976; Auriemma and Solinas, 2009).

Archaeological evidence for RSL variations is wide and varied (Flemming and Webb, 1986). Broadly speaking, it can be recovered within three zones.



Paleoshores (Lakes and Sea), Figure 2 Biological zoning on a wooden stake from the 1993 excavation of two sixth-century BC archaic Greek ships at the Place Jules-Verne site in Marseille (Morhange et al., 2001). Barnacles (*Balanus* sp.) mark the submerged infralittoral range on the piling, while the midlittoral and supralittoral sections are clearly discernible higher up.

1. The *supralittoral zone* includes residential units such as villae maritimae, private and public buildings, or town quarters (foundations, floors, roads, and pavements), thermal baths, plumbing installations (wells, aqueducts, cisterns, sewers, drains, gullies), tombs, and quarries. When inundated by rising seas, these remains can provide estimates for the amount of submersion.
2. The *midlittoral zone* includes interface structures such as quays, piers, breakwaters, or fishponds that exist at the sea level of the time. These constitute the most precise type of archaeological RSL indicators.
3. Finally, the *infralittoral zone* hosts structures such as wrecks or harbor foundations, which again provide broad estimates on the magnitude and direction of relative sea-level changes.

Under favorable conditions, measurements must be taken in relation to the mean biological sea level (MBSL), as defined by Laborel and Laborel-Deguen (1994). Marine biologists have demonstrated that, on hard substrates, the limit between the midlittoral and infralittoral zones is marked by a well-defined qualitative and quantitative change in the composition of benthic algal and animal populations (Figure 2). These subfossil zones can be preserved in the case of coastal uplift or silting of the archaeological site (Pirazzoli, 1977; Morhange et al., 2001). This limit also corresponds to distinct morphological features such as the vertex of tidal notches or the floor of erosion platforms (Pirazzoli, 1986). Seasonal or aperiodic sea-level changes have little or no influence on these biological and geomorphological belts.

Archaeological evidence brings with it varying degrees of precision when used to indicate the former RSL, and therefore care must be taken to ensure the indicator chosen has a reliable maritime association. It is also important to evaluate critically the functional elements of the indicator and the dimensions of the emerged part (if it has risen above the water) relative to present sea level (Auriemma and Solinas, 2009). Consequently, it is important to determine the chronology and the dynamics of its abandonment or destruction. This is achieved by archaeological surveys, sampling of the chronological indicators (ceramics, etc.), and excavation. Interdisciplinary work, drawing on archaeology, the geosciences, and marine biology, aims to (1) measure RSL variations based on the best preserved archaeological remains, (2) evaluate the height and functional depth of the indicator relative to mean sea level and if possible the MBSL, and (3) establish chronological and altitudinal error bars with relation to MBSL.

Geoarchaeological case studies of eustatic sea-level changes and recent RSL variations

Quaternary marine oscillations: the prehistory of land bridges and coastal resources

It is now well established that large sea-level fluctuations accompanied the glacial-interglacial cycle. The maximum amplitude of eustatic variation in response to continental glaciation was approximately 120 m, with relatively short periods of highstand punctuating much longer periods of lowstand. The pattern of sea-level change is best attested for the last glacial-interglacial cycle, but earlier cycles were accompanied by similar fluctuations back to 2.5 Ma (Lambeck et al., 2002).

The archaeological implications of these sea-level changes have been recognized for a long time. They significantly influence the visibility of marine resources at different periods, the preservation of coastal archaeological sites, human dispersal (the creation and submergence of land bridges), changes in shoreline ecology, and alterations in the paleo-economic potential of coastlines (Masters and Flemming, 1983; Bailey and Flemming, 2008). For example, prehistoric peoples were able to exploit exposed coastal and continental resources during sea-level lowstands, and crossings by land routes were facilitated by marine regressions; the Bering Strait lays above sea level and acted as a land bridge for human migration and the movement of other biota in the late Pleistocene until 11,000 years BP (Elias et al., 1996).

As Bailey (2004) stresses, the received wisdom of world prehistory has been dominated by land-based narratives, where hunter-gathering societies gradually adopted agriculture and domestication. Little emphasis has been placed on the use of coastlines and marine resources due to three consistent biases: (1) sea-level changes have removed evidence through erosion or submergence, (2) research biases have traditionally neglected coastal hunters and gatherers, and (3) a focus on technological "primitivism" in which the tools and knowledge to exploit coastal resources were a late development in human cultural development (Bailey, 2004). Nevertheless, coastal habitats are among the most attractive for human settlement, and they have played key roles as gateways to human movement and the rise of civilizations (Flemming, 2004).

Postglacial marine transgression and the prehistory of continental shelves

Popular interest in marine archaeology, combined with the democratization of scuba equipment, has resulted in remarkable offshore discoveries (Masters and Flemming, 1983). Recent advances in bathymetric mapping and geophysics have shed fresh light on the dynamics of shoreline changes and human ecology in coastal areas.

Key problems relate to the preservation of submerged material, the sequence of burial, and taphonomy processes. What are the possibilities of coastal/marine prehistoric deposits surviving into the present, either in primary or reworked contexts? What processes are most favorable to the survival of prehistoric sites? Can the pre-transgressive landscapes be precisely reconstructed? Destruction is greatest for sites located in areas directly exposed to breaking waves. It is important, therefore, that sediments rapidly cover archaeological sites in order to ensure their long-term survival in the geologic record (Bailey and Flemming, 2008; Bailey et al., 2008).

Based on sea-level data and local geological and geoarchaeological records, Perissoratis and Conispoliatis (2003) have established that, during oxygen isotope stage 2 (21,500 years BP, sea level at −120 m), extensively exposed continental shelves existed in the northern and eastern Aegean Sea (Greece) and central parts of the Ionian Sea. Many islands formed larger complexes and were connected with the mainland. The peripheries of many gulfs were subaerially exposed, while freshwater lakes formed in their central parts. At 11,500 years BP (sea level at −60 m), the surface area of the exposed shelf was already greatly diminished, and the advancing sea overflowed into most of the gulfs; just a few islands retained land bridges to the mainland. Finally, from 8000 years BP and onward, the sea drowned the lowlands and gulfs, but subsequent sediment input by fluvial systems induced rapid coastal changes. Thus, many human settlements and ancient cities with maritime orientations during Hellenistic or later times are today located tens of kilometers inland.

At shorter time scales, historical relative sea-level rise has submerged numerous archaeological sites, such as the settlement of Atlit Yam (Israel). Galili et al. (1993) were able to reconstruct a precise sea-level curve based on archaeological and sedimentological evidence from submerged sites. This work has elucidated two main stages of sea-level rise: from 8900 to 7000 years BP (sea level rose from −35 to −7 m) and from 7000 to 4000 years BP (sea level rose from −7 m to its present position). The resulting rapid landscape changes, combined with the loss of vital terrestrial and underwater resources (i.e., agriculture, pasture, hunting, and fishing grounds), must have necessitated ongoing adaptations by the coastal communities. By contrast, no major RSL changes have been attested in the last 4000 years (Galili and Nir, 1993; Sivan et al., 2001).

Recent crustal movements, tectonism in Crete versus isostasy in the Pacific

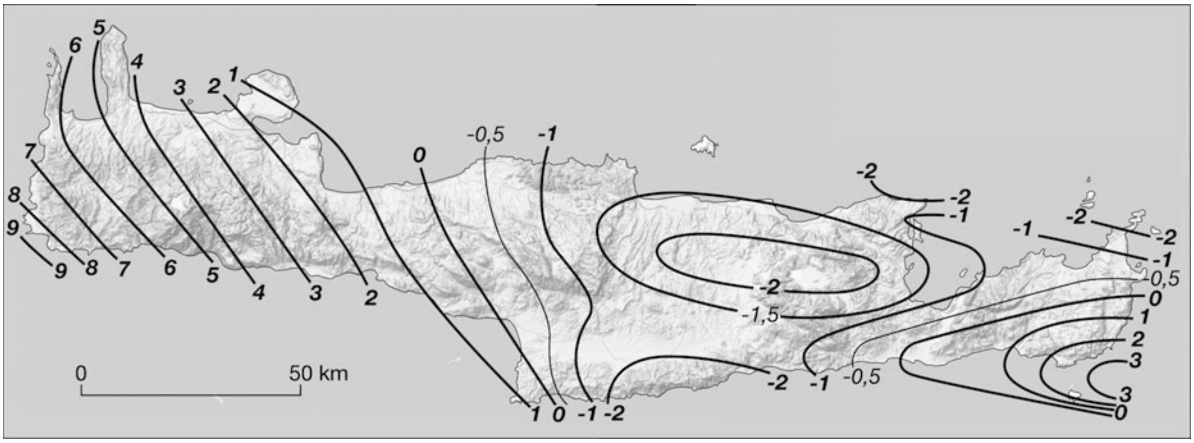
Western Crete was uplifted by up to 9 m in the fourth to fifth centuries AD (Stiros, 2010). At the scale of the Eastern Mediterranean, a cluster of coastal uplifts is attested by radiocarbon and archaeological data around this time. Detailed analysis of geological, historical, and archaeological data suggests that a major earthquake in Crete was responsible for coastal uplift in 365 AD. Despite significant changes in the coastal morphology, widespread destruction, and human loss of life, the 365 AD earthquake was not responsible for any major cultural change in Cretan society (Figure 3).

In a different crustal context, many studies of the Pacific islands suggest that relative sea-level fall has driven cultural change during the 3000-year history of human settlement. This is notably the case for the Lapita culture, which was dependent on coral-reef foraging but disappeared almost simultaneously around 600 BC (Nunn, 2005, 2007a; Carson, 2008). Most colonizing Lapita settlements were established on coastal fringes, perhaps on sandspits or sand-floored reef flats. As relative sea level fell and sediment accreted, these areas emerged inducing changes in settlement character and distribution (Nunn and Heorake, 2009). It is also clear that around 1300 AD, there was a rapid fall in relative sea level of 70–80 cm that induced food shortages in coastal areas across the Pacific Islands region and led to an abandonment of coastal settlements in favor of upland fortified settlements (Nunn, 2007b; Field and Lape, 2010). Environmental change was therefore an important cause of societal transformation during the prehistory of the Pacific Islands.

Geoarchaeology of Holocene coastal changes, from marine transgression to coastal progradation

Glacio-eustatic sea-level rise after the Last Glacial Maximum brought about worldwide flooding of coastal areas, controlling the evolution of marine embayments, fluvial mouths, and rocky coasts. By contrast, its significant deceleration during mid-Holocene times resulted in shoreline progradation, which was particularly pronounced along sediment-rich clastic coasts.

These shoreline modifications forced ancient societies to adapt their settlements continuously to the evolving landscape. Such rapid changes in sedimentary environments have been investigated in detail throughout the world using many methods and disciplines, including



Paleoshores (Lakes and Sea), Figure 3 Holocene land-level changes in Crete (After Kelletat (1991), and Stiros (2010)). Western Crete has been generally rising and eastern Crete sinking; numerical indicators are in meters.

geography, geomorphology, geology, biology, and archaeology. These studies have demonstrated that Holocene sea-level rise led to a general marine transgression, which was later countered by a strong progradational trend on alluvial-rich coasts that in turn slowed the rate of sea-level rise due to an increase in sediment yields from fluvial systems. During the last 3000 years, these sediment yields were enhanced by greater erosion rates due mainly to human-induced impacts on soil, vegetation, and fluvial systems.

All over the world, extensive coastal changes have played out on deltas, which act as depocenters storing large volumes of sediment produced by terrestrial erosion and delivered to the coast by fluvial systems. Deltas constitute excellent geo-archives for the study of settlement phases and coastal deformations. Paleogeographical studies have been important in developing new scenarios for delta and floodplain evolution. For example, Brückner (2005), Brückner et al. (2005, 2006), and many others have investigated the evolution of a number of eastern Mediterranean deltas during the last six millennia. The spatial and temporal evolution of the deltas has been reconstructed using geoarchaeology, combining delta stratigraphy and geomorphology with archaeological sources. For example, the siltation of the seaport of Ephesus (Kraft et al., 2007) was associated with the progressive deltaic growth of the Küçük Menderes (Kaystros) river and its tributaries. Ancient Troy, too, overlooked a large marine bay that has gradually silted up with sediment from the advancing Karamenderes (Scamander) and Dümrek (Simois) river deltas, weakening the city's strategic position (Kraft et al., 2003) (Figure 4).

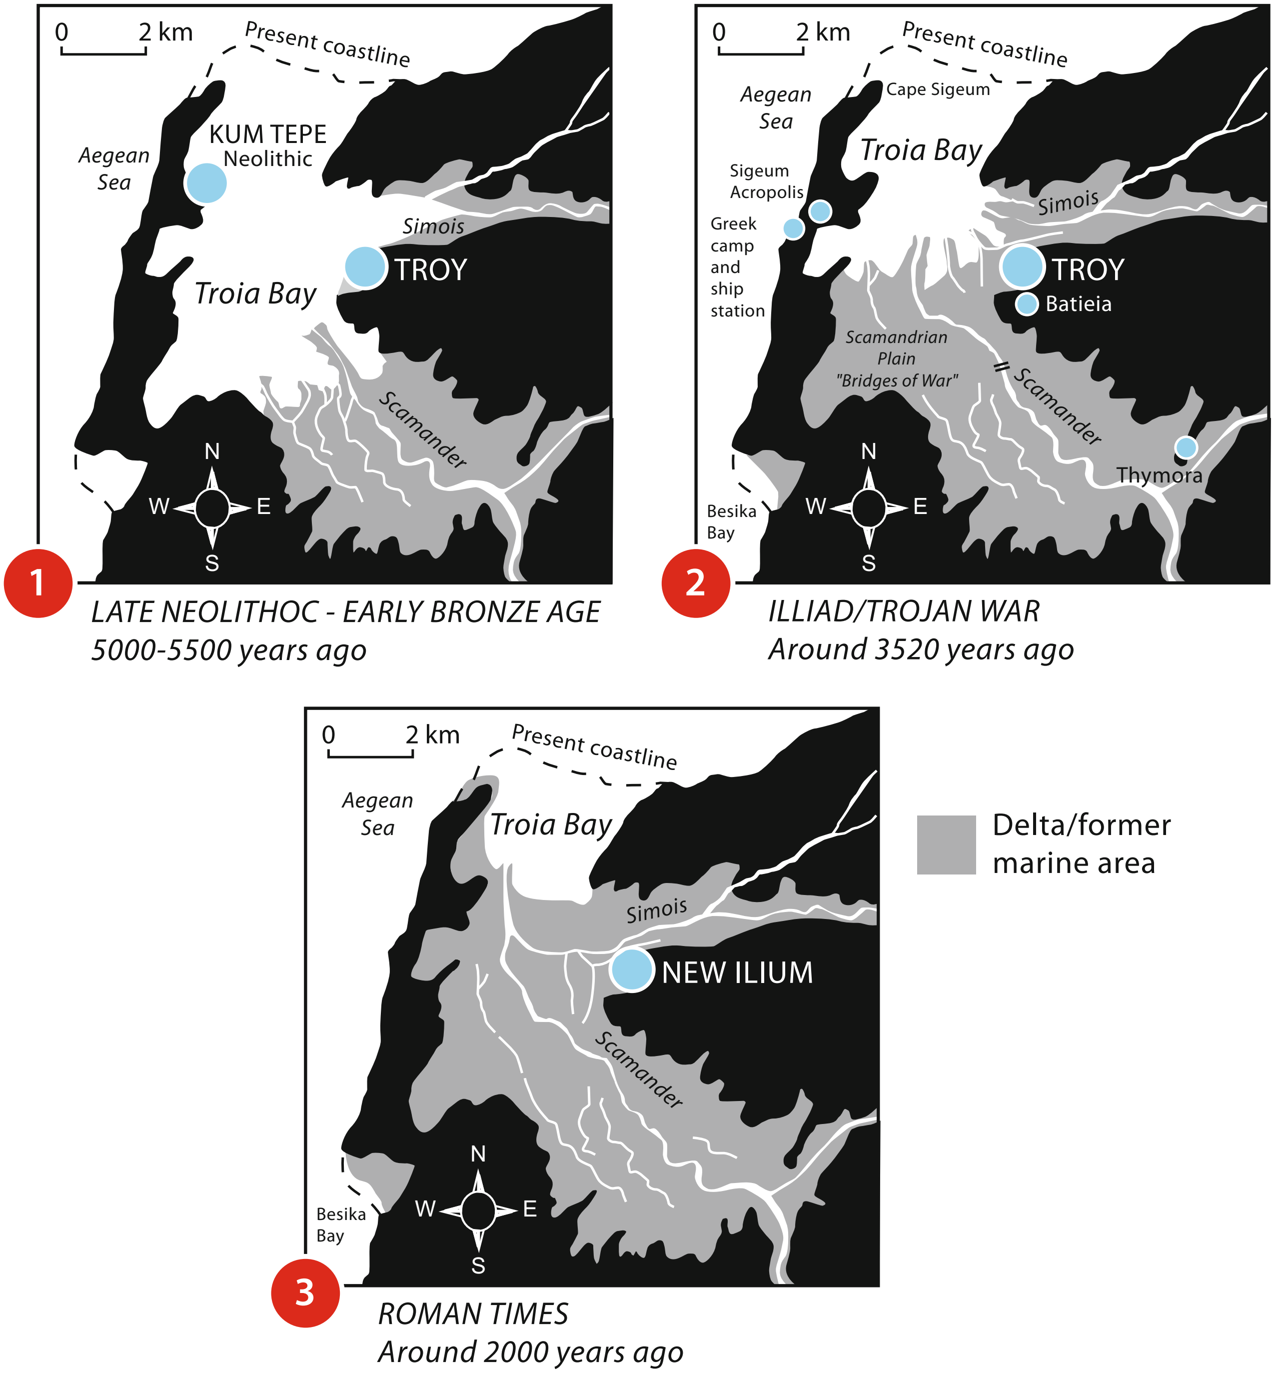
In Greece, Vött et al. (2007) have shown precise evidence for delta growth, based on chronostratigraphic data. The shipsheds of Oiniadai, dating to the fifth–third centuries BC, are today located 9 km inland on the Acheloos River (Acarnania) delta attesting to considerable coastal changes since the mid-Holocene. It has been demonstrated that Oiniadai's ancient shipsheds were accessible to the sea via a lagoon (Figure 5).

During the past 30 years, an acceleration in RSL rise and upstream sediment trapping by fluvial dams has led to accelerated erosion that has exposed archaeological remains, such as in Gaza (Morhange et al., 2005) and Tunisia (Trousset et al., 2004). Although coastal progradation has been the general trend during the past few millennia, many coastlines are, paradoxically, undergoing erosion linked to a human-induced decline in sediment supply that is currently destroying a great number of coastal sites.

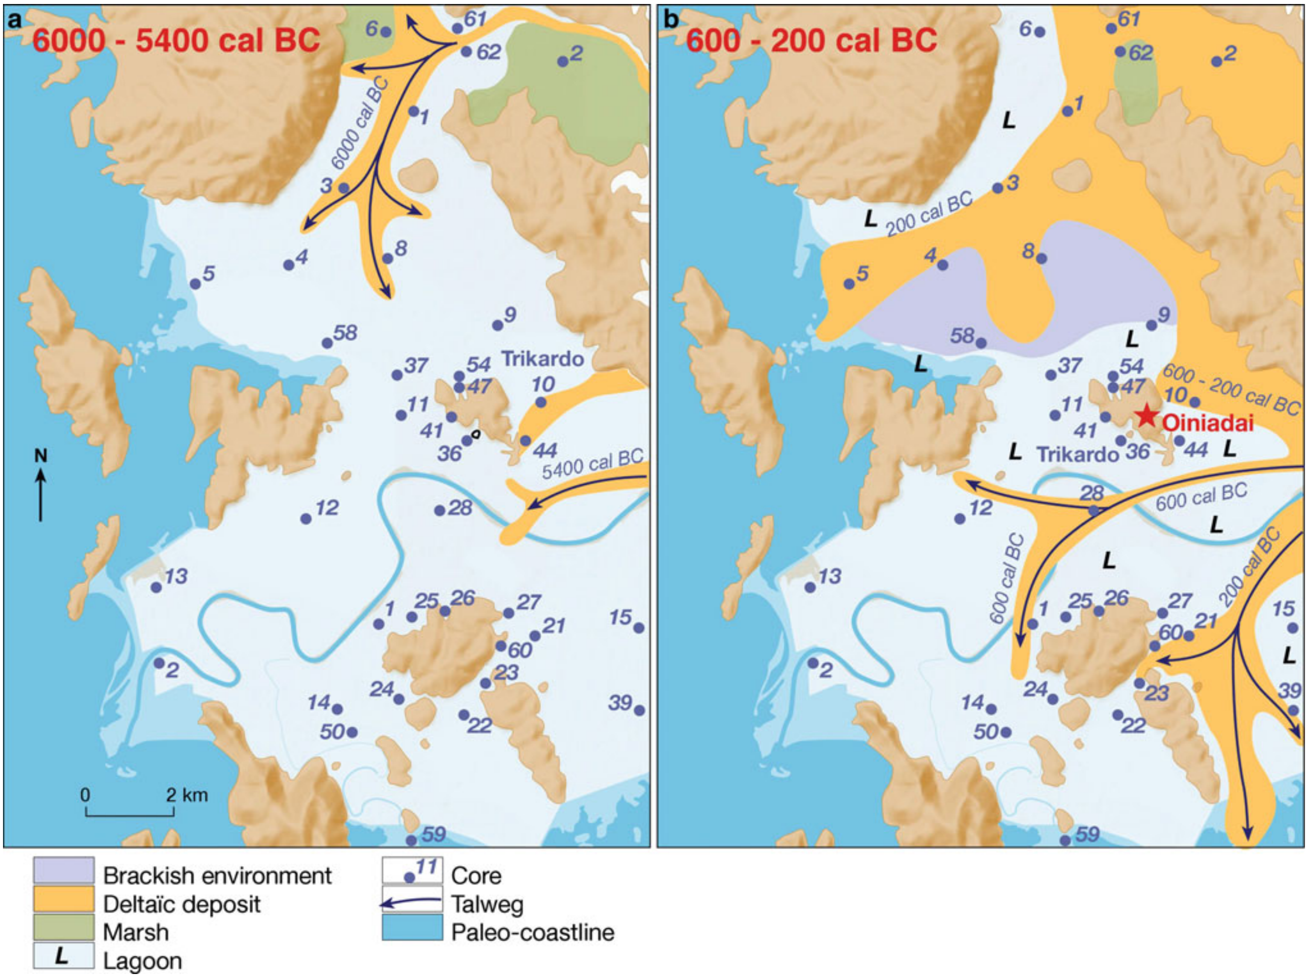
Lacustrine geoarchaeology: a long-standing controversy

Archaeological investigations have shown that lakeshores were attractive areas for ancient societies not only in Europe, where the sub-Alpine area has famously yielded Neolithic and Bronze Age lake dwellings, but also in other parts of the world, such as the many pre-Hispanic sites around the lakes of South and Central America. Because of the abundance of limestone rocks in their catchment area, most sub-Alpine lakes are characterized by a littoral platform at least partly composed of carbonate lake marl. In the shallow water on the surface of these littoral platforms, the remains of Neolithic and Bronze Age villages were discovered in the mid-nineteenth century, first in Switzerland and then rapidly all around the Alps in France, Germany, Austria, Italy, and Slovenia. Up until the late 1970s, these discoveries were controversial and vigorously debated: how could one explain settlement remains below present water level?

The mid-nineteenth-century Swiss researcher F. Keller interpreted the hundreds of wooden posts emerging from lake sediments as piles supporting platforms for lake dwellings (Figure 6). This hypothesis assumed that lake level and climate had not varied since the Neolithic period.



Paleoshores (Lakes and Sea), Figure 4 Paleogeography of the coastal area around Troy (Adapted from Kraft et al. (2003)) made famous by Homer's epic Greek poem the *Iliad*. At the time the *Iliad* is set, more than 3000 years ago, Troy overlooked a vast marine embayment that has since been infilled by sediments from the Scamander and Simois rivers. The archaeological remains at Troy today lie more than 6 km from the present coastline and bear testimony to the rapid changes in geography that can take place on deltaic systems with high sediment supply.

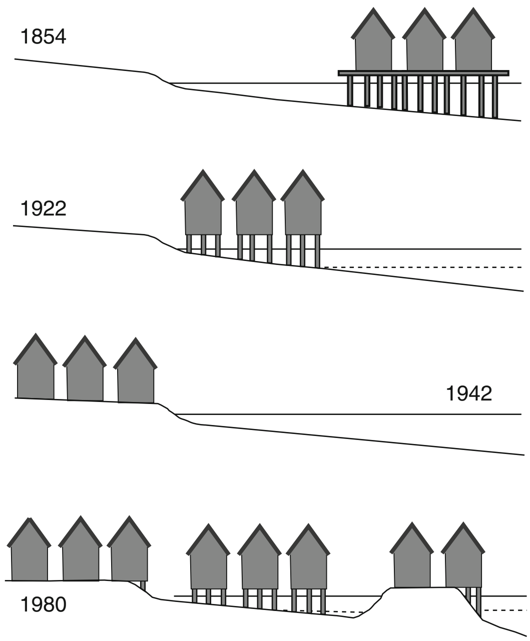


Paleoshores (Lakes and Sea), Figure 5 Progradation of the Acheloos River delta since 6000 years BP and location of the ancient seaport of Oiniadai (northwestern Greece), from Vött et al. (2007). The numbers denote core locations used in the paleogeographical reconstruction.

In the first half of the twentieth century, investigations by the German H. Reinerth led to a reinterpretation. On the basis of careful archaeological excavations and observations of architectural structures in the lakes Federsee and Bodensee (Germany), Reinerth postulated that the prehistoric lakeshore dwellings had been built directly upon the ground, or with slightly raised floors to accommodate seasonal floods, when the lake level was lower than today due to phases of drier climate. Reinerth's proposal was also consistent with the first paleoclimatic reconstructions developed for the Holocene period by the Scandinavian palynologists A. Blytt and R. Sernander, as well as by the palynologist H. Gams, and the geologist R. Nordhagen in Central Europe.

In the mid-twentieth century, a group of German and Swiss archaeologists led by O. Paret and E. Vogt went even further and affirmed that prehistoric lake dwellings had never existed, relegating them to mere myths. Neolithic and Bronze Age villages were built on the ground when lake levels were lower than today due to drier subboreal climatic conditions.

Since the 1970s, the adoption of more rigorous archaeological techniques, in addition to exceptional findings such as the Bronze Age settlements of Fiavé-Carrera in northern Italy (Perini, 1994), has progressively demonstrated that a great diversity of lakeshore dwellings developed during the Neolithic and Bronze Age around the Alps. The French archaeologist P. Pétrequin (Pétrequin and Pétrequin, 1988) has even shown that all types may have coexisted in the same village! As the debate on sub-Alpine prehistoric lake dwellings gradually abated, paleoclimatic investigations undertaken during the last three decades have provided detailed insights into Holocene climate history. These studies have shown that the last 11,700 years have been punctuated by successive centennial-scale phases of higher and lower lake levels



Paleoshores (Lakes and Sea), Figure 6 Successive interpretations of Neolithic and Bronze Age lakeshore villages in the sub-Alpine zone (Modified from Schlichtherle and Wahlster (1986)).

in West-Central Europe, in response to various forcing factors (Berglund, 1986; Magny, 2004, 2006).

Lakeshore archaeological sites and past environmental conditions

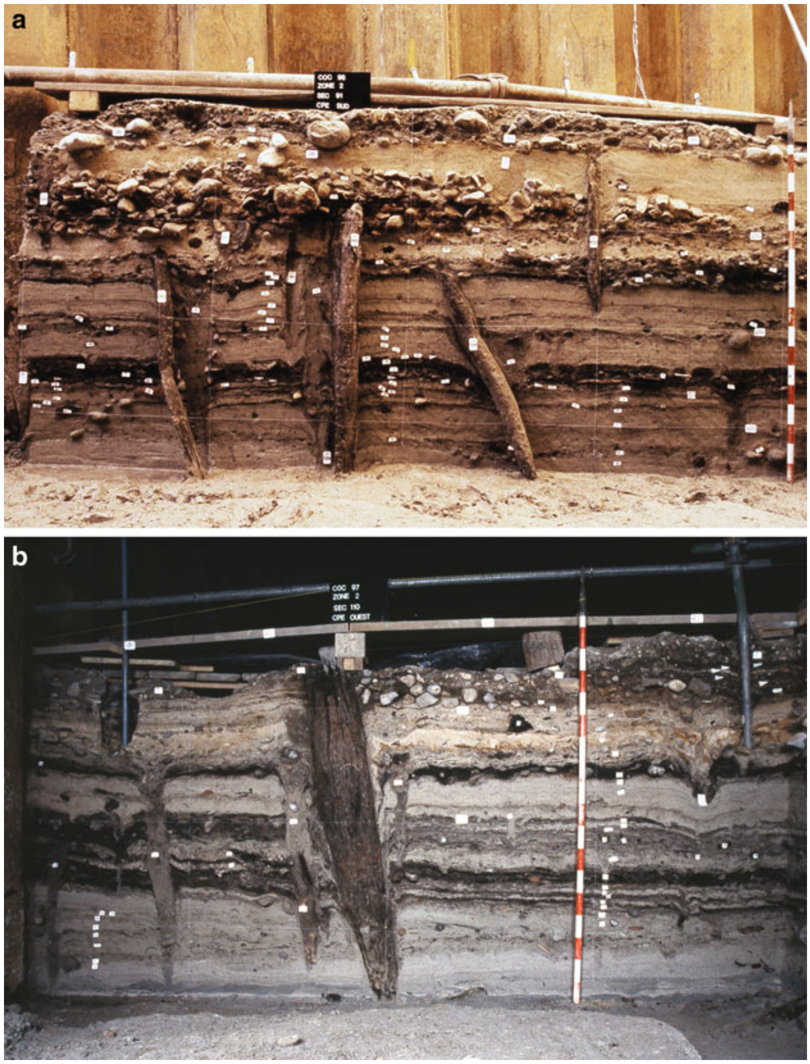
Despite these long-standing controversies regarding the general interpretation of sub-Alpine prehistoric lake dwellings, present-day investigations now operate within a more diverse and developed scientific framework. Generally, geoarchaeological studies have focused on the reconstruction of environmental conditions within these prehistoric villages built along the shores of sub-Alpine lakes. On one hand, this has entailed reconstruction of past positions of (and changes in) the water table during settlement phases in order to make more informed interpretations of architectural structures and/or to explain successive occupation and abandonment phases observed at a site. On the other hand, this has also involved the reconstruction of site paleogeography and past configurations, in addition to the general climatic and human contexts. The following section provides a brief overview of the types of proxies and strategies used in geoarchaeological studies of lakeshore sites, looking not only at reconstructions of local environmental conditions but also at the explorations into regional interactions between climate, environment, and land use.

As illustrated in Figure 7, the stratigraphic sections exposed during archaeological excavations of lakeshore sites often reveal sediment sequences displaying an alternation of layers resulting from natural lacustrine sedimentation and anthropogenic activities. Such sediment sequences reflect the successive phases of occupation and abandonment of the site by former agricultural societies. Moreover, the archaeological layers are also characterized by a more or less marked juxtaposition of anthropogenic deposits with natural sediments, which may indicate lake transgressions during the village occupation depending on both the architectural structures (houses directly on the ground or with raised floors) and the height of the water table (sensitivity to seasonal floods).

In the field, a key prerequisite for paleoenvironmental studies at lakeshore sites is the establishment of long stratigraphic sections and/or core transects within and outside the archaeological excavations, to probe the general environmental context of the site (Fouache et al., 2010). This provides evidence for phases marked by an extension of allochthonous terrestrial influxes (lowering of the water table) and those characterized by lake-dominated sediments (rising water table) (Figure 8). This also highlights layer geometry, lateral variations in lithofacies, local sediment hiatuses, stratigraphic unconformities, and sedimentation limits that can be used to reconstruct (1) the paleogeographical context of a site, as shown by investigations at Lake Clairvaux in the Jura Mountains of eastern France (Figure 9) or at the former Lake Texcoco in the basin of Mexico (Lamb et al., 2009) and (2) past variations in the lake level, as demonstrated by lake-level studies at Lake Chapala in Central America (Davis, 2003). Similarly, multiple littoral cores studied in the Upper Lerma Basin (Central Mexico) have shown how the construction of man-made islands reached a peak around 550–900 AD during a phase of shallow water and how an increase in lake level around 1100 AD may have led to the abandonment of this living strategy (Caballero et al., 2002). High-resolution seismic investigations based on GPS positioning offer an additional tool to produce reflection profiles, with a vertical resolution of 0.2 m (Chapron et al., 2005; Anselmetti et al., 2007; Chapron, 2008).

Finally, such a strategy helps to pinpoint relevant sites for sampling and analyses, based on sediment hiatuses as well as keeping in mind constraints linked to the types of proxies used for analyses.

Regarding the analyses, various proxies are available within sediment archives that can be used to reconstruct past lake levels. Beginning with the Swedish researcher T. Nilsson in the 1930s, then further developed by Digerfeldt (1986, 1988), Birks (1980), Jacomet (1985), and Hannon and Gaillard (1997), the first type of approach is based on the analysis of plant macrofossils from cores along a transect oriented perpendicular to the shore. This transect yields information useful in reconstructing changes in the spatial distribution of aquatic vegetation belts that reflect water depth (successive zones of emergent, floating-leaved, and submerged vegetation belts that fan outward from the shore). Thus, a decrease in water depth (lake-level lowering) leads to an outward extension

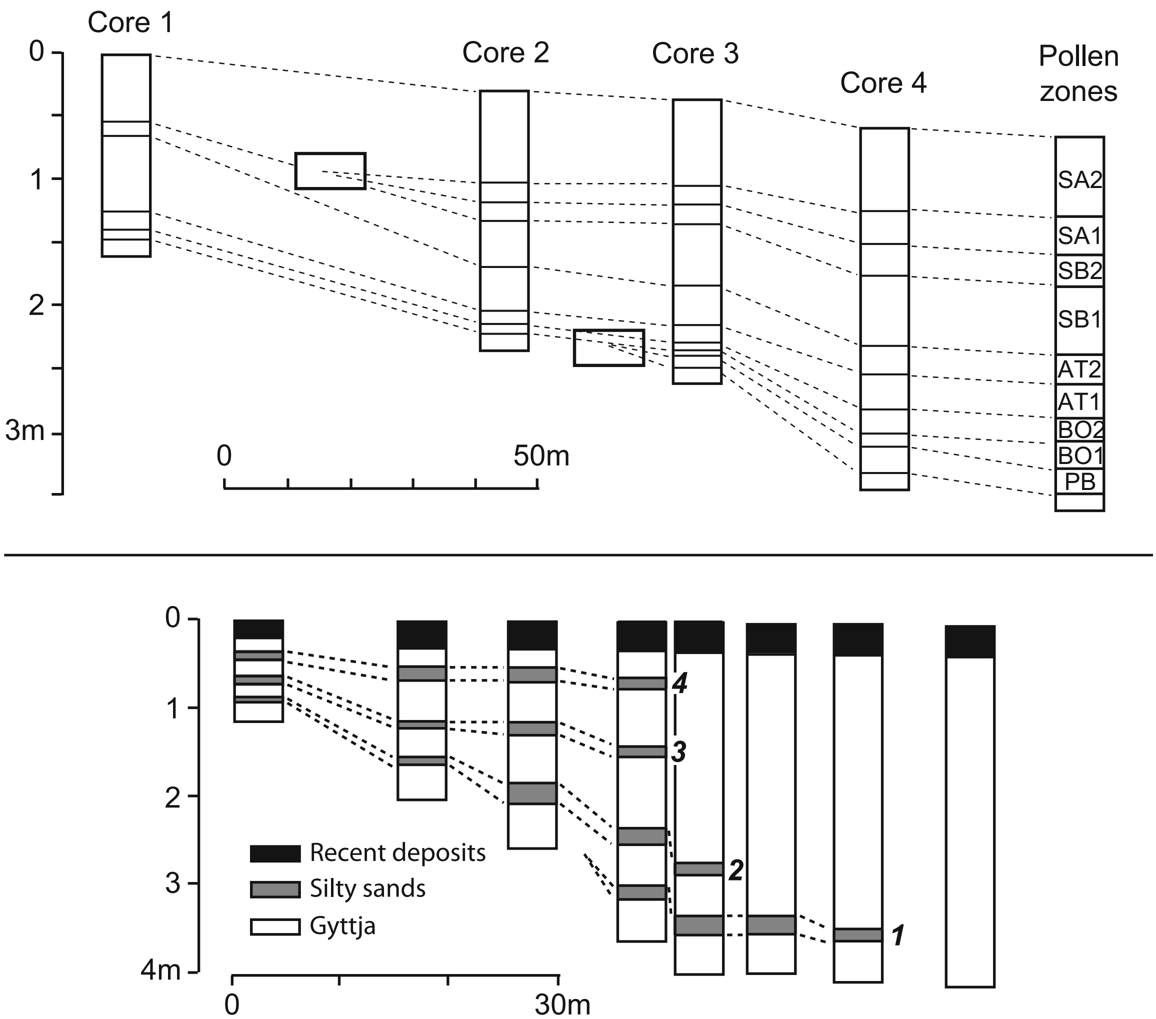


Paleoshores (Lakes and Sea), Figure 7 (**a**) and (**b**) show two stratigraphic sections at an archaeological lakeshore site from Concise, Lake Neuchâtel in Switzerland (photograph by P. Muller, Section de l'Archéologie Cantonale Vaudoise, in Magny (2008)). Note the alternation of (1) dark organic archaeological layers sedimented during the occupation phases and (2) light (carbonate) lake-marl layers deposited during the intermediate abandonment phases. Also note remains of vertical wood posts used by prehistoric people for the construction of houses.

of macrophytes, while an increase in water depth (rising lake level) leads to their inward displacement.

Another similar method of reconstruction using core transects is based on a combination of several sediment markers as follows:

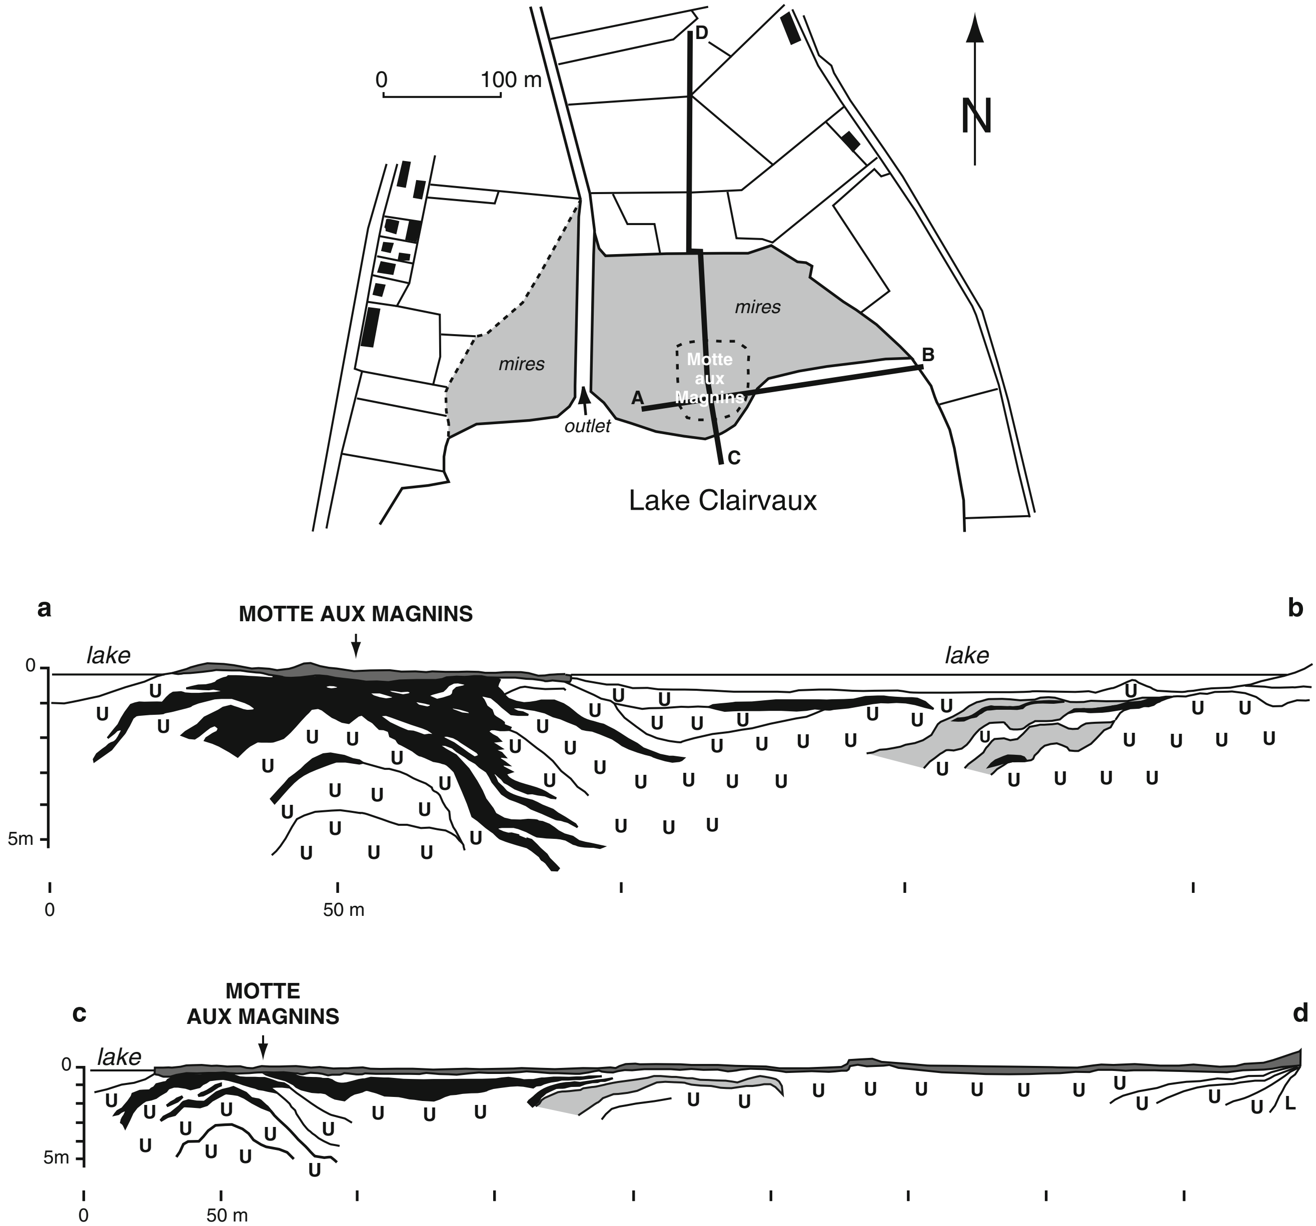
1. Grain-size analyses: coarser deposits correspond to nearshore areas, characterized by shallower water and higher hydrodynamics.
2. Lithology: silty (carbonate) lake marl is deposited in lake water, whereas organic deposits such as coarse gyttja, peat, and anmoor (hydromorphic soil with high humic content) reflect nearshore areas (eulittoral zone, littoral mire). Lake-level lowering results in an outward extension of organic lithofacies possibly associated with sand (terrestrial influxes over the margins of the lake basin favored by lake-level lowstands), while a rise in lake level results in their inward retreat (Figure 8). Variations in the humification of littoral organic deposits may also provide further indications on the more or less pronounced drying of a site during a lake-level lowering.
3. Macroscopic components of lake marl: it has been shown (Magny, 2004, 2006) that in carbonate lakes, the coarser fractions (>0.2 mm) of lake marl are mainly composed of (a) carbonate concretions of biochemical origin, (b) mollusk tests, and (c) plant



Paleoshores (Lakes and Sea), Figure 8 Upper panel: core transect established in Lake Trummen, southern Sweden (Modified from Digerfeldt (1986)). The section shows two distinct periods of lower sediment limit (*rectangles*) and associated sediment hiatuses (*thick lines* in cores 1 and 2) indicating lower lake level at phases PB–BO1 (Preboreal to Boreal 1) and SB1–2 (Subboreals 1–2). At both times, low water level prevented lacustrine sedimentation above the shoreline. *Lower panel*: core transect of Lake Växjösjon, southern Sweden (Modified from Digerfeldt (1986)). Sandy-silty layers mark phases of lower lake level favoring an extension of (allochthonous) terrestrial minerogenic material within the lake basin. Gyttja, marking the lake margins, is a mud produced from the aerobic decay of peat.

macroremains. The concretions can be divided into several morphotypes (Figure 10). Modern analogue studies have demonstrated that, in the >0.5 mm fraction, each morphotype shows a specific spatial distribution from the shore to the extremity of the littoral platform, with the successive domination of oncolites (nearshore areas with shallow water and a high-energy environment), cauliflower-like forms (littoral platform), platelike concretions (encrustations of leaves from the Potamogetonion and Nymphaeion belts), and finally tubelike concretions (stem encrustations from the Characeae belt on the platform slope). In addition to variations in the assemblages of carbonate concretions, the relative frequency of plant macroremains and mollusk shells provides further information on the depositional environment. The abundance of mollusk shells increases toward the shore, as do vegetal remains partly inherited from littoral vegetation and mires – particularly woody plant remains and particles of anmoor (a hydromorphic soil with up to 30 % humus content). After wet sieving, the macroscopic components of the >0.5 mm fraction are identified and counted using a binocular microscope.

4. Geometric micro-unconformities that are visible to the unaided eye resulting from erosion or nondeposition

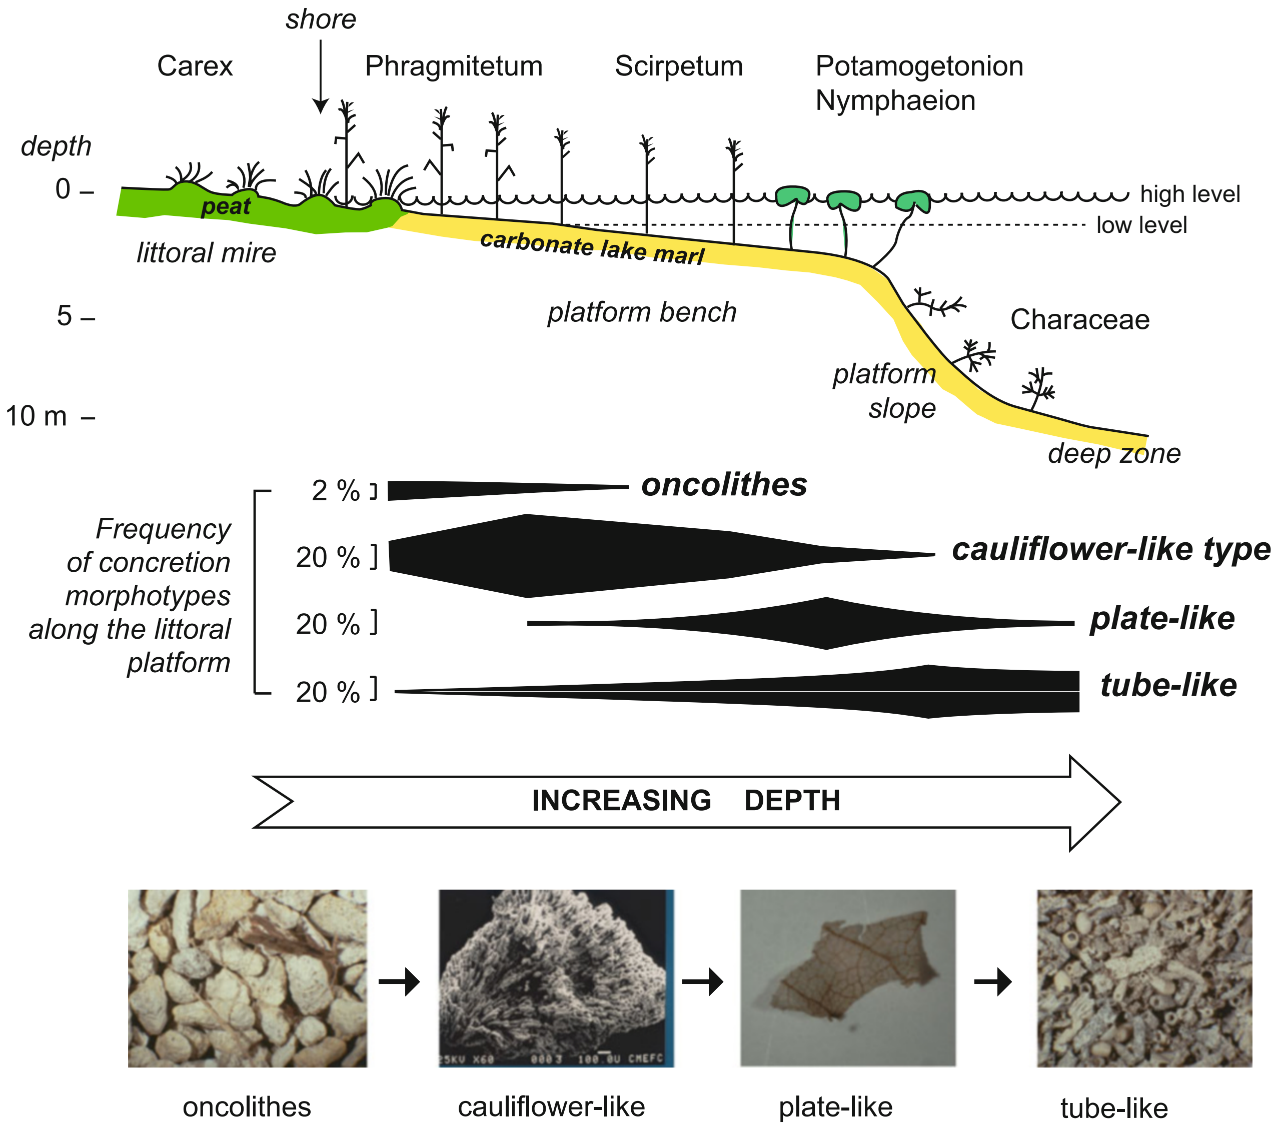


Paleoshores (Lakes and Sea), Figure 9 Reconstruction of the paleogeographical changes at the northern extremity of Lake Clairvaux, Jura Mountains in eastern France, using core transects. Note that the site of Motte aux Magnins (indistinct within the present-day northern littoral mires) was an island during the mid-Neolithic (Magny, 1991). The *arrow* shows the intersection between the stratigraphic sections *AB* and *CD. Black*, archaeological layers; *dark gray*, peat; *light gray*, gyttja; U, carbonate lake marl; L, silts.

(lake-level lowering), or micro-shrinkage cracks observed along core profiles, offer additional information about sediment deposition.

Other proxies have been used to reconstruct past variations in the water table from Holocene sediment sequences in lakes and mires (Berglund, 1986), including changes in mollusk assemblages (Clerc et al., 1989), diatoms and cladocera (Hyvärinen and Alhonen 1994; Korhola et al., 2005), chironomids (Kurek and Cwynar, 2009), and testate amoebae (Charman et al., 2007).

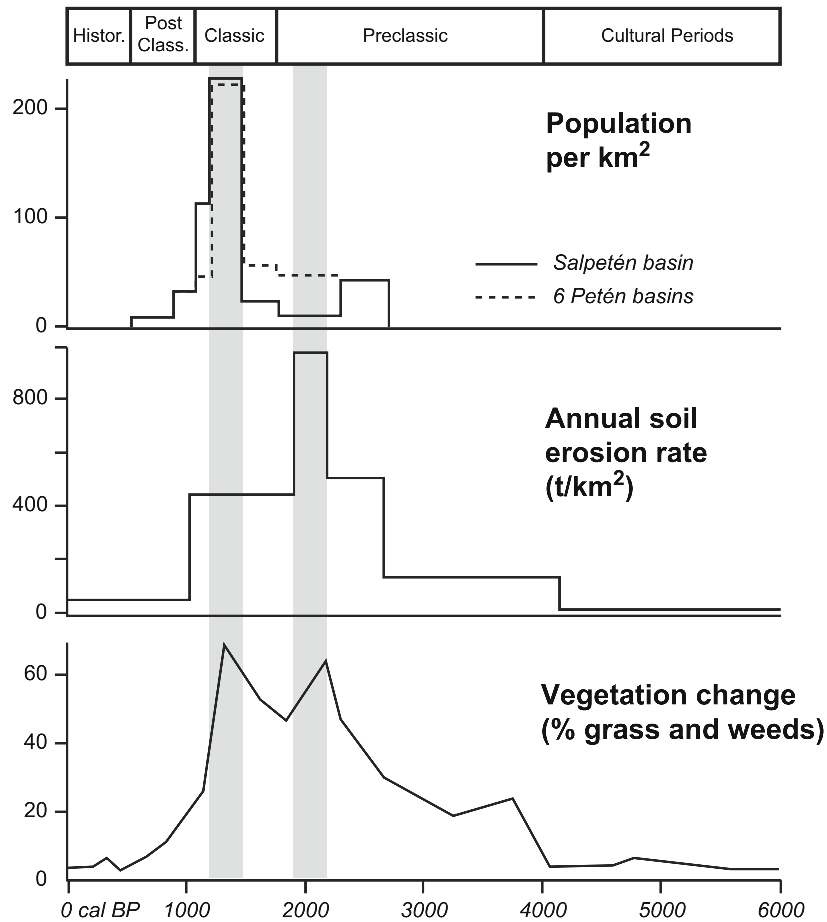
The study of archaeological layers may be more time-consuming due to a possible dilution of natural elements by anthropogenic material (organic and mineral). Micromorphology offers an additional means to study archaeological layers using microscopic examination of loose sediments impregnated with epoxy resin in thin section.



Paleoshores (Lakes and Sea), Figure 10 Section showing the distribution of carbonate concretion morphotypes along the littoral platform of Lake Clairvaux (Jura Mountains) in relation to morphology and vegetation zones. The relative frequency of each morphotype is indicated as a percentage of the sample components (Modified, after Magny (2006)).

Such a microscopic analysis used at Marin/Les Piécettes (Lake Neuchâtel, Switzerland) has revealed depositional characteristics similar to those of a lake-margin marsh, with soil formation processes, advanced decomposition of organic matter, and traces of bioturbation. Micromorphology can also provide a very high-resolution record of successive events with an accumulation of occupational remains, dismantling or reconstruction, trampling by inhabitants, and reworking by lake water (Guélat and Honegger, 2005).

Finally, the study of sediment archives from the deepest areas of lacustrine basins also provides useful continuous records of regional interest to complement local data deriving from a lakeshore archaeological site (Arnaud et al., 2005). Magnetic susceptibility measurements, geochemical (isotopes, XRF), and mineralogical analyses, in addition to pollen and charcoal studies, offer the opportunity to establish continuous records not only for past variations in environmental and climatic conditions but also for human impact and land use history. Thus, paleoenvironmental and archaeological data obtained from a littoral site may be seen in a more general (i.e., regional), long-term perspective. As an example, investigations undertaken by Anselmetti et al. (2007) from a deep core at Lake Salpetén (Guatemala) have revealed how peak soil erosion rates may have occurred not during but several centuries



Paleoshores (Lakes and Sea), Figure 11 Annual soil erosion rates compared with the population densities in the Salpetén region in Guatemala.

before the period of maximum population density in the ancient Maya zone (Figure 11). Cross-correlations between deep cores and littoral sediment profiles need to be based on high-resolution chronological frameworks (Vannière et al., 2008).

Conclusion: should greater attention be paid to anthropological themes?

Multidisciplinary approaches can be difficult and complicated to implement; however, geoarchaeological methods have evolved by integrating new geochemical and physical techniques that have improved the ability of researchers to date, delineate, and interpret the different aspects of coastal and lake excavation sites. The convergence of many disciplinary inquiries has led to more accurately established chronologies and greater understanding of past environment and human behavior.

The role of natural hazards and the evaluation of paleorisks are two questions that have received significant focus in recent years. Present neo-catastrophic research bias has falsely led public audiences into thinking that ancient societies lived and developed under the constant threat of upheavals caused by natural disasters. This overly simplistic outlook masks the true problems of environmental vulnerability faced by human societies since prehistoric times. Coastal areas have changed dramatically through time, and their impact has been significant to local populations, but geoarchaeological studies must assess coastal vulnerability over long intervals (Morhange and Marriner, 2011). As Leveau (2006) has stated, the history of ancient coastlines can no longer be written using ancient texts describing calamities as the sole source of information, as was the case in the nineteenth century. During the last three decades, the development and application of geoscience techniques to such problems have radically changed our perception of the history of coastal and lacustrine shorelines.

Definition

Wetlands are ecosystems created at the interface of terrestrial and aquatic environments. They arise due to inundation and accumulation of plant material dominated by anaerobic processes (Middleton, 1999, 7; Mitsch and Gosselink, 2007, 26; Burton and Tiner, 2009, 507; Keddy, 2010, 2). The Ramsar Convention of 1971 characterizes wetlands as follows: "Wetlands can be natural, permanent or temporary, with water that is static or flowing, fresh, brackish or salt. . ." (Middleton, 1999, 7; Burton and Tiner, 2009, 508; Dodds and Whiles, 2010, 86). Based on their hydrology, wetlands can be systematized into coastal wetlands within marine and estuarine systems (tidal marshes, mangrove wetlands, deltas), and inland freshwater wetlands within riverine, lacustrine, and palustrine systems (van der Valk, 2006, 7; Mitsch and Gosselink, 2007, 260; Lillie and Ellis, 2007, 3). Palustrine areas can be defined according to their dominant vegetation as follows: swamps are dominated by trees and marshes by herbaceous plants (cattail and reed beds). Both of them are often associated with river floodplains. Peatlands (bogs and fens) accumulate decaying organic matter from mosses and sedges (Dierssen, 2003, 202; Mitsch and Gosselink, 2007, 31; Dodds and Whiles, 2010, 95ff.; Keddy, 2010, 5ff.; Menotti, 2012, 11).

Archaeological sites can be found in wetland areas. After Nicholas (2012), waterlogged archaeological sites can be distinguished as "wet sites," like coastal, lacustrine, and riverine sites or as "wetland sites," located in swamps, marshes, and peatlands. Lakeside settlements are categorized within the latter, as they are placed at the amphibian interface between limnic and terrestrial environments (Menotti, 2012, 13f.).

Introduction

About 5 % of the land surface of the earth is covered by wetlands. Depending on the kind of water source and its position in the landscape, wetlands show a wide range of environments (van der Valk, 2006, 8; Menotti, 2012, 13f.). Wetland research is not covered by a single field but refers variously to limnology, hydrology, and estuarine and terrestrial ecology. This is also why wetland investigations require a multidisciplinary approach spread across several fields (Mitsch and Gosselink, 2007, 19).

Wetlands have always been important for people, as they were long utilized for resource procurement, e.g., reed, cattail, and moss cutting as building materials, as well as for food and fuel collection (Mitsch and Gosselink, 2007, 5; Nicholas, 2012, 762). Archaeological sites connected to wetlands play a very important role in archaeological research. Because of their waterlogged, anaerobic conditions, they may contain well-preserved archaeological remains in situ and offer great promise for reconstructions not only in archaeology and paleoenvironment but also in the diet and hygiene of people (Cole, 1995, 3; Kenward and Hall, 2004, 4, 2008, 585; Menotti, 2004; Larsson, 2007, 80; Menotti, 2012, 9f.).

Wetland archaeology is relevant in almost every part of the world (Menotti, 2004, 2012). In this contribution, the focus is on freshwater wetlands around lakes, where lakeside settlements developed during the Neolithic and Bronze Age in the Circum-Alpine region of Europe (Menotti, 2012). Bog and fen sites, which are common in Great Britain and Scandinavia, and hydric soils are not part of this contribution (see, e.g., Cole, 1992; Lillie, 2007; Mitsch and Gosselink, 2007, 169ff.; Menotti, 2012).

Prehistoric lakeside settlements have been known for more than 150 years (Cole, 1995, 3; Ruoff, 2004; Menotti, 2001, 2004, 2012), and since their discovery, questions concerning the depositional environment have been addressed using the archaeological sediments to obtain answers (e.g., Brochier, 1983; Jacomet, 1985; Brochier and Bocquet, 1991; Magny, 2004; Jacomet et al., 2004; Magny et al., 2012). Since 2011, 111 pile-dwelling sites from six countries around the Alps have been added to the UNESCO World Heritage List (http://whc.unesco.org/en/list/1363). Micromorphological investigations of lakeside settlements started in the early 1990s and are today often a part of the standard analyses for pile-dwelling sites (Krier, 1997; Wallace, 2000, 2003; Ismail-Meyer and Rentzel, 2004; Lewis, 2007; Karkanas et al., 2011; Ismail-Meyer et al., 2013; Ismail-Meyer, 2014).

Lakeside settlements span several depositional environments from terrestrial and paludal to littoral and limnic, and all reveal different features (Jacomet et al., 2004;

Mitsch and Gosselink, 2007, 29; Nicholas, 2012, 762). One of the most remarkable features of pile-dwelling sites is that they often contain a significant amount of organic accumulations, which in general are underlain and covered by deposits of limnic sediments. A main research issue is to explain the formation of those organic accumulations and their mostly excellent preservation in a changing environment. Geoarchaeological research provides hints to the site formation processes and environment of wetland sites between episodes of deposition and any subsequent or intermittent episodes of erosion (Menotti, 2012, 252). Recent multidisciplinary studies have produced archaeological results based on archaeobotanical, palynological, geoarchaeological, and dendrochronological analyses, leading to new insights into formation processes (Menotti, 2012, 267ff.; Heitz-Weniger, 2014; Ismail-Meyer, 2014; Bleicher, 2014; Pollmann, 2014; Jacomet et al., 2014; Wiemann and Rentzel 2015).

To understand the context of these special archaeological deposits, a look at natural wetland environments, especially peatlands, and their hydrology is essential. In this contribution, some important processes regarding anthropogenic accumulations under paludal conditions will be discussed by comparing them with natural processes in wetland environments.

Methods

There are several geoarchaeological methods for analyzing lakeside settlements. Bulk samples for sedimentological and geochemical approaches are taken on-site from representative zones. An example demonstrating such methodologies can be found in Braillard et al. (2004). The carbonate content is normally related to lake input or to ashy layers in an archaeological context. Using a binocular microscope, limnic carbonates can be separated into different types, such as “tubes,” “cauliflower carbonates,” and “plates,” which may give hints to the height of the lake level (Brochier, 1983; Magny, 2004; Magny et al., 2006; Digerfeldt et al., 2007; Magny et al., 2012). Sand content can be linked to regressions in the littoral area, inwash from the hinterland, or it can be of anthropogenic origin (Magny, 2004; Ismail-Meyer, 2014). Evaluation and interpretation of phosphate, humus, and organic content can be difficult because phosphate may have been partially washed out, humus formation may not have occurred normally, or other factors may have complicated the analysis. The pH reflects usually the near-lake environment (generally between 6 and 8), but it may differ across the anthropogenic accumulations (e.g., due to a locally acid milieu or possibly the presence of humic acids).

Good results can be obtained using micromorphological investigation. By analyzing thin sections, it is possible to observe the structure, layer composition, and degree of preservation of each deposit (FitzPatrick, 1993; Stoops, 2003; Goldberg and Macphail, 2006). It permits the reconstruction of lake levels, site formation processes, and environments during and after the deposition of sediments, and it demonstrates whether anthropogenic layers remain in situ or were reworked. Very delicate traces such as trampling features, ashes, and dung can be detected (Ismail-Meyer and Rentzel, 2004). The autofluorescence of different types of organic matter can be used to identify them (Goldberg and Macphail, 2006, 358). The determination of well-preserved organic matter in thin section is possible but difficult because of the randomness inherent in differing section planes. Thanks to a substantial literature, close cooperation with archaeobotanists, and the existence of reference sections, it is possible to identify wood, bark, twigs, leaves, moss, grass, and some of the most common seeds (Babel, 1975, 1985; Ismail-Meyer and Rentzel, 2004; Stolt and Lindbo, 2010; Ismail-Meyer, 2016). Scanning electron microscopy (SEM) methods and punctuated (spot) microchemical data allow the examination of materials at sizes smaller than 2 μm on uncovered thin sections (Goldberg and Macphail, 2006, 362).

Selecting an appropriate sampling strategy for micromorphological investigations of lakeside settlements is crucial. A site can be fairly complex (i.e., having several occupation layers, substantial depth, and variable preservation of the archaeological deposits), and it is therefore important to adapt the sampling strategy to the existing conditions. But the strategy depends also on the size of a site and if it is underwater. The right strategy might be to sample along transects from the lake toward the beach, within the area of best preservation, or following the floor plans of the houses (if known). Usually, cores or plastic boxes of about 50 cm height and at least 10–15 cm width are used in sampling for multidisciplinary analyses. Generally, it is important to sample the anthropogenic accumulations as well as the limnic sediments above and below, in order to reconstruct the regressions and transgressions of the lake. Until the opening of the samples for analysis, it is recommended that they be stored in waterproof containers under dark and cool conditions to prevent the growth of fungi and algae.

Photographs of freshly opened and cleaned profiles are important for documenting the stratigraphic sequence. A division of the sequences into layers (preferentially with the collaboration of an archaeobotanist and palynologist) and a description with special attention to carbonate and sand content are useful. The micromorphological subsampling of the profiles (anthropogenic and limnic sediments) for further investigations, including archaeobotany and palynology, can be done with smaller plastic boxes.

Features and processes in paludal environments

Lake environments are a result of many complex factors influencing the ecosystem, including limnological, geological, hydrological, geomorphological, and biological processes operating in the catchment area. These factors are mainly controlled by fluctuations of the groundwater table and/or lake level, due often to climatic influences, but in Western Europe over the last 7,500 years, humans have increasingly interacted with the environment (van der Valk, 2006, 13; Digerfeldt et al., 2007; Keddy, 2010, 270; Zolitschka et al., 2010, 90). The size of the wetland area (and the area of preserved, waterlogged, archaeological remains) depends on the local geomorphology, e.g., inclination and type of shore belt (Platt and Wright, 1991; Magny, 2004; Jacomet et al., 2004). Generally, the greater the long-term amplitude of water-level fluctuations in a lake, the larger the wetland area (Keddy, 2010, 68).

The main processes in wetland environments are accumulation, reworking, erosion, and desiccation, and they depend on the height of the lake level and/or groundwater table. In this contribution, these processes will be highlighted through the example of natural peatlands and compared to proper observations in lakeside settlements. The study results derive from eight pile-dwelling sites analyzed during the past 10 years in Switzerland: Arbon-Bleiche 3, Cham-Eslen, Zug-Riedmatt, Risch-Aabach, Stansstad-Kehrsiten, Wetzikon-Robenhausen, Hombrechtikon-Feldbach West, as well as Lake Luokesa in Lithuania (see Ismail-Meyer et al., 2013; Ismail-Meyer, 2014).

Paludal Settings (Wetland Archaeology), Figure 1 Zug-Riedmatt, Switzerland: Paludal Neolithic site (3200 cal BC) during geoarchaeological fieldwork at the archaeological excavation. In the foreground appears a dark organic layer of anthropogenic origin containing many vertical posts of different construction phases. Note the succession of gray, lumpy loam lenses interfingered with dark, organic occupation deposits (in the angle of the profile). On top, the archaeological deposits are eroded and covered by light gray, laminated limnic sediments (Photograph by D. Brönnimann, Integrative Prehistory and Archaeological Science, IPAS, University of Basel).

Lake platform and limnic sediments

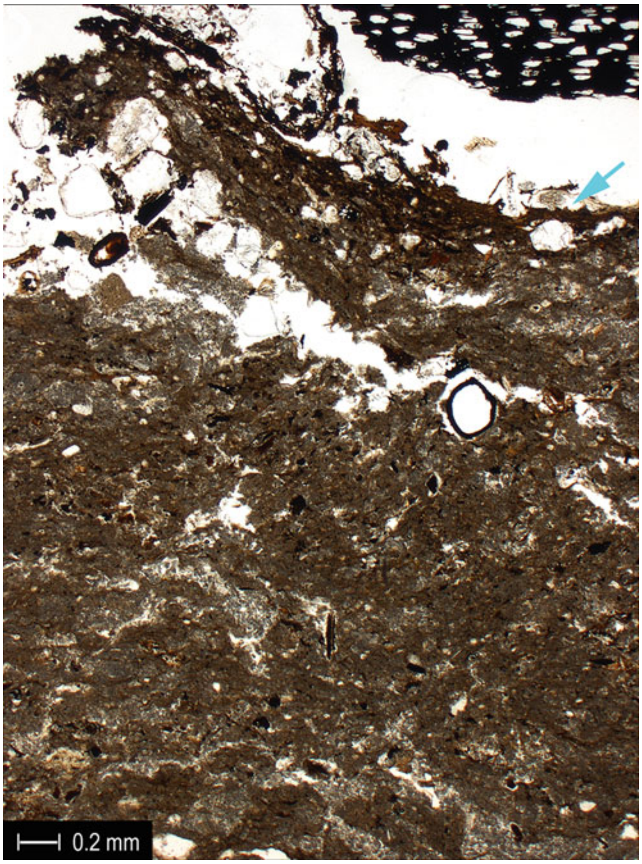
Lakeside settlements are usually deposited atop carbonate platforms along lakeshores (Figure 1). In shallow waters, carbonate precipitates as lake marl, formed mainly by different algae (mainly stonewort – Characeae), bacteria, and diatoms. Benches are formed due to progradational deposition (Murphy and Wilkinson, 1980; Platt and Wright, 1991; Freytet and Verrecchia, 2002; Magny et al., 2006). Undisturbed, layered lake marl accumulates in the deeper sublittoral zone in about 1–10 m water depth (Murphy and Wilkinson, 1980; Platt and Wright, 1991; Magny, 2004; Haas and Magny, 2004). The lowering of the lake level results in the reworking of this lake marl due to wave action and enrichment with sand (Platt and Wright 1991; Magny, 2004; Magny et al., 2006; Digerfeldt et al., 2007). Even small-scale water-level fluctuations may cause exposure of large areas depending on the slope of the shore area. In geological sections, the tops of such regressive sequences commonly show evidence of subaerial exposure (hiatus), e.g., alteration and fragmentation of mollusk shells (Platt and Wright, 1991, 62; Cutler, 1995; Digerfeldt et al., 2007). Walking on wet lake marl is almost impossible because of the slippery surface and tendency to sink deeply into the sediment. Some lakeside settlements were placed in areas with no standing water and as far as we know on an already hardened surface (Jacomet, 1985; Ismail-Meyer, 2014). The platforms, which are poor in nutrient matter, were often almost vegetation-free, but longer regression phases permitted pioneer vegetation to grow there (Jacomet, 1985; Monnier et al., 1991; Jacomet and Brombacher, 2005).

Micromorphological analyses of lake marl offer clues to the height of the lake level before, during, and after a settlement phase on the basis of layering, sand enrichments, and preservation of mollusk shells. The installation of a settlement in a sufficiently dry area generally led to compaction of the lake marl and enrichment of charcoal, wood, and bark chips due to house-building activities (Figures 2 and 3; Ismail-Meyer and Rentzel, 2004; Jacomet et al., 2004; Ismail-Meyer et al., 2013). These remains of scattered wood and bark chips may have helped to make these areas more easily accessible (Jacomet et al., 2004).

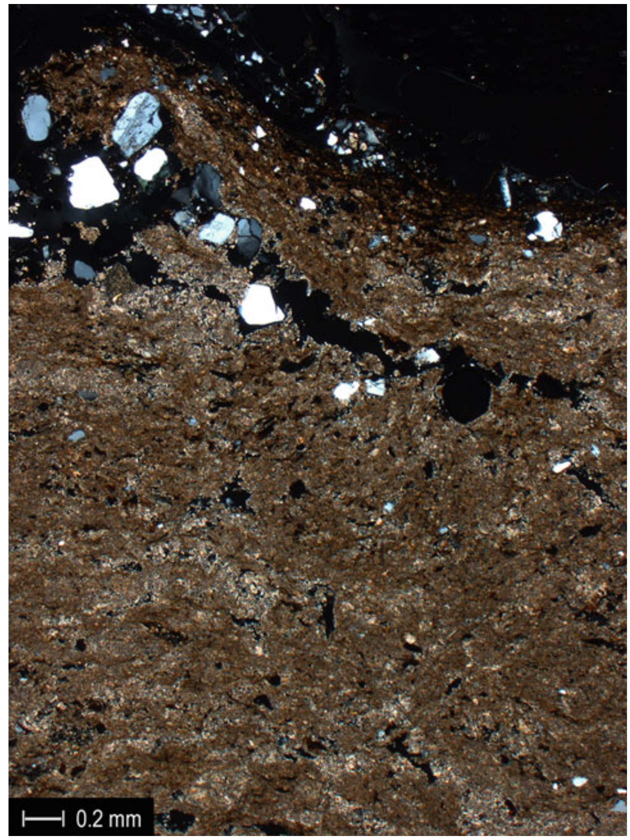
Hydrology

Hydrology in natural wetlands

Under waterlogged conditions, organic matter can accumulate over time at the surface by a sedentary process



Paludal Settings (Wetland Archaeology), Figure 2 Lake Luokesa, Lithuania, photomicrograph of a thin section in plane-polarized light (PPL): Limnic carbonate (lake marl) overlain by an archaeological deposit. The sediment of the lower part has a heterogeneous aspect due to dense gray lake marl peds enriched with some brown organic detritus. It is supposed that limnic influence led to mixing of the lake marl peds with organic matter. In the uppermost third of the picture, some transparent quartz sand grains are covered by compact organic remains, leaves (*arrow*), and a piece of charcoal at the top, the whole representing an activity surface with possible trampling features.



Paludal Settings (Wetland Archaeology), Figure 3 Same section as Figure 2, with crossed polarizers (XPL): The carbonate marl is *pale*, organic remains appear *dark brown to black*, and quartz grains *white and bluish gray*.

because anaerobic conditions reduce decay rates (French, 2003, 17; Charman, 2009, 542). The organic matter derives mainly from locally growing mosses, herbaceous material, and leaf litter (Mitsch and Gosselink, 2007, 168; Dodds and Whiles, 2010, 95ff; Menotti, 2012, 11). In natural peatlands, the water table is determined by the balance between inputs from precipitation and surface inflow and losses through evaporation and transpiration (evapotranspiration) and seepage (van der Valk, 2006, 25; Mitsch and Gosselink, 2007, 107; Digerfeldt et al., 2007; Keddy, 2010, 66).

One of the most important characteristics of peatlands is a high groundwater table, which lies at, or near, the surface (van der Valk, 2006; Keddy, 2010, 22; Armstrong, 2010, 30). In the temperate zone, groundwater fluctuates seasonally from a high in winter to a low in summer due to changing transpiration rates (Middleton, 1999, 9; Corfield, 2007, 144; Baker et al., 2009, 141). According to Holden and Burt (2003, 91), in a natural environment, the water table does not drop more than 5 cm below the peat surface. In raised bogs, the water table is naturally raised above the normal height because of capillary conduction by the growing plants adapted to waterlogged conditions, such as sphagnum mosses (Armstrong, 2010, 31). It seems that organic accumulations can also act as a “sponge” and raise the local water table so that the fringe of capillary water rises above it (Kenward and Hall, 2000, 522). The hydraulic conductivity (capacity of soils to retain water) is generally low in peats, meaning that they have strong water retention and remain wet for lengthy durations of time (Corfield, 2007, 147; Charman, 2009, 541).

Peats reveal an internal succession: in the upper, active zone called the *acrotelm*, fresh plant material is added at the surface. Here, the organic matter is loosely packed and loses more water due to evaporation (higher hydraulic conductivity). Fungal and bacterial growth leads to rapid decomposition of organic matter. The thickness of the acrotelm layer ranges from a few mm up to 75 cm, depending on the local hydrology (Mitsch and Gosselink, 2007, 173; Lindsay, 2010, 6). Water can move quickly horizontally and vertically (Dierssen, 2003, 204; Baker et al., 2009, 133; Charman, 2009, 542f.). The deeper, less active zone, the *catotelm*, lies below the local water table, where water moves slowly through the more compacted matter. Due to the constantly waterlogged conditions, there is minimal decay by anaerobic bacteria (Dierssen, 2003, 204; Baker et al., 2009, 133f.; Charman, 2009, 542f.).

With a vegetation cover, evapotranspiration rates are higher, but a dense covering of dead vegetation prevents sunlight from reaching the soil surface and lowers the evaporation rates (Baker et al., 2009, 139).

Wetlands lying adjacent to a lake or river may be termed "surface water slope wetlands". They are fed mostly by precipitation, surface flow, and flooding from the lake or river (Mitsch and Gosselink, 2007, 136), and they form only where the topography of the lake margin is flat (Jacomet et al., 2004; Baker et al., 2009, 125).

Hydrology in lakeside settlements

Lakeside settlements were constructed at the interface between limnic and terrestrial environments (Menotti, 2012, 13f.). They may be compared to "surface water slope wetlands," fed mainly by surface flow and lake inundations. The presence of large amounts of organic accumulations, often showing neither limnic nor terrestrial signs, demonstrates the complexity of the hydrological balance in lakeside settlements (Jacomet, 1985, 385; Ismail-Meyer and Rentzel, 2004). There is evidence that the acrotelm-catotelm model observed in natural peats also fits anthropogenic accumulations in several ways. Following the hydrology in peatlands, it is assumed that organic accumulations in pile-dwelling sites have significant water retention, which is due to a "sponge" effect. Without a dense active plant covering over the organic layers (there is some evidence for locally growing plants: Jacomet et al., 2004; Jacomet and Brombacher, 2005), evapotranspiration must have been rather low. The accumulations must have been water saturated over most of the time in order to maintain conditions that allowed such excellent preservation of organic matter (Kenward and Hall, 2004; Jacomet et al., 2004).

Organic accumulation

Organic accumulation in natural wetlands

Plant parts transported into lake bodies accumulate at the sediment-water interface and in shallow water (Gastaldo and Demko, 2011, 254f.), usually in areas with minimal wave action or flowing water (Keddy, 2010, 22f.). Wetlands develop only in areas that possess water-saturated surfaces during the major part of their existence in time and where the rate of accumulation exceeds that of organic-matter decay (French, 2003, 17; Mitsch and Gosselink, 2007, 156; Charman, 2009, 542f.; Gastaldo and Demko, 2011, 256).

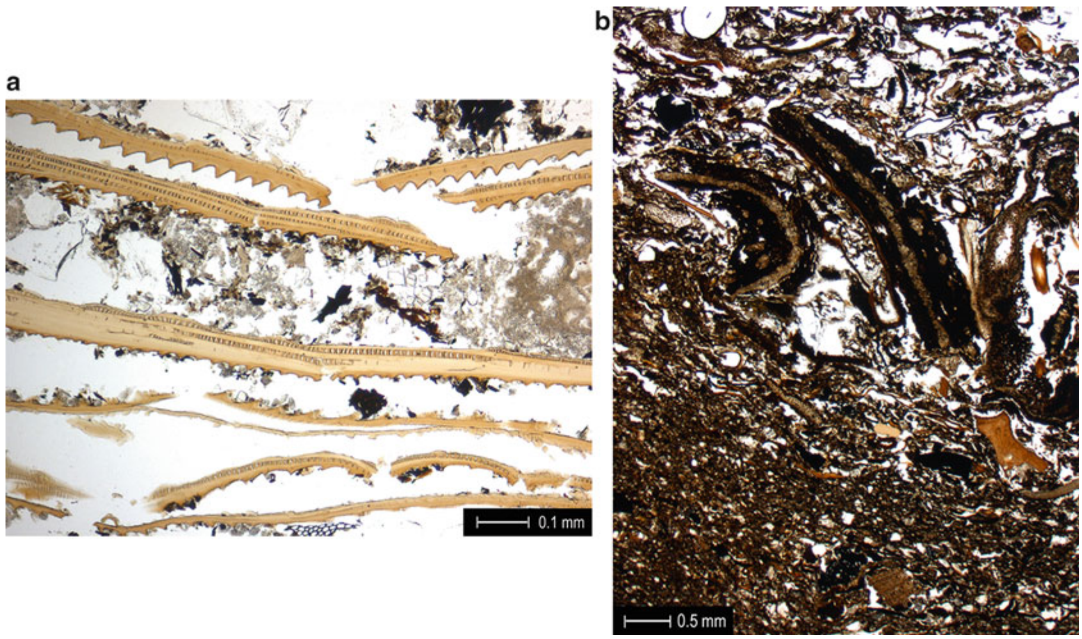
The fibrous composition of peats provides a strong structure and very high moisture content because of high capillarity. In the acrotelm, fresh plant material from mosses, sedges, and grasses is added at the surface, where most of the decay takes place (Charman, 2009, 541ff.). The residence time of the organic remains in the acrotelm may be about 100 years before they pass into the waterlogged catotelm. This implies a very slow growth rate of 0.5–2 mm per year (Lindsay, 2010, 78; Keddy, 2010, 193). Bones found in peat bogs are tanned by humic acids and often demineralized, which can be attributed to the lowering of pH or the presence of sphagnum moss, which decalcifies bone (as it does with "bog bodies"). Framboidal pyrite may form within cracks and pores in bones due to the colonization by sulfate-reducing bacteria (Turner-Walker and Mays, 2008).

Anthropogenic accumulation

In archaeological contexts, organic accumulations in wet environments resemble natural peats, but they are often of pure anthropogenic origin (Kenward and Hall, 2008, 585). Natural peat growth can also occur in settled areas, but this should be confirmed by botanical analyses (e.g., Maier, 2011).

Anthropogenic accumulations of organic matter consist mainly of wood and bark chips, leaves, twigs, mosses, agricultural remains, dung, bones, charcoal, ashes, sand, and loam (Figure 4a, b). Due to their morphology, wood, bark, foliage leaves, needles, mosses, and some seeds may be identifiable (see Schoch et al., 2004; Ismail-Meyer, 2016). The structure and shape of excrements sometimes allow the identification of the animal (Brönnimann et al., 2016a, 2016b). Bones of large animals, fish, and amphibians may also accumulate within the organic sediments; often, they still show their histological features (Huisman et al., 2009). Ashes can be distinguished due to their internal structure (Braadbaart et al., 2012). The accumulations are the result of different activities in the settled area – house building, food preparation, disposal of waste, handicrafts, animal husbandry, gathering, hunting, and fishing (Ismail-Meyer and Rentzel, 2004; Jacomet et al., 2004).

The well-preserved cultural layers show horizontally oriented remains of different sizes in a small-scale patchwork. This arrangement is the result of complex interaction between erosive and accumulative processes and various human and animal activities (Jacomet et al., 2004). The organic remains are usually very well preserved under waterlogged conditions. The presence of chlorophyll in some cases indicates a very fast sealing and burial, perhaps in less than 3 days or even within hours (Meyers and Ishiwatari, 1993, 886; Jacomet et al., 2004; Kenward and Hall, 2004, 8). Generally, such preservation is possible only because of a rapid accumulation rate (e.g., several centimeters every year) that occurred in the central



Paludal Settings (Wetland Archaeology), Figure 4 (**a**) Zug-Riedmatt, photomicrograph in plane-polarized light (PPL): Several well-oriented fish remains (gills and scales) in different stages of preservation (well preserved at the *top*) and showing layers of micropores (possibly due to chemical dissolution) in the rest of the picture. (**b**) Zug-Riedmatt, photomicrograph in plane-polarized light (PPL): Highly organic anthropogenic deposit and in the lower part, a laminated layer composed of highly fragmented organic matter (detritus). The upper, more porous part contains bigger organic remains with many dark brown bark fragments. An example of an outdoor area within a water-saturated, paludal depositional environment.

part of a village or in protected, swampy areas beneath raised houses (Jacomet et al., 2004; Ismail-Meyer and Rentzel, 2004; Ismail-Meyer et al., 2013). Such features demonstrate that, compared to the annual growth rate of a natural peat, lakeside settlements demonstrate a very different kind of accumulation process. Signs of decay in such waterlogged accumulations occur and can usually be attributed to anaerobic bacteria. This includes degradation of wood (Huisman and Klaassen, 2009). Bones may show a dark staining of the surface due to humic acids, precipitation of framboidal pyrite due to sulfate-reducing bacteria, tunneling caused by cyanobacteria, and loss of collagen, the major organic component of bones (Bocherens et al., 1997; Turner-Walker and Mays, 2008, Huisman et al., 2009).

Flooding events

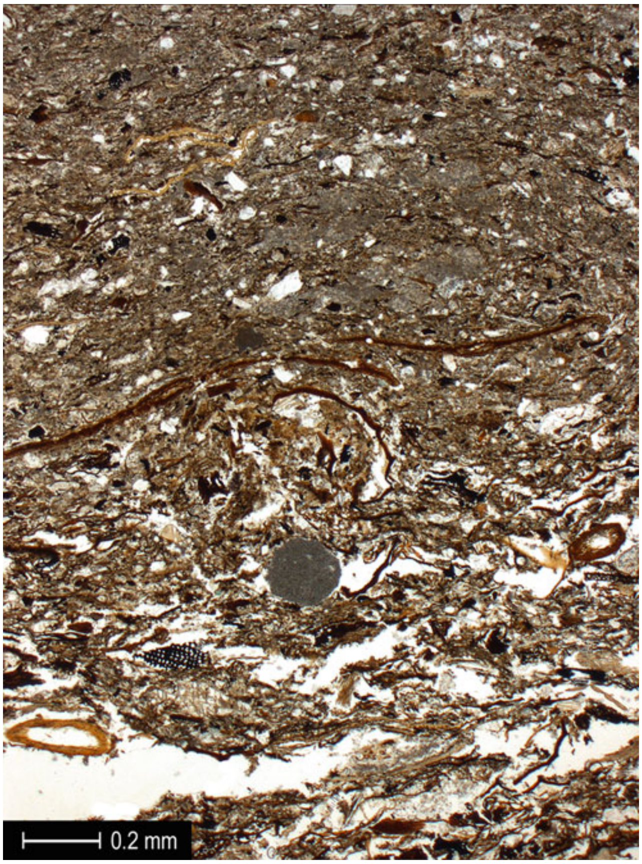
Lake-flooding events in natural peatlands

Flooding in wetland areas represents a natural event, and it occurs either seasonally or interannually. In the temperate zone, floods are produced each spring by the rapid melting of the precipitation accumulation of an entire winter, especially in mountainous areas (Middleton, 1999, 9; Mitsch and Gosselink, 2007, 132; Baker et al., 2009, 127; Keddy, 2010, 44). Therefore, large lakes depending on an alpine water regime may show yearly fluctuations in the water table of a few meters, while in small lakes and ponds, such fluctuations are rather weak (Keddy, 2010, 77). Long-term fluctuations in rainfall due to climate change may cause dramatic changes in the shoreline (Keddy, 2010, 44, 59).

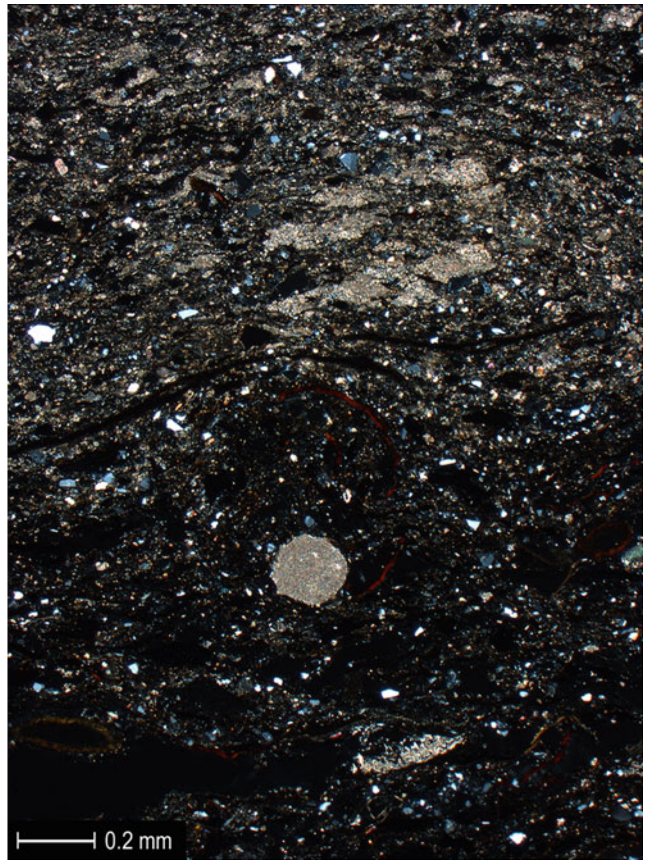
The major effects of flooding are erosion and deposition (Turnbaugh, 1978, 595). During flooding, wetland areas may be exposed to wave action, which imposes complex effects on littoral areas. The amount of wave energy impacting a shoreline increases with distance to the opposite shore and with the number of directions from which waves can arrive (Keddy, 2010, 121). With high levels of exposure to waves, fine particles and biomass tend to be removed, and sorted, coarser substrates such as sand and gravel are left behind (Magny, 2004; Digerfeldt et al., 2007; Keddy, 2010, 121). Resuspension of sedimented organic matter can be considerable, but it is usually more frequent in large rather than in small lakes (Meyers and Ishiwatari, 1993, 868).

Lake flooding in lakeside settlements

Flooding events may be frequent in lakeside settlements of the Circum-Alpine region, and they are also mainly linked to the spring flood. Climatic changes in late prehistoric times led to more permanent inundation of shore areas and may have caused the abandonment of a number of lakeside settlements (Menotti, 2001, 2004). High lake levels led to flooding, erosion, and/or redeposition of remains (Figures 5 and 6).



Paludal Settings (Wetland Archaeology), Figure 5 Zug-Riedmatt, photomicrograph in plane-polarized light (PPL): In the lower half of the picture appears an organic cultural layer, truncated and overlain by limnic sediments with gray lake marl peds mixed with some eroded organic remains. Example of a flooding event after an occupation phase in a paludal environment.



Paludal Settings (Wetland Archaeology), Figure 6 Same section as Figure 5, with crossed polarizers (XPL): In the upper half of the picture, the limnic carbonates appear gray, and the layered organic remains are black.

Micromorphological analyses show that organic layers may be eroded by water movements coming from the lake. Erosion boundaries are difficult to detect, even in a thin section. Often, parts from the flooded organic accumulations are suspended and redeposited together with limnic sediments. Such layers consist of homogenous limnic carbonates containing mollusk shells, algal remains, and frequently large amounts of highly fragmented organic detritus (see below). It is also possible to observe organic layers with very rare algal remains, diatoms, sponge needles, and mollusk shells which seem to be in situ, but they must have been in suspension for a short period without any visible effect of wave action (Jacomet et al., 2004). It is obvious that palisades, house constructions, and on-site vegetation, such as reeds, have influenced the water movement through a lakeside settlement by breaking down wave energy.

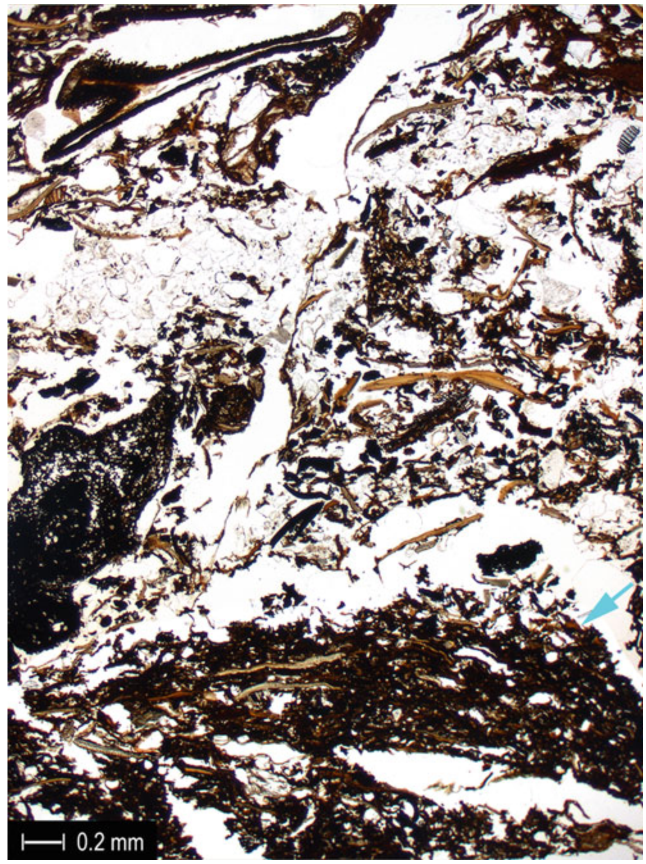
Deposition of reworked lake marl, which shows no signs of laminations, may be the result of a single storm event. During longer phases of transgressions, laminated lake marl precipitates in situ (Digerfeldt et al., 2007).

Flooding due to runoff in natural peatlands

Erosion by water also occurs during spring through runoff from the upper slopes caused by rains and snowmelt, especially when the vegetation cover has been disturbed by forest clearance and agriculture (Turnbaugh, 1978, 606; French, 2003, 17, 22; Goldberg and Macphail, 2006; Keddy, 2010, 193; Zolitschka et al., 2010, 82). Infiltration into unsaturated peat (acrotelm) is fast. When a peat is already completely water saturated, surface flow occurs and may affect a large area of a floodplain (Baker et al., 2009, 126). Therefore, surface runoff can be strong, occurring even on gently sloping areas (Turnbaugh, 1978, 597). About 80 % of surface water flows through the acrotelm, and 98 % of the runoff occurs in the topmost 3 cm (Holden and Burt, 2003, 91; Baker et al., 2009, 122). Runoff follows immediately after rainfall or spring thaw. Even small amounts of precipitation produce long-lasting surface flow, and just 1 day of heavy rain will cause a sharp rise in the water table (Holden and Burt, 2003, 91f.; Mitsch and Gosselink, 2007, 126; Lindsay, 2010, 129). The waterlogged catotelm, where water moves very slowly, is usually not affected by flood events (van der Valk, 2006, 25, 150; Charman, 2009, 543f.; Lindsay, 2010, 128).

Wetlands that are characterized by inflows from a wider catchment receive allochthonous sediment inflows. The rate of sediment brought in depends on the magnitude and frequency of precipitation (Baker et al., 2009, 153). The main sediment charge arrives during the short, intensive period of water discharge in spring (Mitsch and Gosselink, 2007, 133). But it is also known that forest clearing and human land use lead to destabilization of slopes. The consequences are soil erosion, increased runoff, and higher levels of minerogenic sediment transfer from the catchment area into the lakes (Dierssen, 2003, 199; French, 2003, 24; Digerfeldt et al., 2007; Baker et al., 2009, 153; Zolitschka et al., 2010, 82; Menotti, 2012, 256). Except under very low flow velocities, silts and sands are quite easily detached from the soil mass and redeposited (French, 2003, 24).

Vegetation, such as reeds and bushes, slows down surface flow, so that in summer the flow resistance is high, and in winter the resistance declines. Seasonal cycles of plant growth have an impact on the timing of sediment mobilization (Baker et al., 2009, 136). A plant cover, roots, and leaf litter at the surface may also protect wetlands from erosion (Turnbaugh, 1978, 597; Baker et al., 2009, 158). Burial by successive layers of sediment leads to compaction and consolidation, so that only a little of the sediment is resuspended (Baker et al., 2009, 158).



Paludal Settings (Wetland Archaeology), Figure 7 Lake Luokesa, photomicrograph of a thin section in plane-polarized light (PPL): Dense organic crust (*arrow*) of decomposed organic matter, probably due to desiccation. A sandy layer, possibly an inwash from the hinterland, covered the organic layer.

Flooding due to runoff in lakeside settlements

Micromorphological analyses show that flooding from the hinterland also results in erosion and inwash by surface flow of well-sorted and graded sands from the catchment area (Figures 7 and 8). Due to surface water outflow into the lake, highly fragmented organic matter (detritus; see below) may be lost from the settlement site (Mitsch and Gosselink, 2007, 158f.). Unsorted layers rich in sand can also be anthropogenic in origin due to (1) loss of organic matter, (2) alteration of cultural layers, or (3) disaggregation of construction material such as loam walls.

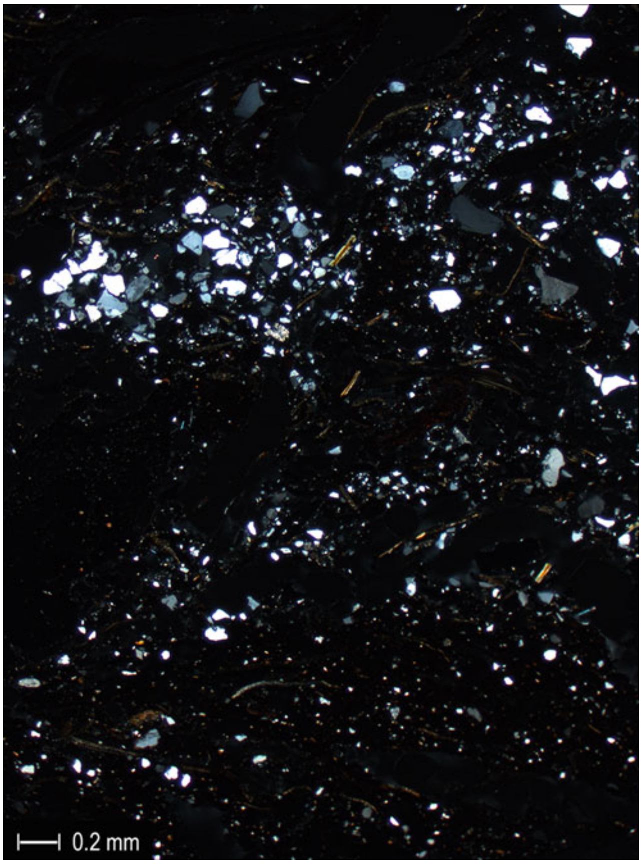
Sequences of alternating organic layers and sandy inwash are interpreted as seasonal deposits (see below). Microstratigraphic observations have documented that flooding and/or reworking of organic layers does not involve the entire anthropogenic sequence – as such a result would yield homogeneous sediments without laminations – but only the uppermost part of the sequence is affected (Jacomet et al., 2004). This situation may be explained by the acrotelm-catotelm model, indicating that surface flow occurs mainly in the uppermost part, while the denser, waterlogged catotelm is not affected. Obviously, it is impossible to know how much of the sediment was previously removed by erosion, but it was probably not more than a few cm per flooding event. Generally, the lakeward parts of sites were more affected by lake flooding, while the areas toward the landward side were influenced instead by surface runoff (Jacomet, 1985; Jacomet et al., 2004; Ismail-Meyer and Rentzel, 2004; Ismail-Meyer et al., 2013). House constructions, palisades and on-site vegetation may have slowed water movement through the site.

Lowering of the water table

The preservation of organic remains in wetlands is connected to the height of the lake level or the groundwater table. This section will explain how and why organic matter decays in wetlands and waterlogged archaeological sites.

Lowering of the water table in natural wetlands

During the summer, the water table in wetlands may drop due to higher evaporation rates, causing desiccation and decomposition of organic matter (Keddy, 2010, 66;



Paludal Settings (Wetland Archaeology), Figure 8 Same section as Figure 7, with crossed polarizers (XPL): The quartz grains from the sandy inwash are visible in *white and bluish colors* in the upper half of the picture.

Gastaldo and Demko, 2011, 255). Decay of plant remains occurs in approximately three stages. First, plant cell contents and food stores of seeds disappear through fermentation; second, plant cell walls and insect remains decay; and third, most remaining organic matter disintegrates, and only the most resistant plant residues survive and can be recovered, such as cuticles, lignin-containing cells from wood and bark, and phytoliths (plant silica) (Kenward and Hall, 2000, 520, 2004, 5; Gastaldo and Demko, 2011, 255). The so-called detritus or particulate organic matter – also a result of organic decay in wetlands – measures between 0.45 µm and 1 mm in size. In wetlands, oxygenation, desiccation, and bacterial and fungal activity (without arthropods and other typical soil animals) lead to detritus formation. Dried-out peats are reduced to a loose detritus powder as a result of the combined effect of sun and wind – without further physical abrasion (Mitsch and Gosselink, 2007, 157; Lindsay, 2010, 85; Gastaldo and Demko, 2011, 255). Detritus appears after the dry period due to peat erosion, and it accumulates at the surface during a short period of stability. Due to precipitation, it enters into streams mainly between September and the end of November (Blazejewski et al., 2005, 1323f.; Lindsay, 2010, 110; Marxsen and Wagner, 2011, 77; Gastaldo and Demko, 2011, 255).

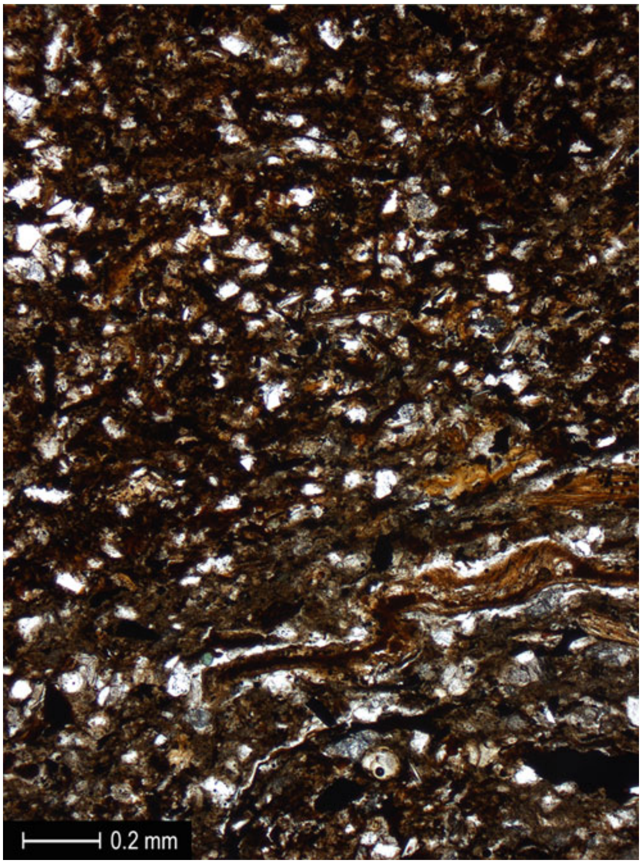
Fluctuations in the groundwater table also introduce oxygenated waters leading to biochemical processes that play a part in reducing plant parts (Gastaldo and Demko, 2011, 255). For instance, the redox potential, or Eh (the tendency of oxidation or reduction), is probably one of the most significant variables influencing the rate of organic degradation (Retallack, 1984). Oxidation occurs mainly in aerobic conditions and leads to decomposition and humification (Kenward and Hall, 2004, 6f.). When oxygen-rich water is introduced into peats, it normally takes only a few hours or days until the oxygen in the flooded layers is depleted by bacterial and fungal activity (Mitsch and Gosselink, 2007, 173). Under reducing conditions, anaerobic bacteria are the primary active microorganisms that are responsible for organic decay (Lillie and Smith, 2009, 17, 21). Rotting of wood has been observed due to fungi (white and red rot; Schweingruber, 1982; Huisman and Klaassen, 2009). Faunal activity in wetlands also leads to a reduction in peat volume and the development of humus, such as mull or moder (Babel, 1975; Malterer et al., 1992). Peats possess about 80 % pore space, which is filled with water in saturated areas (Mitsch and Gosselink, 2007, 166). Lowering of the water table in a natural peat leads to rapid subsidence of the surface because the porosity collapses. The increasing weight of the drier sediments above affects the peat column beneath. Every centimeter of drawdown in the water table results in an increased load of 10 kg m^{-2} (Lindsay, 2010, 123). Drying out and alteration of bogs, the so-called peat ripening, can also lead to compact sediment showing cracking and prismatic or granular microstructure (Malterer et al., 1992; Stolt and Lindbo, 2010, 385; Lindsay, 2010, 135). Dissolution of organic matter in acidic waters, probably combined with desiccation, may cause a transformation into amorphous, dark brown, jellylike concentrations, called dopplerite (Stolt and Lindbo, 2010, 385). As a consequence of syn- and postsedimentary dissolution phenomena, gelatinous dopplerite may be formed, but needs a phase of drying out to become insoluble (Wetzel 2001, 631). Another result of low water table in peats is the formation of amorphous organic matter (AOM) (Comont et al., 2006).

Bones from desiccated peat bogs show signs of demineralization, shrinkage, and cracking due to drying and may contain gypsum crystals (see below; Turner-Walker and Mays, 2008).

In wetlands, a slow process called terrestrialization may take place whereby wetlands become shallower and shallower with time; eventually, the wetland turns into dry land (van der Valk, 2006, 98).

Lowering of the water table in lakeside settlements

For archaeological remains, the main phase of decay generally occurs before, during, and for a short period, after



Paludal Settings (Wetland Archaeology), Figure 9 Stansstad-Kehrsiten, Switzerland, photomicrograph of a thin section in plane-polarized light (PPL): Compact organic detritus with fine-grained sand – the result of an alteration (desiccation) of the organic matter and runoff from the hinterland.

deposition. Soon after burial, ground conditions typically become more or less stable (Kenward and Hall, 2000, 522). Later episodes of decay due to dewatering (drainage or lake level corrections) lead to uniformly and poorly preserved remains within the near surface deposits (see below).

Micromorphological signs of dropping groundwater level, desiccation, and decay include a very dark brown color of the organic matter, a higher rate of compaction, fragmentation to the size of detritus, and the formation of dopplerite, organic crust, and AOM (Figure 7, see below). Mesofaunal droppings in decomposing wood and bark, fungal spores, and hyphae occur, but usually there are no signs of arthropod or other soil animal activity (Pawluk, 1987; Stolt and Lindbo, 2010).

Lowering of the water table in lakeside settlements allows the entry of air and rainwater rich in oxygen. Repeated wetting and drying cycles produce fragmentation of the organic remains and the development of detritus (Figure 9). Desiccation also leads to the collapse of porosity and, consequently, surface subsidence (Lindsay, 2010, 123). The formation of organic crusts, i.e., compact, layered, organic aggregates, may be connected to such processes, as seen in peat environments (Comont et al., 2006). Fungal and bacterial activity may also reduce plant parts to detritus (Gastaldo and Demko, 2011, 255). Wood may be heavily attacked by fungi, such as white and red rot (Schweingruber, 1982; Huisman and Klaassen, 2009). After hiatuses, e.g., due to abandonment of a site, organic layers showing strong signs of decay and mesofaunal droppings, of e.g. springtails (Collembola) and/or pot worms (Enchytraeidae) may be observed (Ismail-Meyer, 2014). Due to weathering, sediment can become more minerogeneous. The presence of dopplerite and amorphous organic matter (AOM) seems to indicate drier parts of lakeside settlements or may be formed during acidic phases, but it may also have been precipitated as a result of modern drainage in wetland areas (see also below). Animal bones may show diverse signs of degradation, such as loss of birefringence due to loss of collagen (Gilbert, 1989, 59), tunneling as a result of aerobic bacteria and fungi (microfocal destruction or bioerosion), cracking, and signs of dissolution due to chemical weathering. Gypsum crystals may also occur in cracks and pores as a result of the reaction of dissolved calcium with sulfate released by pyrite decay (Bocherens et al., 1997; Jans et al., 2004; Turner-Walker and Mays, 2008; Huisman et al., 2009).

Heterogeneous conservation of the organic remains indicates synsedimentary alteration (and inherited elements) if conditions have been stable through time. If signs of decay appear confined to single layers of lakeside settlements, followed by well-preserved ones, a possible interpretation is that these altered levels reveal seasonal drying, with decay having occurred pre- or immediately post-burial (see below; Kenward and Hall, 2000, 521; Ismail-Meyer, 2014).

Postdepositional processes in natural wetlands and lakeside settlements

After burial, only very slow decay and almost no post-burial alteration (diagenesis) occur, as long as the ground conditions persist (Kenward and Hall, 2000, 522, 2004, 6f.). Under permanent waterlogged conditions, organic remains from pile-dwelling sites may show, more or less, the same preservation upon excavation as existed shortly after their burial. But the recent growth of reed belts around lakes could have major effects on the arrangement of the remains, leading to mixing of several layers (Ismail-Meyer and Rentzel, 2004; Jacomet et al., 2004).

Human activities such as agriculture, forestry, stream canalization, dam and dike construction, mining, groundwater extraction, and the creation of water pollution have major impacts on wetlands (Middleton, 1999, 56ff.; Mitsch and Gosselink, 2007, 289), which are disappearing very fast (Menotti, 2012, 226). Modern drainage leads to peat loss due to consolidation, compression, oxidation, and pedogenesis (Lindsay, 2010, 124; Gastaldo and Demko, 2011, 261), and as an example, the drainage of a freshwater lake in England led to the loss of 4 m of peat volume (Lindsay, 2010, 123ff.). Archaeological wetland sites experience the same effects as natural wetlands due to drainage, and such changes can be seen in the landward part of Arbon-Bleiche 3 (Jacomet et al., 2004).

When the natural wetland environment vanishes, our cultural heritage is lost, too. Maintaining the natural environment by stabilizing the water table, controlling water quality, and taking anti-erosion measures can protect many wetlands and archaeological wetland sites from post-burial decomposition (Cole, 1995, 31ff.; Mitsch and Gosselink, 2007, 305; Menotti, 2012, 19, 226). Thanks to the Ramsar Convention, an international contract originally begun in Ramsar (Iran) in the early 1970s, the protection of wetland habitats around the world has been promoted (Mitsch and Gosselink, 2007, 519; Ramsar Convention). The interest group "Preserving Archaeological Remains In Situ" (PARIS) regularly organizes international conferences about in situ preservation. Discussion of in situ protection for wetland sites can be found in Cole (1995), Vernimmen (2002), Lillie (2007), Lillie and Smith (2009), and Kenward and Hall (2008).

Excellent preservation in lakeside settlements

Organic matter in wetlands often shows excellent preservation because of waterlogged, anoxic conditions (Figure 4a, b; Kenward and Hall, 2000, 521), and the best preservation of organic remains occurs in areas that lie between the limnic and terrestrial environments. On very flat and protected lakeshores, plant remains may accumulate, constantly soaking up humidity from the groundwater as happens in natural peatlands (Jacomet et al., 2004; Gastaldo and Demko, 2011, 254f.).

Under waterlogged, anoxic conditions, often only the first stage of organic decay occurs, i.e., loss of cell content and food stores of seeds before, during, or shortly after deposition (Kenward and Hall, 2000, 520–522, 2004, 5). Rapid sealing of the remains under a high sedimentation rate during the growing season – possibly enhanced by compaction caused by human and animal trampling – leads to excellent preservation. In many lakeside settlements, green leaf tissue is still preserved, cattle and sheep/goat dung has kept its original shape (and smell), and dung-dwelling insects are practically absent (Kenward and Hall, 2004, 8; Jacomet et al., 2004; Ismail-Meyer et al., 2013). The bones often show very good preservation, and even highly fragile fish gills and scales can be recognized (Figure 4a). Soon after burial, ground conditions become more or less stable because of the quickly depleted oxygen resulting from fungal and bacterial activities (French, 2003, 17; van der Valk, 2006, 19; Kenward and Hall, 2008, 585; Lillie and Smith, 2009, 11; Keddy, 2010, 22; Menotti, 2012, 228f.). This is probably the reason why there are almost no signs of fungi in waterlogged areas (van der Valk, 2006, 40). Waterlogged organic material may account for 75–90 % of all the material recorded (Lillie and Smith, 2009, 9). If such conditions that are conducive to long-term preservation are not stable over time, remains usually decay quickly and completely (Kenward and Hall, 2000, 522).

Trampling effects on waterlogged organic accumulations

In settled, terrestrial areas, occupation activities generally produce compacted surfaces. In wetland sites, the most clearly visible effect of trampling can be seen in the minerogenic lake marl sediments at the base of the anthropogenic accumulations and loam floors in houses (see, e.g., Rentzel et al., 2016). Highly organic accumulations seem not to preserve clear signs of trampling over a long period of time because they expand to their original shape like a sponge (Jacomet et al., 2004; Ismail-Meyer and Rentzel, 2004). Dense organic crusts are not the result of trampling, but refer to phases of decay (Figures 7 and 8; see above; Ismail-Meyer, 2014).

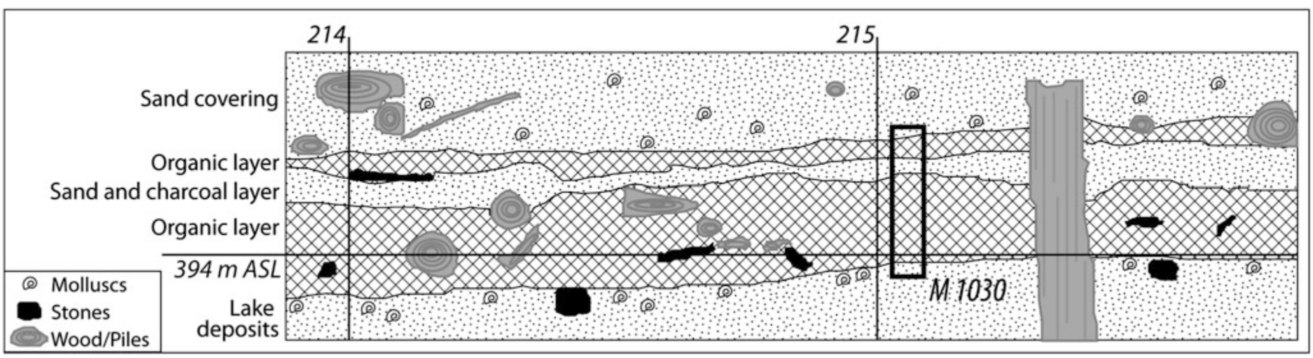
Seasonal processes

Many processes observed in lakeside settlements are linked to seasonal events. Micromorphological observations often show organic laminations (from a few millimeters up to several centimeters in thickness), which may confirm a decomposition and compaction of organic matter at the surface. Sometimes, they are covered by a tiny layer of well-sorted and graded sand, which shows a sharp lower boundary. In near-shoreline areas, the sandy layers can be replaced by lake marl layers containing substantial amounts of detritus and amorphous organic matter (Figure 9). These sequences may be the result of seasonally induced changes, as observed in Lake Luokesa, Arbon-Bleiche 3, and Stansstad-Kehrsiten. Multidisciplinary investigations have demonstrated that they can be interpreted as follows. During phases with high water tables, large amounts of fresh material accumulate in the settlements as a result of human (and animal) activities. A quick sealing by covering deposits under waterlogged conditions leads to extremely good preservation. During the hot season, the groundwater level can drop a few cm causing desiccation, as well as fungal, mite, and bacterial involvement. In spring, flooding and substantial surface flow can lead to erosion of the topmost layer (a maximum of a few cm) as well as deposition of sand from the catchment area. Sand inwash seems to occur especially during settlement phases which are associated with forest clearing and agricultural activities. Near the lake, flooding may occur at the same time, depositing lake marl with eroded detritus from the site (Ismail-Meyer, 2014).

Fire events

Fire events occur regularly in wetlands when the peat surface is sufficiently dry during seasonal or interannual dry

Paludal Settings (Wetland Archaeology), Figure 10 Arbon-Bleiche 3, Switzerland: Field view of the south profile through House 1. The laminated, gray lake and beach deposits are overlain by the dark brown cultural layer. Note also the effects of modern trampling of the water-saturated lake marl in the right foreground, leading to ductile deformation phenomena (By Amt für Archäologie Thurgau, www.archaeologie.tg.ch, D. Steiner).



Paludal Settings (Wetland Archaeology), Figure 11 Arbon-Bleiche 3: West profile through House 1 showing the sequence with two main organic cultural layers divided by a charcoal-rich sandy layer. The rectangle M1030 corresponds to the micromorphological block sample (see Figure 12) (Drawing by Amt für Archäologie Thurgau, www.archaeologie.tg.ch and K. Ismail-Meyer, modified from Ismail-Meyer et al., 2013).

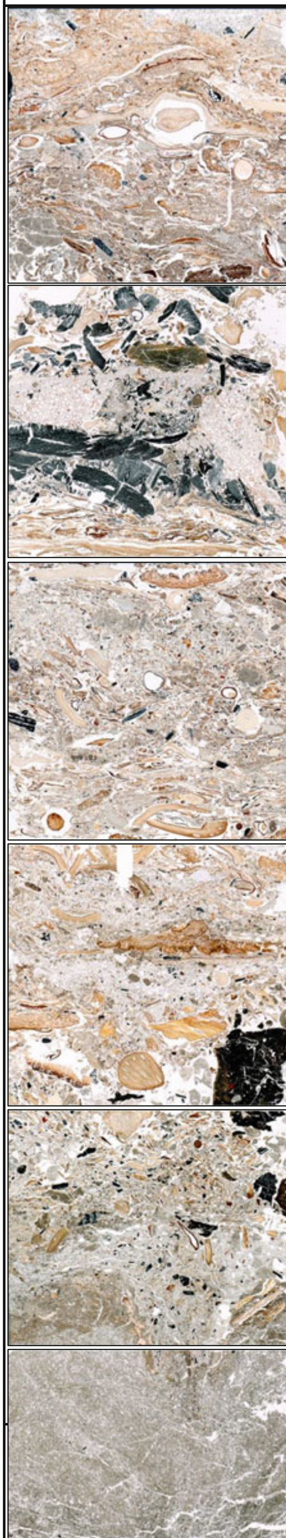
periods. The major sources of combustion are human activities and lightning (Middleton, 1999, 42ff.; van der Valk, 2006, 98; Lindsay, 2010, 215). Fire affects only the surface vegetation of a peat (Charman, 2009, 545) and produces much ash, which is easily removed by wind or washed away by rain. Fire is one of the most important causes for extensive peat erosion (Lindsay, 2010, 144, 248).

Lakeside settlements show signs of fire events that led to the destruction of single houses or even entire villages. The use of fire must have been dangerous, especially during the dry season. Thin sections reveal organic layers that bear indications of heat in the form of burnt plant material, ashes, and organic slags (melted phytoliths). Entire layers of charcoal occur, too, but these are rare, which must be due to the fact that charcoal is easily dislocated, fragmented by trampling, and removed by flooding events (Macphail et al., 2010, 47). For instance, a village destroyed by a fire will most likely be subsequently flooded, at which time substantial parts of the burned layers will be removed by wave action (Jacomet et al., 2004; Ismail-Meyer and Rentzel, 2004).

Case study: House 1 from Arbon-Bleiche 3

A micromorphological case study from Arbon-Bleiche 3 is presented here to illustrate the main processes in the

House 1: Scanned thin sections



Phase	Seasonal process	Microscopy	Dating
	Lake flooding	Erosive sandy layer with limnic aspect. Final flooding.	3370 cal BC
Stable	Winter?	Compact organic layer with altered and well preserved sheep/goat coprolites, mistletoe, and needles of white fir. Pollen indicating winter season.	
House in use	Dry Summer (low water table)	Compact organic layer with sandy clay matrix and detritus, fish scales, ashes, and altered sheep/goat coprolites.	
House in use	Dry Summer (low water table)	Compact organic layer with large amounts of matrix and detritus, altered sheep/goat coprolites, some seeds.	
House in use	Dry Summer (low water table)	Fine sand with clay and detritus, well preserved and altered bark remains.	
Renovation	Accumulation with high water table	Loose organic layer with charcoal, white fir needles, clay aggregates, twigs, no detritus.	
Renovation	Accumulation with high water table	Compact layer with charcoal, loam aggregates	3375 cal BC
	Hinterland spring flooding	Erosive sandy layer with well sorted sand and large amounts of poppy seeds. Disturbed.	
fire	?	Layer of large charcoal fragments with some fine sand.	
Raised house with goat/sheep staying sometimes beneath	Dry Summer (low water table)	Loose organic layer with wood, bark, white fir needles, moss, some detritus.	
Raised house with goat/sheep staying sometimes beneath	Accumulation with high water table	Organic layer with bark, white fir needles, wood, no detritus.	
Raised house with goat/sheep staying sometimes beneath	Hinterland spring flooding	Well sorted sandy layer.	
Raised house with goat/sheep staying sometimes beneath	Winter?	Compact layer with sand, gravel, twigs, some charcoal, and altered coprolites. Pollen indicating winter season.	
Raised house with goat/sheep staying sometimes beneath	Autumn?	Loose organic layer with many hazelnut shells, moss, twigs, leaves and loam aggregates, some sheep/goat coprolites. No detritus.	
Raised house with goat/sheep staying sometimes beneath	Accumulation with high water table	Compact layer with fine sand and clay matrix, some ashes and bark.	
Raised house with goat/sheep staying sometimes beneath	Hinterland spring flooding	Sandy layer.	
Raised house with goat/sheep staying sometimes beneath	Autumn?	Loose sand with bark, mollusk shells, organic remains, loam aggregates, twigs, mistletoe, fish bones, 1 ceramic fragment on the right side.	
Raised house with goat/sheep staying sometimes beneath	Lake flooding	Dense sandy layer with organic remains, charcoal, ashes, melted phytoliths, seeds (poppy and flax), mollusk shells, many bones, some with heat signs, loam, leaves, mosses, white fir needles, and one sheep/goat coprolite.	
Raised house with goat/sheep staying sometimes beneath	Lake flooding	Loose sandy layer with limnic elements, bark, charcoal, some seeds and bones, all reworked.	
Raised house with goat/sheep staying sometimes beneath	Dry Summer (low water table)	Compact lake marl (disturbed) with detritus, bark, weathered mollusk shells, bones, seeds, and leaves.	3384 cal BC
	Lake flooding	Sandy lake marl without layering, disturbed probably by a post. Many mollusk shells, some with signs of weathering. Precipitated in the littoral area, reworked by wave action, lake level flucuations occurred.	

Seasonal processes

- Lake flooding
- Hinterland spring flooding
- Accumulation with high water table
- Dry Summer (low water table)
- Autumn?
- Winter?

Paludal Settings (Wetland Archaeology), Figure 12 Arbon-Bleiche 3, House 1, sample M1030 (see location of sample in Figure 11): A compilation of scanned thin sections with a brief micromorphological description and a suggested interpretation of the archaeological layers, including possible seasonal processes (based also on botanical and palynological evidence).

formation of lakeside settlements. Arbon-Bleiche 3 is one of the most suitable examples for this purpose, as it is an extensively explored pile-dwelling site in the Circum-Alpine region that has received much interdisciplinary study (published by Jacomet et al., 2004; Menotti, 2012). This Neolithic site lies in northeastern Switzerland on the southern shore of Lake Constance, south of the town of Arbon. Today, the site lies inland compared to its original setting, which was located directly on the shore of a protected bay. The settlement was built in 3384 BC and was inhabited until 3370 BC (all dates coming from dendrochronology). This period falls in the middle of a cold phase (Piora 2) that experienced generally high lake levels. The site was constructed during a brief favorable climatic phase, when lake levels dropped for a short span of time (Haas and Magny, 2004).

The economy of Arbon-Bleiche 3 was based on the cultivation of plants, animal husbandry, and on gathering, hunting, and fishing. Animals were kept within the settlement during the winter months. The village was settled only once and for a relatively short time (15 years). Because the ground plans of the dwellings were clearly visible during the excavation, it was possible to take micromorphological samples from different functional areas of the site (e.g., within houses and alleys).

The basic stratigraphy of Arbon-Bleiche 3 consisted of sandy lake marl at the base, followed by a thin sandy beach layer that formed due to a regression of the lake before the settlement was installed (Figures 10 and 11). During the occupation, a 5–40-cm-thick archaeological stratum with several organic and sandy bands was deposited. The floors of the buildings were raised above ground level (Leuzinger, 2000). During the interval of settlement, depositional conditions must have been continually humid but without permanent standing water covering the area. The layers represent a complex puzzle of deposition and erosion. The entire anthropogenic deposit was covered by 2 m of sandy deposits almost "immediately," thereby promoting excellent preservation of the site until the moment of excavation.

Detailed geoarchaeological interpretation of the organic accumulations has enabled a reconstruction of the chronological biography of house number 1 (Figure 12). House 1 was the first to be constructed, dated to 3384 BC, and it was located in the middle of the settlement (and excavated area; Leuzinger, 2000). After its installation, a 10 cm sequence of organic layers was deposited, interrupted several times by sandy inwash from the hinterland. A local burned layer was then partially eroded by a further sandy inwash. The accumulation of a 7-cm-thick organic layer followed; it contained large amounts of sheep/goat coprolites and mistletoe.

This sequence can be interpreted as follows. The installation of House 1 led to compaction of the dry carbonate platform surface beneath it. During the time of settlement, organic layers accumulated but were repeatedly eroded and covered by thin sand layers, probably during spring floods and increased runoff. After 9 years of occupation, House 1 burned down and was subsequently flooded for a short period. A renovation in 3375 BC is demonstrated by dendrochronological investigations. Later, the roof collapsed and the house was abandoned. Botanical and palynological analyses confirm that the accumulation of the ovicaprid coprolites is an indication that the ruin was used as a stable for sheep and/or goats during the winter. In the spring of 3370 BC, the entire village burned down completely, and shortly after, the area was flooded by the lake (Haas and Magny, 2004; Ismail-Meyer and Rentzel, 2004, 76f.).

Summary

Geoarchaeological methods, including especially micromorphology, have become essential tools for the study of archaeological settlements in wetlands. In this contribution, special emphasis has been placed on micromorphological analyses of several prehistoric lakeside settlements in the Circum-Alpine region.

By comparing with actual processes ongoing in natural wetlands, the site formation processes of ancient lakeside settlements can be studied, and they are here summarized as accumulation of organic matter and its erosion, reworking, and decay, which is closely related to the height of the groundwater table and/or lake level.

Micromorphology, possibly combined with standard sedimentological investigations, shows great potential in reconstructing environments and site formation processes in wetland sites. Collaboration among different disciplines is fundamental, especially with archaeobotany, palynology, and dendrochronology, to obtain optimum results. In this way, it is possible to use the mosaic of different accumulations within a lakeside site to detect many human activities as well as natural processes, from flooding and erosion to dry periods associated with seasonal changes (Jacomet et al., 2004; Keddy, 2010, 131; Menotti, 2012, 19f.; Ismail-Meyer et al., 2013). The results of research obtained so far in this field have been remarkable, but there is much potential for significant applications of geoarchaeological methods to wetland archaeology in the future.

PASTORAL SITES

Giovanni Boschian
Dipartimento di Biologia, Università di Pisa, Pisa, Italy

Definition

Pastoral sites are those devoted to or based on livestock raising. This definition should be applied with care, because stock rearing may have played a variable role in the economies of past populations, and consequently, traces of pastoral activities may be more or less evident in sites where other subsistence practices were more apparent. In the majority of cases, the term applies to cultural contexts in which a production economy was at least partly engaged in pastoral pursuits for subsistence. Through time, pastoral sites were integrated into economic systems of increasing complexity, and they also included settlements with different pastoral functions, many of which exploited, managed, and modified the surrounding and intervening territories.

Introduction

Due to the diffusion of stock rearing practices from its earliest appearances, pastoral sites are widespread and can be found in extremely diverse environments from the lowest latitudes to the edge of the polar ice caps and from lowlands to high mountains. As a result, a very wide range of "natural" geological processes can be involved in the formation processes of these sites. These processes will be not treated here, as more information about them can be found in specific manuals.

On the other hand, the anthropogenic and human-influenced animal components tend to be less variable and depend more on the animal species involved than on specific practices connected with pastoral economy or – more simply – with stock rearing. Nevertheless, it must be noted that the species of animals raised are partly a consequence of the environmental characteristics of the area where the sites are located. This entry will focus on the components that are distinctive of pastoral sites.

Eventually, it can be argued that pastoral sites may represent just a minimal part of much larger agropastoral systems of landscape use, because animals (and shepherds) spend more time on pastures than in the limited areas that are normally considered to be typical pastoral sites in the strict context of a settlement site. Unfortunately, the traces directly left by ancient shepherds and their flocks on the landscape are ephemeral and elusive, and their preservation through time is unlikely. Conversely, indirect results of pastoral activities may leave strong traces on the landscape (soil erosion, scree activation, etc.), which also fall under the category of more general geological studies and of landscape archaeology.

Pastoral site typology

Livestock raising is generally presumed to be a high-mobility activity, with animals moving over more or less wide territories on daily and/or seasonal cycles. Therefore, populations or groups relying on pastoral economies or more simply shepherds, live nomadic or seminomadic lifestyles, and their settlements tend to be characterized by ephemeral or movable/transportable dwellings, like huts or tents (Simms, 1988), whose traces in the archaeological record can be extremely scanty, if they are preserved at all. During the night or in other peculiar occasions connected with the management of the flocks, animals can be kept in pens delimited by wattle or fences, or by less precarious stone walls. In such cases, postholes or stone alignments/accumulations may be the only trace of the presence of domestic animals on the territory, even if it is argued that it may be quite difficult to find clear traces of organization in the generally random clusters of postholes that derive from the periodic shifting and rebuilding of pens. Caves and rock-shelters are typical places on the landscape where flocks can be stabled to provide shelter from rain and safety from predators. Such sites were exploited for stabling animals from the Neolithic onwards throughout Mediterranean Europe (Angelucci et al., 2009, and literature therein), and in several areas, they are still being used today for the same purpose.

Domestic animals can share spaces more or less closely with humans in more stable settlements, like villages and proto-urban or urban sites (Matthews, 2010). In these cases, the problems are approximately the same, because the animals – if not sharing dwelling spaces with humans – may be kept in specific enclosures or buildings whose traces in the stratigraphic sequences may also be unclear. Even if traces of animal husbandry are quite evident and abundant, as indicated by meter-thick coprogenic deposits that commonly fill spaces between houses in Near Eastern tells, these sites cannot be considered as strictly pastoral but more like mixed economy (agropastoral) settlements.

Indicators of pastoral activities

Pastoral signals introduced into a site by continuing relationships between humans and livestock include two basic indicators that suggest the permanence of animals: bones and droppings. The archaeological significance of coprogenic material is much more diagnostic than that of zooarchaeological data because animals may have been kept for reasons other than meat consumption and consequently may not have been butchered on-site. Therefore, “Dung is sounder evidence of the presence of flocks than sheep bones are” (Boschian and Montagnari-Kokelj, 2000, 347). Most aspects of dung in anthropogenic contexts, like its composition, accumulation modes, preservation versus decay, and archaeological significance, were thoroughly examined by Shahack-Gross (2011).

Macro- and microscopic scale indicators of dung in sediments were first identified by J. É. Brochier (1983) in a seminal study of fine-grained sediments in Neolithic cave contexts in France. Later, these indicators were better formalized (Courty et al., 1989; Brochier, 2002; Shahack-Gross, 2011). Such evidence should nevertheless be evaluated with care and its significance confirmed using other cultural markers, because the clues may point to spontaneous stabling of wild animals, as in the case of the chamois or ibex dung occurring in the Balma Margineda rock-shelter between the Younger Dryas and Early Atlantic (Brochier, 1991).

The most reliable indicators of the presence of dung within archaeological deposits can be observed at the microscopic scale using micromorphological techniques: spherulites, phytoliths, and ash, the former being sufficient indicators, while the others make sense when all the indicators are found in association. Ash occurs when dung is burned, which happened often in most cases. Charcoal is almost always associated with these components as well, even if it may derive also from a very wide range of other activities.

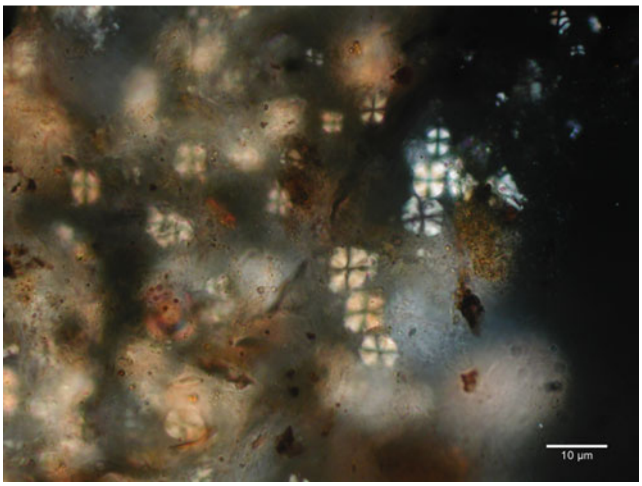
Spherulites (Canti, 1997, 1998) are extremely common in herbivore dung because they are produced within the ruminant gut during the digestion process – but see also Courty et al. (1989) for occurrence in the dung of nonruminants. They are made up of acicular calcareous crystals radially arranged in spheres whose diameter can range from 4–5 to 10–12 or sometimes up to 20 μm (Figure 1); they are transparent and colorless and can be easily detected under crossed polars because of their cross-shaped pseudo-interference figure. When burned, they may have a dark blackish, almost opaque core.

It should be pointed out that even if spherulites are almost certain indicators of ruminant dung, their absence is not conclusive of the absence of dung. In fact, not all ruminants produce spherulites, or they may produce them in variable amounts depending on season, fodder type, etc. Moreover, spherulites may decay and disappear from the sediments. These aspects were recently stressed by Lancelotti and Madella (2012), whose actualistic work on dung fuel cakes suggests that an association of phytolith and chemical analyses may help in sorting out the occurrence of dung.

Hydrated silica phytoliths commonly occur in dung, as indigestible by-products of grass-fed animal alimentation, but they may be present in archaeological deposits because of other practices connected to pastoral or even pre-pastoral use, like accumulation of fodder or litter for animals (Courty et al., 1991; Macphail et al., 1997;

Boschian and Montagnari-Kokelj, 2000; Brochier and Claustre, 2000; Boschian, 2006), as well as from a wide range of non-pastoral activities. This aspect, and mostly the accumulation of special types of fodder, is particularly relevant in Early Holocene horizons of some Saharan pastoral caves, as inferred from the results of multidisciplinary studies (Cremaschi et al., 1996; Cremaschi and Trombino, 1999; Di Lernia, 2001).

Ash is also a frequently occurring component of sediments generated by pastoral activities, though obviously not exclusively. Ash comprises micrite aggregates that are pseudomorphic after calcium oxalate cubes, lozenges, crescents, and other regular crystalline shapes (Figure 2); they result from the burning and re-liming of 1- or 2-hydrated calcium oxalate (whewellite and weddellite, respectively) crystals that occur in wood, leaves, bark, and other vegetal tissues (Canti, 2003). At higher temperatures, these aggregates may collapse and produce a very fine micritic "dust" with petrographic interference colors that are relatively low compared with the typical calcite ones.

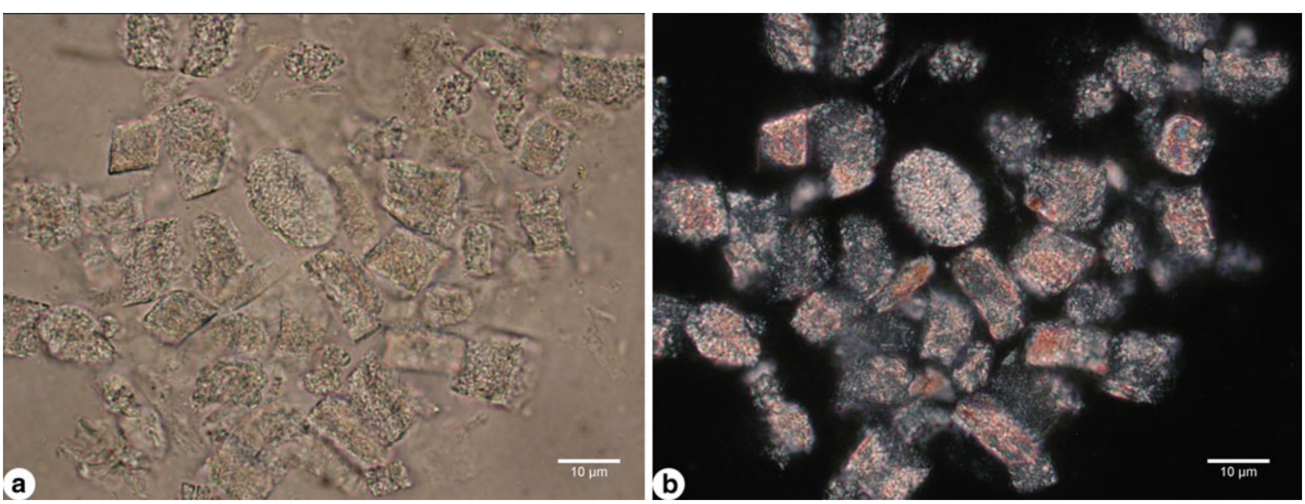


Pastoral Sites, Figure 1 Photomicrograph of fecal spherulites. Note the black crosses (pseudo-interference figures), which are characteristic of these features under crossed polarizers. S. Angelo Cave (Abruzzo, Central Italy), Middle Neolithic Painted Ware levels. 100× oil immersion objective, crossed polarizers.

Rock polish may result from the stabling of livestock in caves and rock-shelters, and it may be used as a reasonably reliable indicator of pastoral practices. This polish is due to the rubbing of sheep and goat fleece on the walls of the caves where large flocks are crowded, and it appears as a smoothed and glossy band of rock, some tens of centimeters wide. Its height above the cave floor corresponds roughly to the size of the sheep, but its present-day position on the wall can be much higher than the floor, indicating changes in cave sediment thickness. These changes may be due to erosional processes emptying the cave, as well as volume reduction due to intentional burning of the dung accumulation. The latter can be a common practice in pastoral caves, where the whole inner volume can be quickly filled up by dung after occupations by large flocks (Brochier et al., 1992).

Coprogenic sedimentary facies

The abovementioned basic components are usually organized into two main deposit facies that can be easily identified at the macroscopic scale. Nonetheless, these facies are usually variable, and several subtypes with intermediate characteristics can also be observed.



Pastoral Sites, Figure 2 Photomicrograph of *Tilia cordata* (European lime or linden tree) experimental ash. Micrite pseudomorphs on Ca-oxalate crystals. 100× oil immersion objective, (**a**) plane polarized light, (**b**) crossed polarizers.

Pastoral Sites, Figure 3 Homogeneous coprogenic facies. Brownish homogeneous or poorly layered horizons mostly comprising randomly dispersed spherulites, phytoliths, and ash, interlayered with black/white lenses of ashed coprolites. Zemunica Cave (Dalmacija, Southern Croatia), Neolithic to Bronze Age levels. Distance between white markers, 50 cm.

Homogeneous facies

Seen with the unaided eye, this facies appears to contain brownish to grayish homogeneous deposits, often somewhat thick and sometimes crossed by isolated thin black/white lenses that may be several square meters wide (Figure 3). Unsorted stones can also occur, usually scattered randomly throughout the sediment. The soil strength class is "moderately weak to moderately firm," i.e., dry sediment blocklets fail if gently to firmly pressed between the forefinger and thumb (Catt, 1991).

At the microscopic scale, the bulk of this facies comprises phytoliths and spherulites, randomly scattered throughout the sediment and creating a homogeneous and compact mass with few voids. In some cases, the spherulites are even more abundant and apparently prevail over the phytoliths. Micrite aggregates pseudomorphic on oxalate crystals (ash) are present in various quantities in these sediments, and their aspect is grayish and "dusty" under plane polarized light. Small bits of amorphous organic matter are ubiquitous, the larger ones sometimes preserving traces of vegetal tissues. Charcoal may also occur, in variable quantities. Sand- to fine silt-size silicate grains may occur within this facies, depending on the geological characteristics of the surrounding environment.

"Layer-cake" facies

At the macroscopic scale, this facies is typically banded black and white, with strikingly regular alternating horizons that, in fact, represent pairs of layers or lenses that can be very dark gray to black and grayish to brownish to very light gray. After drying, these colors become black and light gray to whitish (Figure 4). The individual horizons are thin (2–3 cm for the dark ones, up to 10–12 cm for the light ones) by comparison to their extension, which may be up to several square meters. The matrix possesses grain sizes in the range of sandy silt loam to sandy loam; the coarse component of the sediment is rare and comprises randomly scattered angular stones of various sizes. The soil strength class is "moderately weak to moderately firm," i.e., dry sediment blocklets fail if gently to firmly pressed between the forefinger and thumb (Catt, 1991). These deposits – called *fumiers* by French authors – are typical of caves used for stabling animals and can be considered diagnostic even at a macroscopic scale. These sequences are often interrupted, or vertically crossed, by thin vertical features, probably postholes that testify to the use of wattle or wooden enclosures.

The dark horizon always represents the bottom horizon of the pair; it is usually thinner than the overlying lighter part, and in some cases, it can also be discontinuous. The structure is medium to well-developed very fine to fine granular, with large pores and rather loose. The light horizon is less porous and more compact, and sometimes it includes two or three subfacies that differ in texture, color, and porosity and that are organized in mottles and patches or in layers bounded by complex surfaces. The limits between these units are generally sharp and plain or very slightly undulating.

This facies can occur in isolated pairs usually embedded within the homogeneous facies (see above) or in homogeneously layered decks. These decks can be up to several meters thick and somewhat domed, resembling a sort of finely layered "heap."

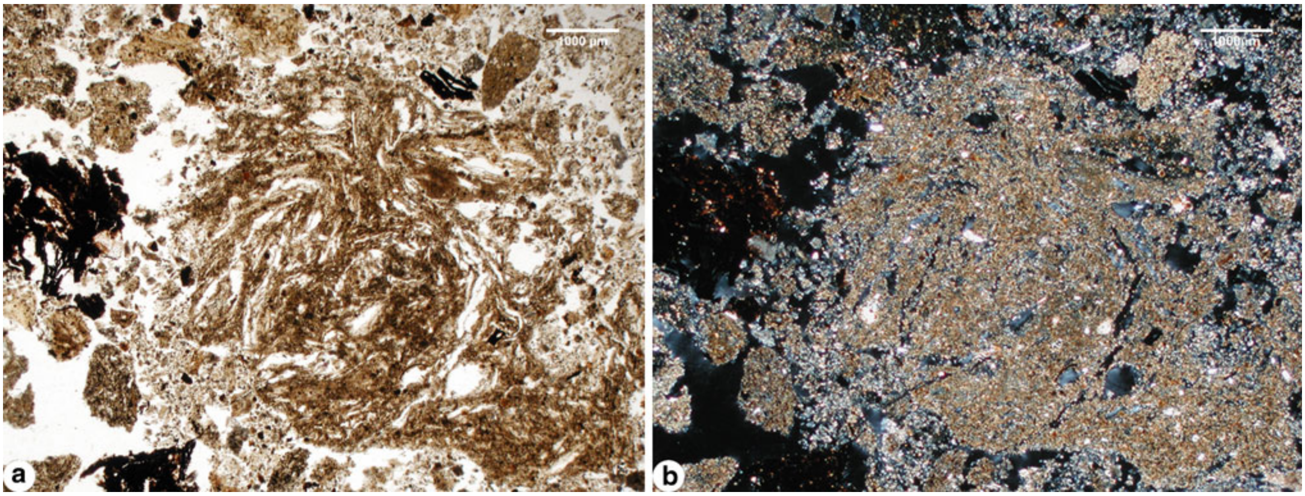
Pastoral Sites, Figure 4 Layer-cake coprogenic facies. Alternating grayish/whitish and black levels comprising completely ashed coprolites (often with layered-undulating microstructure) and dark charred coprolites with vegetal residues, respectively. The white lenses are made up almost exclusively of phytoliths. Vela Cave (Istria Peninsula, Northern Croatia). Frame height about 42 cm.

At the microscopic scale, the dark levels are mainly made up of partially to almost completely charred vegetal remains, mostly leaves, twigs, and young wood fragments. These can be quite large, up to 10–15 mm or more, and preserve their original structure. Under crossed polarizers, they are usually amorphous, though some weak birefringence can be detected in the less charred fragments. Micrite aggregates pseudomorphic on Ca-oxalate crystals and higher temperature ash are relatively frequent, as well as calcareous spherulites. The organization of the white layers at the microscopic scale is somewhat more complicated and may include different subfacies, which apparently do not follow a specific cyclical sequence. The most relevant ones are the granular and the finely layered subfacies.

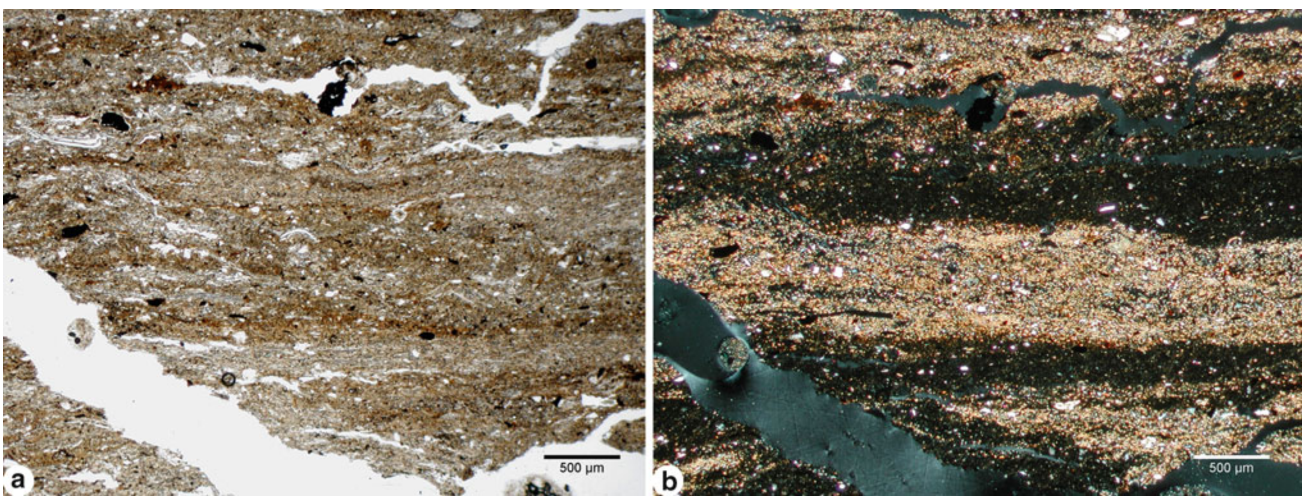
The granular subfacies is composed mainly of subrounded to slightly elongated aggregates of organic remains (Figure 5); these aggregates are poorly sorted, ranging from few hundreds of micrometers to about 1–2 cm. They are made up of fibrous features 5–20 μm thick and up to 1–2 mm long, which are made up of partially articulated hydrated silica phytoliths and transparent colorless to semiopaque brownish organic matter that, in some cases, may have been partly transformed to carbonates by ashing. The size and spatial organization of the fibrous features often depend on the shape of the aggregates; they are somewhat short and randomly compressed within the subspherical aggregates or sometimes longer and arranged in less compact wavy bundles inside the elongated aggregates. Spherulites are often present within the aggregates. The packing voids between aggregates are (partly) filled by a matrix of spherulites, phytoliths, amorphous organic matter, and mineral components embedded in a fine micritic micromass. Therefore, this micromass may be brightly colored by high-order interference colors under crossed polarizers.

These rounded aggregates are interpreted as sheep/goat droppings, which are typically pellet shaped, whereas the elongated ones with fluidal fabric represent cattle droppings.

The finely layered subfacies is characterized by a fine lamination of regularly alternating lighter and darker layers that are slightly undulating, with sharp or clear limits, 60–80 to 2,000–3,000 μm thick, and with a homogeneous micromass (Figure 6). The light ones are almost transparent and colorless under plane polarized light and show an amorphous b-fabric under crossed polarizers; they are made up almost entirely of hydrated silica phytoliths with a few fine silicate grains. The phytoliths are often articulated and regularly arranged parallel to the layer limits, building up some sort of "fluidal" feature. By eye, they usually appear whitish. The darker layers have a brown-yellowish color under plane polarized light and a crystallitic b-fabric under crossed polarizers; they are made up of phytoliths, bits of amorphous organic matter, fine silicate grains, spherulites, and micrite. The pores may range from frequent to totally absent, and they may be elongated with their longer axes parallel to the layering, while the phytoliths are usually not regularly arranged as they are within the light layers. Micrite aggregates



Pastoral Sites, Figure 5 Photomicrograph of granular subfacies. Medium to poorly developed granular microstructure, the aggregates are burned sheep/goat coprolites, including remains of convolute vegetal fibers. Spherulites and some mineral (quartz) grains can be observed under crossed polarizers. S. Angelo Cave (Abruzzo, Central Italy). 2.5× objective, (**a**) plane polarized light, (**b**) crossed polarizers.



Pastoral Sites, Figure 6 Photomicrograph of microlaminated undulating facies. Thin beds of phytoliths (dark under crossed polarizers), sometimes mixed with sparse mineral grains, alternating with levels rich in spherulites, with variable amounts of ash, phytoliths, and mineral grains (bright under plane polarized light). In the upper left corner, a reddish aggregate of *terra rossa*-like soil (Alfisol) was probably transported into the cave under the sheep/goat feet. Pupićina Cave (Istria Peninsula, Northern Croatia). 2.5× objective, (**a**) plane polarized light, (**b**) crossed polarizers.

pseudomorphic on Ca-oxalates (ash) may occur in variable amounts in the darker layers. Ash may be dominant in some of these levels.

Significance of coprogenic sediments

The interpretation of these sediments is reasonably straightforward and relies mostly on micromorphological and microstratigraphic observations, as well as on geo-ethnoarchaeological considerations. The information obtained at the lowest interpretive level explains mostly the formation processes of single lithological units and homogeneous sequences of units, whereas complex inference about site use, distribution of activity spaces, and diachronic evolution of the site derive from higher level interpretation, which involves the study of cultural remains and faunas and the assessment of the chronological framework.

Regarding the layer-cake sequences, the black levels embed charred plant remains, mostly young wood and leaves, and partially burned coprolites. Conversely, the white levels are made up of thoroughly ashed, more or less fragmented, and usually well-compacted coprolites and possibly some completely burned wood remains. In fact, each black/white pair resulted from the burning of one layer deposited during one phase of livestock stabling. Twigs and grass were initially laid down, as their remains are observed at the bottom where they are most frequent; they probably represent litter and/or fodder that can hardly be differentiated by soil micromorphology or other techniques (Brochier and Claustre, 2000, 469). Subsequently, they were covered by the droppings of the animals living upon them.

The evidence indicates that the dung (and possibly straw, hay, or even young branch litter remains) was systematically burned after the end of the stabling period, an operation performed in order to reduce the volume of the deposit and possibly in an attempt to sanitize the pen interiors. Stabling, burning, and abandonment were cyclically repeated, probably following a transhumant routine. The dung layer burned slowly because it was compacted by animal trampling and partially soaked by their liquid micturitions or by karstic drip water. The bottom part of each pair burned in a low oxygen environment, and thus its organic components were (partially) charred leading to the formation of a dark horizon. Conversely, the upper part burned under high-oxygen conditions and its vegetal components were thoroughly ashed, thereby creating the white layer. The very well-defined laminations indicate trampling, with consequent compaction of the dung or dung-rich sediment, and the rearrangement of elongated particles perpendicular to the compressive forces.

Unfortunately, the meaning of the homogeneous facies is still not fully clear. The basic components are the same as in the layer-cake facies, even if the degree of organization is almost null, and its components show a completely random distribution. It may be inferred that both facies originated from the stabling of domesticated herbivores. J. É. Brochier (2002) suggests that they may derive from complete primary mineralization of the organic components of herbivore dung without burning, and he employs the Provençal term *migon*. This process would result in a much lower final volume of deposit, and it would yield a complete rearrangement and randomization of the original fabric.

At a higher interpretive level, one should first observe that these basic sediment facies do not always fill up caves with continuous homogeneous sequences, but they are frequently juxtaposed laterally to other coprogenic facies or to sediments originating from domestic habitation. This may indicate specific spatial partitions within the cave, which sometimes change through time as some areas previously occupied by humans were later occupied by animals. This aspect is also reflected in the distribution of artifacts, which is usually lowest in the layer-cake facies and higher elsewhere. Two ideal extremes can be envisaged: (1) caves (or facies) mostly containing spherulites and phytoliths, and characterized by a low concentration of cultural remains, were used almost uniquely for penning animals, and (2) caves (or facies or lateral associations of facies) containing mostly ash and substantial amounts of cultural remains served mostly as shelters for humans. The variability is extreme between these two alternatives and provides a basis for complex interpretations about site use, links with lowland open-air sites, and complex land exploitation systems (Brochier et al., 1999; Brochier, 2002; Boschian and Miracle, 2007).

Caves versus open-air pastoral sites

Though they are not exclusively found there, the abovementioned deposits can be best observed in caves and rock-shelters, where they are well preserved because of the relatively limited action of water percolation. In fact, the specific surface areas of the particulate matter within these very fine-grained deposits are extremely large. As a result, the reactivity of the carbonate component (spherulites and micrite aggregates pseudomorphic on Ca-oxalates) is extremely high when affected by CO_2-acidified water. A major part of the diagnostic evidence that demonstrates prior pastoral uses (spherulites) may be rapidly destroyed in open-air contexts within relatively moist regions, unless the carbonate-rich horizons are shielded by reasonably impermeable overlying layers.

As observed by Shahack-Gross et al. (2003) regarding East African open-air contexts, enclosures for livestock are typical of pastoral sites, and they can be considered to be indicators of penning. This assumption is generalizable to other areas and cultures, and it is valid for open-air sites and caves, but it becomes stronger evidence in the former because of the more thorough deterioration of the coprogenic sediments due to alteration from the action of rainwater flowing through the site earth. Following the results of a geoarchaeological and ethnoarchaeological approach, the occurrence of a "microlaminated undulating structure . . . composed of alternating laminae of acellular organic matter and opal phytoliths" (Shahack-Gross et al., 2003, 450), in association with large amounts of grass phytoliths, calcareous spherulites, and authigenic phosphates, was identified as strongly suggestive of degraded enclosure sediments. Nonetheless, it was also argued that complications may frequently arise in identifying the concurrence of these markers (Shahack-Gross et al., 2008, and literature therein), whereas stable nitrogen isotope measures on bulk sediment samples are apparently more reliable, showing a major concentration of ^{15}N in enclosure deposits, and may be used to provide supplementary evidence in uncertain contexts. Conversely, carbon isotope ratios are not affected by site use, but they may give hints about the composition of the herds, indicating C3 (browsers) versus C4 (grazers) ratios.

Summary

Pastoral sites are usually more or less ephemeral campsites or settlements, in which the main activities are connected to livestock raising. Pastoral caves were used for stabling animals temporarily, in connection with more complex agropastoral systems of land exploitation that implied transhumance. Typical features of pastoral (cave or open-air) sites are enclosures used to pen the animals.

Calcareous spherulites, grass phytoliths, and authigenic phosphates, usually organized into microlaminated undulating microstructures, all resulting from animal dung accumulation, are the best indicators of pastoral sites. Nitrogen isotope analyses can be used as accessory indicators in open-air sites, where calcareous components may undergo dissolution and leaching and where the microstructures may be reworked.

Various coprogenic sediment facies can be observed within pastoral caves, where the preservation of the sediments is optimal; these can be used as indicators of specific pastoral practices, including transhumance and cyclical burning of the dung accumulations.

Abraded groove or tool-sharpening groove; Rock art; Rock carving; Rock etching; Rock imagery

Definition

Rock art is the general term for any human-generated modification to a rock surface, generally meaning engraving or painting. The term *petroglyph* is used for any rock art made by removing part of the rock surface to create an image or design, as opposed to *pictographs* or rock paintings, images, or designs made by adding pigment to the rock surface. Most researchers today include intentional, but nonpictorial, rock markings, such as abraded grooves, cupules, or so-called tally marks, in the petroglyph category; however, some place these and bedrock grinding surfaces into a separate archaeological feature category.

Introduction

Petroglyphs are intentional modifications to a rock surface made by removing part of the surface. Geoarchaeology enters petroglyph studies on several levels: (1) the type and structure of the rock surface, (2) the landform on which the modified rock surface occurs, and (3) the larger landscape context of the petroglyph site. These aspects of petroglyph geology contribute to the researcher's understanding of how, when, and why past people made and used petroglyphs.

Rock as medium

By definition, rock is the medium in which petroglyphs are made. The term refers only to works on immobile stone, not to such items as statuettes or incised tablets. Petroglyphs occur on cliffs, monoliths, horizontal bedrock exposures, boulders, and inside caves and rockshelters. Petroglyphs are found in almost all kinds of rock, but sandstone and basalt are the most common. In glaciated areas, petroglyphs are found on glacially smoothed beds of quartzite, limestone, and slate, as well as on boulder erratics. In short, petroglyphs occur on whatever suitably hard, smooth rock was available in a given area.

Though petroglyphs are made by removing parts of the rock surface, the amount of rock removed varies. On one end of the spectrum are those petroglyphs made by lightly scratching the rock surface to create relatively inconspicuous and short-lived marks. Others are more heavily incised into the surface, generally using an edged tool such as stone, bone knife, or graver. These techniques produce outlines formed of shallow cuts with a V- or U-shaped cross-section. Another common technique involves striking or pecking the rock with a hard object. The impact dents or craters the rock; a line of such dents makes up the outline of the design, and more dents may fill in all or part of a figure. Most pecked rock art has a "hill and valley" texture, with tiny circular or elliptical dents surrounded by unmodified rock. Depending on the angle at which the hammer strikes the rock, the tiny dents will be symmetrical or oblique in their cross-section. Fine, controlled lines are possible in pecked rock art through the use of indirect percussion (hammer and chisel). A small pointed stone or bone stylus is held in one hand with the point against the rock, while the butt of the implement is struck with a stone or bone hammer. This allows the artisan to produce precise outlines and silhouettes with even widths and depths. Pecking is frequently used to fill in the interior of figures in one of three ways: by solidly covering the space with overlapping peck marks, by filling in portions of the figure's interior with solid pecking, or by scattered pecks marks that do not overlap.

Either incised or pecked rock art designs can be further modified by rubbing the modified areas to smooth out the incisions or peck marks. This involves abrading the lines or silhouettes with a bone or stone tool to grind down the high points and create a smoother surface.

A third technique of petroglyph production is to grind away portions of a rock surface by direct abrasion with bone, stone, or wooden tools. A repeated back-and-forth movement typically results in a narrow, elliptical groove, deepest in the middle and tapering at the ends and sides. These banana-shaped grooves are sometime referred to as tool grooves or sharpening grooves. Multidirectional abrasion produces a shallow, dish-shaped feature, which sometimes serves as a "canvas" for additional petroglyph production. Circular ground areas, referred to as cupules, are another common form of petroglyph, formed by grinding pits into the rock surface. These occur on vertical as well as horizontal surfaces and sometimes cover the entire surface of a boulder or outcrop. The term pit-and-groove petroglyph is applied to these as well because, at many sites, the cupules are connected by incised or grooved lines. Related to abraded petroglyphs are images created by scraping away lichen or moss to create a design on a rock surface.

Recognizing petroglyphs

Because a petroglyph is made on rock and almost always remains within its natural setting, recognizing a petroglyph is often a matter of distinguishing human-generated features of the rock surface from natural ones. When a petroglyph is fresh, large, and in the shape of something complex, it is easy to recognize as rock art. Problems arise when petroglyphs are very lightly scratched into the rock surface, when they are worn down by erosion or remineralized to the same color as the larger rock surface, when calcite or silica accretions have built up over them, or when they are small or very simple in design. Merely as a consequence of human perception, highly visible petroglyphs tend to overshadow inconspicuous ones.

Another complicating factor is that the ancient petroglyph makers sometimes incorporated natural features of the rock surface into their petroglyphs. A slight bulge in the surface might become the rounded shape of an animal's back (Keyser and Poetschat, 2004). With the addition of a few extra lines, a natural crack or crevice might be transformed into a human or animal figure. An entire boulder might be carved to represent an animal, such as the so-called ribstones of the Canadian Great Plains (Wormington et al. 1965, 170–172). A columnar speleothem might be transformed into a humanlike creature by carving facial features into it (Stone, 2005).

It can be very difficult for even an experienced rock art researcher to decide whether a particular line is a petroglyph or a natural crack or scratch in the rock. In such cases, it may be necessary to apply lights from different angles or intensities or revisit the site at a different time of day. Petroglyphs that do not form complex designs or figures can be tricky to recognize. Further, petroglyphs that are simple and small are sometimes missed at sites where more complex, showy petroglyphs dominate. Abraded grooves and surfaces are often mistaken for natural features, and unusual natural features are often mistaken for petroglyphs by untrained observers. An experienced researcher, however, can usually make this distinction. If not, a geologist can advise as to whether the feature in question occurs naturally within the rock unit.

Geology of petroglyph distribution

In any distribution study of rock art, a first step is mapping the location of rock outcrops suitable for the kind of petroglyph under consideration (Chippendale and Nash 2004b, 10). Lithology factors into petroglyph distribution in several ways. First and most obviously, rock art is limited to areas that have, or previously had, exposed rock. Places without rock do not contain petroglyphs. In humid regions, petroglyph-bearing rock may have been subsequently covered by moss or buried by soil formation such that the formerly exposed rock faces now lie under a blanket of sod, peat, or vegetation. Thus, mapping rock outcrops may entail more than a simple snapshot of a currently visible outcrop. A second factor in petroglyph distribution concerns the durability of various kinds of rock. Very soft rock is not likely to preserve petroglyphs. Exposure to the elements and chemical and physical reactions to light, water, fire, and temperature affect the resistance of a given type of rock to granular deterioration and spalling. Third, lithology helps determine physical characteristics of a rock surface that may affect (1) whether it will be selected by a maker of petroglyphs and (2) the degree to which the carvings will be subject to erosion. Specifically, some kinds of rock are likely to form large horizontal "floors"; others are likely to contain crevices or caves; others contain springs or seeps. Finally, ancient peoples may have also selected rocks for other characteristics such as color, hardness, the sound produced by striking the rock, patterns of inclusions or interbedding, or whether striking the rock produces sparks.

Once the lithology of the area is mapped, the distribution of petroglyphs can then be mapped over it to see the degree to which the two correlate. Important caveats in any such studies are, first, that some rock art may not have survived to the present day and, second, that the study includes only areas for which complete geological and archaeological data are available (Hyder 2004, 92). In other words, a blank on the map should be demonstrably the result of the decisions of ancient people and not merely an artifact of a lack of survey there.

Geoarchaeology of petroglyph dating

Geoarchaeology contributes to attempts at dating petroglyphs in several ways. Perhaps the most direct involves dating sediments that cover all or part of a petroglyph to indicate a minimum age for the carving. Assuming that sediment gradually built up over the petroglyph, the age of the petroglyph must be greater than that of the sediment (Butzer et al., 1979, 1202; Loendorf, 1991). This dating technique requires careful analysis of the pattern of sedimentation and erosion. Deposits in sandstone rockshelters and below sandstone cliffs present special problems because the sediments are often extremely friable and unconsolidated. This can result in rapid, sporadic movement of sediment, rather than gradual buildup of stable surfaces and soils. Rock art sites frequently attract looters, and thus, the fill inside rockshelters or below cliffs may have been displaced by digging and the pits thus created quickly refilled with loose sand. It is, therefore, imperative that researchers carefully evaluate the integrity of datable material, such as charcoal, recovered while excavating. Another complicating factor is that these high energy depositional situations can undergo rapid alternations between erosion and sedimentation. The sediments covering a petroglyph today may represent the last of a series of cycles, rather than a long-term buildup that has been continuous since the petroglyph was made.

A less direct, geomorphic dating method involves reconstructing the history of alluvial terraces formed over or below petroglyphs, then determining the likely age of the terraces that would have been present when the petroglyphs were made. In some areas, petroglyphs are stranded high above the current ground surface. Reconstructing the terrace sequence could demonstrate that portions of the rock were formerly accessible from a terrace that had not yet been removed through erosion. The chronology of deposition and subsequent removal of that terrace provides a clue to the age of the petroglyphs, because the researcher can reasonably assume that the terrace was in place in order to provide access to the rock surface when the petroglyphs were made. The same would hold for a terrace that covers a petroglyph, with the assumption that the petroglyph was made before the stream deposited the sediments. Reconstructing the history of terrace formation is the first step in linking petroglyphs to the chronology of landscape development. The second step is dating discrete events in the process of alluvial feature formation. If a terrace contains datable material, such as organic-rich buried soils, estimated dates can be imposed on the timeline of terrace formation. The age of the petroglyph can then be estimated in relation to these events. This may be only a minimum or maximum age for the petroglyph, or it may be a range of time between two dated events.

For example, imagine a canyon cliff on which petroglyphs are stranded above the current ground surface. In many such instances, the only reasonable assumption is that the petroglyphs were made when the ground surface was higher than it is today and that the petroglyph-bearing portion of the cliff would then have been within easy reach or at least accessible by ladder. Reconstructing the terrace sequence and dates of terrace formation in the canyon can indicate the last time the petroglyphs could have been created – in other words, their minimum age. In another example, imagine a petroglyph low in the landscape that is now partially or completely covered by terrace sediments. Dating the terrace would again give a minimum age for the petroglyph, because it must have been made before the terrace formed. If the terrace is 4,000 years old, the petroglyph would have to be greater than 4,000 years old.

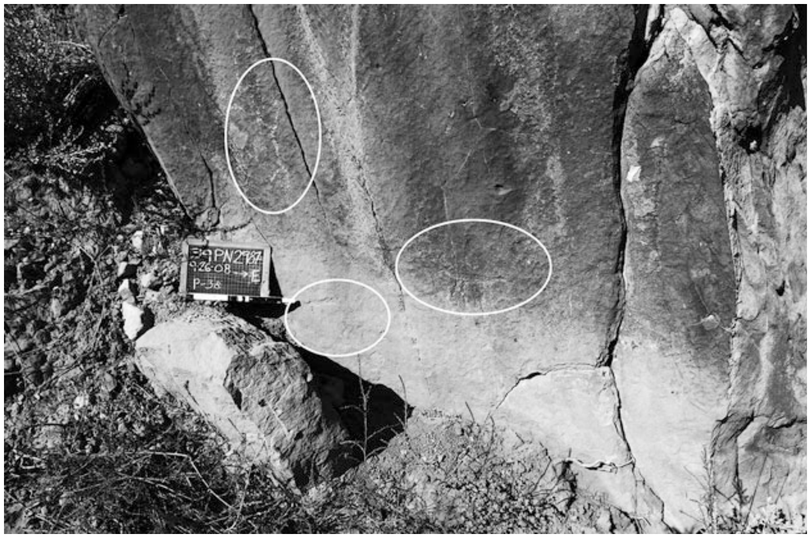
In the situation described above, petroglyphs high up on a rock face will be older than those farther down, because the terraces that provided access to the higher cliffs were removed by erosion after those petroglyphs were created. An opposite pattern would obtain, however, where sediments build up against a cliff, burying the lower petroglyphs and creating access to the higher portions of the rock face for the production of newer ones. A similar situation can occur when lateral dunes migrate along a cliff in arid areas. Petroglyphs in this situation will be covered and uncovered as dunes pass along the base of the cliff. If geomorphologists can estimate a rate of dune migration, this may provide a clue to the age of petroglyphs that show signs of having been made, then covered by dune deposits, then uncovered again by natural processes or archaeological excavation.

In formerly glaciated areas, petroglyphs incised into glacially scoured bedrock or made on glacial erratics are clearly younger in age than the glacial episode that formed or situated the surfaces on which the petroglyphs were made. Alluvial terraces formed on top of till or glacially scoured bedrock also must postdate the last glacial episode in the research area. Such terraces might cover petroglyphs made on bedrock – thus sandwiching the age of the rock art between the glacial retreat and formation of the terrace. Alternatively, such terraces might provide access to high cliffs that were out of reach just after the glacial episode but before the terrace sediments accumulated to a sufficient height to allow access for petroglyph creation on that section of the cliff face. In the former instance, the petroglyphs will be more recent than the glacial retreat that exposed the rock, but younger than the terrace that covers them. In the latter instance, the petroglyphs will postdate both the glacial episode and terrace formation. The more accurately the glaciation and terrace formation can be dated, the more securely the age of the petroglyphs can be estimated (Butzer et al., 1979, 1207–1209).

Weathering, lichens, and petroglyph dating

Though the degree of weathering on a petroglyph is an unreliable indicator of its calendar age (Dorn, 2001), comparison of weathering on petroglyphs of the same rock face or in very similar physical settings can indicate their relative ages. The apparent freshness of a petroglyph relies on three factors: (1) the degree of cortication (discussed in the following section), (2) the degree to which the indentations or incisions forming the design are rounded down by granular rock face deterioration or abrasion by agents such as animals or windborne sediments, and (3) whether or not the loose powdery rock residue created by pecking or incising the surface still adheres to the rock. The latter generally is lighter in color than the surrounding rock and thus makes the lines and shapes of the petroglyph stand out as if colored with white pigment.

Lichens vary widely in their rates of growth. Factors affecting this are species, the roughness and porosity of the rock surface, amount and angle of exposure to light, moisture, and the composition of the rock. Lichen dating has been applied to studies of alpine glaciations; however, its use in rock art dating has proved difficult because of the necessity for an independently verified calibration table and variability of growth rates in temperate zones (Jochimsen, 1973; Friedmann and Galun, 1974; Dorn, 2001, 173). The presence of lichens is no indicator of great age, as a visit to a modern cemetery will demonstrate. Nor does the absence of lichens mean a petroglyph is recent. Many rock surfaces do not provide a suitable habitat for lichens. Lichens colonizing a surface may be inadvertently removed by people tracing the petroglyph with their fingers. Further, petroglyphs may have been periodically renewed by removing moss or lichens or by recarving them along the original lines. Despite these limitations,



Petroglyphs, Figure 1 Petroglyph panel on sandstone, Black Hills, South Dakota, with pecked petroglyphs circled. The petroglyph at the *left* shows up better because the pecked lines cut through a darker surface cortex. The petroglyph at the *right* has reacquired its dark mineral and clay cortex so that it no longer stands out from the surrounding rock. The petroglyphs at the *bottom* were recently exposed by erosion of soil deposits from the base of the rock; here, neither the petroglyphs nor the surrounding rock has formed a cortex.

slow-growing lichen species may be reliable indicators of the relative ages of petroglyphs on a single rock surface or in a limited geographic area. In that instance, those petroglyphs that are partly or wholly obscured by lichens are older than those with no visible lichens on them. To make such comparisons, the rock art researcher will need to be familiar with the relative growth rates of various species in the area. Radiocarbon dating the lichen on a rock surface is not likely to succeed because the organisms comprising the lichen colony are still living.

Microstratigraphy and petroglyph dating

When two petroglyphs occur on the same rock surface, but one is corticated (covered by a dark crust or rind formed by ferromanganese compounds in a cemented skin of clay minerals) and the other uncorticated, the latter is obviously younger than the former. One has been exposed to the air long enough for the rock surface to reacquire the crust of oxidized iron or manganese that was removed when the petroglyph was created, while the other has been exposed to the air for a shorter time (Figure 1). Unfortunately, the rates at which these mineral rinds form vary widely according to the mineral content and porosity of the parent rock, as well as the climate regime in operation at the time of, and following, creation of the petroglyph (Butzer et al., 1979, 1202; Dorn, 2001). Comparing cortication rates on a single rock art panel thus may be helpful in determining the relative ages of elements on it – assuming that all carvings receive roughly the same amount of moisture and sunlight – but less reliable in estimating calendar ages for the rock art. Researchers have sought to expand the usefulness of this method of petroglyph dating by quantifying rates of formation for the mineral crusts or cortexes (Dorn and Whitley, 1984; Nobbs and Dorn, 1988; Dorn, 1983; Francis et al., 1993; Whitley and Annegarn, 1994). Referred to as cation-ratio dating, this method measures the ratios of cations of various elements such as potassium, calcium, and titanium in small samples of the mineral crust to quantify the degree of recortication since the petroglyph was first cut into the rock surface. Large numbers of these ratios are then combined to form a cation-ratio curve that represents the change in ratios over time. These rates of change must be calibrated to rock surfaces in the same region for which ages have been determined through some independent means (Dorn, 1989). Calibration has proved difficult, and the method has further been limited by variability in cation ratios across individual layers of encrustation (Watchman, 2000; Smith et al., 2009; Brook et al., 2011).

Deposits of calcite or silica can also form part of the microstratigraphy of a rock art panel. In limestones and dolomites, calcite compounds dissolve from the rock and redeposit as translucent skins. As these calcite deposits build up, the rock art they cover becomes less distinct. In equable climates, these deposits may build up as regular, uniform layers, with each layer representing a single year's wet season. In places subject to less regular moisture regimes, the layers may form only in wet years or only during wet climatic episodes, and their thickness may vary year to year and with the duration of climatic episodes, similar to tree rings. Although not widely used, calcium carbonate and calcium oxalate skins can be dated by radiocarbon or uranium-series methods to give a minimum age for the petroglyphs they cover (Smith and Turner, 1975;

Dragovich, 1986; Watchman, 2000; Bednarik, 2002; Aubert et al., 2007). Petroglyphs in granite, sandstone, diabase, gneiss, and mica schists can similarly build up deposits of silica. This process is the beginning of cortication and involves iron and manganese compounds cemented by clay minerals to form a transparent skin on the rock surface (Butzer et al., 1979, 1211, n. 6).

Since moisture is a factor in the formation of silicate and calcite deposits, these microstrata, as seen in a thin section of the rock surface, may serve as climate indicators. Generally speaking, dry conditions favor the formation of orange, manganese-poor crusts, and wet conditions favor black, manganese-rich crusts (Liu and Dorn 1996). In regions with pronounced climate fluctuations, the pattern of climate shifts thus revealed may aid in pinning the microstrata and the rock art they superpose to calendar dates (Liu et al., 2000; Zhou et al., 2000).

While researchers have successfully applied radiocarbon dating to pigments, this method is not yet reliable for petroglyphs. Since making a petroglyph does not involve organic carbon compounds, such dates would instead measure the age of a subsequent event, such as formation of a mineral crust over the petroglyph (Chippendale and Nash 2004b, 5). Experiments in dating microscopic organics, such as bacteria, trapped under a calcite or silica skin have thus far proved contradictory and not replicable (Dorn, 1996, 2001; Beck et al., 1998; Dragovich, 2000; Watchman, 2000). Two problems have hindered this method: current radiocarbon dating methods require much larger samples than the very minute amounts of organic material trapped between mineral skins, and formation of such organics does not reliably represent a single event, but may compound periods of bacterial growth separated by hundreds or thousands of years (Beck et al., 1998; Dragovich, 2000; Dorn, 2001; Brook et al., 2011). Better results were obtained at Rhino Cave in the Kalahari Desert, where mineral crusts and interbedded organics formed much thicker layers (Brook et al., 2011). Besides obtaining a consistent column of radiocarbon age estimates, Brook et al. (2011) argue that a shift from phosphate to carbonate and then to silica between the base and surface of the coating indicates a gradual trend toward a drier climate in the late Holocene.

Paleontology, ecology, and petroglyph dating

Convincing depictions of extinct or locally extinct species have long been considered a clue to the age of petroglyphs. The great cave art traditions of the European Upper Paleolithic are the best known example of dating ancient art by the species it depicts. Other regions also contain rock art representing Middle and Late Pleistocene fauna (Butzer et al., 1979, 1206). While this method of age estimation seems straightforward, it has its limits. First, it can indicate only a minimum age for the rock art, which presumably was made before the animal went extinct. Second, the human ability to carry information through time and across space may have allowed an extinct species to be pictured in places outside its actual habitat or long after it disappeared locally or altogether. A third limit to using this method is the ability of the researcher to recognize what animal the ancient artist intended, if any. All cultures seem to invoke notions of mythic creatures that combine features of various species, such as the dragon of Asian and European tradition. Fossils, vision experiences, and the human imagination are capable of suggesting the appearance and behavior of living things that do not exist in the real world. And even if an actual living species was intended, researchers may not understand the reference. For example, two petroglyphs on a petroglyph panel in Utah have recently been put forth as depictions of Columbian mammoths (Malotki and Wallace, 2011). The petroglyphs actually match more closely the form of the tobacco moth than that of a mammoth, however. The purported mammoth trunk may be the proboscis of the moth, and the "tusks" may be the moth's antennae. Although one is a huge, and the other a tiny, animal, nothing on the panel provides scale.

At the same time, a rock art style that contains depictions of a wide variety of animals should include species consistent with the age proposed for it. Pleistocene-aged petroglyphs can be expected to include Pleistocene species. The absence of extinct Pleistocene species where modern species are depicted argues for a post-Pleistocene age for the body of rock art.

Similarly, the presence of introduced or domesticated species also limits the potential age of petroglyphs. In Native American rock art, depictions of horses date petroglyphs to the post-Columbian era. In South Africa, petroglyphs of domesticated sheep and cattle are also known to date to the last few centuries (Butzer et al., 1979, 1207). In Australia, depictions of horses, pigs, cattle, and water buffalo postdate the mid-nineteenth century (Chippindale and Taçon 1998, 95).

To the extent that species depicted in rock art indicate a specific environment, petroglyphs can be tied to paleoecological sequences derived from other data. In northern Australia's Arnhem Land, pictures of riverine and marshland species mark the progress of rising sea levels during the postglacial era, and they indicate local shifts from saltwater estuarine to freshwater riverine species (Taçon 1988; Chaloupka, 1993; Chippindale and Taçon, 1998). In Scandinavia, the distribution of petroglyphs in coastal areas has been correlated to shifting postglacial sea levels (Helskog, 1999).

Geoarchaeology of petroglyph preservation

Petroglyphs present preservation issues different from those of other historic and archaeological sites. On the positive side, the difficulty of moving petroglyphs means they are more likely than other kinds of archaeological remains to retain their physical context (Chippendale and Nash 2004b). Petroglyphs are so embedded in their landscape that removing them takes extraordinary effort. On the negative side, the surrounding environment can be subject to extensive damage. For example, the city of Albuquerque, New Mexico, has expanded to the edges of, and around, Petroglyph National Park. In other areas, the exposed and visible nature of petroglyphs has attracted people to sites, with concomitant increase in graffiti and unintentional damage to the rock art. The open, exposed nature of petroglyphs also makes them vulnerable to various forms of physical and chemical alteration that would not occur to buried archaeological materials. Because petroglyphs are incorporated into a rock surface, they are subject to the same physical and chemical deterioration as the rock itself.

Any attempt to mitigate damage to petroglyphs requires an assessment of their physical setting at various scales, from their macroenvironment to the mineralogy of the rock surface (Watchman, 1992; Thorn and Dean, 1995; Loubser, 2001). Physical damage to petroglyphs can operate on the scale of complete loss of the rock surface on which the petroglyphs occur to damage on the microscopic level, including everything in between. Large-scale damage to rock art surfaces occurs in three main ways: seismic activity, cliff and rockshelter collapse, and mass wasting of hillslopes resulting in displacement or burial of rock surfaces and monoliths. Blocks of fallen cliff frequently migrate downslope. This can result in petroglyphs being buried on the downside of the block or subsequently buried by sediment piling up against the rock. The openings to caves containing rock art can be sealed by large-scale sediment movement.

Cliffs collapse for two reasons. First, if the bedrock has a blocky structure, sediment and water can build up in fissures. Ongoing freeze-thaw cycles then result in expansion of fissures and calving off of blocks of the cliff. Climate patterns affect this, in that wet years and wet climate periods tend to encourage this process. The second way cliffs fail is when resistant, relatively heavy strata overlie weak strata. The lower strata erode more rapidly than the higher ones, leading to undermining of cliffs. This creates rockshelters that may attract human habitation and petroglyph production. A cave or rockshelter formed in this way can eventually collapse under its own weight as the underlying strata are further eroded.

On a smaller scale, petroglyphs can be damaged or lost if a small portion of a cliff surface breaks off. Sometimes this involves the lower edge of a cliff or a protruding aspect of the rock. More commonly, the underlying rock remains intact, but the outer layer spalls off, taking part or all of a petroglyph with it. The extent and timing of this process depends on the underlying rock type, the nature of any mineral rind that forms on the surface of the cliff, rock porosity, and exposure to freeze-thaw and to wildfires. A heavy, nonporous mineral crust on the outside of a relatively porous cliff allows the buildup of moisture behind the crust. As this moisture expands and freezes, it exerts pressure on the crust, causing it to spall or flake.

Soft and grainy rock is subject to erosion at the microscopic level. Sandstones and quartzites were often selected for petroglyphs. These rocks vary widely in grain sizes, angularity of grains, and in the hardness of the matrix (often silica) that cements the grains together. Some sandstones are so soft that just brushing against them removes the loosely cemented particles. On the other end of the spectrum, some quartzites and basalts are so hard that one must apply considerable force to chip away a small portion of rock.

Geology and rock art interpretation

Archaeologists are increasingly recognizing the importance of physical setting in attempts to understand the meaning and significance of ancient rock art (e.g., Deacon, 1988; Taçon, 1990; Bradley, 1997; Hartley and Vawser, 1998; Helskog, 1999; Arsenault, 2004a, b; Chippindale and Nash 2004a, b; Hyder, 2004; Taçon, 2010; Norder, 2012). Geological features may have been imbued with special meaning if they were unusual; visually striking; sources of tool stone, pigments, or other scarce resources; or evocative of faces, animals, or shelters. Such places are likely to contain petroglyphs that reflect their importance in indigenous geographies (Arsenault, 2004b; Flood, 2004, 194–195). Unique geological features, such as "drum rocks" (hollow rocks that produce drumlike sounds when struck), rocks with echoes, and rocks that align to astronomical cycles – such as winter solstice or seasonal appearances of particular stars – and high and low points in the landscape are likely to be important landmarks in indigenous geographies (Ouzman, 2001; Goldhahn, 2002; Rainbird, 2002; Loendorf, 2004; Waller and Arsenault, 2008; Lahelma, 2010; Hultman, 2010). Passes and other places that facilitate travel also attracted rock art (Wallace and Holmlund, 1986, 138–141; Hedges and Hamann, 1992; Bradley, 1997, 214). Placement of petroglyphs and other rock art is not simply a matter of finding a flat, smooth surface, as any rock art researcher can attest. Sometimes a place of purported supernatural power will contain numerous petroglyphs – even in locations that are rough, hard to access, hard to see, or already covered with rock art – while other wide open cliffs will contain no rock art at all. Some rock art was meant to be seen, and some was meant to be hidden. Sometimes the sounds of ceremonies, including the sounds produced by making or renewing petroglyphs, were meant to be within earshot of a village or ceremonial ground. The scale at which archaeologists consider environment will vary according to the data available and the research questions. In analyzing a body of petroglyphs, "environment" can mean the position of the rock art within a site, the position of the site within a local setting, or the local setting within a regional environment (Butzer, 1982, 38).

A particular contribution of geoarchaeology to this aspect of rock art research is its methods of reconstructing past landscapes and geological features. As noted above, in alluvial settings, such as canyons, surface elevations may have changed dramatically since the petroglyphs were made, and so the archaeologist needs an accurate picture of the place at the time the rock art was produced. In the same way, a sense of the fluvial and biological settings is also important to such contextual studies. Was the area treeless when the petroglyphs were carved, or did brush and trees hide the rock surface from sight? Did water run across the rock after a storm or during the spring thaw? Were there seeps and springs along geological contacts that no longer flow today? Has a rockshelter collapsed, hiding rock art panels behind the resulting rubble cone? Has the hillslope below a panel eroded to the point of making the petroglyphs impossible to reach today? Has movement of terrace or dune deposits completely obscured some rock art panels? Have some panels been lost to mass wasting or micro-erosion? These possibilities need to be addressed in any interpretations that rest on distributional data, because the current dispersal pattern of panels may be quite different from that of ancient times.

Summary

Geoarchaeology contributes to petroglyph studies by providing contextual information important to estimating the age of the rock art and sometimes its meaning, as well. A petroglyph site can be said to have two environmental settings: the current one and the one in place when the petroglyphs were made. These may be the same or distinctly different, depending on the age of the petroglyphs and the rate at which natural or human forces have modified the landscape. The manner in which ancient peoples placed petroglyphs within their effective environment reflects their particular cultural beliefs about landscape. Research into such ancient geographies obviously relies on the methods of geomorphology to reconstruct an accurate picture of the past form of the landscape, stream courses, passes, and the distribution of important natural resources. Each site also has its own distinctive setting, which again is best approached through reconstruction of former landscapes. On an even closer level, the rock surface itself is a microenvironment. The exposed rock into which petroglyphs were engraved, pounded, or ground is a complex interface between the parent rock, water, air, microorganisms, lichens, and the forces of wind, sunlight, precipitation, and fluctuating temperatures. Various methods have been developed for obtaining age estimates from the microscopic stratigraphy of petroglyphs.

PETROGRAPHY

Ian K. Whitbread
School of Archaeology and Ancient History, University of Leicester, Leicester, UK

Definition

Petrography. The systematic description of geological materials, their composition, and organization, in hand specimens and thin sections.

Petrology. Study of the origin, structure, and composition of rocks.

Ceramic petrology. The interpretation of raw materials selection, ceramic technology, and provenance determination based upon the results of petrographic investigations.

Introduction

Geological materials such as the various types of igneous, metamorphic, and sedimentary rocks are diverse in both composition and structure. These properties have been distinguished and repeatedly exploited by people in the past based on their own culturally specific interpretations of the natural world. Petrography includes key analytical techniques used in modern science for identifying and characterizing rocks and sediments based on their mineralogical compositions and structures. It has many archaeological applications as diverse as regional landscape studies, site formation processes, raw materials exploitation, building construction, and the fabrication of artifacts such as stone tools and pottery.

Petrography incorporates two analytical procedures based on the nature of the analyzed surface and the instrumentation used. *Hand specimen analysis* of minerals and rocks requires no more than a freshly broken surface and is accomplished using the unaided eye (macroscopic observation), a hand lens (approximately 10×), or stereomicroscope (typically 10–200×) to improve visibility. *Thin section analysis* requires the laboratory preparation of samples for study under a transmitted light polarizing microscope (approximately 20–600×) enabling much greater accuracy and precision in determining mineral compositions and examining microstructures.

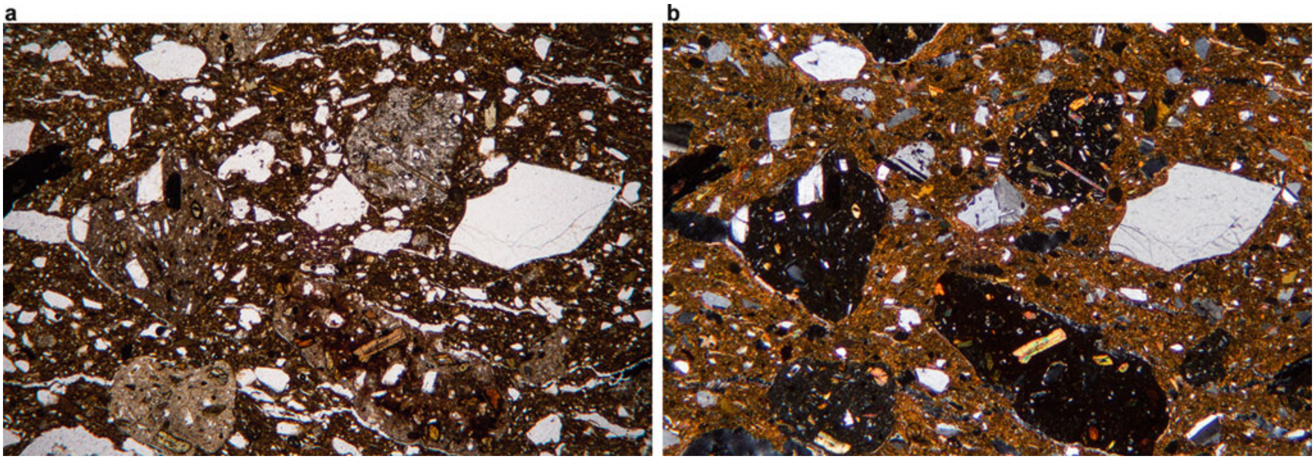
Petrography is a mature technique that bridges the divide between field and laboratory studies. It is often used in conjunction with instrumentally more advanced methods of materials analysis, such as chemical analysis (e.g., NAA, ICP-MS) and scanning electron microscopy (SEM), and it continues to be a widely applicable and cost-effective technique, most importantly because it addresses visually observable properties at both macro- and microscopic scales. Indeed, at these scales, compositional and structural markers, such as lustrous inclusions and grain size, may be recognizable with the unaided eye or through touch and therefore potentially noticeable or intended by people in the past. Another advantage of petrography is that the rocks and minerals identified can be further explored through geological literature and maps for the region under study, both of which are significant aids in studying raw material procurement patterns and the provenance of artifacts. Basic petrographic skills can be learned relatively easily by nonspecialists, but considerable experience is necessary when researching complex geological materials or difficult archaeological problems.

Hand specimen petrography

Hand specimens are routinely studied during fieldwork for rapid on-site characterization of rocks and minerals. Rocks are described on the basis of their composition (types and quantities of constituents), texture (overall appearance in terms of the size, shape, sorting, intergranular relationships, and orientations), and color. Minerals within a rock are usually identified by means of their form and habit, cleavage and fracture, twinning, hardness, specific gravity, color, streak, and luster (Dietrich and Skinner, 1979). Hand specimen studies may be the only means of analysis available if samples cannot be removed from their location of origin or destructively sampled, as in the examination of architectural components and precious objects. Where samples can be taken for further analysis, the selection procedure often starts by taking account of variation identified in hand specimen study. This procedure is equally valuable in reverse. Where results from the laboratory study of a few thin sections can be expressed in terms of characteristic macroscopic features, then hand specimen techniques can be used to identify these materials within regional landscapes or the substantial assemblages of artifacts found through excavation.

Thin section petrography

Petrography usually refers to the microscopic analysis of thin sections. Microscopic analysis of rock thin sections



Petrography, Figure 1 Thin section of Neolithic coarse ware (sample 73) from the Cave of Euripides, Salamis, Greece. The fabric contains volcanic inclusions consistent with a source on the neighboring island of Aegina (Whitbread and Mari, 2014). Width of the field = 4.6 mm, (**a**) plane-polarized light, (**b**) crossed-polarized light.

was pioneered by Henry Clifton Sorby in 1849, followed shortly by its first application to archaeological material with Sorby's 1869 attribution of rocks found in excavations at Frilford, Oxfordshire, United Kingdom, to volcanic sources at Niedermendig in the Eifel Mountains, Germany (Worley, 2009). From this beginning, petrography has been widely applied within geoarchaeology, principally in the study of worked stone, pottery, and soils, but also for specialized materials such as plaster (Goren and Goldberg, 1991; Karkanas, 2007), mortar (Hughes and Cuthbert, 2000; Pavía and Caro, 2008), and concrete (St John et al., 1998; Oleson et al., 2004; Walsh, 2007; Vola et al., 2011).

To make a thin section of soft materials, such as sediments, soils, or poorly fired pottery, they first need to be consolidated with an impregnating medium, such as an epoxy resin. Thin sections are then prepared by grinding a flat surface on the sample and bonding it to a glass slide (measuring either 75 × 25 mm or 46× 27 mm). The mounted sample is then ground to a standard thickness, usually 0.03 mm, at which point it either receives a concluding fine polish or is protected by attachment of a glass coverslip (Nesse, 2004). At this thickness (30 µm), many common minerals are translucent and can be identified by optical effects when light is refracted through them.

Thin sections must be studied using a polarizing (or petrological) microscope (Kile, 2003). The thin section is placed on a rotating stage above the microscope light source. Light reaching the thin section is polarized by a filter (the polarizer) beneath the stage so that it vibrates in one direction only. This light is refracted as it passes through most minerals in the thin section. A second polarizing filter is situated above the sample, between the microscope objective lens and eyepiece. This filter (the analyzer) is set at 90° to the polarizing filter below the stage but it can be moved in and out of the light path. When the analyzer is inserted into the light path with no sample on the stage, it blocks out all light from the polarizer so that the observer sees only darkness. With a mineral sample on the stage, transmitted light is refracted, and in most cases, the vibration direction is split and twisted slightly (double refraction) so that the analyzer does not cancel out all the light.

Examination of the thin section takes place under two types of illumination, plane-polarized light (analyzer removed) (Figure 1a) and crossed-polarized light (analyzer inserted) (Figure 1b). Minerals in the thin section can be identified from their optical properties, some of which need to be determined by using the rotating stage to align minerals with the polarizing filters. The properties studied in plane-polarized light include color and changes in color on rotation (pleochroism), form and habit, cleavage, and refractive index. Most rock-forming minerals are optically anisotropic in that they have different optical properties in different orientations of the mineral. Under crossed polarizers, the property of double refraction in these minerals interferes with the light path to cause a spectrum of artificially produced colors (interference colors). The maximum interference colors and angles at which they are extinguished on sample rotation are distinctive properties for mineral identification.

Lithic petrography

The geological materials most suited to petrographic analysis are coarse-grained rocks, especially those with discrete distribution patterns within the landscape so that an analyzed sample can be traced to its likely area of origin. For example, sedimentary rocks such as sandstone or limestone are often employed as building stone because they are widely available and easily worked. Petrography can be used to identify the selective use of particular types of stone for construction, but in the case of limestone and sandstone, it may be difficult to track examined samples to specific sedimentary deposits within a landscape where similar material is the dominant rock. Even where petrographically distinctive sedimentary rocks can be isolated, the distribution of sedimentary formations is usually extensive, and this makes it challenging to identify a specific locality from which the material was quarried. Materials such as marble and limestone are now sourced more effectively using chemical techniques if visual or structural peculiarities do not identify them unequivocally (see Herz and Waelkens, 1988; Olson, 2011). By contrast, igneous rocks often occur as discrete outcrops or locations in the terrain and are therefore more amenable to provenance determination. As a further example, during the Neolithic period in Britain, ground stone axes were produced in considerable numbers from various discrete igneous and related sources and transported across the country through extensive exchange networks. A major program of petrographic analysis has identified many of these sources and attributed individual axes to their respective origins throughout the country (Clough and Woolley, 1985). Extensive sampling has produced a substantial data set and numerous distribution patterns, but petrography on its own cannot address the many archaeological questions concerning how and why stone axes were produced and distributed. This study demonstrates very clearly the role of petrography as an analytical tool, but also the necessary interdisciplinary nature of geoarchaeological research in order to achieve archaeologically meaningful interpretations.

Petrography has been particularly effective in studying millstones (King, 1986; Heldal and Meyer, 2011; Santi et al., 2013), although in this case, analytical programs have tended to focus on specific questions, products, and sources. Well-consolidated, coarse-grained rocks are best suited for grinding stones, but vesicular volcanic rock was particularly sought after as the round voids (vesicles) which developed in the rock from trapped gases create natural cutting edges. The various volcanic sources in the Mediterranean region and the ease with which heavy goods could be transported by sea led to an extensive Roman trade in millstones made from volcanic rock (Williams-Thorpe, 1988).

Ceramic petrography

The most common use of petrography in archaeology is for studying ancient pottery, an application that was pioneered in the 1930s by Anna O. Shepard and Frederick R. Matson (Thompson, 1991). It is most effective with coarse fabrics, in which rock and mineral inclusions can be detected with the naked eye and under the microscope. Fine-grained pottery is often devoid of inclusions and therefore more appropriately studied using methods of chemical analysis (e.g., NAA). In association with compositional studies, ceramic petrography is an effective tool for studying both ancient pottery technology and trade.

In technological studies, compositional and textural information is used to identify potential raw materials and the various ways in which they may have been processed during pottery production. Unlike lithic tool production, in which the stone is shaped but otherwise remains largely unchanged, pottery is a synthetic product of human interaction with clay-based materials. Potters may combine different clays to achieve a preferred paste mixture with which to make a pot. Depending on the clay properties, the size, and the function of a vessel, they may refine their raw materials by removing coarse inclusions (using sieving or levigation) or adding additional nonplastic inclusions (temper), such as sand, to achieve a more workable and effective clay body. The choices made by potters in selecting and working their materials are in many cases defined by their social environment and learning networks, such that differences in technology may be used to identify social boundaries. Petrography is particularly effective in studying these processes because it can determine both the composition and micromorphology of pottery fabrics. It can also compare this information with the results of experimental replication tests (Whitbread, 1995).

Imported pottery can be identified by the presence of nonlocal rocks and minerals in a pottery fabric compared with the geology surrounding the site from which it was excavated. Ceramic fabric refers to the constituent properties of a fired ware, including aspects of its matrix, inclusions, voids, internal structures and organization, and color, but not surface coatings and treatments (Rye, 1981: 145). Although geological literature and maps provide a rapid means of identifying potential source areas, direct comparison with rock, clay, and pottery from the field is also necessary to account for the extent to which potters might have processed their materials. In this respect, direct comparison with pottery fabrics of known origin (control groups), ideally based on material from kiln sites, is especially helpful in distinguishing the products of different potters working in geologically similar areas. Shepard's (1965) study of Rio Grande glaze-paint pottery is a classic example of the basic principles that underlie the application of petrography in studying ancient pottery exchange networks. By comparing the compositions of inclusions in pottery from several archaeological sites along the Rio Grande river, she mapped the distribution of pottery with respect to the occurrence of different geological sources. Shepard was able to propose changes over time in the distribution of locally produced and imported pottery at the various sites.

Perhaps the greatest archaeological impact of ceramic petrography has been in demonstrating the early movement of pottery and particularly the movement of coarse utilitarian pottery. Prior to the application of petrographic studies to pottery, there had been a general assumption among archaeologists that fine decorated pottery was distributed as prestige items but that coarse-grained pottery, generally lacking in decoration or purely utilitarian in function, would have been produced locally.

Numerous studies have shown the fallacy of this assumption (e.g., Quinn, 2009). One of the earliest of these is Peacock's (1969) petrographic analysis of Neolithic "Hembury" ware, distributed across southwestern and southern Britain, which showed that the pottery matched gabbro outcrops on the Lizard peninsula of Cornwall. This finding demonstrated that the pottery was imported rather than locally made when found beyond the extent of the gabbro. Moreover, its distribution roughly coincides with that of Cornish stone axes, possibly resulting from similar exchange networks.

As a technique, ceramic petrography has borrowed heavily from the geological sciences, especially sedimentary petrography, but there have also been a number of attempts to develop and improve its application to archaeological problems. Many properties of pottery fabrics differ from those of sediments owing to the large component of clay matrix and the effects of anthropogenic actions, such as firing of the clay to make pottery. One way to address this issue has been to combine the descriptive methodology of sedimentary petrography with that of soil micromorphology and pottery-specific attributes to provide a more comprehensive system for identifying and describing the micromorphological features encountered in ceramic thin sections (Whitbread, 1995). Ceramic petrography is generally applied as a semiquantitative technique with the relative frequencies of constituents estimated with the aid of comparator charts. Though time-consuming, quantification can produce valuable results, most notably with the technique of point counting in which the area of a thin section is systematically sampled to either count the occurrence of different constituents (Miksa and Heidke, 2001) or to select grains which are measured for size (Stoltman, 1989). Digital image analysis has occasionally been undertaken, but the complex arrangements of polycrystalline grains and voids found in many ceramic fabrics poses a significant challenge to its routine application. Microfossils such as foraminifera and ostracods have been used in aiding the identification of clay sources used for ceramics. In some cases, these fossils are specific to particular chronological units within the sedimentary stratigraphy, and in such situations, the problem posed by widely distributed sedimentary rocks can be reduced by focusing on potential sources from stratigraphic units that lie within the date range represented by the fossil traces (Quinn, 2008).

Anthropogenic materials other than pottery are also suitable for petrographic analysis. This includes the study of mortars, plasters, and cements in which petrographic analysis plays a valuable role in identifying constituents and their interaction during formation of the material (Karkanas, 2007).

Soil micromorphology

Soil micromorphology is a technique for analyzing soils and related sediments that incorporates a significant petrographic component both in hand specimens and thin sections. It is widely used to study natural processes through soil composition and structure, but in archaeological contexts it is especially effective for examining the nature and origin of anthropogenic deposits. An example is the study of "dark earth," apparently homogeneous deposits of dark-colored soil commonly found in urban occupation areas of European medieval sites. Soil micromorphology of such deposits in London, dated by coins to the third to fourth centuries AD, showed that they are composed of decayed materials from timber-framed buildings, mud huts, and occupational refuse mixed through biological activity including rooting plants, burrowing animals, and garden cultivation. They are believed to be a result of intensive occupation by a population that relied heavily on the use of timber and mud building materials (Courty et al., 1989: 261). Soils differ from rocks in many morphological and compositional properties, such as void structures and the presence of humic materials. As a consequence, the technique has developed specialized methods of sampling, thin section preparation, and analysis.

Summary

Petrography is a widely applied and versatile technique for the mineralogical study of rocks and sediments. It complements most alternative methods of materials analysis but is most powerful when undertaken by researchers experienced in the technique and its application to specific archaeological materials.

PIGMENTS

Ian Watts
Athens, Greece

Synonyms

Earth pigments; Hematite; Iron oxides; Ochre; Paints

Definition

Pigments are typically insoluble colorants comprising inorganic compounds; they are distinguished from soluble dyes made from organic compounds. Earth pigments may be any soil, clay, rock, or mineral producing a colored powder with staining power. Informal criteria include the ease with which a material can be powdered, whether the powder is relatively free of gritty impurities, how well it adheres to or stains a surface, and the particular color.

Introduction

By far the most widely reported earth pigments, ethnographically, historically, and archaeologically, are materials enriched in iron oxides (sensu lato), providing colors ranging from pale yellow to dark red, extending to orange and brown (iron oxides providing a black streak, notably magnetite, rarely served as pigments). Yellower forms are commonly called "yellow ochre" (Greek ώχρα – "pale yellow"), while the redder forms are called "red ochre" or "hematite" (generally applied to relatively pure, massive or macrocrystalline expressions of this mineral). The concentration of iron oxides typically results from ubiquitous chemical weathering processes (reductive dissolution followed by migration of Fe^{II} and oxidative reprecipitation as Fe^{III}, with or without hydration). In Paleolithic archaeology, the only other prominent pigment is black manganese (but see Heyes et al., 2016); other forms (e.g., white clay, chalk, graphite, ilmenite) are rare. In the Neolithic and with the formation of early states, a wider range of materials began to be used, improving the color qualities of the existing palette (e.g., mercury and arsenic sulfides [cinnabar, realgar, and orpiment] in the red/orange/yellow range) and expanding the palette to green (primarily "green earths") and blue (primarily copper compounds). This entry focuses on the iron oxide pigments; research on the expanded range of post-Neolithic pigments has largely been restricted to paints and vitreous materials (glass and glazes).

Currently, the earliest secure evidence for pigment use is scraped specularite (a dark, glittery form of hematite), together with a redder form of hematite, from a ~500 ka context at Kathu Pan, Northern Cape, South Africa (Watts et al., 2015). The associated Fauresmith industry is considered transitional between the Acheulean and the Middle Stone Age (MSA), spanning the period from ~600 to ~300 ka. At Kathu Pan and other pigment-associated Fauresmith contexts in the region, pigments are absent in large, underlying Acheulean assemblages, suggesting evidence of absence. At the younger end of this time frame, there is circumstantial evidence for the transport of these pigments over considerable distances (*ibid*.). By ~300 ka, red pigments are also documented in India and possibly in Europe (*ibid*. with refs.), implying a behavioral innovation shared by several hominine lineages. This correlates with early evidence for the establishment of campsites. By ~170 ka, red pigments are ubiquitous to southern African MSA rock shelter occupations (Watts, 2014). This regular and widespread use has been interpreted as the earliest evidence for a symbolic tradition, radiating with the Upper Pleistocene dispersal of Homo sapiens (Watts, 2009). Middle Pleistocene occurrences remain restricted to the pigments themselves, but the African earlier Upper Pleistocene (128–74 ka) provides evidence of paint manufacture (Henshilwood et al., 2011), and a range of objects and contexts (shell beads, bone tools, geometric engravings, and burials [Levant]) are implicated in pigment use (d'Errico and Stringer, 2011).

In Europe, after a few occurrences between ~240 and 200 ka, there follows a prolonged find gap, and occurrences remain rare until ~60 ka. Thereafter, while falling short of the ubiquity seen in southern Africa, Neanderthal use of red ochre and black manganese is widely documented. From ~50 ka, some Neanderthal occurrences are no less suggestive of symbolic culture than earlier African counterparts (Zilhão et al., 2010). The earliest dated rock paintings are contemporaneous in Europe and SE Asia, at ~40 ka (Pike et al., 2012; Aubert et al., 2014). In the European Upper Paleolithic, in addition to rock painting, red ochre is recurrently found in mortuary contexts, and a wide variety of artifacts bear ochre residues. Neolithic usage extends to pottery decoration and wall murals. The Neolithic also sees the first use of cinnabar, a mercury sulfide providing a vermillion pigment (Gajić-Kvaščev et al., 2012). Use of "green earth" as a pigment is largely restricted to literate societies, but it is reported among the stratified hunter-gatherers of the American northwest coast and in Argentine rock painting (Eastaugh et al., 2004, 175). Copper-based synthetic blue pigments first appear in Egypt in the third millennium BC (Riederer, 1997), with a similar development in China around 500 BC (Berke, 2002). Blue glass and glazes, using cobalt compounds, were developed in Mesopotamia and Egypt around 1600 BC (Rehren, 2014; Rehren and Freestone, 2015 with refs.).

Foundational research questions are largely epistemological. Given that typical natural formation processes are ongoing nearly everywhere, when can a pigmentaceous material be considered artifactual (Watts, 2010, 395 with refs.)? To what extent may taphonomic processes have altered the colors of archaeological pigments (Wadley, 2010a)? What warrants an interpretation as pigment rather than for some purpose where color is irrelevant or of secondary importance (Wadley et al., 2009; Watts, 2010)?

Most research concerns procurement, processing, and use. Issues that have received attention are the discrimination of different use-wear traces (Salomon, 2009; Hodgskiss, 2010; Rifkin, 2012; Hodgskiss, 2013); identification of past selection criteria (Watts, 2010); provenancing (e.g., Eiselt et al., 2011; MacDonald et al., 2011); incidental alteration of yellow ochre to red ochre (Wadley, 2010a); deliberate alteration of yellow ochre to red ochre (Salomon et al., 2012); pigment preparation (Wadley, 2010b; Henshilwood et al., 2011); and identification of paint constituents, i.e., pigments and binders/fillers (Rowe, 2001; Jezequel et al., 2011 with refs.; this field overlaps with biochemistry and rock art conservation). Several of these research topics have contributed to a *chaîne opératoire* approach to Paleolithic art (Menu, 2009). Related research has investigated some non-pigment uses (e.g., Audouin and Plisson, 1982; Lombard, 2007; Wadley et al., 2009; Rifkin, 2011; Rifkin et al., 2015).

Evolutionary questions include: What selection pressures motivated this novel behavior, and should it be considered a costly or relatively cheap form of signaling (Power, 2009; Kuhn, 2014; Watts et al., 2015)? Under what conditions might pigment use be considered symbolic (Knight et al., 1995; Kuhn and Stiner, 2007; Pettitt, 2011; Mithen, 2014; Watts, 2015)? How are commonalities and differences in pigment records between hominine lineages to be interpreted (e.g., d'Errico, 2008; Power et al., 2013; Dayet et al., 2014; Watts, 2014)? What can the technology of use tell us about cognitive abilities (Wadley et al., 2009; Henshilwood et al., 2011; Hodgskiss, 2014)?

General characterization

Cornell and Schwertmann (2003) provide an overview of the properties of iron oxides (oxides, hydroxides, and oxide-hydroxides). The principal oxide of interest is hematite (α-Fe_2O_3), which produces a red streak when rubbed across a streak plate to produce a powder. The oxide-hydroxides and hydroxides, with the ligands O^{2-} or OH^- bonded to the Fe^{III+}, comprise a large group, including goethite (α-FeOOH), which produces a yellow streak; lepidocrocite (γ-FeOOH), which produces an orange streak; and ferrihydrite ($Fe_5HO_8.4H_2O$), which produces a red-brown streak. Among these, goethite is probably the most common pigment. Color may be influenced by crystal size and admixtures of iron oxides with or without other chromophores (e.g., manganese). Relatively small amounts of hematite can mask goethite's streak. Elias et al. (2006) evaluate how phase state and accessory minerals influence color.

The hydroxides are transformed to oxides by heating at relatively low temperatures, resulting in dehydration or dehydroxylation, with streaks becoming redder. This may occur incidentally through proximity to hearths or natural fires (Watts, 2010; Wadley, 2010a), or deliberately, with the goal of obtaining a redder pigment (Salomon et al., 2012).

In ochreous admixtures, the most common accessory minerals are phyllosilicates (clay and mica minerals) and framework silicates (quartz), followed by carbonates (e.g., dolomite) and sulfates (e.g., gypsum). The scale at which chemical weathering occurs ranges from cortical surfaces of long exposed nodules, along faults and joints, to the formation of ferruginous lenses and concretions to industrially exploitable ore bodies (frequently involving supergene enrichment, which is a concentration of mineral formation at depth as meteoric water entrains ions lower within an ore body). Almost any sedimentary rock and several igneous rocks (e.g., basalt) may develop ochreous expressions, and there is typically considerable variation within a weathering profile. Iron oxides may also form via metamorphic processes.

Relatively pure hematite – massive or macrocrystalline – is fairly common. Specular hematite (specularite) is characterized by platy crystals and is anomalous in that its principal perceptual salience lies in its glittery appearance rather than color. Depending on platelet size and the fineness of the processed powder, the color may be silvery-black or a dark, low-chroma red.

Iron being a first-row transition metal on the periodic table, small amounts of other transition metals may be substituted within the iron oxide matrix. The patterns most diagnostic of the parent rock, regardless of weathering history, typically concern substitution of transition metals and enrichment of rare earth elements (REEs); elements positively correlated with Fe are the focus of provenance research (Popelka-Filcoff et al., 2008; MacDonald et al., 2011).

The chromophores of "green earths" are clay minerals, most commonly glauconite, which is formed in marine-deposited sandstones and clays, or celadonite, which is a weathering product of basalt (Eastaugh et al., 2004). Malachite (a basic copper carbonate) may occasionally have been used as a green pigment in ancient Egypt, but most green pigments were synthetically produced, using a similar procedure to the production of Egyptian blue (see below) (Lee and Quirke, 2000).

Obtaining a stable blue pigment presented a considerable technological challenge. The most widely available potential chromophore is azurite, a hydrated copper carbonate associated with malachite. Although used as a pigment in classical Greece (Eastaugh et al., 2004, 33), its use in earlier contexts is questionable (Lee and Quirke, 2000, 111). Its major drawback is that the color is unstable. This impermanence is thought to have promoted the development of the first synthetic pigments, Egyptian blue and Chinese blue, alkaline-earth-metal copper silicates, using sand and copper minerals, synthesized with either lime (Egypt) or barium minerals (China) (Berke, 2002). Lapis lazuli (ultramarine) is a rare and complex sodalite mineral (a sulfur-containing aluminum silicate), related to feldspars, where the blue mineral, lazulite, occurs in combination with calcspar and iron pyrite. Although exploited as a precious stone since the Neolithic, its hardness was a factor making it unsuitable as a pigment; it was incorporated into pigments and glazes only in the last two millennia (Eastaugh et al., 2004, 219).

Semiotic uses

The most common ethnographically documented uses of pigments are as body paints and cosmetics, followed by the decoration of a wide range of artifacts (ritual paraphernalia, clothing, tools, and utensils) and rock painting. Much of this usage, particularly among hunter-gatherers, occurs in a wide range of ritual contexts (e.g., Sagona, 1994; Watts, 1999). From an evolutionary perspective, the theoretical focus has to be on ritual display, a form of signaling with well-established characteristics that do not presuppose symbolic culture, but also the mechanism by which collective representations were established and faithfully transmitted in the first place (Watts, 2009 with refs.). In this context, exploitation of perceptual biases to create eye-catching effects are to be expected, with cross-cultural uniformities in the naming of colors (Kay and Maffi, 1999) indicating a preeminent role for dark, saturated reds (Watts, 2010). This is consistent with the finding of preferential use of the reddest and most saturated materials in some MSA assemblages (*ibid.*; Hodgskiss, 2012). To date, the only models engaging with signal evolution theory that generate refutable predictions of early pigment use are the Female Cosmetic Coalitions hypothesis (Knight et al., 1995; Power, 2009; Power et al., 2013) and the "cheap but honest signaling" hypothesis (Kuhn, 2014). Regardless of how late Middle Pleistocene pigments are interpreted, by the early Upper Pleistocene in Africa, and by ~50 ka in Europe, pigment use occurs within and helps define symbolically constructed universes.

Non-semiotic uses

While "pigment" is appropriate as a general term, iron oxide-rich materials have served a variety of other roles (aside from metallurgy), obliging archaeologists to be alert to the many possibilities. Hematite (jeweler's rouge) is used as an abrasive for fine polishing. Ethnographically reported uses include wood preservation (Santhakumaran and Jain, 1983), incorporation into hafting mastics (Dickson, 1981, 164), medicine (Peile, 1979), sun block (de Lange, 1963, 88), and food preservation (Thomson, 1949, 23). Ethnohistorical sources have been cited in support of the use of ochre as an insect repellent (Rifkin 2015), but the present author considers this a contentious interpretation of the literature. Hafting and food preservation currently rest on unique observations, but in the case of hafting, a compelling archaeological case has been made (Lombard, 2007), as also for abrasive uses of hematite (Philibert, 1994; White, 1997; Henshilwood et al., 2001). Such uses are currently documented only from contexts younger than 80 ka. The most widely cited possible utilitarian use is as a tanning agent or hide preservative (e.g., Wadley et al., 2004). This has been questioned because, unlike iron salts, iron oxides are relatively insoluble (Watts, 2009). Experimental research has put the hypothesis on a firmer functional footing (Rifkin, 2011) but also suggests inordinate labor in grinding the large quantities of ochre required (Rifkin, 2012, 191). Social correlates of tanning (prestige goods production) suggest it may not be relevant to early contexts (Hayden, 1990). Most ethnographic accounts indicate that ochre's association with hide working was primarily as a pigment (Dubreuil and Grosman, 2009). Experimental research has demonstrated that ochre powder provides negligible protection against mosquito bites (Rifkin, 2015), but it may provide an effective sun block (Rifkin et al., 2015).

It has recently been proposed, also on experimental grounds, that Neanderthals used manganese dioxide for fire making (Heyes et al.,2016). This might account for the initial appearance of manganese in the glacial conditions around 70 ka (Power et al., 2013).

Analysis

Preliminary steps in a comprehensive assemblage analysis should include a brief inspection of all curated inorganic categories to identify potential pigments, and an evaluation of site geology and geomorphology to identify possible autochthonous, non-artifactual pigmentaceous materials. Watts (2010) provides a framework for physical description, including streak properties and traces of utilization (see also Dayet et al., 2014). Thin section petrography aids fabric characterization and provides insight into overall mineralogy and secondary alteration processes (Iriarte et al., 2009). Field survey of local and regional environments is essential to identifying the variety of potential pigments. For provenancing research, multiple samples from each potential source are needed to establish within-source variation.

Any investigation beyond basic physical characterization requires mineralogical and geochemical analyses. Selection of appropriate techniques will depend on the research questions addressed, the size of available samples, whether nondestructive procedures are requisite, whether quantitative measures are needed, and the sensitivity to rare earths and trace elements required. Paint and residue analyses involve very small samples (milligrams), generally requiring minimally destructive or nondestructive techniques. The most appropriate methods are likely to be spectroscopic. Scanning electron microscopy coupled to energy dispersive X-ray analysis (SEM-EDX) is good for mineralogy and identifying the major oxides and those elements present at the level of a few percent or more. Raman spectroscopy is also suitable for mineralogy and some aspects of crystallography (Edwards, 2005). Transmission electron microscopy (TEM), revealing the size and shape of nanoparticles, has been used to investigate phase transitions (Pomiès et al., 1998; d'Errico et al., 2010). Proton-induced X-ray emissions (PIXE) can provide elemental concentrations in parts per million and have recently been used as a nondestructive method to investigate provenance (Beck et al., 2012). With large assemblages that permit some destructive procedures, traditional X-ray diffraction (XRD) and X-ray fluorescence (XRF) may be sufficient (requiring samples of a gram or more). XRD is primarily used to characterize and identify crystalline materials; amorphous materials aside, XRD can be adapted to become a quantitative method using the Rietveld refinement (Jercher et al., 1998). XRF is suitable for bulk elemental analysis (major oxides); it is appropriate for trace elements only if large samples (5–10 g) can be sacrificed (*ibid.*). If dealing with very small samples and/or requiring full spectrum elemental analysis, inductively coupled plasma mass spectrometry (ICP-MS) or instrumental neutron activation analysis (INAA) is appropriate. Robust provenancing inferences need to demonstrate greater inter- than intra-source variation (the provenance postulate), before characterizing the iron oxide signature (fingerprint) of particular groups. INAA, ICP-MS, and PIXE have also been successfully used (see below). Whatever method is used, bivariate and multivariate statistical techniques are needed to identify groups within the data.

Utilization

As earth pigments have to be reduced to powder, they are typically relatively soft rocks. The principal utilization traces on the raw material are grinding and scraping. A body of observational and experimental work exists distinguishing these different traces (Couraud, 1983; d'Errico and Nowell, 2000; Salomon, 2009; Hodgskiss, 2010; Rifkin, 2012). Scraping tends to be of softer materials, which may provide paler streaks that are less red (Henshilwood et al., 2009). Very soft pigments may have been directly rubbed onto organic surfaces (hides or human skin). Grinding followed by rubbing was identified in a late Mousterian manganese assemblage (Soressi et al., 2008) and in an MSA red ochre assemblage (Hodgskiss, 2013). Rubbed surfaces are particularly hard to identify (Hodgskiss, 2010). Pounding of harder forms, while plausible, would probably require secondary processing of residual coarse particles. To the author's knowledge, it has not been archaeologically identified. In some Middle Pleistocene contexts, flaked pigmentaceous materials have been interpreted as part of the lithic assemblage rather than as pigments (Watts, 2010 with refs.). Rare forms of utilization include notching (*ibid.* with refs) and engraving (Henshilwood et al., 2009; d'Errico et al., 2012).

The survival of use-wear depends on the softness of the material and the depositional environment. White and yellow pigments are particularly likely to be soft and friable. Among red pigments, more hematite-enriched expressions tend to be harder (Watts, 2010; but see Watts et al., 2015). Shelter contexts are more likely to preserve use-wear than open sites; corrosion of surfaces may be particularly severe in sites subject to fluctuating water tables (e.g., spring and pond margins).

Powder production is a general requirement, irrespective of end use as a pigment or for some non-semiotic role. However, pigment use should have more explicit implications for color selection. With large assemblages, past selective criteria can be investigated by comparing the streaks of utilized versus unutilized pieces, controlling for size (Watts, 2010). The intensity of use-wear may also be informative in this respect (Watts, 2009; Hodgskiss, 2013).

History of research

The belated acceptance that painted caves were (Upper) Paleolithic prompted the first chemical analysis of paint constituents (Moissan, 1902) and one of the earliest archaeological reports on ochre processing (Breuil and Cartailhac, 1906). Neanderthal use of manganese and red ochre was established shortly afterwards (Capitan and Peyrony, 1912). The association of pigments with African MSA assemblages was established in the mid-twentieth century (Armstrong, 1931; Tobias, 1949). Mason (1957) regarded the appearance of red ochre in the later stages of the MSA Pietersburg industry as one of the traits indicating directional evolutionary change (see also Watts, 2014). In the early 1970s, MSA specularite mining, which had already stimulated some interesting, if theoretically unconstrained speculation about its symbolic significance (Dart, 1968), was pushed back beyond the limits of ^{14}C dating (Dart and Beaumont, 1971).

Ochre residues on late Upper Paleolithic scrapers began to receive attention in the 1970s, leading to the hide preservation or tanning hypothesis (Keeley, 1980; Audouin and Plisson, 1982), which stimulated a considerable body of work (references in Watts, 2002; Dubreuil and Grosman, 2009; Rifkin, 2011).

The first detailed descriptive account of a pigment assemblage was Couraud and Laming-Emperaire's work at Lascaux (1979). Wreschner (1980) and Schmandt-Besserat (1980) provided literature-based surveys of early use, and Wreschner went on to undertake experimental work addressing heat alteration (1983). Couraud (1983) continued to refine descriptive methods, producing an account of the large Arcy-sur-Cure late Neanderthal assemblages (Couraud, 1991; see also Salomon, 2009). Few other European assemblages have been described in any detail, although recent studies are methodologically exemplary (e.g., Dayet et al., 2014).

In the 1990s, growing acceptance of our recent African origin and the paradox of the apparent lack of evidence for symbolic culture until ~40 ka led to renewed interest in the African MSA pigment record, being the only redundant category of evidence bearing on the issue (Knight et al., 1995; Watts, 1999; Watts, 2002). More detailed descriptive accounts of newly excavated MSA pigment assemblages followed (Watts, 2010, 393 with refs; Hodgskiss, 2012; Dayet et al., 2013; Hodgskiss, 2013).

It was also in the 1990s that archaeometric pigment analyses reached maturity. There are several reviews of the history of these studies (Clottes et al., 1990; Smith et al., 1998; Rowe, 2001; Edwards, 2005; Popelka-Filcoff et al., 2007; Trąbska 2014), each bringing slightly different aspects of the field into focus. After Moissan's pioneering studies at the start of the twentieth century, little archaeometric work had been done until the 1970s. French and Australian analyses in the 1980s focused largely on paints, making extensive use of SEM-EDS and XRD for mineral identifications. In the early 1990s, PIXE began to be applied, being more sensitive for elemental analysis than SEM-EDS (Rowe, 2001). From the mid-1990s, Raman spectroscopy (also for mineralogical identifications) was increasingly used in paint analyses (Edwards, 2005).

Much of the early work on provenancing was Australian. Initial studies worked on improving characterization of source materials using PIXE (David et al., 1993). Some success was achieved by combining Rietveld refinement of XRD spectra (for quantitative phase analysis) with XRF elemental analysis (Jercher et al., 1998). The large sample size requirements of XRF led to the adoption of ICP-MS for elemental study, together with Rietveld XRD (Smith et al., 1998). This study demonstrated changes in procurement behavior in a central Australian site spanning the last 32,000 years, with fingerprinting of two sources. Similar studies were attempted in Israel and the USA (Popelka-Filcoff et al., 2007 with refs.). Notwithstanding the study of Smith and colleagues, most conclusions were tentative.

The real breakthrough occurred in the last decade, with the systematic application of INAA (Popelka-Filcoff et al., 2007; Kiehn et al., 2007; Popelka-Filcoff et al., 2008; Eiselt et al., 2011; MacDonald et al., 2011). This has proved successful in meeting the provenance postulate in a variety of different contexts. Not only can it discriminate fundamentally different pigments, but it opens up prospects for identifying different groups within geologically fairly uniform regions, where the principal differences lie in weathering histories (MacDonald et al., 2011). The proposed underlying mechanism in this instance was clinal geographic differences in rainfall, with concomitant effects on water pH. Most recently, nondestructive PIXE has been used for provenance research (Beck et al., 2012; Mathis et al., 2014).

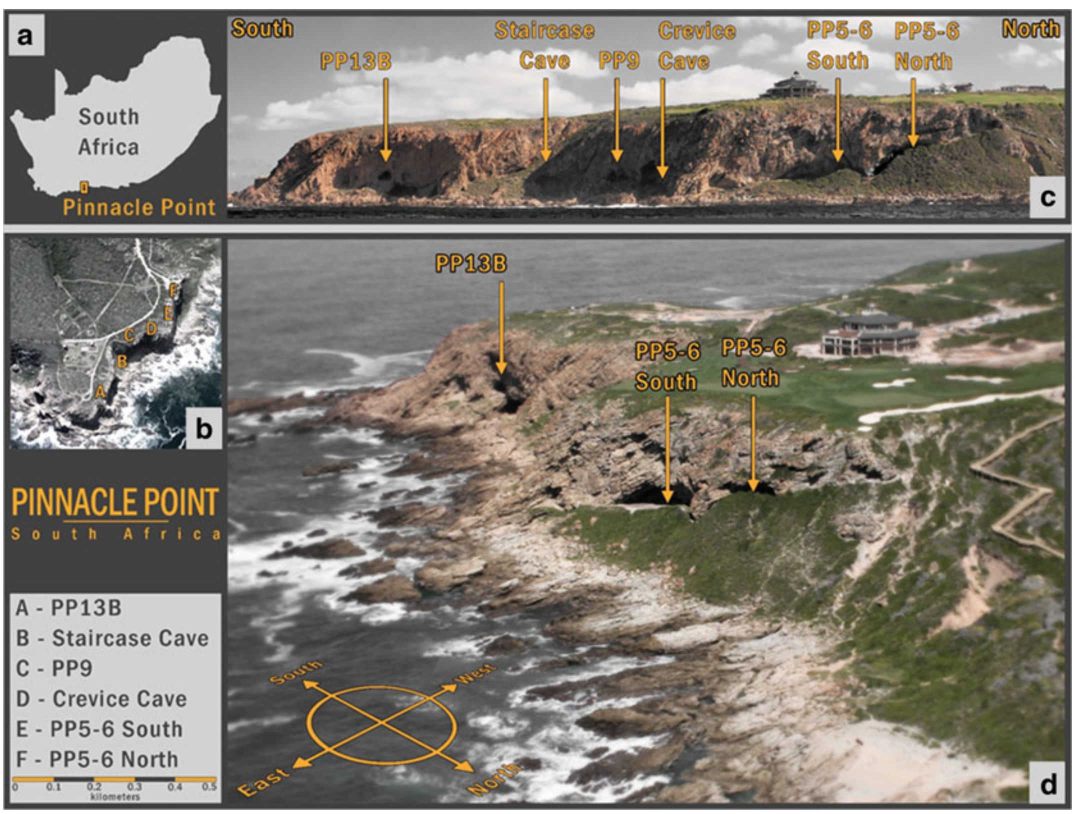
PINNACLE POINT

Curtis W. Marean
Institute of Human Origins, School of Human Evolution and Social Change, Arizona State University, Tempe, AZ, USA
Centre for Coastal Palaeoscience, Nelson Mandela Metropolitan University, Port Elizabeth, Eastern Cape, South Africa

Pinnacle Point is a rocky headland on the south coast of South Africa (Figure 1) on the Indian Ocean that preserves an abundance of caves and rock-shelters. These sites have gained scientific renown from the rich, well-preserved archaeological records dating to the origins of modern humans and also from the widely multidisciplinary approach of the scientific team working there (the South African Coast Paleoclimate, Paleoenvironment, Paleoecology, Paleoanthropology Project, or SACP4). Research began in 1999 and continues today. The regional environmental context is notable for being near the east-west center of the highly diverse Greater Cape Floristic Region (GCFR), which has the world's greatest diversity of geophytic plants, as well as being on a coast with one of the world's richest intertidal zones. These resources are thought to have been resistant to the aridification brought on by glacial phases that affected most of Africa and depressed its resource productivity, therefore making the south coast of the GCFR a likely glacial refugium zone for the progenitor population of modern humans (Marean, 2010, 2011).

The caves and rock-shelters occur in quartzite of the Table Mountain Sandstone formation, which in much of this area is overlain by calcrete formations (Figure 2). All of the caves and rock-shelters were eroded by ancient high sea levels, and recent dating by the SACP4 team using uranium–lead on speleothem and thermal transfer optically stimulated luminescence (TT-OSL) on sands provides concordant evidence that the caves were in place by ~1.1 Ma (Jacobs et al., 2011; Pickering et al., 2013). Our studies show that the peak of the Marine Isotope Stage 11 high sea stand at ~400 ka in this area was at +13 msl (Roberts et al., 2012), which would have washed out most of the >400 ka sediments from the caves, though some of the sites have portions that are sufficiently high to preserve older sediments.

Extending beyond the south coast is a wide, gradually sloping continental shelf called the Agulhas Bank. This



Pinnacle Point, Figure 1 The location of Pinnacle Point and the major sites mentioned in the text (Graphic by Erich Fisher).

Pinnacle Point, Figure 2 The PP13 cave complex; PP13B is the large cave with the constructed stairway leading up to it. The rock into which the caves extend is quartzite of the Table Mountain Sandstone formation; the capping calcrete is too thin at the cliff edge to be apparent.

shelf would have been variably exposed during lower sea levels of the Pleistocene (van Andel, 1989), exposing an entirely novel ecosystem for this area called the Paleo-Agulhas Plain (Marean et al., 2014). SACP4 developed a 3D model of this offshore platform that is integrated with the global sea-level curve, allowing the continuous temporal projection of the coastline distance and configuration over the last 420,000 years (Fisher et al., 2010). A geophysical study of the offshore sediments is enriching our knowledge of that now submerged ancient paleoscape and its ecology (Cawthra et al., 2015). It is hypothesized that there was an east-west migration ecosystem of large ungulates that wintered in the west and summered in the east, taking advantage of the seasonally bipolar rainfall systems (Marean, 2010).

As sea levels rose and fell with glacial retreats and advances, sources of sand were exposed that regularly formed dunes in the region. These dunes sometimes covered the coastal cliffs and closed the caves and rockshelters partially or completely. During these phases of closure when people were excluded, speleothems formed in the caves. SACP4 researchers have identified a series of dune pulses at ~120 ka, 90 ka, and 70 ka (Jacobs, 2010) and have studied the speleothems to develop long and continuous sequences of climate and environmental change for this region. These studies suggest that during MIS 4 (~74–60 ka), the area received greater amounts of rain from the east, which falls in the summer, resulting in a westward expansion of the more classically tropical vegetation of the east coast (Bar-Matthews et al., 2010). Ongoing studies of the speleothems have now pushed this record back to 500 ka and beyond (Braun, 2014).

The timespan of modern human origins in Africa is referred to as the Middle Stone Age (MSA), a technological phase recognized by the way stone artifacts were made. SACP4 has developed at Pinnacle Point the longest and highest resolution record of MSA occupation for Africa. So far, the earliest numerically dated occupations at Pinnacle Point begin at ~160 ka during MIS 6 (~190–125 ka), and this is the only coastal occupation numerically dated to MIS 6 yet discovered in South Africa. Our coastline model shows that at this time, the coast had approached the site to within 7–5 km and people exploited shellfish from the upper portions of the intertidal zone, scavenged seals (Thompson, 2010), and worked ochres that were intentionally selected for their redness. This is the earliest evidence for these behaviors worldwide (Marean et al., 2007; Jerardino and Marean, 2010; Watts, 2010). At this time, people were using heat treatment of stone for artifact production, which is the earliest record yet for this technology, though its use does not become intensive until much later in MIS

Pinnacle Point, Figure 3 The location of PP5-6. The vegetated slope indicated by the *red arrow* is a dune that drapes the outer eroded section of the site.

4 (Brown et al., 2009). The site was alternately lightly occupied or abandoned throughout the rest of MIS 6, and then occupation intensity rises abruptly as the coastline returned to the proximity of the site at the beginning of MIS 5 around ~110 ka. During the rest of MIS 5, occupation intensities were high to moderate as the coast remained within reach of the cave occupants, and then at 90 ka, the cave was abruptly closed to human occupation when a dune sealed it (Karkanas and Goldberg, 2010; Marean et al., 2010).

PP5-6 (Figure 3) is currently still under excavation and analysis, but an intensive OSL dating study complemented by a detailed analysis of micro-facies using micromorphology has provided a high-resolution sequence through the ~14 m tall vertical sediment stack (Karkanas et al., 2015). This sequence dates from ~90 to 50 ka, picking up at the time when PP13B was sealed. The sequence documents a turnover from roof spall-dominated sedimentation to aeolian-dominated sedimentation near the MIS 5–MIS 4 boundary. Occupation intensities actually rose with the glacial MIS 4 (Karkanas et al., 2015), while at the same time there was a shift to the world's earliest known microlithic technology (Brown et al., 2012). Mollusk exploitation continued through the sequence, and there is clear documentation of shell midden production and formal coastal adaptations (Marean, 2014). In the near future, the PP5-6 sequence will be published in detail, and PP13B and PP5-6 together will deliver a record of early human use of coastal environments unrivaled in detail and completeness.

POMPEII AND HERCULANEUM

Maria Rosaria Senatore
Dipartimento di Scienze e Tecnologie, Università degli Studi del Sannio, Benevento, Italy

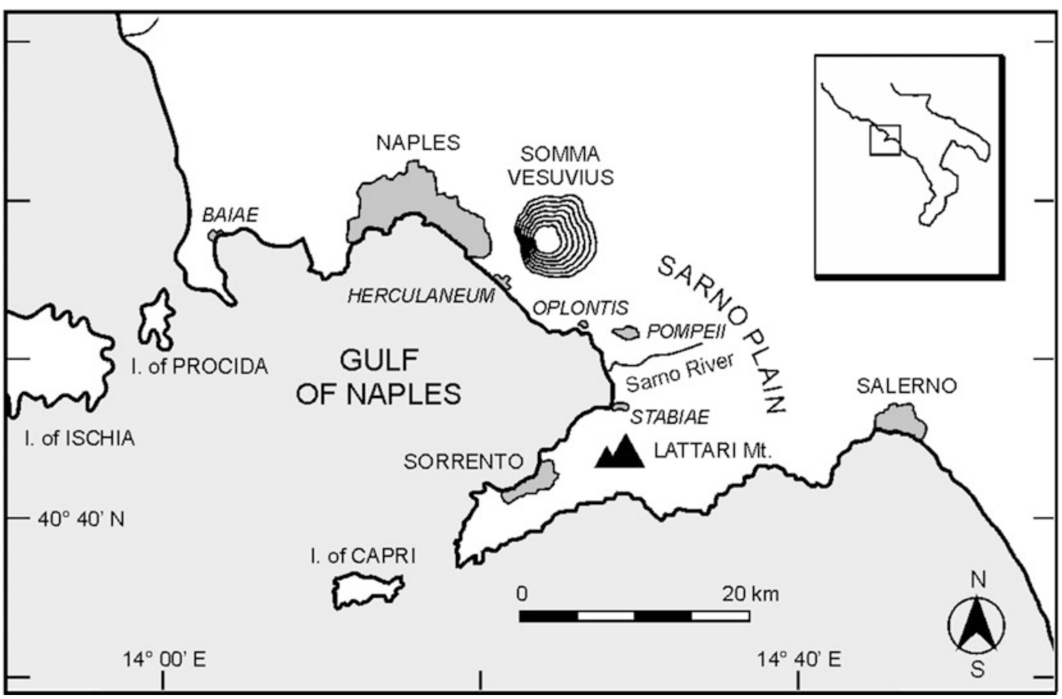
The famous AD 79 volcanic eruption of Vesuvius buried the cities of Pompeii (Figure 1), Herculaneum, and Stabiae, as well as many villas located along the coast south of Naples in southern Italy (Figure 2). The event was described by Pliny the Younger in two letters that were sent to inform Tacitus that the eruption had killed his uncle, Pliny the Elder. It began with a phreatomagmatic explosion followed in the early afternoon of August 24 by a very intense explosive phase leading to the formation of an eruptive column 32 km high, elongated toward the southeast by stratospheric winds. Pliny the Younger compared the shape of the volcanic cloud to a Mediterranean pine. The pyroclastic products related to this phase consisted of pumice fall deposits that mantled the topography to the southeast as a uniform layer with decreasing thickness downwind from Vesuvius. The next day, August 25, volcanic activity changed as a result of collapse of the eruptive column within the volcano. Dense clouds formed as the plume descended, sending gases and pyroclastic products (pyroclastic flows and

Pompeii and Herculaneum, Figure 1 Pompeii, the Arch of Caligula and the view of Vesuvius through it.

surges) rapidly down the slopes at speeds greater than 100 km/h and a temperature of about 400 °C. The first two surges struck Herculaneum on the southwestern side of the volcano, killing all the residents still in the city. Subsequent surges and pyroclastic flows reached as far as Pompeii and the plain of the Sarno River up to Stabiae, all lying to the southeast, destroying everything and killing the inhabitants who, after fleeing during the initial, Plinian (explosive) phase of the eruption, had returned to retrieve their belongings. The products of these pyroclastic flows and surges completely buried Herculaneum and partially covered Pompeii and Stabiae. Volcanic activity continued for some weeks with phreatomagmatic explosions (Sigurdsson et al., 1985; Rolandi et al., 1998; Guest et al., 2003).

The best exposures of these successive volcanic deposits are seen in the excavations of the Herculaneum waterfront and outside the walls of Pompeii at its Herculaneum Gate (northwest, Figure 3) and in the necropolis near Nocera Gate (southeast).

The AD 79 pyroclastic deposits represent a tephra layer that has completely preserved the natural environments existing prior to the eruption; it also serves as a stratigraphic marker useful for paleoenvironmental reconstructions. Stratigraphic and sedimentological research carried out on sediment cores from 25 boreholes collected over a wide area around Pompeii, as well as the reinterpretation of about 400 stratigraphic records from

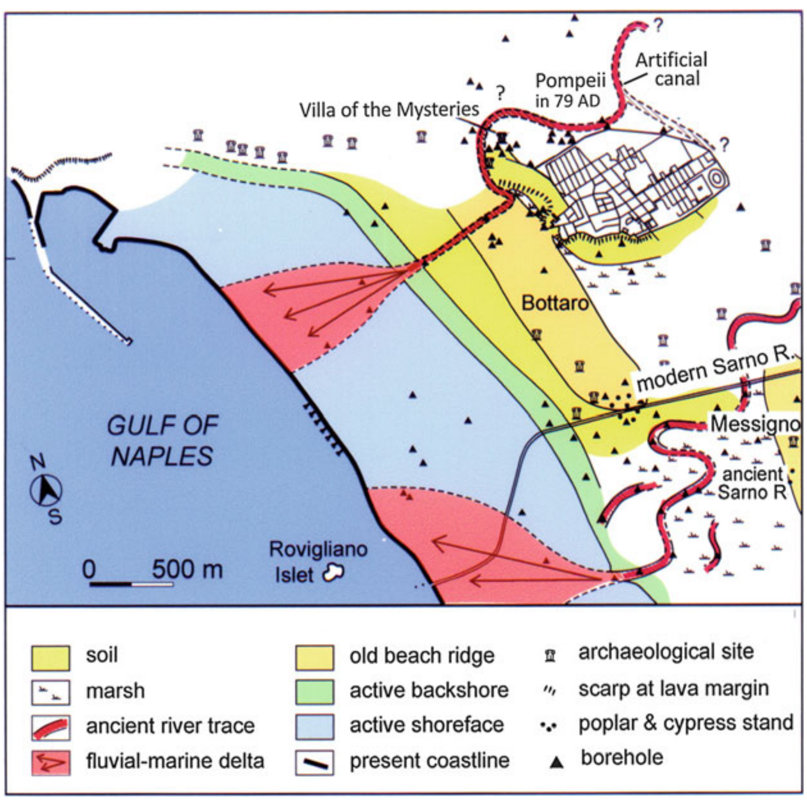


Pompeii and Herculaneum, Figure 2 Location of Pompeii, Herculaneum, Stabiae, and the Sarno River in southern Italy's Campania region. Mt Vesuvius is a younger volcanic cone that has risen within the caldera of a larger and older volcano, Mt Somma. They are often considered together as Somma-Vesuvius.

Pompeii and Herculaneum, Figure 3 AD 79 pyroclastic deposits outside the northwestern walls of Pompeii.

old boreholes, has permitted the reconstruction of the natural Pompeian landscape prior to the eruption (Pescatore et al., 1999, 2001; Pescatore and Senatore, 2005; Ciarallo et al., 2007; Senatore et al., 2010, 2014). Findings suggest that the ancient shoreline of the first century AD was located about 1 km landward of the modern one (Figure 4). Inland and running parallel to the coast, there were two elongated ridges consisting of beach sand deposits, dated by ^{14}C to the Bottaro (3600 BP) and Messigno (5600 BP) stages, marking progressive shoreline progradation over the course of the late Holocene. These coastal ridges were cut by alluvial sand and gravel and by marsh mud deposits related to the ancient Sarno River, which flowed through them and into the sea, forming a well developed delta just southeast of the Rovigliano Islet.

The city of Pompeii was built on an ancient Vesuvian lava flow or, as interpreted by Cinque and Irollo (2004), on remains of a separate volcano and stood in relief with respect to the surrounding plain (Figure 4). To the north of the city, there was an artificial canal. It flowed close to the city (Ciarallo et al. 2003; Senatore et al., 2004, 2014) and probably represented Pompeii's water supply until construction of a Roman aqueduct in the first century BC. The canal flowed toward the Villa of the Mysteries (northwest of the town), then turned toward the south, collected the city's wastewater, and finally turned westward, reaching the coast where it formed a small delta.



Pompeii and Herculaneum, Figure 4 Reconstruction of the territory of the Sarno plain around Pompeii prior to the AD 79 Vesuvius eruption (Modified from Senatore et al., 2004).

POVERTY POINT SITE, LOUISIANA

Anthony L. Ortmann
Department of Geosciences, Murray State University, Murray, KY, USA

Location and description

Poverty Point is a prehistoric community in northeastern Louisiana that was occupied during the Late Archaic period (ca. 3700–3100 BP). The cultural landscape of the site includes five earthen mounds and six concentric, arc-shaped earthen ridges that surround a large, level plaza. The entire Poverty Point earthwork complex covers an area of over 1 km^2.

Geoarchaeology at Poverty Point

Systematic archaeological research at Poverty Point began as early as the middle of the twentieth century, and over the past decade, archaeological investigations at the site have increasingly incorporated geoarchaeological techniques.

Mound A

Excavations in Mound A, the largest mound at the site, were designed to test how the earthwork was constructed, when it was built, and how quickly it was erected (Ortmann and Kidder, 2013). Mound A rises to a height of over 21 m with basal dimensions of approximately 200 m on each side and a volume of nearly 238,000 m^3 of earth. Mound A comprises two distinct sections. The western portion of the mound is a tall (~21 m), cone-shaped feature, while the eastern portion is a shorter (~10 m), flat-topped platform. Excavations have revealed that the mound was built in at least three major stages overlying an Ab soil horizon (a buried A horizon). Thin sections from this Ab horizon have revealed the presence of single-celled freshwater organisms called thecamoebians, indicating this area of the site was a naturally inundated swamp prior to construction of the mound. The first construction stage consists of a thin (6–10 cm) deposit of light gray silt that completely covers the underlying Ab horizon and makes up the base of the platform section of the mound. The second construction stage consists of the tall, western, conical portion of the mound. Soil cores removed near the junction of the cone and platform revealed that a small portion of the eastern edge of the conical portion of the mound overlies the initial construction stage. The final construction stage comprises the bulk of the platform portion of the mound, which was built rapidly in one continuous effort using basket loads of earth and raised to a height of approximately 10 m. This third stage overlies the first construction stage, but also overlaps the second stage near the junction of the cone and platform sections of the mound.

The entire mound appears to have been built quickly. The upper boundary of the first construction stage lacks any evidence for exposure to weathering, such as bioturbation or depositional microlaminae; this evidence suggests that the initial stage was covered by the second and third construction stages almost immediately after it was emplaced. Similarly, micromorphological analysis of the boundaries between the individual basket loads of earth that make up the third construction stage revealed no evidence for bioturbation, size sorting of sediments caused by exposure to rainfall, or the formation of incipient A horizons, which would take time to generate.

Historic climate data for northeastern Louisiana indicate the longest recorded period without measurable rainfall was approximately 1 month. Using these data as a conservative proxy, it seems likely that Mound A was constructed in as little as 30–90 days. Radiocarbon dates from the Ab horizon underlying both the platform and conical sections of the mound indicate Mound A was built sometime after 3261 BP and was likely the last major architectural feature built at Poverty Point.

Earthen ridges and site plaza

Poverty Point's earthen ridges, which demarcate the site's plaza, are traditionally interpreted as habitation areas for the residents of the site. A magnetic gradient survey covering nearly the entire plaza, most accessible portions of the two innermost ridges, as well as large portions of five of the southwestern ridges revealed the presence of numerous magnetic anomalies (Hargrave and Clay, 2014). The earthen ridges are manifest in the magnetic data as linear bands of positive and negative anomalies that probably represent features, discrete deposits of different soils, fired earth cooking balls, fired clay features, hematite artifacts, and other cultural remains with magnetic signatures. Downhole magnetic susceptibility cores suggest that linear positive anomalies associated with the ridges in many areas are flank midden redeposited from the ridge tops and/or upper slopes of the ridges (Dalan et al., 2010). Linear negative magnetic anomalies that occur along the ridge perimeters in many areas are more difficult to interpret. Thirty-nine circular magnetic anomaly complexes ranging in diameter up to about 80 m (with one possible larger outlier) were located near the outer edges of the southern portion of the plaza (Hargrave and Clay, 2014). Interpreted as "post circles," some appear to be composed of discrete anomalies, whereas others appear as continuous circles. Downhole magnetic susceptibility surveys have been used to verify and obtain stratigraphic information on several of the magnetic anomalies and to place test units over different types of circular anomalies. Excavations and magnetic susceptibility surveys within these excavations revealed that the circles are massive post features and large pits variously filled with magnetic and nonmagnetic fill (Greenlee, 2009; Dalan et al., 2010).

PRE-CLOVIS GEOARCHAEOLOGY

Andrea Freeman
Department of Anthropology and Archaeology and Earth Science Program, University of Calgary, Calgary, AB, Canada

Definition

Pre-Clovis geoarchaeology involves the geoarchaeological investigation of the material remains of people predating the Clovis complex in the Americas – i.e., before 11,500 ^{14}C years BP (Haynes, 1993; cf., Haynes et al., 2007; Waters and Stafford, 2007; and Waters et al., 2015 for further discussion). Typically, geoarchaeological investigations of this kind must study the context of the material remains embedded within geologic strata and interpret the depositional history and postdepositional alterations at the site and, occasionally, the archaeometric aspects of the finds, such as determining chronology.

Historical background

The geoarchaeological investigation of pre-Clovis sites in the Americas began long before the term "geoarchaeology" was commonly used (Rapp and Gifford, 1982) and before the Clovis projectile point type was formally defined (Cotter, 1937; Howard, 1943). Throughout the history of scientific archaeology in the Americas, archaeological sites indicating potentially deep human antiquity were investigated by throngs of scientists, including geologists (Meltzer, 1983). Among those geologists of the twentieth century called upon to evaluate such finds critically were glaciologist Richard Foster Flint, fluvial geomorphologist Kirk Bryan, and varve chronologist Ernst Antevs. Even the eminent nineteenth-century British geologist Charles Lyell was involved in the early evaluation of the Natchez find (Lyell, 1863, 1873). The principal focus of geoscientific study at these sites was evaluating the context of the remains (mainly fossils and stone tools) within the surrounding stratigraphy and determining, at least initially, the relative (stratigraphic) age of these sites. The goal was to separate solid evidence for a pre-Clovis occupation from poor quality evidence (see Quimby, 1956 on the history of the Natchez pelvis) or even hoaxes like the Calaveras skull in California (Dexter, 1986). Even today, possible pre-Clovis sites initially investigated decades ago are reevaluated by geologists, chronologists (Taylor and Payen, 1979), paleontologists, and archaeologists (Cotter, 1991; Rogers and Martin, 1984). With each newly emerging pre-Clovis contender, new questions arise.

By the 1970s, scientific interest in finding potential pre-Clovis sites had peaked. This intensified concern was perhaps spawned by the eloquent assertion that the timing of an available ice-free landscape in western Canada from ca. 12,000 BP coincidentally fell within the expectations of the new radiocarbon ages on Clovis sites (Haynes, 1964). The investigations of Meadowcroft Rockshelter and the Calico Hills sites, in particular, led to rigorous geoarchaeological examination of the evidence for an "earlier than Clovis" occupation of the Americas. Often, local geologists were called on to help archaeologists interpret the stratigraphy at these sites (Rapp and Gifford, 1982). As the evidence became more complex, C. Vance Haynes, Jr., a skilled geochronologist and geoarchaeologist, emerged as the scientist most called upon to elicit an opinion on the veracity of the finds. Haynes's investigation of Paleo-Indian sites in the San Pedro Valley of Arizona, at Blackwater Draw and Folsom in New Mexico, Hell Gap in Wyoming, and the Tule Springs site in Nevada, gained for him a reputation as an expert in stratigraphy and in the emerging methods of radiocarbon dating. Early experience with limitations of the method caused him to evaluate critically any potential sources of contamination or error. The ensuing, decades-long argument over radiocarbon samples from Meadowcroft Rockshelter created a polarity among scientists that compared with the earlier debate over the existence of an "American Paleolithic" in the late nineteenth and early twentieth centuries (Meltzer, 2005).

Curiously, the mid-1970s was also the time when Monte Verde was discovered in Chile. While archaeologists and geoarchaeologists in North America battled over other pre-Clovis contenders, the excavation of Monte Verde in Chile quietly took place over an 8-year period, conducted by an interdisciplinary team of specialists, including geologists. It took until the 1980s for publications to emerge that promoted Monte Verde as the best candidate for a substantiated pre-Clovis occupation of the Americas, and following similar "expert" visits, Monte Verde was presented to the world as a "verified" pre-Clovis site (Meltzer et al., 1997). New sites continued to emerge throughout the late twentieth century, and geoarchaeologists continued to play a critical role in the evaluation of their age and context. The requisite geoarchaeological research is undertaken by professionals with varied backgrounds and wide-ranging experience; both archaeologists with formal or informal training in the geosciences and geoscientists with formal or informal training in archaeology are involved.

Geoarchaeological studies at pre-clovis sites

Although archaeological sites in Alaska, such as the Nenana and Tanana Valley sites (Powers and Hoffecker, 1989; Holmes, 2001), predate the Clovis occupation, Alaska represents a special case in terms of early occupation of the Americas. During the last glacial advance, it was connected by the Bering Land Bridge (commonly referred to as Beringia) to far eastern Siberia, which possessed its own history of Pleistocene occupation that predated Clovis (Goebel, 1999; Madsen, 2004; Goebel et al., 2008). But Alaska was isolated from unglaciated North America by ice sheets that covered nearly all of Canada. Therefore, the term "pre-Clovis" refers to early human habitations that lie south of the late Pleistocene North American ice sheets, including a widely diverse landscape encompassing North, South, and Central America and the coastlines of those continents.

Pre-Clovis sites that have recently gained the attention of geoarchaeologists include (1) sites in caves and rockshelters (Paisley and Connley Caves in Oregon, South American sites including Pedra Furada in Brazil, Cueva Fell and Cueva del Milodon in Chile, and El Abra and Tibito in Colombia), (2) sites along the western coast of the Americas (underwater caves of Haida Gwaii off the coast of British Columbia and the Channel Islands of California), (3) sites along the sandy coastal plains of eastern North America (Cactus Hill and Saltville in Virginia and Topper in South Carolina), (4) sites in offshore locations (Page-Ladson in Florida, the Hoyo Negro skull in Yucatan, and the Cinmar site off the coast of Virginia), (5) sites in peatlands (the Schaefer and Hebior sites in Wisconsin), and (6) sites in river valleys (the Friedkin site in Texas, Big Eddy in Missouri), dry draws, and eolian landforms in many parts of these continents, where the accumulation of sediments has promoted preservation of archaeological and paleontological specimens.

Also important to note, the recent trends in the investigation of pre-Clovis occupations in the Americas are not restricted to the exploration of newly discovered evidence. Geoarchaeologists have spent considerable effort looking at the evidence recovered from previously studied, yet unresolved sites, as well as exploring the Pleistocene stratigraphy at Clovis and Folsom sites to determine if there is any likelihood of finding pre-Clovis material remains there (Holliday and Meltzer, 1996; Meltzer et al., 2002). A significant aspect in the evaluation of this stratigraphic evidence is the necessary paleoenvironmental reconstruction to determine whether or not the ancient environments in question were favorable for preserving evidence of human activity at these sites.

Emergence of new methods

In addition to the application of accurate chronometric methods to date possible pre-Clovis deposits, another prominent focus of geoarchaeological research at these sites has been the interpretation of whether the ancient late glacial environments were suitable for human mobility and colonization during pre-Clovis time periods (Mandryk, 1990; Erlandson et al., 2007). A pre-Clovis passage for human travel through a corridor free of ice in western Canada was likely temporally and environmentally narrow, and geoarchaeological evidence of such requires detailed reconstruction of glacial geology and age estimates on postglacial features (Holliday, 2009; Freeman, in press). Meanwhile, coastal models for human entry must contend with the environmental viability of a highly mobile seafaring population (Erlandson et al., 2007) and the complexity of deglaciation and sea-level change (Josenhans et al., 1995; Fedje and Christensen, 1999; Fedje et al., 2004).

The recovery of new types of evidence – such as the cordage found at Monte Verde, Chile, and a coprolite from Paisley Caves, Oregon – requires continued and extensive cooperation among geoscientists, chronologists, and biologists.

PRIVIES AND LATRINES

Richard I. Macphail
Institute of Archaeology, University College London, London, UK

Synonyms

Cesspits, garderobes; Human waste and coprolites

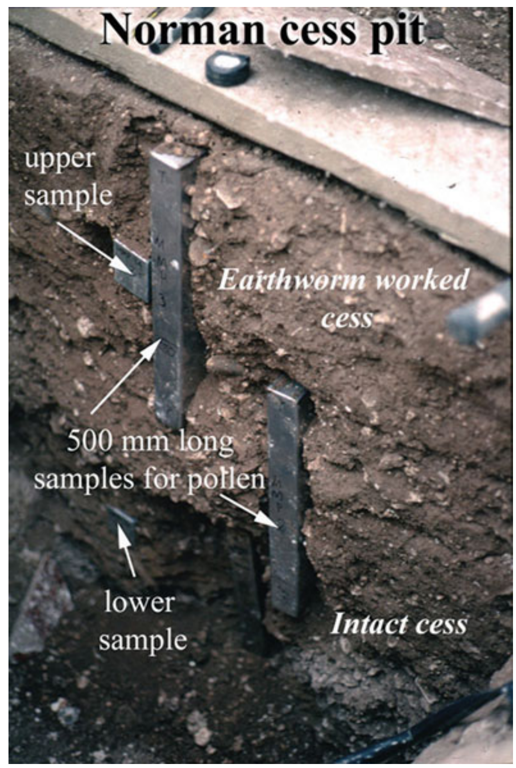
Definition

Privies and latrines are associated with the generation, disposal, and storage of human waste, often in pits and soakaways termed cesspits.

Introduction

Wherever humans congregate there is the need to manage their fecal waste, and such waste can therefore serve as evidence of human occupation, usually preserved as a coprolite, coprolite fragments, or as totally or partially mineralized accumulations in cesspits and drains from latrines (Figures 1 and 2). Cesspit deposits have more commonly been studied through their biological remains, insects, parasite eggs, and food residues. These fills, however, can also be regarded as a specific anthropogenic sediment type, and they have been investigated by soil micromorphology (Macphail and Goldberg, 2010) and associated microprobe and bulk chemical analyses. The key chemical is phosphorus, which with H, C, N, and O is a primary element in the biosphere and is concentrated in fecal waste. Sometimes, this waste is collected in a toilet bucket, the contents of which are disposed of elsewhere (cf. "night soil"). Our studies have shown that where humans are concentrated, this will be mirrored in the amount of human waste present. This can stain and contaminate earlier deposits, and completely skew chemical analyses of these earlier deposits if this contamination is unrecognized. Channels and voids in juxtaposed soils and sediments can be lined with phosphate from cesspit leakage; bulk analyses may show anomalously high phosphate contents. It is therefore important to be able to recognize mineralized fecal material, be it as layered in situ cess, intact coprolites, coprolite/cess fragments, or simply as secondary concentrations of phosphate minerals. In addition, it is important to be able to differentiate human cess and coprolites from other mineralized fecal material, especially that of omnivores such as canids (e.g., dogs) and pigs, which also scavenge sites of human occupation. Fecal material of human origin has been studied from the intestines of mummies (Holden, 1990) and from convincing cesspit and latrine channel contexts where eggs of parasitic nematodes specific to humans and other fecal indicators (bran, mineralized fly pupae) have been found through palynology, parasitology, and macrofossil analyses. In addition, some specific reference material was first identified employing specific nematode egg extractions and analyses (Kenward and Hall, 1995).

Privies and Latrines, Figure 1 Monkton (Thanet, Kent, UK): Norman medieval cesspit cut into chalk (see Figure 2).



Privies and Latrines, Figure 2 Monkton (Thanet, Kent, UK): fill of Norman cesspit, composed of intact layered cess at the base and earthworm-worked dispersed and oxidized cess at the *top*. *Upper* and *lower* Kubiena box samples are shown (see Figure 1 and Table 1).

Human coprolites

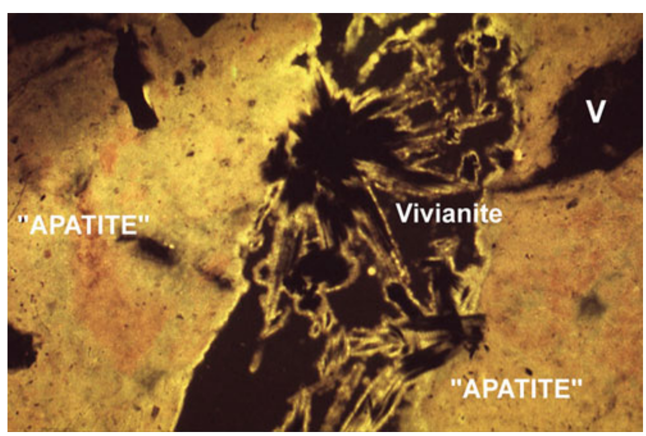
Examples from Saxon Maiden Lane (the Strand, London) and Viking Coppergate (York), identified on the basis of human nematode egg content (appropriate size range of human whip worm *Trichuris* eggs found by C. De Rouffignac and A. Jones, respectively, pers. comm.), have been analyzed in detail (full analyses in Macphail and Goldberg, in prep). Chemically, the Maiden Lane coprolite has a dominantly calcium phosphate content, and its autofluorescence under blue light (BL) fluorescence microscopy suggests a probable apatite mineralogy. Autofluorescent materials – bone apatite, plant cellulose – when irradiated with short-wave radiation, such as blue light, emit radiation with a longer wave length ("luminescence"), but only as long as the excitation lasts (Stoops, 2003). Microprobe produced the following data: 18–34 % Ca, 8–14 %P, 0.6–3.5 % Fe, 0.2–4.4 % Mn, <0.1 % Al, <0.1 % K, 0.1 % Mg, 0.0–0.1 % Si; $n = 7$). It has a yellowish brown color under plane polarized light (PPL; Figure 3) and is isotropic (under crossed polarized light, XPL), with reddish to whitish colors under oblique incident light (OIL) (Courty et al., 1989: Plate IVa). It shows low to high autofluorescence (BL). Reddish to blackish streaks seem to relate to iron and manganese staining of amorphous organic matter, presumably of dietary origin. The Coppergate Viking coprolite is exceedingly rich in dietary residues, including fine- and medium-sized bone fragments, ubiquitous plant fragments including articulated sheets of phytoliths (cereal bran), and legume testa (seed cases) (Macphail et al., 1990). A blackberry seed is also present. These findings testify to a broad diet. When employing blue light, non-autofluorescent *Trichuris* eggs can be seen as "negatives" within the autofluorescent matrix; secondary iron phosphate occurs as blue vivianite crystals or "ghosts" within the coprolite, and these are also non-autofluorescent (Figure 4). These findings helped the identification of coprolite fragments elsewhere, for example, at the large Late Bronze Age/Early Iron Age site of Potterne, Wiltshire, where the presence of roundworm (*Ascaris*, P. Wiltshire, pers. comm.) and other nematode eggs was noted in the thin section sample, alongside embedded cereal remains and fine bone.

It is likely that the presumed hydroxylapatite forming mineralized cess and coprolites is in fact carbonate hydroxylapatite, as it is found so often as a secondary mineral in archaeological sites employing FTIR studies (Karkanas et al., 2002; Weiner, 2010, 83–84; Karkanas 2011, pers. comm.). It can also be noted that an example of bone-eating carnivore scat from the Cretaceous included minute bone, teeth, and plant remains, and vesicular pseudomorphs of fine organic matter, some interpreted as relict fecal bacteria, were embedded in francolite (Ca-P dominated carbonate fluorapatite) because of an intake of dietary calcium phosphate (Hollocher et al., 2010).

Comparing canid and pig coprolites

In the field, human coprolites are yellowish brown, while dog coprolites are often whitish and may contain large bone fragments. In thin section, dog coprolites can be whitish, or grayish, with very fine blackish speckles (bacterial activity? M-A Courty, pers. comm.), and they are whitish under OIL. They also show a marked autofluorescence under BL. Bone inclusions often show grayish (digestive) leaching, and such bone fragments occur within occupation deposits where dogs have been scavenging. Dogs also ingest silt (when drinking), fur, or wool producing pseudomorphic voids. For example, sheep bones showed gnawing at Saxon West Heslerton, North Yorkshire, UK, where many dog coprolites included wool-size voids. Another characteristic is the

Privies and Latrines, Figure 3 Maiden Lane (The Strand, London, UK): photomicrograph of Middle Saxon human coprolite (according to human nematode egg analysis); it has a pale yellow matrix of probable Ca-P apatite according to microprobe analysis, with brown and blackish Fe and Mn staining of indeterminate plant food residues. Voids likely record trapped gas. Plane polarized light (PPL), frame width is ~5.5 mm.



Privies and Latrines, Figure 4 Coppergate (York, UK): photomicrograph of Viking coprolite (according to human nematode egg analysis); the "apatite" matrix is autofluorescent under blue light, and this material has coated iron phosphate vivianite and ghosts of vivianite, which also formed under anaerobic conditions. Blue light illumination, frame width is ~0.6 mm.

amount of vesicles present, caused by trapped gas, which is also a trait of hyena coprolites (Horwitz and Goldberg, 1989).

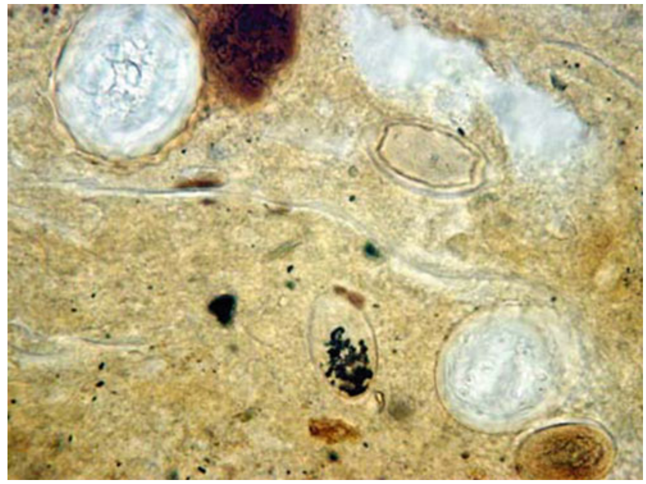
Generally, wild pig feces and coprolites should be easily distinguishable from human material, because they are dominantly composed of amorphous and fragmentary plant material, much less phosphate-rich, and often reveal very poorly, or non-autofluorescent matrix material (Courty et al., 1994). This is also the case for modern pigs fed a cereal diet, for example. In the archaeological record, however, it seems likely that some deposits include phosphate-rich pig fecal deposits, because they were fed/scavenged on meat and bone-rich waste. Such deposits, however, seem to be non-autofluorescent and contain Fe and Mn in addition to Ca and P. Pig feces are less phosphate-rich and include high quantities of plant remains when fed purely a vegetarian diet.

Cess

This occurs as in situ layered deposits in cesspits, which are located beneath the privy or latrine itself, or in the channels that drain privies. These are best preserved at the base of the fills, whereas upper deposits are more likely to have been subject to oxidation and biological working. This post-depositional weathering is discussed below, after some pristine deposits are described. Three cases are presented. These are a latrine drain fill at the London Guildhall eleventh-century settlement site, a twelfth century cesspit privy fill at rural Monkton, Kent (see Figures 1 and 2), and a late medieval (AD 1400–1480) cess-filled pit at the priory and hospital of St. Mary Spital (Spitalfields), London. Complementary environmental analyses found *Ascaris* eggs, mineralized fly pupae, and bran residues at Monkton, and the nematode eggs, of *Ascaris* and *Capillaria*, were identified within the thin section of the Guildhall cess (M. Robinson and P. Wiltshire, pers. comm.); palynology of the Spitalfields cesspit indicated human fecal inputs (R. Scaife, pers. comm.). Although bulk analyses of this cess were carried out at different times, these show a consistent high organic (LOI) and very high phosphate content and very low magnetic susceptibility (Table 1). Heavy metal concentrations of Zn and Cu in particular were noted. Such concentrations are of biological origin and are not related to industrial activity (e.g., as corroborated by statistical analysis at the Guildhall site; Bowsher et al., 2007; Macphail et al., 2007).

In thin section, cess is often layered or occurs as fragmented layers. It is commonly yellow to finely speckled yellow (PPL), isotropic (XPL), dark yellowish brown (OIL), and strongly autofluorescent under BL and often includes food remains similar to those found in human coprolites, such as sheets of articulated phytoliths (cereal bran), legume testa, fine bone, and nematode eggs (Macphail and Goldberg, 2010: Figure 18) (Figures 5 and 6). This visible organic content is consistent with bulk analyses; microprobe analyses and associated Ca-P mapping show that cess is probably formed of apatite. Localized anaerobic and acidic conditions in cesspits are also believed to be responsible for the formation of Ca-P mineralized seed remains (as internal casts) (Carruthers, 2000). This is consistent with a lack of magnetic susceptibility enhancement and carbonate. Poorly preserved cess deposits have been observed at a number of sites, where the organic component has become oxidized, and the mineralized material has become finely fragmented by soil

Privies and Latrines, Figure 5 London Guildhall (London, UK): scan of 150 mm long thin section (977-1) through ditch fill within the Early Medieval (eleventh to twelfth century AD) settlement. A 20 mm thick series of yellow Ca-P cess layers toward the *top* of the thin section occur within generally organic fill composed of stabling residues and wood fragments.

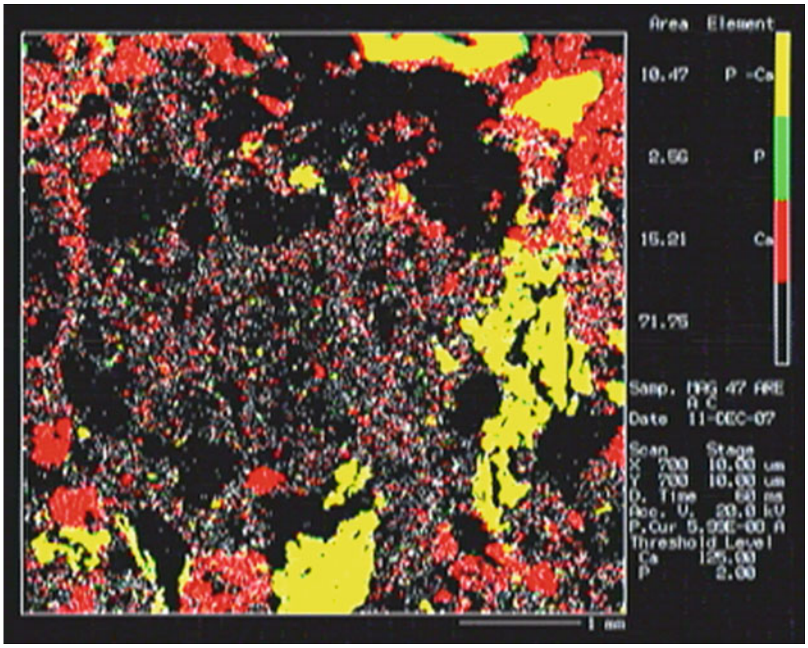


Privies and Latrines, Figure 6 London Guildhall (London, UK): photomicrograph of sample 977-1 (see Figure 5) detailing cess. Yellow phosphate embeds a number of unidentified nematode eggs (see Table 1). PPL, frame width is 0.23 mm.

fauna such as earthworms. At Monkton, intact cess was examined from a depth of 157 cm (Figure 2, lower fill). A second sample was studied from 45 cm (upper fill), where a much lower organic and phosphate content, but higher magnetic susceptibility, were recorded (Table 1). Here, a scatter of fine BL-autofluorescent cess fragments occurred within earthworm excrements.

At all three examples, pure Ca-P cess occurs within other dumped materials. At the Guildhall and Spitalfields, this included herbivore stabling waste, which itself is rich in plant material and moderately phosphate-rich (Figures 5 and 6). The Monkton deposits also included layers of charred and ashed stabling waste. Here, it can be considered that the addition of ash was a way of "sweetening" the cesspit. In theory, the contents of the toilet bucket were also "sweetened" with ash, and it can be noted that remains of such "night soil" can occur as amorphous phosphate embedding calcite ash crystals and charcoal. When such latrine-waste deposits are found in urban contexts, for example, in Late Roman London and Canterbury, it could suggest that there has been a breakdown in urban ("civilized") organization. On the other hand, this may also indicate horticultural manuring with night soil. Nevertheless, bulk, micromorphological, and microprobe studies of night soil disposal in a Late Saxon street in Canterbury, UK, and at a seventh- to eighth-century settlement at St. Julien, Tours, France, found phytoliths, plant tissues, ash, and charcoal embedded within a BL-autofluorescent Ca-P matrix, which was also present in association with non-autofluorescent amorphous Ca-P-Fe, in which blue vivianite had crystallized (Galinié et al., 2007) (see also Figure 7). In fact, amorphous phosphate, commonly including vivianite, is a good indicator of phosphatic waste disposal in general, but it may have other origins beyond latrine waste (e.g., animal waste and residues from weathered ash, bone). As such, this material has to be interpreted with caution.

Medieval castle garderobes are another source of cess. At Pevensey Castle (East Sussex, UK), occupation deposits were increasingly yellow stained upwards because of the effect of local (garderobes/cesspits) latrine outflow associated with the Norman keep (Trench 2). Microprobe confirmed Fe-Ca-P staining of soils (1.79 % Fe, 0.486 % Ca, 1.17 % P; Macphail, 2011). At the Tower of London (London, UK), garderobes drained into the moat, and although the moat fills are sediment-diluted, phosphate concentrations were sufficiently elevated alongside a very strong relationship with LOI ($r = 0.821$, $p < 0.001$) indicating inputs of organic phosphate (e.g., cess) in both thirteenth-century (Edward I) and post-medieval contexts (Macphail and Crowther, 2004). There were also strong statistical relationships between LOI and heavy metals (Cu, Pb, and Zn), possibly also implying a fecal matter source for these, although unlike

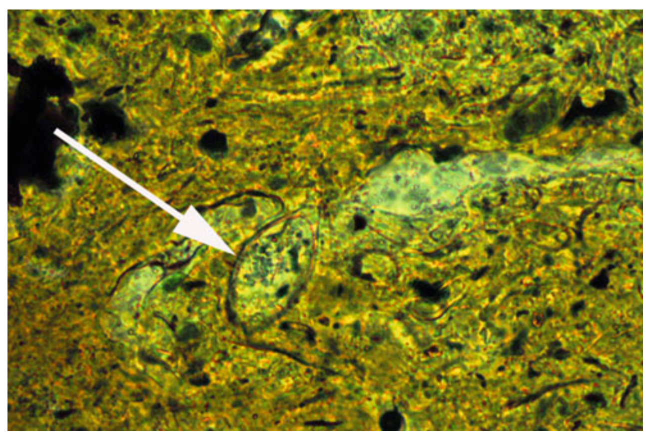


Privies and Latrines, Figure 7 Măgura, southern Romania: early Neolithic pit fill (sample 03–47); microprobe map of the distribution of Ca and P; around the edges of central burrow-mixed soil are yellow fragments of Ca-P cess (see Figure 8). Scale bar is 1 mm.

the Guildhall site (see above) lead roofing and stone "cementation," and industrial activities (Royal Ordnance, use/manufacture of brass; Cu-Zn) appear to be more important sources.

General occurrence of ancient fecal waste

Caution must be similarly employed when fine (50–500 μm) autofluorescent "cess" and/or coprolite fragments occur within occupation sediments, as these could also be of fragmented omnivore animal origin. Such "undifferentiated" fecal remains can be ubiquitous in occupation deposits including house floors and may simply record latrine-waste spillage and tracking-in. Finely layered floor deposits at the Spitalfields contemporary with the cesspit included such tracked-in fecal material. Less accidental occurrences may often persist as small or large coprolites within abandoned structures, such as the Maiden Lane and Coppergate coprolites. All kinds of pits, disused wells, midden spreads, etc., may include coprolitic waste. For example, likely human cess fragments were found in Early Neolithic pits in China (Huizui), Hungary, and Romania, for example, and the last one included a *Trichuris* egg (Macphail et al., 2008) (Figures 7 and 8). Surely, this is not accidental, but a form of human waste management.



Privies and Latrines, Figure 8 Măgura, southern Romania: early Neolithic pit fill (sample 03–47); photomicrograph of probable *Trichuris* nematode egg (*arrow*) embedded in cess. PPL, frame width is ~0.23 mm.

Summary

Deposits associated with privies and latrines are a specific sediment type that can be recognized from their chemistry and micromorphology and occasionally inclusion of recognizable food residues and parasite eggs. The probable apatite mineralogy of cess and human coprolites is recognized from their blue light autofluorescence. Cess, sensu stricto, is usually characterized using techniques such as microprobe, and human coprolites are differentiated from those of other omnivores such as dogs and pigs.

RADIOCARBON DATING

R. E. Taylor
Emeritus, Department of Anthropology, University of California, Riverside, Riverside, CA, USA

Synonyms

^{14}C dating; Carbon-14 dating

Definition

Radiocarbon is a naturally occurring radioactive isotope of carbon used as the basis for a nuclear decay method of inferring age for terminal Pleistocene and Holocene Age organic materials.

Radiocarbon time scale provides a common chronometric time scale of worldwide applicability on a routine basis using the radiocarbon (^{14}C) method. It is effective in age determination for the terminal Pleistocene and, except for the last few centuries, all of the Holocene.

Introduction

Carbon contains three naturally occurring isotopes, two of which are stable (^{12}C, ^{13}C) and one (^{14}C or radiocarbon) which is, at the nuclear level, naturally unstable or radioactive and decays with a half-life of ~5,700 years. Radiocarbon (^{14}C) dating is an isotopic or nuclear decay method of inferring age for organic materials, and it provides a common chronometric time scale of worldwide applicability for the late Quaternary. The technique is widely viewed as the geochronological "gold standard" from the perspective of its potential ability to provide generally accurate and relatively precise chronometric age assignments for a variety of organics for that time interval. Radiocarbon measurements can be obtained on a broad spectrum of carbon-containing samples including charcoal, wood, marine shell, and bone. Using conventional decay or beta counting, the ^{14}C method can be routinely employed within the age range of about 300 years ago to between 40,000 and 50,000 years ago for sample sizes between 1 and 10 g of carbon. With isotopic enrichment and larger sample sizes, ages up to 75,000 years have been measured using decay counting (Taylor, 1996, 2001).

The ^{14}C dating technique was developed at the University of Chicago immediately following World War II by Willard F. Libby (1908–1980) and his collaborators James R. Arnold and Ernest C. Anderson (Arnold and Libby, 1949; Libby et al., 1949). Libby received the Nobel Prize in Chemistry in 1960 for developing the method (Arnold, 1981).

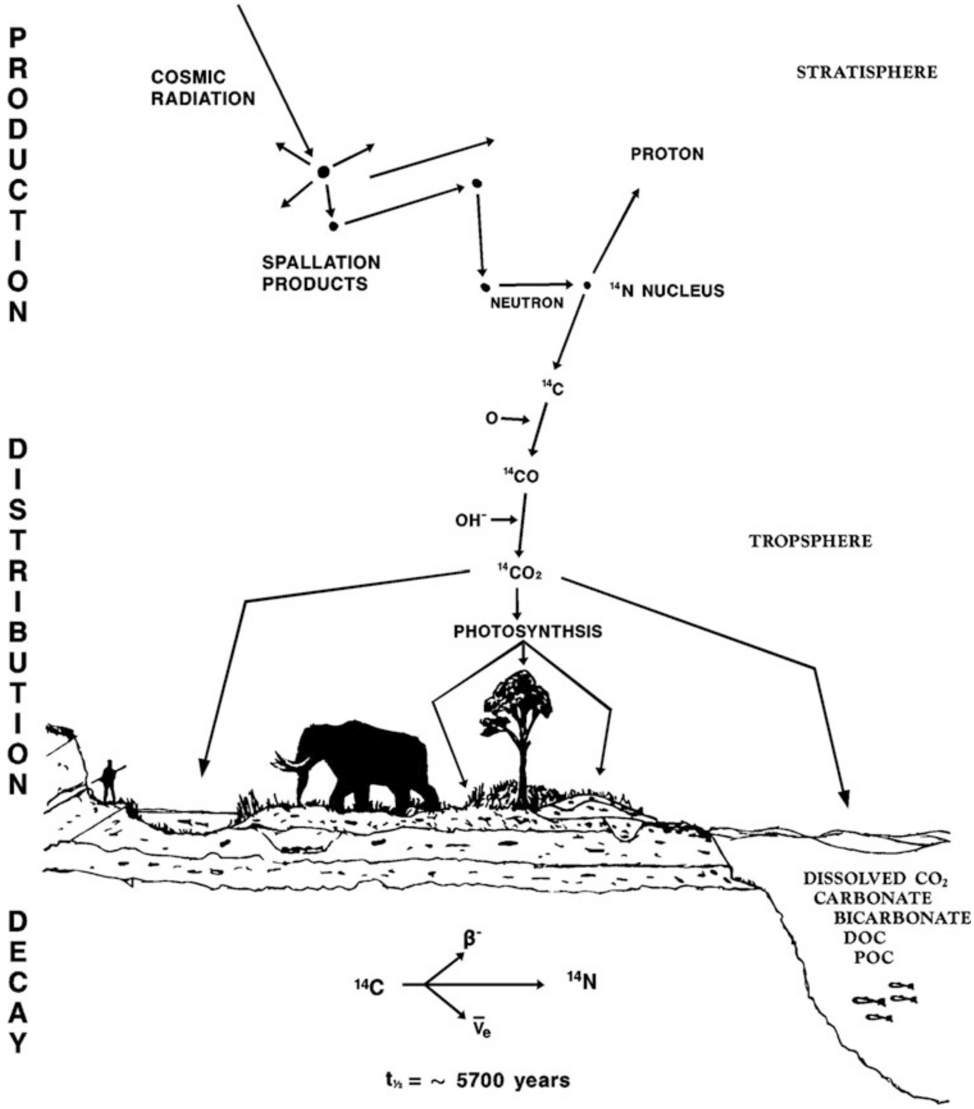
Since the 1970s, the development of accelerator mass spectrometry (AMS) for direct or ion counting of ^{14}C permits measurements to be obtained routinely on samples of 0.5–1 mg of carbon – and with additional effort on as little as 20–100 μg of carbon – with ages up to 40,000–50,000 years. In the future, the use of AMS technology may permit a significant extension of the ^{14}C time frame to as much as 80,000 years if routine strategies can be developed and consistently employed to exclude microcontamination in samples (Knezovich et al., 2007; Calcagnile et al., 2010; Chen et al., 2011).

Dating model

Carbon reservoirs

Carbon-containing compounds in a wide variety of forms are distributed throughout the Earth's highly diverse atmospheric, terrestrial, and hydrological (primarily marine, but also freshwater) environments. On different time scales and by a variety of physical or chemical mechanisms, these compounds are cycled through various actively exchanging carbon reservoirs, which are natural accumulations of carbon (i.e., forests or oceans). The carbon cycle processes are dominated by the operation

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,



Radiocarbon Dating, Figure 1 Radiocarbon dating model: production, distribution, and decay of ^{14}C (Adapted from Figure 1 in Taylor (2001)).

of two major intersecting and interacting physical and geochemical systems.

The first system involves photosynthetic cycles utilizing several complex biochemical pathways involving the fixation of atmospheric carbon dioxide (CO_2) in plant materials, incorporation of a small portion of plant biomass into animal tissue, and subsequent decomposition with the release of carbon dioxide (CO_2) and methane (CH_4) back into the atmosphere. The second system involves the cycling of various chemical species – including carbonates, bicarbonates, dissolved inorganic carbon (DIC) in the form of carbon dioxide, and dissolved and particulate organic carbon (DOC and POC) – primarily between the oceans and atmosphere. Various chemical and physical processes including the deposition of carbonates in terrestrial and oceanic sediments and volcanic activity are also involved in the operation of the carbon cycle on much longer geologic time scales (Trumbore, 2000).

Radiocarbon production, distribution, and decay

The basis of the use of ^{14}C as a dating isotope is illustrated in Figure 1 in terms of its production, distribution, and decay. The production of ^{14}C is a secondary effect of cosmic-ray interactions with the nuclei of atmospheric gas molecules. Primary cosmic rays are mostly composed of protons (hydrogen nuclei) and helium nuclei which have been accelerated to extremely high energies. Because they are charged particles, many are deflected by the various components of the magnetic field of our sun and by the Earth's dipole magnetic field. However, a small percentage of these particles, many of which continue to possess very high energies, reach the top of the Earth's atmosphere. These primary particles produce a cascade of secondary particles. Collisions of both primary and secondary particles in the stratosphere with the nuclei of atmospheric gas molecules yield a range of products through cosmic-ray spallation, including free neutrons (L'Annunziata, 2007, 399–426).

The free neutrons continue to interact with other particles, losing energy in the process. As these particles reach appropriate energies, they can react with the nucleus of ^{14}N to form ^{14}C. This natural cosmogenic (cosmic-ray-formed) ^{14}C is then rapidly oxidized by OH^- (hydroxide ions), initially to form mostly molecules of ^{14}CO (carbon monoxide), and then these ^{14}CO molecules are rapidly oxidized to $^{14}CO_2$ (carbon dioxide). In these forms, ^{14}C is distributed throughout the Earth's atmosphere, first by jet stream stratospheric winds and then by slower, but more complete, mixing within tropospheric air masses. Even though ^{14}C production at the geomagnetic poles is about five times that at the geomagnetic equator, cosmic-ray-produced ^{14}C becomes generally well mixed by the time ^{14}C-tagged CO_2 molecules reach the planetary surface and become incorporated into various forms of biota or dissolved in water at the surface of the world's oceans.

Because oceans cover almost three-quarters of the Earth's surface, the largest percentage of ^{14}C is found in marine environments as dissolved inorganic carbonates (DIC) such as CO_2, or in the form of carbonates or bicarbonates. The majority of this marine ^{14}C is found in the deeper parts of the world's oceans. A very small percentage of the Earth's ^{14}C inventory becomes part of the terrestrial biosphere, first by being incorporated into plant biomass by means of several photosynthetic pathways, then into organisms that depend on plants for food, and then up the entire food chain. Thus all terrestrial living plant and animal communities that are, directly or indirectly, dependent on plants as a food resource are tagged with ^{14}C (Usoskin and Kromer, 2005).

While individual ^{14}C atoms will decay back into ^{14}N in living tissue, they are continually being replaced through the consumption of plant or animal biomass and the physiological processing of this biomass by various life forms. These metabolic processes in most *living* terrestrial organisms maintain the ^{14}C content in *approximate* equilibrium with atmospheric ^{14}C concentrations. However, once metabolic processes cease, for example, because of the death of a plant or animal, the amount of ^{14}C begins to decrease in that organism by negative beta (β^-) decay at a rate characterized by its half-life.

The half-life ($t_{1/2}$) of any radioactive isotope expresses the time interval during which that isotope will decrease by one-half (50 %). For every subsequent half-life interval, its concentration will decrease by a factor of 2 (another 50 %). In large part because of the very high energies involved in binding the atomic nucleus together, the decay rates of radioactive isotopes are highly stable and, with relatively rare exceptions (e.g., <1 % variations in electron-capture rates), cannot be altered by ordinary physical or chemical processes operating in any natural environment that now exists on our planet.

Since ^{14}C exhibits a half-life of ~5,700 years, the amount of ^{14}C contained in a carbon-containing sample will decrease by 50 % during every 5,700-year interval following its withdrawal from an active carbon reservoir at death, unless one or more contaminating processes cause carbon-containing compounds exhibiting different ^{14}C concentrations to be added to the sample matrix.

If all of the assumptions of the ^{14}C dating model are fulfilled for a given organic sample (see next section), a measurement of the residual ^{14}C concentration can be used to infer an accurate age for that sample. However, there are many factors that can impinge on the ^{14}C activity measured in a carbonaceous sample and, thus, affect the degree to which that ^{14}C concentration can be used directly to infer accurately and precisely the age of that sample.

Assumptions

The ^{14}C age of a given sample is inferred primarily based on a measurement of its residual ^{14}C content. To be able to infer an accurate age based on that measurement (at a useful level of precision), a set of major assumptions must hold within relatively narrow limits. These assumptions can be briefly summarized as follows (Taylor, 1987, 2001):

1. The concentration of ^{14}C in each carbon reservoir has remained constant at least over the last 100,000 years (i.e., temporally consistent levels of ^{14}C worldwide).
2. Complete and rapid mixing of ^{14}C throughout the various carbon reservoirs is achieved on a worldwide basis on a time scale of less than a few decades (i.e., relatively rapid achievement of global equilibrium in ^{14}C mixing).
3. Carbon isotope ratios in samples have not been altered except by ^{14}C decay since these sample materials ceased to be an active part of one of the carbon reservoirs (e.g., at the death of an organism when its metabolic or physiological processes stop).
4. The half-life of ^{14}C is accurately known to an appropriate level of precision.
5. Natural levels of ^{14}C can be accurately measured to appropriate levels of precision.

An additional requirement for optimal utilization of the ^{14}C method is that there is a firmly documented and explicit physical contextual relationship between a well-characterized organic sample whose ^{14}C concentration is to be measured and some specific event or phenomenon to be dated (i.e., a secure link exists between the dated sample and an archaeological layer needing an age determination). Field archaeologists, geologists, or historical specialists who collect and submit samples for ^{14}C measurement are generally responsible to insure that such contextual requirements are known and reliable.

Accuracy and precision

In this discussion, "accuracy" refers to the process of obtaining a valid or correct age – the true age as opposed to one that deviates by many years. In contrast, "precision" refers to the degree of uncertainty within which a given value is expressed – usually a plus and minus estimate indicating a range within which the age is likely to fall. In ^{14}C dating studies, a realistic overall level of accuracy and precision for a given sample depends on a consideration of additional factors. When all relevant data are evaluated critically, a review of these factors often results in decreasing significantly the overall *effective* accuracy and precision of a single ^{14}C value; it tends to increase the uncertainty term**.** The measurement of precision is typically based primarily on counting statistics, and it should be regarded as providing a way of defining a *minimum* dating precision associated with a single sample.

One cannot overemphasize the importance of keeping the entire range of relevant variables in mind if one wishes to evaluate any single ^{14}C age estimate, or suite of multiple estimates, to define the effective accuracy and precision of ^{14}C age determinations. Such a consideration highlights the value of duplicating ^{14}C determinations to increase the quality of ^{14}C evidence and therefore the validity of a chronometric temporal assignment for a given feature, stratigraphic level, artifact, or cultural context.

Conventions and definitions

A set of conventions, widely accepted in the ^{14}C research community, has defined and standardized how ^{14}C age determinations are expressed. There are three widely recognized ^{14}C age expressions: (1) conventional radiocarbon age, (2) reservoir-corrected radiocarbon age, and (3) calibrated radiocarbon age.

Conventional radiocarbon age

A conventional radiocarbon age assumes: (1) the use of 5,568 (~5,570) years as the ^{14}C half-life (the original "Libby half-life"), even though the actual value appears to lie closer to 5,700 years; (2) the use of an oxalic acid ($H_2C_2O_4$) preparation – a 1957 "old" (OXI) or 1977 "new" (OXII) oxalic acid – distributed by the US National Bureau of Standards (NBS) [now known as the National Institute of Standards and Technology (NIST)], or another standardized sample material with a known ^{14}C content serving as a secondary standard to define the "zero" ^{14}C age in the terrestrial biosphere; (3) the use of AD 1950 as the zero point from which to count ^{14}C time (i.e., AD 1950 = 0 BP on the ^{14}C time scale); (4) a normalization of ^{14}C activity in all samples to a common $\delta^{13}C$ (the isotopic signature represented by the ratio of ^{13}C to ^{12}C) value to account for isotope fractionation effects; and (5) an assumption that ^{14}C concentrations in living organisms in all reservoirs have remained constant over the ^{14}C time scale. The fifth proviso means that conventional ^{14}C values are *not calibrated* (Stuiver and Polach, 1977).

Primary citation of a conventional ^{14}C age determination must always be accompanied by a term that provides an estimate of the degree of analytical or measurement uncertainty. Since statistical constraints are usually the dominant and most easily quantifiable component of the analytical uncertainty of a ^{14}C age expression, this value is sometimes informally, but strictly speaking incorrectly, referred to as the statistical "error." It is more appropriately termed the *measurement uncertainty.* This "±" term is suffixed to all appropriately documented ^{14}C age estimates. It is typically expressed at the ±1 sigma (±1σ) level, which means one standard deviation above and below the calculated age.

There has been, and continues to be, some variability among laboratories as to the procedural conventions and mathematical protocols used in the calculation of the measurement uncertainty. For this and other reasons, various suggestions have been offered from time to time as to whether some multiplier factor should be applied to such values depending on the demonstrated experimental rigor of a given laboratory in its assignment of a given analytical uncertainty. This is one of the reasons that a laboratory number and an appropriate primary bibliographic reference should be associated with each ^{14}C age citation. Over several decades, the declining practice of laboratories publishing their primary "date lists" makes it even more important that such bibliographic reference information be included in some form when the values themselves or inferences based on them are published. When such information is available, it can facilitate an appropriate examination of the technical background of the measurement when questions are raised concerning its accuracy and/or precision.

For conventional ^{14}C ages, the current practice of the journal *Radiocarbon* is to publish conventional ^{14}C dates as defined above only as BP values. For example, using this terminology, the expression of "2,500 ± 50 BP" is equivalent to "2,500 ± 50 ^{14}C years before AD 1950 where ±50 indicates the measurement precision based on counting statistics expressed as a ±1 sigma range and with the ^{14}C age expression having been normalized to a $\delta^{13}C$ value of −25 ‰" (Stuiver and Polach, 1977; Long, 2000).

Reservoir-corrected radiocarbon age

For samples from some carbon reservoirs, conventional contemporary standards may not define a zero ^{14}C age. A reservoir-corrected radiocarbon age can sometimes be calculated by first documenting the amount of apparent age exhibited in ^{14}C dates determined on modern control samples and then correcting for the observed deviation in other dates on archaeological materials with the assumption that the age of the archaeological specimen and that of the control sample have been subjected to the same offsetting environmental effects. Reservoir corrections can range from less than 100 years to, in exceptional cases, many thousands of years.

The most intensive study of reservoir effects has been undertaken for marine organisms, specifically the carbonate component of marine shells. Reservoir corrections of ages obtained from marine shells currently employ regionally based numerical expressions which define the difference between the worldwide "average" age observed for marine organisms and that exhibited in a particular part of the marine reservoir from which a sample has been obtained. Unfortunately, not only are marine reservoir correction values geographically variable but, in addition, in some regions, these values also change significantly over time (e.g., Taylor et al., 2007). For some samples, especially those from certain nonmarine environments, it is difficult to obtain accurate and consistent reservoir corrections. For example, freshwater gastropods can exhibit great variability in their initial ^{14}C concentrations, reflecting in some cases annual seasonal variations in sources of carbonates in their environments as well as other factors.

Calibrated radiocarbon age

A calibrated radiocarbon age takes account of the fact that ^{14}C activity in living (or zero age) organisms *on a worldwide basis* has not remained constant over time. The offsets, or increases and decreases in ^{14}C abundance, are generally referred to as representing *secular variation* in the radiocarbon time scale (Suess, 1965). Because of these secular variation effects, one must distinguish between "^{14}C time" as defined by conventional ^{14}C ages and "real time" as expressed by a calendar, solar, or calibrated age. Secular variation has been viewed as exhibiting two major components: long-term or major trends and shorter-term higher frequency offsets. The shorter-term perturbations are often referred to as de Vries effects, named after the Dutch scientist, Hessel de Vries, who first focused attention on them (de Vries, 1958). The shorter-term perturbations are sometimes also referred to as "wiggles" or "warps" in the radiocarbon time scale.

As noted above, conventional ^{14}C ages are expressed with the notation BP (before [the] present) and defined in terms of several parameters. Calibrated ^{14}C values are typically expressed with the notation cal BP, cal BC, and/or cal AD. Some publications employ a terminology that includes or substitutes the expressions "CE" (Common or Current Era) for AD and "BCE" (Before [the] Common or Current Era) for BC.

The existence of ^{14}C secular variation reflects the fact that, contrary to the conventional assumption, the concentration of ^{14}C in each carbon reservoir has not been constant over geologically recent times. The long-term variations in ^{14}C concentrations have been largely traced to changes in the intensity of the dipole magnetic field of the earth while the short-term variations are associated with changes in components of the magnetic field of the sun together with various environmental parameters such as exchange rates among the carbon reservoirs

Because of these offsets, "radiocarbon years," as expressed by conventional ^{14}C ages, and "real years," as determined by solar or calendrical reckoning, are not of equal duration for most periods. Since varied terms for "real time" (e.g., solar, sidereal, calendar, or calibrated time) have tended to be used interchangeably, this discussion will use "calendar" or "calibrated" to designate it. Some have nevertheless argued that the term "solar" years would be more appropriate because, strictly speaking, there are (and have been) different types of calendars in use, not all of which have used solar years as the basis of recording the passage of time (Stuiver and Suess, 1966).

Calibrating ^{14}C values into calendar years was initially achieved by consulting tables or plots of the relationship between ^{14}C dates obtained from tree rings that were dated independently through dendrochronology (tree-ring dating). Such a comparison revealed for different periods the amount of offset between ^{14}C dates based on single tree rings or on 10 to 20 tree ring segments and the equivalent solar time based on dendrochronological determinations of the age of that wood sample. With increasing precision of the calibration datasets – initially for the Holocene and now increasingly for the terminal Pleistocene as well – together with the widespread availability of microcomputers and the Internet, a number of approaches using computers and web sites to enable the calibration process are now available.

Figure 2 is a plot of the offset (in years) between calendar (or calibrated) time and ^{14}C time for the period from 0 to 15,000 calendar years BP; the plot is based on the IntCal09 dataset (Reimer et al., 2009). The relationship between ^{14}C ages and calendar ages from 0 to 12,550 cal BP has been calibrated using dendrochronologically dated wood, while the interval from 12,550 to 15,000 years has been calibrated on the basis of paired uranium series/^{14}C dates on samples of corals and foraminifera from marine cores. The ages established from the dendrochronological or uranium-series determinations are plotted on the horizontal axis, while the difference in years between the known age and the ^{14}C age of the calibration samples is plotted on the vertical axis. The data points that are plotted below the "0" line (the period from about 500 to 2,000 BP) indicate conventional ^{14}C values are "too old" with reference to calendar time (meaning that during that period there was somewhat *less* ^{14}C in living materials as compared with ^{14}C contained in recent living materials on a worldwide basis), while the data plotted above the "0" line indicate conventional ^{14}C values are "too young" with reference to calendar time (meaning that during that period there was somewhat *more* ^{14}C in living materials as compared with ^{14}C contained in recent living materials on a worldwide basis). As an example, the data plotted in Figure 2 indicate that conventional ^{14}C age determinations are a little over 1,000 years "too young" at 10,000 cal BP.

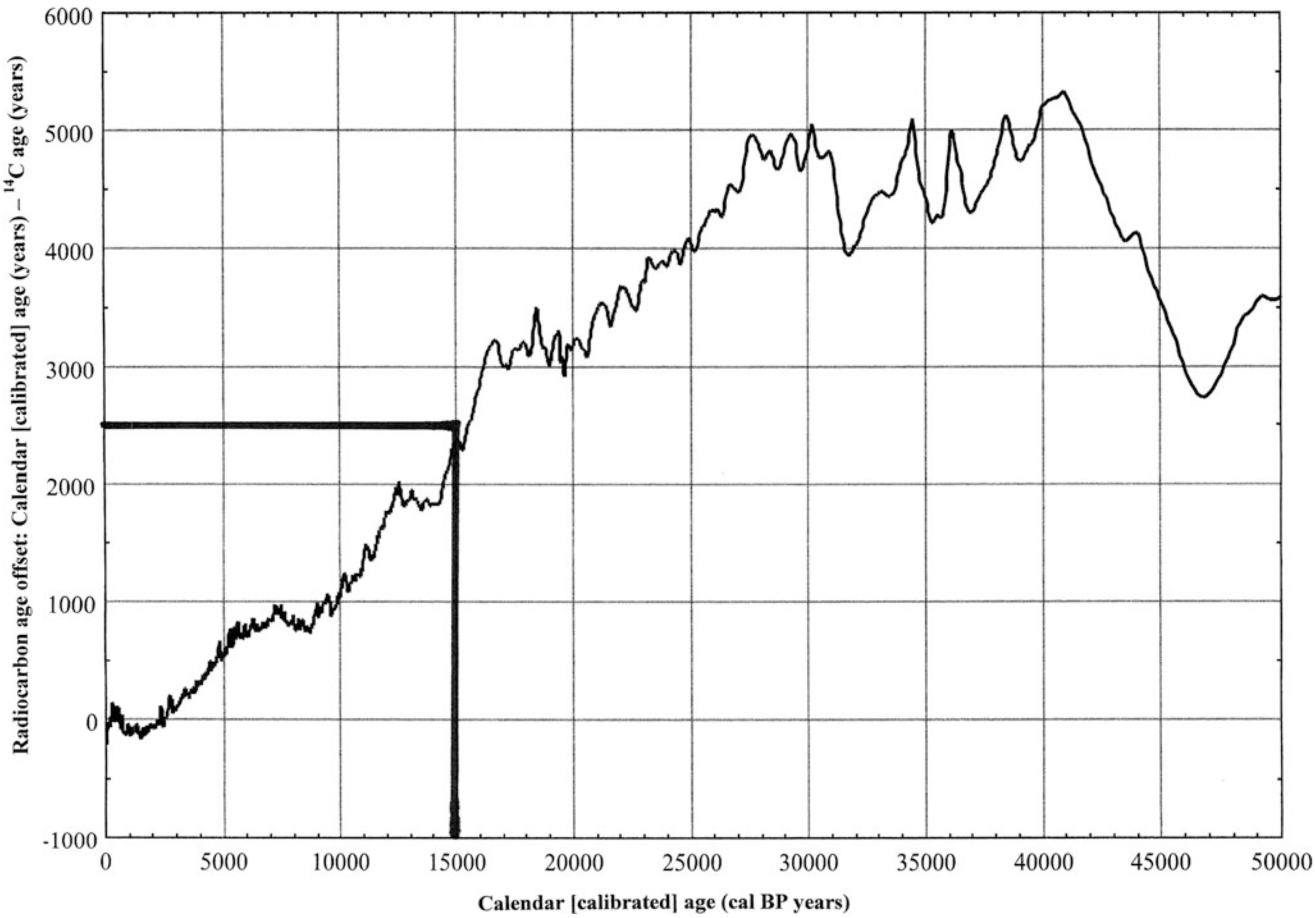
Radiocarbon Dating, Figure 2 Secular variation: major trends over the period 0–15,000 cal BP showing deviations (in years) between calendar/calibrated time and ^{14}C time. Offset values (on the vertical axis) are expressed in calendar/calibrated years based on the IntCal09 data set (Reimer et al., 2009) (Plot by J. R. Southon, University of California, Irvine).

Figure 3 plots the offset from 0 to 50,000 years using the same calibration data set as in Figure 2 (Reimer et al., 2009). The time period covered by Figure 2 is indicated by the rectangle in the lower left corner of Figure 3. As in Figure 2, those conventional ^{14}C values registering "too old" are plotted below the "0" line, and those registering "too young" are plotted above the "0" line. For example, Figure 3 indicates that a conventional ^{14}C age determination is about 4,000 years "too young" at 25,000 cal BP.

Figures 2 and 3 clearly illustrate the long-term trends in ^{14}C secular variation offsets. One can also note in both figures the shorter-term, rapidly changing "warps" in the radiocarbon time scale. The implications for calibration of ^{14}C values due to the magnitude of some of these short-term variations are illustrated in Figure 4. Calibration of the conventional ^{14}C value of 2,300 ± 15 BP is illustrated in Figure 4a, while calibration of 2,450 ± 15 BP is presented in Figure 4b. On the vertical axis of both parts of this figure, the ^{14}C ages of the two examples are plotted to show their $\pm 1\sigma$ (dark shaded area) and $\pm 2\sigma$ (dark and lighter shaded areas) ranges. The dark shaded irregular curves of varying width running approximately diagonally through these plots represent the relationship between the ^{14}C ages and the known ages of the series of samples used for ^{14}C calibration (Stuiver and Reimer, 1993).

Because of the variable or "accordion-like" characteristics of the plotted relationship between ^{14}C time and calendar time as illustrated in this mid-1st millennium BC period, the calibration of these two ^{14}C ages, which are only 150 years apart in ^{14}C years, reveals that the "real-time" equivalents of these two ^{14}C ages are significantly different. The calibration data associated with the 2,300 ± 15 BP ^{14}C-content-inferred age (Figure 4a) reflects a period when the contemporary ^{14}C activity in the atmosphere was undergoing rapid change as shown by the curve with a steep slope. This allows a much more precise resolution of the real-time equivalents of a given ^{14}C concentration measured in a sample. As plotted on the horizontal axis of Figure 4a, the $\pm 2\sigma$-based calibrated range for 2,300 ± 15 BP ranges over a 30-year spread from 400 BC to 370 BC.

In contrast, the calibration data associated with the ^{14}C age of 2,450 ± 15 BP falls on a lengthy plateau formed by



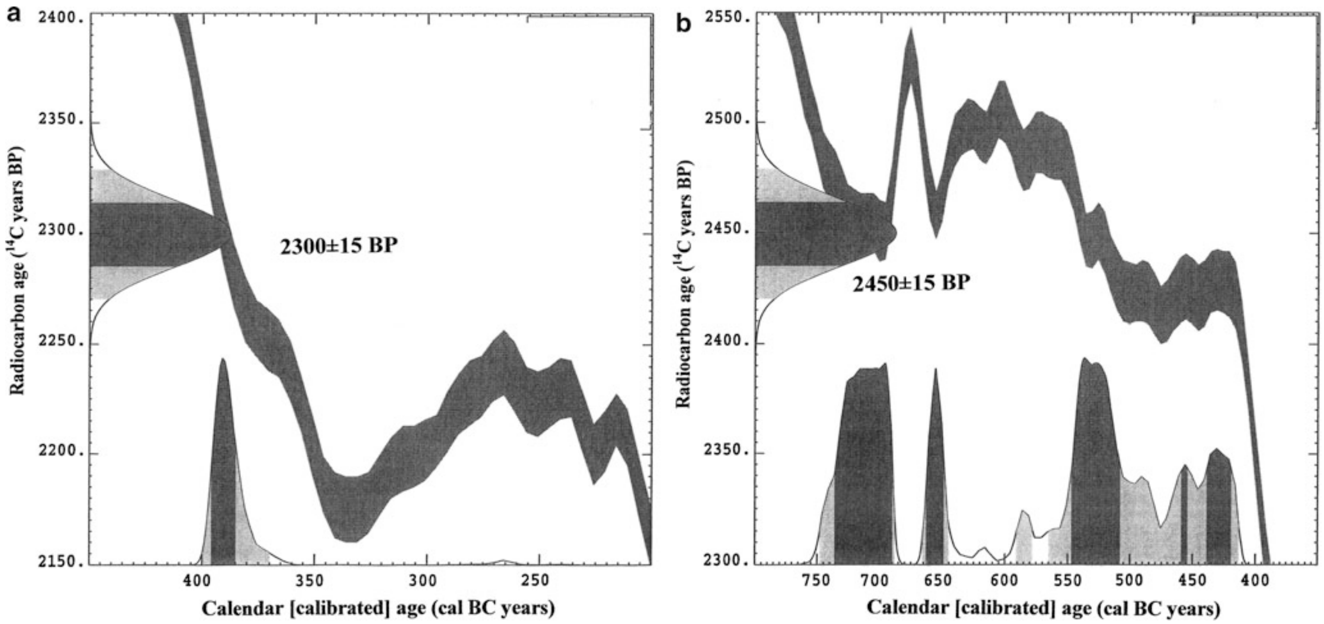
Radiocarbon Dating, Figure 3 Secular variation: major trends over the period 0–50,000 cal BP showing deviations (in years) between calendar/calibrated time and ^{14}C time. The rectangular area in lower left corner defined by heavy lines represents the coverage of the secular variationplot illustrated in Figure 2. Offset values (on the vertical axis) are expressed in calendar/calibrated years based on the IntCal09 data set (Reimer et al., 2009) (Plot by J. R. Southon, University of California, Irvine).

some complex "wiggles" in the ^{14}C time spectrum. In this case, the ^{14}C activity in calibration samples ranges over about a 350-year period. These data indicate that, during this period, the ^{14}C time scale is "warped" or significantly spread out, i.e., the ^{14}C content of samples, on a decade by decade and century by century basis, had not been changing as rapidly as it had only 150 years previously. In Figure 4b, the plotted ^{14}C value intercepts at multiple points and at varying levels of statistical significance, the calibration data over almost the entire 350-year time span of this plateau. Thus the calendar age equivalents of this particular ^{14}C value as expressed at various levels of statistical significance range over the 350-year spread from about 750 to 400 BC.

Defining the lower ^{14}C dating limit

The routine lower dating limit of the ^{14}C method is typically considered to be ~300 calendar years before present, which is equivalent to ~200 ^{14}C years. The physical basis of the lower limit is primarily the product of the interplay of three factors – one of which reflects natural short-term ^{14}C perturbations while the other two are caused by anthropogenic or human impacts. Any statement concerning a lower limit also must take into consideration the statistical precision associated with a given ^{14}C determination. For samples with uncertainty terms of >80 years, the lower ^{14}C dating limit may have to be extended beyond 300 calendar years by up to another century. In most cases, the interaction among these three physical factors together with statistical considerations associated with ^{14}C age measurements produces an ambiguous relationship between ^{14}C content and chronometric time for materials that were living during the last two centuries. Under certain rare circumstances, it is possible to assign a finite age younger than 300 calendar years.

The three major factors which generally limit the resolution of younger ages include: (1) recent natural short-term variations (de Vries effects) in atmospheric ^{14}C concentrations caused primarily by variations in several



Radiocarbon Dating, Figure 4 Secular variation: de Vries effects and their influence on dating precision. (**a**) Calibration of 2,300 ± 15 BP ^{14}C years yields a narrow range of uncertainty of about 30 years. (**b**) Calibration of 2,450 ± 15 BP ^{14}C years yields a wider range of uncertainty of about 350 years (Data from Reimer et al. (2009). Plot by CALIB 6.0; Stuiver and Reimer (1993)).

components of the solar magnetic field or solar wind; (2) the Fossil Fuel, Industrial, or Suess Effect which, beginning in the late eighteenth century, involved the introduction of ^{14}C-free CO_2 into the atmosphere as the result of the combustion of various types of fossil fuel carbon compounds, such as that contained in coal, and then later from petroleum-based products such as gasoline (Suess, 1955); and (3) the nuclear or Libby Effect which, beginning in the mid-1940s, initiated the production of artificial ^{14}C ("bomb ^{14}C") as a consequence primarily of neutrons produced during the detonation of thermonuclear weapon devices in the atmosphere in the early 1960s.

By the early 1950s, the effect of the Industrial/Suess Effect depressed the ^{14}C concentration in the atmosphere by almost 3 %. That process was reversed with the production of bomb ^{14}C which by 1963 had almost doubled the amount of ^{14}C in the atmosphere. These effects were significantly less in marine environments because of the much larger percentage of ^{14}C in the oceans, which moderated the rates of change. Atmospheric bomb ^{14}C levels peaked in 1963 because most atmospheric nuclear weapon testing was halted by the first international test ban treaty. This was followed by a slow decrease as this ^{14}C mixed into other carbon reservoirs.

In general, as a consequence of the complex interplay of these two anthropogenic factors combined with post-sixteenth-century natural ^{14}C perturbations, ^{14}C data cannot be employed to assign a specific age to materials dating to less than about two centuries except under special circumstances and usually with extended efforts. By convention, any sample exhibiting an age equivalency from 0 to 200 BP can be referred to as "modern," and any sample whose ^{14}C content exceeds that of the contemporary standard (i.e., contains bomb ^{14}C) may be referred to as ">modern," i.e., "greater than modern" (Stuiver and Polach, 1977).

Defining the upper ^{14}C dating limit

The current routine ^{14}C upper dating limit, expressed in terms of ^{14}C infinite ages, currently ranges between about >40,000 and >60,000 years depending largely on the characteristics of instrument configurations and computational protocols in different ^{14}C laboratories. Infinite ages, identified by the prefixed "greater than" (>) symbol, generally indicate that the ^{14}C concentration measured in a sample cannot be distinguished from the background values characteristic of a given counting system at some explicitly defined level of statistical significance**.** Background count rates, or $^{14}C/^{12}C$ ratios, are obtained from samples of sufficient geological age that it can be reasonably inferred that they no longer contain measurable amounts of cosmic-ray-produced ^{14}C.

The specific values of the counting background are unique to every instrument system. The maximum infinite ^{14}C ages expressed are a function of the characteristics of a given counting system, which include factors such as the magnitude and stability of the backgrounds, the ratio between that value and the value associated with contemporary ^{14}C reference standards, and the statistical protocols employed in a given laboratory.

The principal *physical* basis of this upper age limit is a function of the decay rate of ^{14}C which, after 8–10 ^{14}C half-lives, reduces ^{14}C concentrations in natural samples below the effective detection levels that are currently routinely possible, whether one uses conventional decay (beta) counting or direct (ion) counting by accelerator mass spectrometry (AMS) technology. An additional factor is the significant challenge of removing modern or significantly younger contamination during the preparation of samples with infinite ages in excess of 40,000–50,000 years.

An extension of the upper dating limit to ~75,000 years has been achieved in several decay counting laboratories on a relatively small number of samples by the combined use of isotopic enrichment and very low and stable background decay counting instrumentation. Isotopic enrichment is accomplished by artificially increasing the concentration of ^{14}C in a sample and monitoring the amount of that enrichment by measuring $\delta^{13}C$ values in the sample. The counting characteristics in these facilities were made possible in most cases by employing special experimental arrangements, such as counting instrumentation located 10–30 m underground to minimize background levels. With regard to the upper dating limit for facilities employing AMS technology, one laboratory reported the equivalent of a 60,000-year measurement on a sample of wood from the Pliocene epoch (5.3–2.5 Ma ago), and another facility obtained the equivalent of an 80,000-year measurement on a special background blank (diamond) as a means of monitoring operating characteristics of an instrument component (Kirner et al., 1997; Taylor and Southon, 2007). However, the *routine* extension of the effective ^{14}C time scale beyond 50,000 years using AMS technology will largely depend on future research that includes the ability, on a long-term consistent and reproducible basis, to minimize carbon microcontamination introduced during the various stages of sample preparation.

Because of misunderstandings of the nature of low-level counting technology terminology employed in some popular treatments, it is probably helpful to emphasize that the >60,000- or >80,000-year figures cited here as examples are *infinite age expressions*. These figures simply indicate the maximum age equivalent that can be inferred from counting data exhibited in a particular instrument using standard statistical protocols for a specific sample. All that can be meaningfully deduced from such expressions is that the ages quoted indicate that the sample ages are *in excess by an unknown amount of the value cited*. The amount of time involved can literally range from a few hundred to many hundreds of millions of years.

Prominent geological and archaeological applications

Of the estimated 500,000 ^{14}C age determinations processed since 1946, some suites of ^{14}C measurements have been applied to topics that elicited special attention from archaeologists and Quaternary geologists. A few of the most prominent scientific applications are briefly noted below.

Two Creeks fossil forest (Wisconsin): Pleistocene/Holocene boundary

For geologists, one of the principal terrestrial characteristics of the Pleistocene epoch was the multiple waxings and wanings of large continental glaciers in North America and northwestern Europe. In the late nineteenth and early twentieth centuries, four major glacial and four major interglacial stages were identified based on the sequence of sediments (glacial moraines) associated with the maximum extent of the glacial advances that were identified in the European Alps. One question raised was whether the most recent of these major glacial periods in Europe, called the Würm, was coincident in time with the last major glacial phase identified in North America, called the Wisconsin.

A number of localities contain geological evidence of events associated with the terminal Wisconsin, and many have been examined. In some of these sites, sediments associated with the retreat of the ice mass, followed by a temporary advance, and then a final retreat have been documented. This series of events has been studied in great detail in sediments located in and around Two Creeks, Wisconsin, a locality on the western shore of Lake Michigan. On land abandoned by the retreating North American Laurentide Ice Sheet, a forest developed. This forest was then subsequently overrun as the glacier temporarily moved south again during the brief colder event called the Valders ice advance. The final retreat of the ice followed thereafter. The geological evidence of this glacial retreat-advance-retreat interval is the Two Creeks fossil forest.

In the pre-^{14}C period, the Two Creeks interval had been dated between 24,000 and 19,000 years ago based in part on the correlation of North America varve sequences with those in Scandinavia. In an early group of ^{14}C dates run by Libby, seven samples of wood and peat collected from the Two Creeks forest bed and from two nearby sites exhibiting the same stratigraphy were dated. The resultant ^{14}C ages ranged from 10,877 ± 740 BP to 12,168 ± 1,500 BP and were averaged for a composite age of 11,404 ± 350 BP (Libby, 1952, 88). By 1963, 14 additional ^{14}C measurements on wood or peat from Two Creeks and adjacent localities had been obtained by four other laboratories. Two of these dates were clearly aberrant. The remaining 12 measurements spanned 10,400 ± 600 BP to 12,200 ± 400 BP. The average of the 19 acceptable measurements obtained up to that date was 11,350 BP. If only measurements associated with statistical errors of less than 500 years obtained by newer technologies were averaged, the value was 11,600 BP (Broecker and Farrand, 1963).

Additional ^{14}C measurements on samples collected from the Two Creeks locality in the 1990s yielded a range of dates from 11,640 ± 160 BP to 11,800 ± 160 BP which, when the error terms in the measurements were considered, essentially confirmed the earlier suite of measurements. Cross dating tree rings from a series of tree segments recovered from Two Creeks sediments indicated that forest growth in this area occurred over a period between 200 and 300 years (Leavitt and Kahn, 1992).

Tule Springs, Nevada: Clovis or pre-Clovis?

In the early 1960s, the decision to undertake large-scale excavations at Tule Springs, Nevada, was stimulated in large part by a single ^{14}C determination of >23,000 years obtained by Libby's Chicago group (Libby, 1952, 121). The sample analyzed was characterized as "charcoal" recovered from what had been labeled a "hearth-like feature" by earlier excavators at the site, who associated it with sediments containing the bones of extinct fauna. The significance of this date from the site was that it suggested an antiquity for the initial peopling of the New World significantly earlier than was realized in the 1950s. By that time, the earliest well-documented hunters and gatherers in North America were those associated with a distinctive fluted projectile point known as Clovis and commonly found in mammoth kills, followed by groups who made the distinctive Folsom point associated with late Pleistocene bison (Sellards, 1952). Subsequent radiocarbon dating by Libby (1955) and others suggested that Clovis and Folsom occupations dated around 10,000 ^{14}C years BP. The date in excess of 23,000 BP from Tule Springs was obviously of considerable interest to many New World archaeologists.

Prompted by the very early ^{14}C determination, extensive excavations were carried out at Tule Springs in the early 1960s. This work represented one of the first examples in New World archaeology of a research design that included recovery of a large suite of ^{14}C samples during the excavation campaign, and a total of 59 ^{14}C determinations were obtained from Tule Springs and associated sites.

After the 1960s excavations, the only uncontested artifacts recovered at Tule Springs were associated with sediments dating in the 10,000–11,000 BP range. No artifacts were associated with earlier sediments. More significantly, the features originally identified as "hearths" containing "charcoal" were determined to be concentrations of decayed plant remains associated with water channel debris or spring deposits.

The results of the research at Tule Springs led to the site's removal from the category of potential pre-Clovis localities. More broadly, the Tule Springs project demonstrated the need for an on-site geoarchaeologist (in this case it was C. Vance Haynes, Jr.) to document the stratigraphic context of ^{14}C samples in the field, to evaluate their origins, and to interpret the resulting dates (Haynes et al., 1966).

Monte Verde (Chile): pre-Clovis in South America?

Beginning in 1976, excavations at Monte Verde, a site located in the Lakes region of south-central Chile, recovered a wide-ranging cultural assemblage of wood, stone, fiber, and bone materials in seemingly well-defined, multicomponent, stratigraphic contexts with associated wood and charcoal samples. During the course of a decade, 35 ^{14}C determinations were obtained from several kinds of samples from this site. The earliest ^{14}C dates reported as being clearly associated with artifacts and other cultural materials ranged from 12,230 ± 140 to 12,780 ± 240 years BP (Dillehay, 1989, 1997; Dillehay et al., 2008).

If these ^{14}C values from Monte Verde are, on the whole, accepted as valid, it would indicate that the lithic artifact inventory from Monte Verde, which appears to have no developmental relationship to the Clovis assemblages of North America, was present on the coast of South America ten centuries prior to Clovis. Acceptance of the validity of this conclusion renewed discussions about how humans could arrive in South America so early, i.e., which routes were taken by early human populations as they moved south from presumed entry points in eastern Beringia into the New World. If humans were indeed present on the coast of Chile a millennium prior to Clovis, then a migration route might reasonably be sought along Pacific coastal zones and not through the narrow ice-free corridor between the Laurentide and Cordilleran ice sheets in the northwestern interior of North America. Unfortunately, many of the sites where evidence of a coastal route might be found are submerged beneath as much as ~100 m (~300 ft) of the ocean as a consequence of the terminal Pleistocene-early Holocene rise in sea level inundating the coastal plains.

Naturally with such an important and controversial site, considerable discussion arose about the integrity of the artifact assemblage, including the quality of the associations claimed with ^{14}C values at all levels in the site. Potential problems with the validity of ^{14}C values from Monte Verde have been addressed in several studies (e.g., Taylor et al., 1999). The excavators argued that there was no reasonable basis on which to suspect major sample contamination given the range in materials that were sampled, the overall consistency in the values obtained, and the character of the sediments from which the samples were recovered. However, attention had been called to a significant ^{14}C dating anomaly centered on a single sample from Monte Verde. Two segments of the same mastodon bone yielded ^{14}C ages of 6,550 ± 160 BP and 11,990 ± 200 BP. A redating of both of these segments using molecular fractions (total amino acids and ultrafiltered gelatin) isolated from both segments yielded a set of four ^{14}C values ranging from 12,455 ± 40 BP to 12,510 ± 60 BP. In this way, the younger ^{14}C age assigned to one of the mastodon bone segments was demonstrated to be clearly erroneous (George et al., 2005).

Others have pointed to the possibility of major marine and/or terrestrial reservoir effects on samples from the vicinity of the site. The basis for this inference is that there are several active and extinct volcanoes situated along a north/south axis at the western base of the Cordillera de Los Andes. However, all of them are situated to the east and thus leeward of Monte Verde with the closest located ~65 km southeast of the site. Because the current prevailing winds consistently blow from the coastal zone located ~45 km to the west of the site, volcanic emissions from known volcanoes would not be expected to reach the region around Monte Verde. Even if wind patterns in the late Pleistocene were such that trace amounts of CO_2 laden magmatic gas (which would be "dead" with respect to ^{14}C content) might be present, attenuation factors would be significant, and any postulated effect would be expected to produce, at most, an offset of a few hundred years, unless a heretofore unknown magmatic vent existed closer than a few tens of meters from the site. Although questions remain and studies continue (e.g., Dickinson, 2011), there is currently no evidence of major anomalies which could significantly affect the validity of the Monte Verde ^{14}C values.

The Kennewick human: the most complete early Holocene Paleoamerican skeleton

In 1996, first a skull and then, over a period of several months, a substantial number of postcranial bones were recovered from a lake created by a dam in the Columbia River near the community of Kennewick in the state of Washington. This skeleton, found in shallow water sediments adjacent to a collapsing embankment, exhibited morphological features which, to some biological anthropologists, appeared to be distinct from those exhibited by contemporary Native American populations. The initial suggestion was that it represented an early Euro-American settler, but it was then observed that the bones exhibited several morphological characteristics indicating a possible connection to several ancient Southeast Asian populations (Chatters, 2001). Multiple ^{14}C determinations established the age of the Kennewick skeleton as being early Holocene in date – in excess of 7,000 BP (Taylor et al., 2001). The implications of these two apparent facts – an early Holocene age and a distinct anatomical morphology – for understanding the processes involved in the peopling of the Western Hemisphere from Asia continue to be debated.

One immediate question raised by the Kennewick skeleton is whether one or more early Holocene New World hunter and gatherer groups may have at some point in the Holocene become extinct, thus leaving no living Native American descendants. This possibility has prompted the development of a distinction between Paleoamerican, i.e., early New World populations which may have no modern descendants, and Paleoindian, i.e., early New World populations having modern Native American descendants.

Ötzi, the Iceman: European Chalcolithic mummy

Radiocarbon determinations were employed to assign an age to mummified human remains discovered in 1991 within an ice field on a mountain pass in the Ötztal Alps on the Italian side of the border with Austria. Results of ^{14}C measurements on the corpse, clothes, gear, and associated plant remains, including mosses, of Ötzi, the iceman, indicated that he had died about 5,300 years ago, placing his lifetime within the European Chalcolithic or Copper Age (Prinoth-Fornwagner and Niklaus, 1994; Dickson et al., 2003, 2005).

The mummy has received widespread publicity as well as extensive scientific studies in an attempt to determine where the individual had lived, his dietary habits, and cause of death. He appears to have died from blood loss due to an arrow wound; thus he met a violent end. A recent examination of the distribution of the artifact materials associated with the body has led to the suggestion that the original context of Ötzi had been a "ceremonial burial" along with grave goods, the contents of which had been later dispersed when the grave environment thawed, and the body and its contents slumped downwards into a rocky hollow that preserved it from deterioration through exposure and destruction by glacial ice that covered the location (Vanzetti et al., 2010). This interpretation has been rebutted by Zink et al. (2011).

The Shroud of Turin

Probably the most widely known example of the use of ^{14}C to determine the true age of an important cultural object was its application to the Shroud of Turin, a piece of linen that many Christian adherents believe had captured the real image of Jesus of Nazareth when he was wrapped in it after his crucifixion. The question was whether the object dated from the first century CE when the execution occurred or the later part of the fourteenth century CE when the shroud was first noted in the historical record. Results of dating of the Shroud of Turin by three AMS ^{14}C laboratories determined that the flax from which the linen had been woven was growing at some point between the late thirteenth and the late fourteenth centuries CE (Damon et al., 1989). Thus, the Shroud of Turin was determined to be, in fact, a European medieval artifact. Concerns have been voiced by some that repairs or contaminations to the cloth may have skewed its dating, making it appear more recent than Roman in age, but such criticisms have been addressed, and the medieval date is considered reliable among dating specialists (Freer-Waters and Jull, 2010).

Summary

The "radiocarbon revolution" (Renfrew, 1973) initiated more than six decades ago by Willard Libby and his research collaborators actively continues, with ^{14}C typically playing a central role as the court of final appeal for archaeological chronology. Radiocarbon data often serve as the prime arbiter in resolving uncertainties and controversies about the chronological ordering of cultural materials, including in some cases historical period artifacts of problematic authenticity as well as human skeletal remains of disputed age.

For archaeologists and geologists, the most immediate and obvious impact of the ^{14}C method on the conduct of archaeological research has been the availability of a fixed-rate temporal scale of worldwide applicability for the late Quaternary. In providing a common frame of temporal reference for the late Pleistocene and Holocene, ^{14}C data has made possible a prehistory of the world by providing a time scale that transcends local, regional, and continental boundaries. As Grahame Clark (1970, 38) noted, radiocarbon "has contributed more than any other single factor to complete the world coverage of prehistoric archaeology, not to mention the way it has helped scholars to synchronize phenomena in different parts of the world." Without the time scale provided by ^{14}C data, prehistorians would still be, in the words of the late J. Desmond Clark, "foundering in a sea of imprecisions sometimes bred of inspired guesswork but more often of imaginative speculation" (Clark, 1979: 7).

For archaeologists, a less immediately recognized contribution of ^{14}C data has been the fact that ^{14}C-based age estimates provide a means of deriving chronological relationships totally independent of assumptions about cultural processes and completely unrelated to any type of manipulation of artifacts. When pressure to derive chronology primarily from the analyses of artifact data was reduced, inferences about the evolution of human behavior based on variations in environmental, ecological, or technological factors could be aggressively pursued employing an independent chronological framework (Bronk Ramsey, 2008).

The great technical success of the ^{14}C method also encouraged a major impetus for interdisciplinary research. It represented one of the major catalysts that moved both geologists and archaeologists increasingly to direct their attention toward analytical and statistical approaches in the manipulation and evaluation of data, as well as to maintain long-term collaborative relationships with colleagues in other scientific disciplines. It was therefore entirely understandable that an early proponent of interdisciplinary studies in archaeology, Frederick Johnson, also became an early advocate of the ^{14}C method among his colleagues. The general theme of his concerns at the inception of the method is still relevant as we observe the continuously expanding horizons of ^{14}C application in archaeological and geoarchaeological studies: "[P]rogress in the development of . . . [radiocarbon dating] depends to a large degree upon the character of the collaboration [between archaeologists and other scientists]. The laboratory procedure involves theories in physics and chemistry which for the most part are outside the experience of almost everyone who has a sample to be dated. On the other hand, the results secured are of little consequence unless they are directly or indirectly related to some stratigraphic sequence. The value of the laboratory results is enhanced by critical evaluation by other scientists. Most particularly, the reverse is true. This involves continual examination of all basic theory and hypotheses by everyone concerned. The future value and usefulness of the method depends in large measure upon the success of continued collaboration between physicists, archaeologists, geologists, botanists, and others" (Johnson et al., 1951, 62).

This injunction assumed an even greater significance with the introduction of accelerator mass spectrometry (AMS) technology for ^{14}C measurements. AMS methods permit analyses to be conducted on microgram amounts of organics and open up the possibility of extending the ^{14}C dating range. For archaeologists and Quaternary geologists, the utilization of submilligram-size samples will require even more rigorous attention to the evaluation of geological, geochemical, and archaeological contexts of samples. The need for interdisciplinary cooperation and collaboration will become even more critical as AMS technology assumes an ever increasing role in the ^{14}C measurements of archaeological and other late Quaternary paleoenvironmental and paleoecological materials.

Definition

Raman spectroscopy is a technique used to identify and characterize organic and inorganic compounds, and it has been used in the examination of materials possessing archaeological significance (Smith and Clark, 2004; Vandenabeele et al., 2007). It relies on inelastic scattering (i.e., Raman scattering) of monochromatic electromagnetic radiation, typically a laser, interacting with molecular vibrations in a sample. Specifically, photons of incident light strike the surface of a target specimen, and most of the photons are absorbed, reflected, or transmitted by the target material. A small part of the photon beam interacts with the specimen by deforming the atomic charge and inducing an instantaneous dipole moment in the molecule under investigation. Molecules affected in this way are excited to a higher energy state that is unstable and decays immediately; the decay process occurs mostly by elastic scattering (known as Rayleigh scattering) in which the molecules emit photons of equal energy and return directly to their original ground state of vibration. A small percentage of the photon emission is inelastic and leads to Raman scattering, which means that energy is emitted at levels both higher than and lower than that of the elastic Rayleigh scattering, i.e., the incident photon energy is not conserved. The frequency shift corresponding to the energy difference (positive or negative) between the incident and inelastically scattered photons is termed the Raman shift, and it is this aspect that informs about the target material by revealing spectra that are determined by its atomic and molecular composition.

Raman spectra can be plotted by graphing the energy differences between incident and Raman scattered photons against wave number/cm^{-1} (number of waves per cm). If the deformation of the electron charge caused by incident photons corresponds to a vibrational state of the molecule, the mode is Raman active, and a Raman scattering peak will be observed. The shape of a resultant curve with its peaks is typical of both elemental and structural features of the specimen and can be used for accurate identification and characterization of the compounds analyzed.

In modern Raman spectrometers, lasers are used as the incident light source. This source is necessary, as the Raman effect is weak, typically ~10^5 times weaker than the elastic component (i.e., Rayleigh scattering). Light beams with high monochromatic nature and flux are needed for satisfactory generation. Commonly, Raman spectrometers are coupled to an optical microscope to focus the laser beam onto a spot that can be as small as 1 μm in diameter. Raman-shifted radiation is then detected with a charge-coupled device (CCD) detector, and a computer is used for data acuisition and curve fitting. Modern Raman spectrometers are based on interferometer systems and Fourier transform-based signal treatment to improve the quality of the measured spectra (FT-Raman). In Raman spectroscopy, the main experimental variables are the laser wavelength, laser power, and time of excitation. The most commonly used lasers have the following frequencies: 514.5 nm (Ar+), 632.8 nm (HeNe), 647.1 nm (Kr+), 780 nm (diode), and 1,064 nm (Nd:YAG).

Raman spectroscopy probes molecular bond vibrations and therefore is sensitive to the composition, chemical environment, and crystal structure of the material sampled. It is thus an exceptional complementary method to FTIR for fingerprinting and unambiguously identifying crystalline or amorphous materials in any physical form, in both laboratory and in situ field locations. Appropriate experimental conditions are needed to avoid sample alteration during laser excitation and to suppress the fluorescence of naturally fluorescent organic materials – the atomic fluorescence of all organic and some inorganic materials – and fluorophores that have become incorporated into artifacts from handling, burial, or other processes. Raman spectroscopy is used to analyze a variety of materials, though it turns out to be particularly suitable for the analysis of metal oxides and pigments. Extensive Raman spectral libraries are openly available from numerous institutions (Vandenabeele et al., 2007).

Raman spectroscopy has also often been applied as a powerful analytical technique in mineralogy and gemology. The technique is particularly useful for the study of mineral inclusions, and from these examinations conclusions can be drawn about the geological genesis of the minerals and their provenience. Raman spectroscopy is also used for the analysis of rock art and tomb paintings, ceramics and glazes, glass and faience, lithics, metals, textiles and plant fibers, resins, waxes, organic residues, and biomaterials such as hair, skin, bone, and ivory (Smith and Clark, 2004).

Nondestructive archaeology

Definition

Remote Sensing – or *Télédétection* (French), *Fernerkundung* (German), *Percepcion Remota* (Spanish), 遙感 (Chinese) – can be defined as the science of identifying, observing, interpreting, and measuring objects or surfaces without coming into direct contact with them.

In the archaeological process, the scientific community has taken at least two different approaches to the definition of remote sensing. Some archaeologists define it as the technique of obtaining information about objects through the analysis of data collected by sensors (cameras, scanners, imaging radar systems, etc.) that are not in physical contact with the objects under investigation, mostly using spaceborne and airborne instruments. From this point of view, remote sensing differs from ground-based sensing, in which the instruments physically touch the ground surface. A common example of a ground-based instrument is ground-penetrating radar (Doneus et al., 2011).

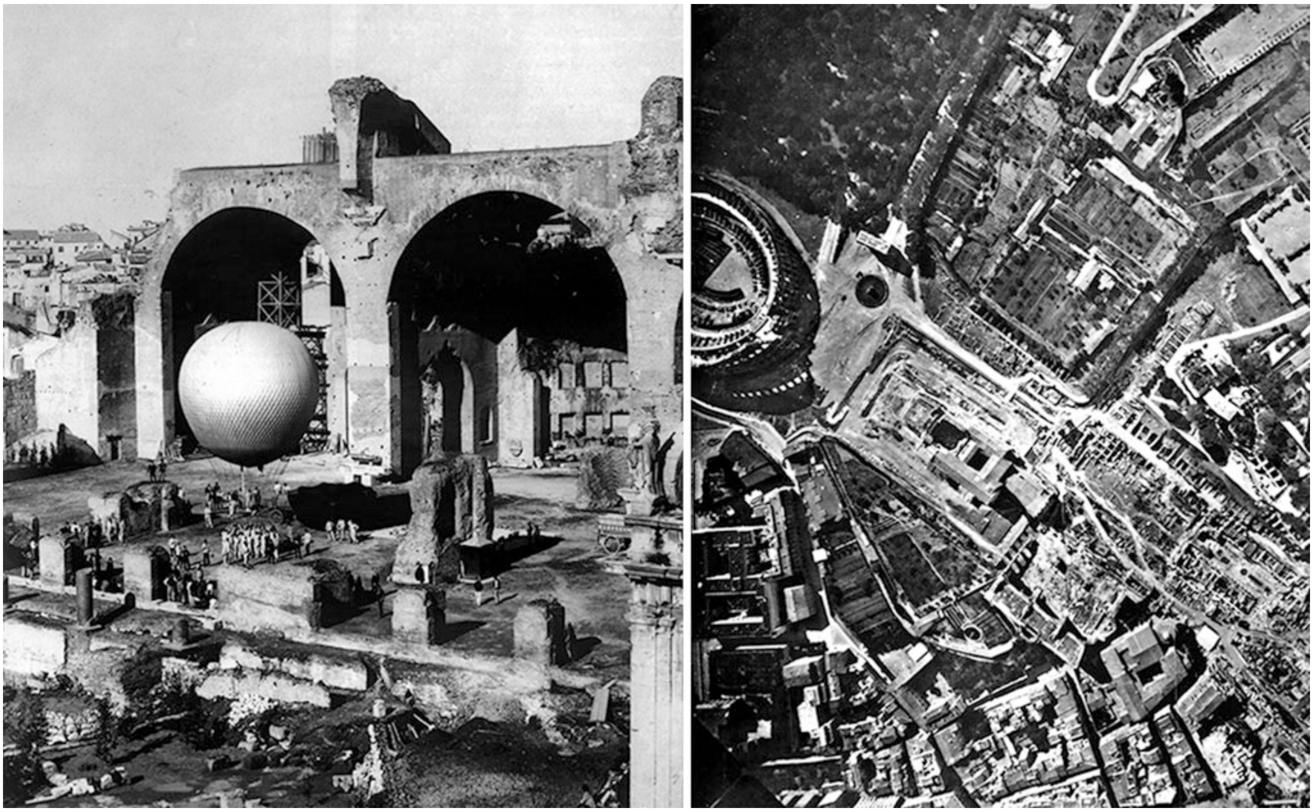
Other archaeologists prefer to include within remote sensing any nondestructive approach to viewing the buried and nominally invisible evidence of past activity. These approaches include spaceborne and airborne sensors (traditional or digital air photographic sensors, technology-based multispectral or hyperspectral scanners, etc.) but also ground-based geophysical instruments (see other entries on geophysics, magnetometry, ground-penetrating radar, and electrical resistivity). Undersea remote sensing can also fall into this category, as can noninvasive techniques such as surface collection or field-walking survey, in the eyes of some archaeologists. Within this interpretation, any method that enables observation of the buried evidence without impacting the surviving stratigraphy is included within remote sensing (Powlesland, 2010).

Introduction

For a long time, remote sensing in archaeological studies consisted almost entirely of aerial photography along with mapping and interpretation of the resulting images. The first application was related to the documentation of archaeological excavations and similar contexts. The earliest episode of air photographic recording, by F. Stolze and F. C. Andreas, took place in 1874 at Persepolis, Iran (Stolze, 1882). In Europe, the Italians played a prominent role in the early history of aerial archaeology, starting with the famous images of the Forum in Rome, taken by Giacomo Boni in 1899 (Figure 1). These pioneering efforts were followed by others along the Tiber near Rome in 1902–1903 and 1908 and then in and around Venice, Ostia, and Pompeii (Boni, 1900; Piccarreta and Ceraudo, 2000).

Similar initiatives also took place in other European countries, particularly in Britain. In 1906, during experiments using an untethered military balloon, Lieutenant P. H. Sharpe took the first aerial photographs of the great megalithic monument of Stonehenge (Bewley, 2002). At this time, the only platform available for aerial photography was the hot air or gas-filled balloon. In this early phase, aerial photography offered a new perspective in the recording of already-known surface features, the purely documentary objective being to obtain a faithful representation of the site or features concerned. Balloons were later used in the 1930s for pioneering photography of the famous excavations at Biskupin in Poland (Rączkowski, 2005). Both balloons and a variety of kite-based systems remain in use to the present day for site-related or locally focused aerial photography.

The Great War of 1914–1918 had a significant impact on the development of a completely new type of platform, the powered aircraft. Along with related advances in cameras and films, aircraft-based aerial photography was exploited as a novel source of intelligence by all combatants. If the number of aerial photographs taken prior to 1914 could be counted in the dozens, then by the end of the war, the UK's Royal Air Force alone had collected about half a million images (Rączkowski, 2001). The war had also introduced a number of pilots and observers to the archaeological potential of aerial photography. In Britain, one of these was O. G. S. Crawford, while another, in a rather different setting in the Middle East, was the expatriate Frenchman Antoine Poidebard. These two men are considered globally as the fathers of aerial archaeology and its application to landscape studies. In 1928, Crawford published (with Alexander Keiller) *Wessex from the Air*, which demonstrated the vast potential of aerial photography and established the main



Remote Sensing in Archaeology, Figure 1 Tethered air balloon used to record the archaeological excavations of Giacomo Boni in the Foro Romano. (Courtesy of Guaitoli (2003).)

principles of the technique – Crawford and Keiller (1928); see also Deuel (1969) and Barber (2011) for accounts of the early days and later development of archaeological air photography.

The Second World War of 1939–1945 brought about methodological and technical developments in both aerial platforms (aircraft) and cameras, and it witnessed the development of new remote sensing techniques such as radar technology, which was not yet used in archaeological contexts. Perhaps the link between the prewar "pioneering" phase and the beginnings of the postwar "interpretative" phase could be identified most clearly with John S. P. Bradford, a former British RAF intelligence officer, who in the months immediately following the cessation of hostilities became involved in aerial photography and archaeological mapping on the Tavoliere Plain around Foggia in southern Italy. There, he and a fellow RAF officer, Peter Williams-Hunt, discovered extraordinary evidence of previously unrecognized landscapes, consisting of hundreds of Neolithic enclosures along with Roman remains, villas, farmsteads, and centuriation, as well as a "lost" town, medieval field systems, mounds, roads, trackways, and various kinds of settlements. However, it was the significance of Bradford's subsequent book, *Ancient Landscapes* (1957), which stands as his greatest achievement, because of the message it conveys about the potential of aerial evidence in archaeological and landscape studies, not just in Italy but also across large swathes of Europe.

In the 1950s, new platforms for Earth imaging became available through the use of satellites and high-altitude aircraft, and new sensors were introduced in the form of near-, medium-, and thermal-infrared imaging systems, along with instruments for the collection of microwave and multispectral data. To take account of the widened perspectives introduced by these new sensors and the early satellites, Evelyn L. Pruitt, a geographer formerly with the Office of Naval Research in the USA, coined a new term, "remote sensing," in the 1950s. In doing so, she added another important phrase to the technical lexicon. The new term, promoted in a series of symposia at the Willow Run Laboratories of the University of Michigan, gained immediate and widespread acceptance.

Although the term itself has a relatively recent origin, the technique has, nevertheless, been used by humans since the dawn of history. Every time we sense our surroundings with our eye-brain system, we are determining the size, shape, and color of objects from a distance by collecting and analyzing reflected visible light. This is all done cognitively without coming into direct contact with the objects that we are observing. In a similar manner, certain snakes use special heat sensors to perceive impressions of their surrounding environment; the snakes detect natural heat signals passively in the same way satellite infrared detectors image the Earth's surface based on its emitted heat. Bats use sound echoes to navigate and to detect prey; similarly radar systems use transmitted radio waves and their reflections to sense a variety of distant objects and surfaces remotely.

Notwithstanding the great improvements in remote sensing during and after the Second World War, the archaeological community continued to rely almost entirely on aerial photography and interpretation of the resulting images for at least the next three decades. The technologies involved in the newer forms of remote sensing were considered to be the "leading edge," reserved for military and other purposes, and it was unusual for archaeologists to make use of them. Eventually, however, remote sensing became more widely used in the field of archaeology, starting in the late 1980s and early 1990s. This period witnessed the application of innovative techniques, including the analysis of satellite imagery; the acquisition through airborne sensors of multispectral, hyperspectral, and radar data; and the use of ground-based geophysical methods, such as magnetometry, electrical resistivity tomography (ERT), and ground-penetrating radar (GPR).

Experience in the following decades, along with technological progress and an increasing understanding of the extraordinary complexity of archaeological contexts, led to the inescapable conclusion that only through the integration of remote sensing techniques with archaeometry and traditional methods such as excavation and ground-based field survey could archaeologists possibly achieve the quantum leap in quality that everyone hoped for and expected. One factor played a central role in the maturing of archaeological remote sensing during this recent period, a factor that is synonymous with the integration and management of the wide range of information resulting from the subject's inherent complexity: geographical information systems or GIS.

While engineers, physicists, and computer scientists improved the quality or effectiveness of individual systems, sensors, and techniques or designed entirely new ones, archaeologists through the application of GIS started thinking *beyond* the individual image or dataset to produce and map broader integrations, and therefore interpretations, and in this way they brought together a wide variety of data. The stratification and overlaying of information within the single "container" of GIS provided an essential tool in the search for and development of a new and more integrated approach to the representation and interpretation of evidence from the past.

Currently, the use of remote sensing in archaeology is growing rapidly at universities, some of which have created highly specialized departments and institutions with undergraduate, graduate, postdoctoral schools, and specific research programs. This trend is also seen at institutions aimed at the protection and conservation of archaeological heritage, as, for instance, in the nationwide mapping of air photographic evidence in England (see below). International associations, such as the Aerial Archaeology Research Group (AARG) (http://www.univie.ac.at/aarg) and the International Society for Archaeological Prospection (http://www.brad.ac.uk/archsci/archprospection/), have also played a significant role in the dissemination of these methods and techniques.

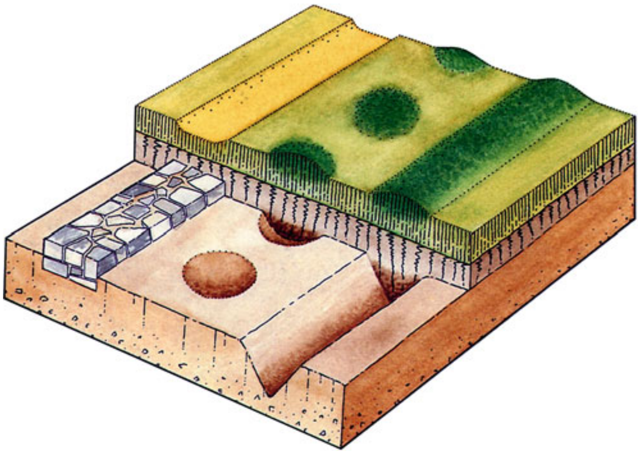
Principles of remote sensing

Remote sensing may reveal archaeological features *directly*, where they are still extant (albeit perhaps heavily eroded) in the form of topographical variations. Alternatively, when they no longer exist above the ground surface, they may be revealed *indirectly* in the form of variations in the coloring and height of the vegetation. These may appear as visible discontinuities in bare soil exposed by agriculture, erosion, or other surface indications or in an intermediary form, as micromorphological discontinuities where the features are buried (Wilson, 2000).

When sites are extant, remote sensing can play a special role in documenting their general form and constituent parts from a high-level viewpoint, allowing rapid mapping with the aid of purpose-designed computer programs (Remondino, 2011). Many sites, of course, could alternatively be mapped from the ground, but the use of remote sensing data can be extremely valuable for mapping sites and features which, for one reason or another, are not readily accessible for ground-based survey.

The *indirect* identification of archaeological evidence is particularly valuable in the discovery of previously unrecognized sites and features. The main principle in this context is the capacity of techniques like aerial photography, LiDAR, radar, or thermal-infrared imaging to recognize evidence that provides indirect indications in the natural soil of past human activity. Several methodologies have been developed to identify relative (though never absolute) environmental variations for this purpose. The recognition of archaeological features represented by indirect evidence exploits a number of interlinked "phenomena" (Musson, 1994), including:

1. Variations in the coloring, height, or density of arable crops or other vegetation. These have variously been described as *vegetation marks* or (more commonly) *cropmarks*. They represent one of the most striking tools for the discovery of previously unrecorded sites. Cropmarks appear as differences of height and/or color in crops that are under stress, usually based on the lack of water or some other nutrient. This is more likely to occur in light and well-drained soils, above soft and permeable rocks or gravels. As a result, the distribution across countries, regions, and local areas is irregular. Cropmarks appear most frequently in ripening grain, especially when the weather has been dry at critical stages of growth or maturing. In these conditions, cropmarks can be seen over a period of 2–8 weeks during the late stages of ripening or for shorter periods in



Remote Sensing in Archaeology, Figure 2 The formation of cropmarks: crops grow taller and ripen later over the deeper, more nutritious, and damper soil of a buried ditch or large pit. Growth is stunted, and the ripening of the crop occurs earlier in shallower soil above buried walls or other impervious deposits. Ditches and pits create *green* marks in the *yellowing* crop. Walls and similar obstructive features cause *yellow* marks in the *green* crop. Both can persist as *yellow-on-yellow* marks in the ripened crop. (Courtesy of Royal Commission on the Ancient and Historical Monuments of Wales.)

the early stages of growth (Figure 2). During damper years, the crop may never come under enough stress to produce cropmarks, even where they have been regularly seen in the past. Cropmarks occasionally appear at other times of the year in a wide variety of vegetation: cereals, grass, root crops, green fodder crops, weeds, and various flowering plants.

2. Differences in bare soil exposed by agricultural activity or erosion. These are usually known as *soil marks*. They appear as changes of color, texture, or dampness in the surface of the soil and reflect subsurface features, such as ditches or wall foundations. The marks may appear for only short periods as the soil dries or reflects the sun in particular ways. The main difficulty in detecting them lies in recording them at the right moment, especially when the soil is damp and fresh from the plow or harrow.
3. The effect of light and shade, producing what have sometimes been described as *shadow marks*. In this case, shadow and highlight are used to emphasize physical features which still exist but may be almost invisible on the ground, such as the barely detectable earthworks of prehistoric field banks or heavily eroded burial mounds. Archaeological air photographers, therefore, take advantage of low sunshine in the winter or of early-morning/late-evening light at other times of the year. This "low-light" or "shadow" technique is particularly effective in upland areas where there has been less erosion by modern plowing. It can also be productive, however, in lowland zones, throwing very slight patterns of topographical variation into relief by the play of light and shade, thereby making the overall form of the archaeological feature more intelligible.
4. Special conditions created by frost, ice, and floods create situations that can offer good opportunities for archaeological air photography. A thin covering of snow, for instance, suppresses distracting color and provides excellent conditions for low-light photography. The differential melting of frost by sun or wind, or the persistence of ice and snow above buried ditches at the end of a cold spell, can also reveal otherwise unsuspected subsurface features. Flooding may redefine old river courses and explain the location of roads or farmsteads in a way that could otherwise be achieved only by painstaking survey on the ground. Prolonged drought can produce cropmarks in otherwise unresponsive grassland, revealing evidence that is rarely, if ever, available at other times.

Important parameters in remote sensing

The success of remote sensing in archaeological applications depends not only on the date of data capture but also on the quality of the collected evidence. At least four parameters are involved here: spatial, spectral, radiometric, and temporal resolutions (Lillesand and Kiefer, 1994).

Spatial resolution relates to the level of detail that is visible in the image; it is dependent on the resolving power of the sensor and the distance between platform and object. In a raster image, spatial resolution depends on the area of ground surface that is represented by each recorded pixel. Typically, pixels may correspond to surface areas ranging from 30 m square to 1 m square, or even as little as 5 cm square. Spatial resolution represents one of the most important parameters for archaeological remote sensing, in that it is critical to determining the size of archaeological features that can be identified in the resulting data.

Spectral resolution refers to the range width and number of specific dimensional units to which a sensor is sensitive. The limited spectral interval of the electromagnetic spectrum visible to the human eye (wavelengths from about 390–750 nm) is greatly extended by the use of photoelectric sensing devices. This increase in the capability of recording different regions of the electromagnetic spectrum demonstrates a desire to exploit their full potential, separating information on different layers (bands) to produce multispectral images (2–10 spectral bands) or hyperspectral images (10–200 spectral bands). This quality may play an important role in the detection of archaeological features.

Radiometric resolution refers to the number of different intensities of radiation that the sensor is able to distinguish. Typically, this ranges from 8 to 14 bits in each band, corresponding to 256 levels of the gray scale and up to 16,384 intensities or "shades" of color.

Temporal resolution relates to the frequency of overflights by the satellite, aircraft, or any other recording platform. It is extremely relevant in archaeological studies, making it possible in some instances to monitor landscape or site transformations over time (measured in days, years, or even decades). “Historic” data from remote sensing, such as early aerial photographs or the data from the early generations of satellites, can be very valuable in providing the only available source of information about long-term landscape transformations over time.

Image examination and archaeological interpretation

Remotely sensed images contain a detailed record of features on the ground at the time of exposure, relating both the modern landscape and that of the past. In the process of interpretation, the archaeologist examines the images systematically and often draws on other relevant material, such as maps and reports of field observation. The interpretation derived from this study aims to “read” and make sense of the phenomena and features appearing in both the modern and the “ancient” landscape and to distinguish between them. The basis for sound interpretation is a secure understanding of the peculiarities of the modern landscape in the area concerned. The identification of the present pattern, and its constituent parts, can draw attention to “nonconforming” elements, which might form part of earlier features, sites, or landscape patterns. In carrying out the systematic initial examination, attention is paid to a variety of basic characteristics or variations of them, such as shape, size, pattern, tone, texture, shadow, topographical position, and association (Lillesand and Kiefer, 1994).

Aims and peculiarities of archaeological remote sensing

Archaeology and its use of remote sensing have often been compared with medicine and medical diagnostic procedures. The development of the clinical picture, as well the archaeological process, comes through understanding of the personal and family history and through the developmental story of archaeology itself. Semiotics, representing the analysis of phenomena and signs visible from outside, finds a close parallel with field-walking survey and surface collection. The last stage of medical diagnosis involves instrumental analysis (evidence-based medicine) through the use of laboratory tests, and this phase finds parallels with archaeometry. Special equipment or tools, such as ultrasound and radiology, are used, and these are in a real sense similar to the remote sensing tools used in archaeology.

The main aims of remote sensing in archaeology can be identified as follows:

- The documentation of archaeological contexts in great and objective detail
- The acquisition of information on buried deposits sometimes completely invisible at ground level, describing in some detail the metrical, geometrical, and physical-chemical properties of the subsurface features
- The well-balanced and representative recording of both positive and negative kinds of archaeological evidence
- The monitoring, from very large scale to small scale, of landscape transformations, allowing the development of conservation and planning policies
- The mapping of archaeological data, interpretations, and reconstructions through the use of GIS technology that can cope with the inherent complexity of past landscapes and archaeological sites

Main weaknesses

Remote sensing in archaeology is subject to a number of limitations. In the case of optical sensors operating in the visible part of the electromagnetic spectrum, the higher limit can be summarized by the concept of serendipity. Serendipity is the discovery of something unsought and unexpected, but not by chance alone. The positive result must be the outcome of planned experiments, taking place in the framework of systematic scientific research. In the case of archaeological remote sensing, the serendipitous recovery of information is influenced by a number of parameters: pedology, climate, cultivation patterns, the plants or crops being grown, the historical development of the landscape, etc. Archaeologists understand from a theoretical point of view the scientific principles that make underground archaeological features visible at the ground surface (Jones and Evans, 1975). They cannot, however, control the environmental and anthropological factors that affect the way subsurface archaeological features modify the appearance of bare soil or vegetation to reveal their presence. As a result, the distribution of archaeological features in remotely sensed evidence is as much a reflection of these influencing factors as it is of the real presence or absence of archaeological sites (Figure 3).

To a certain extent, the techniques that rely on portions outside the visible part of the electromagnetic spectrum – such as near-, middle-, and thermal-infrared, radar, LiDAR, and geophysical prospection – can also be affected by serendipity, though generally the influence on these techniques is less substantial.

Systems and methods

Remote sensing systems and related methods of data analysis are numerous and have traditionally been divided according to the platform used (satellite, aerial, terrestrial, etc.) and the type of sensor employed (optical, thermal, LiDAR, radar, magnetic, etc.).

Satellite imagery

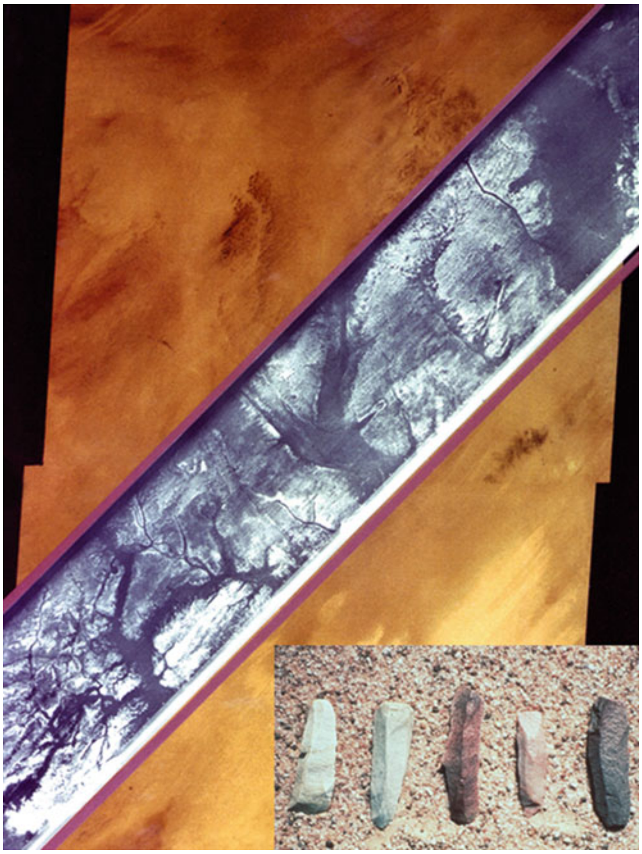
In 1957, the Soviet Union (USSR) put the first satellite, Sputnik 1, into orbit, and the era of satellite remote sensing began. The first *systematic* satellite observation of the Earth was undertaken by the meteorological satellite

Remote Sensing in Archaeology, Figure 3 Above *left*, oblique aerial photograph showing a large grain cultivation field where cropmarks are clearly visible (details above on the *right* side); they are interpreted as features of a Roman villa. The photographs were collected in 2005 during the ripening season when cropmarks are at their best visibility for archaeological prospection. *Bottom left* and *right*, oblique aerial photographs showing exactly the same area photographed 2 years later (2007). The aerial survey was carried out during the cropmark season, but this time serendipity did not work. As a result, no features are visible in the aerial photography. This is a paradigmatic example showing how distribution of archaeological features is as much an echo of serendipity as it is of the real presence or absence of archaeological sites.

TIROS-1 in 1960 by the USA space program. The era of satellite photogrammetry started in 1960 with the CORONA military reconnaissance program, also an American project. The use of satellite images for more general mapping and measurement studies began in 1962 with the design and launch of the CORONA KH-4 satellite (Galiatsatos, 2014).

Civilian satellites started with the advent of Landsat-1 in 1972. Later, several satellite sensor systems similar to Landsat were launched, such as the French SPOT HRV and the Indian LISS systems. In this period, applications to archaeology were constrained by the poor geometric resolution (about 20 m per pixel) and use of the images being restricted to high-end scientific research laboratories. In archaeological as well as other contexts, the satellite imagery available at this time was mainly used to study or characterize the environmental background and current agricultural patterns or to generate cartography in areas where maps were not available, as in parts of Central Asia, the Near East, Africa, and Central America (Musá et al., 1977; Khawaga, 1979).

Other highlights in the history of satellite remote sensing include the launch of radar systems into space, the proliferation of weather satellites, a series of specialized devices dealing with environmental monitoring or with thermal and passive microwave sensors, and the more recent hyperspectral sensors. For instance, radar imagery attracted global media attention following the discovery of such things as the lost city of Ubar in southern Oman (Bloom, 1992) and the so-called radar rivers (Figure 4), former riverbeds still extant beneath the sands of the Sahara (McCauley et al., 1982). Since the turn of the millennium, the archaeological use of satellite data has become both more widespread and more common. Despite long-lasting and important work by a small number of scientists and archaeologists from the 1970s



Remote Sensing in Archaeology, Figure 4 Above: Shuttle Imaging Radar-A flew on the second flight of Space Shuttle Columbia in 1981. The images show SIR-A radar over Landsat Multispectral Scanner in southwestern Egypt where thin sand cover (0 to a few meters) obscures an underlying, older fluvial landscape. L band (23 cm) radar images through 2+ meters of dry sand show buried integrated drainage systems (Courtesy of R. G. Bloom, JPL-NASA); below: Neolithic stone artifacts abundant near the "radar rivers" reveal evidence for significant human presence. (Courtesy of R. G. Bloom, JPL-NASA.)

onward, the main change that has influenced the development of satellite archaeology has been a radical improvement in the geometric resolution of the images.

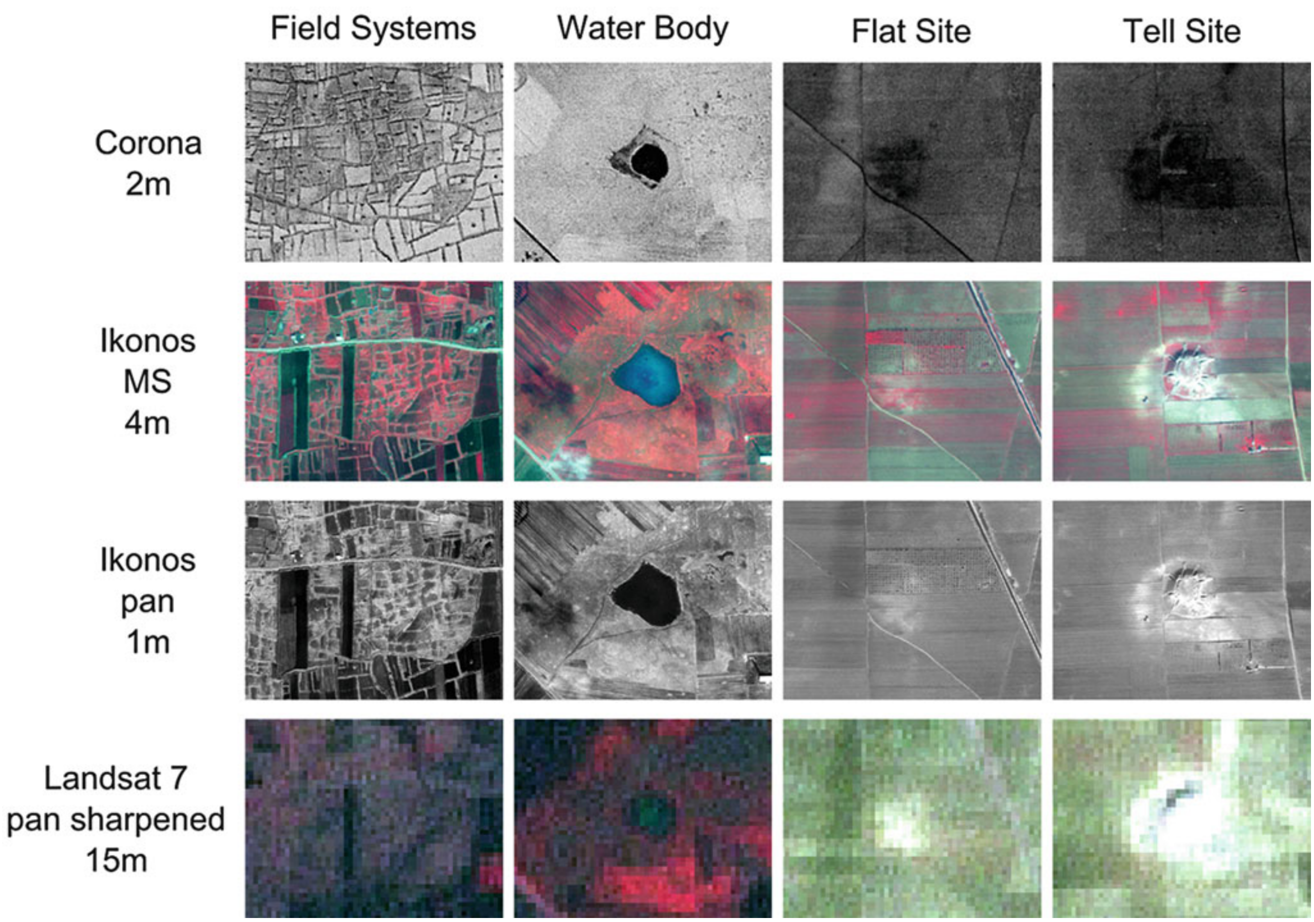
The development of very high-resolution satellite imagery (HRSI) began with the appearance of the first commercial satellites (Parcak, 2009; Lasaponara and Masini, 2012). The first successfully launched commercial satellite was IKONOS-2 in 1999. This was followed by QuickBird in 2001, OrbView-3 in 2003, and later by KOMPSAT-2, EROS-B1, and Resource-DK-1 in 2006. In the last 15 years, the resolution of available satellite images has improved from 20 m per pixel (SPOT) to 0.40 m per pixel (GeoEye-1, launched in September 2008), representing a 2,500 times increase in the capacity to detect small objects (Figure 5).

The opportunities for archaeological applications have, therefore, vastly increased, though there are still some significant limitations.

- *Scheduling*: There are still difficulties (and costs) in scheduling image capture to coincide with archaeologically advantageous conditions or time of year. Archaeologists need more flexibility to plan image capture during the right time windows, e.g., during the cropmark season at the locality concerned.
- *HRSI spectral resolution*: This is mainly characterized by the use of only three bands in the visible part of the spectrum and a fourth in the near infrared.
- *Geometric resolution*: In contrast to these limitations, the newest GeoEye-2 satellite (on July 31, 2014, DigitalGlobe announced that the GeoEye-2 satellite sensor will be renamed WorldView-4) due for launch from 2013 onward and the "next-generation" commercial satellites – planned for launch during 2016 – will have a spatial panchromatic resolution of 30 cm and spatial multispectral resolution of 1.20 m. Many archaeologists, however, feel that they need something closer to the 5 cm or higher resolution provided by traditional aerial photography.

As a final observation, it should be pointed out that a casual observer wandering through a library, particularly in the USA, might be forgiven for believing that satellite remote sensing is the prime technique for archaeological research. This is not, in fact, the case. According to Powlesland, "for every 'site' identified from space, thousands have been identified through air-photography" (2010, 9). In Europe, aerial photography has been used to observe and document archaeological landscapes for more than a century, and this method remains by far the most significant contributor to the ever-expanding archaeological record. For instance, from the papers presented at the annual meetings of the Aerial Archaeology Research Group, it is possible to see the tremendous impact that aerial survey and photography are having in European countries where, until the political changes of the early 1990s, flight restrictions made photography from light aircraft virtually impossible.

There has been extensive use of satellite imagery, *in the absence of* available data of a higher standard from less costly and more effective remote sensing techniques such as aerial photography, geophysical prospection, airborne laser scanning, and multispectral or hyperspectral data capture. It is important to recognize, however, that a significant but often underemphasized contribution of satellite imagery is its worldwide coverage and, therefore, (1) the impact such imagery has on the analysis of large geographical areas and (2) the scale that can be incorporated within "landscape" studies. The combination of satellite imagery and "virtual globe" geographical information systems, such as Google Earth, makes possible the observation of very broad areas of the planet at a high level of detail – an unimaginable concept only a few years ago.



Remote Sensing in Archaeology, Figure 5 Comparison of satellite sensors with different spatial and temporal resolution: CORONA 1969, IKONOS 2002, and Landsat 1999. (Courtesy of Beck, 2011.)

Airborne remote sensing

Leaving aside photography from light aircraft for the moment, airborne remote sensing at its more sophisticated and commercial levels uses downward- or sideward-pointing sensors mounted on specialist aircraft so as to obtain vertical or oblique images of the Earth's surface. One advantage, compared to satellite remote sensing, is the capacity to achieve very high spatial resolutions, between 20 and 5 cm per pixel. The disadvantages are lower areal coverage and higher cost per unit of ground surface. This kind of remote sensing is not cost effective for mapping very large areas, such as whole continents, though it has been used (cumulatively and over considerable time) to map whole countries and regions. Airborne remote sensing missions are usually carried out as single (but occasionally repeated) operations, whereas Earth observation satellites offer the possibility of truly continuous monitoring of the planet's surface. Both analog and digital photography are commonly used in airborne remote sensing. Multispectral and hyperspectral imaging, synthetic aperture radar (SAR), and LiDAR scanning are also carried out from airborne platforms.

Air photography

Archaeologists use two types of air photography: "oblique," or perspective views, and "vertical" photography that point straight downward at the Earth's surface. Vertical photography (originally analog, but now more frequently digital) is taken with sophisticated cameras from specially equipped aircraft, mainly for survey and mapping purposes. It is relatively expensive, and archaeologists can rarely afford to commission it for their own research purposes (Musson, 1994). Therefore, archaeologists draw on vast collections of air photographs already available in existing archives (Figures 6 and 7). During the Second World War, approximately 50 million aerial photographs were taken (Going, 2002). In modern Europe, public services collect perhaps millions more frames each year.

Oblique photographs are generally taken by archaeologists themselves, from the open window of a small aircraft hired from a local airfield (or occasionally owned by the archaeologists themselves or by their employers). The cameras and film are quite simple and inexpensive. While vertical photography records the whole of the landscape,

Remote Sensing in Archaeology, Figure 6 Vertical historical aerial photography collected in 1955 in the countryside of Foggia (southern Italy). The photography shows clear features of Neolithic enclosures, medieval mounds, and field systems. (Courtesy of Guaitoli, 2003.)

oblique photography is selective and covers only what the photographer sees and judges to be archaeologically significant (Figure 8). What he or she fails to see, or understand, inevitably fails to be recorded. Vertical photography, therefore, has a special value in the study of the whole landscape, or of settlements in their broader context. Oblique photography, by contrast, is unrivaled in recording individual sites of historic interest, the more so because the photographer can choose the time of day or year and the kind of lighting that will illustrate or reveal archaeological features to best advantage (Figure 9).

Vertical photographs do, of course, contain archaeological information, but more by accident than design, and for the most part at shadow-free times of the day or year that suit mapping, rather than specifically archaeological recording. Nevertheless, there are examples of extraordinary results being achieved through vertical photography carried out explicitly for archaeological proposes, such as when conditions for cropmark or soil mark recording are at their best.

Austria, Italy, and the UK all document cases confirming that if vertical coverage can be arranged within the best timeframe for the visibility of archaeological evidence, then the whole area, along with all of the sites that are visible at the moment of photography, can be depicted in stereo pairs of photographs that provide a 3D replica of the target landscape. This kind of documentation can lead to a vast improvement in the analysis and understanding of past landscapes (Doneus, 2001; Guaitoli, 2003; Palmer, 2007). The main difficulties with this practice are its relatively high cost and the short time that is available to plan and execute vertical coverage on the limited number of occasions when the conditions are ideal for recording.

In their professional work, archaeologists use the two types of aerial photography, vertical and oblique, more or less equally. For instance, the comprehensive National Mapping Programme for England (NMP), begun in the late 1980s and still in progress at English Heritage, had covered approximately forty percent of England by April 2009. Teams of experienced archaeological air-photo interpreters working on the NMP have unlocked information held in millions of vertical and oblique aerial photographs, mainly taken since 1945. NMP projects continue to provide information and synthesis for archaeological sites and landscapes of all periods from the Neolithic to the twentieth century, priority being given to those areas of the country that are under the greatest threat or are poorly documented (Horne, 2011).

Remote Sensing in Archaeology, Figure 7 Vertical historical photography collected over Cerveteri in 1930. Visible in the photograph are a number of *white round* features distributed nearly everywhere and corresponding with round barrows. (Courtesy of Guaitoli, 2003.)

Remote Sensing in Archaeology, Figure 8 Oblique aerial photography collected in 2005 at Vulci (Italy). The photograph shows clearly a substantial number of square and other geometrical features related to the settlement area of the Etruscan and Roman city of Vulci.

Multispectral and hyperspectral scanning (MSS and HSS)

The effectiveness of aerial photography is limited by the differential visibility of cropmark, soil mark, or earthwork evidence in response to conditioning factors, as mentioned above. It is widely recognized that multi- and hyperspectral imagery can address some of these contextual problems because they are potentially more sensitive to changes in vegetation status than the visible or panchromatic ranges (Donoghue, 2001; Shell, 2002). Indeed,

Remote Sensing in Archaeology, Figure 9 Oblique aerial photography collected in 2003 in the countryside of Foggia (Italy). The photograph shows stratified ancient landscapes. It is possible to recognize at least two main periods: prehistoric and Roman. Two Neolithic circular enclosures (single and double ditch enclosures), probably related to different chronological phases, are distinguishable (*bottom* and *top*). Over the Neolithic features are a number of traces related to a centuriation pattern (road and cultivation systems) in association with a settlement (*bottom left*), which is also plainly observable.

multispectral or hyperspectral sensors are able to look simultaneously at a wide range of wavelengths, many of which lie in the near- and shortwave infrared spectrum, and add important collateral information to the visual wavelengths. These factors thus improve the ability to discriminate vegetation stress, soil moisture, and temperature variations (Beck, 2011).

Pioneering studies have been undertaken in the American Southwest using airborne thermal imaging to define areas of past agriculture more clearly than was possible with black-and-white photography (Schaber and Gumerman, 1969). These early studies were carried out to assess the efficacy of multispectral data for recording areas of Pueblo Indian archaeology and their environmental settings at Chaco Canyon in New Mexico and elsewhere (Lyons and Avery, 1977; Lyons and Mathien, 1980; Avery and Lyons, 1981).

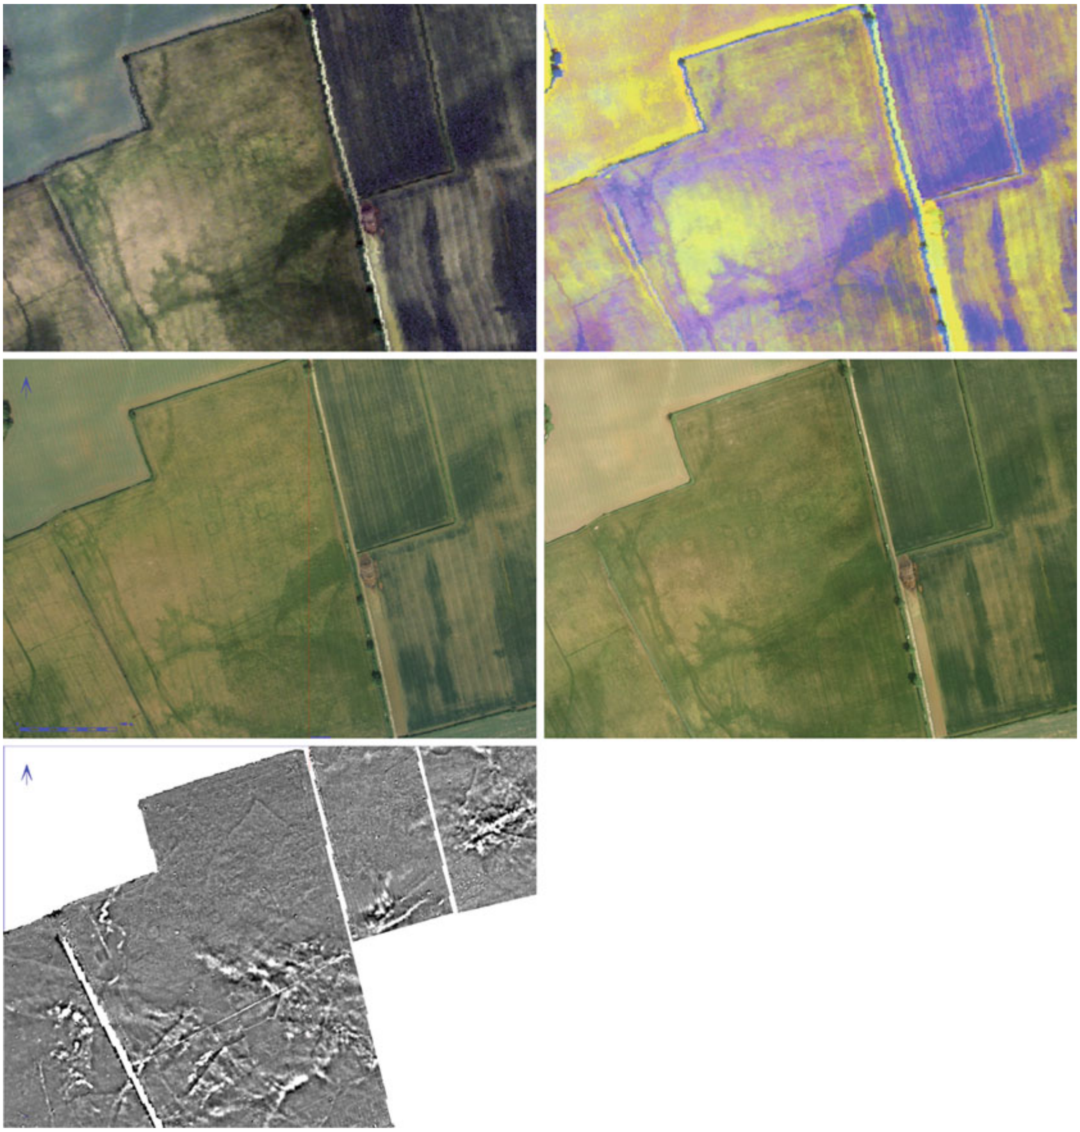
In Europe, thanks to the development by national research agencies of multi- and/or hyperspectral systems, Britain and Italy are recognized as leaders in the field, having carried out a number of important studies from the 1990s. In Britain, airborne multispectral scanners have been used to assess the archaeological potential of multispectral data at a number of sites. This imagery has complemented vertical photography and revealed new information in the infrared wavelengths in places such as the former wetland environments of the Fenlands in eastern England and the Vale of Pickering farther to the north (Figure 10; Powlesland and Donoghue, 1993). These studies showed that the red and infrared images provide good definition for soil marks and cropmarks and that the near- and shortwave infrared wavebands are particularly sensitive to plant health and, therefore, to the effective detection of water stress in vegetation (Shennan and Donoghue, 1992). In Italy, experiments have been carried out mainly by geologists and earth scientists in the use of the airborne thematic mapper (ATM) multispectral scanner to detect paleoenvironmental patterns and geomorphological features, such as ancient river channels, areas of marshland, and evidence of coastal change.

The increasing availability of hyperspectral imagery, as well as thermal imagery, presents very significant possibilities. In Britain, the main data source of multi- and hyperspectral data is the Airborne Research and Survey Facility managed by the Natural Environment Research Council (NERC), while in Italy this research has been conducted through the National Research Council (CNR). Since the late 1990s in both countries, researchers have been applying multi- and hyperspectral imagery in landscape analysis (Cavalli et al., 2003; Shell, 2005; Traviglia, 2007; Aqdus et al., 2008). The general trend, emerging from a substantial number of case studies in differing physical and cultural contexts over the past two decades, has demonstrated that these kinds of sensor can be a valuable resource, complementing information obtained through other remote sensing techniques and adding specific support in the identification of features in the non-visible domain (Donoghue et al., 2006).

Currently, a major disadvantage, however, is the poorer resolution of the multispectral and hyperspectral data, generally between 3 and 4 m per pixel depending on the characteristics of the sensor and the altitude of the aircraft. Within archaeology, this level of resolution is suitable only for the detection of large-scale features.

Synthetic aperture radar (SAR)

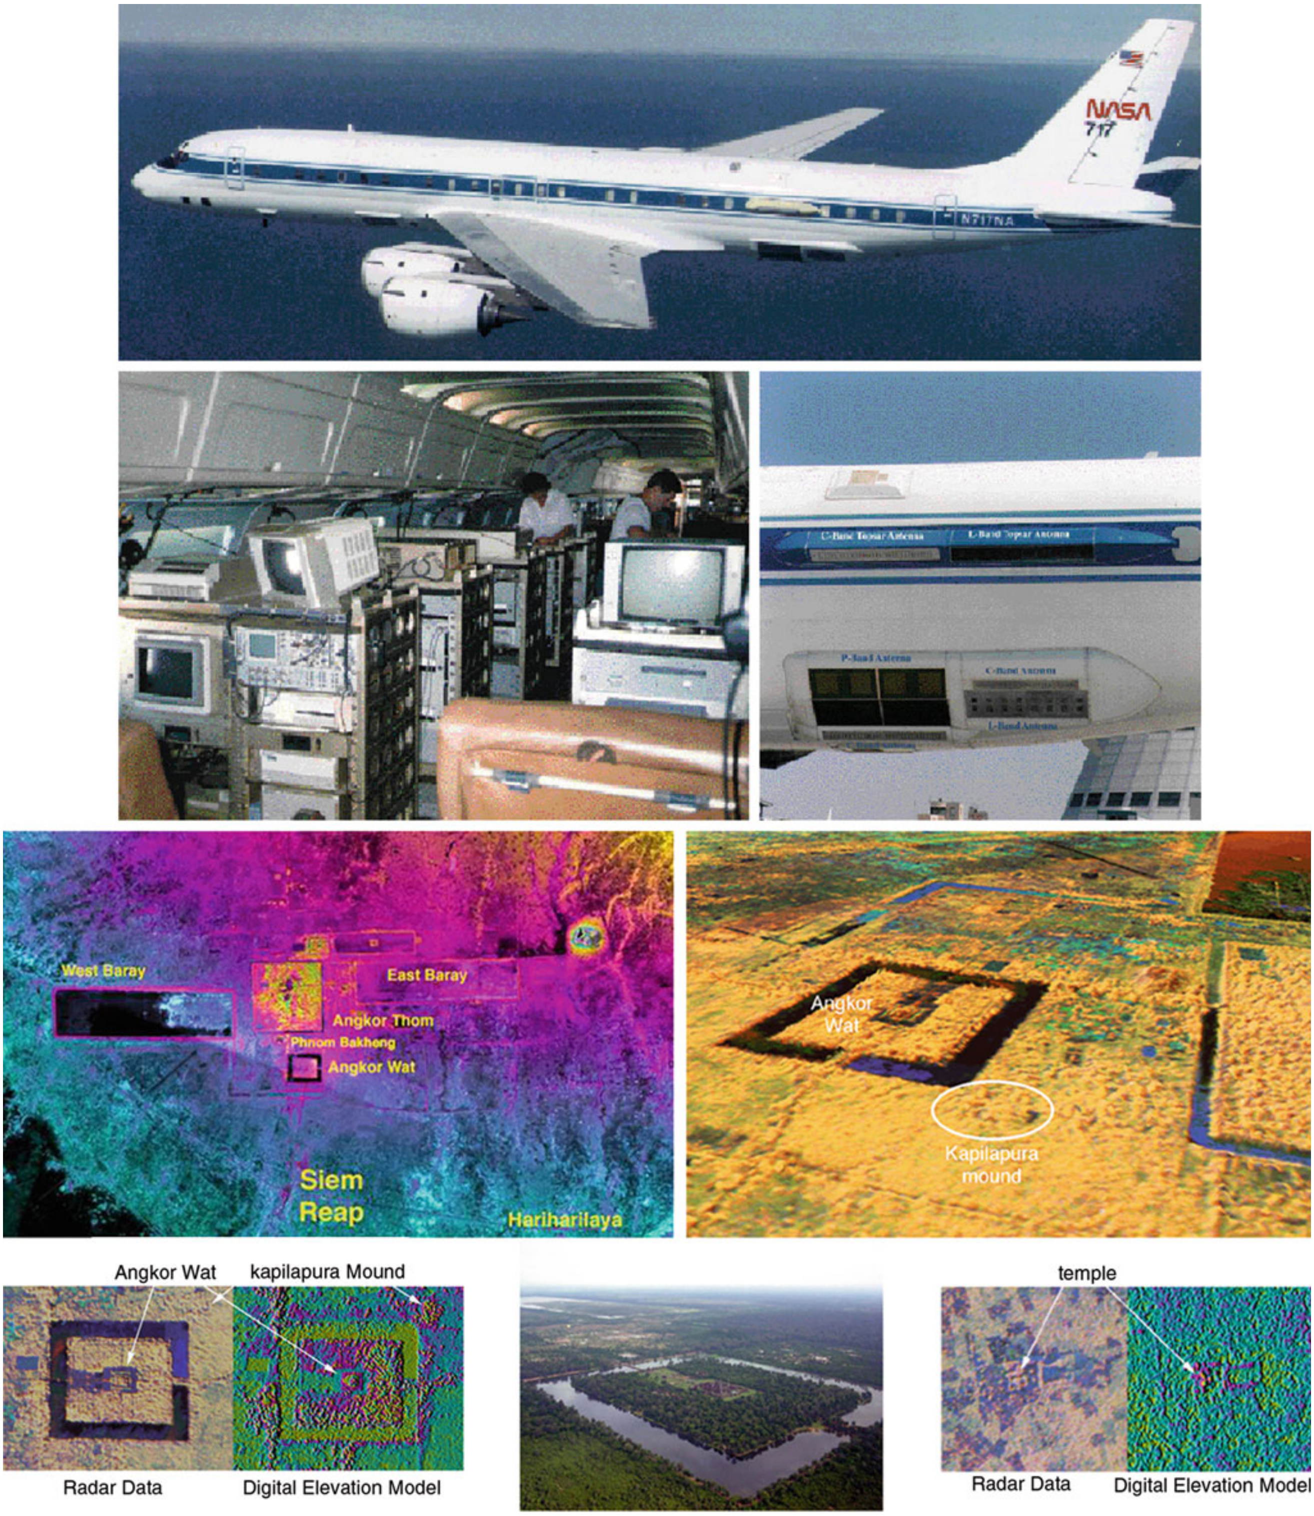
Radar is an active microwave sensing system, sending directional pulses of electromagnetic energy and detecting the presence and position of objects by analyzing the portion of the energy reflected back to the transmitter (Lillesand and Kiefer, 1994). A key advantage is its ability to penetrate through cloud, haze, light atmospheric precipitation, and smoke, making this an “all weather” sensor. The system has a variety of applications in archaeology (Figure 11).



Remote Sensing in Archaeology, Figure 10 Images from the Daedalus 12 band multispectral scanner flown by the Natural Environment Resource Council (NERC) covering a field in West Heslerton, Vale of Pickering, North Yorkshire, UK. The principal features documented in the images include a number of Iron Age square ditched barrows and a prehistoric trackway. (Courtesy of D. Powlesland, Landscape Research Centre.)

From the end of the 1970s, radar has been used for archaeological prospection in regional surveys to detect cultural, natural, and anthropic features (Adams, 1980; Pope and Dahlin, 1989; Sever, 1998). It has also been used for paleolandscape analysis (McHugh et al., 1989), as well as in ecosystem studies and cultural heritage monitoring (Moore et al., 2007). The most important work in this field has been carried out in the USA (Wiseman and El-Baz, 2007), particularly by the NASA's Jet Propulsion Laboratory at Caltech (JPL/NASA). In this context, protocols have been developed for using synthetic aperture radar, or SAR, in the recording of archaeological sites for cultural resource management so as to reduce the risk of costly delays during construction projects (Comer and Blom, 2007).

The application of radar imaging in archaeology is still fairly limited, especially in Europe, where archaeologists and remote sensing scientists have focused more attention on LiDAR, multispectral, and hyperspectral systems. Generally speaking, the main limitation of radar systems is the relatively high cost of commissioning it from a commercial contractor. The maximum penetration of the signal into the soil can be as much as 3–5 m, but this requires very dry ground conditions and fine-grained soil.



Remote Sensing in Archaeology, Figure 11 (Continued)

Specialized training is also essential in image processing and archaeological data interpretation (Holcomb and Shingiray, 2007).

Light detection and ranging (LiDAR)

Airborne LiDAR measures the relative height of the ground surface and other features (such as trees and buildings) across large areas of landscape with a resolution and accuracy hitherto unattainable except through labor-intensive field survey or photogrammetry (Remondino, 2014a). It provides, for the first time, highly detailed and accurate digital 3D models of the land surface at meter and submeter resolution. LiDAR operates by using a pulsed laser beam which is scanned from side to side as the aircraft flies over the survey area, measuring by the length of the time that the signal takes to return to the aircraft between 20,000 and 100,000 points per second to build an accurate, high-resolution model of the ground and the features upon it.

Airborne LiDAR was conceived in the 1960s for submarine detection, and early models were used successfully in the early 1970s in the USA, Canada, and Australia. The possibility of using the technique for archaeological recording was first recognized in the USA thanks to pioneering research in the vicinity of the Arenal Volcano in Costa Rica under the leadership of Tom Sever. In an archaeological study in 1984, Sever and his colleagues used LiDAR, TIMS (thermal infrared multispectral scanner), SAR, and color infrared photography to detect pathways of prehistoric settlers and document trade routes and movement between settlements (Sheets and Sever, 1991).

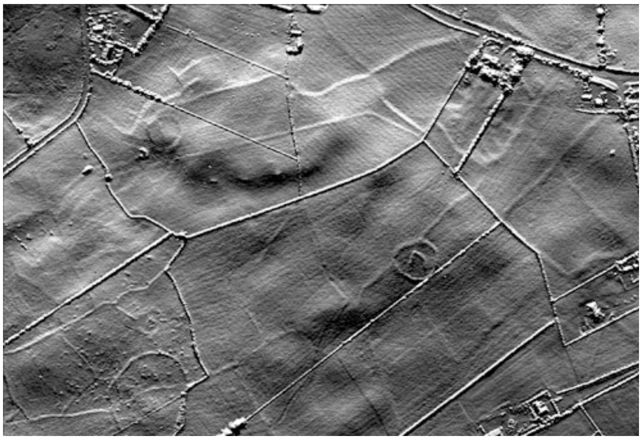
In Europe, the potential of LiDAR applications in archaeology was first discussed at a workshop in Leszno, Poland, in November of 2000. This related to a survey covering the River Wharfe in Yorkshire, which revealed evidence for the survival of a Roman earthwork fort that had previously been thought completely leveled by plowing (Holden et al., 2002). A few years later at Ghent University in Belgium, Robert Bewley, then Head of English Heritage's Aerial Survey Unit, argued that ". . .the introduction of LiDAR is probably the most significant development for archaeological remote sensing since the invention of photography" (Bewley, 2005, 25).

In the following years, LiDAR applications have been developed widely around Europe and particularly in the UK, Austria, France, Germany, Norway, and Italy. Currently, the principal advantage of LiDAR survey for archaeologists is its capacity to provide a high-resolution digital elevation model (DEM) of the landscape that can reveal micro-topography that is virtually indistinguishable at ground level because of erosion by plowing (Figure 12).

An extremely important characteristic of LiDAR is its ability to penetrate woodland and to reveal features that are not distinguishable through traditional prospection methods or that are difficult to reach for ground-based survey (as, for instance, in work at Leitha Mountain, Austria, described in Doneus and Briese, 2006). There have been other notable applications at Elverum in Norway (Risbøl et al., 2006), at Rastatt in Germany (Sittler and Schellberg, 2006), in the Stonehenge landscape and at other locations in the UK (Bewley et al., 2005; Devereux et al., 2005), and, returning to the Americas, at Caracol in Belize (Weishampel et al., 2010). It is worth noting that interest in this technique is not limited to its potential for penetrating woodland areas but also for its contribution to the study of open contexts, such as pastureland and arable areas. In these zones, as under woodland cover, the availability of extremely precise digital models of the ground surface will make it possible to highlight every tiny variation in level and, by using computer simulations, to change the direction or angle of the light and/or to exaggerate the value of the Z-coordinate (height).

Techniques have been developed for the digital removal of "modern" elements such as trees and buildings so as to produce a digital terrain model (DTM) of the actual ground surface, complete with any remaining traces of past human activity (Figure 13). Initial LiDAR pulses reflect from tree canopies or denser branching just beneath, but last pulses can reflect off the ground surface. If these last pulses are used exclusively, the indicators of covering vegetation can be largely eliminated. At present, the cutting edge of LiDAR applications in archaeology is

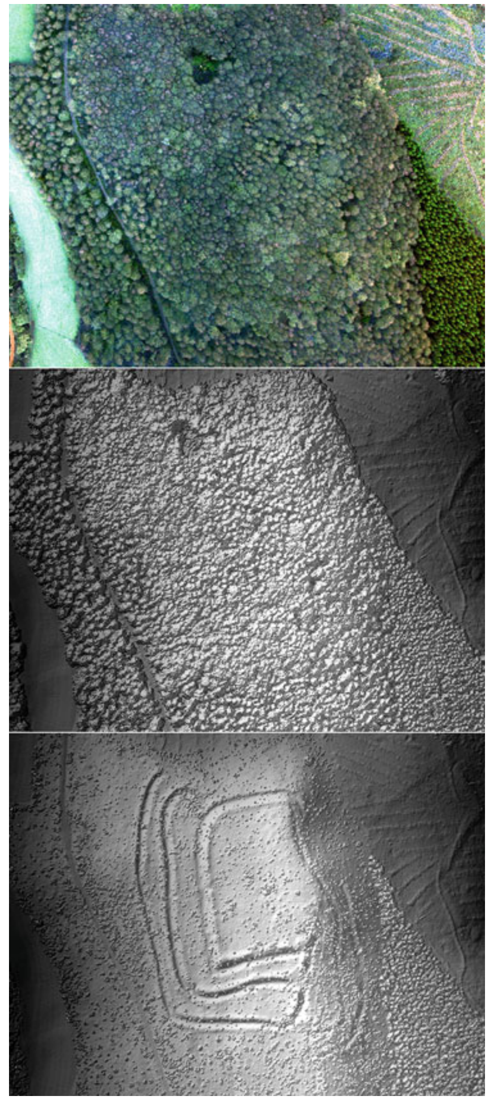
Remote Sensing in Archaeology, Figure 11 Top: Flying Laboratory AIRSAR instrument (panels behind wing) mounted aboard a modified NASA DC-8 aircraft. During data collection, the plane flies at 8 km above the average terrain height at a velocity of 215 m per second. Second row: AIRSAR-JPL's experimental Airborne Synthetic Aperture Radar System. POLSAR-3 wavelengths and full polarization diversity help characterize targets P, L, and C band at HH, HV, VH, and VV polarizations' 3 modes 20, 40, and 80 MHz bandwidth. Resolution increases with bandwidth while swath decreases 80 MHz L, band resolution is 1.7 m, 40 MHz is 3.3 m, and 20 MHz is 6.7 m. Swath width is 5 km at 80 MHz, 10 km at 40 MHz, and 15 km at 20 MHz. TOPSAR generates Hi Res DEMs (digital elevation models) at two wavelengths. Cross-track interferometry L and C band digital elevation models (DEMs) postings at 5 m (40 MHz), 1–3 m height accuracy. Second and third rows: Angkor Wat is a major religious/urban center and has a sophisticated associated water system, ~ninth to fifteenth centuries. The population peak estimate is perhaps one million. Angkor region imaged by SIR-C and AIRSAR. The AIRSAR campaign also collected high-resolution TOPSAR DEMs. Collaborative work advances historical understanding thanks to the detection of previously unknown structures. Angkor lessons: archaeological structures sometimes show both in radar images and DEM but often show only in DEM providing water management insight. From *left* to *right*: Angkor Wat religious/urban center general view. Angkor perspective view: AIRSAR on TOPSAR DEM. Angkor Wat and Kapilapura mound: RADAR data and digital elevation model. Sman Teng Temple: RADAR data and digital elevation model. (Courtesy of R. G. Bloom, JPL-NASA.)



Remote Sensing in Archaeology, Figure 12 Photo shows the landscape below the Loughcrew passage tombs, County Meath, Ireland: relief-shaded LiDAR image of enclosures and field boundaries in "improved" pasture grassland subject to stone removal and periodic plowing. Note the better preservation of the earthworks in the legally protected unplowed area at *lower left*. (Courtesy of Dr. Colin A. Shell, Department of Archaeology, University of Cambridge, UK.)

represented by the use of helicopters as imaging platforms, allowing slower and lower flight paths, a multiple return feature (in which several reflections can be recorded from the same impulse, indicating, for example, tree canopies and ground as in Figure 13), combined with ultrahigh frequency, enabling much higher ground resolution. Densities of up to 60 pts/m^2 (about 10 cm resolution) can be obtained by these methods, allowing effective penetration of even the most densely vegetated areas and permitting the recording of micro-topographic variations even where the remains of archaeological features are severely degraded (Shaw and Corns, 2011).

Nevertheless, a degree of caution is needed. The production of a DTM using LiDAR technology is a complex process that involves several assumptions and decisions throughout the workflow of project preparation, data acquisition, and subsequent analysis. The archaeologist has to consider and understand the meaning of meta-information about the original point density, the time of flight, the instrumentation used, the type of aerial platform, the DTM-generation procedure, etc. (Doneus and Briese, 2011; Opitz and Cowley, 2013). If properly applied, the LiDAR technique could prove revolutionary in its impact on the process of archaeological mapping by making it possible to record previously hidden archaeological resources within woodland areas and (apparently) leveled landscapes. In favorable circumstances, it may even be possible to uncover whole "fossil" landscapes. This could have a dramatic impact on opportunities for archaeological and landscape conservation and management, as well as on scientific investigation of settlement dynamics in various phases of our history.



Remote Sensing in Archaeology, Figure 13 *Top*: conventional aerial photograph of Welshbury Hill Fort (UK) showing the dense tree canopy. (Image courtesy of the Forestry Commission, Source Cambridge University, Unit for Landscape Modelling (ULM), March 2004.) The dense woodland is not conducive to standard field survey, so it was felt that any technique that might better enable the recording of features in such woodland must be worth investigating further. The project used data flown by ULM and collected at a higher than average resolution allowing the creation of a 0.25 m grid. This was provided to staff at English Heritage as gridded files of both first and last pulse data together with an image file of the data once it had been processed using the vegetation removal algorithm. *Middle*: this image shows that the first pulse data simply recorded the canopy in much the same way as the standard aerial photograph: what is recorded is the top of the tree canopy. *Bottom*: the last pulse effectively removed the bulk of the tree cover revealing the features beneath. Last pulse data "removes" the trees revealing the ground surface. The remaining "trees" probably represent areas of particularly dense foliage or thick tree trunks/stumps. (LiDAR courtesy of the Forestry Commission, Source Cambridge University, Unit for Landscape Modelling (March 2004).)

Close-range aerial photography

From the end of nineteenth century, when Giacomo Boni used a balloon to take aerial photographs of the Foro Romano, to the present day, archaeologists have understood the desirability of acquiring low-altitude aerial imagery for purposes of documentation, conservation, and cultural resource management; the discovery of previously unidentified features plays only a minor role in this case. Various kinds of unmanned platforms have been used in archaeology and other scientific fields to lift the photographic camera so as to acquire large-scale imagery from relatively low heights (Figure 14).

Each of the methods noted below has its own distinct advantages and drawbacks (Verhoeven et al., 2009):

1. *Mats, poles, booms, and towers*. Although these platforms are cost effective, stable, and very easy to move, they are limited by their moderate maximum operational height of no more than about 20 m.
2. *Kites*. The use of kites in low-level aerial photography has been common since the 1970s, as these highly inexpensive and portable platforms can accommodate several kilograms of payload. Furthermore, the only thing that is needed for their effective operation is wind. This dependency, however, is also the method's main drawback: irregular winds are not suitable for kite-based photography, and the size of the kite is dependent upon the wind speed.
3. *Balloons and blimps*. These devices contrast with and complement kite photography in that they can be used in windless and very light wind conditions. Moreover, balloon photography is extremely flexible in its setup procedures, and operation is easy. However, balloons and blimps become difficult to position and to hold in windy conditions. Helium is also expensive and difficult or sometimes impossible to find in many countries. The gas containers, too, are heavy and unwieldy.
4. *Helikite*. This is a unique design, patented by Sandy Allsopp in 1993, and currently manufactured by Allsopp Helikites® Ltd. It combines a (small) helium-filled balloon with kite wings, securing the best properties of both platforms. The helium-filled balloon allows it to take off in windless weather conditions, whereas the kite components become important when there is wind, improving stability and providing the capacity to reach higher altitudes.
5. *Unmanned aerial vehicles (UAVs) or drones*. This category, which includes remote-controlled model aircraft and helicopters, generally involves high-end devices that allow very accurate control of the platform so as to produce photographic ortho-mosaics and, in the most advanced cases, photogrammetric stereo pairs (Eisenbeiss, 2009; Remondino and Campana, 2014). The use of such devices is growing in archaeology thanks to the improvement of photogrammetric software capable of producing accurate 3D models in a short time (Remondino, 2014b). There is also the possibility of equipping UAV platforms with a wide range of sensors, from thermal or infrared cameras to airborne LiDAR systems, video cameras, etc.

Ground truthing

Information collected from remotely sensed systems loses much of its potential meaning without detailed field survey on the ground. Effective ground truthing is often the key that unlocks the information content of remotely sensed data. Fieldwork represents the step in the process that aims to verify and enhance the results of a remote sensing study through comparison with independent evidence.

It is essential in this context to stress that the word "truthing" refers to the *interpretation* of remote sensing data; it does not imply that the actual data may be false (Hargrave, 2006). If remote sensing analysis is properly executed, the probability that interpreted features have some cultural or paleoenvironmental source is very high. The need for archaeologists to ground-check the features seen from the air has been a fundamental concept from the very origins of remote sensing (Poidebard, 1927; Crawford and Keiller, 1928). This step in the process is essential in order to define the interpretation keys and, hence, to develop or to advance the classification of anomalies into useful archaeological categories with differing levels of detail and interpretative precision, in a sequence such as:

1. Ditch, pit, wall, earthwork, etc.
2. Burial mound, grave, enclosure, settlement, etc.
3. Round barrow, long barrow, rectangular enclosure, Roman villa, etc.

The ground evaluation of anomalies can be done in a variety of ways. The conventional scheme uses a series of increasingly invasive and expensive techniques, removing some parts of the anomalies at each stage and consequently applying the more expansive and invasive techniques to a minority that have survived earlier stages of the screening process. The techniques used depend upon the conditions encountered at each site: land use, vegetation, material culture, conservation policies, etc. The basic sequence of this multistage approach might be summarized as follows:

1. *Visual inspection through field-walking survey*. Here, there is great value in the use of a mobile GIS device provided with a satellite navigation system (GPS) and up-to-date maps of the selected features for ground truthing. This guarantees the necessary accuracy to ensure the inspection of each anomaly. Common features, possibly recognizable during fieldwork, are localized depressions or ridges with regular shapes, differences in soil moisture, concentrations of gravel or apparently nonnative rock, archaeological artifacts, etc.
2. *Core sampling*. Ideally, cores should be taken from within the targeted anomaly as well as outside its apparent limits. Evidence could include the presence of charcoal, burned soil, bone, fragments of pottery,

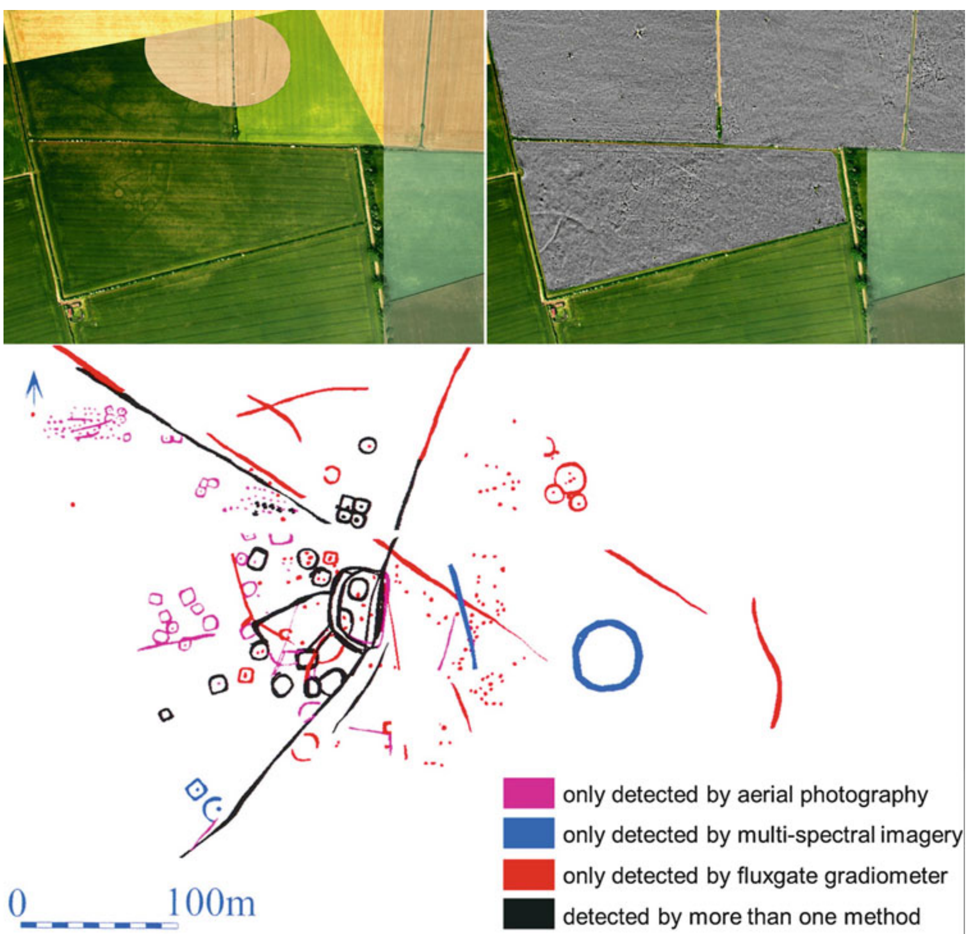
Remote Sensing in Archaeology, Figure 14 From *top* to *bottom* and from *left* to *right*. Ladder for documentation on archaeological excavation; watch tower aimed at the collection of photography, laser scanner data, etc.; giraffe photography uses a telescopic mast to elevate a high-quality digital SLR camera to heights generally between 5 up to10 m. This platform is used for collection of vertical photography and creation of a photomosaic of small areas at a very high level of detail; blimp of the University of Siena, Centre for GeoTechnologies, San Giovanni Val d'Arno; kite; helikite; balloon; from high-end UAV (unmanned aerial vehicle) systems to very low-cost UAV platforms. (Photos courtesy of the University of Siena, Laboratory of Landscape Archaeology and Remote Sensing (LAP&T) and Centre of GeoTechnologies (CGT), H. Eisenbeiss and F. Remondino.)

or other kinds of artifact. Often, one will not be able to determine whether a feature is present solely on the basis of such a soil core.

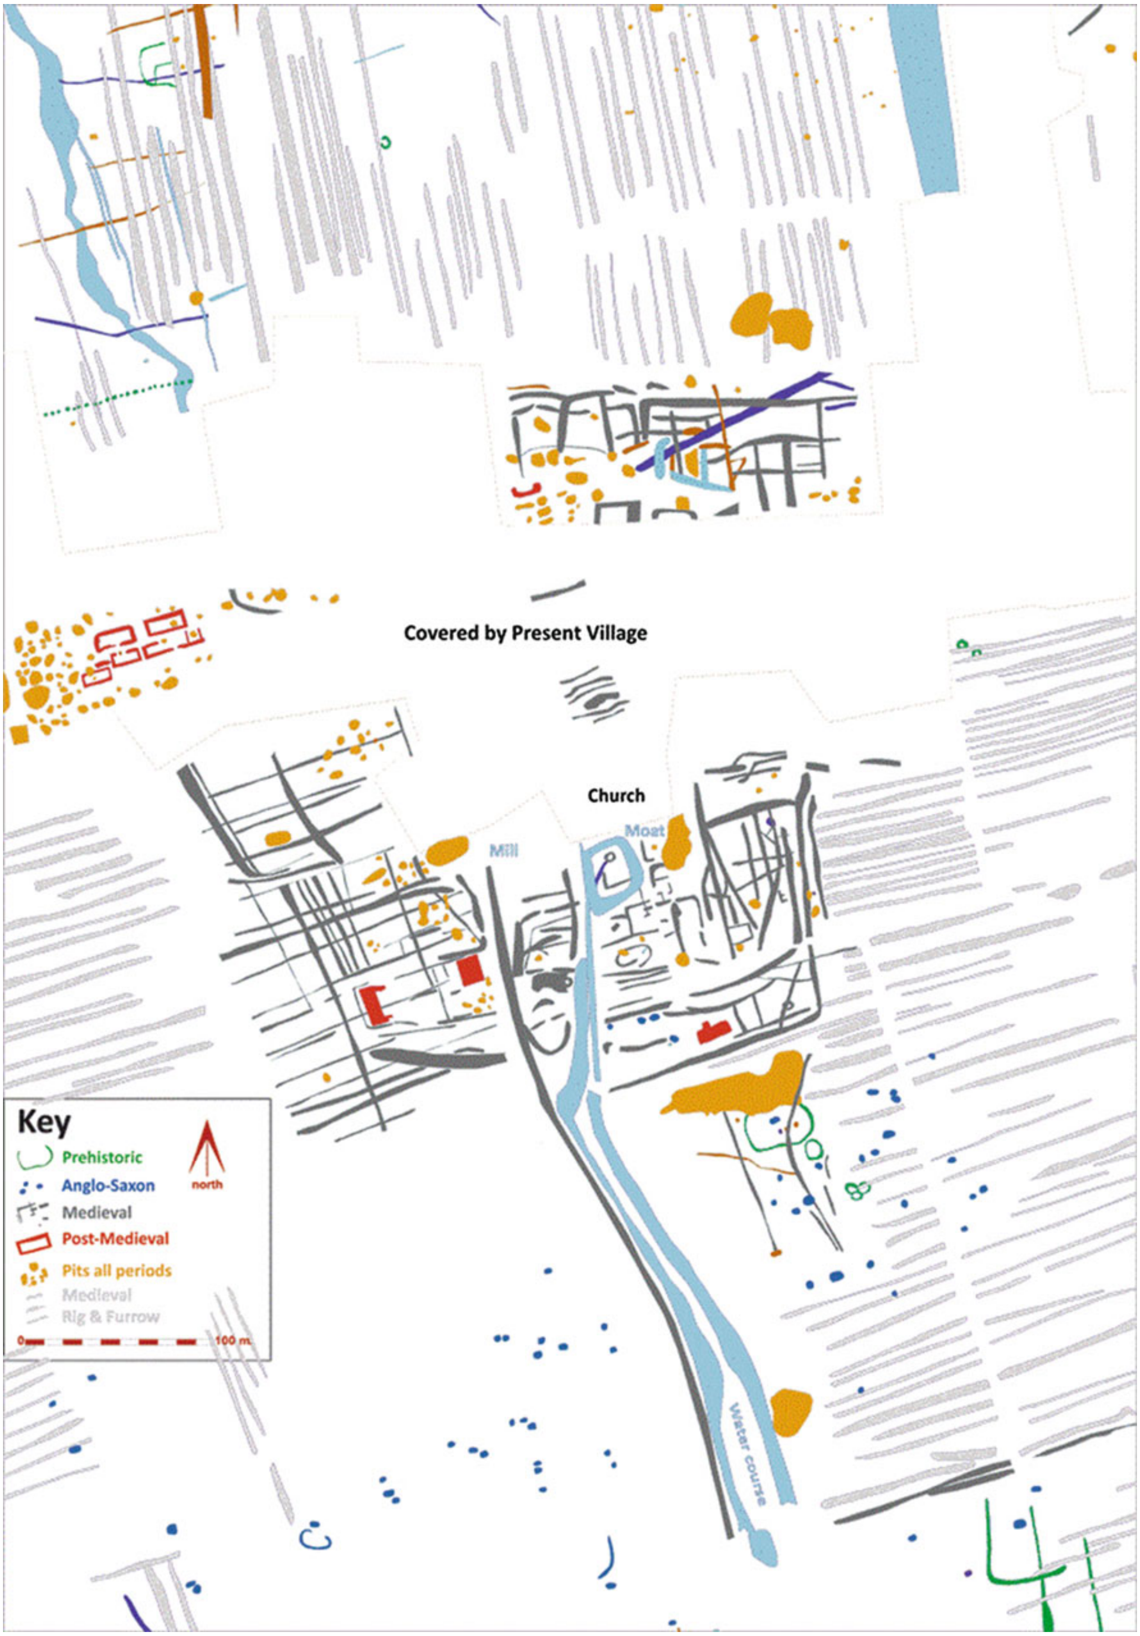
3. *Test pits or shovel test*. This is a common method, consisting of excavating small pits (generally measuring 1 m by 1 m) to the surface of sterile soil or to a depth of 70–120 cm (depending on the stability or instability of the sections). This makes it possible to note in the field any presence or variation in the concentration of artifacts or other cultural material. As with core sampling, the test pits should be excavated in pairs, one within and the other outside the anomaly. The main advantages of core sampling and test pits are their low cost and minimal invasiveness.
4. *Minimalist stratigraphic excavation*. Minimalist and well-planned stratigraphic excavation can be extremely efficient and reliable in verifying the presence of features in a way that is relatively noninvasive and cost effective. Unfortunately, this technique (as well as core sampling and test pitting) may not be possible in countries where social and political factors require ground truthing to be largely or wholly noninvasive.
5. *Mechanical excavation*. Perhaps the most convincing type of ground truthing is removal of the topsoil or plow-disturbed strata over large and contiguous areas. Subsurface features can then be marked, mapped, and wholly or partially excavated (Campana, 2011). This practice is mainly applied to verify the results of archaeological impact assessments in the case of infrastructure and other types of major construction work.

GIS data integration: mapping and interpretation

Lillesand and Kiefer, authors of one of the most authoritative manuals of remote sensing, maintain in their section on the basic concepts and founding principles of remote sensing as follows: "...successful application of remote sensing is premised on the integration of multiple, interrelated data sources and analysis procedures. No single combination of sensor and interpretation procedures is



Remote Sensing in Archaeology, Figure 15 Combining aerial campaigns with geophysical data shows that neither approach gives the same returns, confirming that identifying the archaeological capacity of the landscape requires the use of a multi-sensor approach; map of a site in West Heslerton (North Yorkshire, UK). (Courtesy of Dominic Powlesland, Landscape Research Centre.)



Remote Sensing in Archaeology, Figure 16 (Continued) appropriate to all resources inventorying and environmental monitoring applications" (Lillesand and Kiefer, 1994, 35). This is absolutely true for archaeological remote sensing (Powlesland, 2006).

A prerequisite for data integration of remotely sensed imagery is knowledge about each measurement's position in relation to a known system of geographical coordinates. Failure to satisfy this condition results in an inability to localize the acquired information. The entry of the data into a GIS is the basis for any attempt at integration of the information so as to develop a historical/archaeological narration or to ensure conservation of the archaeological resource. Georeferencing of the remotely sensed data does not represent the end of the archaeological mapping process, but only an intermediate stage. On their own, satellite imagery, aerial photographs, LiDAR imagery, and geophysical imagery signify little.

It is the responsibility of the archaeologist (often in collaboration with specialists) to give archaeological sense to the photographs or to the measurements of chemical and physical parameters in the soil. In summary, the interpretation of the data is made real and communicable through cartographic drawing of the elements perceived as anomalies (Palmer, 2000).

This is, therefore, the critical phase in landscape and archaeological research. In practice, the process advances through the drawing, digitally or by hand, of the anomalies and other elements deemed to be of archaeological interest. The georeferenced graphical restitution of the information contained in vertical or oblique aerial photographs, in high-resolution satellite imagery, in LiDAR data, and in maps derived from geophysical measurements makes it possible to overlay on topographic maps the results of the various investigative methods, along with a mass of other data that have been stratified layer upon layer over the years (Figure 15). The result is a jigsaw puzzle, a complex representation in which it is possible to measure and position each piece of information. At the same time, it is often possible to perceive the overall picture, whether single phase or spread across time, along with the overlapping and stratified fragments of whole systems of ancient and medieval landscapes. Through archaeological mapping and the use of GIS, it becomes possible to study these fragments together with other layers of archaeological and non-archaeological information in the writing of history, in heritage protection through the planning process, and through conservation or monitoring of the shared cultural inheritance (Figure 16; Campana, 2009).

Remote Sensing in Archaeology, Figure 16 A map of East Heslerton (North Yorkshire, UK) drawn by Dominic Powlesland demonstrates the integration of methodologies and data in the process of mapping evidence and understanding landscapes. While the surviving earthworks of the later medieval village show up well in English Heritage air photographs, geophysical surveys reveal much more detail of the medieval and later village, particularly in the areas beyond the present village to the north and west. To the west of the present village, the series of long rectangular enclosures with their short sides aligned to the present track coming down from the Wolds are termed crofts and tofts. The toft is where the house was built surrounded by a small garden area, and beyond it the croft was probably used for domestic food production. The land beyond the village was divided into "rig and furrow," the strip field system that dominated the medieval landscape of much of lowland England. The village was supplied with water from springs at the foot of the Wolds. To the south, the natural stream channel was managed from an early date with the water used to drive a mill and fill the moat associated with the Manor House. The site of the Manor is thought to have been largely destroyed when the present church, commissioned by Sir Tatton Sykes of Sledmere and designed by the celebrated Victorian architect G. E. Street, was built between 1873 and 1877. Street also designed the vicarage and had further buildings constructed to house the building team. The remains of a number of houses were demolished during the last century in the field immediately to the west of the village and to the south of the A64 trunk road, which cuts through the northern part of the medieval village. The evidence indicates that the village that survives today is considerably smaller than it had been in medieval times and, thus, is termed a shrunken village. (Map provided courtesy of D. Powlesland, Landscape Research Centre.)

Definition

Rockshelter. A natural cavity enclosed by one or more rock walls and an overhang that provides protection from the elements (wind, precipitation, sun, or a combination thereof).

Introduction

Rockshelters are important settings for archaeological sites because they form in numerous ways and in a variety of bedrock types and landscapes. The same properties of rockshelters that provide protection to their human and animal inhabitants also contribute to the protection and preservation of archaeological deposits left within them.

Humans exploit rockshelters for a variety of reasons. Ethnographic studies have revealed many different human behaviors and spatial patterning of material remains within these sites. For example, Binford (1996) notes that ethnographic uses of rockshelters tend to emphasize transient needs or short-term exploitation over long-term habitation. These transient functions can include use as refuges and hiding places; caches and storage; sources of food, water, and material resources; and ritual localities. In sites that are used for habitation, both Binford (1996) and Galanidou (2000) describe a "modular pattern" of use, which includes arrangement of activities, demarcation of areas for different families, construction of depressions and hearths, use of space for sleeping purposes, patterned discard of waste, and movement of large rocks. Finally, as documented in an ethnogeoarchaeological study by Brochier et al. (1992), humans extend the desirable properties of rockshelters to other species and utilize these natural spaces as stables or byres for domestic herbivores.

The geoarchaeology and sedimentology of rockshelters are frequently classified with that of caves (e.g., Collcutt, 1979; Butzer, 1981; Farrand, 1985; Funk, 1989; Straus, 1990; Farrand, 2001; Woodward and Goldberg, 2001).

In site distribution and settlement pattern studies, rockshelters are also generally grouped with caves, rather than with open-air localities. In fact, the terms "cave" and "rockshelter" are sometimes used interchangeably when naming sites (e.g., Sibudu Cave, which is actually a large shelter; Goldberg et al., 2009), either as a consequence of local naming conventions or due to the fact that the site morphology changed over time. Indeed, some types of rockshelter are created as a result of the collapse of larger cave systems, and in some geomorphic settings, caves and rockshelters may be clustered together. Davis (1990, 332), coming from a North American perspective, defines three types of caves: "caverns," which are formed overwhelmingly in calcareous or volcanic bedrock and have portions that are not lit by the sun; "traps," which are also predominantly calcareous or volcanic and are vertical in morphology with no outlets; and "rockshelters," which are for the most part lit by sunlight and also provide some form of shelter for organisms. Other researchers consider caves to be deeper than they are wide and rockshelters to be wider than they are deep (Miller, personal communication).

In the archaeological literature more broadly, rockshelters and caves differ in several ways. Caves are subterranean systems containing areas that are, to some degree, permanently dark. Rockshelters are cavities that are always lit by direct or indirect sunlight. Additionally, not all caves contain natural conduits to the Earth's surface. In contrast, active rockshelters are surface features that can be accessed from the surrounding landscape. Although most caves form through karstic processes, some, such as lava tubes, do not. Compared to rockshelters, cave formation processes are limited in variability.

Rockshelters are extremely diverse features that exhibit myriad forms. As outlined below, rockshelters are created in igneous, metamorphic, and sedimentary bedrock, as well as in semi-consolidated sediments. Rockshelters occur in coastal marine, lacustrine, glacial, eolian, and interior orogenic settings, and they exist in all latitudes and environmental regimes. Due to the high variability in their formation processes, rockshelters are impacted by different depositional and erosional processes, and they are more abundant than caves. Hence, archaeological sites located in rockshelters are also more abundant than true cave sites.

On the other hand, the entrance portions of caves that humans typically utilize most heavily (Butzer, 1971) share many features in common with rockshelters:

1. They provide protection from the elements (e.g., precipitation, wind, sun) and have unique internal environments that are generally warmer in winter and cooler in summer compared to open-air sites (Straus, 1990).
2. They are within the zone illuminated by sunlight.
3. They can be populated by plants of various types.
4. They frequently open onto broad spaces that can be occupied or utilized in different ways.

Although cave systems may be physically bigger than most rockshelters, they may be comparable in terms of usable occupation space.

Because rockshelters are not geomorphic features in the strictest sense – in that they are classified as such based on their morphological suitability for human or animal occupation rather than their formation processes – the identification of an archaeological site as being situated within a rockshelter is colloquial rather than formalized. Rockshelters are also transient features (Straus, 1990; Farrand, 2001). The life history of a rockshelter is determined by its host bedrock type and the rate of erosional processes. Despite their transient nature over geological timescales, rockshelters can be highly visible on the landscape, and thus their sedimentary sequences are impacted by the effects of repeated human and animal visits over much longer periods of time relative to open-air sites (Barton and Clark, 1993). A clear understanding of the variations in geologic settings and rates of formation processes of rockshelters is therefore very important for effective incorporation of rockshelters into local and regional studies of landscape use, site distribution, and human mobility patterns.

Currently, the geoarchaeological literature lacks a formal classification system for rockshelter sites. Heydari (2007) proposed a classification system for shelters found in the Zagros Mountains of Iran; however, his system is specific to inland karstic limestone regimes in arid environments. Other classifications, such as the boulder shelter system outlined by Mercader et al. (2003), are specific to other regions or geologic settings. The lack of a global organization system has resulted in haphazard descriptions of shelter morphology and formation processes in archaeological site reports, and this has limited the development of a standardized protocol for rockshelter sedimentological analyses.

This entry provides the foundation for a comprehensive organizational system and outlines the range of approaches to the geoarchaeological study of rockshelter sites. First, an expanded classification system describes shelters formed in sedimentary, igneous, and metamorphic bedrock types, as well as within terrestrial deposits. Second, sedimentological issues are presented, indicating that rockshelters contain sediments of geogenic, biogenic, and anthropogenic origin that may be deposited as a result of human or animal activities or natural processes. Third, rockshelter sediments are also subject to geological, biological, and human-induced post-depositional modifications, both mechanical and chemical. Finally, appropriate analytical strategies by geoarchaeologists working on the sediments of rockshelter sites depend upon a complete understanding of all possible sources of sediment and rockshelter life histories.

Rockshelter formation processes

A global rockshelter classification system is outlined in Table 1. Rockshelters can be divided into two main

Rockshelter Settings, Table 1 A rockshelter classification system organized by primary formation process. A number of secondary processes (e.g., salt and frost spalling, tectonic movements, human activity) may contribute to morphological changes during shelter formation histories

Rockshelter type	Cavity type	Formation regime	Primary process	Bedrock	Geomorphic features
Lava shelters	Primary	Subsurface	Lava flow dynamics	Basalt and andesite	Collapsed lava tubes, inflationary caves, liftup caves, blisters
Karstic rockshelters	Secondary	Subsurface	Chemical (phreatic and meteoric) dissolution, combined with mass movement that contributes to collapse or breach of cavities	Calcareous rock, including limestone, dolomite, marble, travertine, and tufa	Karst rockshelters, collapsed caves, collapsed dolines, footcaves
Etchform shelters	Secondary	Subsurface	Etchplanation	Coarse crystalline and coarse clastic rock	Cliff face cavities, boulder piles
Scarp foot and surface karst shelters	Secondary	Near surface	Sapping, scarp-foot weathering, chemical dissolution, biological activity	Any	Basal notches, flares, solution hollows, swamp slots, footcaves, flared boulders, mushroom rocks, haystacks, cliff face cavities, theater heads, overhangs
Tafoni and spall shelters	Secondary	Surface	Salt weathering and spalling, hydration weathering, frost spalling, biological activity	Coarse crystalline and coarse clastic rock	Hollows, arches, visors, tortoiseshell rocks, alcoves, cliff face cavities, boulder piles
Abrasion and entrainment shelters	Secondary	Surface	Differential weathering as a result of scouring by particles entrained in a fluid (wave abrasion, fluvial abrasion, glacial abrasion, eolian winnowing); deposition of entrained materials as flood boulders and glacial erratics	Any, although common in sedimentary and metamorphosed sedimentary rocks	Overhangs, cornices and horizontal cavities in sedimentary rocks with horizontal or mildly dipping bedding sequences; vertical or arched cavities in faults, folds, and jointed rocks; horizontal cavities near former glacier, lake, river, or sea levels; yardangs, wind eddy hollows; flood boulders, glacial erratics, and till piles
Tectonic shelters	Secondary	Surface	Faulting, collapse of fault breccia, earthquakes	Any	Fault scarps, cliff face cavities, boulder piles
Pseudokarstic shelters	Secondary	Surface	Differential weathering, undercutting, piping	Semi-consolidated sedimentary surface deposits, marl, tuff, tufa, travertine, fine-grained intrusive dikes and sills	Pseudokarst, loess karst

groups: those that occupy primary cavities and those that occupy secondary cavities. The latter grouping includes cavities that form as a result of subsurface and surface weathering processes. Despite these broad groupings, most shelters form as a result of a combination of primary and secondary processes. For example, karstic shelters may be further modified by ceiling collapse due to frost spalling or tectonic activity. In addition, human activities can contribute to weathering as secondary processes. For example, the construction of fires within shelters can induce or contribute to thermoclastic weathering of bedrock (Kourampas et al., 2009). Abrasive rubbing of shelter walls by people and livestock has been observed in ethnographic contexts (Brochier et al., 1992; Ward et al., 2006), and some bedrock types and their inclusions may be quarried for lithic raw materials, pigment manufacture, or construction purposes (see Figure 1d). These behaviors may contribute to both sedimentation and morphological modification of some sites.

Primary cavities result from bedrock formation processes and are limited to mafic igneous bedrock types. Types of primary cavities that can form rockshelters include lava tubes, inflationary caves, and liftup caves. Lava tubes form in one of two ways, and both formation processes yield long, hollow cavities within a basalt bedrock. In one way, molten lava flows within cooler portions of a pahoehoe-type basalt (lava with low viscosity and smooth flow patterns). After the lava exits, a long, sinuous tube is left beneath the surface of the basalt flow. In the second way, a channel of lava hardens from the exterior inward. Emptying of the center of the channel yields a tube. Collapse of the roof or lateral erosion of the basalt flow may expose a portion of the tube, producing either a cave or a rockshelter, depending on the cavity morphology. Inflationary and blister caves (Figure 1) form when gas bubbles or areas of high pressure build within a lava flow. Collapse of one or more of the walls of the bubble following the cooling of the rock can result in the formation of a cavity, with later erosion exposing a shelter. Liftup caves form in a similar manner, but they are located along the edge of a flow, resulting in one or more horizontal cavities along its perimeter. Erosion of these features, as with lava tubes, can lead to the exposure of small cavities or shelters. An example of an archaeological site located in a lava shelter is the Upper Paleolithic site of Aghitu-3 in Armenia (see Figure 1b). Because lava tube shelters, inflationary caves, and liftup caves form only in basalt and rarely in andesite (more viscous lava richer in silica), their worldwide distribution is limited to active and relict volcanic provinces.

Secondary cavity rockshelters form within rocks during subsurface or surface weathering processes. Subsurface or subaerial weathering processes that can lead to the formation of rockshelters include solution karst and etchplanation.

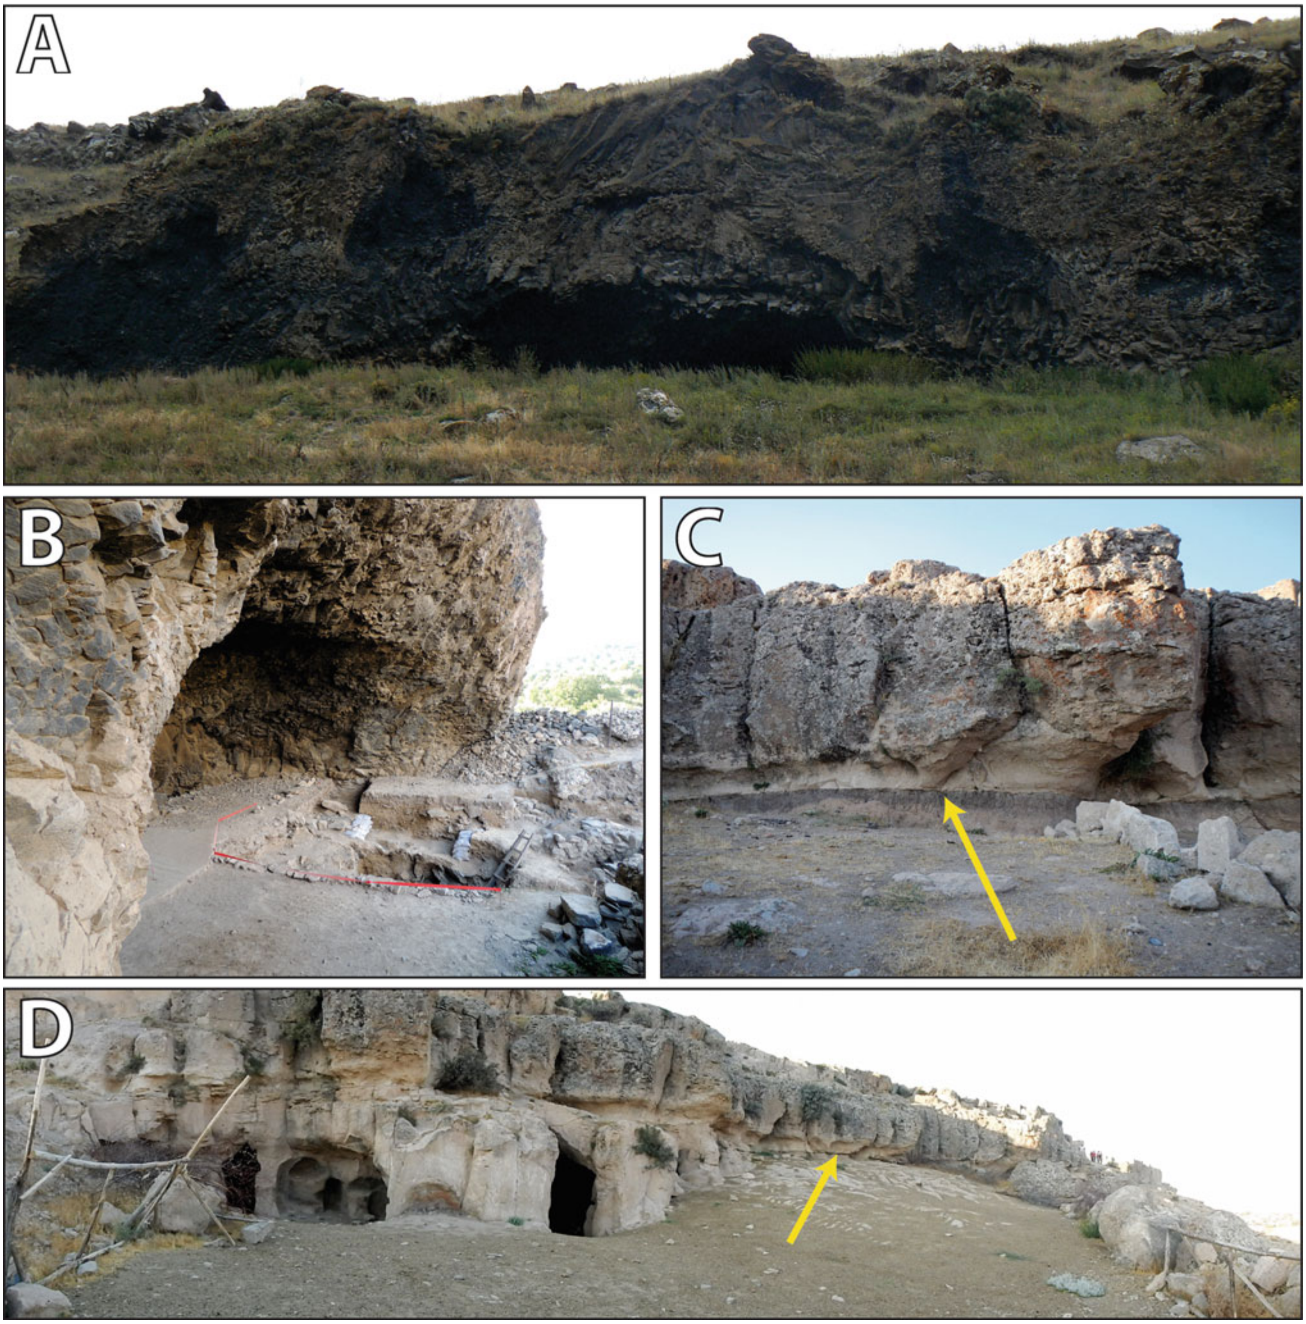
Solution karst forms in calcareous bedrock of sedimentary or metamorphic origin (e.g., limestone, dolomite, and marble) due to chemical weathering by acidic groundwater (Ford and Williams, 2007). Solution karst may form at considerable depth within the bedrock, but karstic systems are exploited by people only when non-karstic surface weathering processes, such as cliff face retreat, breach subterranean chambers to form accessible caves. Rockshelters form when exposed caves collapse further (Figure 2a). Because a single system may be breached in several places, caves and rockshelters of various shapes and sizes may be clustered on the landscape. An example of a cave and rockshelter cluster containing archaeological sites is the Middle and Upper Paleolithic Hohlenstein Stadel complex in the Lone Valley of Germany (Figure 2b). Rockshelters and caves may also form when surface karst processes breach subterranean systems (Sweeting, 1973). As an example, collapse dolines, also known as sinkholes, may be bounded by cave and rockshelter systems that may be accessed from above. Karstic shelters are found in areas with calcareous bedrock, but are most common in middle latitudes. Thus, they are present on every continent except Antarctica but have limited distribution in South America and most parts of Africa.

Etchplanation is another type of subsurface weathering that can produce natural cavities in bedrock, as well as boulder piles that provide sheltered areas (Twidale and Vidal Romani, 2005). Etchplanation occurs most commonly in jointed or faulted granitic and gneissic bedrocks that are buried by sedimentary deposits or surrounded by more highly weatherable bedrock types. Etchplanation occurs in two phases: subsurface weathering followed by exhumation. During the subsurface weathering phase, water percolation along joints and faults causes the alteration of micas and feldspars, transforming them into clay. During the exhumation phase, the overlying sedimentary deposits, as well as the weathered clays, are removed by water or wind. The resulting geomorphic features include boulder piles, domes, inselbergs, kopjes, and tors. Spaces between and beneath boulders form cavities and provide shelter from the elements. Examples of archaeological boulder pile shelters that formed as a result of etchplanation include the Ituri Rock Shelters in the Congo (Mercader et al., 2003). Hollows and overhangs are also present within domes, inselbergs, kopjes, and tors, where they form from over-widened joints or partial collapse of the bedrock. The Middle Stone Age site of Diepkloof Rock Shelter in South Africa formed in this manner when a large sandstone boulder, undermined by differential subsurface weathering of a shale layer, detached from the cliff face, leaving a cavity and overhang in a kopje (Miller et al., 2013) (Figure 3a). Etchform shelters are most commonly found in Paleozoic shield complexes in the humid subtropics where annual temperatures and precipitation are high. Elsewhere, these features may be considered relicts of periods in Earth's history when average temperatures were warmer or when now arid areas previously received higher precipitation.

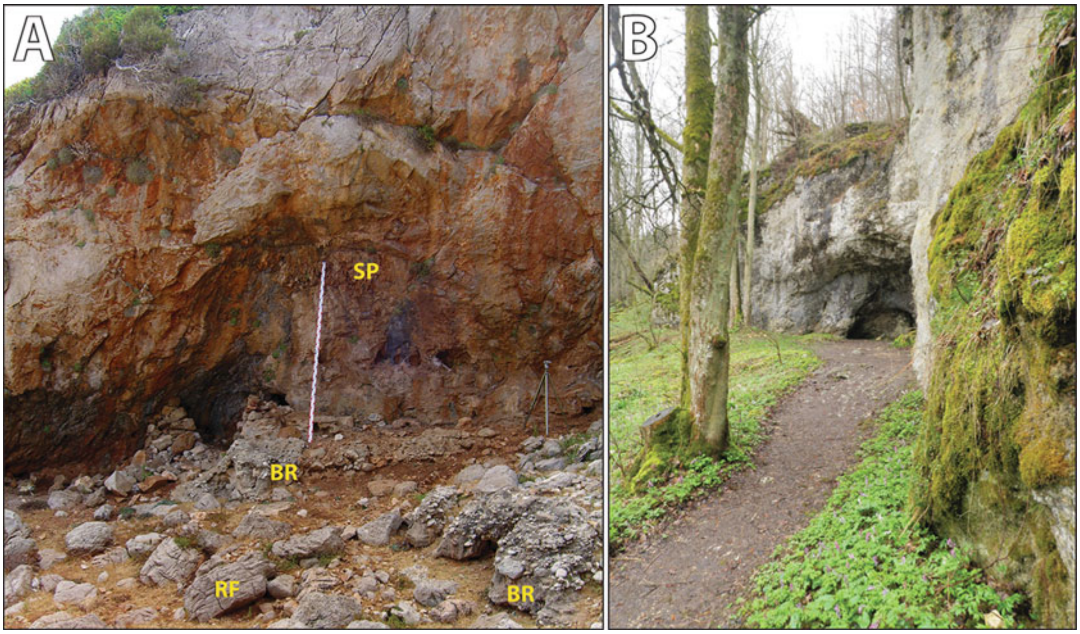
Scarp-foot weathering and sapping are near-surface weathering processes that operate in the same manner as etchplanation and karst, but at considerably shallower depths and in a wider range of bedrock types and climatic regimes. Scarp-foot weathering occurs at the bases of cliffs or large boulder edges. At these locations, increased moisture, sometimes combined with the activities of plants and other organisms, leads to increased chemical dissolution of carbonate bedrock (surface karst) or alteration of crystalline rocks (McDonald and Twidale, 2011). As in etchplanation, a later phase of deflation may expose the weathered area, producing concavities or notches at the base of the cliff. These features may also be termed solution hollows and flares. When large boulders are weathered in this manner, they may be termed flared boulders, mushrooms, or haystacks. Archaeological examples include the site located in a basal notch illustrated in Figure 3c, and Akrotiri *Aetokremnos*.

Surface weathering processes produce rockshelters in nearly any type of rock or terrestrial sedimentary deposit. The four main groups of shelters that form as a result of surface weathering processes are (1) tafoni and spall shelters, (2) abrasion and entrainment shelters, (3) tectonic shelters, and (4) pseudokarstic shelters.

Tafoni (Figure 4) are surface features of highly variable shape and size that form frequently in arid environments or coastal settings as a result of salt weathering, sometimes in combination with biological activity, frost spalling, thermal shock or insolation weathering, hydration weathering, and abrasion. These processes can operate at a variety of scales. Hydration weathering, salt weathering, and frost spalling can impact individual mineral grains, with chemical weathering of nearby mineral grains to swelling clays, precipitation of salt crystals from



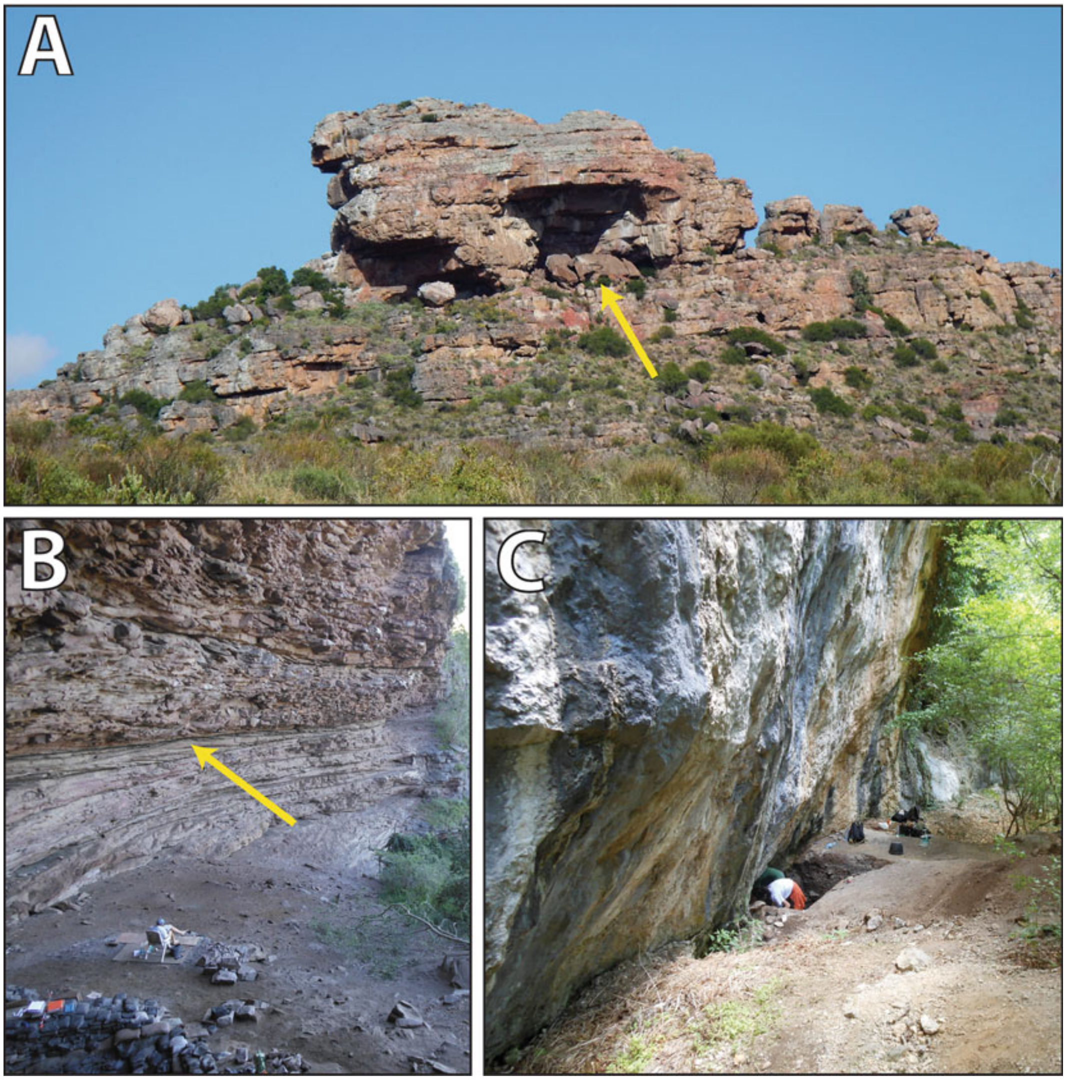
Rockshelter Settings, Figure 1 Shelters formed in extrusive volcanic rocks or lava shelters. (**a**) Inflationary caves and blister shelters are present at the edge of a basaltic lava flow. Erosion along the face of the lava flow has exposed internal primary cavities formed by gases that were trapped within the lava as it cooled. Sisian Caves, Armenia (Photo credit: Andrew W. Kandel). (**b**) Close-up view of a blister shelter in basalt. Collapse of the ceiling and retreat of the drip line has resulted in deposition of blocky roof fall (*éboulis*) visible in the excavation profile. Aghitu-3 (Upper Paleolithic), Armenia (Photo credit: Andrew W. Kandel). (**c**) A small secondary cavity shelter formed due to differential erosion at the contact between an ash-flow tuff and the underlying soil (*arrow*), possibly exacerbated by the abrasive activities of livestock (see Brochier et al., 1992). This shelter may be a type of pseudokarst. Aksaray Province, Turkey. (**d**) The shelter and related features in (**c**) have been recently utilized as a sheep stabling area. The *arrow* indicates the position of the shelter pictured in (**c**). Sheep dung accumulates as sediment and is concentrated here, as both the cliff face and the overhang at the tuff soil contact provide protection from wind and sun. Man-made cavities and shelters have been carved into a lower tuff – likely during Byzantine times – and today are incorporated into the stabling area. These areas contain thick deposits of partially degraded dung and other organic materials. Aksaray Province, Turkey.



Rockshelter Settings, Figure 2 Karstic shelters. (**a**) This limestone shelter formed as a result of collapse of a former karstic chamber. Speleothems (*SP*) formed within a large karstic system, remnants of which are still present, and today, these features are eroded and are visible along the shelter wall. The sediments infilling the shelter are also largely eroded; however, beachrock (*BR*) deposits (cemented littoral sands and cobbles) are locally preserved. Blocks of roof fall (*RF*) are visible in the foreground and are related to collapse of the former cave ceiling as a result of tectonic activity. Archaeological deposits overlying the beachrock are capped with cave wall speleothems and flowstones. This stratigraphic relationship indicates that the earliest Paleolithic occupation of the site postdated a drop in sea level and predated a major phase of cave collapse. Scale is 3 m. Üçağızlı Cave II (Middle Paleolithic), Hatay Province, Turkey. (**b**) The Hohlenstein Stadel complex contains phreatic tubes, as well as rockshelters formed in limestone. Lone Valley (Upper Paleolithic), Germany (Photo credit: Jennifer Ort).

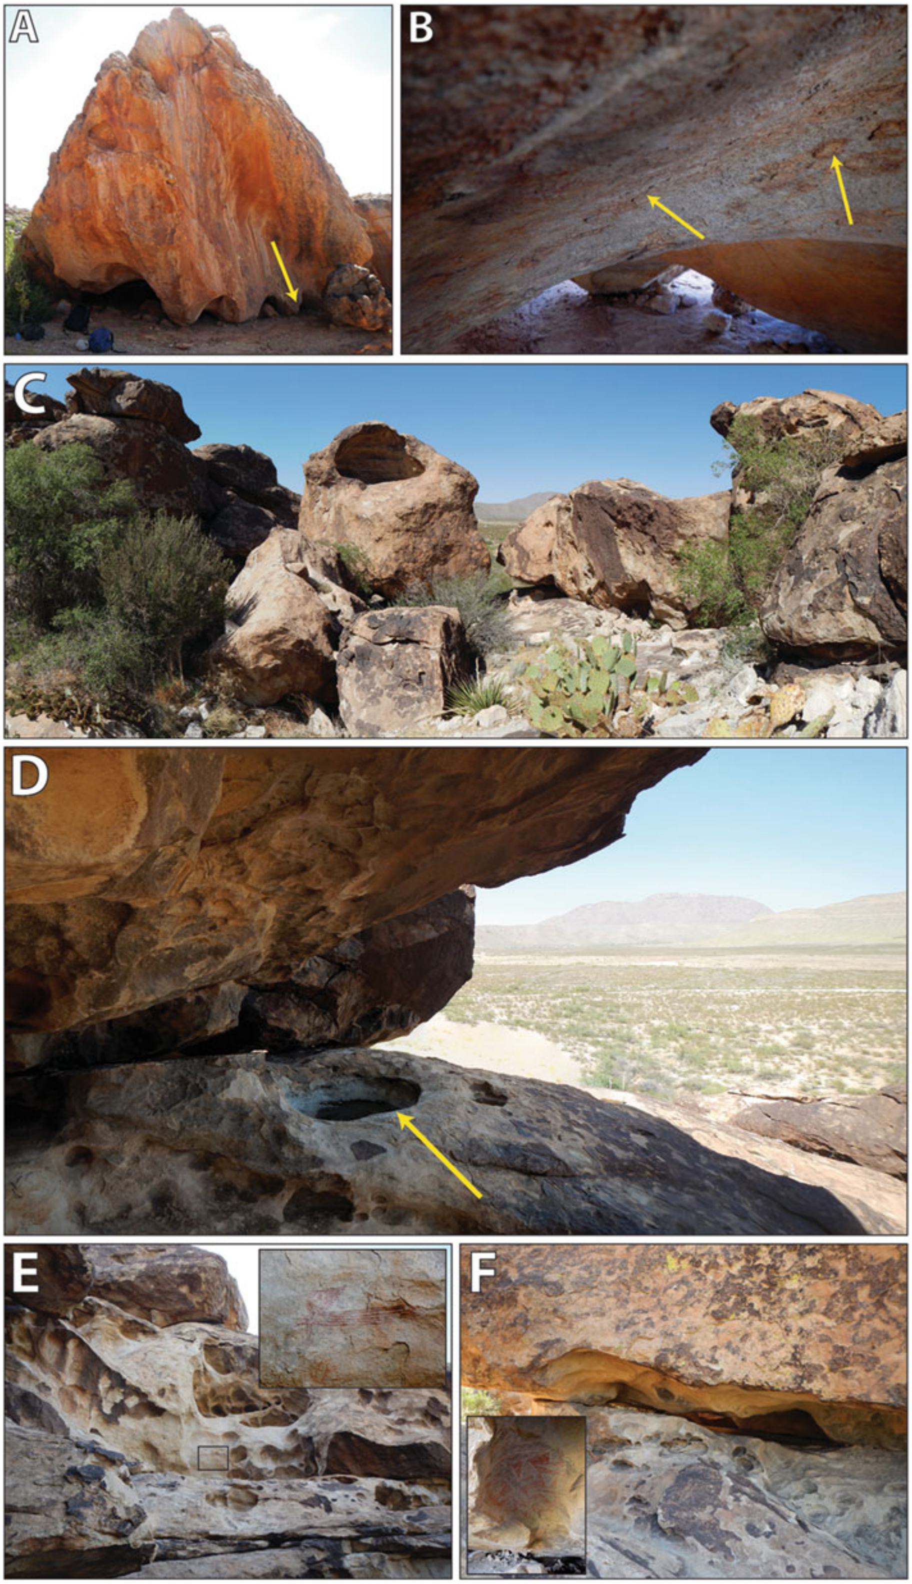
percolating solutions, or growth of ice causing individual particles to detach from the bedrock or boulder. These processes, along with thermal shock and insolation weathering, can also impact sand- and gravel-sized aggregates of material (see Figure 4b), the latter producing exfoliation when bedrock expands and contracts in response to heat. Tafoni and other spall features are common on vertical cliff faces and boulders. Of the many concave features, which include honeycombs, hollows, alveoli, lattices, alcoves, visors, and tortoiseshell rocks, only some are large enough to be exploited for human purposes, although smaller features such as basins and alcoves might be utilized as water sources and pictograph sites (see Figure 4c–f). Tafoni cavities can develop internal conditions that are cooler and moister than the surrounding environment, thus accelerating erosional and biological processes within the sheltered areas and contributing to their expansion (Cooke et al., 1993). Examples of archaeological localities located within tafoni are Hollow Rock, a Middle Stone Age shelter located in South Africa (see Figure 4a, b), and portions of the Hueco Tanks site in the USA (see Figure 4c–f). Salt weathering and cryoclastic processes can also operate at a variety of scales, producing other types of spall shelters in environments that are outside the typical range for tafoni. In the site of Sibudu, salt spalling and biological weathering have largely contributed to the present-day morphology of the site (see Figure 3b, also Goldberg et al., 2009). In high latitudes and elevations, freezing and thawing of water within bedrock cracks and joints can impact existing shelters and contribute to rockshelter sedimentary deposits (see below).

Abrasion shelters (Figure 5) form as a result of scouring and differential weathering by particles entrained in a fluid, such as air, water, or glacial ice. The location of an abrasion shelter within its host landform is determined by the position of the fluid source, as well as internal differences in bedrock type that influence their resistance to weathering. Abrasion shelters that form as a result of wind typically form by winnowing of individual mineral grains or clasts from soft bedrock by silt- and sand-sized particles entrained in the wind. Yardangs are elongate, wind-scoured features that can contain narrow concavities along their edges. Wind eddies along cliffs can also produce hollow cavities, usually with rounded morphologies. Abrasion of bedrock and boulders by sedimentary particles and ice carried by flowing water or waves can occur along rivers and streams, lake margins, and coastlines. The resulting features typically exhibit horizontal morphologies (see Figure 5a), although focusing of flow in waves and waterfalls and differential erosion can produce



Rockshelter Settings, Figure 3 Etchform shelters and cliff face and scarp-foot weathering processes. (**a**) Collapse of large blocks along the face of a kopje (*arrow*) – possibly aided by tectonic activity – has formed a shelter in sandstone. Diepkloof Rock Shelter (Middle and Later Stone Age), Western Cape Province, South Africa (see also Miller et al., 2013). (**b**) Salt spalling and biological activity have contributed to granular disintegration and cliff face retreat of sandstone along bedding planes (*arrow*), forming a large, amphitheater-like shelter. Fluvial activity also contributed to the formation of this site; however, the geogenic component of the sedimentary sequence is autochthonous fine material derived from weathering of the shelter walls and larger bedrock fragments. Sibudu Cave (Middle and Later Stone Age), Eastern Cape Province, South Africa (see also Goldberg et al., 2009). (**c**) A basal notch shelter along a limestone cliff contains archaeological materials of varied age. Basal notches form as a result of biological activity and increased moisture at the interface between soil and bedrock along a cliff. Subsequent erosion can expose these features for human exploitation. Sokobanja, Serbia.

cavities of varied shape. In water, abrasion weathering can be further compounded by biological activity, such as dissolution and boring by mollusks. In marine settings, biological activity can play a significant role in the formation of tidal notches and nips (Pirazzoli, 1986), which can reach depths of up to several meters. Humans may utilize active abrasion shelters as harbors for boats, while river channel migration and changes in base level, regional moisture, and lake and sea levels can expose inactive cavities for human habitation (e.g., Mehlman, 1979). Finally, glacial scouring can produce horizontal cavities along bedrock outcrops, and isolated erratics and boulders in till piles can provide local sources of shelter in high elevation or high-latitude settings. Abrasion shelters form in a variety of environmental settings, but they are most commonly created in easily eroded sedimentary bedrock types. Along coastlines, abrasion shelters can develop in uplifted coral reefs. Archaeological examples



Rockshelter Settings, Figure 4 (Continued) of abrasion shelters include Rodgers Shelter, USA, and the Middle and Upper Paleolithic sites of Abric Romaní and Abric Agut in Spain (Vallverdú-Poch et al., 2012).

Tectonic movements can result in the formation of cavities (Figure 6, also Figure 3a) and can contribute to the modification of shelters of all types. Faulting and folding of brittle rocks can produce fault breccias and loose clastic deposits that can erode once exposed to surficial weathering processes. For example, portions of the Zhoukoudian site complex formed as a result of erosion of fault breccias (Goldberg et al. 2001). Steeply angled fault scarps may also form small rockshelters. In addition, earthquake activity can contribute to the collapse of existing karstic caves (see Figure 2a) and etchplanation or cliff face features (see Figure 3a).

Pseudokarstic cavities (Figure 7) are highly transient types of shelters that form in surficial deposits, such as semi-consolidated sediment, tuff, tufa, marl, travertine, and easily eroded fine-grained intrusive dikes and sills. Archaeological sites located within collapsed pseudokarst may initially be classified as open-air settings. The Lower Paleolithic site of Dmanisi (Republic of Georgia) contains several collapsed pseudokarstic shelters that formed as a result of piping of volcanic ash. Man-made shelters, such as those carved into the soft ash-flow tuffs of Central Anatolia (see Figure 1d), are difficult to classify but can be considered as types of pseudo-cavities.

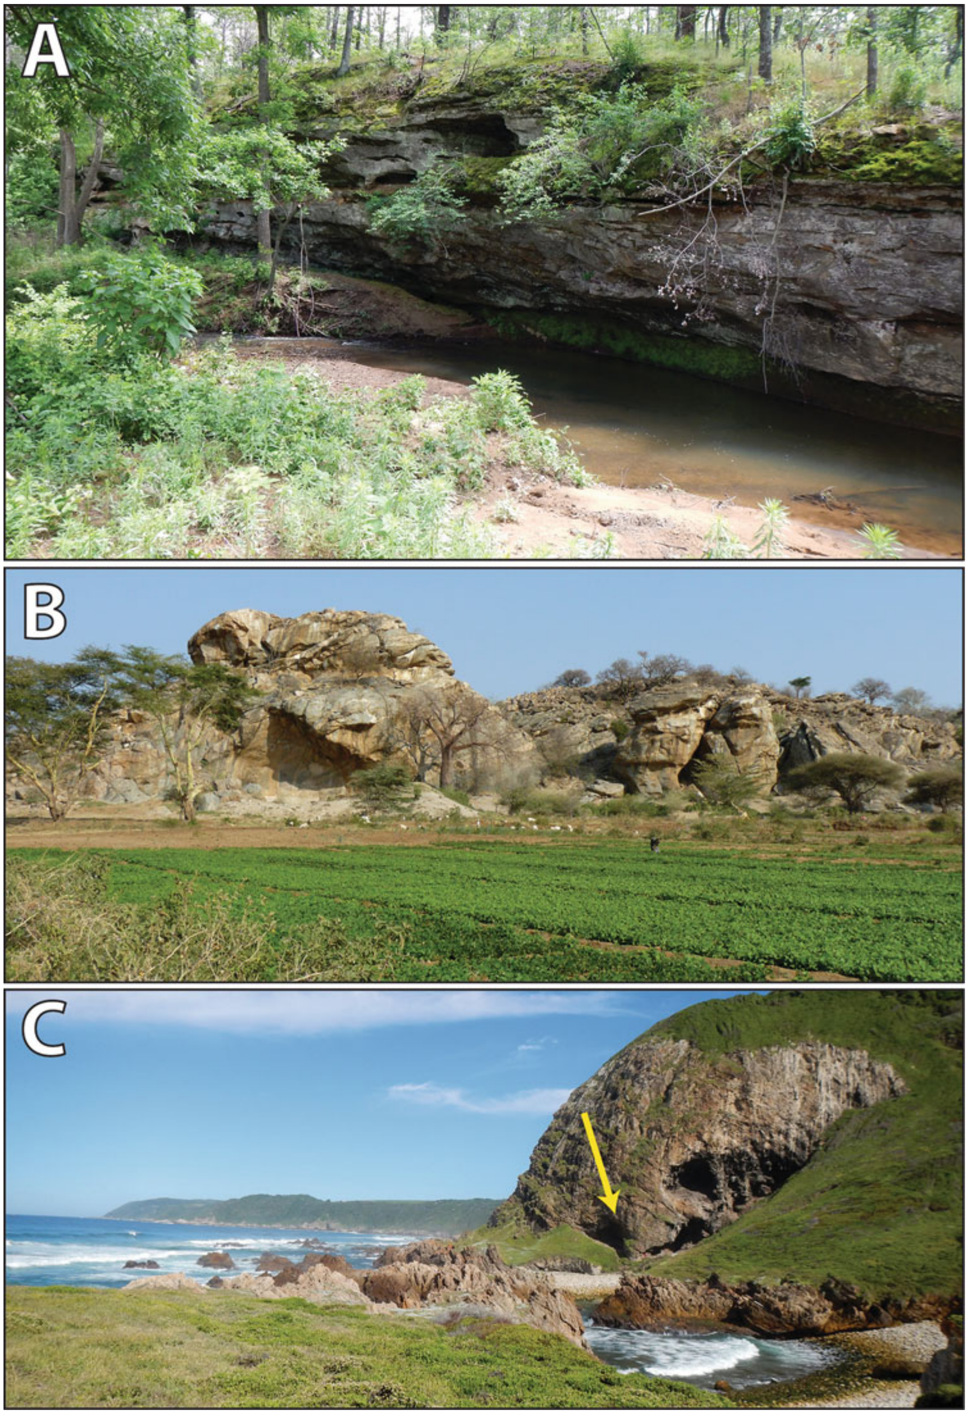
Sedimentation in rockshelters

According to Farrand (2001), sedimentation in rockshelters is idiosyncratic. The depositional and post-depositional processes are similar to those of cave entrances. In archaeological contexts, there are often a minimum of two sediment sources. First, roof blocks or bedrock fragments accumulate within most sites, and second, human beings function as depositional agents (Farrand, 2001). However, several types of formation processes described above are not conducive to the accumulation of sediment, although remnants of human activities may still be present. For example, in wind-scoured abrasion shelters, the same processes that contribute to the formation of the cavities are responsible for winnowing of fine materials from the shelter floors. In the Hueco Tanks tafoni shelters illustrated in Figure 4, erosional processes outpace accumulation, and sedimentary deposits are scarce. Nevertheless, petroglyphs (see Figure 4e, f), abrasive residues from clothing, and other modifications to the bedrock surfaces remain.

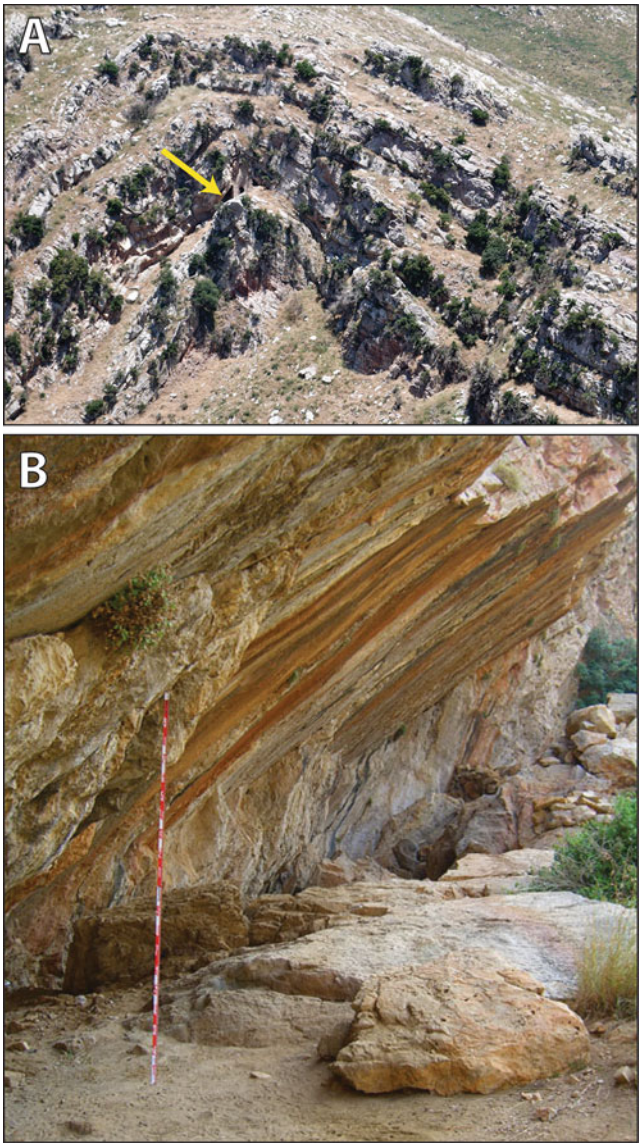
In other types of shelter, sedimentary deposits accumulate, and their sources are geogenic, biogenic, or anthropogenic. Furthermore, geogenic sources can be autochthonous (endogenous), related to both primary and secondary cavity formation processes, or allochthonous (exogenous). There are innumerable potential sources for sediment in rockshelter sites, including the bedrock, groundwater systems, rivers, lakes, oceans, slopes, wind, plants and animals, and humans. These sources and their depositional processes are described in more detail in Table 2. In addition, Figures 1b, 2, 3b, 4b, 5, and 6b include or illustrate settings in which different types of geogenic materials might accumulate, while selected biogenic and anthropogenic deposits are shown in Figures 8 and 9 (for herbivore dung, see Figure 1d).

Table 2 includes a number of sediment types that are not unique to rockshelter settings. Indeed, the extreme variety of rockshelter formation processes practically guarantees an almost limitless combination of ways to fill them. Although alluvial, fluvial, colluvial, and lacustrine sediments located in open-air and rockshelter settings share many features in common (e.g., presence of laminations, textural sorting, flow fabrics), a few depositional processes are unique in their expression within rockshelter sites. These processes include a specific type of eolian accumulation, "doming" (Davis, 1990, 337), wherein deposition is influenced by patterns of airflow and attenuation of currents at the entrance to the shelter. Doming causes the majority of windblown particles to accumulate in the center of the chamber. In addition, rockshelter morphologies – in particular the presence of a ceiling or overhang – can yield rockfall, spall, and attrition deposits with little to no lateral displacement from beneath their source. The drip line, or the line formed by dripping from the edge of the roof overhang (if present), can become a zone of accretion or erosion, depending on the environmental setting. In rainy settings, water falling over the brow of the cavity can contribute to erosion of sediment, in particular,

Rockshelter Settings, Figure 4 Tafoni shelters in sandstone and intrusive volcanic bedrock. (**a**) A tortoiseshell rock formed at the base of a sandstone boulder was exploited during the Middle Stone Age. *Arrow* shows the two low entrances pictured in (**b**). Hollow Rock, Western Cape Province, South Africa. (**b**) Shelter formation processes are ongoing, as evidenced by visible salt spalling, which has loosened cm-scale flakes of sandstone on the interior ceiling (*arrows*). The thin sedimentary deposits contain autochthonous geogenic materials derived from internal weathering; however, surface runoff contributes to erosion as well as allochthonous sedimentation as evidenced by rills that transverse the site. (**c**) Numerous types of tafoni shelters formed in syenite are visible here, including boulder shelters, alcoves, and tortoiseshell rocks. Hueco Tanks State Park, Texas, USA. (**d**) These shelters were exploited during the Holocene, from the Paleo-Indian period to the present, for protection from elements, as well as for surface water, which accumulates in circular pools and natural basins (*arrow*) – a *hueco* (Spanish for hollows). Here, erosional processes outpace sedimentation, and internal deposits are thin to nonexistent. (**e**) Tafoni features were also used as localities for Archaic and Formative Period rock art (pictograph visible in inset). (**f**) Erosion along a bedrock joint created a small shelter, the ceiling of which was utilized for artistic purposes (*inset*).



Rockshelter Settings, Figure 5 Abrasion rockshelters and entrainment shelters. (**a**) A horizontal shelter, approximately 3 m in height, carved by a stream flowing along sandstone. The sediments filling the shelter are fluvial in origin. Non-archaeological locality near Goodson Shelter, Oklahoma, USA. (**b**) A series of shelters was carved by wave abrasion of an inselberg formed in gneiss. Cavities are present at similar elevations, and portions of the sedimentary deposits are lacustrine in origin, both of which suggest that the formation and infilling of the sites are related to former high lake levels. Mumba Rockshelter (Middle and Later Stone Age), East African Rift, Tanzania (see also Mehlman, 1979) (Photo credit: Nicholas J. Conard). (**c**) A small shelter (*arrow*) formed, in part, by wave abrasion near a complex of sea caves in quartzite. Sedimentation in the site is complicated but includes eolian components related to coastal dunes and anthropogenic materials. Klasies River main site (1B; Middle Stone Age), Tsitsikamma Coast, Eastern Cape Province, South Africa (see also Butzer, 1978).



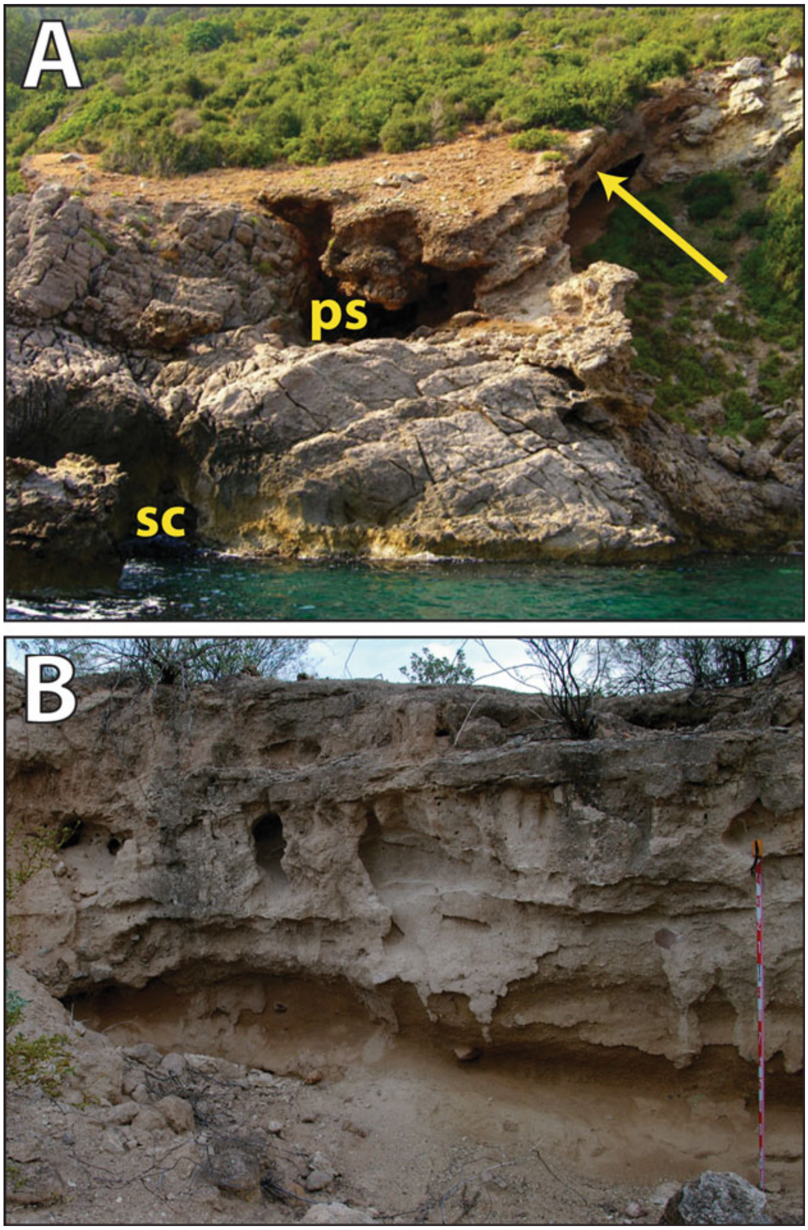
Rockshelter Settings, Figure 6 Tectonic shelters. (**a**) A shelter formed in the axis of an anticline fold in limestone (*arrow*) was used by Greek villagers in the nineteenth century as a refuge against Ottoman invasions. Mt. Lykaion, Peloponnesus, Greece (Photo credit: George H. Davis, Mt. Lykaion Excavation and Survey Project). (**b**) A small limestone shelter formed along joint planes related to a fault scarp. Scale is 2 m. Sedimentary deposits within this site are limited to autochthonous geogenic materials, primarily large slabs of roof fall. Non-archaeological locality near Üçağızlı Cave II, Hatay Province, Turkey.

washing of fine materials. The accumulation of large blocks of roof fall along the drip line also locally influences the direction of sediment movement, in some cases producing a characteristic downward slope of sediment into the shelter (e.g., Farrand, 1975). These depositional patterns can result in spatial variability in sediment accumulation rate and surface morphology. Furthermore, in contrast to open-air sites, depositional mechanisms and post-depositional processes can vary laterally within meters of space.

Post-depositional processes further contribute to the nature of the stratigraphic sequences observed by archaeologists working in rockshelter sites. Like primary depositional processes, post-depositional modifications can be generated by geological, biological, or human agents. Many of the geogenic depositional processes in Table 2 can contribute to post-depositional reworking of sediments within rockshelters. For example, waves can both deposit materials and move them laterally within sites, while wind can deposit fine-grained materials, or winnow, leaving lag deposits. Furthermore, post-depositional processes and their relative impacts can be influenced by environmental factors (e.g., cryoturbation), as well as the composition and structure of the over- and underlying primary deposits – e.g., chemical diagenesis (Karkanas, 2010), or effects of human foot traffic (Hughes and Lampert, 1977). Post-depositional geological processes that are unique to rockshelter and cave entrance settings include pooling, ponding, and washing by water flow focused at the drip line.

Soil-forming processes, although limited in some cave environments, can occur within rockshelters. For example, Angelucci (2003) describes weak soils and pedofeatures developed in sediments located in Abric Cantivera, Spain; similar processes impacted the deposits at Akrotiri, Cyprus. Other soil-forming processes that impact rockshelter sediments include decalcification, calcite recrystallization, precipitation of carbonates at depth, clay translocation, humification, and bioturbation by insects, rodents, and larger animals (Braillard et al., 2004). In other types of sites, such as dry shelters, soil-forming processes can be completely inactive, with very localized hyperaridity preventing humification and other biological activities and as a consequence preserving rich organic sequences (Davis, 1990).

Erosional processes – both related and unrelated to cavity-forming processes – can impact rockshelters in various ways. On a basic level, erosion can remove sediments of all types and produce depositional unconformities in the stratigraphic sequences. Erosional events can be localized, or like some sedimentation processes described above, can be proxies indicating regional climatic events. Humans can contribute to erosional processes within shelters by intentionally removing or modifying sediment in order to obtain resources such as guano or animal dung (Brochier et al., 1992) or to change the internal organization of space (Hughes and Lampert, 1977). Thus, evidence for erosion can have implications for human behavior. Erosion can also significantly complicate the interpretation of the archaeological record. For example, Mercader et al. (2003) state that in the Ituri rockshelters of the Congo, regional erosional processes have biased the history of human occupation toward the most recent 20,000 years. O'Connor et al. (1999) review similar



Rockshelter Settings, Figure 7 Pseudokarstic shelters. (**a**) A pseudokarstic shelter (*ps*) formed in calcite-cemented colluvium. The bedding layers within the colluvium are visible along an eroded face (*arrow*). Only the upper portion of the deposit is cemented by pedogenic carbonate, which acts as a caprock and contributes to differential erosion of the underlying loose sediment. An actively forming sea cave (*sc*) and marine notch in limestone are also visible in the foreground. These types of feature, when exposed due to uplift or lowered sea level, may be used as shelters. Non-archaeological locality near Üçağızlı Cave I, Hatay Province, Turkey. (**b**) Small cavities formed due to differential erosion of layers of palustrine and pedogenic carbonates. Non-archaeological locality near the El Fin del Mundo complex of sites (Paleo-Indian), Sonora, Mexico (Photo credit: Vance T. Holliday).

processes in Australian sites and note that (1) proper identification of erosion events (in some cases, evidenced by lag deposits) and hiatuses in deposition and (2) the distinction between these and hiatuses in occupation are essential for understanding regional responses of human populations to the effects of Pleistocene environmental change. O'Connor et al. conclude by proposing a number of analytical methods and strategies that might be employed in future studies to address this issue.

Sedimentological analyses in rockshelter sites

High variability in shelter formation processes, landscape and environmental settings, and human activities within

Rockshelter Settings, Table 2 Sediment types and potential sources in archaeological rockshelter sites

Sediment type	Depositional process	Main characteristics	References and/or archaeological example
Geogenic, autochthonous			
Mass wasting: rock fall	Many; tectonic activity, freeze-thaw, salt weathering	Coarse blocks and slabs of bedrock, degraded bedrock	Donahue and Adovasio (1990); see also Figures 1b and 2a; e.g., Akrotiri *Aetokremnos*
Insoluble residues, “cave earth”	Granular disintegration following chemical weathering, localized reworking by water	Fine materials that are present as inclusions within the bedrock	Woodward and Bailey (2000)
Mass wasting: attrition, spall	Granular disintegration due to salt weathering, hydration weathering, frost spalling	Texture, composition, and rounding of mineral grains are determined by the bedrock	Donahue and Adovasio (1990), see also Figures 3 and 4; e.g., Akrotiri *Aetokremnos*
Chemical: travertine, some tufa	Precipitation from alkaline springs in karstic settings can include biological activity	Typically calcareous with variable crystal size, fabric, and degree of cementation	Mallol et al. (2009), Vallverdú-Poch et al. (2012); see also Figure 8d
Geogenic, allochthonous			
Infiltration	Material from outside the bedrock system transported into the shelter through cracks and conduits	Composition is variable; texture determined by size of conduits and mode of transport	Woodward and Bailey (2000); e.g., Akrotiri *Aetokremnos*
Fluvial and alluvial	Deposition of clastic materials by flowing water or rivers	Variable composition, texture, and sorting; laminations	Farrand (1979), Woodward et al. (2001); see also Figure 5a; e.g., Rodgers Shelter
Lacustrine	Mechanical and chemical deposition within lakes	Variable composition, texture, and sorting	Mehlman (1979), Woodward and Goldberg (2001); see also Figure 5b
Marine/littoral	Deposition by water in near-shore environments, storm events	Variable composition, texture, and sorting	Woodward and Goldberg (2001); see also Figure 2
Colluvial	Mass wasting and movements of material down slopes	Poor textural sorting, flow fabrics	Mercader et al. (2003), Kourampas et al. (2009); e.g., Rodgers Shelter
Eolian	Deposition of material entrained in wind	High degree of sorting, typically fine sand- to silt-sized materials; volcanic ash	Byrne et al. (*1979*), Davis (1990); e.g., Akrotiri *Aetokremnos*
Biogenic			
Guano, coprolites, and non-anthropogenic herbivore dung	Digestive and urinary waste elimination by animals living within or utilizing the shelter	Typically high in phosphate content, can also contain abundant phytoliths, calcareous dung spherulites, gastroliths	Byrne et al. (*1979*), Davis (1990), Brochier et al. (1992), Braillard et al. (2004), see also Figure 8b
Middens, nests, and mounds	Accumulation and nesting activities of rodents, birds, and insects	Plant material, phytoliths, calcium oxalates, fecal pellets, urine-derived minerals,	Davis (1990), Wallis (2002), Scott et al. (2004), see also Figure 8a,b
Bone beds, owl pellets, shell accumulations	Residues of carnivory or death assemblages of animals living within the site	Bones and bone fragments; shell	Martin and Borrero (1997), Cremaschi and Negrino (*2005*)
Organic debris	Decay of plants growing inside or near the shelter, eolian biogenic materials (e.g., pollen)	Plant material in various states of humification, phytoliths, calcium oxalate crystals	Byrne et al. (*1979*)
Stromatolites, some tufa	Biogenic precipitation of calcium carbonate	Porous micrite with biological fabrics	Mallol et al. (2009); see also Figure 8d
Diatomite, diatomaceous earth	Algal bodies in standing and flowing water	Siliceous shells	
Anthropogenic			
Combustion features	Burning of wood and other fuels; sweeping or dumping of burned materials	Ashes, charcoal, burned substrates	Mentzer (2012), Miller et al. (2013); see also Figure 9a

Rockshelter Settings, Table 2 (Continued)

Sediment type	Depositional process	Main characteristics	References and/or archaeological example
Middens and refuse	Discard of food processing debris and other forms of trash	Variable	Hughes and Lampert (1977), Galanidou (2000); see also Figure 9b
Prepared surfaces, floors, bedding	Intentional modification of geogenic sediment within the shelter or transport of sediment and other materials for the purposes of constructing a floor or other forms of prepared surface	Beaten earth; mud, lime, dung, and gypsum plaster; organic material and phytoliths; mudbrick; stones	Galanidou (2000), Goldberg et al. (2009), see also Figure 9c
Stabling materials, livestock dung, *fumier*	Use of a shelter for the stabling of animals, commonly herbivores, bedding of birthing areas; periodic burning of dung	Typically high in phosphate content, often containing abundant phytoliths and calcareous dung spherulites; humified and/or burned organic material; rare inclusions of diatoms	Brochier et al. (1992), Angelucci et al. (2009), see also Figure 1d
Latrines	Human digestive and urinary wastes; caches of feces	Typically high in phosphate content, contain diagnostic coprostanols	

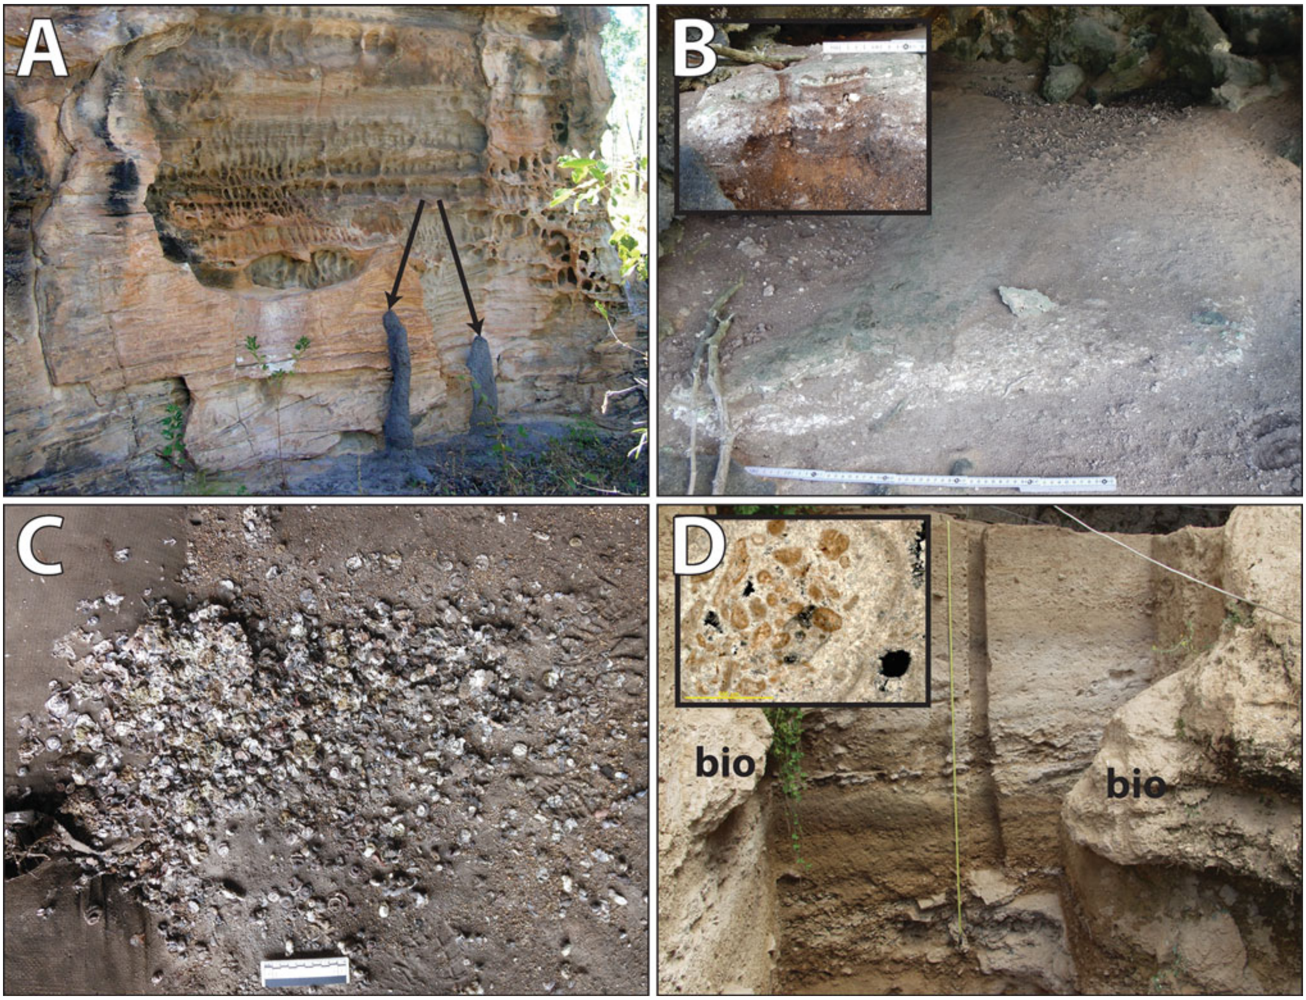
the sites yield a wide range of sedimentary sequences, such that there are no "rules" to follow when developing analytical strategies. As advocated by O'Connor et al. (1999), successful geoarchaeological analyses of rockshelter sequences aimed at understanding sedimentation history typically employ a mixture of approaches conducted at a variety of scales and target both "bulk" samples and in situ materials. These analyses include granulometry (grain size analysis), mineralogy and lithology (see also Woodward and Bailey, 2000), soil micromorphology and sedimentary petrography, magnetic susceptibility measurements, and chemical and elemental analyses. Of these, micromorphology is considered by some to be the most holistic approach, especially when analysts aim to understand anthropogenic sedimentation (Goldberg and Sherwood, 2006; Mentzer, 2012). Additional analyses may be employed in order to reconstruct paleoenvironmental conditions. For example, rockshelters may function as traps for pollen (Davis, 1990; Woodward and Bailey, 2000; Woodward and Goldberg, 2001). Furthermore, certain types of rockshelter deposits (e.g., chemical precipitates, organic materials, eolian silts) can be directly dated using radiometric techniques (U-series dating, radiocarbon dating, OSL, etc.) to reconstruct the timing of formation or deposition.

The choice of analytical methods can be constrained by the types of deposits that are present and the specific research questions related to paleoenvironmental reconstruction and human behaviors, including the desired resolution of the observations. Because rockshelter sequences are both unpredictable and influenced by a variety of conditions, a process-oriented approach to site formation is advocated (e.g., Ward and Larcombe, 2003). Testable models may be developed for specific types of rockshelters in similar landscape settings and environments (e.g., Donahue and Adovasio, 1990). Analytical priorities might be framed in terms of proximal and distal sources and processes (Woodward and Bailey, 2000).

Rockshelter life histories

As noted above, rockshelters are transient geomorphic features related to bedrock weathering processes and surface sediments. Rockshelter morphologies therefore change over time, including throughout the duration of their utilization by humans. Changes in rockshelter morphology have a number of possible consequences for their use as occupation areas and thus the potential for containing anthropogenic sediments, as well as for the overall preservation of archaeological deposits.

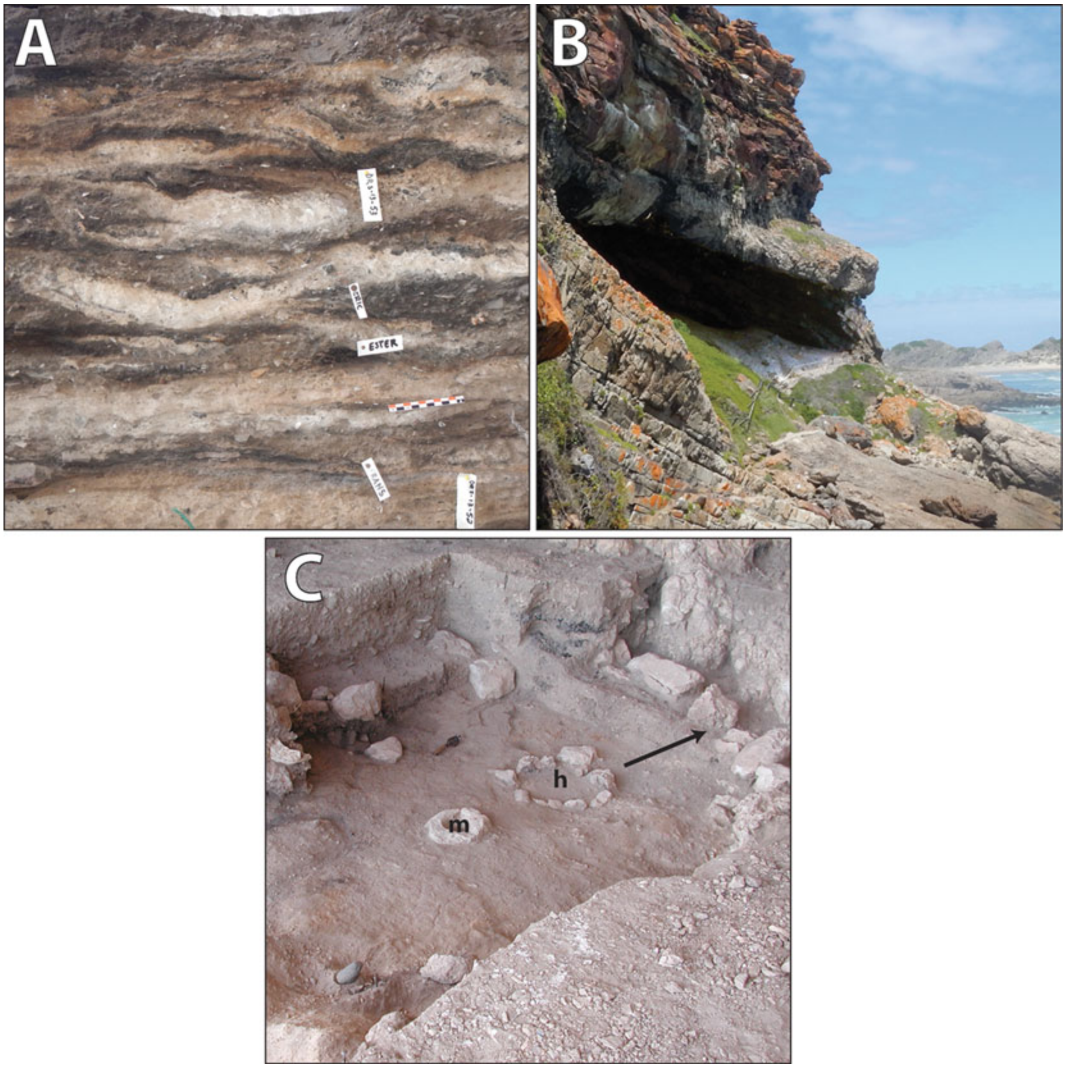
Shelters can become larger over time due to a combination of ongoing primary and secondary formation processes. Enlargement of shelters or migration of the position of walls and overhangs can produce complicated site stratigraphies. For example, in the well-studied sedimentary sequences at the Abri Pataud and Combe Grenal (France), both the bedrock morphology and the imbrications and positioning of roof block layers indicate gradual retreat of the bounding cliff faces during the occupation history of the sites (Bordes, 1972; Farrand, 1975; 2001). In the Abri Pataud, younger strata were positioned to the east with respect to older strata, and due to this progressive lateral shift in sedimentation, the entire sequence cannot be displayed in any single area of the site. When multiple layers are present, some of the younger layers are colluvial in origin or exhibit a marked slope compared



Rockshelter Settings, Figure 8 Different types of biogenic sedimentary deposits in rockshelters. (**a**) Termite mounds (*arrows*) within a sandstone tafoni shelter. Termites and other insects such as ants introduce material into shelters from outside, sort sediment by texture, modify or obliterate primary sedimentary fabrics, and consume and rework organic refuse. Tafoni features, including honeycomb rocks, are visible on the shelter wall above the mounds. Non-archaeological locality near Gledswood Shelter, Queensland, Australia (Photo credit: Kelsey Lowe). (**b**) A biogenic midden containing coprolites interbedded with plant-derived nesting material and partially cemented by urine. The inset shows the internal stratigraphy, which includes subsurface formations of nodular secondary minerals. This feature, which fills a small abrasion shelter, was accumulated by rock hyrax (dassies; *Procavia capensis*), although similar features can accumulate in North America through the actions of pack rats (*Neotoma* sp.). These types of deposit can contain rich paleoenvironmental records, e.g., pollen and insect carapaces (Davis, 1990; Scott et al., 2004), and they can also ignite and burn due to non-anthropogenic processes (e.g., forest fires and lightning strikes). Non-archaeological coastal locality in sandstone/quartzite near Blombos Cave, Western Cape Province, South Africa. (**c**) Bird guano and swallow nests (not pictured) accumulate in Diepkloof Rock Shelter, South Africa (see also Figure 3a), introducing organic material and allochthonous clay- and silt-sized sediment to the deposits. (**d**) Tufaceous materials can include biological components. Here, large, cemented bioconstructions (bio) and softer biogenic calcite layers are formed within a karstic limestone shelter. The inset is a photomicrograph of a sample of tufa under cross-polarized light illustrating a biological fabric. Obi-Rakhmat Grotto (Middle Paleolithic), Uzbekistan (see also Mallol et al., 2009) (Photo credit: Patrick J. Wrinn).

to the older layers. In many cases, enlargement has finite limits. According to Farrand (2001), enlargement of rockshelters can yield more usable space for periods of time, but this process ultimately makes the shelter more susceptible to collapse.

Collapse of portions or the entirety of a rockshelter overhang can contribute significantly to sedimentation at the site. This phenomenon is evidenced in stratigraphic sequences as layers of roof fall (see Table 2). For this reason, rockshelter sequences are particularly poor



Rockshelter Settings, Figure 9 Anthropogenic deposits in archaeological rockshelters. (**a**) Thick deposits of ashes and charcoal are sourced from Middle and Later Stone Age burning activities at the site of Diepkloof Rock Shelter (see Miller et al., 2013; also Figure 3a here). In some rockshelters, burned materials can comprise the majority of sediments infilling the cavities. (**b**) A large Khoisan (4000–3000 BP) shell midden fills Hoffman's/Robberg Cave on the Robberg Peninsula, Western Cape Province, South Africa (see also Kyriacou and Sealy, 2009). (**c**) The upper surface of a *red-colored*, constructed earthen floor with an embedded mortar (*m*) and rock-lined hearth (*h*). The rock wall (*arrow*) marks the edge of the structure that was built within the limestone shelter and is associated with the floor. Humans may contribute to sedimentation in a rockshelter by utilizing local materials for construction purposes or by intentionally transporting material into the site. Baaz Rockshelter (Natufian), Syria (see also Conard, 2002) (Photo credit: Andrew W. Kandel).

candidates for calculation or interpretation of sedimentation rate (O'Connor et al., 1999). Continued weathering and collapse can also lead to complete destruction of the shelter, limiting or preventing the recovery of archaeological materials. An example of this phenomenon is the complete erosion of all but two Pleistocene rockshelter sites in the Ma'aloula and Jaba'deen localities of Syria (Conard, 2002).

In this light, the role of a geoarchaeologist working on excavations within rockshelters is not only to consider the combined impacts of infilling, erosion, and morphological change on the preservation of archaeological deposits but also to address and interpret within this framework the variations in human activities that occurred over time. For example, infilling of a small space could reduce available headroom, which in turn could cause a number of changes in human behavior, including abandonment of the site, shifting from regular to occasional habitation, or intentional modification of the substrate. Collapse of portions of a shelter can likewise impact human utilization, change local erosional regimes thereby causing removal of archaeological deposits, or seal and protect the underlying archaeological sediments from further erosion and weathering (an example would be Akrotiri *Aetokremnos*). These interrelated aspects of rockshelter life histories can make archaeological sequences within them particularly challenging to reconstruct.

Summary and conclusions

The preceding sections have provided a comprehensive overview of (1) rockshelter formation, including archaeological examples and expected distributions grouped according to a classification system organized by the primary processes of cavity development, (2) a catalogue of sediment sources and types of deposits, (3) analytical techniques employed in the study of rockshelter sediments, and (4) approaches to the reconstruction of rockshelter life histories. The goal of geoarchaeology in reconstructing rockshelter life histories is not only to understand the formation processes of the sites but to aid in the interpretation of the archaeological record. By the definitions outlined above, rockshelters must afford their occupants some relief from the elements, including extreme heat or cold, direct light, wind, and precipitation. For this reason, in combination with their relatively high visibility on the landscape, intact rockshelters can be targets of archaeological survey. The likelihood of their exploitation in the past is intuitive; however, rockshelter deposits can be highly variable and are often difficult to categorize owing to, in some cases, complicated combinations of allochthonous and autochthonous geogenic processes, as well as contributions from biological and human activity.

Acknowledgment

William R. Farrand (1931–2011) laid the foundation to a comprehensive framework for the study of rockshelter sequences and, in doing so, influenced and motivated a generation of geoarchaeologists, including the author, whose work here depends greatly on his research.

SANTORINI

Floyd W. McCoy
Department of Natural Sciences, University of Hawaii – Windward, Kane'ohe, HI, USA

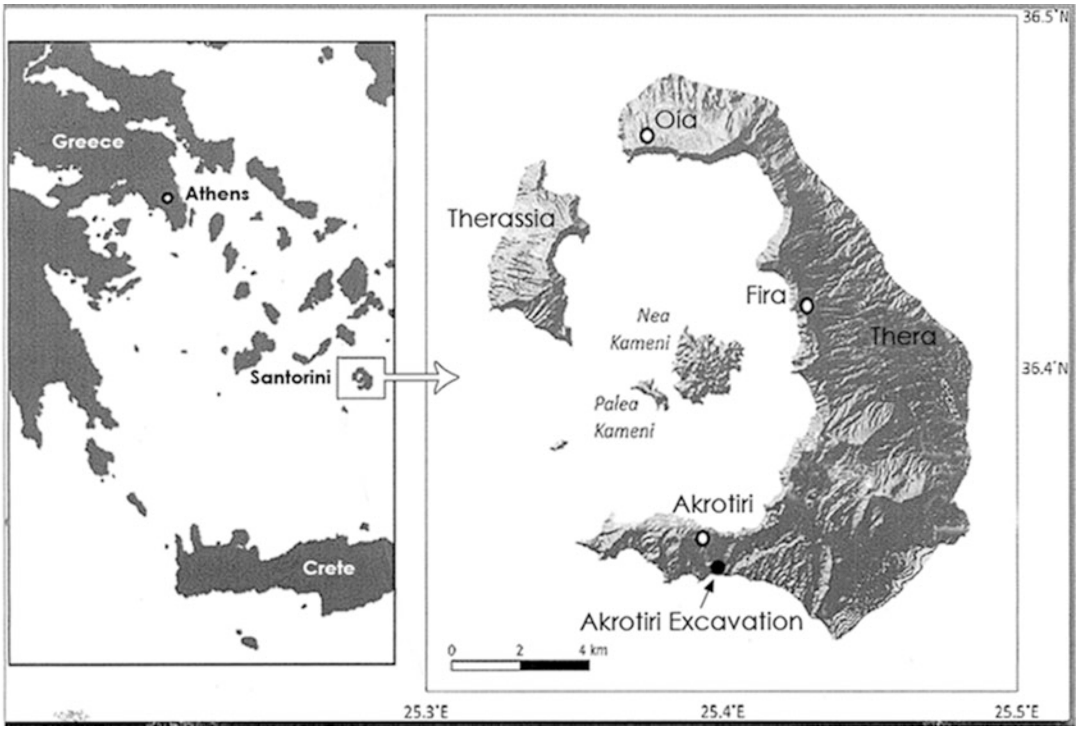
Santorini is the modern name for a collection of small islands in the southern Aegean Sea, the southernmost group in the Cyclades Islands. The ancient name is Thera, which is also the geographic name for the largest of the five islands in this archipelago (the other four are Therasia, Aspronisi, Nea Kameni, and Palaeo Kameni) (Figure 1). Theras, from Sparta, established a colony here in the fifth century BCE. Another ancient name is Kalliste, mentioned by Apollonius in the myth of Jason and the Argonauts in apparent reference to a spectacular geographic setting created by a ring of islands surrounding a water-filled depression within which were additional islets that today have either subsided below sea level or been merged into Nea Kameni island. "Santorini" refers to the entire island cluster, and this name was applied during Venetian occupation of the islands from the early thirteenth century AD in reference to Santa Irini, the patron saint of sailors (who is reputedly buried on Therasia). The official government designation for the archipelago is "Thera" or "Thira," depending upon the transliteration of the Greek "θηρα."

Santorini is best known for an enormous explosive eruption that occurred approximately 3600 years ago. The eruption of Thera is considered the largest volcanic event in the past 10,000 years and one of the largest in human antiquity (McCoy and Dunn, 2002; Druitt, 2014; Johnston et al., 2014; and references therein); it devastated local and regional cultures, and it fueled later legends. The eruption occurred in the Late Bronze Age (LBA) of the archaeological ceramic chronology developed for the Aegean. In the geologic chronology, the eruption was simply the latest explosive affair in a long sequence of such events, some of which may have been more than twice the size of the LBA event (Keller et al., 2014) (Figure 2).

The consequence of this last eruption is the current Santorini archipelago, which forms one of the grandest landscapes on earth, a stunning geomorphological feature created by spectacular episodes of volcanism (Figure 3). The islands are the summit of a largely underwater volcanic feature, and the surface expression is more appropriately referred to as a volcanic field rather than a "volcano." An assortment of eruptive vents and their products (tephra and lava flows) are exposed here and represent repeated episodes of volcanic activity over the past 645,000 years. The result is a dramatic and astounding scenic feature defined by a central water-filled caldera encompassing two small central islands where current volcanic activity is concentrated. This caldera has emerged from repeated, highly explosive, Plinian-type eruptions, each having excavated portions of this depression to form the modern feature. Repeat times for major explosive eruptions are on the order of about 20,000 years, although this has been hugely variable.

Effusive volcanism during the intervals between Plinian eruptions has been less explosive (see Figure 2), characterized by Strombolian-Pelean-type activity with minor accumulations of tephra but extensive outpourings of thick (a'a and block) lava flows and extrusion of domes. Some of these eruptions constructed large shield-shaped structures, relics of two being the Skaros area on Thera and the modern island of Therassia. Volcanism as it exists today on the Kameni islands represents the volcano in a rebuilding stage. Interestingly, this rebuilding has apparently never constructed a high and lofty cone-shaped feature such as characterizes volcanoes such as Fujiyama or

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

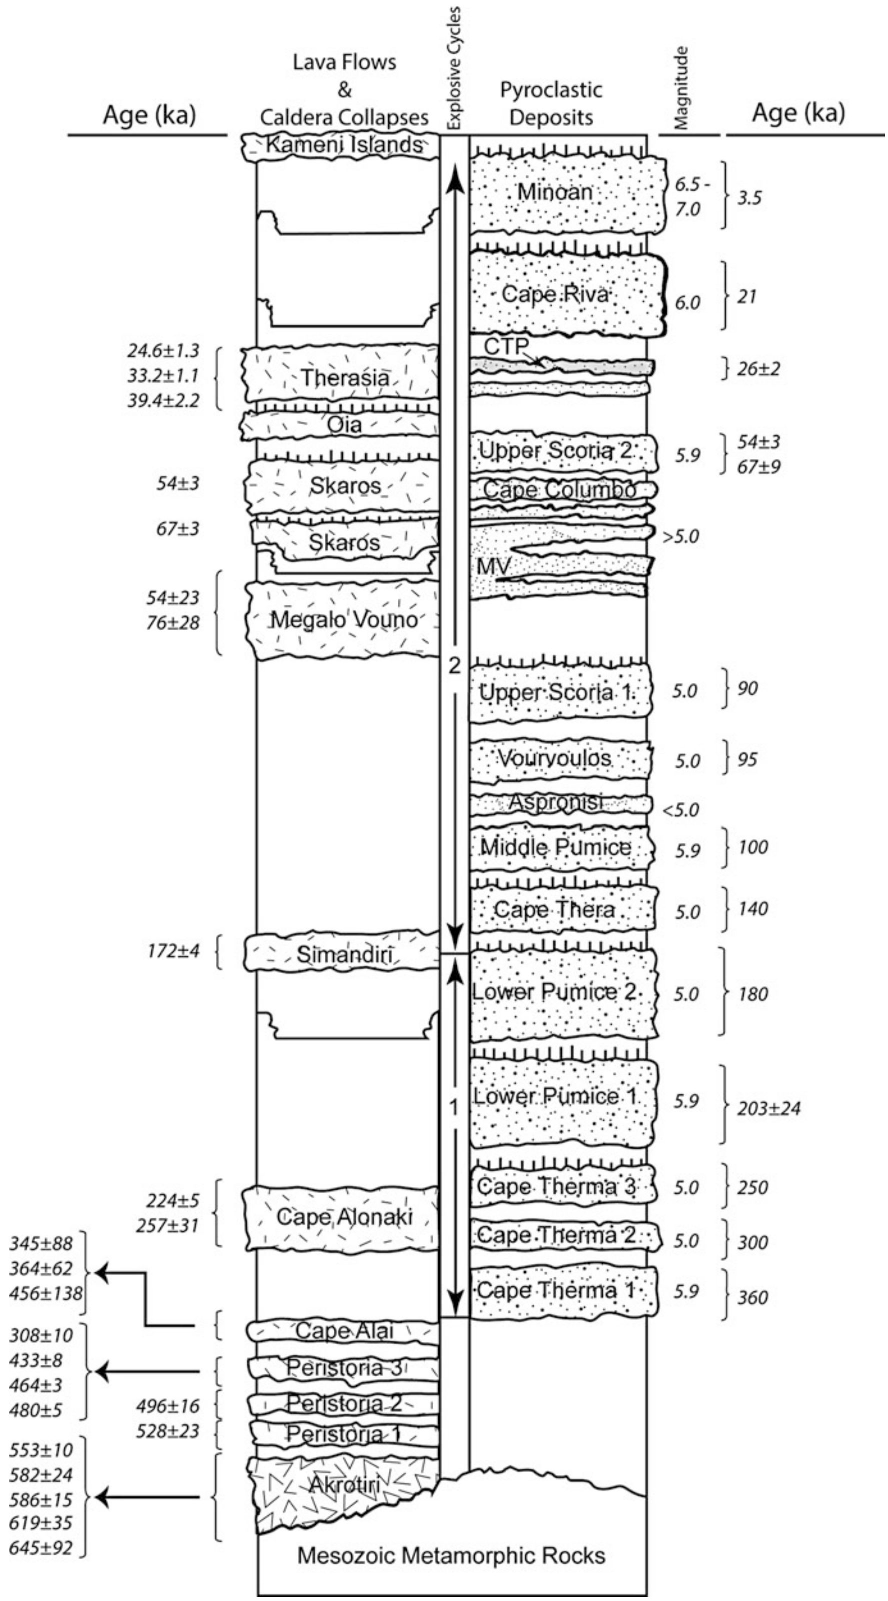


Santorini, Figure 1 The modern geography of Santorini, an archipelago of five islands surrounding a water-filled volcanic caldera. Current volcanism is focused on the island of Nea Kameni. Archaeological excavations have been conducted within the ancient city at Akrotiri, which was buried during the catastrophic eruption in the Late Bronze Age.

Mt. Aetna; a variable-sized caldera seems to have usually been a major physiographic feature of the Theran volcanic landscape. Prior reconstructions of the volcanic edifice before the LBA eruption imagined such a cone shape by extrapolation of outer topographic slopes in the modern geomorphology upward to form a peak centered over the modern caldera. Geologic evidence has shown this to be incorrect.

The last huge eruption – which was a 2–4 day event – occurred while the island was occupied by a flourishing Cycladic culture in the LBA. This eruption was far larger than the 1980 eruption of Mt. St. Helens and greater than that of Krakatau in 1883 and the 1815 Tambora eruption (Figure 4). It must have been an enormous shock to the inhabitants of Thera, who may have had no knowledge that they lived on a dangerous volcano, if they even understood volcanism, though they certainly enjoyed its benefits in the form of hot springs, fumeroles, mineral deposits, easily quarried and shaped stones, productive soils, and more. Their landscape, like today, was also a - water-filled caldera but with a large central island (Figure 5). Interestingly, a rendering of the pre-eruption LBA landscape seems to be portrayed in a portion of the Marine Fresco from the West House in the Akrotiri archaeological excavation, the only depiction left to us by an ancient artist (Doumas, 1992) (Figure 6).

The consequences of the LBA eruption to the Cycladians on Santorini and nearby Aegean islands, especially Crete, were catastrophic. An island central to trade by the Cycladians with surrounding Aegean cultures such as the Minoans on Crete was gone, now an altered inhospitable landscape of hot steaming ash and pumice. In the Aegean and eastern Mediterranean region, tephra fall, earthquakes, pumice rafts, tsunamis, violent thunderstorms, climate change, health hazards, and more contributed to crippling these ancient societies (for a summary of the geologic consequences, see McCoy and Heiken, 2000; for societal consequences, see Driessen and MacDonald, 1997). Tephra clouds reached as far north as the Black Sea and perhaps as far southeast as the Nile Delta. Tsunamis radiated out from Santorini north into the Aegean, south to Crete, then eastward to the shores of the Levant and the Nile Delta, as well as westward into the Ionian Sea, assuredly with significant damage to ancient ports. It must be emphasized that numerous tsunami wave sets were generated by numerous tsunamigenic mechanisms during the eruption. Within the Aegean Sea, with its relatively shallow water depths and scattered islands, tsunami



Santorini, Figure 2 (Continued)

wave interactions through wave reflections, wave refractions, and harmonic trapping of wave energy likely established complex wave patterns (seiches) that would have kept that sea in turmoil not only during the eruption but for some days afterward, with consequent erratic and repeated inundations along its coastlines. Whether there was significant climate change due to the eruption is yet to be established, as are human health effects such as from ash inhalation. Still to be determined is potential damage to surrounding islands by hot, low-density portions of pyroclastic flows that might have traversed the sea surface, a phenomenon documented in ancient and historic eruptions, and perhaps fatal to escaping Cycladians on boats at sea.

While the Minoan culture persisted for another few generations, it is clear that this cataclysm significantly contributed to their demise. Certainly the eruption terminated the Cycladian culture. An eruption of similar magnitude today would have a huge impact on the region, but for a culture 3600 years ago, it was a stunning disaster.

Yet the eruption preserved, virtually intact, a LBA city on the southern slopes of Thera at Akrotiri. Here, a city lies buried under volcanic ash, containing buildings, paintings and frescos, housewares, furniture, jewelry, and more. Limited damage to the town came during the latter phases of the LBA eruption when pyroclastic flows and lahars/debris flows eroded into already deposited tephra to damage structures (Figure 7). Much like Pompeii in AD 79, the Akrotiri site is a small city but almost twice as old; it is a spectacular archaeological site providing a window into a sophisticated culture of about 3600 years ago, certainly the "Pompeii of the Aegean" (Doumas, 1983).

A chronometric (absolute) date for the LBA eruption remains controversial. The relative dating scheme of the Aegean ceramic chronology indicates a date at, or very near, the final Late Minoan (LM) IA or perhaps into the following period LM IB. Carbon 14 dates on archaeological materials from stratigraphic horizons considered equivalent to the Aegean LM IA period found in excavations in the Aegean and the surrounding eastern Mediterranean region suggest a date of about 1500–1515 BCE, and this is termed the "low chronology" (Warren and Hankey, 1989; Wiener, 2007, and references therein). Additional criteria used to support this chronology come from analyses of records preserving accounts of ancient historical events and listings of ruler successions, the latter focused on Egyptian king/pharaoh lists. ^{14}C dates derived from trees buried within the tephra deposit on Santorini and presumably killed by the eruption, however, suggest a date of about 1600–1620 BCE, and this is referred to as the "high chronology." Additional criteria in support of this date come from ^{14}C dates of (1) materials found within LM IA contexts in the Aegean and surrounding regions; (2) acid-ice layers in Greenland ice cores; (3) deep-sea, marsh, and lake sediments encompassing tephra; (4) fossils incorporated within the tephra on Santorini; and (5) dendrochronological studies in Anatolia, Ireland, China, and California (Friedrich et al., 2006; Manning, et al. 2006; Warburton, 2009, and references therein). Historic records of severe climatological changes in China may also support this chronology. The discrepancy between the two chronological ranges is about 100 years or less. This is the consequence of, first, an inability to apply the current ^{14}C calibration curve for resolving the discrepancy (at exactly this time period, the curve is nonlinear and contains minor oscillations that make it difficult to assign a date with precision) and, second, an inadequate understanding of aspects in the carbon geochemical system. Clearly, another radiometric dating technique is called for to resolve the matter.

The LBA eruption probably occurred during the late spring–early summer. This information comes from using the regional distribution of ash found on land as a proxy for the atmospheric movement of the ash plume, then applying contemporary weather systems best suitable for tropospheric and stratospheric winds to cause this movement (assuming modern weather circulation patterns are similar to those during the LBA) (Sewell, 2001; McCoy, 2009; Johnston et al., 2012). Archaeological criteria provide additional support for this suggestion (Marinatos, 1939; Doumas and Papazoglou, 1980; Panagiotakopulu et al., 2013).

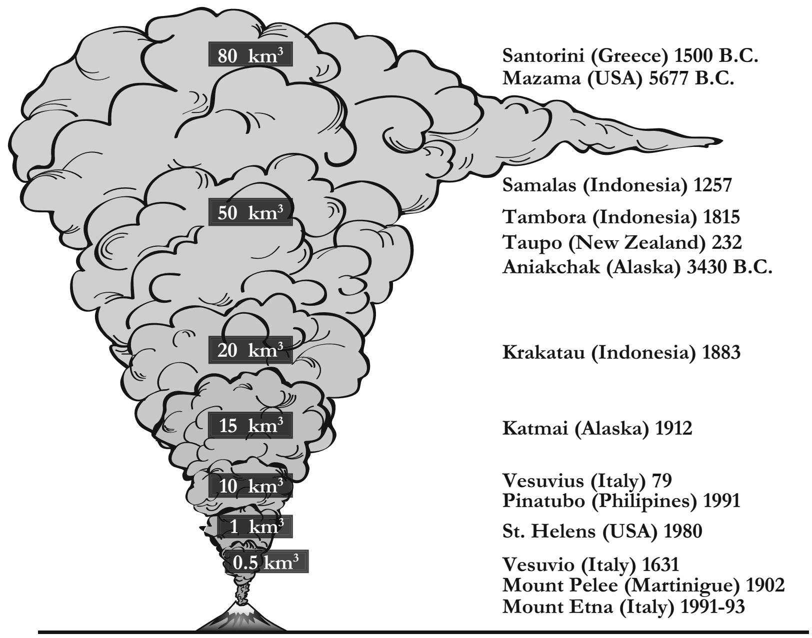
Volcanicity on Santorini speaks to two outstanding questions in volcanological research, both critical to understanding hazards and mitigation for contemporary cultures in similar settings. First, why was the LBA event so explosive, when other eruptions here in the past had not been as violent? Second, what are the repeat times for explosive eruptions, and can they be predicted? Certainly volcanoes typically producing quieter types of eruptions can be monitored and their activity somewhat predicted, such as in Hawaii, where much of this research has been done. Yet predicting how explosive an eruption might be

Santorini, Figure 2 Stratigraphic column exposed at Santorini depicting the eruption sequence over the last 645,000 years. Pyroclastic eruptions are depicted on the right and indicated by layers filled with a stippled pattern. The Thera Pyroclastic Series incorporates two major explosive cycles as indicated by numbers and arrows in the narrow central column (*MV* Megalo Vouno tephra). Eruption magnitudes noted follow the Volcanic Explositivity Scale, or VEI, of Newhall and Self (1982). Depicted on the *left* are eruptions that produced subaerial lava flows (fill consisting of randomly oriented dashes) and submarine flows (randomly oriented "v" pattern at the very bottom of the column: Akrotiri volcanics), in addition to major episodes of caldera collapse (*solid line* with *dropped middle portion*). Growth of paleosols is indicated by short *vertical lines* on *top* of various pyroclastic units and lava flows. Eruption ages in ka (1000 years before present) are given (Data are summarized from Druitt et al. (1999) and Friedrich (2000)).

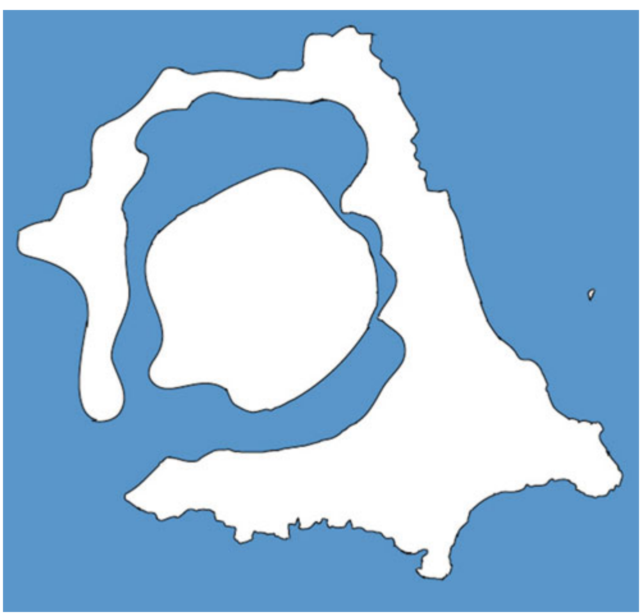
Santorini, Figure 3 Photograph looking west across the northern part of the water-filled caldera at Santorini. Surrounding the caldera are the islands of Thera (in the foreground and *right side* with a limited glimpse of the city of Fira on the *lower right* and the town of Oia in the distance appearing as a *white line* at the *top* of the caldera cliffs), Therassia (*far background*), and Nea Kameni (*left*) where current volcanic activity occurs in the form of steam vents, sulfur deposits, hot water springs, seismicity, and inflation/deflation events. The last eruption, a minor one, was here in 1950, and unrest in 2011–2012 signaled an intrusion of magma at depth that did not result in an eruption. The floor of the caldera lies more than 400 m below sea level, and the cliffs plunge straight down to those depths. Layers exposed in the caldera cliffs provide a dramatic record of volcanism over the past 700,000 years, as well as a geologic history from the Pliocene Epoch. The present caldera is the consequence of several highly explosive eruptions, the last occurring about 21,000 years ago (the Cape Riva eruption), and its configuration has persisted as a relatively stable geomorphological feature throughout much of the history of Santorini. In the Late Bronze Age, a flourishing Cycladic culture occupied a similar landscape of caldera cliffs with a much larger central island, but much was vaporized by the enormous eruption of 3600 years ago (Photograph courtesy of Walter L. Friedrich).

remains elusive outside of assuming somewhat equivalent timing based upon prior activity, which for Santorini seems about every 10,000–30,000 years (Druitt et al., 1999). Such repeat times are an order of magnitude more frequent than approximate repeat times for global eruptions of similar magnitude during the entire Quaternary (Brown et al., 2014). Current research focusing on magmatic plumbing systems and their interaction through injections of fresh magma, in addition to ascent times of magma to the surface, promise significant insights into understanding and perhaps predicting large eruptions (Cottrell et al., 1999; Jellinek and DePaolo, 2003; Parks et al., 2012; Druitt, 2014). Precursory activity to modern eruptions is well documented, and we can apply such activity to what the Cycladians on Santorini might have experienced prior to the explosion (likely no more than months in advance); it is assumed that some signals must have alerted the LBA inhabitants to leave since no fatalities related to eruption consequences have been found on Santorini, and archaeological evidence from the Akrotiri excavation suggests an abrupt and rapid evacuation of the island immediately prior to the disaster.

Why is a volcano sited here? Santorini is one of a dozen volcanic centers that formed behind, and in connection with, the southern Aegean island arc (Nomikou et al., 2013, and references therein). Here, tectonic closure (rates on the order of 5–6 cm/year) of the African continent against the European continent has created the Aegean Sea by the subduction of ancient seafloor attached to the African continent beneath the Aegean



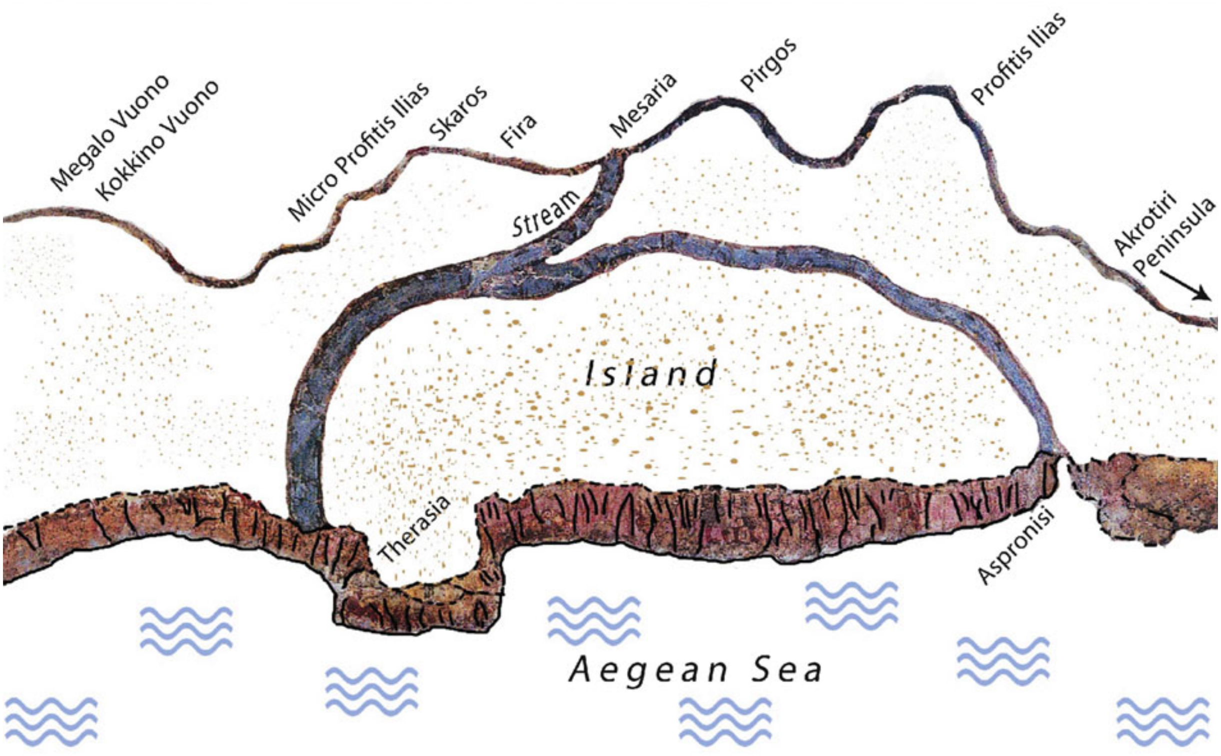
Santorini, Figure 4 Graphic representation of the relative explosiveness of the major eruptions during the past 3 millennia, as estimated by the volume of pyroclastic ejecta from that eruption (Data are from Druitt (2014), Johnston et al. (2014), and the Global Volcanism Program, Smithsonian Institution).



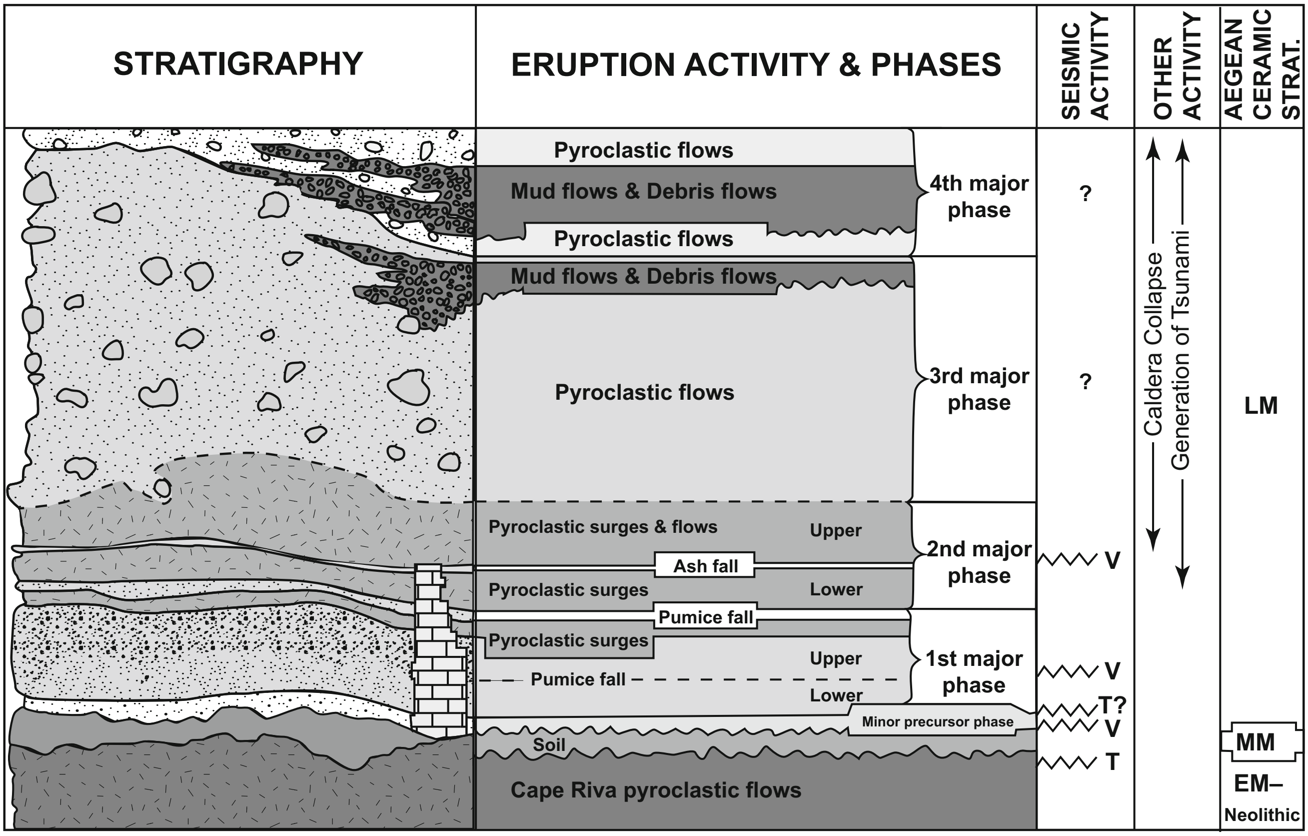
Santorini, Figure 5 Reconstruction of the ancient landscape of Thera prior to the massive LBA eruption. Then, as now, the geography generally described a central, water-filled caldera with a central island. As the figure shows, previous volcanism over 20,000 years or so had constructed a larger island prior to the LBA eruption than is seen today. The current configuration is the result of only 3600 years of volcanic activity to rebuild the two Kameni islands within the caldera. This depiction builds upon those proposed by Eriksen et al. (1990), Druitt and Francaviglia (1990, 1992), Druitt et al. (1999), Friedrich (2000), McCoy and Heiken (2000), Pfeiffer (2001), McCoy (2009), Druitt (2014), and others.

(Faccenna et al., 2014, and references therein). It is estimated that up to 850 km of lithosphere have disappeared beneath the Aegean seafloor over the past 38 Ma, dragged down into the deep hot mantle (Royden and Papanikolaou, 2011, and references therein). At depth, melting of the subducted seafloor occurs, producing magma that episodically rises to form these volcanic centers. Closure between Africa and the Aegean is enhanced by a complicated plate-tectonic pattern in the eastern Mediterranean region that results in a southern push of the Aegean against Africa, which is moving north. In short, the modern Mediterranean is being destroyed; it is, in essence, a modern remnant of far wider sea that existed during the Mesozoic era. In response to this tectonism, the Aegean crust is highly fractured and faulted. The Santorini volcanic field appears sited at an offset along one of these fractures, where a regional fault approximately orthogonal to the arcuate trend of the Aegean island chain intersects other fractures (Druitt et al., 1999) (Figure 8). Santorini represents only one of six major volcanic centers along this tectonic arc, all with geologic histories of eruptions, many violent; of them all, however, Santorini is certainly the most famous in mythology, history, science, and scenery. The consequence is a dynamic and dangerous setting.

Given this dramatic history and the geologic uncertainties accompanying this setting, it is interesting to find the reaction and concern of people living on Santorini today to volcanic hazards. In short, it is dismissed (Dominey-Howes and Minos-Minopoulos, 2004). As on other volcanoes, the hazards of living there are largely ignored, often not understood or not considered seriously.



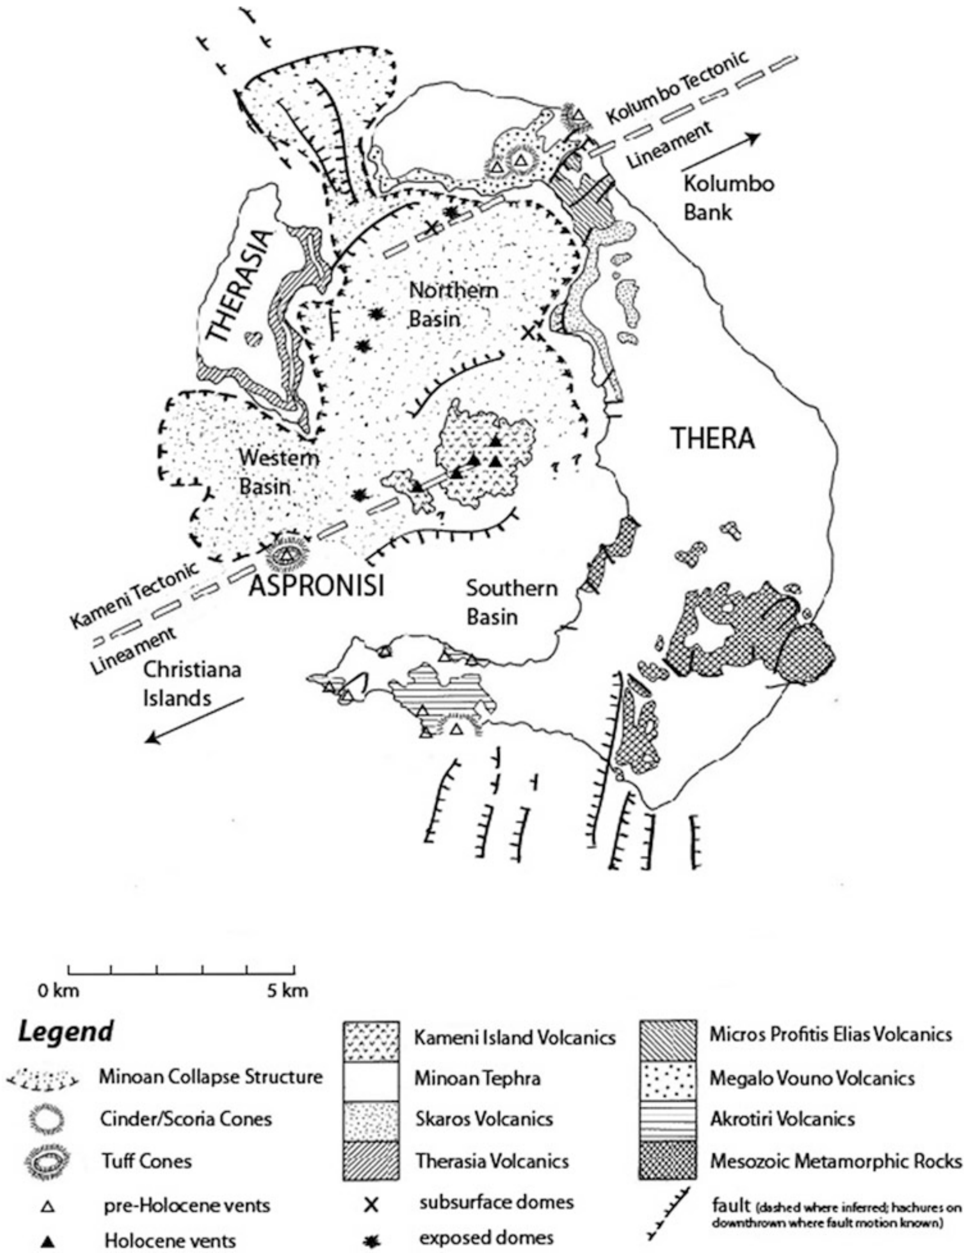
Santorini, Figure 6 (*Upper Panel*) A portion of the Marine Fresco as reconstructed from fragments found on the *upper* floor of the West House at the Akrotiri excavation (Doumas, 1992). It is argued that this scene represents the pre-eruption landscape by a Cycladic painter from a boat off the west coast of the island, looking toward the east, and depicting the physiography and skyline of the LBA landscape. (*Lower Panel*) Outline of the physiographic elements depicted in the Marine Fresco, with modern geographic names identifying prominent peaks that were not buried in tephra by the LBA eruption but remain today forming the modern skyline. This interpretation corroborates the reconstruction presented in Figure 5. Given the perspective in the LBA depiction, the western portion of the circular waterway surrounding the central island would not appear in the painting as it would have been hidden by the LBA Therassia-Aspronisi peninsula (see Figure 5). Note that a large city may occupy either the central island or the Therassia-Aspronisi peninsula and was subsequently destroyed by the eruption.



Santorini, Figure 7 Stratigraphic sequence of the LBA eruption deposit. Related seismic activity is indicated, as determined from unpublished geologic data at the Akrotiri excavation and elsewhere on the island, with the origin of seismicity indicated as due to the eruption (*V*) or regional tectonic activity (*T*). Aegean ceramic stratigraphy is identified with *EM* Early Minoan, *MM* Middle Minoan, and *LM* Late Minoan period. Preservation of the ancient city at Akrotiri occurred with partial burial by tephra up to the middle of the second major phase (indicated by the brick pattern), whereupon strong lateral pyroclastic flows and surges removed portions of buildings not already buried; additional destruction came with mud and debris flows during the third and fourth phases of the eruption.

Mitigation planning is lacking. Instead, the hazard becomes marketable. With one of the most spectacular landscapes on this planet, and an infamous antiquity in volcanology, archaeology, and mythology, Santorini is a major tourist attraction. Over the past 100 years, the island has seen its traditional economy based on agriculture (barley, tomatoes), replaced first by quarrying of pumice from the LBA eruption (creating an environmental mess on Santorini and throughout the Aegean Sea from huge floating rafts of pumice), and finally taken over today by viniculture and tourism. Nea Kameni island in the middle of the caldera, the site of eruptions during the past 2000 years and likely in the future, has been made a volcanic park managed and protected by the local municipality; it is an impressive effort in sustainability and landscape preservation but with minimal focus on future hazards. Beneath the northern part of the island from 2011 to 2012, an injection of magma at depth occurred that provided precursory indicators of a possible eruption (Newman et al., 2012). While this did not result in effusive activity, new mapping of the caldera seafloor (Sakellariou et al., 2012, and references therein) has disclosed features indicative of continuing volcanicity (Figure 8).

The setting of Santorini provides one of the most dramatic landscapes on earth that attracts huge populations of tourists every year. The combination of volcanic landscape with contemporary Greek culture mixed with the mythology surrounding the ancient Bronze Age disaster creates one of the major attractions on earth. The past is packaged and advertised; potential disasters are dismissed by local inhabitants and visitors. There seems an attitude, as with populations on most active volcanoes, that eruptive activity is marketable rather than threatening. We can suppose that the ancient Cycladians might disagree.



Santorini, Figure 8 Tectonic and geologic map of the Santorini archipelago (Modified and updated from Novikova et al. (2011), with additional data from Nomikou et al. (2013), and Sakellariou et al. (2012)). The position of this volcanic center may be related to the tectonic offset between the Kameni and Kolumbo tectonic lineaments.

SCANNING ELECTRON MICROSCOPY (SEM)

Ellery Frahm
Department of Anthropology, University of Minnesota-Twin Cities, Minneapolis, MN, USA

Definition

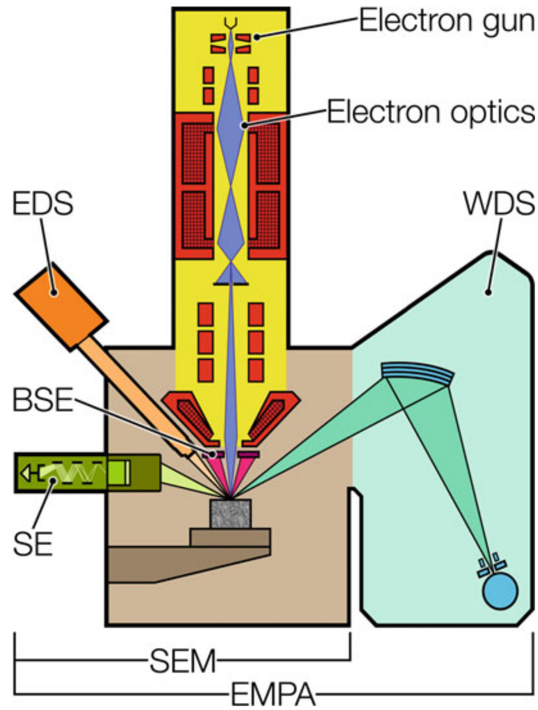
Scanning electron microscopy. A form of microscopy in which a focused beam of accelerated electrons is scanned across the surface of a specimen, generating a number of signals that yield information about its morphology, elemental composition, and, when outfitted with appropriate detectors, crystalline microstructure or other features.

SEM. Scanning electron microscopy or microscope. This acronym is often used interchangeably to describe the imaging/analytical technique and the instrument itself.

SEM in geoarchaeology

Introduction

SEM is a highly versatile imaging and microanalytical technique that has been used throughout the archaeological sciences for almost five decades (e.g., Pilcher, 1968; Brothwell, 1969). Most instruments are equipped for two primary functions: imaging (commonly at high magnifications) and providing compositional (i.e., elemental) information. Instruments can also be outfitted with detectors that offer additional information, such as the crystalline microstructure and orientation of a specimen. Hence, SEM has been frequently used in geoarchaeology whenever a researcher wishes to observe magnified images of a specimen and/or establish its elemental composition on a microscopic scale. Electron microprobe analysis (EMPA; sometimes known as electron probe microanalysis, EPMA) developed alongside SEM and is a closely related technique for electron imaging and X-ray microanalysis. These two techniques essentially exist on an analytical continuum, and their capabilities considerably, and increasingly with time, overlap. Figure 1 illustrates the principal systems of SEM and EMPA.

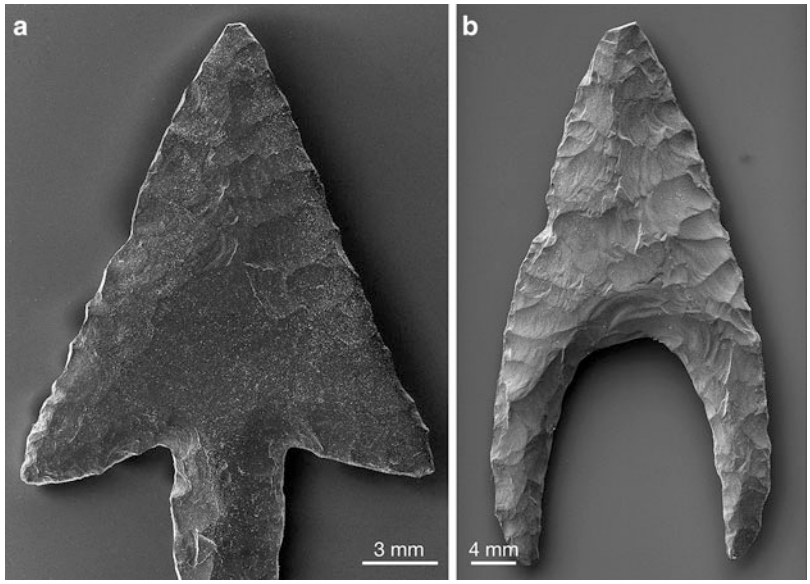


Scanning Electron Microscopy (SEM), Figure 1 Simplified cross-section of a typical scanning electron microscope (*SEM*) and electron microprobe analyzer (*EMPA*). A beam of energetic electrons is produced by the electron gun and focused by an optical system (composed of a series of lenses and apertures) onto a specimen. The primary detectors are shown: a secondary-electron (*SE*) detector, a backscattered-electron (*BSE*) detector, and an energy-dispersive spectrometer (*EDS*) for X-rays. Additionally, EMPAs measure X-rays using a number (typically five) of wavelength-dispersive spectrometers (*WDS*). Not shown are detectors that only certain instruments have (e.g., electron backscatter diffraction or EBSD) (Image by the author).

SEM enables high-magnification imaging of a specimen, and the magnification range with SEM is much greater than that with visible-light microscopy (VLM), from as low as 5× (equivalent to a hand lens) to as high as 200,000× (about two orders of magnitude higher than a petrographic microscope) or even more. In addition, SEM has a superior depth of field (about 300 times better than VLM), which means that the full height of a specimen can appear focused (Figure 2). Most SEMs can also quantitatively or semiquantitatively measure elemental composition based on the X-rays emitted by a specimen under energetic electron bombardment.

SEM fundamentals

An "electron gun" atop the instrument (Figure 1) creates a beam of electrons either via heating (thermionic emission) or electric fields (field emission) and accelerates them toward a specimen. A column of apertures and electromagnetic lenses focus the electron beam onto the



Scanning Electron Microscopy (SEM), Figure 2 SE images of (**a**) a Neolithic stemmed chert point from the Arabian Peninsula and (**b**) a Neolithic hollow-base chert point from Egypt. The greater depth of field for SEM (relative to conventional visible-light microscopy) means that each projectile point appears in focus, not just its edge or topmost surface (Images by the author).

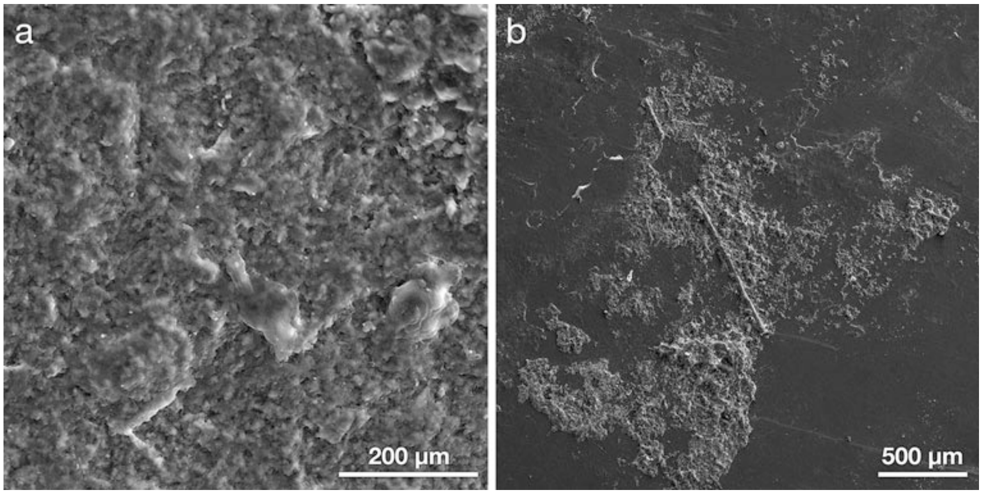
surface of the specimen. To produce an image, the beam quickly scans across the surface, very much like an old CRT-based monitor or television. This process often occurs under high vacuum to reduce scattering of the electrons by air molecules and other undesirable effects. A fairly recent development, though, is imaging at pressures closer to atmosphere, generally called environmental SEM (ESEM), but a number of manufacturer-specific terms have also been introduced (e.g., variable-pressure SEM, low-vacuum SEM, wet SEM). The main advantage is that additional air inside the chamber prevents an electric charge from building up on nonconductive specimens. With the chamber under vacuum, it is necessary to coat specimens with an ultrathin layer (about 100 Å thick) of conductive carbon or gold to prevent the charge buildup from disrupting the imaging. The layer can subsequently be removed if needed, but the use of ESEM eliminates the coating procedure.

When the accelerated electrons strike a specimen, a variety of signals is generated. Some signals are used for imaging, while others are useful for compositional or microstructural analyses when an instrument is outfitted with appropriate detectors. One of the two principal imaging signals is secondary-electron (SE) emission. Low-energy SEs escape from only the outer few nanometers of a specimen's surface. Therefore, they are most sensitive to specimen topography and useful for imaging surface details (Figure 3). SE images are the stereotypical SEM-type images, and many people have seen such images of insects, salt crystals, or pollen as examples.

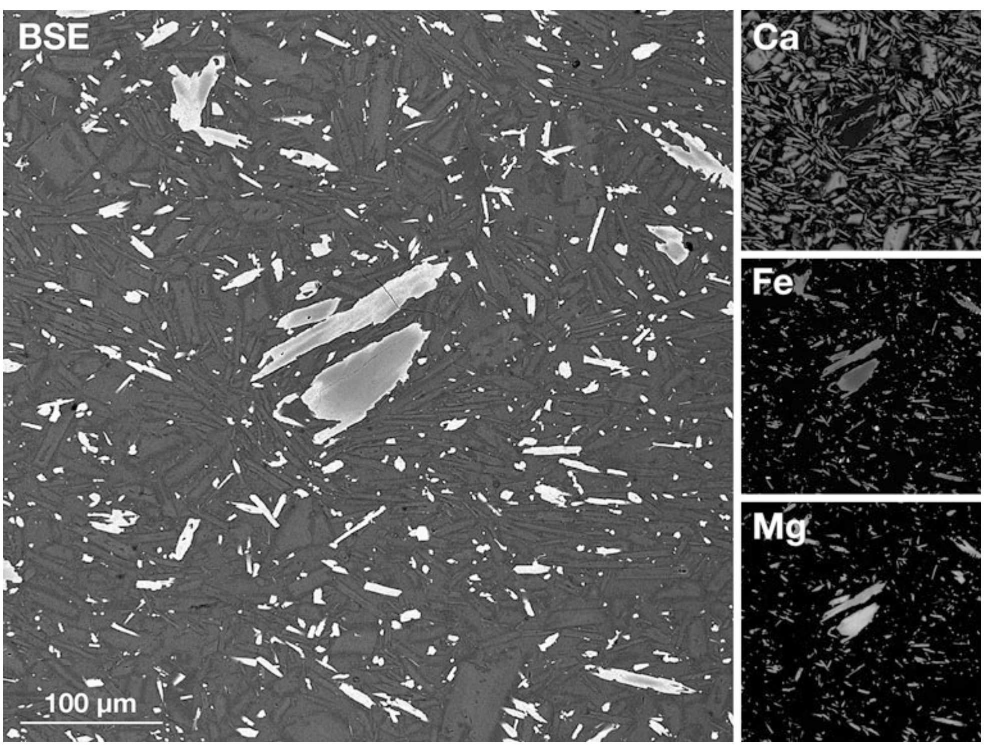
The other principal imaging signal is backscattered-electron (BSE) emission. BSEs are energetic beam electrons that have been deflected back out of a specimen and, as a result of energies much higher than SEs, are less influenced by surface topography. Instead, they are strongly affected by the elemental composition of the specimen: elements with higher atomic numbers deflect back a higher proportion of BSEs. This phenomenon is used to produce images that have compositional contrast (although there is still a topographic component for non-flat specimens). The resulting BSE images exhibit bright regions where the mean atomic number of the specimen is higher and dark regions where it is lower (Figure 4). Contrast in such images reveals relative differences in composition, not the actual elements or their concentrations.

Identifying elements involves measuring the electron-induced X-ray emissions from a specimen. Characteristic X-rays have energies (and, therefore, wavelengths) indicative of the elements from which they are emitted, and their intensities (i.e., the number of X-rays emitted) reflect the concentration of each element. Thus, X-ray spectrometers can reveal a specimen's composition. A modern SEM is typically outfitted with an energy-dispersive spectrometer (EDS; sometimes abbreviated as EDX, EDXA, or the trade name EDAX) to measure these X-rays. Thus, SEM-EDS measures characteristic X-rays at energies that correspond to elements in the specimen, and their intensities can be converted into quantitative elemental abundances. Individual analyses are short, frequently requiring less than a minute or two to measure the X-ray spectrum.

These same characteristic X-rays are measured somewhat differently in EMPA. A microprobe is outfitted with several (usually five) wavelength-dispersive spectrometers (WDS). EMPA discerns X-rays by wavelength,



Scanning Electron Microscopy (SEM), Figure 3 SE images of (**a**) the surface of a Mousterian (i.e., a Middle Paleolithic lithic industry associated with Neanderthals) chert tool from France and (**b**) residue adhering to the surface of an obsidian artifact from Syria. Residues on stone tools have been a recent focus of study with SEM to determine the tools' uses (e.g., Monnier et al., 2012, 2013; Borel et al., 2014) (Images by the author).



Scanning Electron Microscopy (SEM), Figure 4 BSE image and element maps of sanukite, a fine-grained andesitic volcanic rock from the Okayama region of western Japan, where it was intensively used alongside obsidian during the Paleolithic to craft stone tools. The SEM enables examination and elemental analyses of the rock's different minerals, including the enstatite-ferrosilite [$(Mg,Fe)SiO_3$] series pyroxenes in the middle of the images (i.e., bright areas in the Mg and Fe element maps and dark areas in the Ca map) (Images by the author).

instead of energy, for more precise and sensitive measurements. Each analysis is reasonably short, requiring only a few minutes in many instances. Additionally, these instruments are equipped with EDS and can acquire magnified images of a specimen (although the maximum practical magnification is commonly lower than that of SEM).

SEM-EDS is often considered a spot analytical technique. The electron beam is focused on a spot or small area (typically a few micrometers to several millimeters in diameter), and a specimen's composition is measured for the area beneath the electron beam, rather than the entire specimen. Consequently, a researcher can acquire highly localized compositional data, analyze specimens too small to be studied using other techniques, or measure elemental variation across the surface. Therefore, SEM-EDS is well suited to studying mixtures (e.g., different minerals that compose a rock), and a high-resolution array of X-ray measurements permits researchers to map differences in elemental concentrations across the surface of a specimen (Figure 5).

SEM-EDS can also be considered a nondestructive technique in that it does not alter or destroy a specimen, which may be repeatedly analyzed. Specimens, however, must be small enough to fit inside the instrument. Typical maximum dimensions for specimen chambers are ordinarily about 10 cm horizontally and 5 cm vertically. Certain instruments, though, can accept larger specimens. For instance, the Mira-X, owned by the United States Air Force, is the world's largest SEM. With its 3.5 m^3 chamber, the Mira-X was used to examine a 1.8-m-tall terra-cotta warrior from Emperor Qin Shi Huang's mausoleum. Echlin (2009) details various specimen preparation methods for SEM.

Quantitative elemental analysis with SEM-EDS (and EMPA), like most analytical techniques, is comparative. It entails measurement of X-rays from a specimen as well as reference standards, the compositions of which are well known. For each element, one measures X-rays emitted by a standard and those emitted by the specimen, and software calculates the ratio between them and corrects the measurements for various phenomena (e.g., reabsorption of X-rays by other atoms in the material) to calculate a specimen's composition accurately. In the past, such corrections used either empirically derived coefficients or calibration curves based on a number of standards, but these approaches are outdated. Instead, modern software and faster computers use physics-based models to calculate and apply corrections directly to raw data instantaneously.

SEMs have diverse capabilities and configurations. It would be remiss, however, to overlook the importance of an analyst's choices and savoir faire as factors in instrument performance and the resulting images or analytical data (e.g., Goldstein et al., 1981). Long (1995: 15) explains that "these are determined not only by the design of the instrument but also by the expertise of the operator in choosing and setting the optimum operating conditions." Reed (2005: 137) similarly notes: "It is difficult even for an experienced operator to arrive at optimal choices for all the relevant parameters." The considerations governing these choices can fill entire books (e.g., Goldstein et al., 2003; Reed, 2005) and, thus, cannot be explored in detail here. However, it should be appreciated that such choices and practical experience can be significant in SEM (and, especially, EMPA) operation.

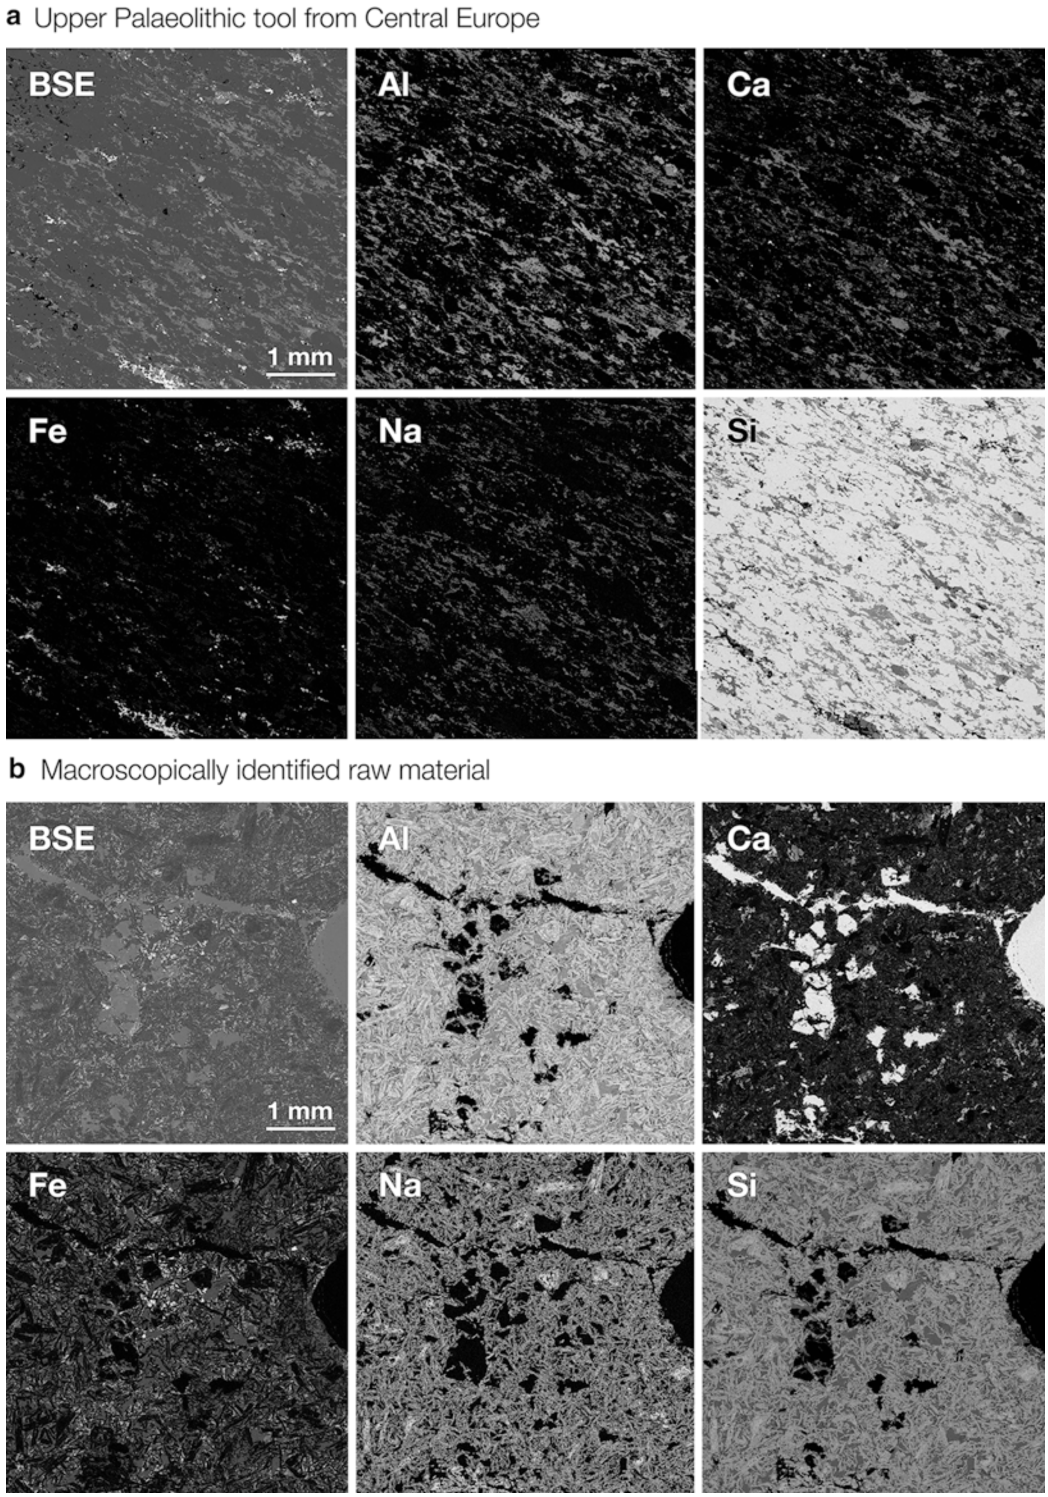
Nevertheless, SEM is more user-friendly than many other analytical techniques and safe enough for students to use. Therefore, it is often incorporated into hands-on exercises in archaeological science courses (e.g., Ponting, 2004; Nicolaysen and Ritterbush, 2005; Hill et al., 2007). Usually low fees also mean that these techniques are broadly accessible to projects without large funding sources, including public and community archaeology projects (Figure 6).

Recent advances

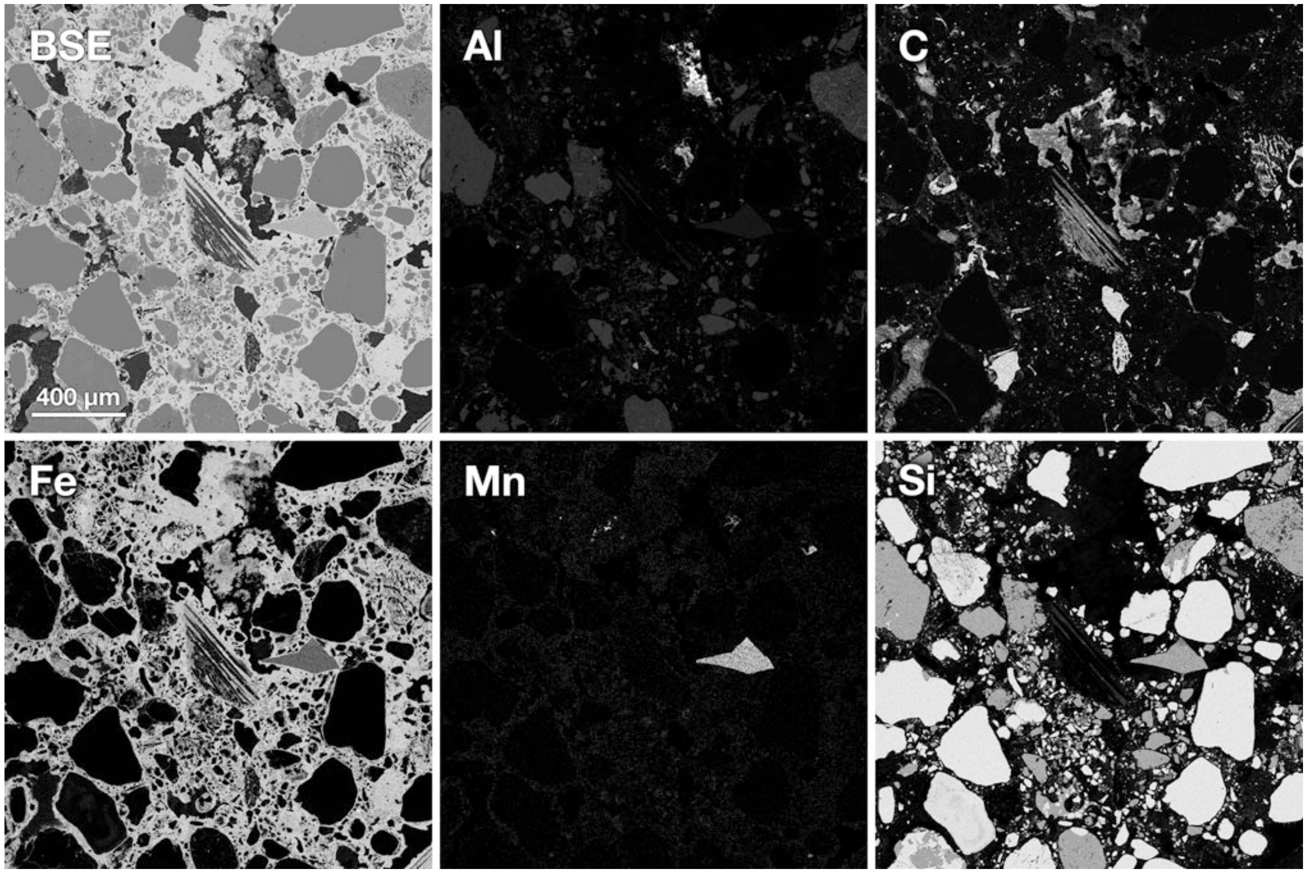
The conference "Scanning Electron Microscopy in Archaeology" was convened at the University of London in 1986, and the proceedings were published 2 years later in a volume edited by Sandra Olsen (1988a), the same year she published a review paper on the same topic in *Advances in Electronics and Electron Physics* (Olsen, 1988b). Most of the instruments in these papers date to the 1970s and early 1980s, but now, nearly three decades later, advances in SEM, especially concerning hardware and data processing, have improved dramatically on early models.

SEMs have seen marked developments since Olsen's publications. For example, the newer type of dedicated BSE detector in a modern SEM yields images superior to those in older papers. SE imaging has also improved due to the development of a new type of electron gun, called a field-emission gun (or FEG), which enables higher-resolution imaging due to an even smaller diameter of the electron beam. With other advances in electron optics, the resolution of a modern research-grade SEM is about 2 nm, a full order of magnitude better than just two decades ago. Digital imaging is another significant advancement. Instead of taking photographs of CRT screens, images are now digitally acquired, stored, and processed. Similarly, the X-ray "dot maps" illustrated in several of those early papers are obsolete, long since replaced by digital X-ray intensity maps.

Furthermore, new detector systems now allow researchers to investigate new problems with SEM. In particular, a system already available on select SEMs detects the beam electrons that diffract out of a specimen due to its crystalline structure and orientation. This phenomenon is called electron backscatter diffraction (EBSD), and it has already been applied in archaeological research (Peruzzo et al., 2011). The main advantage for archaeologists is being able to differentiate in situ minerals with the same elemental composition but distinct crystalline structures and origins. For example, calcite from limestone and aragonite from shell are both chemically calcium carbonate ($CaCO_3$) and indistinguishable with EDS, but EBSD can discriminate between them. In addition, innovative



Scanning Electron Microscopy (SEM), Figure 5 BSE images and X-ray element maps of (**a**) a tool from an Early Upper Paleolithic site in Central Europe and (**b**) a geological specimen from the proposed raw material source based on macroscopic identification. Microscopically, however, the tool and the geological specimen are clearly different. The tool is made of a metamorphosed siliceous (Si-rich) quartzite, conducive to conchoidal fracture. The geological specimen, however, is composed of coarse aluminosilicate minerals and has sizable calcium carbonate veins and inclusions (perhaps filled voids), yielding a material ill-suited to knapping stone tools (Images by the author).



Scanning Electron Microscopy (SEM), Figure 6 During the Elliot Park Neighborhood Archaeology Project, excavations of a nineteenth-century residential neighborhood near downtown Minneapolis turned up slag. BSE imaging and element maps, as shown here, established that the slag was waste from a puddling furnace. This process removes the carbon, silicon, and other impurities from pig iron to produce wrought iron, but there is considerable loss of iron to the slag, resulting in an iron-rich matrix (Images by the author).

X-ray detectors under development combine the speed and ease of EDS with the precision and sensitivity of WDS.

Recent years have seen the introduction of so-called "tabletop" SEMs by several manufacturers. At present, these instruments do not produce results at the highest "research grade," but their advantages include lower purchase and maintenance costs, smaller space requirements, and relative portability, making them attractive for many archaeological applications. The trade-off is that their capabilities are limited (e.g., restricted magnification, sometimes absent EDS), and they vary by model. Their performance, however, will certainly improve in coming years. Eventually, most likely soon, it will become easier and cheaper for archaeologists to bring portable SEMs into the field, therefore making it unnecessary to export artifacts to distant microscopy facilities.

Geoarchaeological applications

SEM and the closely related EMPA have been applied in all subsets of geoarchaeology: soils and sediments, paleoenvironmental research (e.g., microfossils, pollen, phytoliths), raw materials and geological resources (e.g., stones, clays, metal ores, mineral pigments), site formation processes (e.g., sediment micromorphology, erosion), geochronology, and more.

These techniques are commonly applied in sediment micromorphology and microstratigraphy. Courty et al. (2012) used SEM-EDS to find evidence of combustion features in microfacies at the site of Abric Romani in Spain, attesting to Neanderthal pyrotechnology. Similarly, Goldberg et al. (2012) examined the micromorphology of combustion features at two Neanderthal sites in southern France, Pech de l'Azé IV and Roc de Marsal. Karkanas (2002) also used SEM-EDS for micromorphological investigations at several Greek cave sites to link environmental changes and human habitation. Schiegl et al. (2003) were able to discern fireplaces and dumping areas at Upper Paleolithic Hohle Fels cave in Germany with SEM and EMPA, while Mallol et al. (2009) studied site formation processes at a Late Pleistocene rock-shelter in

Uzbekistan. Goldberg and Sherwood (2006) summarize how micromorphologists use cave sediments to elucidate prehistory.

Paleoenvironmental and paleoecological studies often exploit the imaging capacities of SEM. In fact, identifying pollen was one of its earliest archaeological applications (Pilcher, 1968), and it continues to be of great value for that purpose. For example, Lee et al. (2004) used SEM to examine pollen from Canadian wetlands as a means to explore habitation and wild rice exploitation in the region. Similarly, phytoliths (microscopic siliceous plant remains) are frequently examined with SEM. Based on phytoliths recovered from sediments inside Amud Cave, Madella et al. (2002) investigated Levantine Neanderthals' use of plant resources, such as herbaceous plants used as bedding, food, and possibly fuel.

Other botanical remains also yield environmental information. Messager et al. (2008) used SEM to examine fossil fruit remains at the site of Dmanisi in the Georgian Republic and established, based on the taxa present, that the environment was arid. Similarly, Cartwright (2013) identified wood charcoal at the site of Diepkloof rockshelter in Western Cape, South Africa, as a means to study the environment, ecological change, and the use of plant resources during the Middle Stone Age. Likewise, Gómez-Orellana et al. (2014) applied SEM to the examination of charcoal, pollen, and other botanical remains to reconstruct coastal, vegetation, and other ecological changes in a Portuguese river estuary and adjacent archaeological sites.

Another common use of these techniques is identifying minerals used as pigments, including pigments apparently used by Neanderthals. For example, SEM-EDS was one of the tools used by d'Errico et al. (2010) and Salomon et al. (2012) to study the various pigments from Middle Paleolithic strata of Es-Skhul, one of the Mount Carmel caves, and similarly, Dayet et al. (2014) identified the different pigments found at Châtelperronian sites in France. Similar SEM-based studies of Paleolithic pigments include Iriarte et al. (2009) at two cave sites in Spain.

Just as petrologists frequently use SEM-EDS and EMPA to characterize rocks and their mineral components, so, too, do archaeologists. These techniques are often used in petrographic studies of a broad variety of stone artifacts. For example, Tripati et al. (2010) established that stone anchors recovered from shipwrecks off the western Indian coast were made of igneous and sedimentary rocks that occur together in the Rajasthan region using SEM-EDS. Virtually every kind of stone artifact has been investigated with these techniques.

Geochronologists often rely on these techniques in tephrochronology to analyze tiny volcanic glass shards and chemically match them to a specific eruption as a means of correlating strata at sites across an entire region (i.e., areas where the volcanic ash fell). For example, Tryon et al. (2009) produced a chronostratigraphic framework for Paleolithic sites in volcano-rich central Turkey based on EMPA analysis of tephra, enabling more detailed studies of spatial and temporal variation in hominin behavior throughout the region. Sulpizio et al. (2010) used SEM-EDS of tephra layers from lake cores in the Balkans to link them to the same layers found throughout the Central Mediterranean. Researchers in Oxford's Research Laboratory for Archaeology and the History of Art (RLAHA) and the Royal Holloway and Oxford Tephrochronology Research Group (RHOXTOR) routinely pursue SEM-EDS and EMPA analysis of tephras from archaeological sites around the world (e.g., Lane et al., 2011; Lowe et al., 2012; Douka et al., 2014; Lane et al., 2014).

Given the widespread application of SEM-EDS and EMPA to analyze tephra, it is not surprising that these techniques are also helpful in studying obsidian. After early endeavors with the SEM-EDS (e.g., Biró and Pozsgai, 1984; Biró et al., 1986; Keller and Seifried, 1990) and EMPA (e.g., Merrick and Brown, 1984; Merrick et al., 1994; Tykot, 1997), archaeologists have returned to these techniques for obsidian sourcing, that is, geochemically matching obsidian artifacts to their volcanic origins to identify where the raw material was procured. Due to recent advances, obsidian sourcing in the Old World has become highly successful with SEM-EDS (e.g., Acquafredda and Muntoni, 2008; Lugliè et al., 2008; Mulazzani et al., 2010; Poupeau et al., 2010; Reepmeyer et al., 2011; Orange et al., 2013) and EMPA (e.g., Frahm, 2010; Sanna et al., 2010; Nash et al., 2011; Frahm, 2012a, b; Brown et al., 2013; Frahm and Feinberg, 2013a, b; Summerhayes et al., 2014).

Ultimately, the full range of SEM applications is extremely diverse. McLaren (2004) employed SEM to study calcrete deposits that infill paleochannels of the Wadi Dana (Jordan), one of which was associated with a Middle Paleolithic biface, to reconstruct their development and distribution. Van Hoesen and Arriaza (2011) used SEM-EDS to analyze clays used in the mummification of Chilean mummies, whereas Pirrie et al. (2014) investigated the mineral assemblages of soil samples reportedly associated with artifacts as a means to authenticate their contexts. Bello et al. (2013) used SEM-EDS to recognize small chert flakes embedded in antler hammers used in knapping experiments, and Eren et al. (2014) quantified differences in lithic raw material quality and its effects on variation in stone tool shape. A wide variety of applications is also discussed in Weiner's (2010) book *Microarchaeology: Beyond the Visible Archaeological Record*.

Further reading

In-depth considerations of electron and X-ray physics are beyond the scope of this entry. Details regarding electron orbitals, ionization energies, and absorption cross-sections have been avoided deliberately. Here, it is simply accepted that the electron beam generates characteristic X-rays. In *The Quantum Dice*, Ponomarev (1993) proposes that "physics is a vast country with a rich and deep culture" (13), drawing an analogy amenable to archaeologists. He maintains that if one does not "get acquainted with the customs and culture" of the physics involving a particular phenomenon, one will only "know as much about it as tourists know about an unfamiliar country whose culture is foreign to them and whose language they do not understand" (13). Admittedly, readers are left here at what Ponomarev (1993) sees as the level of "bright neon signs and posters" (13). Those interested in greater detail regarding the physics of SEM and EMPA are forwarded to Goldstein et al. (2003) and Reed (2005). Unfortunately, these largely application-focused books are about a decade old and, in turn, increasingly do not reflect the current state of the art. As of this writing, however, there is a lack of newer, geoarchaeologically relevant texts.

Summary

SEM is among the most versatile techniques in geoarchaeology, and it is well suited to studies of a broad range of artifacts as well as archaeological and geological materials. Just a few of the applications could be introduced here. These instruments are routinely used to acquire magnified images of a specimen (SE images) and study elemental compositions and their spatial variation (BSE images and X-rays measured with EDS and/or WDS). Common applications, therefore, include examination of small objects or features, identifying different components of a specimen or mixture, and measuring a specimen's elemental composition and/or structure quantitatively. The instruments are widely available at most universities, often in geological departments and/or core analytical facilities, contributing to their frequent use.

Given the proliferation of "tabletop" SEMs, it will eventually become easier and cheaper to bring such portable instruments into the field rather than send artifacts or geological specimens to distant microscopy facilities. It will also be much faster. For example, stone tools could be examined for residues in a field lab shortly after their excavation, not months or years later halfway around the world. By transplanting such observations to a field context instead of a laboratory one, portable SEM instruments become a facilitating technology for geoarchaeology, minimizing physical and temporal barriers that have often segregated such research between distant places and often lengthy intervals. This portability can unite field- and laboratory-based activities within a shared setting. SEM observations, previously available only after artifacts or specimens have been long separated from their contexts, can now be made locally, providing rapid feedback while researchers are still actively excavating.

SEDIMENTOLOGY

Katherine A. Adelsberger
Environmental Studies, Douglas and Maria Bayer Chair in Earth Science, Knox College, Galesburg, IL, USA

Definitions

The scientific study of sediment and sedimentary rocks.

The study of material found at the earth's surface and composed of unlithified rock fragments, chemical precipitates, or biogenic matter.

Sedimentology in geoarchaeology

Introduction

Sediments serve as the primary matrix for most archaeological materials (Goldberg and Macphail, 2006), and they are therefore the main focus of much geoarchaeological research. Although the broader earth science definition of sedimentology includes the study and classification of sediments and sedimentary rocks, in many cases geoarchaeology deals almost exclusively with sediment alone due to the unconsolidated sedimentary nature of many late Quaternary geologic settings, the generally loosely deposited materials that make up archaeological sites themselves, and the nature of the questions geoarchaeologists commonly ask. The majority of the sedimentary concepts are the same in both geology and geoarchaeology, but those interested in a review of sedimentary rocks specifically should consult a more typical earth science source (e.g., Middleton, 2003). Sedimentology is considered here as separate from the study of stratigraphy, and therefore, this discussion does not include concepts such as the layering or bedding of sediments or the structures that may develop during the depositional process.

Sediments and sedimentary rocks are found in a wide range of environmental settings created by a variety of depositional mechanisms. Many of these settings (e.g., alluvial, colluvial, eolian, paludal, glacial, and coastal) are covered individually in some detail in the current volume, making a discussion here unnecessary. However, within the context of geoarchaeological studies, anthropogenically deposited sediments and anthropogenic alteration of naturally deposited sediments must also be considered, particularly in cases where intentional movement and deposition of sediment within cultural contexts have occurred. The most relevant sites to consider include those of mound-building or other site construction processes, but differentiating between human deposits and natural sediments is one of the primary purposes of many geoarchaeological studies regardless of the scale of human impact on sedimentary settings.

Methodologically, the inclusion of human influence on sedimentation requires the use of traditional methods of sedimentology within a more complex interpretive context, as additional kinds of influences must be considered within archaeological settings (such as living surfaces, landfills, hearths and combustion features, etc.). Sedimentology in geoarchaeology includes inquiries into the sources of sediments and the erosional processes that produced them as well as attempts to identify the environmental conditions present when they were deposited. For geoarchaeologists, the topic of depositional (or sedimentary) environment is often foremost among many potential research questions, as the depositional setting can serve as the dominant control over sedimentary characteristics and also provide a great deal of information about the context of any archaeological materials recovered from a sedimentary deposit (Stein and Farrand, 2001).

Sediments and sedimentary rocks are traditionally divided into three major categories, which also apply to geoarchaeological sedimentary studies: clastic, chemical, and biogenic. These serve as the primary matrices for the majority of archaeological artifacts, and understanding their characteristics serves as an initial step toward a more detailed interpretation of depositional or cultural context in sedimentary settings.

Clastic sediments

Sediments composed of weathered pieces of preexisting rock, or clasts, are known as clastic sediments. These sediments are classified by a combination of clast size, shape, and sorting, which together can be referred to as the texture of the sediment. Composition is also a common aspect of clastic sedimentary description, as compositional data may allow for interpretations of sediment provenance. These aspects of clastic sediments are generally described in the field as well as in the lab, and together, they serve as a basic description of a clastic deposit.

Size

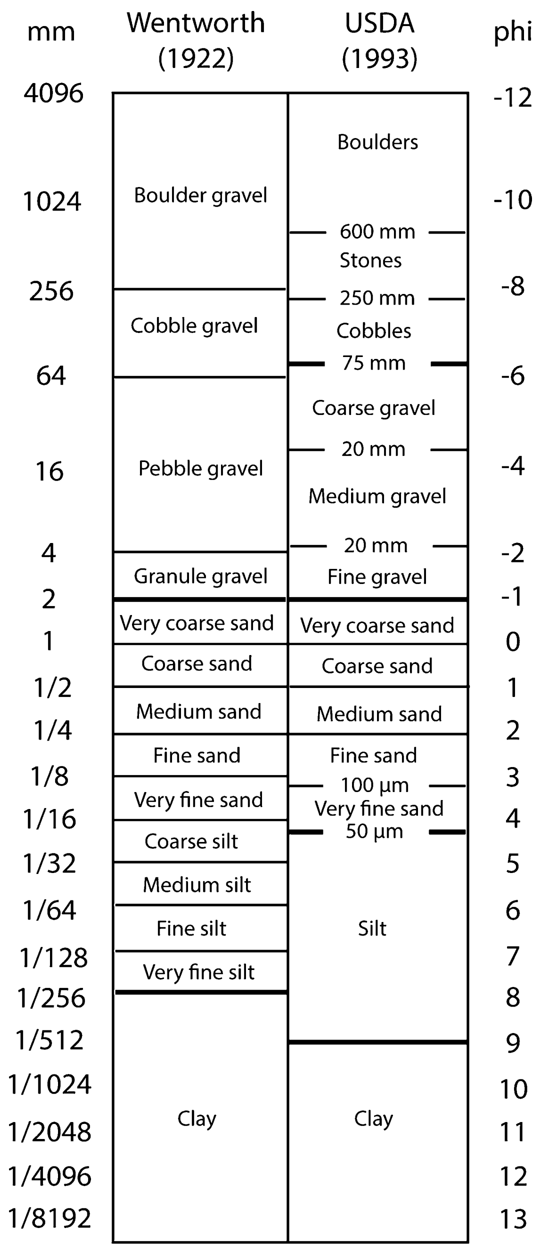
Clast size is determined using one of several scales developed for the purpose of defining the breaks between size categories such as clay, silt, sand, and gravel. Most frequently, sedimentologists utilize the Udden-Wentworth scale (Figure 1), originally proposed by Udden (1898) and further developed by Wentworth (1922). This scale defines breaks between size categories in millimeters. A later addition by Krumbein (1934) provided a unit for the equal distribution of particle size values, known as phi (ϕ), which is calculated using the diameter of a clast in millimeters (d) as

$$\varphi = -\log_2 d \quad (1)$$

The availability of the phi scale allows for better graphical representation of grain size data, among other applications, and is used when quantitatively defining some characteristics of sediments, such as sorting. When working with soils, geoarchaeologists may also use the USDA grain size scale (Soil Conservation Service, 1975; US Division of Soil Survey, 1993), which varies from the Udden-Wentworth scale in the placement of the breaks between particle size categories (Figure 1). Soil scientists also employ terminology unique to soil studies in the use of the word "loam" and the evaluation of texture via a textural triangle where percentages of sand, silt, and clay are used to identify a textural class. Regardless of the scale being used, clast sizes are reported as particle size distributions following laboratory analysis to separate particles into the relevant size categories and to measure distributions as percentages of the overall sample. Although the terms (such as clay, silt, sand, etc., Figure 1) employed by these different scales are the same and are used with the expectation of a general understanding within the geoarchaeological and sedimentological communities, efforts to improve and standardize the size classification system have continued into more recent research (Blott and Pye, 2012), though without significant adoption for practical applications. Laboratory methods for separating and measuring these various size fractions constitute an important component of basic sedimentary analysis in geoarchaeology, as particle size is a fundamental characteristic of sediments, and particle size distribution data can provide keys to depositional interpretations.

Sorting

Sorting refers to the range of particle sizes represented within a sample, which is measured as the standard deviation of clast sizes (Harrell, 1984). These values are computed from grain size values in the phi scale so that ϕ must be attached to the standard deviation values (Boggs, 2006). These standard deviations are also associated with descriptive terms, where a sample containing a wide range of particle sizes is referred to as "poorly



Sedimentology, Figure 1 Comparison of the Wentworth (1922) and USDA Division of Soil Survey (1993) grain size scales (After Blott and Pye, 2012).

sorted" and a sample containing a small range of particle sizes is referred to as "well sorted" (after Folk and Ward, 1957; Folk, 1966, Folk, 1974; Boggs, 2006):

ϕ Standard deviation	Description
<0.35ϕ	Very well sorted
0.35–0.50ϕ	Well sorted
0.50–0.71ϕ	Moderately well sorted
0.71–1.00ϕ	Moderately sorted
1.00–2.00ϕ	Poorly sorted
2.00–4.00ϕ	Very poorly sorted
>4.00ϕ	Extremely poorly sorted

The descriptive terms that correspond to these standard deviation measurements are also often used to describe sediments in the field by following visual guides for estimating sorting (e.g., Harrell, 1984), instead of measuring standard deviations. Although the statistical measurement is preferred for the sake of consistency and clarity, the use of these terms as estimates alone within a field setting provides comparative phrases for field description that can later be verified in a laboratory setting.

Shape

Clast shape is defined as a combination of the form, roundness, and surface texture of particles (Barrett, 1980). The first of these characteristics, *form*, refers to the similarity between the lengths of the three axes of any clast. A clast with similar lengths along all axes has high sphericity (Wadell, 1932), whereas a clast with highly unequal lengths will be elongated along one of them, a form referred to as platy. This idea of sphericity initially laid out by Wadell (1932) was later altered by Krumbein (1941) to define sphericity (ψ) as

$$\psi = \sqrt[3]{\frac{\text{volume of particle}}{\text{volume of circumscribing sphere}}} \qquad (2)$$

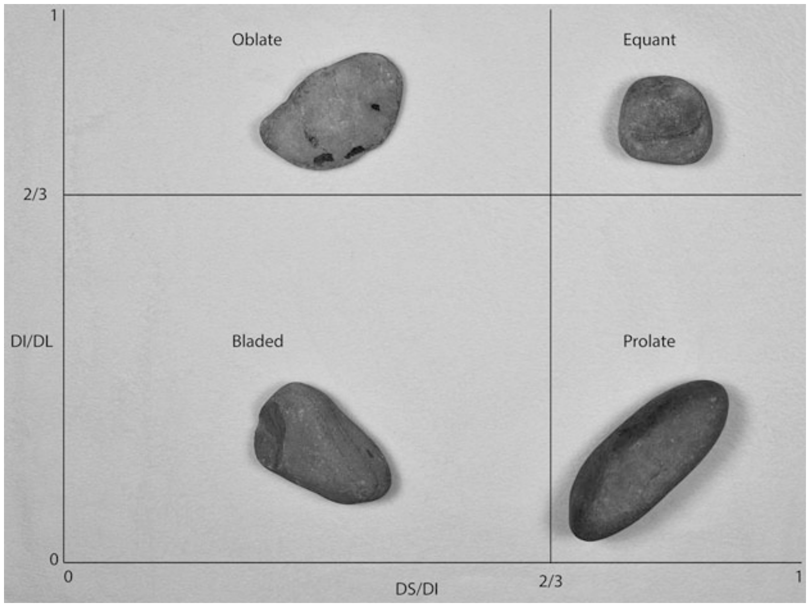
Because any clast with three axes would have three diameters (D) for the long, intermediate, and short axes (D_L, D_I, and D_S, respectively), this can also be expressed using the volume of a sphere, $\pi/6\ D^3$, so that (Boggs, 2006)

$$\psi_I = \sqrt[3]{\frac{\frac{\pi}{6} D_L D_I D_S}{\frac{\pi}{6} D_L^3}} = \sqrt[3]{\frac{D_S D_I}{D_L^2}} \qquad (3)$$

Another way of measuring sphericity was proposed by Sneed and Folk (1958) in order to predict more accurately the behavior of a particle in a fluid, as the sphericity calculation developed by Krumbein (1941) did not produce values that would correspond with clast settling velocity or the orientation of platy clasts due to fluid flow (Boggs, 2001). This alternative sphericity measurement, referred to as maximum projection sphericity (ψ_p), is defined as (Sneed and Folk, 1958)

$$\frac{\text{maximum projection area of a sphere with the same volume as the clast}}{\text{maximum projection area of the clast}}$$

This can also be expressed using the maximum projection area as



Sedimentology, Figure 2 Examples of clast form after Zingg (1935).

$$\psi_p = \sqrt[3]{\frac{D_S^2}{D_L D_I}} \quad (4)$$

Using this definition of sphericity, Sneed and Folk (1958) were able to demonstrate a closer correspondence between sphericity and clast behavior within flowing fluids, but maximum projection sphericity is otherwise not considered to be more valid than the quantification method developed by Krumbein (1941) for describing particle form (Boggs, 2006).

One shortcoming of sphericity measurements is the lack of correspondence between a sphericity value and actual clast shape, regardless of the sphericity measurement that is utilized (Boggs, 2001). In an effort to solve this problem, Zingg (1935) plotted the ratios of the particle axes D_I/D_L versus D_S/D_I in order to categorize particle shapes. In this system, high D_I/D_L values indicate *oblate* (disc-shaped) particles when D_S/D_I is low and *equant* particles when D_S/D_I is high, in which case all axes are approximately the same length. If D_I/D_L is low, particles may be classified as *bladed* when D_S/D_I is low or *prolate* when D_S/D_I is high (Zingg, 1935) (Figure 2). This method of categorization of form is more easily operationalized in the field than other measurements, because these qualitative descriptions can be made upon visual inspection of clasts. Axis ratios can be compared to quantitative sphericity measurements if necessary.

As with particle size, later research was built upon these foundational studies of shape in an attempt to create more functional descriptions of form; these ranged from an attempt to return to a version of Wadell's (1932) original sphericity measurements (Aschenbrenner, 1956) to the development of a more simplified, visually determined method of describing form in the field (Crofts, 1974). Most modern work, however, depends upon the original definitions provided by Wadell (1932) and Sneed and Folk (1958), which can be utilized to examine the role of particle form on laboratory methods (Fernlund, 1998) or on clast transport in different geologic settings (Pizzuto et al., 1999; Larsen and Piotrowski, 2003; Bluck, 2011).

The second component of particle shape is the *roundness* of a clast. This topic was pioneered quantitatively by Wentworth (1919), who used the curvature of the corner of a clast with the largest projection in order to measure roundness. However, most modern work follows Wadell (1932), who separated roundness from form and specified that a spherical particle may have minimal roundness or vice versa. The roundness of a clast, taken as the mean of the sum of the roundness of all the corners of that clast, is known as the Wadell roundness (R_W) (Boggs, 2006), where a radius (r) can be measured for a sphere that fits inside each of a number of corners (N) of a clast, and R is taken as the radius of the largest sphere that can be inscribed within the particle's outline and aligned with the plane being measured (Wadell, 1932). This is expressed as

$$R_W = \frac{\sum \frac{r}{R}}{N} \quad (5)$$

Due to the number of individual measurements required to evaluate the Wadell roundness quantitatively, later work attempted to provide simpler methods of roundness calculation (Russell and Taylor, 1937; Pettijohn, 1949; Dobkins and Folk, 1970). However, the primary alteration to Wadell's work commonly utilized in current field studies was the development of comparative scales that allow for a visual estimation of roundness (Krumbein, 1941), including the terms angular, subangular, subrounded, rounded, and well rounded to describe the smoothness of the angles of a clast (Powers, 1953). Similar to visual estimations of sediment sorting, such methods are much more functional in field settings, as they allow for the practical use of roundness as a characteristic of sedimentary particles in field descriptions.

The final component of clast shape is *surface texture*, which is a term describing the presence of pits, fractures, scratches, or other variations present on the surface of a clast. This method of particle description is primarily laboratory based, as it involves the use of either a petrographic or, in most studies, an electron microscope in order to view surface variations at magnification (Krinsley and Takahashi, 1962; Wolfe, 1967; Krinsley and Doornkamp, 1973). Studies of surface texture may provide evidence of transport and depositional mechanisms within sedimentary contexts (Helland et al., 1997; Timireva and Velichko, 2006; Marshall et al., 2012), and they can therefore be useful in paleoenvironmental work as well as site formation inquiries in geoarchaeology.

Fabric

Fabric refers to the arrangement of clasts within a sedimentary package along with the textural characteristics such as size, shape, and sorting. This concept includes the orientation of clasts as well as how they are spaced, which is known as packing (Boggs, 2001). Grain orientation in clasts with one elongated axis (platy) will preferentially align with the direction of fluid flow, either parallel (Rusnak, 1957; Parkash and Middleton, 1970) or perpendicular to the flow direction (Boggs, 2006; Goldberg and Macphail, 2006). Transported clasts may also display imbrication, where clasts overlap with dips of similar angle while simultaneously displaying orientation according to the current direction (Rusnak, 1957; Byrne, 1963). These features of sediment fabric are primarily found within environments of fluid flow, such as fluvial and colluvial deposits.

The packing of grains determines the porosity, or the amount of void space, within a sediment package, as well as the permeability, which is a measure of the interconnectedness of the void spaces. Poorly sorted sediments generally have lower porosity and permeability because void spaces can be filled by smaller particles, whereas grains of similar size will be limited in their packing (Boggs, 2006). Sorting will also determine whether sediments are *grain supported*, wherein all clasts are in contact with other grains of similar size, or whether the deposits are *matrix supported*, where coarser clasts are not in contact with one another but are instead supported by the surrounding matrix of smaller particles (Goldberg and Macphail, 2006). Concepts such as sorting and clast size are therefore difficult to separate from sediment fabric, as they are controlling factors for fabric characteristics such as grain packing. Fabric may also be relevant to smaller-scale features visible via micromorphology techniques or the structural development of soils, making the concept of fabric more encompassing within geoarchaeological studies than would be the situation in traditional sedimentology.

Composition

Clast composition plays a significant role in the determination of the characteristics described thus far, as lithology will control hardness and resistance to weathering during transport. The composition of clasts will therefore determine the rate at which they break down to smaller particle sizes (Wilson, 2004) as well as the extent to which a grain surface will be scratched or otherwise affected by contact with other geologic materials. For this reason, the majority of clast surface texture analyses are conducted on quartz, which is a more resistant mineral and can be maintained in an environment long enough to accumulate indicative surface textures (e.g., Krinsley and Doornkamp, 1973; Culver et al., 1983). The lithology of clasts found within sedimentary settings can also allow for the identification of the parent rock for a given deposit (Lindsey et al., 2007), providing evidence for transport mechanisms and distances, with the understanding that the original composition may have been altered significantly by differential weathering during transport processes. Finally, the composition of clastic sedimentary deposits may be controlled or altered by the development of precipitate minerals within or around the clasts themselves, which may also serve as cement during lithification.

Chemical sediments

Chemical sediments are the result of precipitation of mineral crystals from solution. From a geoarchaeological standpoint, these sediments are most relevant in the context of lacustrine, paludal, cave, or freshwater environments. The sedimentary deposits that result from the precipitation process are determined primarily by the ions available in solution within the environment of precipitate formation. One common chemical sediment, known as an evaporite, is composed of evaporite minerals such as gypsum and halite, which accumulate as the evaporation of water concentrates ions in solution (Boggs, 2006). Evaporite deposits may provide evidence for climate shifts, and so they are useful in paleoenvironmental studies where their presence makes examination of climate change possible (Renaut and Tiercelin, 1994; Deotare et al., 2004), particularly in arid zones and within the sedimentary records of saline water bodies. Mineral accumulations, especially those resulting from groundwater activity, can also be composed of a variety of other precipitates, such as iron oxides including goethite and jarosite

(Schwertmann et al., 1987; Long et al., 1992; Herbert, 1995; Zheng et al., 2007; Adelsberger and Smith, 2010). This is particularly true in cases where precipitation occurs in acidic conditions, due either to the depositional environment or contamination. In addition to providing evidence for depositional conditions, the nature of these precipitates is controlled by water chemistry, which can be determined largely by aquifer characteristics. In cases where solutions are supersaturated with silica, the precipitation of microcrystalline quartz will lead to the formation of chert, also known as flint, which is important to geoarchaeological work because of the prevalence of this material in early stone tool manufacture (Renfrew and Bahn, 2008). However, the combined geoarchaeological literature on all of these chemical deposits would not match the focus on carbonates, which comprises the most commonly encountered category of chemical sediments utilized in geoarchaeological studies.

Carbonates

Carbonate rocks include any sedimentary rocks composed of carbonate minerals, such as calcite, dolomite, or aragonite. The carbonate-bearing sediments relevant to most archaeological contexts include tufa/travertine and speleothems, all of which result from the deposition of $CaCO_3$ via the degassing of CO_2 from calcite-saturated freshwater, thereby increasing the pH and decreasing the solubility of calcite (Ford and Pedley, 1996; Chen et al., 2004). The terms tufa and travertine may be used interchangeably, with "tufa" more often used to refer to more friable deposits and "travertine" used for harder, crystalline, often layered deposits of calcium carbonate. Historically, the term "travertine" was initially utilized to describe hydrothermal deposits in Italy (Pentecost, 1993); accordingly, some authors continue to separate these terms according to the nature of the water body in question, with tufas originating from ambient-temperature freshwater environments (Sweeting, 1972) and travertines forming in hydrothermal conditions (Ford and Pedley, 1996). However, this is not always the case in the modern literature. Tufas are often described in environments where carbonate-rich surface waters or springs lead to carbonate deposition (Ford and Pedley, 1996; Smith et al., 2004), and although travertines can be described as deposits originating from hydrothermal groundwater sources (e.g., Renaut et al., 2013; Pola et al., 2014), this term may also be used to describe the more general case of freshwater carbonate deposition, particularly within fluvial deposits in karst terrains (e.g., Zhang et al., 2001; Drysdale et al., 2002). Regardless of the terminology used, microbial and plant associations may facilitate carbonate deposition in addition to creating biogenic structures within the resulting sediments (Chen et al., 2004; Pentecost, 2005; de Wet and Davis, 2010).

Cave deposits serve as another potential area of significant carbonate sedimentation from freshwater. The mineralogy of these deposits is often similar to those found in other settings, but they form via the percolation of water through overlying limestone within a karstic terrain and the resultant growth of features such as stalactites and flowstones (Hill and Forti, 1997; Tooth and Fairchild, 2003). In all of these settings, carbonate sediments are useful as potential chronostratigraphic units due to the presence of trace amounts of uranium within the deposits. Carbonates may therefore afford chronologic control within an archaeological site or provide contextual dates on any archaeological materials contained within the sediments themselves (Smith et al., 2007). Carbonates may additionally serve as paleoenvironmental proxies via measurement of Mg/Ca ratios, which serve as a proxy for paleotemperature, as well as through stable isotope measurements on the carbon and oxygen components of $CaCO_3$ (Drummond et al., 1995; Andrews, 2006; Kieniewicz and Smith, 2007; Lojen et al., 2009). Speleothems in particular can serve as paleoclimate proxies over periods of continuous deposition under the right conditions (Lauritzen, 2005; Fairchild et al., 2006). These applications of carbonate sediments make them particularly valuable when they are found within archaeological contexts, as the environmental conditions interpreted via these proxy data would have direct relevance to human activities and landscapes.

Biogenic sediments

Sediments composed of biological materials, such as shell or plant fragments, are known as biogenic sediments. In archaeological contexts, such sediments may include natural accumulations of organic matter such as peat, anthropogenically derived deposits such as shell middens, or plant remains transported into a site. These types of deposit are not relevant to the majority of archaeological contexts, but they can be particularly useful to geoarchaeologists where they are found because they provide unique preservational settings and paleoenvironmental data.

Peat is an accumulation of decomposing vegetation that forms in wetland environments. The organic richness of these deposits allows for chronological control of some sites via carbon 14 dating methods, which can be enhanced by the fact that the reducing conditions present in the catotelm layer of peat bogs provide an opportunity for prolonged preservation of organic matter, including human bodies and wooden artifacts (van den Berg et al., 2010). Peat has also served as an important paleoenvironmental proxy since the early 1900s (Dachnowski, 1922), providing evidence for changes in vegetation via pollen and fossil records (Barber et al., 2003; Blaauw and Mauquoy, 2012) as well as preserving elemental evidence of atmospheric compositions and human influence (Yu et al., 2010).

Shell middens are anthropogenically deposited accumulations of mollusk remains that result from the consumption or ritual use of these organisms at coastal sites. Although anthropogenic in origin, they can still be categorized as sediments because they are collections of biogenic matter, and they are of particular interest to geoarchaeology because they may provide evidence for diet, marine exploitation of resources, settlement patterns, or paleoenvironmental change (Álvarez et al., 2011; Gutiérrez-Zugasti et al., 2011). Because they are human creations, shell middens must be considered only within the context of human activity and may contain significant bias when they are used to interpret anything other than human activity itself; this is not the case for the other sedimentary deposits examined here, but it is a relevant consideration for anthropogenic sedimentary environments examined elsewhere in this volume.

Summary

Sedimentology has been a key component of geological and archaeological studies since the initial development of these fields, and it remains central to the methods employed in answering geoarchaeological questions. Clastic, chemical, and biogenic sediments all serve as matrices for archaeological materials, and they may additionally contribute to the studies of paleoenvironmental conditions and site formation that inform our understanding of human decision-making and behaviors in the past. Recognizing the basic components and applications of sedimentary data collection and analysis is mandatory for the majority of geoarchaeological studies, and sedimentary characteristics will therefore feature prominently in many of the more specific environmental and methodological entries in this volume.

Definition

A refuse deposit in which molluscan shell is one of the major constituent materials.

Identifying shell middens

Shell middens are refuse deposits composed solely or primarily of molluscan shells. Although they are most frequently thought of as comprising the refuse of ancient human meals, shell waste piles can also be accumulated through other cultural behaviors such as building and industrial activities. The recognition of shell middens in the landscape is not always a simple matter. Some nonhuman animals (e.g., crabs, octopuses, and muskrats) create shell middens. Additionally, a range of natural coastal and landscape processes can generate piles of molluscan shell prompting debates as to their origin. Thus, from a geoarchaeological perspective, the task of differentiating cultural middens from natural geomorphologic shell-bearing features and nonhuman animal middens is fundamental.

There is no simple checklist that allows archaeologists to distinguish naturally and culturally accumulated shell deposits, and frequently, shell-bearing deposits are formed and then transformed by *both* natural and cultural agents. Nevertheless, through consideration of stratigraphy and evidence for formation processes, constituent elements, and taphonomic signatures, a robust case as to origin can be built.

Location

Shell middens tend to be accumulated close to the aquatic area from which the mollusks derive, whether in a coastal, lacustrine, or riparian location (Peacock, 2000). Such middens may represent, among other things, processing points where bulky and heavy shells were discarded to facilitate easier transport of the meat, mealtime camps used while moving from one place to another, seasonal occupation areas, or zones within a larger habitation area or site complex. The locations of middens today may be broadly indicative of the locations of coastlines and watercourses in the past (e.g., Cannon, 2000). The global rise of sea levels at the end of the Pleistocene surely drowned innumerable coastal midden deposits (Bailey and Flemming, 2008).

Middens may also indicate the nature of past aquatic environments and thus provide valuable evidence for long-term ecological modeling (e.g., Graham et al., 2003). Considerable potential exists for developing research relationships with coastal and earth scientists by introducing shell midden data into integrated ecological models. Shell middens are not accreted through standard littoral processes, and they often lie beyond the reach of many natural taphonomic processes of the coastal zone (e.g., wave action and its associated actions of sorting, fragmentation, and attrition). As such, they present an entirely different category of evidence that is frequently well dated and well preserved. In a freshwater context, Peacock (2000, 193) adroitly sums up this potential: “[l]

arge archaeological shell assemblages can, in general, be considered qualitative collections that provide a good representation of past aquatic environments and how these environments changed through time."

Natural geomorphic accumulations vs. cultural middens

Natural geomorphic accumulations of shell often form in places similar to those where shell middens are accumulated by humans. Given this similarity, debate and methodological attention have been devoted over the past decades to distinguish the signatures of these two broad types of shell deposit. Attempts have been made to outline criteria that would assist in separating natural and cultural shell accumulations (e.g., Attenbrow, 1991; Henderson et al., 2002; Rosendahl et al., 2007); however, all authors rightly point out that assessment is always context driven, and there is no universally applicable checklist. Despite these limitations, the following key attributes and useful lines of inquiry can help guide assessment.

The most common and widespread type of large natural shell accumulation is the *chenier*. Cheniers are a form of stranded beach ridge that is often composed of poorly sorted shells. They can be accreted through a variety of coastal processes, but usually through longshore drift depositing coarse material over a finer substrate or through wave action winnowing out finer sediment on a prograding shoreline (Augustinus, 1989; Woodroffe and Grime, 1999). Their position, shell-rich nature, and the fact that major constituent taxa are frequently the same mean there can be confusion differentiating these from anthropogenic shell middens (Henderson et al., 2002). The inclusions of artifacts, other faunal remains, and charcoal are clear indicators of human agency (Figure 1); however, midden deflation and reworking, as well as dedicated processing sites which may have little in the way of unequivocal archaeological material (see the northern Australian case below), may complicate recognition.

Cheniers and chenier plains have been extensively studied within the field of coastal geomorphology, and both the general approach to analysis employed and the specific criteria developed to identify chenier-building processes can assist archaeologists in the assessment of ambiguous shell-rich deposits. The geomorphological approach to shell deposit analysis developed by Kidwell et al. (1986; see also Kidwell and Holland, 1991) offers a useful framework for field description that further assists interpretation: the lateral extent, geometry, thickness, dip, and nature of contacts are all considered along with observations on taxonomic composition, bedding, and the orientation of shells relative to each other and other facies. An initial geomorphological assessment of shell-bearing deposits not only helps to determine whether the shell assemblage has been accreted through natural processes, but it also helps in pinpointing potential disturbances of shell middens by factors such as later wave action or deflation through aeolian action (e.g., Rick, 2002). Moreover,

Shell Middens, Figure 1 Surface bone, lithic artifacts, charcoal, and midden shell indicating the presence of a shell-bearing archaeological site, northwestern Australia (Photograph by Brent Koppel).

the structured language provided by geomorphology allows communication between fields of inquiry and provides a clear set of descriptors for archaeological reporting.

Taphonomic signatures

Geomorphological methods are most useful in characterizing shell accumulations; however, distinctive patterns of individual shell breakage and taphonomic alteration can also provide practical clues to processes involved in the formation and transformation of the deposit. Many archaeologists, notably specialist archaeomalacologists (archaeologists who specialize in the study of archaeological shell), routinely assess samples for evidence of bioerosion, natural aquatic encrustations, and natural attrition such as beach-rolling and sand-blasting (see Claassen, 1998, 54–70). Much of this knowledge has been adapted from the natural sciences, where the literature on taphonomic processes and molluscan shell is more extensive (e.g., Vermeij, 1995; Zuschin et al., 2003). The study of bioerosion and the recognition of various trace fossils (ichnos) comprise a well-developed field of study within (1) marine biology and paleontology (e.g., see Chazottes et al., 1995; Kowalewski and Labarbera, 2004) and (2) the ecology and diagnostic traces of taphonomic agents such as boring sponges (*Cliona* spp.) and fungi, encrusting algae, and a wide variety of worms (especially polychaetes and sipunculids). Detection of the distinctive traces of these creatures can provide important proxy information on the nature of inshore habitats, as well as whether the shell was introduced to the site live or dead.

Although shell accumulations with extensive evidence of the action of natural taphonomic agents may indicate that the deposit is of natural rather than cultural origin, there are some circumstances where natural shell may be introduced – sometimes in considerable quantities – to archaeological sites. Empty shells may be collected as raw materials for artifact production, and on a much larger scale, considerable amounts of natural shell may be introduced into archaeological sites as construction material (e.g., see Ronen, 1980).

Species and size-class representation within a shell accumulation has also been used to argue for or against an archaeological origin. It is generally assumed, and often true (e.g., Anderson, 1981), that gatherers will focus their collecting upon particular molluscan taxa and/or shells of larger sizes. Following from this, middens tend to be a selective subset of the species and size classes found in local habitats. Although this is a useful rule of thumb, human practices such as fine-grained gathering strategies and mass harvesting, or differential survivorship in natural shell accumulations due to taphonomic factors, will produce assemblages that diverge from this norm.

Animal agents of midden formation and transformation

Some animals capture and consume mollusks as part of their diet and in the process create localized middens. Such species include octopuses (Ambrose, 1983), mud crabs (Silliman et al., 2004), muskrats (Hanson et al., 1989), and birds (Jones and Allen, 1978; Erlandson et al., 2007). While there has been little dedicated study on the predation patterns and signatures of such fauna within archaeology, research within various natural science disciplines has outlined distinctive breakage patterns and characteristics (e.g., see Vermeij, 1995, for a variety of taxa, but especially crabs; Nixon et al., 1980, for octopus drilling). These signatures, coupled with the location, species composition, and additional constituent elements of the midden, can indicate a nonhuman agent of accumulation.

One of the more high-profile debates surrounding the natural or cultural origins of concentrated shell deposits concerned the Weipa shell mounds of northeastern Australia. This complex of around 500 shell mounds situated around the convergence of four river mouths in Albatross Bay, Cape York, comprises small deposits less than 5 m in diameter and 0.5 m thick to step-sided mounds reaching 13 m in height (Bailey et al., 1994). An intensive study by Bailey in the 1970s (Bailey, 1977) specifically addressed suggestions that the shell mounds were of natural origin (e.g., Stanner, 1961). Through comparison of natural shell bank and hypothesized midden deposits, Bailey (1977) argued that the midden material showed deliberate selection of both species and size classes of mollusk as well as yielding animal bone, charcoal, and bone and stone tools. He further argued, following Peterson (1973), that the larger mounds provided a wet-season refuge above the floodplains, thus promoting ongoing use and deposition (Bailey, 1977).

Bailey's cultural interpretation of the Weipa middens was insistently challenged by Stone (1989), who argued that the sites were the product of the mound-building scrub-fowl megapode. These birds (*Megapodius reinwardt*) build nest mounds alongside waterways and estuaries, and the nest mounds can remain in use for sufficient time to attain sizes of up to 5–10 m in height (Stone, 1989). The birds will rake up any surrounding material with their feet, including extant shell middens (Stone, 1989). The ensuing debate involved further test excavations, radiocarbon sequences, and geomorphological research, as well as considerable dissection of both data and interpretations (Bailey, 1991; Stone, 1991, 1995; Bailey et al., 1994).

Although never resolved to Stone's satisfaction, the debate served to draw out many of the finer points regarding how a midden is constituted and what is sufficient evidence to argue that a shell deposit is a midden-mound. Taken individually, features such as size selection in shells can be interpreted as wave sorting and ash lenses as the result of bushfires rather than campfires. A paucity of stone tools can point to the scarcity of raw materials on the landscape or the absence of cultural input into a deposit. However, the strength of Bailey's argument was in drawing together the different lines of evidence, from positioning on the landscape to radiocarbon sequences showing incremental deposition through time to the various constituent materials and their taphonomic condition (Bailey, 1977, 1991; Bailey et al., 1994).

Another permutation of the natural/cultural debate surrounding shell deposits involves the transformation of cultural middens by nonhuman agents. In these cases, there are likely to be items of material culture and other clear indicators of human cultural input. Bioturbation on different scales, from insect activity to crab burrowing (Specht, 1985) to rodent burrowing (Bocek, 1986), and earthworm activity (Stein, 1983), as well as trampling (Gifford-Gonzales et al., 1985), can mix deposits and introduce noncultural material into a cultural shell midden. Cultural material can also be removed or destroyed through the actions of scavengers or birds such as bowerbirds of Australia and New Guinea, the males of which are known to take shell midden material for display in their "bower" designed to attract a mate (Dwyer et al., 1985) (Figure 2). Terrestrial hermit crabs (Coenobitidae), which are common across the tropics, are not only scavengers but also remove gastropod shells from cultural middens and replace it with their old shell of unknown original age and provenance (Szabó, 2012).

Midden formation and taphonomy

A variety of taphonomic signatures exist that can help researchers distinguish between natural and cultural shell accumulations, yet there is a further layer of analytical questioning that can provide insights into the formation and taphonomic processes of definite midden deposits. These analytical directions can inform on such diverse things as aspects of past human mobility, settlement patterns and logistical landscape use, the processing and

Shell Middens, Figure 2 Bowerbird (Ptilonorhynchidae) bower with shells taken from a nearby prehistoric midden forming the "court" (Photograph by Yinika Perston).

consumption of food, and establishing the different uses of shell on the spectrum from the everyday prosaic to ritual deposits.

Deposition patterns and signatures

An enduring discussion of the broad types of shell accumulations in the archaeological record was presented by Widmer (1989) as a conference paper in the context of Florida archaeology, and it has been reiterated and discussed, and sometimes adopted, in a number of published works (e.g., Claassen, 1991; Rabett et al., 2011). He defines four key types of shell-bearing site (as summarized in Claassen, 1991, 252):

1. Shell midden site – secondarily deposited shell from food consumption with no other activities evident at the site.
2. Shell midden – discrete lens or deposit of shell only.
3. Shell-bearing midden site – a site composed of secondary refuse of many kinds, including shell, generated by a wide range of activities.
4. Shell-bearing habitation site – primarily shell debris in the site matrix used for architectural needs; the shell may or may not have originated as food debris.

Such attempts at classification to untangle the nature and formation of different types of cultural shell accumulation are useful heuristics, particularly at the local level. However, when applied more broadly than their intended descriptive context, the divisions are often uncomfortably narrow or all-inclusive. Aside from potential culturally specific "types" being omitted or undifferentiated within the general schema, the type boundaries themselves may be open to question for different regions and time periods. This is especially so when particular "types" are linked as a matter of course to particular behaviors or sectors of society. As Claassen (1991, 252) explains, sites with quantities of shell and few artifacts are often interpreted as women's dinnertime or food processing camps – an interpretation that may or may not be fair depending on the site, time period, and social group under discussion.

Regardless of time period or area of the world, investigation of a number of significant criteria can help to determine how a shell midden accumulated and what information the shell midden site may contain about aspects of past cultures.

Ethnoarchaeological studies into aspects of shell midden site formation, such as those presented in Godino et al. (2011), contribute to refining interpretations and enhancing methodological approaches to excavation, sampling, and analysis. Godino et al. applied multiple analytical techniques, including micromorphology, phytolith, and lithic analyses, to ethnographically documented deposits, allowing process and interpretation to be linked with a high degree of certainty. A multistranded analytical approach informed by ethnographic observation was also used by Ham (1982) in his study of Coast Salish shell middens of northwestern North America.

A central concern of these and other similar studies is to investigate the variety of activities that contributed to the building of shell midden deposits and the length of time over which this took place. This concern is often coupled with the recognition that shellfish-gathering behavior recorded ethnographically is often a seasonal undertaking (Figure 3). Investigations of seasonality through the analysis of seasonal banding and stable isotope analysis are discussed below, and other techniques are frequently used to establish the periodicity of site occupation as well. Stein et al. (2003) utilized fine-grained radiocarbon dating to obtain a better understanding of the accumulation rates and patterns in the San Juan Islands, Washington State, United States. In contrast, Parkington (2012) used the differences noted between various site types in the Elands Bay and Lamberts Bay regions of South Africa to argue that coastal "megamiddens" are not residential sites but the remains of intensive, seasonal mussel-gathering, and preservation practices (but see Jerardino, 2012, for an alternative interpretation).

Reworking patterns and signatures

Shell middens may be built up incrementally in either a gradual or more punctuated fashion, slowly or rapidly, but regardless of the original mode and temporality of deposition, there is always a range of processes which can rework shell midden deposits and complicate chronostratigraphic patterning. Bioturbation issues have been discussed above, and plants are also a well-recognized agent of disturbance, but many non-biological processes can also substantially transform shell midden deposits. Most notably, transformational processes are geomorphic, or they stem from the elemental processes of wind and water.

Shell middens in the open, as opposed to protected cave or rockshelter locations, are regularly exposed to the elements. Water will be dealt with in the next section. Wind can have a major effect on shell midden deposits – a fact that has been underplayed in much of the literature. The removal of fine material and matrix sediments by wind leads to deflation, which biases the sequence through attrition. A study of the impact of aeolian processes (Rick, 2002, see also Wandsnider, 1988) revealed that there was major displacement of lighter archaeological elements such as fishbone, leaving relatively denser concentrations of the heavier elements such as mammal bone and shell. Windblown sand can also leave visible traces such as etching, abrasion, and polishing of bone and shell surfaces, affecting deposits to a depth of around 20 cm (Rick, 2002).

Koike's classic study (Koike, 1979) explored, among other things, the degree of displacement of individual shells within a midden deposit. She refitted 380 *Meretrix lusoria* valve pairs from a total of 2,089 unbroken valves from the Natsumidai site near Tokyo Bay, Japan. From the Natsumidai molluscan valve-pairing data, she estimated that less than 70 % of the shell midden material was preserved and that most valves were separated by five or more centimeters from their partner valve. Vertical movement was found to be less than horizontal movement (Koike, 1979).

Humans themselves can also significantly transform deposits through a wide range of actions, including the construction of fires and trampling. Micromorphological analysis of midden sediments has considerably enhanced our ability to detect episodes of burning within a stratigraphic midden sequence (e.g., Shillito and Matthews, 2013), and shell is easily detected within thin sections (Shillito et al., 2011). The effects of trampling on the fragmentation and displacement of shell within middens have received some investigation, but more work on this important process is undoubtedly required. Experimental work on trampling was undertaken by Muckle (1985), who considered fragmentation and vertical displacement using three bivalve species (*Saxidomus gigantea*, *Leukoma* (=*Protothaca*) *staminea*, and *Mytilus edulis*). Unsurprisingly, the more fragile mussel shell, *Mytilus edulis*, was the most heavily fragmented, but downward displacement for all three species was negligible (Muckle, 1985).

Preservation patterns and signatures

There is a close relationship between fragmentation and preservation in midden shell: the less well preserved a shell, the more liable it is to fragment, and the more fragmented a shell, the less resilient it is to taphonomic processes. There are several key factors that can affect preservation within a shell midden, including pH, the percolation and penetration of water, and the dynamics between constituent materials.

Being constructed of calcium carbonate ($CaCO_3$), molluscan shells preserve best in alkaline environments, and by virtue of their mass within a shell midden, they can create an alkaline matrix themselves. This favors the preservation of constituent materials, such as bone, but it is not conducive to the preservation of plant microfossils, such as phytoliths (Piperno, 1985). Conversely, shell and shell middens will not preserve well in acidic sediments, and the release of tannins and acids by plants and decaying plant matter will quickly eat away at shell. In the acidic swampy deposits of the subantarctic Auckland Islands, the calcareous parts of mussels from shell midden deposits were nearly entirely dissolved, leaving only numerous paperlike fragments of the organic outer periostracum of the shells (Anderson, 2005).

The brittleness and size of mollusk shells means that shell middens are often quite porous, allowing for the easy percolation of water. Rainwater is slightly acidic, and thus shell middens exposed to rain will be more prone to dissolution than those in sheltered locales. The process, as explained by Claassen (1998, 60), involves the combination of rain and atmospheric carbon dioxide to form a weak carbonic acid. This carbonic acid reacts with the calcium carbonate of the shell to form water-soluble calcium bicarbonate, thus resulting in dissolution. Groundwater and other freshwater that is undersaturated in calcium will dissolve shell more rapidly than that which is oversaturated (Claassen, 1998, 59). Archaeochemical analyses of elemental concentrations in sediments can also sometimes detect the presence of relict shell middens or those that have visibly disappeared (e.g., Beck, 2007).

Since shell fragmentation is both a result of, and a contributor to, the action of taphonomic processes, analyses focused on fragmentation can provide insights into many aspects of site formation and transformation. One strand of analysis treats shell middens within a geomorphological framework; it sees shell fragments as "bioclasts" that can inform about deposit formation and transformation processes (Stein, 1992). Thus, sedimentological approaches such as grain size analysis can be applied to archaeological shell midden fragments to assess stratigraphic variations in fragment size in order to make inferences about their biological and sedimentological sources (Ford, 1992). Differential fragmentation of midden shell can interfere with the accurate quantification of samples (see Gutiérrez Zugasti, 2011), and it can complicate the construction of metrical profiles for species within a midden (Jerardino and Navarro, 2008; Faulkner, 2010).

Types of shell midden

Morphology and classification

Although shell middens can be broadly construed as shell refuse deposits, variations in density and depositional patterns can produce a number of classifiable, mostly locally specific morphologies – see Claassen (1991) and the discussion above. Among the better known examples are shell rings and shell mounds. Shell rings are most readily associated with the Southeastern United States, being found along the coastlines of Florida, Georgia, and South Carolina. These rings, sometimes fully closed circles and sometimes horseshoe in shape, were deliberately constructed architectural features up to 250 m in length and 6 m high (Saunders and Russo, 2011). Constructed from ca. 4,800 cal BP, radiocarbon dating and geoarchaeological analysis has established that largely unfragmented shell was rapidly amassed to form the ring structure. Whether these distinctive shell midden deposits were refuse heaps associated with residential structures, water traps, or ceremonial spaces of some type is still debated (Trinkley, 1985; Marquardt, 2010; Saunders and Russo, 2011). In Jomon period, Japan, large horseshoe-shaped middens suggest long-term use rather than intensification of resource exploitation (Habu et al., 2011). Smaller-scale shell rings recorded in Tierra del Fuego, Argentina, have been shown through the use of various geoarchaeological techniques, including microfacies analysis (Villagran et al., 2011a; see also Verdún, 2010), to be midden deposits accreted around the perimeter of individual huts.

Shell mounds are found worldwide, although they tend to be concentrated in particular geographic locations due to a variety of factors, such as proximity to extensive shellfish beds, forager logistics and mobility patterns, and favorable conditions for preservation. Three of the best-known archaeological shell mound locales are northern Australia, the United States, and Brazil. Aspects of the northern Australian shell mounds have been discussed above, and steady archaeological work continues to elucidate why shell mounds accrete at particular periods in northern Australian prehistory (e.g., Morrison, 2013) (Figure 4).

In Brazil, *sambaqui* is the term given to large shell mounds – 10–50 m in height and 50–500 m long – located along the coastline of the southeastern states

Shell Middens, Figure 4 Excavation in progress at Garangarri BMB/029, an *Anadara granosa*-dominated shell mound on the northern margin of the Durabudboi River wetland system, Point Blane Peninsula, northeast Arnhem Land, Australia (Photograph courtesy of Patrick Faulkner).

(Villagran et al., 2011b; Wagner et al., 2011). While much of the constituent material of well-studied *sambaqui* can be categorized as "midden" in that it consists of burnt shell, fish bones, and charcoal, archaeofacies analysis suggests that this would be too simplistic an interpretation (Villagran et al., 2009). Human burials are common within *sambaqui*, and detailed studies of the sediments suggest that much of the midden material has been translocated from an original processing site elsewhere and that other faunal remains may be related to feasting associated with mortuary rituals (Villagran et al., 2009). Thus, *sambaqui* shell middens perhaps represent, simultaneously, deliberately redeposited matrix and the remnants of significant cultural rituals. The "Shell Mound Archaic" sites of the south-central United States also present a complex picture of construction and use, with human interments common and the frequency of still-articulated bivalves suggesting a lack of trampling and movement that one would expect to see in a midden associated with a habitation site (Claassen, 1998).

Despite the size of many of these mound deposits globally, detailed study has made it clear that many are not composed of in situ shell midden per se. In many of these cases, such as those outlined above, shell mounds had a social function closely tied to ritual rather than simply evidencing the ordered disposal of waste. Where large mounds are argued to be subsistence detritus, there is frequently debate over the extent to which the mollusks actually contributed to overall diet (e.g., Bailey, 1975; Meehan, 1977, 1982; Erlandson, 1988). The answer, from a simple calorie-based perspective, is generally argued to be not very much (Bailey, 1975). The durability of shells and their large size relative to the meat package they contain are the reasons often provided for the extensiveness of shell midden deposits by analysts (e.g., Bailey, 1975). Nevertheless, ethnographic studies of shellfish gathering demonstrate that mollusks are a reliable food source that can be easily collected by virtually all members of the community, from the very young to the very old (e.g., Meehan, 1982). As such, the niche they fill in subsistence structures in social terms can be very important.

Large shell mounds can also give the impression that the course of their accumulation encompassed a considerable span of time. Although this is sometimes the case, detailed studies in Washington State, United States, have demonstrated that middens can accumulate rapidly (Stein et al., 2003). The commentary of Stein et al. concerning the calculation and interpretation of accumulation rates offers valuable pointers to anyone excavating or studying concentrated shell mounds.

Shell mounds in a number of locations around the world are considered to be at risk, as they are often mined for shell for modern construction and fill (Ceci, 1984). Such is the case with some *sambaqui* (Villagran et al., 2009; Wagner et al., 2011) and some of the deposits considered by Henderson et al. (2002), as well as many more.

Although discussion of large shell mounds has enjoyed a place of prominence within the global literature, shell midden deposits come in a wide variety of shapes and forms. Strictly defined as refuse deposits dominated by molluscan shell, scatters, lenses, and smaller concentrations are common and widespread. While some of these forms bear a close resemblance to their original state of deposition, taphonomic processes (such as midden deflation due to aeolian reworking) can substantially transform the visible appearance, and sometimes internal constituents, of shell midden deposits (e.g., Rick, 2002). Clearly, detection of postdepositional reworking is critical, as small or diffuse shell middens can provide clues about logistical mobility, resource catchments, and use by past peoples.

Non-coastal settings: freshwater and terrestrial shell accumulations

Coastal middens comprising marine and/or estuarine shell are common globally, and discussions of marine shell middens tend to dominate the literature. However, shell middens or shell mounds containing largely freshwater molluscan or land snail remains are important archaeological deposits in particular places and time periods. Some extensive freshwater mussel shell mounds of the Southeastern United States have been discussed above, with freshwater mussel middens related to the historic button-manufacture industry discussed below.

Where freshwater shell deposits contain clear archaeological indicators such as artifacts, burials, and features, there can be little doubt as to their anthropic origins. However, for freshwater shell accumulations lacking such unequivocal archaeological features, demonstrating that they are anthropogenic deposits can be altogether more challenging. In such cases, a geoarchaeological approach is vital. Such was the case with the recently investigated Early and Mid-Holocene "forest islands" of the seasonally inundated savannahs of lowland Bolivia (Lombardo et al., 2013). Hundreds of enigmatic vegetated mounds raised above the grasslands of the Llanos de Moxos had previously been interpreted as bird rookeries and/or relict landforms (Hanagarth, 1993; Langstroth Plotkin, 1996). Coring of several forest islands, and excavations at one, revealed a Holocene sequence dominated by freshwater gastropod remains together with lesser amounts of bones from diverse types of vertebrate fauna (Lombardo et al., 2013). The complete absence of stone tools or other distinctive items of human presence in pre-pottery levels meant that a potential case for human accumulation rested on the chemistry of the sediments, the patterns of shell accumulation and discard, and observed geomorphic patterns in the context of the wider landscape. Archaeochemical analyses indicated elevated concentrations of black carbon, phosphorus, and coprostanol (a biomarker for the presence of human fecal material) in the mound sediments, thereby demonstrating anthropic input. Furthermore, concentrations of black carbon and C_{org} in the mound were 20–30 times higher than in the abutting, contemporaneous paleosol, confirming regular, localized burning on the mound surface (Lombardo et al., 2013).

While freshwater mollusks have been a heavily exploited resource, their remains producing large shell middens in many parts of the world, the role of land snails (gastropods) in past subsistence regimes, and the existence of midden sites associated with land snail consumption are rarer. Land snails are commonly encountered in low frequencies within marine or freshwater middens, especially in well-vegetated settings. Often, they are self-introduced into deposits, with scavenging snails being attracted to fresh refuse deposits and herbivorous land snails drawn toward the rich source of $CaCO_3$ for shell building that a shell midden offers (Evans, 1972). Some analysts have noticed that land snail accumulations are concentrated in sterile layers (Miracle, 1995), thus indicating natural occurrence and also providing a useful stratigraphic marker in complex deposits (Szabó, 2015). Having small home ranges, land snails can be valuable proxies for the nature of the environment and vegetation immediately around the site at particular points in time (Evans, 1972). The presence of stowaway invasive land snails can also provide insights into the movement of people and plants (e.g., Christensen and Kirch, 1981).

In contrast to self-introduced assemblages, land snails were intensively gathered in some parts of the world as an important subsistence resource, as evidenced by large midden mounds. The most well-known land snail middens are the *escargotières* of the Maghreb (Algeria, Morocco, and Tunisia) and Libya (Cyrenaica) (Lubell et al., 1976), of which there are thousands, ranging in size from a few to several hundred meters in spatial extent, and from 1 to 3 m in thickness (Lubell, 2004). Many more land snail concentrations from sites around the Mediterranean and Near East are variously interpreted as either middens or natural death assemblages (see Lubell, 2004, for discussion; Taylor et al., 2011), although a survey of the literature shows that there are no clear and systematically applied criteria for separating one from the other.

Land snail assemblages that are very selective and exclude small or micro-taxa suggest deliberate collection, although modern samples and ecological information should underpin any judgments in this regard. The large Hoabinhian land snail middens of Vietnam (e.g., Rabett et al., 2011) are dominated by one or two large snail species and do not reflect the diversity of species to be found in immediately adjacent environments. The selective presence in hearths of large *Ryssota* sp. land snails in the Batanes Islands of the northern Philippines, coupled with contemporary local traditions of land snail collection and consumption, also presents a strong argument for past exploitation (Szabó et al., 2003). Intra-site and stratigraphic patterning can also provide useful information, such as in the case of sterile layer accumulations noted above as well as the clustering of land snail remains closer to cave mouths rather than further into a cave (e.g., Medway, 1960, 376; Szabó, 2015).

Nonfood refuse middens

Although shell middens are generally composed of discarded food remains, they can represent the cultural waste of other processes in some situations. Such deposits include piles of shell waste from the extraction of bait for fishing (Claassen, 1998, 176–178), preparation areas for the production of lime used in construction and industry (e.g., Panda and Misra, 2007), and shell middens related to the industrial or specialized production of shell artifacts, among others. Cultural accumulations of shell, either from natural deposits or secondarily used midden shell, have also been recorded archaeologically as constructed living surfaces (e.g., Onat, 1985) or deliberate inclusions in agricultural soils (e.g., Barber, 2013). Valuable insights into the cultural accumulation of shell middens not related to food procurement can often be found in relevant historical and ethnographic literature.

One of the most comprehensively reported types of nonfood refuse shell midden is broken shells of particular species within the Muricidae used in the production of colorfast purple dye for textiles (Reese, 1980). Evidence for the production of "Tyrian purple" or "royal purple" and "biblical blue" muricid dyes stretches back around four millennia, with production centers around the Mediterranean basin and Levant through to the Arabian Peninsula (Edens, 1999; Reese, 2010). Text-based resources do not give a full account of the dyeing process, so archaeological and experimental work (e.g., Koren, 2005; Ruscillo, 2005) have been brought together to give an accounting of both the history and process of muricid dye production.

Several species of mollusk within the Muricidae were collected and processed for dye production, including *Hexaplex* (=*Murex*) *trunculus*, *Bolinus* (=*Murex*) *brandaris*, and *Stramonita* (=*Thais*) *haemastoma*, with each species being processed in a different way and yielding a different shade of dye (Ruscillo, 2005). In the Arabian Gulf, the local species *Thalessa* (=*Thais*) *savignyi* was used (Edens, 1999), and there is evidence for the use of the muricid species *Nucella lapillus* and *Ocenebra erinaceus* in dye production in France and elsewhere in Atlantic Europe (Dupont, 2011). A tiny amount of the fluid that generates the dye can be found within the hypobranchial gland of each animal, and thus large quantities of individuals are needed for commercial dye production as evidenced by replicative studies (e.g., Koren, 2005; Ruscillo, 2005). In order to extract the gland, the shell needed to be either pierced or fragmented to expose the salient portions of the animal, and thus large deposits of these shells broken in such ways constitute one line of evidence for purple-dye production.

It is likely that shells were generally collected by hand or by using a baited trap (Ruscillo, 2005; Çakırlar and Becks, 2009); however, biostratinomic evidence from purple-dye middens indicates that occasionally murex shells could have been "farmed." Spanier (1986) described the presence of predatory boreholes in *H. trunculus* made by other individuals of the same species. Through experimental studies, he established that conspecific cannibalism was likely to happen only under artificial conditions, and he suggested that some ancient dyers could have kept quantities of *H. trunculus* alive in containers of seawater for several weeks.

Although large quantities of broken murex shells associated with dyeing paraphernalia or remnants of the pigments themselves provide strong evidence for murex dye production, smaller, inland, or otherwise ambiguous murex deposits have been the subject of much debate. As summarized by Çakırlar (2009,128–129, also Çakırlar and Becks, 2009), murex species used in dye production are also edible and have recorded uses as bait for fishing, as building materials, and in burnt form as lime or pottery temper. Carannante (2011) considers a number of ambiguous murex deposits and suggests that quantities of crushed shell from dye production could have been transported to other locales for transformation into lime or pottery temper. The movement of shell artifact production waste for secondary use is also recorded for Tikal, Guatemala (Moholy-Nagy, 1997). Given the variety of known uses for murex snails in the Eastern Mediterranean, contextual evidence from excavations and careful taphonomic evaluations are critical to robust interpretations of fragmented murex shell deposits.

Industrial waste from the intensive production of shell artifacts can also produce distinctive non-subsistence-related midden deposits. Claassen (2010) provides an instructive example focused upon the historic freshwater mussel-shell button industry of the United States, where tens of thousands of tons of shells were harvested from rivers such as the Mississippi and Illinois. Primary processing of the shells usually happened near the capture site, with the cutting of buttons taking place either in the

Shell Middens, Figure 5 Waste *Pinctada* sp. pearl oyster shell from mother-of-pearl button manufacture (Photograph by Katherine Szabó).

same locale or after transport to a dedicated facility. Claassen (2010, 308) draws attention to the amount of waste produced by this industry in terms of failed blanks and waste shell after cutting (Figure 5). Large piles of shell could also be stockpiled by riverbanks in the hope of a later sale (Claassen, 2010, 305).

Industrial workshops, albeit on a smaller scale, have been identified archaeologically around the world. The presence of broken blanks and preforms, waste shell raw materials, and manufacturing tools underpins the identification of such shell midden deposits. The manufacture of sacred chank shell (*Turbinella pyrum*) objects, predominantly bangles, in Harappan and early historic Indian centers is attested through the presence of quantities of debitage, and some production sites have been identified (Deshpande-Mukherjee, 2008). Intensive, localized shell bead production also leaves significant quantities of shell and lithic waste (e.g., Nigra and Arnold, 2013, for the Chumash, USA; Yerkes, 1989a; Yerkes, 1989b, for Mississippian sites, USA; Allen et al., 1997, for Papua New Guinea).

A number of Caribbean sites show evidence for the systemic production of adzes from the lip of the large queen conch (*Strombus gigas*) shell (Keegan, 1984; Serrand and Bonnissent, 2005). However, as with the muricid shells associated with dye production, *S. gigas* was a valued food source as well. Extensive deposits of shells systematically broken to extract the meat are associated with the intensive harvesting and preservation of *S. gigas* flesh for later transport and consumption (Antczak et al., 2008). The scale of this operation was immense, with over 4.5 million *S. gigas* shells recorded at single locality in the Los Roques Archipelago, Venezuela. Modeling of the nature and ecological impact of such high levels of exploitation have immediate relevance to contemporary resource management issues (Cipriani and Antczak, 2008).

It has been suggested that shell midden deposits in other parts of the world were associated with mass processing and preservation of mollusks, and a significant ethnographic record also exists. The increased number of shell midden deposits in the late prehistory of New England has been interpreted as an intensification of shellfish collecting and preservation by women as part of burgeoning trading activities (Williams and Bendremer, 1997). "Megamiddens" along the Southwest Cape of South Africa contain many thousands of m^3 of fragmented black mussels (*Choromytilus meridionalis*). Megamidden formation has been associated with intensive mussel collecting and drying activities (Henshilwood et al., 1994; Jerardino, 2012).

Fundamental analytical techniques

Identification

Correct taxonomic identification is central to a good midden analysis as well as effective sampling strategies for the application of scientific techniques, such as radiocarbon dating or stable isotope studies. Research within radiocarbon dating has clearly demonstrated that species habitat preferences and ecology can impact the uptake ratio of ^{14}C from terrestrial and marine sources. This ratio affects the radiocarbon age and required calibration (ΔR correction) (Hogg et al., 1998; Petchey et al., 2012). Accurate identification can provide insights into environmental niches targeted for shell collection, and the ecological tolerances of identified taxa can help to define past environmental conditions (Peacock, 2000).

Identification of species present usually draws on both the published literature and reference collections. Given that shell identification books focus on colors, surface patterning, and overall shell morphology, such literature is not always immediately applicable to fragmented and taphonomically altered shell midden assemblages. Nevertheless, they can provide useful descriptions and pictures, as well as lists of the species occupying a particular biogeographic area or habitat to help constrain identifications. A reliable reference collection can be invaluable for more fine-grained comparison of specific shell features, angles, and surface textures. Variations in shell microstructure and internal composition, such as the presence of nacre, may also assist in identification. Depending on the state of preservation of an assemblage, identification to species level may not always be possible. In these instances, identification to genus or family will give the most accurate representation of assemblage contents.

Taxonomic nomenclature is an ever-shifting terrain, and many species names familiar to archaeologists may shift in and out of taxonomic validity. In addition to the most current literature, there are now a number of online resources providing the most up-to-date valid binomials for molluscan species (e.g., the World Register of Marine Species (WoRMS: http://www.marinespecies.org) and the Ocean Biogeographic Information System (OBIS: http://clade.ansp.org/obis/)). The presentation and discussion of taxonomic information should always follow zoological standards as outlined in the International Code of Zoological Nomenclature (International Commission on Zoological Nomenclature, 1999). Using the International Code of Zoological Nomenclature means that expression is standardized but also that scholars from the natural sciences can follow archaeological reporting with ease.

Sampling

There is no gold standard for the sampling of midden deposits. Instead, sampling strategies must be guided by the nature of the deposit and the research questions to be answered. If research questions are focused on paleoenvironmental reconstruction, then samples must be large enough to capture the diversity of species present, and techniques such as the flotation of sediments for land snail retrieval may prove valuable. For larger sites or deposits where spatiotemporal variation is a key issue, strategic core sampling to guide the selection of areas for further investigation can be productive.

A fundamental point about shell midden analyses was made by Claassen (1991) when she stated that sampling approaches during excavation are largely prefigured by the excavator's conceptions of what a midden *is*. The two ends of the spectrum are occupied by those who see shell middens as deflated and time-averaged dumps versus those who conceive of shell middens as the accretion of numerous discrete episodes of behavior. Claassen (1991, 254) associates limited exposures of the deposits and the use of arbitrary spits (levels) with the former and more extensive exposures and stratigraphic excavation with the latter. In a global context, this division is probably as accurate now as when Claassen originally published her paper titled "Normative thinking and shell-bearing sites." Nevertheless, thoughtful sampling strategies closely articulated with research questions have led to a number of productive approaches and discussions.

Given the sheer quantities of molluscan remains in many shell middens, column sampling represents an attractive way of covering considerable spatiotemporal variation while generating more manageable quantities of material. Such an approach was taken by Cannon (2000), whose interests lay in assessing regional patterning of shell midden deposits in Namu, British Columbia, as well as Martindale et al. (2009), who used percussion coring to assess the extent and chronostratigraphy of subsurface middens from insular British Columbia. The strengths of this approach lie in the ability to cover a wide range of terrain, to assess the spatial distribution of deposits in the landscape, and to collect material for radiocarbon dating. However, for studies that are focused at more spatially discrete levels, such as the site or site complex, larger midden samples are required to generate the fine-grained and more representative datasets required at this scale of investigation (e.g., see Estevez et al., 2001, for a comparison of sampling techniques).

The sheer size of many shell midden deposits can lead to questions about where the point of sampling redundancy may lie – although not as frequently as one might think. There have been various calculations and statements of the requisite sample required for the accurate representation of contents (e.g., Poteate and Fitzpatrick, 2013). Though such calculations may be accurate and well justified for particular sites, the combined variation in both deposits and research questions means that there can be no generally applicable number or formula.

Quantification

As with sampling strategies, there are various commonly used quantification techniques, each of which may be more or less applicable to various assemblages and research questions. Quantification by weight was favored in much of the early intensive midden research (see discussion in Mason et al., 1998), but distorting variables such as taphonomic loss of shell mass or the presence of concretions make accurate assessments of the relative contribution of different taxa difficult. Likewise, there is no easy correlation between shell weight and shell size/meat weight. There are certainly circumstances when weights can prove very useful – especially where total shell weights for different layers of a deposit are being compared – however count-based methods are now preferred for providing greater accuracy and comparability in assessing the composition and structure of shell midden assemblages.

The two major approaches to the numerical quantification of shell midden assemblages are recording the "number of identified specimens present" (NISP) and the "minimum number of individuals" represented (MNI). NISP is a taxa-based fragment count, where all shell fragments identified to a particular taxon are counted within each spit or layer. If there is differential fragmentation between taxa or areas within a site/deposit, this will necessarily result in skewed representation data, with inflated counts from the more fragmented species and locales. However, in some instances, such as when shell midden material is sparse within a deep sequence and/or highly fragmented, NISP quantification may be the only viable option. When combined with MNI quantification techniques, NISP counts can provide a valuable index of fragmentation.

MNI counts aim to calculate the minimum number of individual shells required to account for the excavated deposit. In traditional MNI analyses, all discrete, diagnostic elements of a shell present in an assemblage are counted, and the largest total per taxon per layer is taken as the MNI. In an alternative approach to MNI, a unique "non-repeating element" (NRE) is decided upon prior to analysis, and counts are made only of the occurrence of this element, whether it be a spire, aperture, hinge, or other distinctive feature. In the case of bivalves, left and right valves are counted separately, with the higher number taken to represent the MNI. For further discussion regarding the advantages and disadvantages of these two methods, see Giovas (2009). Underestimation of minimum numbers due to fragmentation is a recurring issue that some have addressed through the quantification of various categories of fragment types (e.g., Gutiérrez Zugasti, 2011).

The way in which midden deposits are excavated, and in particular whether they are excavated stratigraphically or using arbitrary spits, has flow-on consequences for the level of accuracy of MNI data. Grayson (1984) outlined in detail the "division into aggregates" problem as it relates to the quantification of vertebrate faunal remains. Where excavations have proceeded in arbitrary spits, different bones of the same animal may be in different spit assemblages, thus inflating counts when all spits are combined into an overall picture. A number of other issues with MNI are summarized in Lyman (2008). For the purposes of shell quantification, it should be stressed that many of these arguments apply minimally if at all. Since mollusks comprise far fewer individual, diagnostic parts than a vertebrate skeleton, it is much more difficult to inflate their counts by counting the same individual a number of times. Equally, the much lower rates of completely non-diagnostic fragments in shell, as compared to bone, assemblages means that NISP counts can easily be very inflated due to fragmentation. In short, the extensive standing arguments about the strengths and weaknesses of different quantification techniques must be thoughtfully adapted to molluscan shell, and, as ever, decisions should be based on the nature of the assemblage being studied and the research questions being addressed.

Research and analytical directions

Approaches to the study of midden shell assemblages are many and varied, but a few central themes of inquiry can be found consistently through the literature. These directions, and the analytical techniques with which they are commonly associated, are briefly discussed here.

Research direction: subsistence and diet

As shell middens are typically composed largely of the remains of meals, investigations into ancient subsistence and diet represent the core of the shell midden literature. The economic emphasis in shell midden analysis in the 1960s and 1970s placed a focus on the calculation of meat weights and assessments of the relative role(s) of shellfish in ancient diets (e.g., Shawcross, 1968; Bailey, 1975). Such detailed and data-rich work paved the way for foraging models that combined aspects of ecology and subsistence gathering (e.g., Anderson, 1981). Since these formative studies, investigations into the role of shellfish in diet and subsistence systems have grown and diversified in myriad directions worldwide. Such studies have also often been informed on some level by important ethnoarchaeological research.

The influential ethnoarchaeological study of shellfish gathering *Shell Bed to Shell Midden* by Meehan (1982) explicitly investigated the contribution of shellfish gathering by women among the Anbarra of northern Australia. While acknowledging that the contribution of shellfish was not substantial in terms of calories, Meehan stressed that shellfish were often gathered by members of society who were otherwise peripheral in subsistence activities: the very young and very old and women in advanced stages of pregnancy. She further pointed out the convenience, ease, and relative safety of shellfish gathering in contrast to other forms of food procurement. Such observations have been pivotal in the development of increasingly complex and nuanced considerations of the role of shellfish and shellfishing that weave in taphonomic, environmental, and visibility considerations (e.g., Dupont et al., 2007; van der Schriek et al., 2007; Porcasi, 2011).

Research direction: gathering strategies, metrics, and predation pressure

How people move and procure resources within a landscape was a central concern of the New Archaeology, and this manifested itself in shell midden studies as a concerted interest in gathering strategies (e.g., Voight, 1975; Anderson, 1981). The way in which people go about gathering a resource such as shellfish has implications not only for the finer structure of subsistence economies but also for mobility strategies and, in the longer term, the impact of human predation upon shell beds. Research into gathering strategies has continued steadily since the early work cited above, with recent explorations developing sophisticated approaches (e.g., Whitaker, 2008; Thakar, 2011).

A logical next step that grew out of this interest was investigation into potential human impact on molluscan resources. The twin themes of this literature are resource intensification and predation pressure, with the former often exploring the structure and composition of molluscan and/or faunal assemblages and the latter frequently using metrical tools to assess change.

Metrics-based analyses of shell midden assemblages have been a consistent presence in the literature, and they have often addressed the hypothesized relationship between shell size, predation intensity, and resource depression. However, such metrics-based studies can be complicated in shellfish where environmental factors can influence shell size and shape (e.g., Andrews et al., 1985; Peacock, 2000; Campbell, 2008). Also, the assumption that gatherers will selectively target the largest individuals of the largest species is only sometimes borne out (e.g., Anderson, 1981) and thus cannot be accepted a priori. Indeed, sometimes the harvesting of shellfish can lead to increases in growth rates, and hence age to size ratios, by providing more room and resources for the remaining shellfish through reduced competition (e.g., Swadling, 1976). Metrics-based approaches therefore need to be sensitive and attuned to the ecology and population dynamics of the species under discussion; a number of exemplary studies exist as guides (e.g., Swadling and Chowning, 1981; Jerardino, 1997; Faulkner, 2009, 2010). Several key ecological factors to consider when modeling the impacts of predation are presented by Catteral and Poiner (1987), with more general approaches to human impact considered by Keough and Quinn (1991).

Ethnoarchaeological studies have been central to generating frameworks for understanding not only human mollusk-gathering behavior and associated variables but also the impacts of these behaviors on the environment (Waselkov, 1987). In addition to Meehan's (1982) classic work discussed above, many ethnoarchaeological studies have investigated issues as diverse as the role of children in foraging (Bird and Bliege Bird, 2000), the gendered nature of marine exploitation (e.g., Malm, 2009), logistical foraging models (Thomas, 2002), and the impact of traditional foraging on littoral shell beds (Swadling and Chowning, 1981).

Research direction: paleoenvironmental reconstruction

In most cases, it is clear that shell middens have accumulated close to the habitats where the organisms originally flourished. Mollusks are bulky given the amount of flesh they yield, and while shells may move considerable distances as raw materials (e.g., Bar-Yosef Mayer, 1997; Dimitrijević and Tripković, 2006), ethnoarchaeological studies indicate that the gathering, processing, and disposal of shellfish tend to happen close to the place of collection (e.g., Meehan, 1982; Thomas, 2002). Spatial analyses considering the relationship of shell middens to paleoshorelines also support this pattern (e.g., Suguio et al., 1992; Ricklis and Blum, 1997). The general proximity of middens to coastal or freshwater habitats has led many analysts to use midden contents to infer aspects of past aquatic habitats. Stein (1992, 9) rightly points out that shell midden assemblages are inherently biased by cultural selection, meaning that caution must be exercised in extrapolating from midden contents to local habitats. Nevertheless, a bevy of techniques and approaches are increasingly helping shell midden analysts untangle the various contributions of cultural selection and local availability in their interpretations. Indeed, shell midden data can successfully act as a check on broader geoarchaeological interpretation (e.g., Morey and Crothers, 1998).

One of the key independent proxies for assessing environmental conditions is the analysis of stable isotopes locked within the structure of midden shells. Although a variety of stable isotopes can be analyzed to provide information on aspects of past environment, oxygen isotopes are the most commonly analyzed with shell midden samples. One of the most long-standing applications is the investigation of the season(s) of shell collection represented within a midden, conducted to inform about frequency of site use and group mobility (e.g., Kennett and Voorhies, 1996; Jones et al., 2008). Fine-grained studies combine sclerochronology, which analyzes the individual incremental growth bands laid down within the hard tissues of invertebrates and corals, with high precision oxygen isotope analysis (e.g., Quitmyer et al., 1997; Mannino et al., 2003; Burchell et al., 2013). Sclerochronological analysis in itself can yield information as to the age of shells at harvest and thus also inform about gathering strategies, harvest intensity, and resource management (e.g., Cannon and Burchell, 2009).

Despite the wide and successful use of oxygen isotope analysis within shell midden studies, there remain some points of caution to heed. Most notable is the fact that variability in $\delta^{18}O$ within water, and hence aquatic shell, is driven by both salinity and temperature. To counter this, some sensitive studies have also used parallel lines of analysis, such as Mg/Ca or Sr/Ca ratios, to disentangle variables (e.g., Schweikhardt et al., 2011). The use of multiple lines of evidence adds considerable weight to interpretations and helps resolve ambiguities (Peacock and Seltzer, 2008).

Research direction: chronometric applications

The most widely used chronometric techniques directly applied to archaeological shell are radiocarbon (^{14}C) approaches and amino acid racemization (AAR). Attempts to apply U-series techniques have been largely unsuccessful due to the "open-system" behavior of molluscan shell post-mortem, resulting in both the uptake and loss of uranium (see discussion in Eggins et al., 2005). However, new research into open-system techniques holds promise (Eggins et al., 2005). Research also continues into enhancing the reliability of electron spin resonance (ESR) techniques (Brumby and Yoshida, 1994; Molodkov, 2012).

When radiocarbon dating molluscan shell, several factors need to be taken into account. First, marine shell dates need to be corrected for the marine reservoir effect (MRE), and spatial variations can be further accounted for through the application of a locality-specific ΔR value (Ascough et al., 2007). The ecology and feeding habits of various species of mollusk can also result in the uptake of carbon from various sources, so careful sample selection with this in mind improves the reliability of radiocarbon dates (Hogg et al., 1998; Ascough et al., 2005; Petchey et al., 2012). Diagenetic recrystallization of the shell can also result in the incorporation of external carbon, so it is recommended to assess the structural integrity of the shell prior to dating (Yates, 1986).

Amino acid racemization has a long history within shell midden research, but persistent problems due to thermal effects on racemization rates – whether it be the temperature of the burial environment or exposure of the shell to burning – have hindered widespread application. The development of closed-system analysis, which investigates racemization of the intracrystalline fraction of the shell, overcomes these obstacles, opening up further possibilities for the use of AAR in shell midden archaeology (Penkman et al., 2008; Demarchi et al., 2011).

Summary

Despite the long history of shell midden analysis within archaeology, the twenty-first century has seen research questions diversify, the number of specialist analysts increase, and the application of scientific techniques to the study of shell middens expand and become more sophisticated. As key components of the archaeological landscape worldwide, shell middens can offer insights into human movement across the landscape, utilization of environmental resources, cultural and industrial practices, and the human impact on aquatic systems. The shells themselves preserve archives of past environmental conditions, which may be accessed through techniques such as stable isotope analyses, and archaeological shell is an important material for radiocarbon dating. Shell middens can create ideal microenvironments for the preservation of other archaeological materials. In other cases, the sensitivity of shells to a range of taphonomic processes can highlight aspects of the history of a site or deposit. As techniques in geoarchaeological and archaeological science continue to be refined, new ways of approaching old questions – such as the relative impacts of human predation and environmental change on molluscan populations in the past – will benefit from more sizeable and robust lines of evidence.

SHIPWRECK GEOARCHAEOLOGY

Rory Quinn
Centre for Maritime Archaeology, School of Environmental Sciences, University of Ulster, Coleraine, Northern Ireland, UK

Introduction

The past two decades have witnessed remarkable advances in seafloor mapping, with high-resolution acoustic imaging now routinely used in archaeological studies (e.g., Plets et al., 2011; Westley et al., 2011). Technological and methodological advances in acoustic imaging and digital rendering now permit shipwreck sites and individual artifacts to be imaged at centimetric resolution in tens or hundreds of meters of water (Quinn et al., 2005). Beyond using acoustics as merely a prospection tool for locating wreck sites, researchers are increasingly exploiting the quantitative aspects of these data, for example, using time-lapse multi-beam echo-sounder (MBES) bathymetric surveys to develop accretion-erosion plots (Quinn and Boland, 2010) and using MBES backscatter data to identify shipwrecks remotely (Masetti and Calder, 2012).

In response to the 1992 Valetta European Convention on the Protection of the Archaeological Heritage and the 2001 UNESCO Convention on the Protection of the Underwater Cultural Heritage, maritime archaeologists are encouraged to adopt nondestructive techniques for wreck investigations and consider in situ preservation as a priority (Plets, 2013). Therefore, marine geophysical techniques are playing an increasingly important role in shipwreck archaeology. They offer rapid, noninvasive, high-resolution, and cost-effective solutions in all phases of wreck investigations – from initially locating the site (Plets et al., 2011) to characterizing the site (Smyth and Quinn, 2014) and finally, managing the site (Quinn and Boland, 2010).

Shipwreck prospection

Shipwreck prospection refers to the noninvasive search for submerged and buried shipwreck sites using marine geophysical (primarily acoustic and magnetic) techniques.

Navigation and positioning

Tight navigational and positional control is essential in all phases of shipwreck investigation. To locate features and objects on the seabed precisely, we need to know where the survey vessel is located on the sea surface, where the sonar platform is located below the sea surface, and which portion of the seafloor is being radiated or sampled at any given time. This control is achieved through a combination of position fixing (latitude, longitude, and altitude above a reference datum), heading, speed, and attitude (heave, roll, pitch, yaw) information.

The minimum requirement for accurate navigation of a survey vessel is the Global Positioning System (GPS). Using the calculated distance and orbital position of a minimum of three satellites, a GPS receiver determines position in degrees of latitude and longitude, conventionally to the WGS84 datum (World Geodetic System of 1984, the default datum for GPS units). This position can subsequently be translated into any global or local metric coordinate system (e.g., UTM). Accuracy of GPS varies with satellite constellation geometry and receiver type, but an accuracy of ±5 m with an update rate of 1 Hz is common. To reduce positional errors to an acceptable level for high-resolution archaeological surveys (±1 m), differential GPS (DGPS) uses a land station to calculate the error in positioning and transmits the error to the shipboard receiver.

For quantitative analysis of the seafloor and/or its subsurface, it is essential to relate depth data to a fixed horizon, and therefore, it is necessary to remove the effects of tidal variation over the survey period. Tidal corrections are achieved with reference to either a static tidal gauge or modeled tidal predictions. For high-accuracy surveys, the tidal curve should be recorded continuously at a site in close proximity (±1 km) to the survey site.

Recently, DGPS has been superseded by Real Time Kinematic (RTK) systems that use the characteristics of the signal carrying the GPS data from satellite to receiver to give horizontal position and vertical altitudes to an accuracy of ±1 cm. Tidal corrections can be derived from the vertical component of the RTK signal, eliminating the need for a static tide gauge.

The position of the remote sensing platform (sometimes hull-mounted and sometimes towed) is determined in one of two ways: either by manual calculation or by acoustic tracking. The portion of the seafloor insonified at any given time is addressed by measuring the motion of the survey platform using an Inertial Measurement Unit (IMU) or Motion Referencing Unit (MRU). This system uses a combination of accelerometers and gyroscopes to track vessel movement. These corrections are applied to remotely sensed data to correct for the effects of pitch, roll, and yaw on the survey vessel and/or towfish (the transmitting instrument towed beneath the sea surface by a survey vessel).

Acoustic prospection methods

A comprehensive discussion on ocean acoustics and instrumentation is beyond the scope of this entry. However, a basic understanding of these concepts is essential to interpret acoustic data collected for archaeological purposes. For a more comprehensive treatment of the subject, Lurton (2010) is recommended. Additionally, review chapters on acoustic remote sensing in maritime archaeology (Quinn, 2011), and underwater survey and acoustic characterization of archaeological materials (Plets, 2013) provide further recommended reading.

Acoustic remote sensing methods rely on the propagation of acoustic waves by mechanical perturbation through an elastic medium (i.e., a gas, liquid, or solid). The mechanical properties of the propagating medium dictate the velocity of the acoustic pulse. In seawater, the acoustic wave velocity (v) typically varies from 1,450 to 1,550 ms^{-1} and is dependent on pressure, salinity, and temperature (Lurton, 2010). Seawater density (ρ) is typically 1,030 kgm^{-3} and is dependent on the same physical parameters as velocity. In conventional acoustic surveys, the acoustic transducer at the sea surface propagates a vertical sound wave to the seafloor and measures the time taken for the wave to travel down, reflect off the seabed (or subsurface target), and travel back to the transducer (the two-way travel time or twt). Depth/distance (d) and time are related:

$$d = \frac{v.twt}{2}$$

Acoustic signals are characterized by their frequency (f, measured in Hz) and period (T, measured in s), where T = 1/f. The frequencies used in active underwater acoustics typically range from 1 Hz to 1 MHz, with source choice dependent on application, water depth, and resolution required. Wavelength (λ, measured in m) is the spatial equivalent of wave period and corresponds to the distance traveled by the wave during one period of the signal with velocity v:

$$\lambda = vT = \frac{v}{f}$$

Typically objects are resolved at one quarter the wavelength of the acoustic source. So, for example, for a sound velocity of 1,500 ms^{-1}, a 1 kHz source will resolve an object larger than 0.375 m, and a 100 kHz source will resolve an object larger than 0.004 m. Two of the main constraints on the usable frequencies for a particular application are acoustic wave attenuation in the water column (energy loss due to viscosity in the propagating medium) and source directivity (the directional effectiveness of the sound source) (see Lurton, 2010). High-frequency acoustic sources are preferred for their resolution and directivity, but high frequencies are attenuated more readily and therefore travel only short distances. This implies compromise and a challenge in terms of survey design and instrument choice.

The transmitted acoustic pulse may be deflected in many ways as it propagates through the water column and seabed subsurface; it may encounter air bubbles, fish, suspended sediment, rough seafloors, and subsurface targets. In each case, a proportion of the sound is *reflected* and *scattered* in various directions, including back toward the survey instrument. Specular reflection is caused by plane interfaces – that is, the incident wave is reflected in a direction symmetrical to the direction of arrival (like light off a mirror), with a loss of amplitude (Lurton, 2010). Scattering is generally caused by rough interfaces and discrete objects in the water column and at the seafloor. The ratio between reflected and scattered contributions decreases at higher frequencies (Lurton, 2010).

In terms of subsurface reflection, materials are characterized by their density and velocity, where the product of the two is termed acoustic impedance (Z):

$$Z = \rho v$$

The strength of the reflection from the boundary between two materials of acoustic impedance Z_1 and Z_2 (a measure of the proportion of energy returned toward the survey instrument) is governed by the reflection coefficient (K_R), where

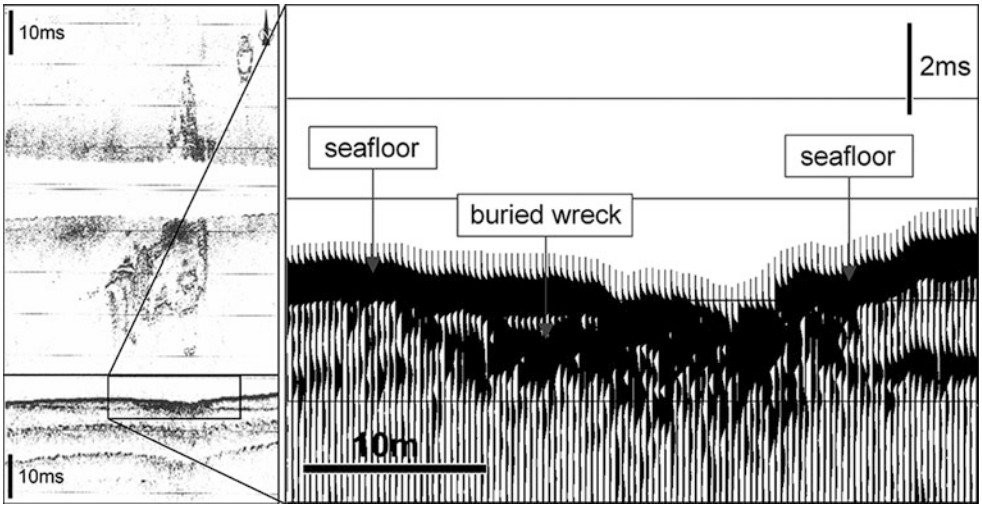
$$K_R = \frac{Z_2 - Z_1}{Z_2 + Z_1} = \frac{\rho_2 v_2 - \rho_1 v_1}{\rho_2 v_2 + \rho_1 v_1}$$

Put simply, this equation means that the higher the contrast in density and/or velocity across the material boundary, the stronger the reflection from the interface. The polarity of the reflection coefficient is dependent on whether there is an increase (positive reflection) or decrease (negative reflection) in the acoustic impedance across the interface.

Acoustic methods fall into two broad categories: profiling methods (which rely on specular reflection and image a narrow profile of the seabed directly beneath the sonar) and swath methods (which rely on scattering and image a wide corridor on either side of the sonar). Swath devices are more effective for regional-scale prospection surveys as they cover larger areas of the seafloor and result in less survey effort, saving time and money.

The most common profiling methods employed in archaeology are single-beam echo-sounders (SBES) and sub-bottom profilers (SBP). Inexpensive SBES are now commonplace, with many vessels equipped to conduct relatively unsophisticated but effective low-resolution bathymetric surveys. SBES systems consist of single hull-mounted or pole-mounted transceivers that transmit single- or dual-frequency pulses, typically within the 50–300 kHz bandwidth. The frequency-dependent, vertical resolution of these systems can be as great as a few centimeters. The pulse, with a 30–45° cone angle, is oriented vertically downward, concentrating the acoustic energy in a small circular area of the seabed (the radius of this circle is dependent on the water depth). Analysis of the return can also provide information on seabed type. The same system is routinely used to detect targets in the water column (fishers commonly refer to SBES as "fish finders"). The horizontal resolution of SBES systems is controlled by a combination of source frequency, cone angle, and water depth. For example, a 200 kHz echo-sounder with a 50° cone angle has a horizontal resolution of 0.14 m in a water depth of 20 m. A disadvantage of SBES systems is that the density of the survey grid controls the effective horizontal resolution of the survey data. In a tidal environment, the maximum survey grid density achievable is on the order of 5 m. Therefore, the highest possible horizontal resolution for the bathymetric survey is ±5 m. Bathymetric data are conventionally represented as profiles, two-dimensional contour plots, or three-dimensional digital elevation models (DEMs). Regional-scale SBES surveys are normally designed with survey lines oriented perpendicular to the coast, as bathymetric variation is usually at a maximum in this direction. Site-specific SBES surveys are conventionally designed with survey lines oriented on a grid.

As many archaeological sites coincide with areas of high sedimentation, partial or complete burial of shipwrecks is common. When nonmetallic sites are buried, the only technique suitable for detecting them is sub-bottom (seismic) profiling (Bull et al., 1998; Plets et al., 2008). These systems produce vertical and three-dimensional pseudo cross sections of the subsurface sediments and buried archaeological material. SBPs operate on similar principles to SBES, but they transmit lower frequencies, allowing them to penetrate the seafloor and

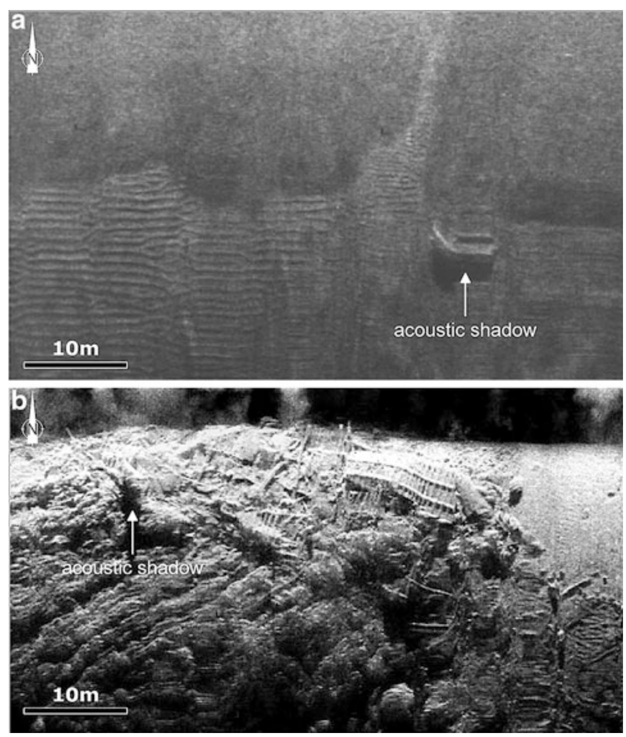


Shipwreck Geoarchaeology, Figure 1 Chirp sub-bottom profile (SBP) acquired over the mid-ship section of the *Invincible* wreck of 1758, the Solent, United Kingdom. These data were acquired with a GeoAcoustics GeoChirp profiler using a 2–8 kHz swept frequency source (Quinn et al., 1998) pulsing at 4 Hz. The Chirp profile over the mid-ship section images the buried oak wreck structure as a high-amplitude reflector with a measured reflection coefficient of −0.27.

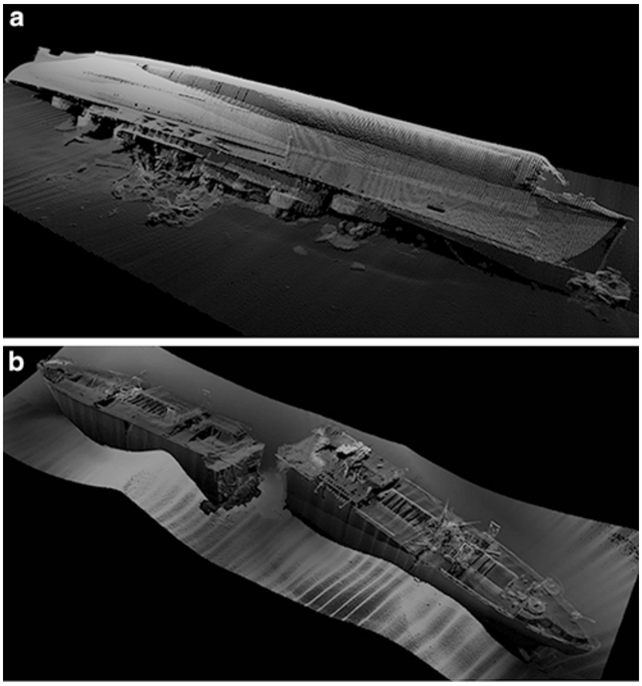
reflect off sedimentary layers in the subsurface. SBP therefore allows archaeologists to detect artifacts and intact wreck structures buried in the upper tens of meters of sediment. At each interface, some of the incident energy is reflected back to the surface, and the remainder is transmitted to deeper layers. For wreck investigations, "Chirp" frequency-modulated SBP (Figure 1) offers the highest resolution solution for imaging buried structures (Plets et al., 2009). The majority of Chirp SBP work is in the frequency range 2–15 kHz, with centimetric vertical resolution theoretically possible. A central frequency of 3.5 kHz is commonly used as a compromise between penetration and resolution.

Side-scan sonar (SSS), traditionally the "workhorse" of marine survey, is a swath sonar technique that provides acoustic images of the seabed generated by two side-looking transceivers mounted on a towfish. The SSS insonifies a corridor of the seafloor underneath the towfish using a highly directed source. SSS relies on backscattered energy and allows users to differentiate material types by measuring the amount of energy returned from each portion of the seafloor. Coarse-grained material scatters the most energy, and fine-grained material scatters the least. SSS systems typically operate as dual-frequency systems, with 100 and 500 kHz sources common (Figure 2). 100 kHz sources are often used for reconnaissance-scale low-resolution wide-area surveys, and 500 kHz sources for detailed high-resolution site-specific surveys.

Multi-beam echo-sounders (MBES), the most effective of the contemporary acoustic mapping systems, are a direct extension of the SBES. Instead of transmitting



Shipwreck Geoarchaeology, Figure 2 Side-scan sonar data from the (**a**) *Appin* (1913) and (**b**) *Oregon* (1945) wreck sites in Belfast Lough (Ireland), acquired using an EdgeTech 272-TD side-scan system operating at 500 kHz with a swath width of 150 m (Quinn et al., 2000).



Shipwreck Geoarchaeology, Figure 3 Multi-beam echo-sounder data of the (**a**) HMS *Royal Oak* and (**b**) SS *Richard Montgomery* wreck sites collected using a Reson 8125 operating at 455 kHz. MBES data were acquired by ADUS DeepOcean for the UK Ministry of Defence.

a single beam vertically downwards, the MBES transmits and receives a fan of narrow beams perpendicular to the ship's axis, producing high-density high-resolution bathymetric data across a swath beneath the survey vessel (Figure 3). Two types of swath systems are commonly employed: true multi-beam echo-sounders and interferometric sonars (also termed bathymetric side-scan sonar). Each of these systems has its merits. In simple terms, MBES systems offer higher-resolution bathymetric data with low-order backscatter data as a by-product, whereas interferometric systems offer lower-order bathymetric data and true side scan. Contemporary MBES can simultaneously acquire depth and backscatter data for each point insonified on the seafloor. These data can be used to derive charts of the seafloor showing relief and backscatter intensity, which can in turn be used to produce geological maps when ground-truthed using direct (grabs, cores) or indirect (video, stills) sampling methods (see below). Despite their complexity and relative expense, MBES now dominate seafloor mapping. MBES have many uses and are designed to operate in various water depths (Lurton, 2010). Deepwater systems are designed for regional survey and operate in the frequency range of 12 kHz (deep ocean mapping) to 30 kHz (continental shelf investigations). The large size and weight of these MBES transceivers limits their installation to deep-sea vessels. Shallow-water systems typically operate at 100–200 kHz and are designed for hydrographic survey of the continental shelves. High-definition systems, operating between 300 and 500 kHz, are used for high-definition work and object detection (Lurton, 2010) that is ideally suited to shipwreck archaeology. Their small size and weight makes them ideal for small-vessel deployment and for mounting on remotely operated underwater vehicles or ROVs.

Non-acoustic prospection methods

Although acoustic methods are by far the most powerful techniques to locate and characterize submerged archaeological sites, magnetic and laser techniques have also proven successful in locating shipwrecks (Gearhart, 2011), and they are therefore sometimes used in combination with acoustic technology. Magnetometers are passive devices that record perturbations in the Earth's magnetic field. They are therefore effective in locating buried shipwrecks containing substantial ferromagnetic components (Gearhart, 2011). Marine magnetometers use either a single sensor to measure the total magnetic field strength or multiple sensors to measure the gradient of the magnetic field. Gradiometers are preferred for archaeology as they are most sensitive to small perturbations in the magnetic field. Proton precession magnetometers have largely been superseded by more sensitive fluxgate and cesium instruments. Differentiating shipwrecks from other magnetic debris can be difficult, especially in busy ports and harbors where magnetic debris is common.

LiDAR (an acronym for Light Detection And Ranging) is an electromagnetic technique used for high-resolution topographic mapping from aircraft. Lasers used in airborne survey are generally in the near-infrared band of the electromagnetic spectrum, between 532 and 1,064 nm. They operate in a similar manner to acoustic devices, transmitting light pulses and recording the time taken for the pulse to travel out, reflect, and travel back to the sensor. The two-way travel time is then multiplied by the speed of light in air and divided by two. When the position and incident angle of the laser scanner is established, the real-world coordinates of the reflecting object can be calculated. Bathymetric LiDAR, recently proven effective in imaging submerged shipwrecks in shallow water (Tian-Yuan Shih et al., 2014), transmits laser pulses at two wavelengths, 532 nm (green) and 1,064 nm (infrared). The green pulse penetrates the water surface and reflects off the seabed, and the red pulse is reflected directly from the sea surface.

Other non-acoustic techniques that have proven successful in imaging submerged shipwrecks are real aperture radar (RAR) K_a band imaging (Hennings and Herbers, 2010) and marine electrical resistivity tomography (Passaro, 2010).

Shipwreck site characterization

Archaeological interpretation of marine geophysical data concentrates on the identification of anomalies, i.e., on appreciable differences between a constant or smoothly varying background and a very strong or "anomalous" geophysical signature. Geophysical anomalies take many forms. For example, a concentration of iron cannon in gullies on a bedrock substrate would give rise to a sharp magnetic anomaly, but may be difficult to interpret from acoustic data. Conversely, a wooden vessel on a planar sand substrate may present an obvious backscatter anomaly, but might be difficult to detect in a magnetometer survey. In reconnaissance surveys, many anomalies are often identified, especially in an area of busy shipping. Larger objects, such as intact shipwrecks, are easy to identify. Smaller objects are often difficult to interpret. Also, some large objects produce relatively small anomalies if a large portion of the structure is buried. Therefore, it helps to have a basis for assigning probability levels to targets. Natural targets tend to possess irregular shapes. Conversely, anthropogenic objects are often regular or angular. Caution is advised, as often man-made objects can be buried (or semi-buried), and therefore the associated anomaly may be masked by sediment. The context of an anomaly is also important. Anomalies sometimes seem out of place in context with the surrounding seafloor. For example, a small angular anomaly on a planar sand seafloor may be deemed of higher interest than a small angular anomaly on a rock-strewn platform. Experience becomes a valuable asset here, as does luck, and it is often advisable to survey a target from different directions. All of these factors highlight the need to develop objective means for classifying and identifying archaeological anomalies in geophysical data.

Geophysical characterization of shipwreck sites

Although some research has been conducted on the geophysical signatures of archaeological materials submerged and buried in marine environments, it remains a relatively poorly understood subject. In nearshore waters, misinterpretation of archaeo-geophysical data is often compounded by the presence of modern anthropogenic debris; however, attempts to distinguish archaeological objects from natural materials through automated classification and controlled detection have met with some success. Lawrence and Bates (2001) successfully detected wood and metallic wrecks in SBES data using acoustic ground discrimination systems (AGDS). AGDS derive estimates of "roughness" and "hardness" from echosounder data by examining the signal characteristics of primary and multiple reflectors in the data.

Research has also been conducted on imaging buried shipwrecks using high-resolution seismic sources. In normal subsurface geological situations, values of reflection coefficients fall into the range of ± 0.1 (Anstey, 1981), with the majority of energy being transmitted. However, Quinn et al. (1997) demonstrated that reflection coefficient values for wood buried in unconsolidated marine sediments are generally large and negative (between -0.2 and -0.8), indicating that seismic instruments can readily image wooden artifacts and structures submerged and buried in the marine environment. Subsequently Arnott et al. (2005) investigated the impact of wood degradation on seismic signatures and concluded that the actual degradation state of buried archaeological material could also be estimated from acoustic properties. This idea was further explored by Plets et al. (2008, 2009) using Chirp technology, proving that the reflection coefficient of buried wood becomes increasingly negative with increased deterioration of the wood structure.

Experimental work to image and detect archaeological material and objects from geological "noise" in backscatter data has also proven successful (Quinn et al., 2005). A control experiment, where a range of organic and inorganic archaeological material was deliberately submerged and surveyed, proved that a very wide range of archaeological materials can be imaged in geophysical surveys, but that individual archaeological targets can be difficult (or impossible) to resolve when they are imaged out of context (Quinn et al., 2005). Recent advances in the processing of MBES-derived backscatter data (much influenced by advances in seabed sediment and benthic habitat mapping) demonstrate that it is possible to detect shipwrecks from the surrounding seabed using remote classification techniques (Masetti and Calder, 2012). Although this approach is promising, more research is needed to develop robust techniques that will successfully identify shipwreck sites in high-volume, high-density MBES data sets.

Ground truthing and direct sampling of shipwreck sites

Whatever subjective or objective methods are used to interpret geophysical data for archaeological prospection, at a minimum, a representative sample of the geophysical data needs to be ground-truthed. Ground-truthing methods traditionally comprise direct sampling (using surficial sediment samplers or coring devices) or optical imaging of the seafloor. A variety of dredges, corers, and grab sampling tools are used for collecting rock and sediment samples from the seafloor and shallow subsurface, including Day Grabs and Van Veen Grabs. Grab samplers employ two spring-hinged jaws that close when the device impacts the seafloor, with sediment samples retrieved for particle-size and contaminant analyses. Gravity , vibra-, and/or push cores can also be used, notably when deeper sedimentary horizons need to be sampled. Optical ground truthing of geophysical data is traditionally conducted using drop-down video cameras (mounted with still and/or video cameras), towed arrays, ROVs, or divers.

Understanding shipwreck sites

Physical aspects of wreck site formation

Research into processes that form the submerged archaeological record is important, as it informs effective in situ conservation and preservation of archaeological sites. Two general classes of formation processes are recognized: culturally created (C-transforms) and naturally created (N-transforms) (Schiffer, 1987). Marine geoarchaeologists tend to be more concerned with understanding N-transforms – specifically, the linked physical processes operating in the water column (hydrodynamics) and on the seafloor (sediment dynamics).

As shipwrecks are inextricably linked with the surrounding natural environment, site formation processes at wreck sites are dependent upon anthropogenic influence and combined physical, biological, and chemical processes. Physical processes tend to dominate in initial stages of site formation, with biological and chemical influences important in the later stages (Ward et al., 1999a). Iron and wooden wrecks tend to deteriorate differently: iron wrecks succumb to physical and chemical processes, and wooden wrecks are destroyed by combined physical and biological processes (Ward et al., 1999a).

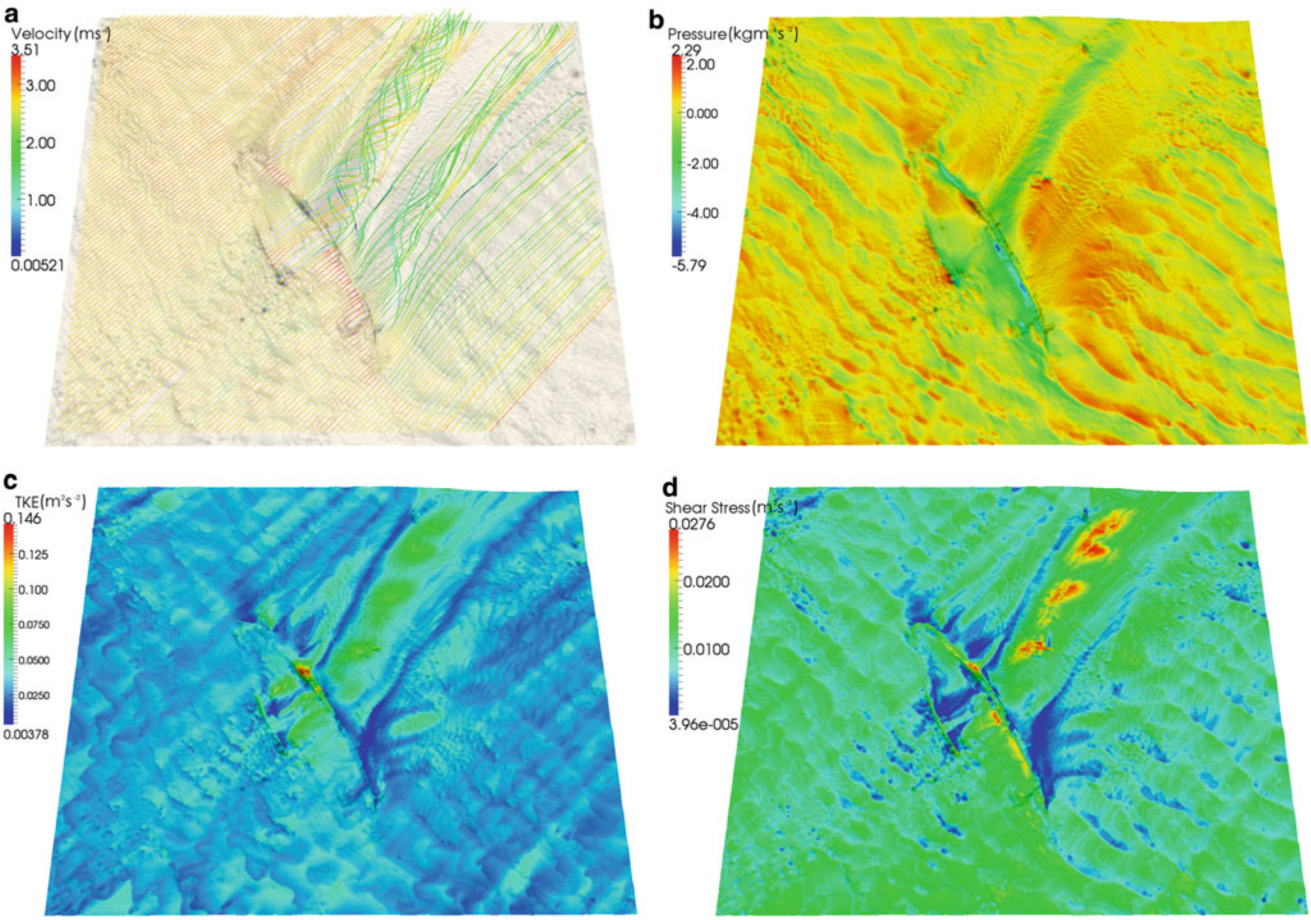
Although many authors describe wrecks as being in some form of equilibrium state with the surrounding environment (Gregory, 1995; Quinn et al., 1997; Ward et al., 1999a), it is important to acknowledge that wreck sites act as open systems, with the exchange of material (sediment, water, organics, and inorganics) and energy (wave, tidal, storm) across system boundaries (Quinn, 2006). Wrecks are therefore in a state of dynamic (not steady state) equilibrium with respect to the natural environment: they are characterized by negative disequilibrium, ultimately leading to wreck disintegration (Quinn, 2006).

Positive and negative feedbacks operate between physical, chemical, and biological processes in the water column, sediment pile, and the wreck as it disintegrates and interacts with the surrounding environment (Ward et al., 1999a; Ward et al., 1999b). Fundamental processes driving site formation are therefore dependent upon the complex erosion (net sediment/material loss) and accretion (net sediment/material deposition) history of wreck sites. In high-energy environments, waves, currents, and sediment abrasion are more significant than chemical or biological processes (Ward et al., 1999a). However, a single shipwreck in a normally low-energy environment may experience high-energy storm events, causing intense periods of structural deterioration and material loss over short durations. Furthermore, exposed parts of wreck structures tend to be affected by aerobic bacteria, wood borers, and increased corrosion rates, while buried wreck components tend to be affected by anaerobic bacteria (Ward et al., 1998). Therefore, even major chemical and biological processes contributing to site formation are constrained by physical process (Quinn, 2006).

The introduction of an object to the seafloor leads to an increase in flow velocity and turbulence (Whitehouse, 1998), causing changes in the flow regime in its immediate environs and resulting in one or a combination of (1) flow contraction, (2) formation of a horseshoe vortex in front of the structure, (3) formation of lee-wake vortices behind the structure (sometimes accompanied by vortex shedding), (4) turbulence, (5) occurrence of reflection and diffraction waves, (6) wave breaking, and (7) sediment liquefaction promoting material loss from the site (Sumer et al., 2001). A horseshoe vortex is formed by the rotation of incoming flow. Under the influence of an adverse pressure gradient produced by the structure, the boundary layer on the bed upflow of the structure undergoes a three-dimensional separation, rolls up to form a swirling vortex around the structure, and trails off downflow (Sumer et al., 1997). The morphology of horseshoe vortices can be strongly distorted, resulting in complicated flow patterns. One such result is vortex shedding, where self-propelling, closed ring structures are formed and transported by flow (Testik et al., 2005). Lee-wake vortices are formed by rotation in the boundary layer over the surface of the object. End effects (from the tips of the structure, in this case the bow and stern of a submerged vessel) play a dominant role in the flow pattern and strongly modify the structure of vortices. Lee-wake vortices emanating from the surface of the wreck are brought together in the vicinity of the structure due to flow convergence. Additionally, two counter-rotating vortices form a vortical region in the near wake on the lee side of the structure (Testik et al., 2005).

These processes act to increase local sediment transport and subsequently lead to scour (Sumer et al., 2001) around wrecks. Scouring subsequently results in the lowering of the seabed from some previously obtained quasi-equilibrium level due to (1) flow velocity increase near the object, (2) resulting increase in the local Shields parameter (a nondimensional number used to calculate the initiation of motion of sediment in a fluid flow), and (3) subsequent divergences in the sediment transport regime (Voropayev et al., 2003). When scour occurs on fine-grained (silt or clay) seabeds, the eroded material is carried away from the wreck site in suspension, leaving a seafloor depression that may not be readily infilled by natural processes (Whitehouse et al., 2011). Where scouring takes place in coarse-grained deposits (sand or gravel), it usually results in local deposition (often comprising the eroded material) in addition to scour. Scouring ultimately leads to wreck site instability and material loss.

Seabed scour operates on a variety of temporal scales, with scouring at static structures initially occurring rapidly (over a period of days to weeks) but approaching ultimate (equilibrium) values asymptotically (Whitehouse, 1998). Due to the dynamic and mobile nature of submerged wreck sites and artifact scatters in the nearshore zone, the process of scouring can occur at a wide range of temporal scales (hours to decades) as sites and objects are invariably covered and uncovered due to external forcing. Furthermore, the total or partial mobility of wreck structures and associated artifacts can lead to archaeological objects acting as mobile nuclei for scour initiation, further



Shipwreck Geoarchaeology, Figure 4 Output from CFD model over a bathymetric surface derived from an MBES shipwreck survey: (**a**) three-dimensional flow velocity, (**b**) pressure map, (**c**) turbulent kinetic energy map, and (**d**) shear stress map of the seafloor.

complicating scour processes (McNinch et al., 2006; Quinn, 2006).

Seabed scour also operates on a variety of spatial scales, from complete wreck sites to individual objects or artifacts. Controls on the spatial extent of scouring at wreck sites include a combination of the orientation, shape, and size of the causative object; the seafloor and subsurface geology; the water depth; and the prevailing hydro- and sediment dynamics (Caston, 1979; Quinn, 2006). Time-lapse MBES surveys have proven effective in quantifying morphological change at wreck sites due to anthropogenic and natural forcing (Quinn and Boland, 2010), with resultant data useful in the development of site formation models.

Mathematical modeling of shipwreck sites

Experimental studies attempting to characterize the hydro- and sediment dynamics at submerged shipwreck sites have traditionally relied on laboratory-based physical models (e.g., Saunders, 2005) or field instrumentation deployments (e.g., Dix et al., 2007). However, lab-based flume experiments using scaled models, although useful in the attempt to replicate the natural environment, are usually limited by scaling factors. Field-based experiments, using high-resolution acoustic Doppler current profiler (ADCP) deployments, are expensive and logistically difficult.

Recently, researchers have investigated mathematical modeling as a relatively inexpensive and adaptable method to characterize hydrodynamic flows around wrecks. Using computational fluid dynamics (CFD), MBES data from a shipwreck site and boundary conditions constrained by field measurements (sediment samples and flow measurements) Smyth and Quinn (2014) successfully simulated the three-dimensional flow velocity field around a fully submerged shipwreck (Figure 4). They demonstrate that the presence of a shipwreck on the seafloor leads to an increase in flow velocity and turbulence, causing changes in the flow regime in its immediate environs. Flow contraction, formation of lee-wake vortices behind the structure (accompanied by vortex shedding), and turbulence were all simulated and quantified in this study. The secondary products derived from the CFD modeling confirm that flow velocity and turbulence are both amplified by the presence of a wreck, causing changes in the morphology of the flow regime. Shear stress and turbulent kinetic energy (TKE) amplification three to four times greater than ambient values were recorded downstream of the wreck structure in the model environment.

The results presented in this CFD study indicate that the secondary products derived from the modeling are crucial in understanding the areas and components of wreck sites most at risk by natural forcing, and therefore those elements should be prioritized when it comes to in situ conservation (Smyth and Quinn, 2014). For example, areas of wreck sites identified as experiencing elevated or amplified TKE, pressure, and/or shear stress are most under threat from mechanical stress and therefore might be targeted in the early stages of preservation and in situ conservation. Related to this, after protecting a site (using additional sediment, sandbags, or geotextiles, see for example Manders et al., 2008), it is suggested that a repeat MBES survey could be conducted and a new CFD model run to test the effectiveness of conservation measures (Smyth and Quinn, 2014).

Summary

Acoustic surveys are now an essential part of shipwreck investigations in (1) locating wrecks, (2) characterizing wreck sites, and (3) modeling the hydrodynamics and sediment dynamics of these sites. Each of these phases of investigation has benefited enormously from technological and methodological advances in acoustic imaging, digital rendering, and numerical modeling over the past two decades, and they will continue to do so into the future.

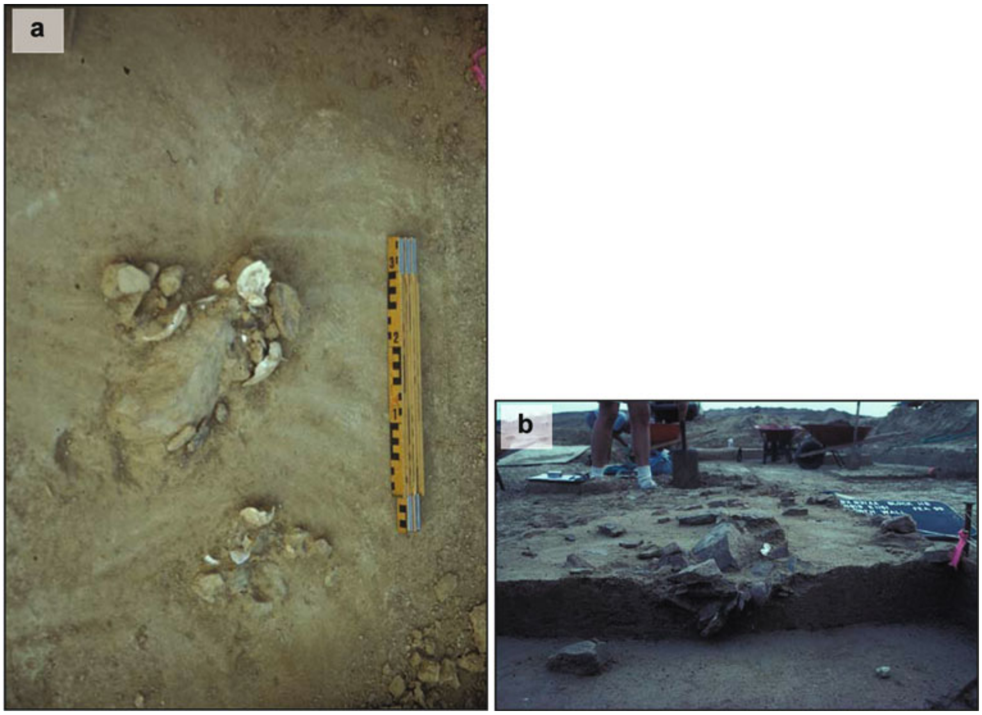
Introduction

Site formation processes are "the factors that create the historic and archaeological records" (Schiffer, 1987, 7). These factors include both natural and anthropogenic forces operating in different depositional environments and contributing to postdepositional disturbances. Formation processes affect the spatial integrity of both artifacts and sites, and they affect cultural deposits in different ways depending on the site's age, geomorphic setting, sediments and soils, climate, and type and the complexity of occupation (Goldberg and Macphail, 2006). Schiffer (1972, 1987) stressed that the reconstruction of human behavior must be inferred from the archaeological context, which he defined as the three-dimensional spatial patterning of individual artifacts, features, and other debris on a site. However, before archaeologists can reach meaningful conclusions about human behavior from the archaeological context, they must know how it was created (Waters, 1992, 11).

According to Schiffer (1987), two processes create a site and its associated context: cultural transformations and natural transformations. Cultural, or anthropogenic, transformations are products of human activities that create the patterns of artifacts and features at a site. Cultural deposits are not emplaced in static environments, however, and natural transformations involving physical, chemical, and biological processes eventually affect the context of the material remains at a site. Geoarchaeologists are concerned with both natural and cultural site formation processes and how these shape the context of a site and the archaeological record.

It is likely that geoarchaeologists were aware of the notion of "site formation processes" long before the term became widely known through the publication of Schiffer's 1987 volume, *Formation Processes of the Archaeological Record*. In the early and mid-twentieth century, both European and North American geoarchaeologists whose research background was in the geosciences investigated Quaternary environments and intrinsically thought about how the archaeological sites they studied were formed, even if they didn't specifically articulate this concept at the time (e.g., Sellards, 1917, 1938; Bryan and Ray, 1940; Zeuner, 1946; Cornwall, 1953; Bordes, 1954; Bonifay, 1956; Laville, 1964; Haynes and Agogino, 1966). By the beginning of the



Site Formation Processes, Figure 1 As floodwaters moved across a former surface soil (now deeply buried) representing the early Holocene floodplain of the Medina River at the Richard Beene site in south central Texas, cultural deposits were modified by the flowing water. (**a**) Photograph of two amorphous Early Archaic (ca. 8800–8600 BP) artifact concentrations showing fire-cracked rock (*FCR*), mussel shells, and chipped stone, some showing a vertical angle of repose. (**b**) Photograph of a cross-sectioned Early Archaic FCR feature. Note the imbricated FCR (From Thoms (2007)).

1980s, a more formal awareness and treatment of the subject of how archaeological sites form was presented by Karl W. Butzer (1982), who articulated the interaction between natural and cultural elements that shape the appearance of a site. Although it is an important topic in archaeology, site formation processes were regarded by Butzer to be the primary task of geoarchaeology. Nevertheless, considering the number of archaeological sites excavated throughout the world, it is remarkable that so few studies of sites included geoarchaeological investigations addressing formation and postdepositional processes.

In evaluating site formation processes, it is useful to consider some logical categories. There are two major types of sites: open-air sites and those in caves and rock-shelters. (For sites involving mostly human agencies in their formation (historic, urban, etc.), see the entries on "Built Environment" in this volume.) In addition, such processes can be operationally broken down into three temporal ranges: those that took place before, during, and/or after occupation. As a whole, these processes may include natural and cultural sedimentation and modifications (e.g., trampling, discarding sweepings), soil formation (pedogenesis), and diagenesis.

Open-air sites

The major depositional systems associated with open-air sites are alluvial (flowing water), eolian (wind), lakes and basins, glacial, and coastal marine. These depositional systems have sedimentary contexts that are addressed here in terms of their role in site formation processes.

Alluvial systems

In the past, humans have been attracted to streams, often living on floodplains, terraces, or alluvial fans and exploiting the abundant resources available in alluvial settings. Although alluvial landscapes are conducive to the initial accumulation of artifacts, fluvial processes may restructure the artifact patterns (Rapp and Hill, 2006, 75). For example, where sites are situated on or near the banks of stream channels, high-energy floods tend to modify cultural deposits dramatically by displacing artifacts vertically and horizontally. At the Richard Beene site in south central Texas (Figure 1), Early Archaic features consisting mostly of large pieces of fire-cracked rock with smaller or lighter items, including chert flakes, mussel shells, and pebbles, were recorded in small scour holes on the surface of a deeply buried paleosol representing an early Holocene floodplain surface (Thoms, 2007, 79).

Many of the flakes and mussel shells, along with tabular pieces of fire-cracked rock, occurred in a near-vertical angle of repose and were imbricated. It is likely that one or more flood-scouring events on this floodplain in the early Holocene removed the fine-grained matrix from burnt-rock features, such that the large clasts remained essentially in place horizontally but were displaced vertically and served as traps for smaller objects being transported laterally by floodwaters moving across the former floodplain.

In some cases, stream erosion may completely remove artifacts, cultural features, and even parts of sites, thereby destroying evidence of human occupation. On the other hand, alluviation (deposition of sediment by streams) can result in rapid burial and preservation of cultural deposits. Because the material remains of human occupation in stream valleys have passed through a geologic filter (i.e., erosion, deposition, and landscape stability) to become the archaeological record, understanding the nature of the temporal and spatial patterns that this filter has imposed on the archaeological record throughout a drainage network is the first task in identifying archaeological patterns that reflect human choices (Bettis and Mandel, 2002a; Mandel, 2006). For example, in a systematic study of drainage basins in the Central Plains of the USA, Mandel (1995) determined that the paucity of recorded Archaic sites, especially those dating between ca. 8000 and 4000 BP, is a result of fluvial erosion or sedimentation and not due to any peculiarities of the prehistoric settlement patterns. Those processes have affected the archaeological record by either removing or burying sites.

Artifact taphonomy can be complex in alluvial settings, and it cannot be assumed that cultural materials were initially deposited in the very sediments from which they were recovered (Rapp and Hill, 2006, 76). Artifacts are often incorporated into the sediments by channel migration and thereby redeposited within the alluvium; in some cases, the artifacts have gone through multiple cycles of redeposition. In a study of Paleolithic cultural materials recovered from deposits of gravel-rich alluvium in the lower Thames River valley, Gibbard (1994) determined that most of the artifacts were in secondary contexts. Such artifacts were sorted, smoothed, and rounded, indicating that they were rolled over great distances by water. In the same deposits, accumulations of unsorted and unabraded artifacts also were recorded, indicating that some of the artifacts were transported minimally if at all by flowing water of low energy.

Schick (1987) and Petraglia and Nash (1987) conducted experiments designed to identify how fluvial processes affected bone and stone artifacts. Their experiments and conclusions were similar. Both groups experientially tested movement and burial of lithic artifacts using test plots in different settings. In their experiments, smaller items were more likely to be transported by water, while larger or heavier items (>15 g in one experiment, cores in the other) tended to remain in situ despite strong flow events. According to Petraglia and Nash (1987, 126), "the integrity of sites located in fluvial contexts is related to the tempo, magnitude and duration of hydrological events." By studying the new "sites" created by redeposited cultural materials, Schick (1987) and Petraglia and Nash (1987) were able to demonstrate that artifacts may be redeposited in multiple locations, they may be sorted by size, and lighter items may be carried farther downstream. When the original site areas and the areas of redeposited artifacts were compared, the researchers discovered that the zones of redeposited artifacts were elongated in the direction of the water flow (Schick, 1987). Petraglia and Nash (1987) recorded the number of artifacts that were buried during the course of the experiment and determined that once the artifacts were buried, they were more likely to remain in place.

Eolian systems

As with water, both depositional and erosional processes are associated with wind, which can both cover and preserve cultural deposits or cause disturbances and exhume an archaeological site. There are two general types of eolian deposits: those consisting of silty sediment, or loess, and those consisting of sand. Loess is widespread in China, Central Asia, Ukraine, Central and Western Europe, Argentina, and the Great Plains and Midwest of North America. Sandy eolian deposits comprise dunes, sand sheets, and sand seas and occur mostly in arid and semiarid environments throughout the world.

Although wind can bury artifacts and cultural features in loess or sand deposits and thus preserve them within a stratified context, eolian processes often cause major transformations of the archaeological record at sites. In particular, where stratified sequences of artifact-bearing eolian sands exist initially, wind erosion can remove sediment, a process referred to as deflation, thereby causing the collapse of the sequences and the mixing of archaeological components (Rapp and Hill, 2006, 65). For example, on sand sheets and sand seas in the Western Desert of Egypt, deflation has created lag deposits consisting of artifacts from different cultural periods (Schild and Wendorf, 1975; Wendorf and Schild, 1980; Mandel and Simmons, 2001). Deflation therefore removes fine sediments causing a reduction in ground level and the formation of denser scatters of the larger particulate matter and artifacts that the wind was not strong enough to move. Wood and Johnson (1978, 359) describe deflation as when "nature had done the excavating and, unfortunately, had left a two-dimensional chronologically blurred site context for archaeologists."

In addition to affecting the vertical integrity of cultural deposits through deflation, wind can cause modification and destruction of artifacts through abrasion. Also, small artifacts, such as micro-debitage, may be redeposited by the wind.

Sand dunes are dynamic geomorphic features, often shifting through time and experiencing episodes of deflation. As a consequence, the context of cultural deposits on or within dunes is prone to severe modification. At the Krmpotich site in the Killpecker Dunes of southwestern Wyoming, it is likely that the assemblage of Folsom artifacts was incorporated into a lag deposit resulting from at least one episode of deflation sometime during the Holocene (Mayer, 2002). Subsequent reactivation of the dunes brought about the burial of the Folsom assemblage.

Experimental studies have been conducted to determine the effects of wind on the distribution of artifacts, especially in sandy sediments (e.g., Bowers et al., 1983; Shelley and Nials, 1983; Simms, 1984; Wandsnider, 1988). Through a series of experiments, Wandsnider (1988) determined that wind can move small artifacts directly or transport items indirectly by forming small obstruction dunes behind the artifact, which then "plow the artifacts along." Also, the wind may excavate small pits behind and beneath larger artifacts into which they may roll. Despite these effects of wind, Wandsnider (1988) argued that it is unlikely such disturbance would impact the artifact distribution to an extent that the spatial integrity of the behavior that created it is compromised.

Cameron et al. (1990) determined that the size of artifacts strongly influences their movement by wind. Whereas small artifacts (<8 mm) tend to move great distances downwind even if this movement involves traveling upslope, larger ones generally are not moved very far if at all by wind. Also, artifacts tend to settle into sandy sediments during the first few months after they are deposited; there, they become partially buried, making them less likely to be moved by wind or water (Petraglia and Nash, 1987; Schick, 1987; Wandsnider, 1988).

Lakes and basins

Archaeological sites are common on the margins of lakes and basins because of the presence of water, either permanent or intermittent, and abundant and diverse food resources that attracted humans. Whereas lakes are large inland bodies of standing water, i.e., larger than ponds, basins are highly variable in size, with surface areas ranging from thousands of square kilometers to a few tens of square meters. Examples of small basins include kettles (also called potholes, formed by the melting of glacial ice blocks that calved off of retreating ice sheets), pans, and some playas created by deflation.

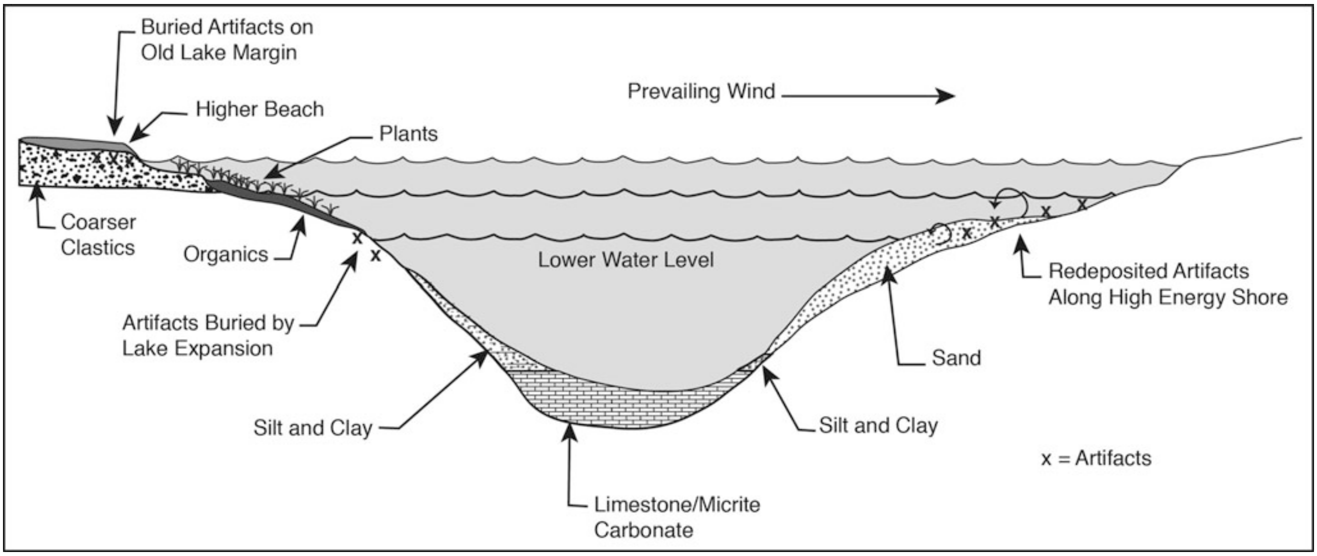
The margins of lakes and basins are diverse and dynamic transitional environments located between terrestrial and aquatic ecosystems. Here, small fluctuations in environmental parameters are often recorded by shifts in sedimentary pattern (Feibel, 2001, 127). These shifts can be especially dramatic when water levels rise and fall, causing facies changes that alternate between subaerial and subaqueous depositional settings. The vertical and horizontal sequence of sediments along the margins of a lake or basin records details of the depositional environment as well as the events that led to burial and preservation of archaeological assemblages (Feibel, 2001, 127).

As a transitional environment, a lake or basin margin is characterized by a complex pattern of sedimentation and sediment modification. Feibel (2001, 134) identified three types of transitions associated with lake margins: (1) the successive shifting of ambient erosional, transport, and depositional processes; (2) the geologically abrupt and often catastrophic effect of large-scale events, such as strong storms that generate waves; and (3) the often subtle but significant switch from subaqueous to subaerial conditions as water levels rise and fall. Also, the effect of time may cause postdepositional modification, including dissolution, cementation, and soil formation, all of which can affect archaeological deposits.

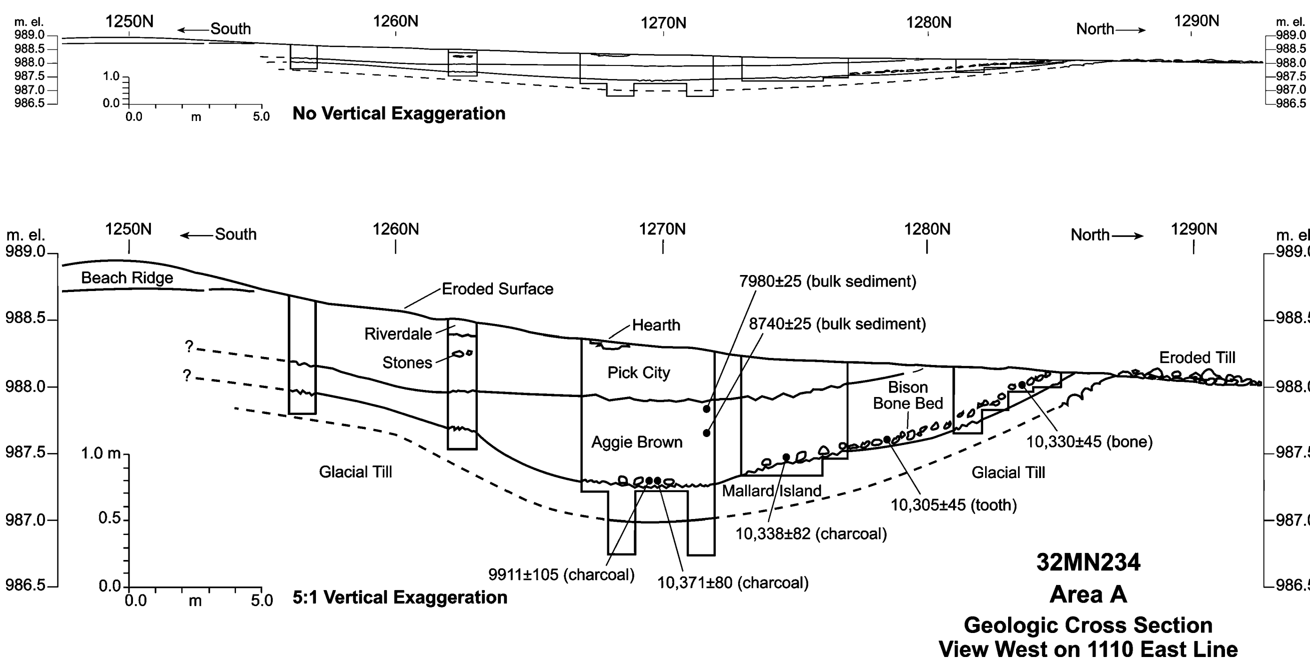
Lake- and other water-basin deposits are usually divided into two general categories: clastic and chemical (Rapp and Hill, 2006, 78). Organic materials can be important constituents of both categories. There is a strong relationship between hydraulic energy and the spatial pattern of coarse- and fine-grained sediment in a lake basin. In general, coarse-grained sediment (sand and gravel) tends to accumulate on the high-energy shoreline at the margin of a lake basin, while fine-grained sediment (silts and clay) and carbonates (limestone and micrite) accumulate near the center of the basin (Figure 2). Organic (carbonaceous) sediment tends to occur along the edges of a basin in quiescent, shallow-water marshes, swamps, and bog settings.

Fluctuating shorelines of lakes and ponds can either bury and protect cultural deposits or erode and destroy them. When water levels are low in a basin, human occupation can occur in locations that can be buried when rising waters submerge them and then deposit deeper water sediment atop the former land surface. At the Beacon Island site in northwestern North Dakota, a dense concentration of bone representing an Agate Basin (Paleo-Indian) bison kill lies deeply buried near the middle of a small kettle basin and less deeply buried near the rim of the basin (Figure 3) (Mandel et al., 2014). It is likely that the bison were killed and butchered on a previously low shoreline of a shallow kettle pond. During the latter part of the Younger Dryas (ca. 10,300 ^{14}C years BP), as the climate became wetter, the water level rose in the kettle basin, and fine-grained pond sediment buried the bones. Because the skeletal remains are articulated and well preserved, the burial process must have been rapid with little modification of the remains by wave action or other dynamic processes at the kettle margins. The bones were thereby protected from various forms of disturbance (Mandel et al., 2014).

Rising waters in a lake or pond can also result in the erosion of cultural features and redeposition of artifacts that were previously deposited on lower shoreline margins, especially if the rise in water level was slow (Figure 2). By contrast, artifacts and features associated with lake margins that were laid down during high water



Site Formation Processes, Figure 2 Generalized diagram showing spatial patterns of site formation in a lake-basin setting (Modified from Rapp and Hill (2006, Figure 3.9)).



Site Formation Processes, Figure 3 Cross section of area A in the kettle basin at the Beacon Island site, an Agate Basin (Paleo-Indian) bison kill in northwestern North Dakota. Because the portion of the bone bed consisting of articulated bison remains extends down the north slope of the basin toward the middle of the depression, it is likely that the bison were killed and butchered on the former low shoreline of a shallow kettle pond. The few bison bones recorded in the middle of the basin probably were eroded from the main bone bed and redeposited (From Mandel et al. (2014)).

levels in the basin will not be affected by wave-driven shoreline erosion during intervals of low water levels; however, other erosional processes, such as gullying and deflation, may disturb artifacts and features on high, abandoned shorelines.

Glacial systems

In some areas of the world, Quaternary glaciation affected the spatial pattern of prehistoric human occupation and the vertical and horizontal integrity of their cultural materials and features. Pleistocene glaciers covered vast areas of land, where they both eroded landscapes and deposited large volumes of sediment. Rapp and Hill (2006, 86) noted that "The growth and melting of continental and mountain glaciers, and the related environmental changes that occurred with these fluctuations, influenced the habitability of certain areas." In glaciated regions, glacial and other processes also determined whether the material remains of humans would be preserved or destroyed.

Glaciers are moving masses of ice that erode and scour the land surface and in the process transport and deposit sediments. Coarse- and fine-grained sediment that becomes incorporated within the mass of ice is transported across the landscape and eventually deposited as till. Till comprises several types of landform, including moraines, drumlins, and till plains. The glacial meltwater that flowed on and under the ice also transported sediment and produced landforms such as eskers, kames, and outwash fans and plains consisting of stratified, well-sorted glaciofluvial deposits. Where meltwater flowed into ice-margin seas or lakes, kame deltas formed. These sedimentological contexts were frequent locations of prehistoric occupation, but such cultural deposits could be destroyed, modified, or preserved by various processes directly or indirectly associated with glaciation (Rapp and Hill, 2006, 87).

Where glaciers moved over landscapes that were once occupied by prehistoric people, archaeological sites were severely eroded or completely destroyed, and artifacts they contained were often incorporated into the glacial sediments and eventually redeposited. Consequently, artifacts associated with an earlier cultural period may occur in deposits of a later (younger) glacial advance. The site of High Lodge in England is a good example of how temporally inverted cultural materials appear in sequences of glacial deposits. At High Lodge, Middle Paleolithic (Mousterian) artifacts were found beneath glacial deposits containing older Acheulean hand axes (Ashton et al. 1992; Roe, 1993; West et al., 2014). It was eventually discovered that neither the Acheulean nor the later Middle Paleolithic artifacts were in situ. The Middle Paleolithic artifacts were contained within fine-grained proglacial lake deposits that were ripped up by advancing ice and transported as large, intact blocks of sediment. The blocks, still containing artifacts that retained their initial integrity, were deposited on top of younger proglacial lake deposits (West et al., 2014). While the Middle Paleolithic lithic artifacts looked fresh and some could be refitted to one another, they were in a disturbed context because they had been transported away from their original locus of deposition within the blocks of matrix that encased them. Subsequently, the older Acheulean artifacts were eroded from a site and transported as part of glaciofluvial and debris-flow materials that buried the deposits containing the transported Middle Paleolithic artifacts. Hence, all of the Paleolithic cultural deposits at High Lodge are in a secondary context.

Late Pleistocene periglacial (ice-marginal) landscapes of North America have yielded a number of stratified archaeological sites. Good examples of these are the Hebior and Schaefer sites in southeastern Wisconsin (Overstreet and Kolb, 2003). These sites are about 3 km apart and lie in a topographic low between two late Wisconsinan end moraines. At both Hebior and Schaefer, a bone pile representing a single mammoth rests on deglacial deposits and is encased in postglacial deposits. At Hebior, the deglacial deposits on which the bones rest consist of glaciolacustrine clays overlain by a thin stratum of glaciofluvial sands, and the overlying postglacial deposits are laminated peat and muck. At the Schaefer site, the bone pile rests on glaciolacustrine clays and is encased in clastic pond deposits together with laminated peat and muck. Based on contextual analysis, the bone piles were preserved initially by inundation within proglacial ponds and subsequently by organic deposition in wetlands. Radiocarbon ages, stratigraphic and geomorphic contexts, and taphonomic studies indicate that both the Hebior and Schaefer mammoths are in situ evidence for human interaction with megafauna very near the active glacial ice margin in the mid-continent by 12,500 ^{14}C BP and perhaps as early as 13,500 ^{14}C BP (Overstreet and Kolb, 2003).

Although the bone piles at the Hebior and Schaefer sites are remarkably well preserved, many processes active in periglacial settings tend to modify such cultural deposits. Most of these processes were associated with seasonal temperature fluctuations. For example, thawing of ground ice would cause disturbance of the surrounding matrix. Other site-disturbance processes included movement of unconsolidated surficial materials over partly frozen ground (solifluction), cryostatic pressure (involutions and cryoturbation), and glaciofluvial processes that were active at peaks during the thaw seasons.

Coastal marine systems

The coastal zones of oceans and seas are critical settings of past human occupation. Such transitional zones between land and water are among the most dynamic of landscape settings, with relative sea level, wave and tide energy, and sediment flux varying on time scales from seconds to millennia (Wells, 2001, 149). Also, depositional environments on the margins of oceans and seas vary over relatively short distances and include beaches, sand dunes, spits and bars, and river-mouth bars and deltas. Changes in the level of the water caused by eustatic and isostatic processes or tectonic forces can either submerge these environments or leave them "stranded" as abandoned shorelines (Rapp and Hill, 2006, 90). Hence, archaeological sites in coastal zones may be affected by an array of terrestrial and marine sedimentary processes. In addition, many of the postdepositional processes described below can modify the vertical and horizontal integrity of the cultural deposits. Defining site formation processes in coastal zones can, therefore, be a challenging task.

Coastal shoreline processes tend to erode or bury cultural deposits. Progradational shoreline sequences, in which land surfaces accrete in a seaward direction, can create a time-transgressive assemblage of sites on and near beaches, with the sites becoming progressively older with increasing distance from the modern boundary between land and water. On the other hand, transgressive episodes where the sea encroaches onto the land can cause beach erosion and destruction of archaeological sites. Archaeological materials eroded from a site may be redeposited on a shoreline and subsequently buried by nearshore sediments, thereby creating a new "site" that lacks in situ cultural deposits.

Archaeologists working in coastal areas around the world have long recognized the destruction of sites caused by marine erosion. For example, on the Channel Islands off the coast of California, natural agents are actively affecting archaeological sites, especially sea-cliff retreat caused by wind and water erosion (Rick et al., 2006). The net effect of daily tidal surges and periodic storms is the loss of many of the island's sea cliffs and headlands every year. Also, strong storms during El Niño and other meteorological events deplete the sand on many island beaches, making marine erosion particularly severe. Numerous stratified archaeological deposits occur on top of many of the island's eroding sea cliffs or along the shoreline (Rick et al., 2006). Although sea-cliff retreat rates vary across space and time, Muhs (1987, 566) suggested that most California sea cliffs retreat at rates averaging between about 0.01 and 0.05 m per year, with much of the retreat occurring during storms and other high-energy events, such as tsunamis.

Tsunamis can result in erosion or burial of cultural deposits. For example, McFadgen (2007) noted how tsunamis completely disarticulated prehistoric Maori village sites on the New Zealand coast. By contrast, late prehistoric sites at the mouths of the Salmon and Nehalem Rivers on the northern Oregon coast were buried by sediment that was transported and deposited by a landward-directed surge of water probably caused by a tsunami (Minor and Grant, 1996).

Waves generated by strong storms can also affect cultural deposits on shorelines. At the Inupiat site of Pingasagruk in northern Alaska, the spatial pattern of prehistoric and historic artifacts appears to be a product of storm surges and associated erosion and transport (Reinhardt, 1993). Rapp and Hill (2006, 95) noted that storm waves erode and transport small artifacts from dunes, often leaving behind larger objects on the beach. They pointed out that "Artifacts eroded from cultural deposits tend to accumulate in secondary concentrations because eddies and turbulence prevent them from washing away. Artifacts like bone, antler, and ivory become waterborne, tumbled, and rolled around before they are redeposited." In addition to being spatially displaced, artifacts transported away from their original location on a beach can be temporally mixed.

Coastal areas that are currently submerged were often areas of human occupation during times of lower sea level. For example, large expanses of continental shelves were dry during the last glacial maximum, about 20,000 years ago. During the terminal Pleistocene and early Holocene, climatic warming melted continental ice sheets and caused global sea level to rise, flooding portions of the shelves and submerging many archaeological sites. This has been confirmed by the discovery of submerged Archaic sites on the continental shelf of North America (Stright, 1995). Also, Paleo-Indian sites have been recorded offshore in the Big Bend region of the Gulf Coast of northwest Florida (Faught, 2002–2004). In some cases, submerged cultural deposits are relatively intact. Early Holocene Mesolithic sites off the coast of Denmark yielded well-preserved organic artifacts (Andersen, 1987; Bailey and Parkington, 1988; Skaarup and Grøn, 2004), as did the submerged Neolithic village of Atlit-Yam off the coast of Israel (Galili and Nir, 1993). Discovery of Acheulean hand axes in Table Bay, South Africa, indicates that some submerged prehistoric deposits can persist for hundreds of thousands of years and remain intact despite several fluctuations in sea level (Werz and Flemming, 2001).

Certain marine contexts strongly favor the preservation of submerged prehistoric archaeological sites (Flemming, 1983; Stright, 1995; Gusick and Faught, 2011). In many cases, structural or geomorphic features of the shoreline allow for preservation of sites (Fedje and Christensen, 1999, 650). For example, coastal caves and rock-shelters have proven to be ideal locations for prehistoric occupation (Erlandson, 1993; Dixon et al., 1997; Fujita and Poyatos de Paz, 1998; Gruhn and Bryan, 2002; Fedje et al., 2004), and these recesses offer some protection from wave and tidal action in a submerged environment (Inman, 1983; Gusick and Faught, 2011). Faught (2002–2004) has shown that submerged karst features, such as those in the Gulf of Mexico, usually contain well-preserved archaeological evidence. Also, shallow bays tend to impose a limited amount of site disturbance from tidal action or storm surges, and site protection from wave energy often occurs on the leeward side of coastal islands and within archipelagos (Flemming, 1983, 138). Gusick and Faught (2011, 36) noted that "Coastlines with gently sloping continental shelves, particularly in locales with reduced wave action, would have been quickly inundated during sea level rise, promoting rapid sedimentation and therefore protection of archaeological sites from environmental elements." According to Dean et al. (1992, 31) and Muckelroy (1978, 52), the anaerobic environment that often occurs in the seabed is favorable for the preservation of organic material associated with archaeological sites.

Even in regions in which conditions are generally favorable for preservation of submerged archaeological sites, various geologic, oceanographic, and meteorologic factors may compromise the preservation of cultural deposits (Gusick and Faught, 2011). While the geomorphology of eastern Pacific coastal environments is characterized by rocky shores and deep basins that provide enclaves and rock-shelters generally favorable for the protection of submerged archaeological sites, the powerful wave action in this area of the world can erode away sea cliffs and cut marine terraces (Inman, 1983; Gusick and Faught, 2011), thereby destroying evidence of prehistoric occupation. In areas with reduced wave action, such as the Gulf of Mexico and Gulf of California, site preservation may be more likely than those areas exposed to the open ocean, but the frequent hurricanes that occur in these regions may destroy or severely modify submerged cultural deposits (Gusick and Faught, 2011).

Stewart (1999) noted that for shipwrecks and coastal archaeological sites, once submergence occurs, the single most important factor for preservation is rapid deep burial by sediment. A thick mantle of sediment "protects the artifacts themselves and their spatial patterning from destruction by water and marine organisms" (Stewart, 1999, 565). When shipwrecks and sites are on the seafloor or shallowly buried in marine deposits, they may be modified or destroyed by natural and/or anthropogenic processes. A range of marine animals that live on the seafloor, such as crabs and lobsters, are known to burrow into sediment, and their burrowing activity can disturb artifacts (faunalturbation) and allow a greater amount of oxygen to penetrate into bottom sediment via their burrows (Stewart, 1999). Oxygenation, in turn, can promote bacterial growth and thereby cause degradation of organic artifacts. Also, the roots of benthic marine plants, especially ubiquitous sea grass, can disturb cultural deposits (floralturbation). Common anthropogenic processes that affect shipwrecks and submerged sites include salvaging, treasure hunting, dredging, and offshore construction.

Postdepositional processes

After artifacts and cultural features are emplaced on the land surface, physical and chemical processes may alter the spatial and compositional character of the archaeological deposits (Leigh, 2001). The major physical (geologic and biologic) processes that can affect the spatial distribution of artifacts are mass movement and pedoturbation. With mass movement, materials move downslope mostly under the influence of gravity, though water may lubricate and assist in the transport. Mass movement may be a slow process, such as creep, solifluction, and subsidence, or it may be rapid, as is the case with mudflows, landslides, and rockfalls (Rapp and Hill, 2006, 99). Pedoturbation, or soil mixing, includes a variety of processes driven by different vectors (Table 1).

Common postdepositional chemical processes that affect cultural deposits include oxidation, carbonation, and humification. These processes generally are associated with weathering and soil formation, and they involve water and other soluble components in soil solution. In archaeological settings, the consequences of chemical weathering are the breakdown or decomposition of lithic and metal artifacts, ceramics, and organic materials, such as bone, shell, and wooden artifacts.

Postdepositional alteration of cultural deposits is frequently attributed to pedoturbation. Bioturbation is one of the most common forms of pedoturbation and often affects archaeological sites. There are two general categories of bioturbation, floralturbation and faunalturbation, which are the mixing of soil and sediment by plants and animals, respectively. Floralturbation processes that affect cultural deposits are mostly associated with trees. Schiffer (1987) noted that, in wooded areas, artifacts and features are often displaced or severely damaged by tree roots soon after site abandonment. Tree roots put tremendous pressure on objects in the soil (Wood and Johnson, 1978; White, 1979), and the in situ disintegration and decay of large, deep tree roots contributes to the vertical movement of artifacts through the soil profile. Root decay produces hollow cavities and tunnels that may collapse, subsequently filling with younger sediments (Macphail and Goldberg, 1990). As the root cavity fills, artifacts at the surface may fall into the root hole thereby becoming translocated and buried within the substrate (Waters, 1992, 309).

Trees are even more destructive when they are blown over by the wind, a process known as tree throw (Schaetzl et al., 1990; Waters, 1992, 307; Rapp and Hill, 1998, 83–84). When a tree throw occurs, the soil and archaeological material entwined in the roots are pulled away from the substrate, leaving a shallow, craterlike depression. Eventually, the soil and cultural debris adhering to the root mass fall back into the depression or accumulate in a mound adjacent to the crater. In a matter of several 100 years, tree throws can significantly rework surface sediment in forested areas. The constant churning of the soil resulting from this process can destroy the spatial patterning of cultural deposits at a site (Waters, 1992, 307). On relatively stable geomorphic surfaces, artifacts may become buried when they fall into tree-throw craters. Holmes (1893) demonstrated that buried artifacts collected from glacial till at the Babbitt site in Minnesota were translocated downward to a depth of more than 1.25 m by tree throws.

Faunalturbation is caused by a variety of fossorial (burrowing) animals, including mammals, earthworms, ants, termites, and other arthropods. Fossorial mammals include small rodents such as gophers, mice, moles, prairie dogs, ground squirrels, gerbils, and cavies as well as larger animals like beavers, foxes, badgers, rabbits, and armadillos. Several studies have shown that burrowing mammals turn over a large quantity of soil and sediment annually (Bocek, 1986; Ohel, 1987; Wood and Johnson, 1978). During burrow construction and maintenance, they commonly move smaller artifacts up while burrowing

Site Formation Processes, Table 1 Major types of soil and sediment disturbance/mixing and the general direction of artifact movement

Process		Type of disturbance or mixing process	General direction of artifact movement
Alluvial		Natural: displacement by stream flow	Downstream. Also, winnowing of fines resulting in superposition of artifacts
Eolian		Natural: displacement by wind	The direction of the wind. Also, winnowing of fines resulting in superposition of artifacts
Mass movement/ graviturbation		Natural: displacement by slope processes, such as solifluction, creep, and landslides	Downslope
Cryoturbation		Natural: mixing by freeze-thaw activity	Up and laterally in sediment
Argilliturbation		Natural: mixing caused by shrink-swell processes associated with expandable clay minerals	Up and down
Aquaturbation		Natural: mixing by water moving forcefully through soil or sediment, such as a spring boil	All directions
Crystalturbation		Natural: mixing by the growth and wastage of crystals, such as salt, gypsum, and ice	All directions
Impacturbation		Natural and anthropogenic: mixing when large objects strike the ground. Includes bombs that hit the ground and explode	All directions
Seismiturbation		Natural: mixing by earthquakes and the surficial settling that occurs after them	Down
Bioturbation	Faunalturbation	Natural: mixing by the activities of burrowing animals	Small artifacts tend to move up and large artifacts tend to move down. With biomantle formation, all artifacts can be buried and appear to move down
	Floralturbation	Natural: mixing by the activities of plants	Root growth: all directions Root decay: down Tree throw: all directions and can cause inverted stratigraphy and mixing of assemblages
Trampling		Natural and anthropogenic: displacement by animals or people walking on soil or sediment	Down
Digging		Anthropogenic	Selected artifacts removed, others redeposited randomly
Collecting		Anthropogenic	Selected artifacts removed, others redeposited randomly

Sources: Schaetzl and Thompson (2015) and Goldberg and Macphail (2006)

under larger objects. Eventually the larger objects collapse into the burrow, moving them down in the profile (Bocek, 1986, 591). As a result of this process, some "observable stratigraphy" may actually represent rodent-related "horizons" (Bocek, 1986, 601). In some cases, one type of animal disturbance can attract another fossorial animal. For example, the matrix of krotovina (soil-filled animal burrows) typically has a lower bulk density and is softer than the surrounding soil or sediment. Consequently, worms are attracted to the krotovina, and their actions account for substantial mixing of material across the boundaries of the original burrow (Pietsch, 2013).

A number of studies have reported how earthworms bury surface-occurring artifacts and features beneath their castings (Darwin, 1881; Shaler, 1891; Atkinson, 1957; Wood and Johnson, 1978; Rolfsen, 1980; Stein, 1983; Johnson and Watson-Stegner, 1990; Balek, 2002; Johnson, 2002; Van Nest, 2002; Peacock and Fant, 2002; Canti, 2003). Rolfsen (1980), for example, demonstrated that earthworms can bury items to a depth of 45 cm below ground surface in about 5 years. Hence, worm castings, combined with soil brought to the surface by ants, burrowing mammals, and uprooted trees, form a biomantle that may quickly conceal artifacts and cultural features on otherwise stable surfaces (Johnson, 1990; Johnson, 1992; Van Nest, 2002). Biomantle formation eventually results in the gradual burial and "downward gravitational displacement" of materials that originally lay on the surface (Balek, 2002, 43). Several researchers have described the role that biomantle formation plays in the burial of upland archaeological sites (e.g., Leigh, 2001; Balek, 2002; Bettis and Mandel, 2002b; Johnson, 2002; Peacock and Fant, 2002; Van Nest, 2002; Johnson et al., 2005).

Other natural mixing processes that often contribute to the disturbance of cultural deposits are cryoturbation and geliturbation. Cryoturbation is associated with permafrost and seasonally frozen ground and is the mixing of soil and sediment by freeze-thaw activity, as ice crystals repeatedly form and melt. Seasonal freezing and thawing of the ground causes buried objects to move up through a soil profile and horizontally across the ground surface (Johnson and Hansen, 1974; Wood and Johnson, 1978; Bowers et al., 1983; Van Vliet-Lanoë, 1985; Bertran, 1993; Bertran, 1994; Van Vliet-Lanoë, 1998). In a series of experiments, Johnson and Hansen (1974) and Johnson et al. (1977) demonstrated that in a single cold season, freeze-thaw action can vertically displace an artifact as much as 10 cm. According to Bowers et al. (1983), such displacement can be as great as 20 cm.

In addition to frost heaving, cryoturbation produces frost cracks and involutions (deformation structures) in soils and sediments. The effect of frost cracks on cultural deposits is similar to that of cracking produced in vertisols (see below), which allows artifacts to be displaced downward and mixed lower in the soil or body of sediment. The formation of involutions, including undulations or folds, also may displace artifacts.

Because seasonally frozen ground affects nearly 50 % of the land area of Earth (all high latitudes and most middle latitudes) (Holliday, 2004, 278), cryoturbation has a significant global impact on cultural deposits. Schweger (1985, 127) considered this impact, noting that "The greatest handicap to northern archaeology is frost disturbance and its effects on archaeological matrix and the artifacts themselves." Case histories of cryoturbation effects on soils in archaeological contexts, however, are relatively rare (Holliday, 2004, 278), though reviews by Bobrowsky et al. (1990), Thorson (1990), and Wilson (1990) provide examples.

Geliturbation, which also occurs in regions where there is permafrost, is a product of gelifluction (also called solifluction), the slow downslope movement of saturated soil above permafrost. Gelifluction usually involves large saturated masses (lobes) of soil whose cohesive forces have been weakened by repeated freeze-thaw activity; it can occur on very gentle slopes (Schaetzl and Thompson, 2015, 257). This process causes dramatic involutions of surface horizons of soils and is widely reported from cold-climate archaeological sites (e.g., Thorson and Hamilton, 1977; Schweger, 1985; Thorson, 1990). Gelifluction can significantly affect archaeological sites by burying cultural deposits, transporting artifact downslope, and/or inverting cultural horizons. For example, at the Iyatayet site on Cape Denbigh, on the west coast of Alaska, the type Denbigh Flint Complex was found in a buried A horizon of a podzolic soil (Hopkins and Giddings, 1953). The soil and associated cultural deposits had been completely folded by gelifluction lobes before burial.

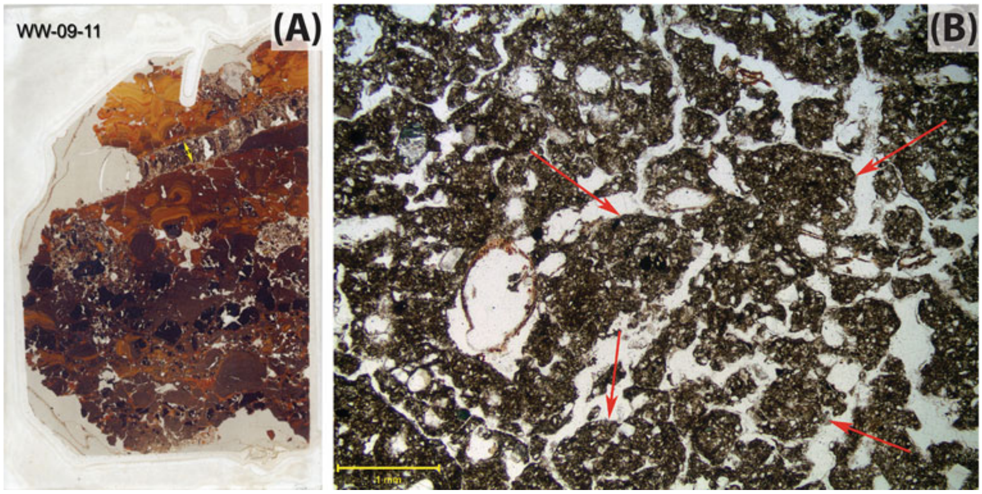
Argilliturbation is another common form of pedoturbation that involves the mixing of soil as a result of the shrinking and swelling of expandable clay minerals, such as smectite. Expandable clays tend to shrink during dry periods, causing large vertical cracks to form at the surface. These cracks are usually <10 cm deep, but under very dry conditions, they can reach depths of over one meter. Artifacts and other surface material can fall into these cracks when they are open. As the moisture content in soil increases, the expandable clay minerals swell, and the cracks close. This process results in the burial of any artifacts that fell into the cracks (Wood and Johnson, 1978; Schiffer, 1987).

Soils defined by extreme amounts of argilliturbation due to high amounts of smectite clays, in a wet-dry climate, are designated as vertisols in the USDA-NRCS system of soil classification (Soil Survey Staff, 2014). The name is derived from the Latin *vertere*, "to turn over or invert." Soils that have high shrink-swell capability but that do not meet the qualifications of vertisols are described as "vertic."

The mixing processes associated with vertisols and vertic soils can have significant effects on artifacts and cultural features. Vertisols are capable of forcing buried artifacts up to the surface and providing pathways for surface materials to move down into the soil (Holliday, 2004, 276). Duffield (1970, 1055), an archaeologist who excavated sites in vertisols in east central Texas, described the effects of these soils, noting that they can "churn archaeological features into a homogeneous mass and totally destroy the original context of a site." At the Cave Spring site in Tennessee, Hofman (1986) determined that artifacts spanning 7,000 years of prehistory were moved vertically 20–40 cm in a buried soil with vertic properties. During the excavation of a site on Crete, Morris et al. (1997) recorded Middle Minoan period artifacts on the surface of a vertisol and at depths of 30–100 cm. Based on the results of laboratory analyses, they concluded that there were no buried Minoan living surfaces and that the artifacts moved downward through cracks in the vertisol.

Field observations (such as documenting the location and angle of repose of artifacts) and recording the abundance and spatial pattern of disturbance features (such as krotovina) are necessary to determine whether the vertical and/or horizontal integrity of cultural deposits has been compromised by processes of postdepositional mixing. Physical evidence of disturbance must be precisely recorded in the field so the information can be used during analysis of the site and assessment of the integrity of the archaeological materials. In some cases, laboratory methods, including grain-size analysis, soil micromorphology (Figure 4), scanning electron microscopy (SEM), three-dimensional scanning, and numerical dating, can help identify soil and sediment disturbances that are not easily detected in the field (Leigh, 2001; Goldberg and Macphail, 2008; Grosman et al., 2011). Information gleaned from laboratory analyses can be used both to identify disturbances and corroborate field observations of depositional and postdepositional processes (Goldberg and Macphail, 2008). Refitting of artifacts and/or bone can also inform researchers about disturbance, even when there are no visible signs of disturbance (Villa, 1982, 287). However, refitting evidence must be used with caution, because the presence of conjoinable items does not mean disturbance has not occurred (Schick, 1987, 102). Hence, refitting evidence is best used in combination with other methods to assist in identifying site disturbances.

According to Michie (1990), several aspects of the archaeological record are indicative of postdepositional mixing processes, especially bioturbation. They include the following:



Site Formation Processes, Figure 4 (**a**) Thin-section scan of pre-cultural deposits at Wonderwerk Cave, South Africa. The contorted phreatic deposits shown here have been penetrated by a 1-cm-wide biotubule (*arrow*). The thin section measures 50 × 75 mm, plane-polarized light (*PPL*), from Goldberg et al. (2015). (**b**) Photomicrograph of a thin section from the upper 10 cm of the ABb horizon at site 32RY473, a heavily bioturbated, multicomponent Woodland occupation located on a beach ridge at Devils Lake in northeastern North Dakota. Note the parts of earthworm casts (*arrows*) and granular matrix (PPL) (From Mandel and Goldberg (2011)).

1. A strong relationship exists between the maximum artifact depth and the visible depth of pedoturbation; for example, artifacts do not continue below the deepest krotovina or root well.
2. Artifacts are oriented >0–90° to the horizontal, i.e., not resting flat on former surfaces.
3. There is an absence of intact cultural features such as hearths.
4. Vertical and horizontal displacement separates artifacts that would otherwise be found together.
5. Evidence of a single behavior activity (i.e., core reduction) or artifact (broken pot) is found mixed throughout the soil.

Michie (1990) also argued that stratified cultural horizons often reveal vertical translocation of artifacts, suggesting that older artifacts have more time to descend within the profile through bioturbation even while vertical separation between cultural strata remains relatively intact. This contrasts with other models (e.g., Bocek, 1986) that point to postdepositional mixing processes as driving forces that modify archaeological deposits while obliterating original features such as primary bedding.

Leigh (2001) considered Michie's (1990) model and noted that the degree of vertical separation of cultural material probably depends on two factors: the types of burrowing organisms that have operated at the archaeological site and the grain-size distribution of the sediment. Leigh (2001, 281–282) points out that "Ants and worms are not capable of moving large artifacts up to the ground surface, which may help preserve vertical separation of cultural strata, whereas larger animals (i.e., gophers, tortoises) are capable of bringing artifacts larger than 3 cm up to the surface. Thus, while the overall integrity of cultural stratigraphy may remain intact, some degree of mixing is to be expected."

Caves and rock-shelters

Archaeological research has focused on caves and rock-shelters for more than a century, especially in Europe (Bordes, 1972; Goldberg and Mandel, 2008). Caves and rock-shelters have yielded significant components of the early archaeological record, including fossil hominins, faunal and floral remains, and extensive assemblages of lithic tools. Some of the earliest evidence of fire use comes from Wonderwerk Cave in South Africa (Berna et al., 2012; Goldberg et al., 2015), Zhoukoudian in China (Goldberg et al., 2001), and Qesem Cave in Israel (Karkanas et al., 2007), as well as from Middle Paleolithic cave sites in Europe (e.g., Abric Romaní (Vallverdú et al., 2012) and Roc de Marsal (Goldberg et al., 2012; Aldeias et al., 2012)) and the Middle East (e.g., Kebara Cave (Meignen et al., 2007)). Caves and rock-shelters also have been the focus of archaeological research concerned with the peopling of the New World, especially South America. Cave sites in the Peruvian Andes, including Telarmachay, Uchumachay, Lauricocha, Huargo, Guitarrero, Pachamachay, Pikimachay, and Panaulauca, have yielded finds suggesting that people were in the region as early as 20,000–15,000 BP, and in eastern Brazil, the rock-shelter at Pedra Furada has produced disputed evidence for human occupation over 30,000 years ago.

Caves and rock-shelters are commonly associated with karstic processes involving dissolution and precipitation of carbonates. However, they can also be found in noncalcareous bedrock, including sandstone (e.g., Meadowcroft Rockshelter (Donahue and Adovasio, 1990)) and quartzites (e.g., numerous sites in South Africa (Marean et al., 2000; Marean et al., 2010; Karkanas and Goldberg, 2010)). In the Great Basin of North America, rock-shelters are associated with former shorelines of pluvial lakes where wave action has created or enlarged them (Rhode et al., 2005; Goebel et al., 2007; Jenkins, 2007). Farther north, on the Snake River Plain of eastern Idaho, caves are often associated with collapsed lava tubes (e.g., Owl, Coyote, and Dry Cat caves comprising the Wasden site (Moody and Dort, 1990)). Also, rock-shelters form by fluvial undercutting of bedrock valley walls. As an illustration, Bonfire Shelter in southwest Texas is a product of fluvial undercutting of a cliff face in Mile Canyon when the elevation of the canyon floor was 18 m higher than it is today (Dibble and Lorrain, 1968).

Depositional processes

Unlike open-air sites, which are open depositional systems, caves and rock-shelters are closed or nearly closed systems. In most cases, what enters the cave/rock-shelter tends to stay there, and thus these sites safeguard detailed records of geologic processes and human activities. However, despite being relatively protected, caves, and especially rock-shelters, are not always isolated from geomorphic and biological processes that may reshape cultural deposits in these settings, and their sedimentary deposits can be subject to physical and chemical modifications (see below).

Sediments derived from within the cave/rock-shelter environment are locally formed, i.e., autochthonous (Goldberg and Sherwood, 2006), and a main depositional process that creates them is attrition – the grain-by-grain disintegration of sandstone or bioclastic limestone, which produces a steady rain of sediment to the floor of a cave or rock-shelter (Donahue and Adovasio, 1990; Mandel and Simmons, 1997) or the accumulation of larger rock and roof fall, *éboulis* (Laville et al., 1980). In both cases, material can be dislodged from the bedrock and deposited on the cave or rock-shelter floor as a result of any one of a number of processes, including hydration, freeze-thaw, salt and solution weathering, and tectonics.

Along with the generally coarse autochthonous sediment (sand sized and larger), finer-grained material, such as clay derived from soil outside the cave or rock-shelter, can be introduced by infiltration of dripping water along joints in the bedrock. Such dripping not only results in the formation of distinct layers of clay but also more subtly as clay coatings and void infillings. Clay that enters a cave or rock-shelter from an external source is allochthonous sediment regardless of its geologic context.

Allochthonous sediments found within a cave or rock-shelter that derive from outside are often similar to sediments deposited at open-air sites. When streams are adjacent to or very near valley walls, coarse-grained sediment including sand and gravel may be delivered to rock-shelters and cave mouths through lateral accretion of point bars. In contrast, fine-grained alluvium (mostly silt and clay) held in suspension may be deposited during floods, a process known as vertical accretion. Rodgers Shelter in the western Ozark Highlands of Missouri exhibits a sequence of lateral and vertical accretion deposits (Ahler, 1976). This archaeologically rich shelter remained at or only a few meters above the elevation of the floodplain of the Pomme de Terre River throughout the Holocene. Similarly, the Abri de la Madeleine (Magdalene rock-shelter) in southwestern France, the type site for the Upper Paleolithic Magdalenian culture, is filled with alluvium from the nearby Vézère River (Laville et al., 1980).

Alluvium also occurs in karstic caves. For example, at Sheriden Cave, a Clovis habitation site in Ohio, fine-grained sediments display evidence of alluvial transport. In general, coarser sediments, including sand and fine gravel, were deposited near the cave entrance, and silt and clay were deposited in laminar layers in the lowest passages (Tankersley, 1997).

Eolian sedimentation in caves and rock-shelters includes both sandy and silty inputs. Many Paleolithic and Middle Stone Age sites contain abundant eolian sand deposits, which in most cases are tied to eustatic sea level changes (e.g., Tabun Cave, Israel (Goldberg, 1973); Die Kelders, Blombos, and Pinnacle Point sites in South Africa (Tankard and Schweitzer, 1974; Goldberg, 2000; Marean et al., 2010); Akrotiri *Aetokremnos* Rockshelter, Cyprus (Mandel and Simmons, 1997)). Finer eolian sediment consisting of silt and clay also occurs in caves and rock-shelters, although it normally is not volumetrically significant. Although eolian dust can blow directly into a cave, as was the case at the Middle Paleolithic/Upper Paleolithic sites of Hohle Fels and Geißenklösterle in Swabia, Germany (Hahn, 1988), it is often found in a secondary context, having been reworked and redeposited into the cave by runoff or colluvial processes. Dust Cave in Alabama is a good example of loess from the limestone plateau above the site being colluvially redeposited in the cave (Sherwood et al., 2004). In Paleolithic sites like Kebara, Tabun, Qafzeh, and Hayonim caves in Israel, eolian quartz silt that is embedded in *terra rossa* soils of the surrounding land surface (1) accumulated in the caves as a colluvial apron and/or sheetwash deposit at the entrance or (2) was washed through "chimneys" (dissolution features) that formed in the limestone roof (Goldberg and Bar-Yosef, 1998). In the case of colluvium, the accumulated deposits are poorly sorted and commonly form a berm below the modern or former drip line at the cave entrance. This sediment can be remobilized and carried back further into the cave, as at Dust Cave and Kebara.

Slope deposits consisting of allochthonous sediment are fairly common in rock-shelters and caves. There are two general types of slope deposits: colluvium and sheetwash. The term colluvium is used to describe poorly sorted deposits of sediment transported chiefly by gravity. Sheetwash (or slope wash) is well-sorted laminated

Site Formation Processes, Figure 5 Photograph of modern-day runoff at Kebara Cave, Israel, produced by a thunderstorm in October of 1985. Water is flowing from the entrance to the back of the cave along a depositional slope produced by sediment accumulating at the brow of the cave beneath the overhang. Two 20 l jerry cans are introduced for scale.

sediment that has been moved down a slope predominantly by the action of gravity assisted by water in the form of sheet flow or concentrated flow in rills (Figure 5). Slope deposits may form a berm or talus cone in front of a rock-shelter or cave entrance (Figure 6). From there, they can be washed back into the shelter or cave by runoff or high-density mudflows.

Marine deposits occur in archaeological caves, but they are not particularly common. These deposits usually consist of littoral boulders at the bottom of stratigraphic sequences, as is the case at Gorham's Cave, Gibraltar (Goldberg and Macphail, 2012), or littoral sands, such as those that occur at the bottom of the sequence in Contrebandiers Cave, Morocco (Aldeias et al., 2014).

Human activities represent an understudied aspect of depositional processes in caves and rock-shelters. Human-derived materials are obvious and widespread in caves and rock-shelters around the Mediterranean, especially those with Holocene deposits (Woodward and Goldberg, 2001); however, significant human inputs are also noteworthy from Paleolithic and Middle Stone Age (MSA) sites in the Old World and Africa (Figure 7). Typically, anthropogenic deposits consist of sediments and materials directly related to burning (e.g., hearths, fire-cracked rock, charcoal, ashes, burned soil, and bones), eating (bones and plant remains), and sleeping (material used for mats) or to activities that redistribute sediments and materials, such as hearth rake-out, sweeping, and dumping of ashes and charcoal (Meignen et al., 2007; Miller et al., 2010; Turq et al., 2011; Wadley et al., 2011; Speth et al., 2012). In certain cases, such as Kebara and Hayonim caves in Israel, anthropogenic accumulations constitute the majority of the depositional fill and substantially exceed geogonic contributions. Prominent anthropogenic deposits also have been documented in caves and rock-shelters in the USA, including Dust Cave in Alabama, Movie Draw Rockshelter in the Black Hills of South Dakota, Burntwood Creek Rockshelter on the High Plains of western Kansas, and Danger Cave in the Great Basin region of Nevada (Figure 8).

Another depositional factor that has been underestimated is that of biological additions and modifications. Bat and bird guano are common in modern cave and rock-shelter deposits, but in Pleistocene deposits, it is difficult to detect them directly in the field. However, guano can be documented by micromorphological analysis (Karkanas and Goldberg, 2010; Goldberg and Macphail, 2012). Indirect evidence is more readily apparent in the form of extensive diagenesis in cave deposits, which is clearly brought about by the former presence of bat guano (Karkanas et al., 2000; Weiner et al., 2002) (see below). Other biogenic inputs in caves and rock-shelters include the products of denning activities by carnivores and omnivores (Goldberg and Macphail, 2006, 179). Hyenas and bears, for example, can produce large accumulations of bones, coprolites, and organic matter (Horwitz and Goldberg, 1989; Andrews et al., 1999; Goldberg, 2001; Schiegl et al., 2003).

Postdepositional processes

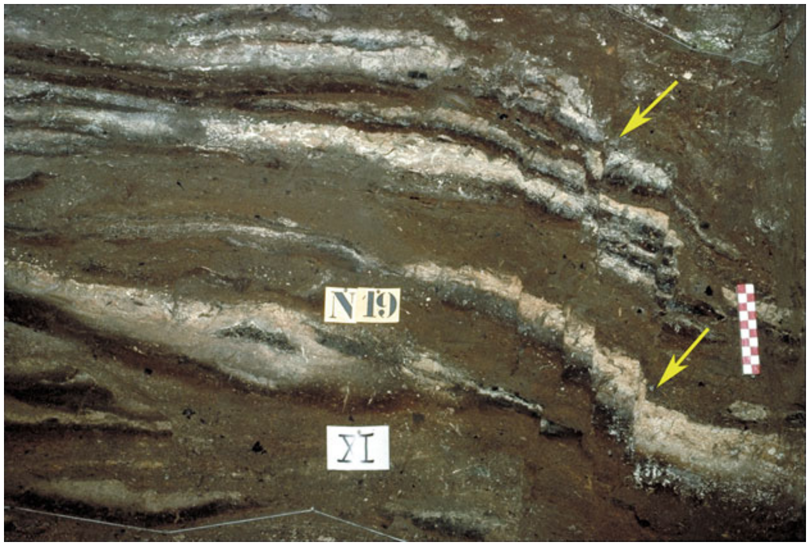
Postdepositional processes, both physical and chemical, are generally described using the term "diagenesis." They are particularly important in caves and rock-shelters where karstic processes and biological additions can seriously alter the nature of the sediments and consequently affect the integrity of the archaeological record. Physical changes can entail movements of bones, lithics, and other anthropogenic components by the depositional processes outlined above, and sheetwash and deflation by wind can transport materials further back into a cave or rock-shelter and, at the same time, selectively sort the materials left behind. Colluviation and slumping can completely displace and dismantle features (e.g., hearths and bedding) or archaeological material from their original positions. Such reworking is readily seen at Dust Cave (Sherwood and Goldberg, 2001) and Kebara Cave (Goldberg et al., 2007). Similarly, ongoing dissolution of limestone caves – roofs, walls, and bedrock floor – can result in differential subsidence and settling of the deposits, expressed as slumping and faulting (Figure 9).

Site Formation Processes, Figure 6 View of the entrance (*arrow*) of Dust Cave, Alabama, located along a limestone bluff face. Visible is a berm of clayey and silty deposits that have washed over the bluff and accumulated as a berm at the cave entrance.

Site Formation Processes, Figure 7 A series of finely bedded combustion layers at Roc de Marsal, a Paleolithic cave in the Dordogne region of France. Similar anthropogenic layers represent most of the deposits at the site.

Site Formation Processes, Figure 8 Early Archaic components (8500–8000^{14}C year BP) at the Danger Cave rock-shelter site in the Bonneville Basin of western Utah contain 5–15-cm-thick beds of well-preserved plant materials (*arrows*), including chaff from pickleweed that was processed in the rock-shelter for its seeds (Photograph courtesy of David Rhode).

Chemical alterations can be important processes in caves and rock-shelters. The most common and well known is the precipitation of calcium carbonate, recognized mostly in the form of stalactites/stalagmites, bedded layers (flowstone/travertine), or massive impregnations of matrix material, so-called cave breccia (Karkanas et al., 2007). A recent study of the Cave 13B deposits at Pinnacle Point, South Africa, revealed massive impregnations of calcite



Site Formation Processes, Figure 9 Combustion layers at Kebara Cave that have been faulted (*arrows*) due to subsidence of the deposits into a karstic cavity. Scale is 20 cm long.

Site Formation Processes, Figure 10 Massively cemented deposits at Cave 13B, Pinnacle Point, Mossel Bay, South Africa. These deposits were cemented at a time of massive root growth producing calcified roots (rhizoliths), which are indicated with *arrows*. Meterstick in the center is 1 m long.

(Figure 10) from an extensive mat system of fine roots (Karkanas and Goldberg, 2010).

In addition, dissolution and mineralogical alterations are common in cave deposits. Guano, organic acids, and associated acidic dripping waters can partially or completely dissolve carbonate, resulting in the formation of other minerals, such as gypsum (Shahack-Gross et al., 2004). In some instances, dissolution can significantly reduce the volume of the original deposits (up to 50 %), as at Die Kelders Cave, South Africa (Goldberg, 2000). In places where extreme diagenesis occurs, major mineralogical transformations can cause the formation of various phosphate minerals, along with the breakdown of clays, and ultimately the neoformation (precipitation) of silica (Weiner et al., 2007). The ramifications of such transformations involve the complete destruction of bone from all or parts of the cave or rock-shelter and concentration of radioactive isotopes. Awareness of such diagenetic changes, therefore, allows for more accurate dating of deposits and a better understanding of the spatial distribution of bone across a site, which may not be related solely to human activities but rather to postdepositional biogeochemical ones.

Methods of analysis

Many of the methods used to unravel site formation processes in caves and rock-shelters are the same as the ones used at open-air sites. Sedimentological analyses typically include a relatively standardized set of analytical techniques, such as grain-size analysis, assessment of clast and grain morphology, analysis of heavy minerals (those with high specific gravities), and other mineralogical analysis using X-ray diffraction. A number of chemical analyses are also employed, such as measuring the amount of organic matter, calcium carbonate, and phosphate. These analyses are typically conducted on bulk samples collected from primary stratigraphic units.

Over the past several decades, micromorphology has become a powerful tool used by geoarchaeologists to study site formation processes in caves and rock-shelters (Courty et al., 1989; Goldberg and Macphail, 2006). This approach involves the examination of intact blocks of sediment under the petrographic microscope. The analysis of thin sections enables the researcher to observe mineralogical composition, size and shape of the particles, and the finer matrix. More importantly, because the original geometry of the components within the sample is preserved, it is possible to isolate depositional effects from postdepositional ones. Thus, original calcite from limestone *éboulis* can be distinguished from secondary (precipitated) accumulations of carbonate, and phosphates from bones can be distinguished from neoformed ones. Also, subtle biogenic features that are not visible to the naked eye can be detected in thin sections, thereby allowing the magnitude of bioturbation to be fully assessed.

Although micromorphology has been effectively used in many studies of site formation processes in caves and rock-shelters, optical microscopy has its limits, and more sophisticated analytical techniques are now more commonly combined with micromorphological analysis, particularly in the study of diagenesis, the stratigraphic integrity of cultural deposits, the reliability of radiocarbon and OSL ages, and the relative amount of geogonic versus anthropogenic sediments. For example, high-resolution stratigraphic and sedimentary analysis, including Fourier transform infrared (FTIR) spectrometry and FTIR microspectroscopy (μ-FTIR), and x-ray microfluorescence (μ-XRF) (Mentzer and Quade, 2013) have proven to be invaluable tools in evaluating the type and extent of diagenesis in archaeological contexts within caves and rock-shelters (e.g., Goldberg and Sherwood, 2006; Schiegl and Conard, 2006; Karkanas and Goldberg, 2007; Berna and Goldberg, 2008; Goldberg et al., 2009; Feathers et al., 2010; Mallol et al., 2010; Weiner, 2010; Wadley et al., 2011; Berna et al., 2012; Miller et al., 2013). Also, "in situ" study of materials within thin section has been enabled with the use of μ-FTIR techniques that permit, for example, evaluation of the degree of heating of bones and clays from prehistoric fireplaces (Berna et al., 2007; Berna and Goldberg, 2008; Jordá Pardo et al., 2008; Berna, 2010; Goldberg and Berna, 2010).
