ENCYCLOPEDIA OF GEOARCHAEOLOGY

Volume Editor

Allan S. Gilbert is Professor of Anthropology at Fordham University in the Bronx, New York. He holds a B.A. from Rutgers University, and his M.A., M.Phil., and Ph.D. in anthropology were earned at Columbia University. His areas of research interest include the Near East (late prehistory and early historic periods) as well as the Middle Atlantic region of the USA. (historical archaeology). His specializations are in archaeozoology of the Near East and geoarchaeology, especially mineralogy and compositional analysis of pottery and building materials. Publications have covered a range of subjects, including ancient pastoralism, faunal quantification, skeletal microanatomy, brick geochemistry, and two co-edited volumes on the marine geology and geoarchaeology of the Black Sea basin.

Aims of the Series

The Encyclopedia of Earth Sciences Series provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists. These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. Go to http://link.springer.com to visit the "Encyclopedia of Earth Sciences Series" online.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the Encyclopedia of Earth Sciences Series. For the past 25 years he has been the Executive Director of the Coastal Education and Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he was Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia; the Caribbean; South America; SW Pacific islands; Southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific, and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil, and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Electronic publication under ISBN 978-1-4020-4409-0 and
Print and electronic bundle under ISBN 978-94-007-4828-6

Springer Dordrecht, Heidelberg, New York, London

Printed on acid-free paper

Cover photo: Photograph of Structure 4 at the Ceren archaeological site, El Salvador, which functioned as the bodega (storehouse) for Household 4 in an ancient Maya village. The village was buried by tephra from the nearby Loma Caldera volcanic vent in about AD 650. The various layers of the phreatomagmatic eruption resulted in extraordinarily good preservation of structures, including the thatch roofs, as well as the foods and artifacts stored within the buildings. Image courtesy of Payson Sheets, University of Colorado.

Dedicated to Rhodes W. Fairbridge

(1914–2006)
with appreciation

Preface

"Geoarchaeology" is the archaeological subfield that uses the methods of geological investigation to gather information and solve problems in the exploration of the human past. Under the label of "archaeological geology," it is also the subfield of geology that explores geoscience aspects of human antiquity. In its varied manifestations, then, geoarchaeological research attempts to build collaborative links between specialists in archaeology and the Earth sciences and, in so doing, produce new knowledge about past human behavior by merging methods and concepts from the geosciences with those commonly applied by archaeologists.

Archaeological recovery and analysis are already geoarchaeological in the most fundamental sense because the buried remains left by former humans are contained within, and removed from, an essentially geological context, and many of the finds are themselves composed of earthen or rock materials. But geoarchaeology moves beyond this simple relationship to pursue a broad range of questions, many of which address the interactions and influences between humans and the environments in which they once lived. The proximate goals of geoarchaeology might be described as elucidating the processes of site formation, reconstructing ancient environments and the influence of humans on them at the local and regional levels, and learning which environmental factors were significant in the evolutionary emergence of humankind and the cultural changes undergone by the world's diverse societies over time. Tactically, the toolkit of research techniques, conducted in both field and laboratory contexts, includes analyses of soils, sediments, rocks, and landforms, and a wide range of geophysical, geochemical, and microscopic methods. At a finer scale of resolution, for example, the study of archaeological deposits to infer past human activities and behaviors – such as agriculture, pastoralism, and fire – lies firmly within the scope of geoarchaeology. There is an overlap of geoarchaeological methods covered in this work with techniques also considered to be part of archaeometry: materials analysis, dating, methods of site location and prospecting, and tracing raw and artifactual materials to their sources. The ultimate goal, like many other subfields of archaeology, is the recovery of new information that would permit fresh and more detailed interpretations of human antiquity.

Early studies of the natural world in Europe and America during the eighteenth and nineteenth centuries often included a concern for humans and their place in nature. Much initial prehistoric research in both hemispheres was in fact conducted by geologists, who took an interest in the remains of human activities (and the remains of humans themselves) deposited along with geological materials. In the 1950s and 1960s, a greater emphasis on environmental factors in archaeology led eventually to a "contextual approach" involving "geoarchaeological" investigations proposed by Karl Butzer in the 1970s. The subfield is therefore relatively young compared to archaeology and the geosciences in general. Yet, for archaeologists, the specialized preparation needed in order to understand the geological complexities of their research has made geoarchaeology relatively inaccessible to many. Most geoarchaeologists working today have had some interdisciplinary training in the Earth sciences, or their degrees were earned wholly in the geosciences. Such credentials are necessary for those exploring prehistoric periods, as they must acquire the expertise to obtain accurate dating of sites and finds, understand the depositional history of a site and its contents over long intervals, and reconstruct paleoenvironmental conditions to interpret ancient lifeways in their original settings. Archaeometric research holds a significant place in the archaeology of historical periods, but with some exceptions, field geoarchaeological practice and familiarity with its methods and knowledge base tend to be lesser components of archaeological research conducted on recent cultures and sites. New World historical archaeology tends to place little emphasis on geoarchaeological matters, while the archaeology of Roman and later periods in Europe is more likely to use it in the analysis of sites.

The potential benefit of geoarchaeological applications to all archaeological investigations has prompted the present volume. While specialized treatises on geoarchaeology began to appear in the 1960s and 1970s, it was Rhodes Fairbridge, founding editor of the Earth Science Encyclopedia Series (EEES), who proposed that an encyclopedic work on geoarchaeology be added to the list of published volumes. He enlisted a newly minted Ph.D. in Anthropology at Columbia University, Allan Gilbert, to help with the project, and the first publication contract was signed in 1981. The geoarchaeological landscape 35 years ago was distinctly incipient, with but a limited number of active practitioners engaged in research and publication, and a small body of basic knowledge that had already accumulated. Had that volume been realized, it would have been restricted to only the few geoarchaeological projects and subject areas that had been explored at the time, and much of the rest would have comprised entries on archaeological or geological topics. Sadly, but perhaps luckily, the contract was cancelled in the mid-1980s due to a change in publishers and a realignment of priorities at the new publishing house. The volume then began a lengthy search for a new agreement elsewhere. It did not find solid grounding with a new publisher until Springer offered to contract the project in 2002. Fairbridge passed away in 2006, and in the subsequent years Gilbert enlisted the assistance of four established geoarchaeologists (Paul Goldberg, Vance Holliday, Rolfe Mandel, and Rob Sternberg) to serve as associate editors and help assemble a new entry list that incorporated the advances and discoveries made within the subfield over the preceding two and a half decades. This volume is dedicated to the memory of Rhodes Fairbridge, whose appreciation for archaeology's contributions to Quaternary geoscience prompted his insistence that a reference work on geoarchaeology belonged within the stable of volumes he guided into print over his 40 years of editing the EEES.

This encyclopedia, appearing so many years after its initial conceptualization, contains data and discussion from a far wider range of practicing geoarchaeologists working within a far more mature discipline than would have been the case at its inception. It defines terms, introduces problems, describes techniques, and discusses theory and strategy, all in a language designed to make specialized details accessible to students and nonspecialists. It covers subjects in environmental archaeology, dating, prospection, materials analysis, soil and sediment investigation, and landforms, among other matters, and it includes a sampling of the most important sites known for their geoarchaeological contributions. The volume does not cover sites, civilizations, and ancient cultures that are less germane to the geoarchaeological focus and better described in other encyclopedias of world archaeology.

As mature as geoarchaeology has become, it is still a young and dynamic area of research. New applications are constantly emerging as the results of novel investigative techniques fill the pages of professional journals (notably *Geoarchaeology, An International Journal*; *Archaeological and Anthropological Sciences*; *Journal of Archaeological Science*; and *Archaeometry*), and as geoarchaeological approaches are aimed at different archaeological problems in different parts of the world. Original insights emanating from such developments will inevitably require revisions of this volume to keep up with progress, and coupled with the fact that lacunae remain in this book and will always exist in any comprehensive compilation, the *Encyclopedia of Geoarchaeology* will doubtless grow in detail and inclusiveness once this first edition appears. We look forward to constructive suggestions from readers about what is missing or in need of updating, as no editorial supervision will ever control the enormous diversity of innovation that will surely characterize the near future of geoarchaeology.

Acknowledgments

The editors wish to thank all the contributors for dedicating time to participate in this project, especially those who were prompt with their entry submission, then waited patiently while the lengthy editorial process steadily took its course.

Together with the support received from the advisory board, we obtained additional help from various persons in the course of volume preparation, and to these we express gratitude: Bruce Bevan, Jim Burton, Jim Dickson, Robert Folk, Charly French, Angelina Guarino, Gary Huckleberry, Rich Macphail, Patrick McGovern, Laura Murphy, Paul Renne, and Steven Shackley. Whether the help was substantial or slight, we value the counsel and effort that was given, and apologize to those we may have inadvertently left off the list.

Appreciation is offered to Payson Sheets for kindly providing the cover photograph depicting volcanic sediments covering the Mesoamerican site of Cerén.

Editing assistance was provided by Suanna Selby Crowley. Graphics contributions were made by Tony Layzell and Mark Schoneweis.

Franklin & Marshall College provided two semesters of sabbatical leave to Rob Sternberg enabling him to conduct much of his editorial activities.

Finally, we extend thanks to our editors at Springer (Petra van Steenbergen, Sylvia Blago, and Simone Giesler), as well as the successive editors of the Earth Science Encyclopedia Series (Rhodes Fairbridge and Charlie Finkl), the first who initiated plans for the present volume, and the second who encouraged and followed the project to its completion.

Definition

'Ain Ghazal ("Spring of the Gazelles") is a major Neolithic settlement located near Amman in northwestern Jordan. The site is situated on footslopes and toeslopes in the Zarqa River valley, the second largest tributary of the Jordan River. Archaeological excavations were conducted at 'Ain Ghazal during seasons beginning in 1982. Although a relatively small portion of the site has been excavated, the findings have been remarkable and have brought about the reevaluation of some basic assumptions regarding Neolithic life (Simmons, 2007). The most significant discoveries at the site relate to chronology, size and population, economy, ritual and artistic life, ecological adaptation, and the ultimate abandonment of the site.

Covering an area of at least 12 ha, 'Ain Ghazal is three times the size of Jericho and represents one of the largest aceramic Neolithic sites recorded in the Near East. Hence, it probably was a major population center, although the entire site may not have been occupied at the same time. At its peak, 'Ain Ghazal probably had a population of several thousand people, but after 8,500 cal years BP, the population dropped sharply.

Based on a large suite of radiocarbon ages, a major occupation occurred at 'Ain Ghazal between ca. 10,200 and 8,000 cal years BP, which corresponds to the Pre-Pottery Neolithic B (PPNB) (Simmons et al., 1988). There also was an occupation during the succeeding Pre-Pottery Neolithic C, and the site continued to be occupied into the Pottery Neolithic component, locally known as the Yarmoukian (Rollefson, 1993). The Yarmoukian component at 'Ain Ghazal dates to ca. 7,700 cal years BP (Kafafi et al., 2012: 27). In addition, Chalcolithic pastoralists appear to have occupied the site during two brief intervals around 7,200 and 6,500 cal years BP (Zielhofer et al., 2012). Aceramic and ceramic components often occur at major Neolithic sites, but they are often separated by a hiatus in the period of occupation. This is not the case at 'Ain Ghazal; a transitional phase from aceramic to ceramic was documented, the aforementioned Pre-Pottery Neolithic C (PPNC) (Simmons et al., 1988). The PPNC component shares elements common to both the PPNB and Yarmoukian, yet it is unique in many ways.

The recovery of abundant faunal and floral remains at 'Ain Ghazal provided a wealth of information about subsistence strategies during the periods of occupation. Goats dominate the faunal assemblage and, along with cattle, were used in a domestic sense (Köhler-Rollefson et al., 1988), although they may not have been morphologically domestic (Simmons et al., 1988). Also, a remarkable variety of wild animals were consumed at the site during the PPNB, with over 50 taxa identified in the assemblage, although by the second half of the 8th millennium, the wild component drops dramatically (von den Driesch and Wodtke, 1997). Gazelle, pig, hare, fox, and turtles are especially abundant. Plant foods appear to be dominated by legumes (primarily peas and lentils), though wheat, barley, chickpea, fig, and a wide variety of wild plants also were consumed (Donaldson, 1984; Neef, 2004).

'Ain Ghazal contains remarkably sophisticated and well-preserved architecture. During the Middle PPNB, housing consisted mostly of two-roomed rectangular dwellings with walls made of stones set in mud mortar. The interior faces of the structures were covered with

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

mud plaster and coated with a thin layer of fine plaster, often decorated with red ochre. Floors were made of a high-quality plaster burnished to a high gloss and usually painted with red ochre. Sunken plastered hearths occur in the main living quarters, and often second rooms appear to have functioned as storage and food-processing areas. Wooden posts ran up some of the walls and from central portions of the floors to support the roof.

The most spectacular discovery at the site was two caches of human statues and busts in the Middle PPNB levels. The statues are 80–100 cm tall and consist of high-quality white plaster around a core of bundled reeds; the busts also are made of plaster. In all, 32 plaster figures were recovered, 15 full figures, 15 busts, and two fragmentary heads. The statues have painted clothes, hair, and, in some cases, ornamental tattoos or body paint. The alignment of the statues in two tiers and the arrangement of the busts in an arc at the feet of the statues point to ritual behavior at 'Ain Ghazal.

Additional ritual behavior at 'Ain Ghazal is evidenced by smaller clay figures, including numerous human and animal figurines. Also, the treatment of the dead is strongly ritualistic. In most cases, the deceased individual was placed in a flexed position beneath the floor of a dwelling, and the burial pit was then plastered over. Sometime later, the burial was exhumed and the skull was removed. The location of most of the detached skulls is unknown; only a few caches of 13 skulls with evidence of plaster have been recovered (cf. Bonogofsky, 2001).

Clearly, the Middle and Late PPNB was a period of prosperity at 'Ain Ghazal, as indicated by the presence of a rich variety of domestic and wild animal and plant resources, an unprecedented level of artistic achievement, numerous animal and human figurines, remarkable statuary, and highly evolved ritual behavior (Rollefson and Simmons, 1987; Simmons et al., 1988). Also, sophisticated architecture evolved during this period, and during the Late PPNB, virtual "apartment houses" were constructed to house up to three to four families (Rollefson, 1997). However, perhaps as early as the PPNC, and certainly by the Yarmoukian, a dramatic shift in the subsistence strategy occurred that led to the abandonment of the site (Köhler-Rollefson and Rollefson, 1990). From heavy reliance on domesticated plants and animals, but supplemented by wild resources, the economy changed to one that relied on pastoralism, with goats or sheep (or both) becoming the primary food source (Simmons et al., 1988). The areal extent of 'Ain Ghazal decreased significantly during the Yarmoukian, and the archaeological record suggests that the village became impoverished and may have been occupied on a seasonal basis.

The results of a geoarchaeological investigation at 'Ain Ghazal indicate that the landscape became unstable toward the end of the PPNB and especially during the PPNC and Yarmoukian periods (Mandel and Simmons, 1988). Also, there is evidence for increased aridity during these periods (Zielhofer et al., 2012). Erosion was stripping soil off the steep sideslopes above the site, and sheetwash was depositing the "soil sediment" on the footslopes and toeslopes, resulting in burial of successive occupations. So what drove the landscape instability? At 'Ain Ghazal, it is likely that nonirrigated cultivation and animal husbandry initially were complementary subsistence strategies before a critical population size was reached and before the local environment began to deteriorate (Simmons et al., 1988). As the economy shifted to a strong dependence on goats and sheep, it is likely that overgrazing affected the fragile environment and accelerated soil erosion. Degradation of the environment would have forced the inhabitants of 'Ain Ghazal to move their goat herds farther and farther away. In sum, the environmental degradation caused by over 3,000 years of intensive land use during the Neolithic, combined with aridification, may have rendered the landscape surrounding 'Ain Ghazal incapable of supporting a major agriculturally based community, leading to the abandonment of the site around 7,000 years ago.

AKROTIRI *AETOKREMNOS*, CYPRUS

Rolfe D. Mandel[1] and Alan H. Simmons[2]
[1]Department of Anthropology, University of Kansas, Lawrence, KS, USA
[2]Department of Anthropology, University of Nevada Las Vegas, Las Vegas, NV, USA

Akrotiri *Aetokremnos* is a collapsed rock shelter on the southern coast of Cyprus's Akrotiri Peninsula. The site is on a steep cliff overlooking the Mediterranean Sea, some 40 m below. Excavations at *Aetokremnos*, in 1987–1988 and 1990, uncovered a 1.0–1.5 m thick package of deposits preserved beneath massive roof-fall blocks. These deposits contained cultural features and artifacts in direct association with huge amounts (nearly 300,000 bones representing at least 505 individual animals) of extinct pygmy hippopotamus (*Phanourios minutus*) and pygmy elephant (*Elephas cypriotes*) representing at least three individuals, as well as numerous bird and shell remains (Simmons, 1999).

Aetokremnos is the oldest well-documented archaeological site in Cyprus. Full details of its radiocarbon chronology are provided in Simmons and Wigand (1994). A total of 36 radiocarbon determinations are available for the site. Three of these were from surface specimens, and the remainder was from sealed contexts. Materials dated included marine shell, *Phanourios* bone, sediment, and charcoal. Based on statistical analyses, *Aetokremnos* was occupied for a relatively short time centered around 11,800 cal. BP. Even with newly documented Pre-Pottery Neolithic A (PPNA) sites on the island (Manning et al., 2010; Vigne et al., 2011), *Aetokremnos* predates the Neolithic occupation by about 500 years.

A total of 1,021 chipped stone artifacts were recovered from *Aetokremnos*. Over 95 % came from subsurface contexts, many in stratigraphic association with burned and unburned bones. Small, well-made "thumbnail" scrapers dominate the assemblage of 128 formal, retouched tools. Other tools include additional scraper forms, burins, retouched pieces, truncations, notches, and microliths. All of these artifacts were manufactured using locally available materials.

Geoarchaeological investigations of *Aetokremnos* were undertaken during the course of the excavation, in part to answer the questions raised concerning the association of the cultural materials and faunal remains (Mandel and Simmons, 1997). Four major stratigraphic units, numbered 1–4 from uppermost to lowermost, were identified at the site, with cultural features and artifacts concentrated in Strata 2 and 4. The duration of human occupation, as represented by cultural deposits in these two strata, was relatively short, perhaps a few hundred years or less.

Most of the sediments that accumulated in the rock shelter are a product of roof fall, disintegration of bedrock (attrition), and wind action. In addition, a small volume of slopewash entered the back of the shelter through solution cavities and is confined to less than 5 % of the site. Although some of the strata have been slightly affected by leaching and clay translocation, there is no evidence of soil development in the shelter. The physical and geochemical properties of the strata indicate that the sediments and associated cultural materials rapidly accumulated on the floor of the shelter soon before the roof collapsed, isolating the underlying deposits from subaerial weathering and other site-disturbance processes. This explains why there has been very little mixing of artifacts and bones between Strata 2 and 4; the cultural deposits at *Aetokremnos* have near-pristine vertical and horizontal integrity.

In summary, *Aetokremnos* is significant for two reasons. First, it is among the best-documented ancient sites on any of the Mediterranean islands. Second, and more controversially, artifacts are associated with the extinct endemic island fauna, notably pygmy hippopotami. Prior to the discoveries at *Aetokremnos*, such an association had never before been demonstrated, and humans may have been partially responsible for the early Holocene extinction of these unique animals (Simmons and Mandel, 2007).

ALLUVIAL SETTINGS

C. Reid Ferring
Department of Geography, University of North Texas, Denton, TX, USA

Definition

The term alluvial geoarchaeology denotes the practice of geoarchaeology in fluvial drainage systems, with an emphasis on the discovery, excavation, and contextual analysis of archaeological records in alluvium, i.e., sediments deposited by water, and existing within varied alluvial settings.

Introduction

The study of alluvial systems and their geologic records has been an important part of the earth sciences since the 1830s, when Charles Lyell focused on alluvial records as part of his famous *Principles of Geology*. In his *Antiquity of Man* (1869), arguably the first major work in geoarchaeology, Lyell recounted many discoveries of artifacts and fossils in alluvium, using these to present one of the first chronicles of human cultural and environmental history.

Since that publication, archaeologists and geologists have constructed an increasingly detailed record of human occupations in alluvial environments. The oldest known stone artifacts, 2.6 million-year-old flakes and cores, were recovered from alluvial sediments of the paleo-Awash River in Gona, Ethiopia (Semaw et al., 2003). Succeeding phases of cultural evolution are documented by Paleolithic finds in Africa and Eurasia that were preserved in alluvial deposits (van Andel and Tzedakis, 1996; Potts et al., 1999; Holliday et al., 2007; Rosen, 2008; Patnaik et al., 2009; Marder et al., 2011), and some of the most important sites bearing on the peopling of the New World are preserved in alluvium (Wagner and McAvoy, 2004; Haynes and Huckell, 2007; Mandel, 2008; Waters et al., 2011). In both the Old World and the New World, intense utilization of fluvial environments by sedentary agriculturalists has also been documented by geoarchaeologists (Rosen, 1997; Guccione, 2008; Huckleberry and Duff, 2008; Nials et al., 2011).

Today, it is both important and challenging to summarize this branch of geoarchaeology because so much highly productive archaeological research is conducted in alluvial settings. Accordingly, alluvial settings figure prominently in major works on geoarchaeology (Butzer, 1982; Needham and Macklin, 1992; Waters, 1992; Brown, 1997; Rapp and Hill, 1998; Holliday, 2004). There are three main reasons for this. First, humans have always exploited alluvial environments because they provide water, diverse food resources, fuel, and means of travel and transport. Second, alluvial sedimentation promotes burial and preservation of archaeological sites. Third, alluvial landforms, sediments, soils, and associated paleontological materials provide excellent opportunities to place archaeological records in temporal and environmental context. Significant overlap in the goals, strategies, and methods of alluvial geoarchaeology exists with geoarchaeological investigations conducted in other geologic settings, and therefore, consulting the cross-referenced entries in this encyclopedia will provide expanded discussions and illustrations of many issues considered here.

The goal of the following discussions is to provide an overview and guide to further study of both alluvial geology and how geoarchaeology is practiced in alluvial settings. This is supported by references to general works and specific investigations that illustrate major features of alluvial systems and many aspects and results of geoarchaeological research.

Alluvial geology and geomorphology

Students of alluvial geoarchaeology can benefit from the extensive treatment of alluvial geology in both introductory and advanced texts. Streams and rivers are introduced in all textbooks on physical geology. Geomorphology texts, such as Bloom (2004) or Ritter et al. (2011), provide thorough reviews of alluvial processes and the resulting geologic records of landforms and bodies of sediment. Other recommended sources on alluvial geology include Schumm (1977) and Leopold (1994). A major focus of many syntheses is the responses by streams to climate change; these responses prove to be especially pertinent to the interests of archaeologists, who seek to document and understand ancient cultural responses to climatic and environmental changes over long intervals (Knox, 1983; Bull, 1991; Frederick, 2001; Macklin and Lewin, 2008). The following discussions will illustrate that geoarchaeologists also contribute directly to alluvial geology in the course of their research. First, an overview of alluvial geology is presented by way of an introduction to the major kinds of processes that have shaped alluvial geologic records; then the discussions turn to major issues in the field of alluvial geoarchaeology.

On the most general level, alluvial geology is the study of landforms, sedimentary deposits, and associated features that are the result of erosion, transport, and deposition within a drainage system. Drainage systems comprise a trunk stream and its tributaries, and they are defined by topographic catchments whose boundaries are in turn delineated by interfluves (essentially, ridges that divert surface runoff of precipitation into one or another drainage). The drainage basin for a given system extends from its headwaters to its termination in an ocean or lake basin. Streams and their tributaries exhibit marked changes in behavior and scale along a downstream (longitudinal) direction. Such changes in typical drainages include: (a) a decrease in channel gradient (steepness), (b) an increase in discharge (the volume of water per unit of time passing a point along the channel), (c) an increase in the sinuosity of the channel, (d) an increase in the load of the stream (the solid and dissolved materials carried in the water), and (e) an increase in sediment storage (alluvial deposits). Over time, a typical stream and its tributaries will erode down through the bedrock creating an increasingly large system of valleys that are connected at confluences. Stream valleys typically preserve sediment (alluvium) that was deposited in channels and on floodplains (the portion of the valley that is periodically inundated by floodwaters). Because archaeological sites are often buried in alluvium, deposits under floodplains and terraces are the target of archaeological surveys and subsequent excavations, as discussed below.

Most alluvial systems are subject to periodic and/or episodic changes in geologic activity. Floods are the most common kinds of change. The frequency and magnitude of floods vary considerably. In general, the common, smaller floods result in (a) the addition of sediment to floodplains (alluviation) when high water overflows a stream's banks and (b) minor shifts in channel positions. Over periods of centuries or even millennia, these changes often appear to have been quite gradual. However, large floods, as well as external forces such as climate change or tectonic activity, can effect more significant changes, including entrenchment of the channel into the underlying bedrock or older alluvium. Such incision can be accompanied by *floodplain abandonment*, which transforms the former floodplain into a terrace (a bench-like landform that stands above the new, active floodplain). Multiple terraces signify several episodes of valley entrenchment, with increasingly older sediments preserved under each higher terrace surface (Bull, 1990; Bridgland and Westaway, 2008).

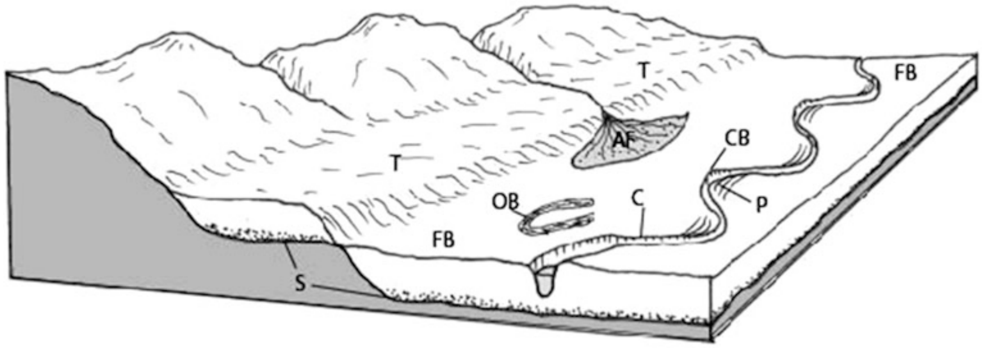
Sedimentation on floodplains

The accumulation (aggradation) of sediments on the floodplains of streams and rivers is usually the most important aspect of alluvial geology for archaeologists simply because this is the means by which archaeological sites are buried and preserved (Ferring, 1986a; Ferring, 2001). Floodplain sediments register the response of the fluvial system to both internal and external agents, and therefore, they are a major focus for geologists who study alluvial records with regard to climate change, tectonics, sea-level fluctuations, and other factors. The most important differences in alluvial geology are caused by climatic and tectonic factors (Frederick, 2001). In terms of climate, it is important to contrast alluvial processes and geologic records that occur within humid environments (Ferring, 1990; Mandel, 1995; Ferring, 2001; Bettis et al., 2008; Guccione, 2008; Kesel, 2008) to those that occur within arid ones (Cooke and Warren, 1973; Patton and Schumm, 1981; Freeman, 2000; Waters, 2000; Cordova et al., 2005; Butzer et al., 2008; Harden et al., 2010). Tectonic controls on alluvial geology are frequently important, especially in ancient contexts (Bull, 1991; Noller, 2001), e.g., many of the important Lower Pleistocene archaeological records from East African Rift valleys come from alluvial settings that were subject to tectonic processes (Potts et al., 1999; Feibel, 2004; Sikes and Ashley, 2007; Feibel, 2008; Domínguez-Rodrigo et al., 2009; Feibel et al., 2009). Within these different settings, the varied contexts condition the general processes of alluviation, soil formation, and erosion on floodplains.

It is convenient to consider floodplain sedimentation in two major settings: in and near channels and farther from channels within the flood basin (Lewin, 1978). Different kinds and rates of deposition on a floodplain result in the construction of distinctive landforms called depositional geomorphic features; these include point bars, cutbanks, natural levees, and the flood basin (Figure 1). In addition to these geomorphic features, the properties and contents of the sediments (called sedimentary facies) are used to reconstruct the particular depositional setting, more properly called the sedimentary environment.

Alluvial sedimentary *facies* are "packages" of sediment in the geologic record that are defined by their texture (grain size), sedimentary structures (such as bedding), and their organic content (Miall, 1992). Facies analysis includes the description and study of those properties in order to identify and reconstruct the sedimentary environments responsible for their creation in space and time. The analysis is conducted together with actualistic comparisons to modern streams so that characteristics of the older sediments can be compared to those typical of ongoing depositional processes. This is especially important in the study of geoarchaeological records, because both past occupation potentials and site formation processes vary considerably by specific depositional environment. Based on extensive studies, many alluvial facies have been formally defined by sedimentologists (Reineck and Singh, 1980; Miall, 1992; Houben, 2007).

An exposure of sediments in a cutbank of the Trinity River in Texas illustrates a sequence of alluvial facies (Figure 2). The lower part of the section consists of steeply dipping beds of sand and silt that "fine upwards," i.e., become finer higher in the section; these were deposited on a point bar. As the channel migrated away from this location, the environment shifted to that of a flood basin, where episodic deposition of clays was accompanied by soil formation from ca. 2000 to 1000 BP (Ferring, 1990; Ferring, 1992). Later, the channel returned to this position, and the natural levee deposits (thin beds of sand and silt) accumulated. This is a common sequence of facies, which are stacked into a vertical "facies association" (Miall, 1992). Note that this sequence of sediments records a spatial shift in sedimentary environment because



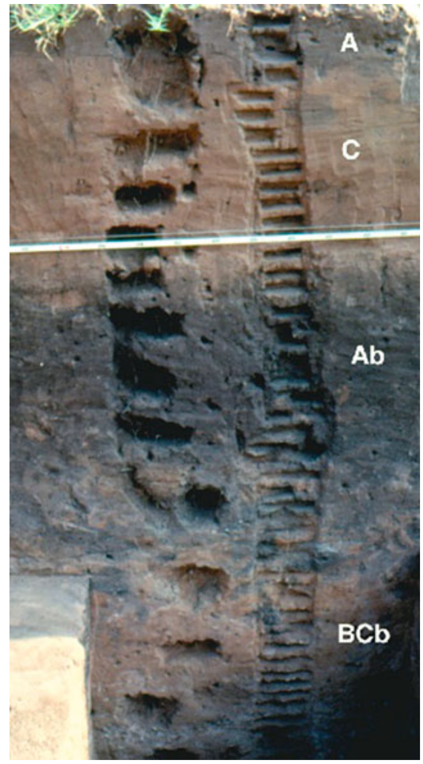
Alluvial Settings, Figure 1 Geologic features of a meandering river valley. Note the major sedimentary environments: *C* channel, *P* point bar, *CB* cutbank, *FB* flood basin, *OB* oxbow lake, *T* terrace, *S* strath, *AF* alluvial fan. Point bars are locations on the inside, or convex, banks of a meandering stream where sediment tends to be deposited. Cutbanks are steep erosional surfaces on the opposite outside, or concave, banks of a meandering stream. Oxbow lakes are rounded bodies of water created when extreme meander bends in the river join and give rise to a straighter main stream and a curved cutoff filled with standing water. Straths are terraces previously etched into underlying bedrock prior to alluvial buildup within a valley.

Alluvial Settings, Figure 2 Sedimentary facies of alluvium on the West Fork Trinity River in northern Texas. This cutbank exposes sediments of a Late Holocene point bar and floodplain, overlain by a recent natural levee.

meandering channels constantly migrate laterally across the floodplain. These normal variations in floodplain alluviation need to be documented prior to making unsubstantiated assertions, for example, suggesting that they reflect a change in climate. As discussed below, the prospects for finding preserved archaeological materials in a section like this are best in the floodplain clays, which accumulated for a longer period of time in a setting favored by Archaic and late prehistoric populations, ca. 3000–600 BP. The levee deposits accumulated after the arrival of Europeans.

Alluvial facies vary significantly in both space and time. Meander belts are the zone within valley floors across which meandering rivers periodically shift their courses; rapid sediment buildup along these meander belts can promote avulsion of the channel system to a lower part of the floodplain (Ferring, 1992; Törnqvist and Bridge, 2002; Phillips, 2011). Longitudinal (downstream) changes in facies are also common, owing to increases in discharge, changes in sediment load, and changes in bedrock geomorphic controls such as valley constrictions. Because of higher gradients, greater erosional potentials, and different vegetation patterns, alluviation in tributary streams can leave records that differ significantly from those in trunk streams. This is well documented in valleys of the Great Plains, which contain rich archaeological records (Mandel, 1995; Bettis and Mandel, 2002; Bettis et al., 2008; Mandel, 2008).

The rate of sedimentation is a significant variable in the record of alluvial sediments and associated archaeological materials (Ferring, 1986a). Indeed, the rate of sedimentation largely defines the potential for preservation of alluvium (Lewin and Macklin, 2003), as well as archaeological materials deposited on floodplains. Even without changes in climate or other external factors, sedimentation rates vary across floodplains, mainly in response to more rapid deposition of coarser (sand and silt) sediments near channels. When flooding rivers overrun their banks, the swift moving water slows down as it escapes the confines of its channel, and coarser sediments entrained by the formerly rapid flow are dropped closer the channel. This deposition results in the construction of raised meander belts, as mentioned above. Slower deposition in distal floodplain settings (i.e., farther from channels) is usually associated with finer suspended sediments (clay and silt) that are carried a greater distance away by floodwaters. Rates of sedimentation are also controlled by geomorphic factors, such as valley constrictions that impound floodwaters. Significantly, overall rates of floodplain aggradation may "wane" in response to long-term aggradation, which effectively raises floodplains above their channel bases. However, one of the most important implications of changing rates of sedimentation concerns soil formation on floodplains (Ferring, 1992).



Alluvial Settings, Figure 3 Profile at Delaware Canyon, Oklahoma, with an overthickened, buried soil (Ab). This soil preserved stratified Plains Woodland artifacts, faunas, and features. The small sample holes were for pollen analysis, while the larger samples were used for physical and chemical analyses of the sediments and soils. The lack of visible stratigraphy within the soil horizons mandated the use of arbitrary 5 cm levels for excavation.

Alluvial soils

The study of alluvial soils is important for both geologic and archaeological investigations. Alluvial soils, like those that form in other environments, are indicators of surface stability (Holliday, 1992; Birkeland, 1999; Holliday, 2004). On floodplains, soil formation signifies reduced rates of deposition, which allows time for soil profiles to develop. While some alluvial soils simply register a shift in sedimentary environments as mentioned above, regional climatic changes resulting in penecontemporaneous soil formation in multiple drainages are well documented (Ferring, 1990; Ferring, 1992; Mandel and Bettis, 2001; Beeton and Mandel, 2011). Particularly in North American settings, where archaeological records are dominantly Holocene in age, floodplain soils are generally weakly developed. Soils with A-C profiles are the most common, although weakly developed B horizons (Bw, Bk, or Bt) are found in some settings (Holliday, 2004).

Especially for geoarchaeological investigations, it is important to consider that floodplain alluviation and soil development often occurred simultaneously. In these cases, soil development alters the original properties of the sediment. This situation led to the definition of "pedofacies" (Kraus and Brown, 1988) or "soil facies" (Holliday, 2004, 79), which recognizes variations in alluvial sediments caused by the formation of soil features. This is particularly common in soils formed on floodplains. One consequence of time-transgressive deposition and soil development is the formation of *cumulic soils* (Birkeland, 1999, 165; Holliday, 2004, 90). A common result of cumulization is the development of overthickened soils, particularly thick A horizons. An example developed in Late Holocene alluvium at Delaware Canyon, Oklahoma, is shown in Figure 3. The overthickened buried A horizon (Ab) formed roughly between 1900 and 1000 BP, and it contains well-preserved artifacts and faunas of Plains Woodland groups who repeatedly camped on the floodplain of Delaware Creek (Ferring, 1986b). In the photo, note that the Ab horizon is underlain by a weakly developed B horizon. Prominent krotovina (rodent burrows), with several generations of fill, testify to post-occupational disturbance. The fill from these burrows was excavated separately and discarded to minimize the effects of mixture of bone and artifacts between occupation surfaces. Analysis of alluvial soils is a key component of site formation studies, as discussed below.

Site discovery

Methods for archaeological survey in floodplain settings must be tailored to the fact that many sites are deeply buried. Perhaps the most common means for discovering deeply buried sites is by careful examination of natural cutbank exposures (Figure 3). During such surveys, particular attention is paid to sedimentary facies and buried soils, which are important guides to both the age and depositional environments pertinent to site discovery. Well-established stratigraphic-soil sequences have been developed to target particular temporal/cultural periods. On the Great Plains, survey strategies have been developed for the whole range of cultural periods, including Paleoindian (Bettis et al., 2008; Mandel, 2008), Archaic (Mandel, 1995), and Late Prehistoric (Ferring, 1990). It should be noted that surface surveys of large, complex river systems are also an important research strategy (Wells, 2001). An exemplary case study is the survey of sites in the Missouri, Red, and Mississippi River valleys by Guccione (2008). Hundreds of sites were located in diverse geologic settings, resulting in a comprehensive analysis of settlement intensity and settlement patterns over the Holocene.

Both mechanical techniques and remote sensing are also useful in the survey of alluvial deposits. Coring and trenching are frequently used to discover buried sites under floodplains. Both methods were used in the Ohio River Valley to define geologic contexts as well as discover deeply buried Woodland and Late Prehistoric age sites (Stafford and Creasman, 2002). Similar approaches were used to explore alluvial deposits that buried a series of Middle Holocene (ca. 5000 BP) Archaic mounds in the lower Mississippi Valley (Arco et al., 2006). Rosen (1997) used trenching as well as natural exposures to locate and study Neolithic-Bronze Age sites in Turkey. Remote sensing techniques include resistivity, magnetometry, and ground-penetrating radar (Kvamme, 2001). These approaches are best geared to defining the lithology and contacts of buried alluvial units, as a prelude to mechanical testing.

Alluvial terraces

Alluvial terraces are landforms created by the abandonment of a floodplain by means of channel incision or entrenchment (Bull, 1990). This process may be caused by tectonic uplift, climate change, or, in localities near coasts, falling sea level (Bull, 1991). When alluvial deposition slows or ceases, permitting a transition to surface stability, the sediments below the terrace surface are subjected to new soil-forming environments. Soils on progressively higher, older terraces (Figure 4) have developed over longer periods, resulting in a soil chronosequence running up through the terrace structure (Birkeland, 1999, 192). Because of the relatively recent peopling of the New World, sites buried in terrace deposits are uncommon in North and South America; however, the surfaces of terraces were favored locations for Late Pleistocene and Holocene occupations because of their proximity to streams coupled with protection from floods (Ferring, 1992; Guccione, 2008). Archaeological records within terrace deposits are quite common in the Old World because of the much greater time depth of occupations compared to the New World (van Andel and Tzedakis, 1996; Cordova et al., 2005; Schuldenrein, 2007; Patnaik et al., 2009).

Alluvial fans and colluvium

Sediments derived from steep valley slopes are frequently deposited along the margins of valleys, where they can accumulate on terrace surfaces or become interstratified with floodplain deposits. These deposits include generalized slope deposits called *colluvium* and more discrete bodies called *alluvial fans*, described below. Because these deposits represent aggrading surfaces usually above the active floodplain, they were frequently occupied and are generally good environments for the preservation of archaeological sites. Colluvium is most often preserved as "aprons" along the base of slopes, underlain by sediments that accumulated as a result of gravity (creep or mass movements) and/or sheet wash (Bloom, 2004). Changes in sediment supply, precipitation, and vegetative cover are among the factors that led to alternating periods of rapid deposition and periods of slower deposition with soil formation along valleys of the Midwestern United States (Bettis, 2003). Numerous archaeological sites are preserved in those colluvial deposits. At the famous Paleolithic Kostenki-Borschevo sites in Russia, colluvial deposits are interstratified with alluvium, loess, and volcanic ashes (Holliday et al., 2007). In China, a Middle-Upper Pleistocene series of terraces, each with associated alluvial fans, has been defined and dated as part of an intensive survey for Paleolithic sites (Lu et al., 2010).

Alluvial fans comprise major sedimentary environments that have been studied in many settings, ranging from humid to arid (Reineck and Singh, 1980, 298; Miall, 1992). In contrast to colluvium, alluvial fans are distinct, fan-shaped depositional landforms that develop at the intersection of steep tributaries with either terrace surfaces or floodplains. In desert settings, adjacent alluvial fans often coalesce into continuous features called *bajadas* (Bloom, 2004). Alluvial fans are characterized by intermittent sedimentation, with frequent shifting of channel/gully positions, and a general fining of sediment texture from proximal to distal positions down the fan to the bottom, where closed playa lakes are common. Especially in

Alluvial Settings, Figure 4 Alluvial terraces and soils: (**a**) Late Pleistocene terrace of the Tedzami River near Gori, Republic of Georgia; (**b**) Late Pleistocene terrace deposits and soil on the Trinity River near Dallas, Texas. The soil of the Trinity River deposits has been forming since the Late Pleistocene floodplain was abandoned by incision ca. 22–25 Ka. Surficial archaeological sites, often palimpsests created by the superposition of repeated occupations, are common on the terrace surface, while fossils of extinct fauna are preserved in the underlying sediments of the sandy channel facies.

humid environments, such as in the Midwestern United States, alluvial fans have built up over earlier Holocene deposits, preserving numerous archaeological sites underneath (Bettis and Mandel, 2002; Bettis, 2003). Periods of slower fan aggradation were accompanied by soil formation, which assist in stratigraphic correlation among different fans. Alluvial fans were commonly chosen for occupation from the Early to the Late Holocene, as illustrated by excavations at the Koster and Napoleon Hollow sites in the Illinois River Valley (Wiant et al., 1983.) Alluvial fans and bajadas are very common in the western deserts of the United States, and they are prime targets for archaeological surveys (Waters, 1992, 2000; Nials et al., 2011).

Eolian deposits

Eolian sands or loess are frequently found in association with fluvial deposits, especially in the Midwestern United States. Pleistocene loess is a major source for younger alluvium that now fills river valleys (Mandel, 1995; Mandel and Bettis, 2001; Bettis and Mandel, 2002; Bettis et al., 2008). Eolian sands accumulated along drainages in the southwestern United States and buried early Holocene sediments in the “draws” of the Southern High Plains (Holliday, 1995). At the Mockingbird Gap site in New Mexico, Clovis artifacts were buried in eolian sands along Chupadera Draw (Holliday et al., 2009). Research in those settings illustrates the careful geologic analysis of sediments and soils necessary to reconstruct sedimentary environments and site formation processes, both of which are important goals of most geoarchaeological studies.

Paleoenvironmental studies

Alluvial deposits often preserve important evidence of past environments, which is frequently studied in concert with archaeological investigations. As described above, alluvial facies provide records of sedimentary change, especially in response to environmental shifts (Knox, 1983; Bull, 1991; Bettis et al., 2009; van de Wiel et al., 2011), and alluvial soils are also used extensively as part of paleoenvironmental studies (Holliday, 2004). Study of stable isotopes of carbon and oxygen is conducted on both organic matter and pedogenic carbonates in alluvial soils (Humphrey and Ferring, 1994; Nordt, 2001; Sikes and Ashley, 2007). Changes in patterns of sedimentation as well as soil formation on floodplains need to be investigated first with respect to normal shifts in sedimentary environments (Figure 3), however.

Site formation processes

Site formation studies are important in virtually all geoarchaeological contexts (Butzer, 1982). In alluvial settings, formation processes and formation histories are complex, owing to different rates and patterns of sedimentation and exposure on floodplains and terraces (Ferring, 1992; Ferring, 2001). In the main, floodplains are good formation contexts because burial occurs by low-energy, post-occupational deposition. However, rates of sedimentation vary markedly both longitudinally (downstream) and in different sedimentary environments within shorter reaches of a valley (Ferring, 1986a). Rates of sedimentation are important to document, for they exert strong controls on formation processes during and after occupations, often resulting in marked differences in artifact density and bone preservation among sites.

Sites in alluvial settings are subject to many weathering and disturbance processes, including bioturbation and pedoturbation (Wood and Johnson, 1978), which highlights the need for careful analysis of both sediments and soils, as at the Cactus Hill site (Wagner and McAvoy, 2004) and the Big Eddy site in Missouri (Hajic et al., 2007), both of which contain important records of Paleoindian occupations. There are often strong textural controls on formation processes. Sites that formed in sandy alluvium may be more prone to artifact trampling and bioturbation by insects and micromammals (see Figure 3). Fine-grained (clay-silt) sediments, common to floodplains, are more prone to pedoturbation by shrink-swell of vertisols and turbation by earthworms. Field observations and standard textural-chemical lab analyses are often supported by micromorphology, providing detailed evidence about sedimentary environments, soils, and anthropogenic features (Courty, 2001; Macphail and Cruise, 2001; Domínguez-Rodrigo et al., 2009). At the Friedkin site in Texas, micromorphology was applied to study possible effects of pedoturbation within Paleoindian and "pre-Clovis" deposits (Waters et al., 2011).

Stratigraphy and dating

Alluvial records often provide excellent opportunities for establishing detailed chronologies for sediments and their entrained archaeological and paleoenvironmental data (van Andel and Tzedakis, 1996; Frederick, 2001; Macklin et al., 2002; Holliday, 2004; Feibel, 2008). As in other settings, most efforts at dating begin with stratigraphic studies of landforms, sediments, and soils. Morphostratigraphy addresses the sequence of alluvial landforms – including terraces – and alluvial fans, as well as depositional landforms such as floodplains, natural levees, cutoff channels, and oxbow lakes (Wells, 2001). The stratigraphic relations of these landforms are usually established by field description and mapping; however, the use of remote sensing (such as air photos and satellite images) is an increasingly productive approach (Guccione, 2008). In many cases, buried soils are critical stratigraphic markers, both within and between drainages (Holliday, 1995; Holliday, 2004). Allostratigraphic units are formally defined stratigraphic units in alluvial contexts (Miall, 1992; NACSN, 2004). These are packages of alluvial sediments, often comprising different facies, which are defined on the basis of bounding discontinuities, such as soils (representing intervals of stability) or erosional disconformities (representing intervals of sediment loss and the creation of abrupt discontinuities within the stratigraphic sequence). Although these are lithostratigraphic units – defined on the basis of sedimentary units in contact with one another – they also provide the necessary framework to support sampling for chronometric dating, leading to the definition of chronostratigraphic units.

Absolute dating of alluvial deposits employs a range of specific methods that are chosen to meet the availability of datable materials as well as the age range of the deposits. Radiocarbon dating is the most commonly employed method for deposits less than about 40,000 years old; however, optically stimulated luminescence (OSL) is increasingly used on silicate fractions of sediments, despite the generally high error factors (Holliday et al., 2007; Waters et al., 2011). For older deposits, uranium-thorium dating of pedogenic carbonates (Sharp et al., 2003) and Ar/Ar dating of associated volcanic rocks and sediments are employed (Feibel et al., 2009; Zaim et al., 2011).

In the central and eastern Great Plains, comprehensive stratigraphic sequences (lithosequences and chronosequences) of Late Quaternary alluvial deposits have been established, resulting in a framework for the discovery and study of archaeological records (Bettis and Mandel, 2002). A detailed stratigraphic framework has been developed for locating Paleoindian sites in the central Great Plains by Mandel (2008); a stratigraphic basis for site discovery was also developed for the Cottonwood River Basin in Kansas (Beeton and Mandel, 2011). Other useful examples of alluvial stratigraphy include the work in the lower Mississippi Valley (Kesel, 2008), the upper Mississippi Valley (Bettis et al., 2008), and in Holocene deposits in France (Berger, 2011). In the southwestern deserts of the United States, complex alluvial stratigraphic records have been established on the basis of both lithostratigraphy and radiocarbon dating (Waters, 2000). An excellent example is the work done in the San Pedro Valley (Arizona), where Haynes (2007) conducted detailed stratigraphic-dating research at the famous Murray Springs site (Haynes and Huckell, 2007). There, a superb record of Clovis activities was recovered at the base of a thick alluvial sequence (Figure 5).

Summary

This brief summary of alluvial geoarchaeology has demonstrated that many important records of human history are preserved in sediments and on landforms created by streams. Although much geoarchaeological research is conducted in other geologic settings, many archaeologists and the geologists/geomorphologists they collaborate with will work in alluvial settings at some time in their career. For them, much can be learned from the older, important works, as well as the many recent examples of research cited here. This is especially true for archaeologists engaged in Cultural Resource Management (CRM), since many land use projects impact archaeological records in alluvial settings. Both CRM investigations

Alluvial Settings, Figure 5 Alluvial deposits along Curry Draw, Arizona. Note the vertical walls of the modern arroyo, typical of desert streams. Clovis artifacts and fossils of numerous extinct megafauna were found just below the prominent "black mat" in the lower part of the section. These have been dated to ca. 10940 BP (Haynes, 2007).

and grant-supported research should exploit the contributions of alluvial geologists and geoarchaeologists as they design and implement research strategies. The extensive body of published research on alluvial geoarchaeology, some of which is cited here, is an important resource for researchers developing programs of site discovery, excavation, and contextual study.

AMINO ACID RACEMIZATION

Kirsty Penkman
BioArCh, Department of Chemistry, University of York, York, UK

Synonyms

Amino acid geochronology; Amino acid racemization; Aminostratigraphy

Definitions

Amino acid racemization: a spontaneous reaction describing the interconversion between the chiral forms of an amino acid.

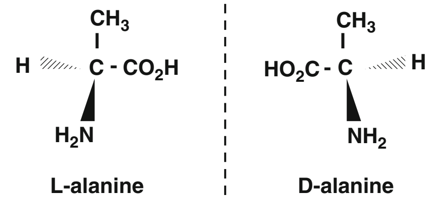
Chiral: describes molecules that may exist as mirror images of themselves that are nonsuperimposable; such molecules exhibit chirality.

Enantiomer: one of a pair of nonsuperimposable mirror images; also called an optical isomer.

Stereoisomer: molecules that possess the same elemental composition but different three-dimensional arrangements of atoms.

Diastereomer: a stereoisomer that is not a mirror image, that is, not an enantiomer.

Amino acids are the building blocks of proteins. They are found in all living tissues and can be preserved in fossil biominerals such as bone, teeth, and shells. The 20 naturally occurring amino acids all have a central carbon atom (the α-C) with four attached groups: an amino group (NH_3), a carboxylic acid group (COOH), hydrogen (H), and a side chain (R) that defines the type of amino acid. In glycine, the side chain is H, but for all other amino acids, the α-C has four different groups. The four distinct groups connected by single bonds make the α-C a chiral center, meaning that it can exist as two stereoisomers: the *levo* (L-form) and *dextro* (D-form), named after the optical activity of glyceraldehyde. Such stereoisomers are enantiomers because they are not only chemically identical, but they are also nonsuperimposable mirror images of each other (Figure 1). In living organisms, proteins are almost exclusively made from the L-form. However, this artificial dominance of the one form is unstable, so after death, a spontaneous reaction occurs to redress the balance. The extent of amino acid racemization (AAR) is recorded as a D/L value; AAR continues until a dynamic equilibrium is reached (usually D/L = 1). Depending on the amino acid, this process can take thousands or millions of years and therefore is applicable over Quaternary timescales. First applied to fossil shells (Hare and Abelson, 1968), AAR geochronology measures the extent of this degradation in fossils as an index of relative age (an aminostratigraphy), which can provide calibrated ages in combination with known-age samples or detailed temperature records.



Amino Acid Racemization, Figure 1 L- and D-amino acid structure of alanine. Bonds depicted as hatched wedges go into the page, while those that are thick wedges come out of the page. The central carbon atom has four different functional groups attached to it; it is therefore a chiral center, and two chemically identical, but nonsuperimposable, mirror images can occur: L- and D-alanine.

Protein degradation consists of a series of chemical reactions that are dependent not only on time but also on environmental factors. The original protein composition is important, so AAR will occur at different rates in different species, precluding direct comparison in most cases. Environmental factors (e.g., temperature, pH, availability of water) can also affect AAR rates, leading to a focus on analyzing "closed-system" protein from fossil samples (Towe, 1980). A chemically protected organic fraction found in mollusk and egg shells (the "intracrystalline" fraction) appears to be shielded from the environment and does not lose any material through leaching, meaning that the protein degradation within this fraction is solely time and temperature dependent and therefore predictable. This technique has been particularly successful in dating carbonate fossils (shells, eggshells, foraminifera, ostracods). Advances in chromatography, preparative methods, and choice of material for dating have resulted in greatly improved temporal resolution, demonstrating the technique's potential for developing regional Quaternary chronologies around the world (e.g., Parfitt et al., 2005; Wehmiller, 2012).

ANALYSIS OF CARBON, NITROGEN, PH, PHOSPHORUS, AND CARBONATES AS TOOLS IN GEOARCHAEOLOGICAL RESEARCH

Michael F. Kolb
Strata Morph Geoexploration, Inc, Sun Prairie, WI, USA

Introduction

In the context of archaeological research soil/deposit chemical analysis should be viewed as an additional data set or tool for interpreting the archaeological record. Because chemical signatures are not exclusively anthropogenic (they are not uniquely of human construction like artifacts), there is always a non-anthropogenic component or effect. Human activity either indirectly modifies a soil's chemical characteristic, as with pH, or it directly adds or subtracts material creating an anomaly by altering the amount of carbon, phosphorus, nitrogen, or carbonates in the deposits. Anomalies can only be detected if there is baseline data that characterizes the deposits prior to human intervention. This is accomplished by setting up control sampling locations or, if that is not possible, obtaining background data from preexisting sources (e.g., from sources like Shacklette and Boerngen, 1984). Interpretation of chemical data in archaeological contexts involves comparisons to control samples and an understanding of the evolution and maintenance of the anthropogenic soil anomaly (Carr, 1982). This is no small feat given the complexity of temporal and spatial occupation histories at many archaeological sites and the complex pedogenic response over time to anthropogenic activity.

Because this entry is about soil chemical analysis in archaeology, it seems appropriate to define soil from a soil chemist's perspective:

> Soils are multi-component, open, biogeochemical systems containing solids, liquids and gases. That they are open systems means they exchange both matter and energy with the surrounding atmosphere, biosphere, and hydrosphere. These flows of matter and energy to or from soil are highly variable in time and space but they are the essential fluxes that cause the development of soil profiles and govern patterns of soil fertility. (Sposito, 1989, 3)

The definition emphasizes that soils are open systems that adjust to variations in input. Knowing or hypothesizing about those adjustments after anthropogenic input over archaeological time scales is important for interpreting chemical data from archaeological contexts. The state factor's model of soil formation first developed by Jenny (1941) and advanced in geoarchaeology by Holliday (1994, 2004a) is an excellent conceptual framework for interpreting soil chemical data in archaeological contexts. The model consists of five external factors that govern soil formation. They are (1) climate, (2) organisms (plants and animals), (3) relief (landscape position), (4) parent material (anthropogenic and non-anthropogenic deposits), and (5) time. Both these factors and soil-forming processes vary, resulting in changes in soil morphology, hydrology, and chemistry. The human animal can be considered with all the other organisms involved in soil formation or, perhaps, more appropriately as the sixth factor. Human populations, although they are just a player in the ecological drama, are the dominant one. They modify all of the factors of soil formation in major ways at scales from a single dwelling to the global climate (Hooke et al., 2012).

Control sampling

Chemical analysis in geoarchaeology is comparative so it demands two or more data sets to be of much analytical use. Control samples should be taken in the field and analyzed to determine the background or natural level of the chemical of interest. This is equivalent to analyzing blanks in the laboratory, a standard and necessary procedure. The point of control sampling is to determine the non-anthropogenic or natural background chemistry of the soil off-site, and the state factor model is again a good conceptual guide. Thus, it is best to pick landscape positions off-site, where all of the state factors are similar to the sampling loci on the site. Multiple control locations may be necessary. In many situations (e.g., modern or ancient urban areas), finding a location that has not been previously utilized or occupied or that you know has not been utilized or occupied is difficult but should be attempted. Certainly a number of authors have advocated using control samples or have effectively used control samples in their research (see Proudfoot, 1976; White, 1978; Bakkevig, 1980; Carr, 1982; Sandor, 1992; Entwistle et al., 2000; Wells et al., 2000; Holliday, 2004a). In addition all samples should be analyzed using the same techniques/procedures and by the same laboratory to reduce unnecessary sources of error and uncertainty (see Holliday and Stein, 1989; Holliday et al., 2004c).

In many geoarchaeological investigations that use soil chemistry, a suite of chemical analyses is used to address research questions. For this reason geoarchaeological applications will follow the discussion of each of the chemical techniques.

Carbon/organic matter

Sources and transformations in soils and deposits

Carbon occurs in soils in organic and inorganic forms (Stevenson and Coles, 1999). Organic forms occur as living plants and animals and as the by-products of the decomposition of plants and animals referred to collectively as the soil's organic matter fraction (SSSA, 1997). Inorganic forms can also be added to the soil by plants that contain crystals of calcium oxalate or opaline silica (Weiner et al., 2002; Piperno, 2006; Prychid et al., 2008). Calcium oxalates would contribute some carbon to a total carbon assay. However, most inorganic carbon is derived from the parent material (carbonate rocks and dust) (Birkeland, 1984; Nelson and Sommers, 1982). In non-calcareous soils almost all of the carbon is in the organic fraction of the soil (Nelson and Sommers, 1982). Carbon is a part of organic matter that is introduced into the soil by natural process and anthropogenically as plant tissue with a more minor contribution from animal tissue. Plant residue consists of 25 % solids that are made up of carbon, oxygen, hydrogen, and ash (Brady, 1974). The ash contains the macronutrients (phosphorus, potassium, calcium, magnesium, and sulfur) and micronutrients (zinc, iron, copper, boron, manganese, and molybdenum) as well as minor trace elements (Brady, 1974). These are relevant to studies of soil chemistry at archaeological sites as they form part of the anthropogenic and natural chemical load in soils and deposits. As soon as organic matter is added to the soil, it begins to decay. The rate of decay and the products of decomposition depend on the soil environment (Brady, 1974). In turn, the nature and strength of any anthropogenic anomaly depend on the nature and intensity of occupation and the soil-forming environment (Carr, 1982).

Anthropogenic additions, subtractions, and transformations

Human populations are major players in cycling organic material in the environment. The organic carbon fraction is of interest in geoarchaeological studies because it is a component of building material (wood and adobe), food, waste, and a by-product of food preparation, material processing, and heating (e.g., charcoal) at human habitations and ultimately in archaeological deposits. It is continually moved from place to place in the process of food production, settlement construction, and waste disposal. As a result, it is added to the soil, directly and indirectly, in the form of waste from a variety of activities in and around settlements, for example, the dark earths in Amazonia (McCann et al., 2001) and Europe (Chapter "FTIR" in Courty et al., 1989). And it is removed from the soil in places where farming or resource extraction (removal of tress or crops), for example, occurs. The most significant anthropogenic transformation of organic matter is by burning. This reduces organic matter to the much more decay-resistant and carbon-rich charcoal. In chemical analyses charcoal is measured as a part of the organic matter or total carbon fraction of the soil. It can also be used, for example, to determine the species (Asouti and Austin, 2005; Marguerie and Hunot, 2007) of wood being exploited for fuel and building material or if the wood was collected dead or alive (Moskal-del Hoyo et al., 2010). Charcoal is only relatively stable. It can be degraded and disseminated into small particles in alkaline soils (Dufraisse, 2006; Braadbaart et al., 2009) and can be attached by soil fauna and flora (Thery-Parisot et al., 2010). Reduced particle size has implication for site formation processes and chronology as the charcoal is more mobile in the soil profile. Stein (1992) provides a general summary of organic matter in archaeological contexts.

Analytical methods

Total carbon in soils can be determined by wet or dry combustion techniques (Nelson and Sommers, 1982). Note this technique measures all forms of both the organic and inorganic carbon in the soil. The basic principle is to drive off and capture the CO_2 and then measure the amount captured gravimetrically or titrimetrically. This is generally done with automated laboratory instruments designed for carbon analysis (see Nelson and Sommers (1982) for examples and procedures). Another measure of soil organic matter is near-infrared reflectance spectroscopy (see entry "Anthrosols" by Woods this volume).

The most commonly used procedures to determine organic carbon are Walkley-Black (Nelson and Sommers, 1982; Singer and Janitzky, 1986) and loss-on-ignition (Dean, 1974) techniques. With Walkley-Black the sample is digested in dichromate and sulfuric acid, and the amount of carbon is determined by titration or colorimetrically. This procedure uses strong acids and needs a laboratory setup to do the digestion.

Loss-on-ignition is a simpler procedure, is as accurate (Dean, 1974) as Walkley-Black, and can also be used to determine carbonate in the sample. The procedure consists of placing oven-dried soil in a small pre-weighed crucible and heating it in a muffle furnace to 550 °C, cool to room temperature in a desiccator and reweighed. The difference is the amount of organic carbon ignited. The sample and crucible are placed in the oven and reheated to a higher temperature to determine the carbonate content (see section on carbonates below). The number of samples that can be done at one time is only limited by the size of the muffle furnace. Loss-on-ignition can also be done using automated thermogravimetric analyzers, which can process many samples at one time with direct computerized calculations, producing immediate tables and plots of results.

Nitrogen

Most nitrogen in the soil is associated with organic matter or soil humus (Brady, 1974) that can be slowly released by the actions of microorganisms and made available to plants. The soluble ammonium and nitrate is readily available to plants but is also easily leached from the soil. Because nitrogen compounds are rapidly fixed (unavailable to plants) and mobile (available but easily leached), heavily cropped soils need a constant artificial supply of nitrogen fertilizer especially in modern mechanized agricultural systems.

Sources and transformations in soils and deposits

Inputs of nitrogen to the soil come from addition of organic matter during the process of plant growth and decay, fixed by microorganisms from the atmosphere, and brought in to the soil in the form of ammonium and nitrate salts by precipitation (Brady, 1974). Once in the soil nitrogen is generally immobile or fixed except for small amounts of inorganic nitrogen in the form of nitrates and ammonium nitrates. Some ammonium nitrogen is also fixed in the lattices of clay minerals where it is very slowly available to plants during weathering. These later forms are available to plants and are mobile in soil water. Most nitrogen is rapidly cycled (Stevenson and Coles, 1999), a process whose rate depends on soil conditions (factors) especially climate.

Anthropogenic additions, subtractions, and transformations

Human activity alters the nitrogen cycle by adding organic matter (waste and garbage) or fertilizer/manure in some places and removing it in others (movement of plants and building material to settlements). Because nitrogen is added to the soil along with carbon and other elements when disposing of plant or animal waste or fertilizing agricultural fields, it creates an anomaly that is closely associated with organic matter (carbon) anomalies. As organic matter breaks down, much of the nitrogen is rapidly volatilized and lost to the atmosphere or becomes mobile in the soil water (Brady, 1974). The remaining nitrogen is fixed by clay mineral or combines with soil organic matter. Because nitrogen cycles rapidly, it may not maintain a anthropogenic anomaly over long time spans, so it is not a good indicator of anthropogenic load (Holliday, 2004a) except, perhaps, on young archaeological sites (Woods, 1982) or in arid areas (Homberg et al., 2005).

Analytical methods

There are two types of analysis that deal with total nitrogen: Kjeldahl wet combustion and Dumas dry combustion (Bremner and Mulvaney, 1982). In the Kjeldahl analysis the nitrogen in the samples is converted to ammonia ($NH_4^+{-}N$) by heating in sulfuric acid in the presence of catalysts. The amount of nitrogen is determined by measuring the amount of NH_3 liberated from the digest when distilled in an alkali. Dumas analysis involves heating the sample with CuO and exposing the liberated gas to hot Cu to reduce the nitrogen oxides and then to CuO to convert the CO to CO_2. The $N_2{-}CO_2$ mixture is then collected and exposed to a concentrated alkali that removes the CO_2, and then the volume of N_2 is measured. Both methods are complex and have recovery problems that researchers should be aware of before choosing a procedure (see Bremner and Mulvaney, 1982). Automated N analyzers are capable of processing samples relatively rapidly and produce results comparable to the wet chemistry methods (Thomas et al., 1967; Schuman et al., 1972).

pH

The measure of the activity of ionized H (H+) in the soil solution is called pH (Mc Lean, 1982). It is one of the most indicative measures of soil chemistry (Boul et al., 1989) and is important in determining (after Mc Lean, 1982) the (1) solubility and hence mobility of compounds in the soil, (2) the bonding of ions to exchange sites, (3) activity of microorganisms, and (4) availability of plant nutrients. The pH scale ranges from 1 (most acidic) to 14 (basic), 7 being neutral.

Sources and transformations in soils and deposits

Soil pH is not an element or compound that can be added or subtracted from the soil but instead is a condition of the aqueous phase of the soil environment that is very dependent on the interaction and evolution of the soil-forming factors. Many chemical reactions, weathering trajectories, and soil–plant relationships are pH dependent. Because soil water system is open, external inputs of water (including its dissolved constituents) and organic and inorganic particles – both natural and anthropogenic – can rapidly change the soil pH (Sposito, 1989) and therefore the pedogenic trajectory and the maintenance of the anthropogenic anomaly.

Anthropogenic additions, subtractions, and transformations

The degree to which soil pH is modified by anthropogenic additions depends on the initial soil pH, buffering, and pedogenic context. Anthropogenic modifications of pH are direct and indirect. Direct addition of wood ash, limestone (especially burnt), and shell maintains alkalinity (Cook and Heizer, 1965). Addition of organic matter indirectly lowers pH because the decay of OM produces acids (Brady, 1974). Soil pH is an important parameter for predicting the degree of bone preservation, including bone proteins used in DNA analysis, and metal and charcoal preservation in archaeological deposits (Tylecote, 1979; Gordon and Buikstra, 1981; Pate and Hutton, 1988; Nielsen-Marsh et al., 2007; Braadbaart et al., 2009; Adler et al., 2011). Sheppard and Pavlish (1992) have shown that among other soil chemical variables, pH is important in the weathering of chert. Soil pH is also one factor in determining the potential for preservation of phytoliths (see Piperno 2006; Cabanes et al., 2011). In most geoarchaeological investigations that use soil chemistry, pH is one of a suite of chemical analyses used to characterize the soil as background for interpretations.

Analytical methods

Determination of pH is accomplished using either colorimetric or electrometric techniques (Mc Lean, 1982). Colorimetric techniques use dyes or acid–base indictors that react by changing color in different pH environments. In its simplest form the electrometric technique consists of a glass electrode that measures the hydrogen ion activity and a reference electrode that completes a circuit so voltage can be measured (Mc Lean, 1982). The pH is typically measured in a 1:1 soil–water mixture (see Janitzky 1986 or Mc Lean, 1982). Many portable colorimetric and electrometric systems are available for field measurement of pH.

Phosphorus

The most widely used soil chemical technique in archaeological research is certainly the analysis of phosphorus. This is because humans are very proficient at concentrating P in and around places where they live and much of the P added to soils is considered fixed (Brady, 1974; Walker and Syers, 1976). The source of the P is the plant and animal remains and waste left at sites that ultimately ends up in the soil. The association of high soil phosphorus levels and human settlements was first documented in the 1920s by Swedish soil scientist, G. Arrhenius (see Eidt, 1985 or Wells et al., 2000 for brief history). Since that time, P analysis has been used in many archaeological contexts to aid in determining site and feature boundaries, intra-site activity areas, intensity of occupation, and types of land use (for recent studies, see Barba et al., 1996; Parnell et al., 2001; Fernández et al. 2002; Barba, 2007; Middleton et al., 2010; Roos and Nolan, 2012).

There are a number of reviews of archaeological/geoarchaeological research using phosphorus that should be consulted as an initial source before developing a research strategy that includes P analysis. The most recent and most thorough reviews can be found in Holliday (2004b) and Holliday and Gartner (2007). They cover basic chemistry, common methods of extracting and measuring soil P, and the use of soil P in chronosequence studies. Proudfoot (1976) provides a general review of the extraction procedures and chemistry of P in soils, anthropogenic additions, and sampling issues as well as an example of P analysis from an archaeological site in Britain. Bakkevig (1980) provides more of a cautionary tale pointing out the importance of understanding the natural P background and the geomorphic context of any sampling site. White (1978) also stresses the importance of having background data.

Sources and transformations in soils and deposits

The chemistry of soil P is complicated, in part because the P anions can bind with a number of cations in the soil to form compounds where the P bond varies in strength. P chemistry is strongly pH dependent which in turn is dependent on the soil factors at a particular site and on the natural and anthropogenic evolution of the site. A detailed explanation of P chemistry is beyond the scope of this entry, so P will be covered in a simple way under the heading of additions, subtractions, and transformation.

Almost all of the phosphorus in the soil system ultimately came from weathering of the inorganic P minerals (primarily apatite) in the soil parent material (Walker and Syers, 1976). The soluble P is taken up by plants, and upon death, they add organic matter to the soil. Once the system is established, most of the soil phosphorus is contained in soil organic matter (Brady, 1974). Soil microorganisms mineralize the organic forms of P to soluble inorganic forms ($H_2PO_4^-$, HPO_4^-) that are available to plants and can be leached out of the soil with the soil water. These latter processes are ways P can leave the soil, although on landscapes that are not cropped, the P is recycled. Of course weathering continues and small amounts of P still enter the soil from that source.

Most of the phosphate anions that enter the soil quickly form calcium (Ca), aluminum (Al), or iron (Fe) phosphates. Which compounds form depends on the soil pH and the amount and kind of each cation present. Brady (1974) divides P compounds in the soil into three major groups: (1) readily available phosphates that are generally water soluble (non-occluded P); (2) slowly available P including newly formed Al, Fe, and Mn phosphates, Ca phosphates, and mineralized organic phosphates; and (3) very slowly available phosphates of Fe, Al, and Mn, apatites and stable organic phosphates. His view of P is from the perspective of agronomy and soil science, where most basic research on P in soils has taken place. Laboratory analyses designed to study P in soils reflect the kinds of P found in soil (see below). Anthropogenic addition of P to the soil is also held at different location in the soil so to detect the anthropogenic anomalies P must be extracted either totally or differentially by chemically targeting the different phosphate compounds.

Soil phosphorus is only relatively stable over time because as soil factors change in response to environmental change and pedogenic processes adjust, P can be removed from the soil system or reorganized within the soil (see Walker and Syers, 1976; Tiessen et al., 1984; Roberts et al., 1985). On geomorphically unstable landscape facets, where erosion or deposition is occurring, the retention of P and the post-depositional evolution of the any anthropogenic P anomaly change.

Anthropogenic additions, subtractions, and transformations

Anthropogenic sources of P come from domestic refuse, food waste, plant and animal remains, human bodies (especially bones), human and animal excrement, and wood ash (Cook and Heizer, 1965; Carr, 1982; Woods, 1982). Human populations are a factor in the P cycle and as such alter the process of P cycling. These alterations can be detected in the soils on archaeological sites.

Analytical methods

Analysis of P in soils has two stages. The first stage is extracting the P from the soil (Olsen and Sommers, 1982; Meixner, 1986a). The extractant used depends on which form or forms of P are being targeted. The second stage is the determination of the amount of P in the extractant. This is accomplished by using a colorimetric method. In P fractionation multiple extractants are used in sequence to determine the different forms of P in the soils.

Spot test or ring test is a qualitative measure of P that can be done in the field with simple tools and reagents (Gundlach, 1961; Eidt, 1973; Woods, 1975). The test uses a weak acid extractant to measure the available P. Color is developed on filter paper based on a qualitative scheme (see Eidt, 1973). The advantage of the spot test is fast, low-cost results, but the disadvantages are qualitative non-reproducible results (Holliday, 2004b).

Available P refers to techniques that extract the water-soluble P and weakly held P fractions (Olsen and Somers, 1982). This involves extracting the P with weak acid and developing color intensity that can be read in a spectrometer. Available P types are often referred to by the name of the person who developed them such as Olsen P, Bray 1, or Mehlich II tests. They are differentiated because they use different extractants. Available P can also be done in the field with a portable spectrometer (see Terry et al., 2000).

Phosphate fractionation is the process of sequentially extracting P beginning with the most weakly bound P using extractants that target specific P compounds (Olsen and Somers, 1982; Meixner, 1986b). As many as eight different fractions, grouped into non-occluded P (three extractions), occluded P (three extractions), calcium bond P (one extraction), and organic P (one extraction), can be involved (see Meixner, 1986b). Most P fractionations in geoarchaeological applications use a three-fraction extraction sequence developed by Eidt (1977). This is an intensive wet chemistry procedure that targets the weakly bound Fe and Al-P and the reabsorbed Ca-P as fraction I (Eidt, 1977). Occluded P is fraction II and calcium P and apatite are fraction III.

Total P can be determined by using very strong acids to completely digest the soil, and P is measured colorimetrically (Olsen and Somers, 1982; Meixner 1986c). Total P can also be measured using ICP spectrometry, usually as one of a suite of elements. The ICP measures the P content so the type of P measured still depends on the extraction procedure.

Carbonates

The origin of carbonate in soils is either from eolian sources, inherited from calcareous parent material, or weathered from non-calcareous parent material (Birkeland, 1984). Pedogenesis results in carbonate accumulations in soils in arid and semiarid climate zones and in its removal from the soil system in humid and tropical climatic zones (Birkeland, 1984; Boul et al., 1989). Carbonates are often measured as a part of soil/deposit characterization by determining the presence or absence of free carbonate using a few drops of HCl or less often by laboratory analysis. Results are used to determine the presence or absence of an anthropogenic carbonate load by comparison of control samples or other regional soil data and, if carried a step further, to interpret the anthropogenic changes in the pedogenic trajectory relative to site formation processes. For example, carbonates can dominate the soil chemistry in part by their effect on pH which in turn affects artifact preservation, especially bone and shell, and the post-depositional evolution of any anthropogenic additions (e.g., see Weiner et al., 2002).

Sources and transformations in soils and deposits

The source of the carbonates in soil is atmospheric dust containing carbonate and Ca^{2+} ions (Machette, 1986; Birkeland, 1984) and carbonate in parent materials (limestone, gypsum, dolostone, loess, glacial deposits from carbonate terrain). Parent material weathering in non-calcareous soils cannot account for the large amount of carbonate in arid and semiarid soils (Birkeland, 1984). In arid and semiarid regions, pedogenic processes form calcic soil horizons (K horizons) (Birkeland, 1984; Machette, 1986). In humid and tropical soils with lower pH, the carbonate is disassociated and is leached out of the soil system or accumulates as minor secondary carbonates in the C horizon (Boul et al., 1989).

Anthropogenic additions, subtractions, and transformations

Anthropogenic additions that may increase the carbonate content in soils or lead to the formation of secondary carbonates are limestone and dolostone for cooking and, in some cases, pottery manufacturing and/or food processing, building material (plaster and stone), wood ash, and shell (Cook and Heizer, 1965; Woods, 1982; Schiegl et al., 1996). The age of the archaeological site, soil conditions, and landscape position are some factors that affect the post-depositional modification of anthropogenic carbonate additions. For example, physical and chemical processes during pedogenesis may destroy or fragment shell or carbonate rock adding secondary carbonate to the soil or removing it from the soil system entirely. Soil – geomorphic and stratigraphic – studies at archaeological sites record the soil carbonate status for characterization purposes with little geoarchaeological interpretations. Woods (1982) interprets the high carbonate levels in a midden in Illinois to be the result of the addition of ash to the midden. Indirectly human activity (e.g., land clearing and agriculture) that causes geomorphic instability may result in wind erosion, which could also add carbonate to soil.

Analytical methods

The simplest measure of the presence of carbonate in soil is to observe the strength of soil reaction to 10 % HCl. The strength of the reaction is measured by the violence of the effervescence. The more carbonate, the more violent the reaction.

The loss-on-ignition (LOI) (Dean, 1974) method is used to determine both OM and carbonate. A sample is placed in a furnace first to 550 °C to destroy the organic matter, cooled and weighed, then put back in the furnace and heated to 1,000 °C to drive off the CO_2 in the carbonate. The sample is cooled and weighed again to determine the percent carbonate. Dean (1974) compared the LOI method with acid extractions and then titration and with determination of total Ca with atomic absorption and found that they yielded very similar results. Thermogravimetric analyzers have now completely automated the above procedure.

In the acid neutralization method, the carbonates are dissolved in acid and the amount of carbonate is determined by titration (Nelson, 1982). The gravimetric method uses a Chittick apparatus to determine the volume of CO_2 evolved during acid digestion (Machette, 1986).

Geoarchaeological applications

The section on applications begins with examples of the use of phosphorus in geoarchaeological studies. Phosphorus data have been used as a tool in geoarchaeological investigations for nearly a century, and the literature is relatively extensive (see Eidt, 1985; Wells and Terry, 2007). The treatment below is not comprehensive and attempts to group the investigations by type. Chemical analyses, including phosphorus, are a part of a suite of measures used in the study of the Amazonian dark earths and are not included here (Glaser and Woods, 2004; see Woods this volume). Most investigations focus on the spatial distribution of P anomalies on the landscape surface within and around sites. The goal of these studies is to find site boundaries or to identify activity areas within sites. This involves examining both positive and negative P anomalies.

Skinner (1986) investigated P levels at five archaeological sites in Ohio. The goal of the investigation is to determine if P can identify anthropic soils and locate site boundaries determined by artifact distributions. Three different extraction techniques are compared for available P and one for total P. The conclusion is that the reliability of P as an anthrosol indicator depends on the geomorphic and pedogenic context specifically whether or not a soil/site was subject to inundation (i.e., located on a floodplain).

Roos and Nolan (2012) used available P (Mehlich II extraction) levels from 131 samples at a late prehistoric village site in Ohio to map intra-site activity areas. They were able to identify a ring midden and plaza using P data supported by magnetic data and artifact distributions.

Schuldenrein (1995) used soil chemistry (pH, OM, K, Ca, Mg) including available P, total P, and P fractionation, to detect activity areas at two sites in contrasting environments: the semiarid plains and humid temperate woodlands, both in the USA. Comparisons of control sample series with on-site and feature sample series indicate anthropogenic anomalies are present at both sites and is most strongly characterized by levels of P and K or P and selected other measures depending on the physical and cultural context. Plots of the three P fraction loadings on ternary diagrams are proposed as a graphic means of differentiating types of activity areas.

Woods (1982) found the following chemical trends at archaeological sites in Illinois. Carbon (organic matter) and nitrogen level were higher in midden soils than in control soils and both decreased in magnitude with depth. He found pH levels to be significantly more alkaline than control samples due to the large amount of wood ash in the middens that in effect neutralizes the acidifying effect of decaying organic matter. He also attributed carbonates in the middens to the addition of wood ash in an alkaline environment. P is high in the middens and absolute levels correlate with soil texture with P levels higher in clayey soils.

A number of interdisciplinary investigations have been conducted at the Piedras Negras site and surrounding modern settlements in Guatemala. These studies all use a field test procedure based on a Mehlich II acid extraction and measurement with colorimetry modified for use in relatively primitive field conditions (Terry et al., 2000; Wells et al., 2000; Parnell et al., 2001). The investigation identified a good correlation between P levels, density of ceramics, and boundaries of disposal areas. Fernandez et al., (2002) and Terry et al., (2004) investigated soil chemical signatures in modern settlements and a Mayan archaeological site to explore the relationship between chemical data (P, pH, Mg, Na, K, and trace elements) and household human activities. Phosphorus was high in areas of food processing, consumption, and disposal. Food preparation areas had high levels of P, Mg, and K and were more alkaline, while food consumption areas had high P and Na and were more acid. Traffic lanes had low P and refuse disposal areas have high P.

Dunning (1993) used total P to distinguish different types of land use and P fractionation to differentiate between agricultural and nonagricultural soils. High P levels are interpreted as areas that were gardens and likely fertilized and areas with depleted P as places of more intensive field agriculture.

Sandor (1992) compared the morphological and chemical characteristic of terraced cultivated soils and uncultivated soils at a 1,000–1,500-year-old prehistoric site in New Mexico, USA. Cultivated soils lost organic matter, N, and phosphorus (total and moderately available) and lowered pH. In contrast soils in terraced fields in Peru have elevated levels, relative to uncultivated soils, of total and available P, nitrate nitrogen (NO_2-N), total nitrogen, and organic carbon. Soil pH tended to be more acidic due to the increased organic matter. The chemical data, supplemented the archaeological evidence and soil morphological data, indicating the agricultural soils in New Mexico were not amended or fertilized and the agricultural soils in Peru were amended and fertilized. More recently similar methods including chemical analysis of soils was applied on a more regional scale to Native American agricultural system in the American southwest (Sandor et al., 2007) and more specifically to prehistoric Zuni agricultural systems (Homberg et al., 2005). Note these studies are among only a few that measured any form of nitrogen in geoarchaeological contexts (also see Woods, 1982).

Cavanagh et al. (1988) used HCl-extractable P data to map boundaries of sites in Greece. A positive correlation was found between high pottery sherd densities and high P levels.

The following investigations examine P distributions stratigraphically. Lippi (1988) used stratigraphic data (including artifacts), obtained from cores, and P data, obtained using the field ring test, to map paleosols and activity areas at the Nambillo site in Ecuador. The strata and soil description and P data provided an excellent framework for planning excavations and for making interpretations of land use on the buried landscape surfaces.

Katina (1992) used fractionation to test Eidt's ideas about the correlation of total P with intensity of land use and the use of fraction II/I ratio to determine relative time elapsed since phosphate enrichment. Results of the fractionation were very difficult to interpret because of the land-use palimpsest, but the total P and fraction II/I ratio was used to support soil landscape degradation during the Bronze Age followed by less intensive use during the Middle Ages.

Davidson (1973) used total P (fused with sodium carbonate and measure colorimetrically) from a tell stratigraphic sequence to measure intensity of occupation. P indicates that the (1) intensity of occupation increased up section and (2) the tell sediments have higher P than the local alluvium. He concluded that "phosphorus analysis confirms what might be expected-the tell evolved as a result of occupation and thus the activities of people who occupied the site.... accounts for the growth of the tell" (Davidson 1973, 146).

Bakkevig (1980) claims to get good results from the spot test in part because large numbers of samples can be processed quickly allowing a researcher to obtain data from a large area. The research questions involved correlation of land use with P levels and identifying cattle trails.

Ahler (1973) investigated the distribution of total P (perchloric acid/nitric acid digestion), available P (Brays Strong P test), OM (Walkley-Black), and pH from a stratigraphic sequence at the Rogers Rockshelter in Missouri. Results of the chemical analysis are compared with the distribution of lithic debris and micro-debris (sand-sized material of cultural origin). Ahler's results point out the importance of context for interpreting the chemical data. There is a strong correlation among lithic debris, micro-debris, and total P throughout the sequence and a strong correlation with available P and total P in the lower part of the sequence. The difference between the upper and lower stratum is due to higher sedimentation rates during the accumulation of the lower stratum not allowing pedogenesis to alter the distribution of the available P. It is concluded that total P is more useful for locating intra-site activity areas and available P is more useful for subsurface detection of sites and buried soils especially in strata with pHs similar to those at Rogers shelter.

Conclusions

This brief overview of the uses of carbon, nitrogen, pH, phosphorus, and carbonate analysis in geoarchaeological investigation is far from exhaustive but hopefully illustrated the potential such analyses have for answering archaeological questions. When formulating research questions that involve data generated by chemical analysis, the plan should always have some type of control sampling and an understanding of the physical context of the samples. Control samples are necessary because all of the elements, compounds, and measures covered in this overview occur naturally without any anthropogenic input. So by default the analysis has to be comparative. Context is always important but it is particularly important for chemical analysis because of the multiple physical (stratigraphic/pedogenic), chemical, and anthropogenic transformations that occur during and after human occupations. In many cases the evidences for some types of human activity are all or in part chemical signatures and as such are a valuable tool for targeted geoarchaeological investigations.

ANTHROSOLS

Vance T. Holliday
Anthropology and Departments Geosciences,
University of Arizona, Tucson, AZ, USA

Definition

Soils or sediments exhibiting significant chemical inputs as well as obvious physical changes resulting from human activity are called anthrosols.

Introduction

In the FAO (2006) soil classification system, anthrosol is one of the major soil groupings for a broad array of soils "in which human activities have resulted in profound modification or burial of the original soil horizons" (p. 61). Anthrosols vary widely in their physical and chemical characteristics, and few traits are universal. There are several characteristics that are common or that serve as clues to the presence of significant modification due to human activity. The most obvious is the presence of archaeological debris within the soil, in particular organic detritus such as bone and charcoal in a surface horizon, i.e., they tend to be associated with middens. Other physical features, typically applying to surface horizons, include: abrupt, smooth boundaries between horizons or layers; abrupt, laterally discontinuous layers; and dark matrix colors (low value and chroma in the Munsell color system) extending to greater-than-expected depths for natural soils in the area (following Collins and Shapiro, 1987). The greater-than-expected depth is usually due to artificial upbuilding. Chemical signatures include higher-than-expected values of organic matter relative to natural soils and, in particular, phosphate (see below). Anthrosols may also have been subjected to some form of pedogenic alteration albeit relatively minor pedogenesis in many instances.

Types of anthrosols

Anthrosols can include a wide array of soils, but three types have been described at some length: Plaggen, Dark Earths, and Terra Preta. Various other kinds of middens may also qualify as anthrosols.

Plaggen soils are most common on the sandy landscapes of the Netherlands, Germany, and Belgium, but similar soils are reported from other parts of northern Europe and Great Britain, Crete, Peru, and New Zealand (Kalinina et al., 2009; Van Mourik et al., 2011). They developed in the Middle Ages, probably around the tenth century (Pape, 1970; Heidinga, 1988; van de Westeringh, 1988). Manure was the preferred fertilizer, so in order to gather it, the floors of stables were strewn with forest litter, heather turves (slabs of heather cut from the ground), or grass sod to absorb the droppings from sheep and cattle. The mixture of manure, bedding, and mineral matter was then hauled out and strewn on fields. The mineral material brought in with the bedding sometimes provided additional nutrients. The mixture of manure, bedding, and mineral matter increased water-holding capacity and also deepened the plow zone, thus minimizing crop failure.

The *Dark Earth* is common in cities throughout much of Europe ("Urbic Anthrosols" of FAO, 2006). "Dark Earth" is a term applied to dark-colored, seemingly homogeneous urban deposits. In many ways, they can be considered anthropogenic sediments rather than soil, but they have undergone surface weathering and are typically considered a soil. In Britain, these soils are linked to late- or post-Roman, Saxon, Viking, Medieval, and perhaps post-Medieval occupation. General characteristics of Dark Earths include "an exceedingly uniform color" of dark grayish brown (with Munsell color coding 10YR 4/2) dry, to very dark gray (10YR 3/11) moist, mildly alkaline pH, some $CaCO_3$ (<10 %), 1–2 % organic carbon, some phosphate, and abundant midden debris (Courty et al., 1989, 262).

The *terra preta do Índio* ("black earth of the Indian") or simply *Terra Preta* soil of the Amazon Basin is a well-drained soil characterized by the presence of a thick black, or dark gray, topsoil which contains artifacts (Figure 1). They are found on upland areas adjacent to waterways along older terraces and also on interior uplands (Woods, 1995; Woods and McCann, 1999; Schmidt et al., 2014). In all settings, the dark colors of the Terra Preta contrast strongly with underlying subsoils which are red to yellow Ultisols, Oxisols, Spodosols, and eutrophic Oxisols (Sombroek, 1966; Smith, 1980; Lima et al., 2002). Terra Preta vary considerably in their distribution, morphology, and genesis. The classic black Terra Preta and associated midden debris represent household or near-household trash dumps (e.g., Birk et al., 2011; Schmidt, 2014), but the more ubiquitous dark brown *Terra Mulata*, largely devoid of artifacts or other obvious human debris, may

Anthrosols, Figure 1 A Terra Preta soil of the Brazilian Amazon containing ceramic debris (Photo by William Woods).

represent agricultural soils modified by repeated mulching and frequent burning. This model of soil genesis has some important archaeological implications. It suggests long-standing habitation sustained by permanent gardens and fields. It also contradicts long-held models of settlement in the Amazon based on presumed agricultural limitations of upland and interior soils (see Denevan, 2001).

More broadly, the most widespread activity leading to development of anthrosols is agriculture (see entry on Soils, Agricultural in this volume). The development of agriculture probably has had more pervasive physical and chemical effects on soils than any other activity by preindustrial societies (Goudie, 2000, 29). Agriculture has imposed host of far-reaching effects on the landscape and on soils. The original plant cover can be partially or completely removed, leaving the ground bare for at least some part of the year and subject to erosion by water or wind. Cultivation loosens the soil and the hooves of domesticated animals can further loosen or compact it. Devegetation alters soil moisture and can affect groundwater. Plowing, excavation of irrigation ditches, and construction of terraced fields all physically disturb soils as well. Devegetation, new kinds of plant residues (from burning and cropping), and additions of fertilizer can all alter soil chemistry. Changes in groundwater conditions can drastically affect the soil forming environment. An elevated water table as well as irrigation also induces salinization if salts are present.

The unique morphological (macro- and micro-) and chemical characteristics of soils provide an excellent backdrop against which agricultural activities may be identified (Limbrey, 1975; Courty et al., 1989; Holliday, 2004). The physical signatures of agriculture in soils are related to the disruption of the lateral continuity of and vertical gradations between soil horizons. These disruptions result largely from plowing and the cutting of ditches and furrows. Probably the most obvious initial effect of farming is mixing of the upper solum by plowing. This process is widely recognized today in the identification of the "Ap" plowzone horizon.

At microscopic and chemical scales, impacts on soils due to human activity are generally much more subtle than physical impacts and usually require laboratory analyses for identification. Microscopically, the effects of agriculture include evidence for rapid infiltration of coarse-grained illuvial coatings from downward percolation of solutes or fine particles due to deforestation, and poorly-sorted mineral coatings and infillings of charcoal and SOM (soil organic matter; see below) due to farming.

Chemical impacts on soils come from human refuse and waste, burials, the products of animal husbandry in barns, pens, and on livestock paths, or intentional enrichment from soil fertilizer. With the advent of metallurgy and later industrialization, a much broader spectrum of chemicals and chemical compounds was added to the soil, such as heavy metals and hydrocarbons. The most common chemical elements added to soils by human activity are carbon, nitrogen, phosphorus, and calcium, with lesser amounts of potassium, magnesium, sulfur, copper, and zinc. The most common chemical compound added to soils by humans in agricultural and preagricultural societies and that is also easily recognizable in the field is soil organic matter (SOM). Human activity, largely through discard of organic waste (either in middens or as fertilizer), can add significant amounts of organic matter to the soil surface. Further, additional SOM can be produced and added to the soil by stimulation of soil biota and above-ground biomass subsequent to human activity due to more favorable nutrient conditions often associated with anthropogenic changes. These are notable characteristics of the anthrosols described below.

Anthropogenic additions of carbon, nitrogen, phosphorus, calcium, potassium, magnesium, and sulfur in theory can be used as indicators of past human activity. Most of these elements are removed from soil more or less readily by leaching, oxidation, reduction, or plant uptake, however (Eidt, 1977; Carr, 1982, 127–131), and the nature and rates of these losses from the soil are determined by local biological and pedological processes. Phosphorus in its common form as phosphate, however, is stable and generally immobile in soils and is thus a sensitive and persistent indicator of human activity. Among the elements left in the soil by humans, only P leaves a prolonged signature of its human origins because natural and anthropogenic P tend to be strongly fixed in soils. The sources of anthropogenic phosphorus include (1) human and animal waste; (2) refuse derived from bone, meat, fish, and plants; (3) burials; and (4) manure used as fertilizer (Provan, 1971; Proudfoot, 1976; Eidt, 1984, 29–30; Bethell and Máté, 1989). When people add P to the soil as organic products or inorganic compounds, the P quickly bonds with Fe, Al, or Ca ions (depending on local chemical conditions, particularly pH) to form relatively stable chemical compounds of inorganic phosphate minerals (Proudfoot, 1976; Bethell and Máté, 1989; Holliday and Gartner, 2007). In most soils, removal of these compounds cannot be stimulated by normal oxidation, reduction, or leaching processes, as is true of other elements (Proudfoot, 1976; Eidt, 1977, 1984, 1985). When humans add P to the soil, therefore, it accumulates at the site of deposition. With prolonged occupation, the accumulation of anthropogenic P can become quite large (by orders of magnitude) in comparison to the content of natural P in the soil. Other elements are cycled much more rapidly, assisted by microorganisms and plants in their cycling through the ecosystem, so the record of their association with people is lost.

Another factor which makes P suitable for geoarchaeological study is that anthropogenic P can exist in the pH range of most soils. Under acidic conditions, P combines with iron and aluminum, whereas under basic conditions, P combines with calcium. Consequently, soil P analysis can be used successfully in a wide variety of archaeological contexts. Indeed, where there is little or no surface evidence of human occupation, soil P analysis may be an appropriate tool for detecting traces of human activity and for determining the particular form and function associated with that presence.

The proportional relationships of certain ions have also been investigated archaeologically. Soil pH, which is an expression of the proportion of H^+ ions (or protons) to OH^- (hydroxyl) ions, has some sensitivity to anthropogenic inputs. The concentration of cations (positively charged ions) in the soil strongly influences pH. Prolonged or more intense occupations tend to release more cations to the soil, and therefore, pH tends to be higher within deposits laid down under longer, denser, or more intensely occupied sites (Carr, 1982, 112).

^{40}AR/^{39}AR AND K–AR GEOCHRONOLOGY

Leah E. Morgan
Scottish Universities Environmental Research Centre, East Kilbride, UK

Synonyms

Ar–Ar dating; Argon–argon dating; K–Ar dating

Definition

K–Ar geochronology. A geochronometer (geologic dating method) used to date potassium-bearing rocks, based on the decay of parent isotope ^{40}K to daughter isotope ^{40}Ar.

^{40}Ar/^{39}Ar geochronology. A variant of the K–Ar geochronometer, where ^{39}Ar is measured as a proxy for the parent isotope ^{40}K.

Introduction

The K–Ar method and its derivative, the ^{40}Ar/^{39}Ar method, are based on the radioactive decay of ^{40}K to the noble gas ^{40}Ar (sometimes symbolically indicated as ^{40}Ar*, or radiogenic Ar). Potassium (K) is a major element in the Earth's crust and is abundant in many rocks and minerals. It possesses two stable isotopes: ^{39}K (93 %) and ^{41}K (7 %). After some early indications that a radioactive isotope of potassium of mass 40 might exist (for details see McDougall and Harrison, 1999, and references therein), it was definitively identified by Nier (1935). It was not until later that rocks enriched in ^{40}Ar were identified and the first K–Ar ages produced on K-bearing feldspar and salt minerals (Aldrich and Nier, 1948). Evernden and Curtis (1965) presented the first application of the K–Ar method to constrain ages of paleoanthropological localities by dating rock layers, such as tephra and basalt at Olduvai Gorge, that lie stratigraphically above or below a significant archaeological deposit. Since then, K–Ar and ^{40}Ar/^{39}Ar have been used to constrain the age of numerous paleoanthropological localities, including archaeological events as recent as the AD 79 eruption of Vesuvius that buried the Roman towns of Pompeii and Herculaneum (Renne et al., 1997).

Problematic issues with the K–Ar method (see below for details) were resolved with the introduction of neutron irradiation of samples prior to analysis (Merrihue and Turner, 1966). Irradiation converts some ^{39}K to ^{39}Ar, allowing for determination of parent and daughter isotopes using single samples and ultimately permitting single-crystal analyses. Early applications of the ^{40}Ar/^{39}Ar method included efforts to constrain the age of the KBS Tuff in Koobi Fora, Kenya (Fitch and Miller, 1970; Fitch et al., 1974; Fitch et al., 1976; McDougall et al., 1980; McDougall, 1981).

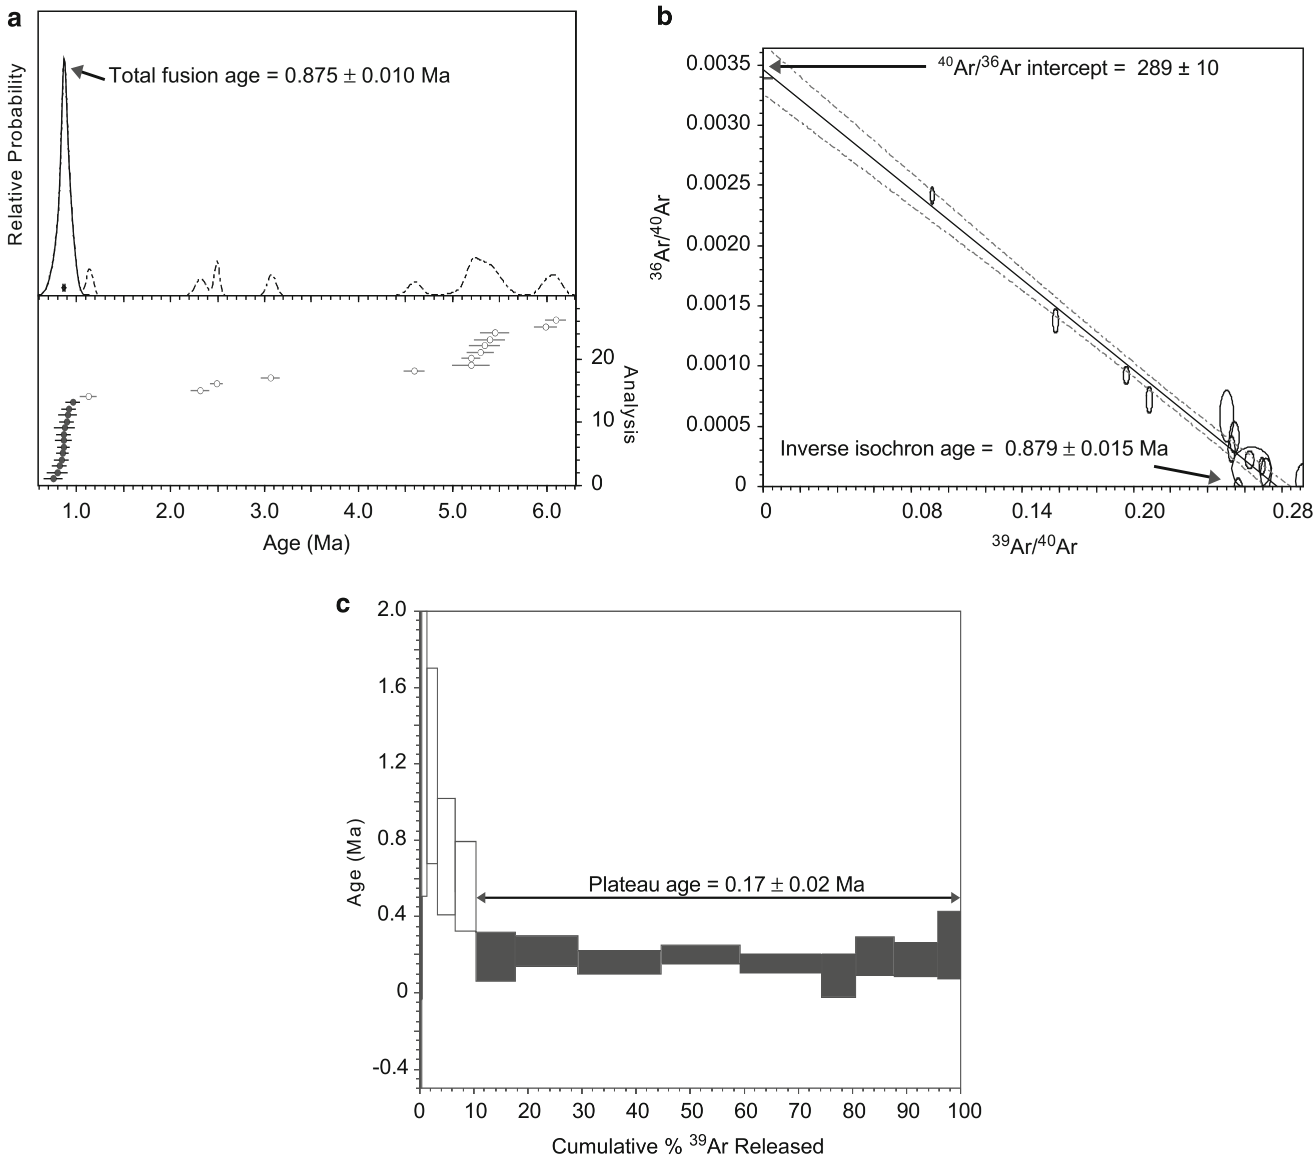
Today, ^{40}Ar/^{39}Ar geochronology has largely superseded K–Ar and is applied to volcanic units at archaeological and paleontological sites globally. The method continues to play a key role in establishing timescales of human biological and behavioral evolution in regions with volcanic deposits.

Principles of K–Ar and ^{40}Ar/^{39}Ar geochronology

The K–Ar and related ^{40}Ar/^{39}Ar methods are based on the constant rate of decay of ^{40}K to ^{40}Ar. A common measure of decay is the half-life, during which time half of the ^{40}K atoms in a given system will decay. The ^{40}K decay is a branched one, where about 90 % of atoms decay to ^{40}Ca, while about 10 % of atoms transform into ^{40}Ar. Application of these systems to archaeological environments is based on their ability to record the age of eruption for in situ volcanic rocks, which have been shown to be related in some way to archaeological remains, e.g., as a capping or underlying layer. Thus, the ages of crystallization for newly formed rocks or minerals are determined and used to bracket the dates of deposition for archaeological or paleoanthropological sites that are stratigraphically related.

The process often begins in a magma chamber within the Earth's crust, where K-bearing crystals of minerals such as feldspars, biotite, and hornblende form prior to eruption. At the high temperatures present in magma chambers, any ^{40}Ar created by ^{40}K decay within a crystal naturally diffuses out of the crystal. Upon eruption and subsequent cooling, argon diffusion is slowed so that any ^{40}Ar created after the eruption is quantitatively retained within the crystal, thereby starting a radioactive "clock." By measuring the ratio of the "daughter" isotope (^{40}Ar) to the "parent" isotope (^{40}K), combined with values of the half-life for the branched decay of ^{40}K, one can calculate the time that has passed since cooling. In the K–Ar method, assays must be conducted on two aliquots of the same sample, i.e., two crystals (or groups of crystals) from the same source: one to determine the amount of ^{40}K and another to determine the amount of ^{40}Ar.

The ^{40}Ar/^{39}Ar method has ameliorated a number of issues involved with application of the K–Ar method, including that it allows for the measurement of K and Ar on a single-sample aliquot. This ^{40}Ar/^{39}Ar variant relies on neutron irradiation of samples prior to analysis to



^{40}Ar/^{39}Ar and K–Ar Geochronology, Figure 1 Examples of ^{40}Ar/^{39}Ar data presentation. (**a**) Relative probability diagram for total fusion data from single crystal analyses. The youngest population, which is interpreted here to represent eruption age, is shown in black; xenocrystic contamination by older grains shown in gray (analytical data) and dashed lines (probability). Reproduced with permission from Morgan et al. (2012). (**b**) Same data as (**a**) graphed onto an inverse isochron diagram. The mixing line fit to the data indicates a trapped ^{40}Ar/^{36}Ar component nearly indistinguishable from the atmospheric value of 298.56, and a radiogenic component with an age of ca. 879 ka. Reproduced with permission from Morgan et al. (2012). (**c**) Age spectrum from incremental heating data. Data from argon released during consecutive heating steps are shown from left to right. Note that consistent ages are identified over the last nine steps represented by the horizontal line; the weighted mean of these steps is presented as the plateau age (ca. 170 ka), which is read on the vertical axis. Earlier steps are inconsistent and omitted. Reproduced with permission from Morgan et al. (2009).

convert some fraction of the ^{39}K present in the sample to ^{39}Ar and therefore permit the measurement of ^{39}Ar as a proxy for the parent isotope ^{40}K. This is possible by using a natural value for the global ^{40}K/^{39}K ratio (for purposes of most applications, this value is reasonably assumed to be constant).

A major advantage of the ^{40}Ar/^{39}Ar system is that it allows for all required measurements to be made on a single-sample aliquot. Thus, analysis of single crystals becomes possible, permitting the identification of contamination from older, embedded crystals (or xenocrysts) that can be masked when using multigrain aliquots (Figure 1a).

In order to provide reliable ages, samples for $^{40}Ar/^{39}Ar$ analysis must be coirradiated with standards of a known age to determine the precise neutron flux of the reactor during irradiation. These standards may have been previously dated via K–Ar analyses (Lanphere and Dalrymple, 1966; McDougall and Roksandic, 1974; McDougall and Wellman, 2011) or based on intercalibration with other systems, such as the astronomical timescale (Kuiper et al., 2008) or the U–Pb geochronometer (Renne et al., 2010; Renne et al., 2011). The standard ages and decay constant values used to calculate $^{40}Ar/^{39}Ar$ ages have changed over time, typically as more precise and accurate values are determined. Understanding and comparing $^{40}Ar/^{39}Ar$ ages thus requires knowledge of the values used for their calculation.

When single grains are sufficiently large and/or old (thereby providing greater amounts of radiogenic ^{40}Ar), the $^{40}Ar/^{39}Ar$ system can be further exploited by incrementally heating samples (rather than releasing all gas in a single, "total fusion" heating step). The "age spectrum" (Figure 1c) obtained by an incremental heating analysis can be used to identify problematic samples, assess the homogeneity of argon in crystals, and understand the thermal history of a sample.

Finally, when using the K–Ar method, one must make the assumption that argon trapped in the crystal upon cooling had an $^{40}Ar/^{36}Ar$ value equivalent to that of the present atmosphere. Most atmospheric argon is ^{40}Ar (99.6 %) and was produced by the decay of ^{40}K, while argon in the solar system and beyond is largely ^{36}Ar (85 %), which is rare on Earth and forms a ratio of $^{40}Ar/^{36}Ar$ in Earth's atmosphere of 298.56:1 (Lee et al., 2006). This assumption can be tested using the $^{40}Ar/^{39}Ar$ method by viewing either total fusion or incremental heating data on an inverse isochron diagram (Figure 1b). This diagram shows the mixing between the trapped component $^{36}Ar/^{40}Ar$ (Y-intercept) and the radiogenic component $^{39}Ar/^{40}Ar$ (X-intercept). Deviations from an atmospheric trapped component, which are particularly important for young samples, can be identified and rectified.

Sample materials

In archaeological settings, K–Ar and $^{40}Ar/^{39}Ar$ geochronology are often applied to various kinds of lavas and consolidated volcanic ashes, or tuffs. Within these materials, frequently analyzed potassium-bearing minerals include feldspars (particularly K-rich sanidine but also anorthoclase and plagioclase), biotite, and hornblende. Because of their young age, samples relevant to archaeological sites require higher potassium concentrations to obtain precise ages, so the utility of minerals with less K, such as plagioclase feldspars, is limited. For all samples, impurities such as fluid inclusions and alteration products should be avoided. For single-crystal work on young samples, desired grains are typically >250 μm. Although recent analytical improvements and optimum samples allow for analysis of grains as small as 50 μm, smaller grain sizes produce unreliable results due to nuclear effects during irradiation (Paine et al., 2006; Jourdan et al., 2007).

Analyses of lava flow samples can be conducted on mineral separates (e.g., one of the K-bearing minerals listed above), groundmass (microcrystalline matrix), or whole rock. Groundmass analyses require the separation of phenocrysts from a crushed sample, while in the case of whole rock, sample fragments are sufficient. Although care must be taken, some volcanic glasses such as obsidian can be a viable material for $^{40}Ar/^{39}Ar$ analyses, but glass shards from volcanic ashes have been shown to yield unreliable results that are difficult to recognize as inaccurate (Morgan et al., 2009).

The method can be applied to rocks as old as the Earth and, depending on their K content and required precision, as young as 1 ka. For example, basalts as young as 3 ka have been dated with precisions of 1 ka (1σ, here and throughout) (Hicks et al., 2012). Similarly, K-rich feldspars as young as the eruption of Vesuvius that destroyed Pompeii in AD 79 have been dated (accurately according to historical records) to 1.925 ± 0.047 ka (Renne et al., 1997). Precision typically degrades as signal size decreases (along with K content, age, and grain size), but it is important to distinguish analytical precision from accuracy, especially when comparing ages from different chronometers. Calibrations of standard ages and decay constants can result in total (analytical + systematic) uncertainties as low as <0.2 % at ca. 1 Ma (Renne et al., 2010; Renne et al., 2011), but perhaps more typical are uncertainties at the 1–2 % level (see case study below). However, recent calibrations of standard ages and decay constants do vary at the 0.3 % level in the same time frame (Kuiper et al., 2008; Renne et al., 2011) and are particularly important to consider when comparing ages obtained using different chronometers.

Sampling procedures

Successful sampling for $^{40}Ar/^{39}Ar$ analyses requires careful preparation and implementation. Typical targets include volcanic ashes (e.g., tuffs) or lava flows that have been identified as having some relationship with the paleoanthropological material of interest. Accurate ages first and foremost require the careful documentation of stratigraphic and structural relationships between the dated unit and the horizons containing the archaeological evidence needing an age determination, as these field relationships ultimately control the significance of any obtained age constraints. Sampling volcanic ashes often requires care to avoid contamination from plant roots, both ancient and modern, which can rework sediments and introduce material of different ages into a sample. Success rates improve by examining a volcanic ash in a number of localities to identify the best one for sampling (i.e., the most crystal-rich and stratigraphically clear area). Lava flows can be variably altered, and success is improved by sampling the least altered regions.

Laboratory procedures

The first step of sample processing involves separating K-bearing minerals from a bulk volcanic ash or lava sample by crushing (if the sample is indurated), sieving, and separation of minerals based on magnetic and density properties. Ultimately, individual grains are visually selected for further analysis; this can involve from tens to hundreds of grains per sample. Lava flows may alternately be run as "whole-rock" or "groundmass" aliquots, where either the entire crushed sample or the groundmass is selected for further analysis. Groundmass analyses require the removal of any phenocrysts present in the sample. Selected grains are often treated with hydrofluoric (HF) acid to remove alteration and weathering products as well as any remaining volcanic glass from grain surfaces. One exception to this is biotite, the argon systematics of which can be affected by acid treatment. Following these procedures, the samples are wrapped in aluminum packets along with appropriate standards and sealed in a quartz glass tube. Standards used should be of an age similar to that of the sample. For example, when dealing with quaternary samples, many workers use the 1.2 Ma Alder Creek sanidine standard (Nomade et al., 2005; Renne et al., 2011). Samples and standards are then sent for irradiation, where they are placed in the core of a nuclear reactor and thus experience a neutron flux. This induces the nuclear reaction $^{39}K(n,p)^{39}Ar$, in which a neutron is captured by the ^{39}K atom and a proton is emitted, creating ^{39}Ar. A number of other interfering reactions also occur, for which corrections must be made.

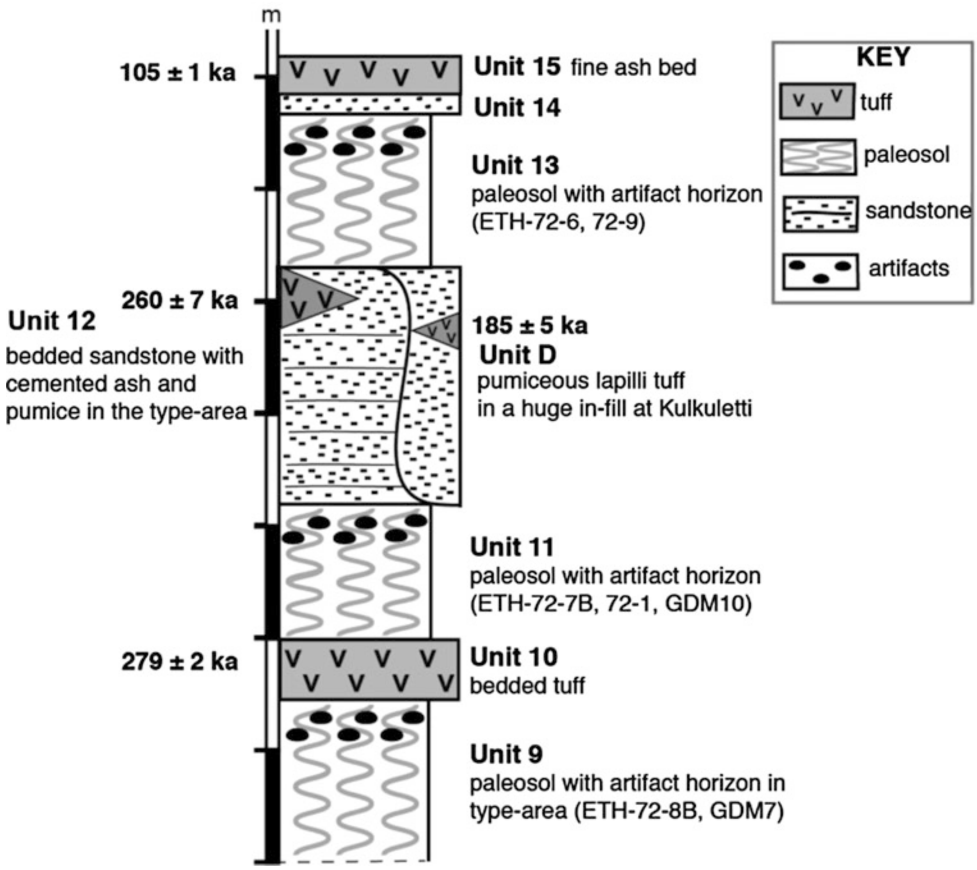
Following irradiation, samples and standard grains are transferred individually from irradiation packets into a disk for laser analyses (typically stainless steel or copper, with small pits for each grain), or foil packets for furnace analyses, which are loaded into the extraction line. The extraction line (which is directly connected to a noble gas mass spectrometer) is heated to ca. 100–150 °C under vacuum for at least several hours to decrease atmospheric argon contamination and reach pressure levels associated with an ultrahigh vacuum (ca. 10^{-9} mbar). Individual aliquots (typically single grains for volcanic ash samples) are then heated with a laser or furnace to release Ar from the grain. Laser analyses have lower "background" contamination than furnace analyses and thus are more commonly used for single-grain work.

The aim of total fusion analyses is to reach a temperature sufficient to release most Ar in a single step. Quantitative release of Ar is not necessary for age determinations. Incremental heating analyses (see above) begin at lower laser or furnace power; subsequent analyses increase that power sequentially. During and following heating (for either total fusion or incremental heating), released gas expands into an extraction line containing "getters" that trap reactive gases and thus serve to purify the noble gases (largely Ar) which do not react with getter material. Some laboratories also expose released gas to a "cryotrap," which freezes out water and other condensable phases.

Purified gas is subsequently expanded into a mass spectrometer, where atoms are ionized via an electron impact source, accelerated through a flight tube, turned and separated according to isotopic mass by a magnet, and then detected. Recent advances allow for the simultaneous detection of multiple isotopes via multicollector detector arrays, though many systems still in use produce excellent data with single collectors by employing peak-hopping methods to measure each isotope multiple times. Between sample and standard analyses, system blank values are measured by reproducing all steps apart from powering the laser or furnace; values determined for each isotope are subtracted from each sample and standard analysis. A correction is also made for mass-dependent isotopic fractionation (or "discrimination") in the mass spectrometer. This is achieved by comparing the difference between $^{40}Ar/^{36}Ar$ values in an aliquot of cleaned natural air and the known $^{40}Ar/^{36}Ar$ values of the terrestrial atmosphere, first estimated by Nier (1950) and updated by Lee et al. (2006). Although this is not always the case for historical ages, sufficient data should be published to allow for future age recalculation using different standard ages and half-life values. See Renne et al. (2009) for a complete description of reporting norms and requirements to allow for age recalculations using updated parameters.

"Absolute" ages, uncertainties, and comparisons with other methods

Age interpretation from any chronometer often relies on the ability to associate or calibrate the system with other chronometers or calendar years. Although some chronometers conventionally calculate ages relative to a particular time (e.g., ^{14}C), the K–Ar and $^{40}Ar/^{39}Ar$ systems yield ages relative to the time of analysis. As discussed above, calibration is dependent on the half-life of ^{40}K and standard ages applied to age calculations. Values for these parameters have been measured numerous times, and results can vary considerably between measurements (e.g., Beckinsale and Gale, 1969; McDougall and Roksandic, 1974; Steiger and Jäger, 1977; Renne et al., 1998; Min et al., 2000; Kuiper et al., 2008; Renne et al., 2010; McDougall and Wellman, 2011; Renne et al., 2011). Fortunately for paleoanthropological situations, relatively recent determinations (Kuiper et al., 2008; Renne et al., 2011) agree within 0.5 % of the age for relatively young samples (Renne, 2014), which is well within the geologic uncertainty (e.g., the association of dated material to the archaeological material) in most cases. Comparisons of legacy data with newer results, however, may require age recalculation to modern standard and decay constant values; this can be accomplished when sufficient analytical information has been provided.



^{40}Ar/^{39}Ar and K–Ar Geochronology, Figure 2 Composite stratigraphic section for Gademotta and Kulkuletti, Ethiopia. The ^{40}Ar/^{39}Ar method was used to constrain the ages of tephra from units 10, 12, and D. Artifacts found in Unit 9 are some of the oldest known Middle Stone Age artifacts in Africa. Reproduced with permission from Sahle et al. (2014).

Case study

Some of the earliest evidence for Middle Stone Age (MSA) archaeology in Africa is found in the Gademotta Formation near Ziway, Ethiopia. First excavated and dated by K–Ar in the 1970s by Fred Wendorf and colleagues (Wendorf and Schild, 1974), the ages of sites in the type locality and the nearby Kulkuletti area were revisited using the ^{40}Ar/^{39}Ar method in the 2000s (Morgan and Renne, 2008). Ages were obtained on sanidine crystals from two key tephras in the stratigraphy, Units 10 and D (Figure 2), and glass shard geochemistry linked the tephras between the two localities. The ^{40}Ar/^{39}Ar method yielded ages even older than those from K–Ar, likely due to incomplete degassing of feldspars during the K–Ar analyses. Artifacts found below Unit 10 (279 ± 2 ka) indicate that Gademotta contains some of the earliest known MSA artifacts. Renewed interest in the site led to further excavations (Sahle et al., 2013; Sahle et al., 2014), in which additional ^{40}Ar/^{39}Ar work yielded an age for a previously undated layer (Unit 12). Archaeological data indicate that the lowermost Gademotta site contains the earliest evidence for stone-tipped projectiles (Sahle et al., 2013).

Summary

K–Ar and ^{40}Ar/^{39}Ar geochronology exploit the decay of ^{40}K to ^{40}Ar. They have been used to constrain the ages of numerous paleoanthropological localities in areas with suitable volcanic deposits around the world. The age constraint is typically obtained for a volcanic rock interbedded or otherwise associated with archaeological and/or paleontological material, and thus the analyzed sample yields minimum or maximum ages for that material, depending on the association.

Introduction

Archaeologists have utilized stratigraphy in order to correlate sediment layers and archaeological assemblages for well over a century (Harris, 1989; Lyman and O'Brien, 1999; O'Brien and Lyman, 1999; Stein, 2000; Mills and Vega-Centeno, 2005). Relative-age determination based on the law of superposition and context is now used in essentially all archaeological excavations, and it is the foundation of almost every other dating technique as well as being more frequently applied than any other method. A site may contain hundreds of superimposed sediment layers, or built structures such as plazas, foundation walls, and streets, but in every case, stratigraphy is needed to interpret the age relationships of the artifacts and architecture. Stratigraphy is also crucial in reconstructing the landscape of occupation and past environments and in understanding *site formation processes* (see entry on Site Formation Processes in this volume). There have been few attempts to establish a systematic approach to archaeological stratigraphy and a nomenclature for its concepts and terms, however.

In contrast, geologists have compiled stratigraphic guides in response to the need "for uniform standards and common procedures in defining and classifying formal rock bodies, their fossils, and the time spans represented by them" (North American Commission on Stratigraphic Nomenclature, 2005, 1555). In these guides, the language used to denote rock units and their spatial and temporal relations has been formalized. In most geological stratigraphic guides, subdivisions of rock sequences are based on lithology (*lithostratigraphic units*), on fossil content (*biostratigraphic units*), and on the time periods in which rocks were deposited (*chronostratigraphic units*). Stratigraphic classification also includes soils and related weathering phenomena (*soil-stratigraphic* or "*pedostratigraphic*" *units*) and bounding discontinuities (*allostratigraphic units*) (see entries on Stratigraphy and Soil Stratigraphy in this volume) (North American Commission on Stratigraphic Nomenclature, 1983, 2005).

To establish stratigraphic schemes at archaeological sites, some archaeologists and geoarchaeologists have simply followed the rules of the *Code of Stratigraphic Nomenclature* established by geologists (North American Commission on Stratigraphic Nomenclature, 1983, 2005) or the *International Stratigraphic Guide* (Hedberg, 1976; Salvador, 1994; Murphy and Salvador, 2000). This can work as far as the Code goes, but it was established by and for geologists working with bodies of rock and spans of time longer than would be encompassed by most archaeological sites. Further, some archaeological sites contain geologic or occupation records that are very complex within very small areas (e.g., a cave or a tell). In geology, local complexities can be subsumed within the characteristics of larger bodies of rock. In archaeology, the localized geologic complexities of sites may be of particular interest because they have a direct bearing on interpreting the occupation record and the site formation processes. For example, local spring deposits may hold a crucial component of the archaeological record in a larger site, and thus establishing a nomenclature for those spring deposits is essential. Typical for many site stratigraphies are simple letter or number sequences (e.g., strata 1, 2, 3 or units A, B, C) with subdivisions (e.g., 1A, 1B or A1, A2). Formation/member terminology, following the North American Commission on Stratigraphic Nomenclature, has been applied in a few geoarchaeological situations (e.g., Laury and Albritton, 1975; Stafford, 1981; Haynes and Huckell, 2007).

Following the example of geologists, some archaeologists and geoarchaeologists have proposed a set of rules for clarifying terminology and classification in archaeological stratigraphy. Schiffer (1972, 1976, 1983, 1987) proposed a classification scheme for the archaeological record based on objects found within deposits rather than on the physical characteristics of the deposits themselves. Harris (1977, 1979, 1989; Harris et al., 1993) made a significant contribution when he proposed a modest classification system, with special emphasis on how to record stratigraphy. The "Harris Matrix" may be the best known and most widely applied archaeological stratigraphic classification system, but it is best applied in sites with a complex history of occupation with numerous features and abundant artifacts (see also papers in Roskams, 2000).

Gasche and Tunca (1983) were the first to propose a formal archaeological stratigraphic nomenclature based on geological guides as well as three separate formal units for archaeological strata based on lithology, artifactual content, and time periods. The purpose of Gasche and Tunca's guide is to "facilitate and even to stimulate the exchange and correlation of all information produced from archaeological sites . . . and to establish a cross-referencing system, which would be as objective as possible . . . and that would eliminate the ambiguities brought about by an arbitrary language" (Gasche and Tunca, 1983, 325).

Gasche and Tunca proposed three stratigraphic units for dividing archaeological sediments: (1) on the basis of lithology, i.e., lithologic units; (2) on artifactual content,

Archaeological Stratigraphy, Table 1 Formal stratigraphic terms used in geoarchaeology and geology

Classificatory basis	Stratigraphic classification Geoarchaeology	Formal subdivisions	Stratigraphic classification Geology	Formal subdivisions
Lithology (physical and/or	chemical composition)	Lithologic unit *Time-transgressive*	Layer Sub-layer Inclusion Elemental sediment unit	Lithostratigraphic unit *Time-transgressive*
Formation, member, bed				
Time	Chronostratigraphic unit *Specific time interval*	Set Phase Sub-phase	Geochronologic unit *Specific time interval*	Eon, era, period, epoch, age
Fossils	Biostratigraphic unit *Time-transgressive*	Biozone	Biostratigraphic unit *Time-transgressive*	Biozone
Artifacts	Ethnostratigraphic unit *Time-transgressive*	Zone Supra-zone Subzone	None	None

i.e., ethnostratigraphic units; and (3) on time periods, i.e., chronostratigraphic units. They argued that archaeostratigraphy can be accommodated by two additions to existing geologic stratigraphic guides and codes: (1) a lower-ranking lithostratigraphic unit called the Layer that would include subdivisions of strata useful for archaeology and microstratigraphy and (2) ethnostratigraphic units called the Zone, Supra-zone, and Subzone that would divide sequences of layers according to their artifactual content. This scheme has not been widely adopted, but it provides a good starting point for a broader discussion of archaeological stratigraphy (Table 1).

Lithologic units

A lithologic unit is a "three-dimensional body characterized by the general presence of a . . . (dominant) . . . lithologic type, or by the combination of two or more of these types, or even by the presence of other particularities that confer on the unit a homogeneous character. . .. Among other particularities, detailed attention should be paid to the lithologic content, the structure, texture, and color of the content, and the degree of erosion or denudation and their geometry" (Gasche and Tunca, 1983, 328, 329). In the archaeostratigraphic guide, the lithologic unit is equivalent to the *lithostratigraphic unit* in other geological stratigraphic guides and codes. Lithologic units are termed "Layers" (the basic unit used in stratigraphic correlations), "Sub-layers" (lithologic units that form part of a Layer), and "Inclusions" (smaller units that are part of a Layer or Sub-layer).

Although Gasche and Tunca (1983) were the first in archaeology to define a lithologic unit comprehensively, Fedele (1976, 1984) had suggested a similar unit earlier. Fedele defined an elemental sediment unit (ESU) as "a unit constituting the smallest geologically homogeneous entity as perceived in excavation . . . (and) contained between two consecutive recognizable discontinuities" (Fedele, 1976, 34). An ESU could be a stratigraphic division, a lateral (facies) differentiation, or a pedological horizon. An ESU is a ". . . formally named fact in the structure of a given site, whose mappable distribution can eventually be used as a marker" (Fedele, 1984, 11).

The proposal to adopt "lithologic unit" in geoarchaeology led to much discussion and some favorable reviews (Colcutt, 1987; Fedele and Franken, 1987; Farrand, 1984; Le Tensorer, 1984; Stein, 1987). The new unit was seen as needed due to (1) problems of scale; (2) disagreement as to the importance and nature of discontinuities in archaeological lithologic units, in contrast to the importance and nature of discontinuities in geological lithostratigraphic units; and (3) the need to describe archaeological sediments with attention to characteristics that are appropriate for archaeological stratigraphic inquiry. Stein (1990), however, argued that there was insufficient reason to propose a new type of lithostratigraphic unit. Rather, there was need for a formal lithostratigraphic unit (i.e., in the North American Commission on Stratigraphic Nomenclature) smaller than the existing unit of lowest rank (the Bed).

The first and most obvious dissimilarity between an archaeostratigraphic "Layer" and other lithostratigraphic units is in scale. The primary lithostratigraphic unit for geologists is the formation. Its spatial characteristics are purposely vague. The authors of the *International Stratigraphic Guide* say that "the thickness of units of formation rank follows no standard and may range from less than a meter to several thousand meters . . . [and that the] practicability of mapping and of delineation on cross sections is an important consideration in the establishment of formations" (Hedberg, 1976, 32). The authors of the *North American Stratigraphic Code* state that "thickness is not a determining parameter in dividing a rock succession into formations; the thickness of a formation may range from a feather edge at its depositional or erosional limit to thousands of meters elsewhere. . .. No formation is considered valid that cannot be delineated at the scale of geologic mapping practiced in the region where the formation is proposed" (North American Commission on Stratigraphic Nomenclature, 2005, 1569). Mappability is a crucial determinant in these two definitions. In archaeology, strata are differentiated in much the same way as in geology (i.e., on the basis of physical characteristics), but typically on the scale of a few meters down to centimeters or millimeters. Archaeological strata are also convenient for mapping at a scale appropriate for an archaeological site, but not always for a geologic region.

Layers that terminate laterally over short distances are common in archaeological sites (Tunca, 1987; de Meyer, 1984), and often they cannot be condensed into one general sequence (Cordy, 1987a). Correlations in stratigraphically complex archaeological sites frequently depend on the order of deposition of small disparate layers (discerned by recording overlapping edges) rather than on major stratigraphic units extending over the whole site. Thus, archaeologists do not expect to use "layers" in the same manner as geologists use "formations."

The importance and nature of discontinuities in archaeological stratigraphy generated some discussion, centering on an argument that discontinuities generated by humans are different from, and more numerous than, geologic discontinuities, and they therefore need their own terminology (Gasche and Tunca, 1983, 329). Logic argues that archaeological discontinuities should be described using a descriptive classification based on geologic terms (e.g., abrupt conformities, angular unconformities, disconformities).

Strata in archaeological contexts tend to be described in much the same way that sedimentologists describe sediments. Basic descriptors include grain size, grain shape, mineral composition, sedimentary structure, and color. Archaeologists have also examined distinctive attributes of cultural deposits to see if they are different from traditional sedimentological analyses. Schiffer (1987) proposed that, in addition to traditional sedimentological descriptions, certain attributes of artifacts are distinctive and diagnostic in the interpretation of cultural deposition (e.g., roundness of sherd edges). Stein and Teltser (1989) showed that grain-size distributions of separate compositional types of artifacts (e.g., ceramics, lithics, bone) provide a basis for interpretations of archaeological deposition (see also Fladmark, 1982; Rosen, 1986; Hull, 1987; Dunnell and Stein, 1989). Whether non-geological or cultural attributes are necessary in archaeological descriptions of sediment, a standardized, descriptive (nongenetic) terminology is necessary for the description of archaeological (and geological) stratigraphic relations.

An important similarity between the geoarchaeological lithologic unit and the geological lithostratigraphic unit is that they can be time-transgressive ("diachronic"), that is, the age of the upper or lower contacts, or both, is not necessarily the same everywhere. This can be due to varying rates and timing of sedimentation, localized erosion, or localized burial. The correlation of lithologic units does not mean that they are of the same age and, therefore, they may not contain archaeological materials or features of the same age.

Ethnostratigraphic units

Gasche and Tunca (1983, 331) proposed the term "ethnostratigraphic unit" for deposits identified on the basis of their anthropic content (i.e., artifacts). The terms "Zone" (the basic unit), "Supra-zone" (contains one or more Zones), and "Subzone" (subdivision of a Zone) are subdivisions of ethnostratigraphic units. Like the fossils that define biostratigraphic units, the artifacts of ethnostratigraphic units must be only those artifacts whose age of manufacture or use is coeval with the age of deposition of the strata, that is, the artifacts must be products of cultural activities taking place contemporaneously with the deposition.

To determine that an object was made or used concurrently with deposition requires that the observer determine the artifact's age and compare that with the age of the depositional event. Identification of an object as contemporaneous with deposition is, of course, an interpretation and a fundamental issue in fieldwork. Thus, because the goal of stratigraphy is to provide a descriptive system, selection of artifacts whose age of manufacture is contemporaneous with deposition is problematic. Clearly, correct interpretation of an artifact assemblage as contemporary with deposition depends on the training of the person examining the artifacts.

Archaeological stratigraphers follow the example of the *International Guide* and the *North American Stratigraphic Code*, by dividing strata that contain artifacts as distinct stratigraphic units on a level with lithostratigraphic and biostratigraphic units (Cordy, 1987a; Cordy, 1987b; Gasche and Tunca, 1983; Le Tensorer, 1984; van der Plas, 1987). Biostratigraphy and lithostratigraphy are recognized as means of subdividing a sequence of rocks based on different kinds of data. Lithostratigraphic units are subdivisions of rock bodies based on lithologic attributes, while biostratigraphic units are subdivisions-based biological attributes. Ethnostratigraphic units, therefore, are subdivisions of archaeological sediments (essentially unconsolidated rock) based on artifactual attributes. Artifacts accepted as being relevant to ethnostratigraphic description derive from artifact typologies and archaeological theory.

Gasche and Tunca (1983, 331) suggested that descriptions of ethnostratigraphic units be based on artifact classes. Lithologic units are characterized by the classes of artifacts they contain and then are regrouped such that all layers with the same classes of artifacts form one ethnostratigraphic unit. Gasche and Tunca did not discuss necessary conditions for defining a class of artifacts, however. Cordy (1987a, 1987b, 31) suggested that the artifact content of units is not the material on which ethnostratigraphy should be described. He suggested that culture (*entité palethnologique*) is the appropriate basis for definition. Cultures are interpreted from artifact assemblages, but archaeologists do not agree whether this is really possible (Willey and Phillips, 1958; Clarke, 1968; Dunnell, 1982; Binford, 1983; Watson et al., 1984).

Using artifact classes provides a more objective means for identifying ethnostratigraphic units, but such classes are not always standardized in a way that makes correlation from site to site possible. Different archaeologists with different research objectives might describe artifacts in grossly different ways and would certainly argue over the appropriateness of any given class, making stratigraphic correlations across regions extremely challenging. As with biostratigraphy and lithostratigraphy, archaeology needs a formal description of artifacts (separate from the concept of types and classes) that is routinely made at every site. A basic set of descriptive attributes on which all archaeologists would agree would be difficult to select, however. Archaeologists have been arguing about artifact classification for decades (e.g., Krieger, 1944; Spaulding, 1953; Ford, 1954).

Archaeologists routinely define so-called cultural groups on the basis of artifact assemblages, however. These seem to be reasonable approaches to ethnostratigraphy whether or not these groupings truly represent discrete cultures. Examples include a wide variety of ceramic assemblages representing cultural-historical groups such as those in the southwestern USA (e.g., Hohokam). Lithic assemblages are widely used to classify and subdivide archaeological records such as Paleo-Indian in North America (and subgroups such as Folsom and Clovis) or Paleolithic or Stone Age in the Old World (including Lower, Middle, and Upper Paleolithic as well as further subgroups such as Acheulean or Gravettian). The assemblages include descriptions of length, width, and shape of lithics and the temper, paste, surface decorations, and shape of ceramics. Once the assemblages are described and established, sequences of deposits can be grouped and divided on the basis of the presence, absence, or abundance of artifacts with certain attributes.

According to the archaeostratigraphic guide, ethnostratigraphic units are defined by the presence of the classes of artifacts that they contain. The decision about which classes are to be used is problematic, but it is best decided by someone trained in the theory and methodology of archaeology. As long as stratigraphers recognize that a body of rock can be subdivided by various schemes of classification, each independent of one another and developed for specific needs, ethnostratigraphic units should be considered as valid stratigraphic units distinct from lithostratigraphic or biostratigraphic units.

The use of artifacts, as opposed to deposits, to establish stratigraphic sequences in archaeology permits interpretations of reversed stratigraphy, and primary and secondary deposits. When labeling a sequence as "reversed," archaeologists are referring to the temporal order of the age of manufacture for objects contained in the deposit. The terms "primary" and "secondary" deposits describe the history of individual objects within the deposit rather than the deposit itself. The concept of secondary deposit in archaeology refers to the source of the individual artifacts within the deposit. A deposit is considered secondary when at least one of the artifacts within it was transported from another location where it was part of a primary deposit.

Like the lithologic unit, ethnostratigraphic units cannot be assumed to be the same age everywhere. They can be time-transgressive. Artifact assemblages can appear later or last longer in some areas, but not others. Unfortunately, artifact or assemblage correlations are routinely used to make numerical age correlations. Artifact assemblages *generally* can be the same age from place to place, but the timing of their appearance or disappearance cannot be assumed.

Chronostratigraphic units

"Chronostratigraphic units" are suggested as archaeological time-stratigraphic units that are characterized by their duration and by their temporal relations (Gasche and Tunca, 1983), similar to their use in formal geological stratigraphy. Chronostratigraphic units include one or several strata whose sedimentation took place during a specific time interval. The term "Phase" is proposed as the basic time unit. A phase is a grouping of adjacent strata of anthropic origins with a separate grouping of adjacent strata for those of natural origins. A "Set" is a group of phases, and a "Sub-phase" is a subdivision of a phase (1983, 330).

Gasche and Tunca (1983) only minimally discussed the chronostratigraphic unit, and they provided no valid arguments for accepting it as something different from geological chronostratigraphic units. Obviously, they considered the phase to be a subdivision of archaeological sediment that was deposited during a certain period of time, but they did not emphasize the difference (if any) between these sediments and geologic sediments. Rather than elaborate on the purpose of these units and how they differ from geological stratigraphy, Gasche and Tunca elaborated on the "constitution of chronostratigraphic units" (1983, 330). They detailed the manner in which a phase is to be grouped. They emphasized the need to separate deposits that have natural origins from those that have cultural origins and the need to distinguish from natural deposits those "… anthropic deposits whose sedimentation is caused by positive occupation by man (occupation of living floors) or negative occupation by man (filling, raising, etc.)" (p. 330). These preoccupations with natural versus cultural origins are another way of saying that they are subdividing the rocks by their artifact content or as ethnostratigraphic units. This perspective is an ethnocentric view of sedimentation, appropriate for creating ethnostratigraphic units, but it has nothing to do with chronostratigraphic units.

In both geology and archaeology, stratigraphers order strata in temporal sequences. In geology the temporal scale is often longer than in archaeology, but the difference is not sufficiently great to warrant, proposing a new time-stratigraphic unit. Lower-ranking time-stratigraphic units appropriate for archaeological stratigraphy are already inherent in the geologic stratigraphic codes. Both disciplines depend on superposition and isotopic dating to order strata, and both have problems with strata representing deposition that transgresses time (Watson and Wright, 1980).

Archaeological stratigraphy needs shorter but nevertheless formal time terms. In the Americas, for example, the Late Pleistocene and the Holocene, both formal components of the geologic time scale, encompass all of archaeological time; both terms are widely used, including subdivisions of the Holocene into Early, Middle, and Late. Formal definitions of those subdivisions were only recently proposed (Walker et al., 2012), however. In the Old World, chronostratigraphic subdivisions of the Pleistocene (Early, Middle, and Late) are widely used time terms and are well defined geologically (Gibbard and Cohen, 2008), but they span long temporal intervals.

With the advent of coring glaciers, shorter spans of time are being formalized for the Late Pleistocene. As formally defined, the Late Pleistocene began at the start of the last interglacial cycle (~130,000 years ago) and ended with the start of the Holocene. This interval encompassed a broad and complex array of behavioral and biological changes among hominins across Europe, Africa, and Asia, so chronostratigraphic subdivisions are useful. In the Americas, archaeological interest in the Late Pleistocene generally focuses on the final few millennia, so subdivisions are likewise useful. The Younger Dryas chronozone is a good example. Originally based on plant assemblages in northern Europe (a biostratigraphic unit), the term eventually became synonymous with a cold interval (a climatostratigraphic concept) in the last millennia of the Pleistocene. But plant assemblages and climate intervals are time-transgressive and not always globally synchronous nor even recognizable (Meltzer and Holliday, 2010). So now the Younger Dryas is most commonly intended as a time term (Björck, 2007) that is useful in both the Old and New Worlds.

Chronostratigraphic units in geoarchaeology, like their geologic equivalent, are not time-transgressive. Their upper and lower boundaries are the same age everywhere. For example, the lower boundary of the Holocene is about 10,000 radiocarbon years ago everywhere (Björck, 2007). Arguments over the age of the boundaries are normal and to be expected, but by definition they cannot be diachronic (shift around in time). The point of chronostratigraphic units is the designation of previously agreed-upon intervals of time. In our modern lives, each month has an agreed-upon beginning and end to serve our purposes of time keeping. If the beginning or end of chronostratigraphic units varied in time, the point of having such stratigraphic subdivisions would be defeated.

Summary

Archaeologists recognize the need to minimize ambiguity and clarify the distinctions among different kinds of stratigraphic units. To this end, Gasche and Tunca (1983) proposed an archaeostratigraphic guide, which introduced stratigraphic units: lithologic, ethnostratigraphic, and chronostratigraphic. The history and viability of archaeostratigraphy and proposed stratigraphic units was further examined and discussed by Stein (1987, 1990, 2000).

Gasche and Tunca proposed the "lithologic unit," similar to the lithostratigraphic units of geologic stratigraphic codes and guides, but subdivided into subunits with rankings of "Layer," "Sub-layer," and "Inclusion." The only characteristic of these subunits, however, that is different from previously proposed geologic lithostratigraphic units is the inferred difference in scale. Rather than proposing an entirely new lithologic unit with three ranks, Stein (1990) proposed that "Layer" suffice as a single, smaller-ranking unit of geological lithostratigraphy.

The "chronostratigraphic unit" discussed in the proposed archaeostratigraphic guide is not sufficiently different from geologic chronostratigraphic units to be justified. For purposes of archaeology, the chronostratigraphic and geochronologic units proposed in the various geological stratigraphic codes are adequate. Chronology is important in both archaeology and geology, and although the intervals of time on which each discipline focuses vary, the differences do not warrant creating a new chronostratigraphic unit for use in archaeology.

The "ethnostratigraphic unit" is a valid unit in which stratigraphic classifications of strata are based on their artifactual content. As with biostratigraphic units, divisions of ethnostratigraphic units are based on their content. The ethnostratigraphic unit requires a separate name because it involves separate theoretical and taxonomic principles. Although archaeologists may not yet agree as to the standardized description of artifact classes, the division of sediment sequences according to the presence of various artifacts is a valid stratigraphic practice and deserves to be recognized. Archaeologists have long used what could be described as ethnostratigraphic unit in various cultural-historical constructs.

Synonyms

Archaeointensity dating; Archaeomagnetism; Directional dating; Magnetic dating

Definition

Archaeomagnetism. The study of the magnetic properties of archaeological materials.

Archaeomagnetic dating. The dating of archaeological materials that retain fossilized records of the Earth's magnetic field by comparing the direction and/or strength of the material's magnetism with known records of changes in the Earth's magnetic field through time.

Geomagnetic secular variation. Changes in the strength and direction of the Earth's magnetic field with periods of a year to millions of years (Merrill et al., 1998); not to be confused with polar reversals, which have periodicities of hundreds of thousands to millions of years.

Introduction

At its root, archaeomagnetic dating grew out of the early observations that fired materials become magnetized parallel to the ambient magnetic field (Boyle, 1691; Gilbert, 1958) and that the geomagnetic field changes through time (Halley, 1692; see Tarling, 1983). More focused research in the late nineteenth and early twentieth centuries on the magnetization of baked clays and lava flows (Melloni, 1853; Folgheraiter, 1899; Mercanton, 1918; Chevallier, 1925) further refined and linked these observations, providing the foundation for modern paleomagnetic studies, including archaeomagnetism. As a discipline, archaeomagnetic studies were firmly established through the work conducted by Émile Thellier and his students between 1930 and 1960 (Thellier, 1936, 1938; Thellier and Thellier, 1959). During this period, these researchers explored and described the magnetic properties of baked clays, developed sampling techniques for recovering archaeomagnetic materials from the field, and designed and developed laboratory equipment and techniques for analyzing archaeomagnetic samples. By 1960, these methods had been greatly refined, and archaeomagnetic studies were undertaken in various parts of Europe (Cook and Belshé, 1958; Aitken, 1958), Japan (Watanabe, 1959), and the Soviet Union (Burlatskaya and Petrova, 1961). A few years later, the technique was introduced to archaeologists working in the American Southwest (Dubois and Watanabe, 1965), and by 1967 it was being used to date archaeological sites throughout that region (Weaver, 1967).

Today, archaeomagnetic dating is well established throughout Europe (Kovacheva et al., 1998; Le Goff et al., 2002; Schnepp and Lanos, 2005; Zananiri et al., 2007), the American Southwest (LaBelle and Eighmy, 1997; Lengyel, 2010), and parts of Mesoamerica (Wolfman, 1990; Hueda-Tanabe et al., 2004), and it is finding increasing success in areas such as the Middle East (Speranza et al., 2006), Northern Africa (Rimi et al., 2004), the American midcontinent (Lengyel, 2004), and parts of South America (Goguitchaichvili et al., 2011; Lengyel et al., 2011). Until recently, the majority of this work had been undertaken by paleomagnetists and geophysicists, who are primarily interested in using archaeomagnetic data to examine changes in the Earth's magnetic field over time. To a lesser extent, archaeological interest in the technique as an alternative dating method has either enabled or driven the development of the technique (Eighmy and Sternberg, 1990). New collaborations between these two groups of researchers – see, for example, the papers in Batt and Zananiri (2008) – have led to more synergistic approaches to archaeomagnetic dating.

Archaeomagnetic principles

Archaeomagnetic dating depends on two related phenomena. First, the Earth's magnetic field changes in strength (intensity) and direction (inclination and declination) through time (i.e., geomagnetic secular variation), with significant changes occurring on the order of decades to centuries. Second, the soils that make up many archaeological features contain ferromagnetic minerals, such as hematite and magnetite, that can record the direction and strength of the geomagnetic field under certain conditions. By comparing the magnetization recorded by an archaeological feature to a calibrated record of secular variation, the age of the feature can be estimated. If the global geomagnetic field was produced by a simple geocentric dipole, similar to a bar magnet at the center of the Earth, it would be uniformly distributed, and a global model of geomagnetic field change through time could be used to determine when an archaeological feature was magnetized. However, only 80–90 % of the geomagnetic field at the Earth's surface can be ascribed to an inclined geocentric dipole. The remaining 10–20 % of the observed geomagnetic field is variably distributed across the global surface and concentrated primarily within six or seven continent-sized features that grow, shrink, and move through time. This is the non-dipole field, and it may add to, subtract from, or have no effect on the main dipole field in any given location. This heterogeneity of the non-dipole field necessitates the use of region-specific secular variation records for areas separated by several thousand kilometers. Thus, the age of magnetization can be ascertained only in areas for which this record has been established.

Typically, archaeological artifacts and features acquire a magnetization through heating. This thermoremanent magnetization (TRM) is acquired when archaeological materials are heated close to or above mineralogically specific temperatures (i.e., Curie temperatures; 580 °C for magnetite, 680 °C for hematite) and then cooled to ambient temperatures. As these materials cool below the Curie temperature, the ferromagnetic minerals will become magnetized parallel to the prevailing magnetic field. The material can retain this remanent magnetization unless it is reheated to a similar temperature, at which point a new magnetization will be acquired. Additionally, the material must remain stationary after magnetization in order to preserve the directional orientation (the declination and inclination) of the acquired remanence; the intensity of the remanence, however, is unaffected by physical movement. For this reason, archaeodirectional studies can be used to date stationary archaeological contexts only, such as fire pits, burned structures, or kilns, while archaeointensity studies can focus on portable objects, such as bricks and pottery, in addition to in situ archaeological features. It should be noted that archaeointensity tends to be less faithfully recorded than archaeodirection by some archaeological materials, and the identification of suitable materials is currently a hot topic in archaeointensity studies (Casas et al., 2005; Ben-Yosef et al., 2008; Shaar et al., 2010; Morales et al., 2011).

In some cases, anthropogenic water transport or containment features, such as canals or reservoirs, can acquire a depositional remanent magnetization (DRM) or postdepositional remanent magnetization (pDRM), which occurs when ferromagnetic grains physically rotate as they settle subaqueously during and/or after deposition to align with the geomagnetic field. As deposits accumulate, it becomes physically difficult for the grains that have been buried to continue rotating, and the magnetization acquired during or shortly after deposition becomes locked in. These types of features are encountered, and archaeomagnetically dated, much less frequently than thermal features (Eighmy and Howard, 1991).

For a more in-depth discussion of remanent magnetism and basic archaeomagnetic principles, see Tarling (1983), Butler (1992), and Merrill et al. (1998).

Sampling methodologies

A variety of terminologies and sampling methodologies have been developed for recovering appropriate materials for archaeomagnetic dating (see Lanos et al., 2005; Trapanese et al., 2008). In all cases, the sampled material relates to a specific archaeological context that is assumed to have been homogeneously magnetized during a single event. For some researchers in the USA, the context is referred to as a feature, and the recovered material is referred to as a single archaeomagnetic sample, which is composed of multiple specimens. In most other regions, the context is referred to as a site from which multiple samples are recovered. In all cases, successful sampling begins with the identification of appropriate contexts for dating, taking into consideration the extent of firing (or deposition), the inclusion of appropriate ferromagnetic minerals, the size and preservation of the context, and, for directional studies, the integrity of the context (see Eighmy, 1990, for a thorough discussion).

For directional studies, sampling methods have been designed to remove individual pieces of material in such a way as to preserve the in situ orientation of the magnetized grains. Typically, between 6 and 20 oriented samples are recovered from a single context, providing a statistically valid dataset for the feature that can be used to calculate the mean direction of the magnetic remanence. This sample size has also been shown to minimize the effects of magnetic noise and random errors on the averaging statistics (Tarling and Dobson, 1995). In many cases, collectors employ some version of the original technique developed by Thellier (1967), which involves isolating material for recovery, with or without the use of square molds, encasing the material in nonmagnetic plaster or plastered bandages (Schnepp et al., 2008), marking the sample orientation on the plaster, and then removing the samples to the lab for further consolidation and subsampling. Typically, subsampling involves cutting anywhere from 1 to 20 cubic specimens (~4–27 cm^3) from each of the oriented samples (Kovacheva and Toshkov, 1994; Schnepp et al., 2004). In the USA, separate specimens are oriented and collected in the field, and the roughly 15 cm^3 specimens arrive in the laboratory ready for analysis (Eighmy, 1990). In the UK, collectors typically glue 2.5 cm plastic disks, leveled with a spirit level, to the flattened surface of well-consolidated material, mark the sample orientation on the disk, and then remove the disk with attached material to the lab for analysis. For less consolidated materials, these collectors push small plastic tubes (2.5 cm in diameter) into the material, mark the orientation, and then remove and seal the tubes before transporting them to the lab (Clark et al., 1988; Linford, 2006). For very hard materials, such as bricks or extremely well-fired kiln floors, samples can be removed with the standard water-cooled drilling method employed by most paleomagnetists (Collinson, 1983; Butler, 1992). In all cases, samples are oriented prior to removal, typically with a magnetic compass or a sun compass.

Archaeointensity sampling is less complicated and typically proceeds much more quickly, since the samples do not need to be oriented. Prepared specimens may be similar in size and shape to those collected for archaeodirectional analysis, or they may be smaller ~1 cm^3 microsamples (Donadini et al., 2008).

Laboratory procedures

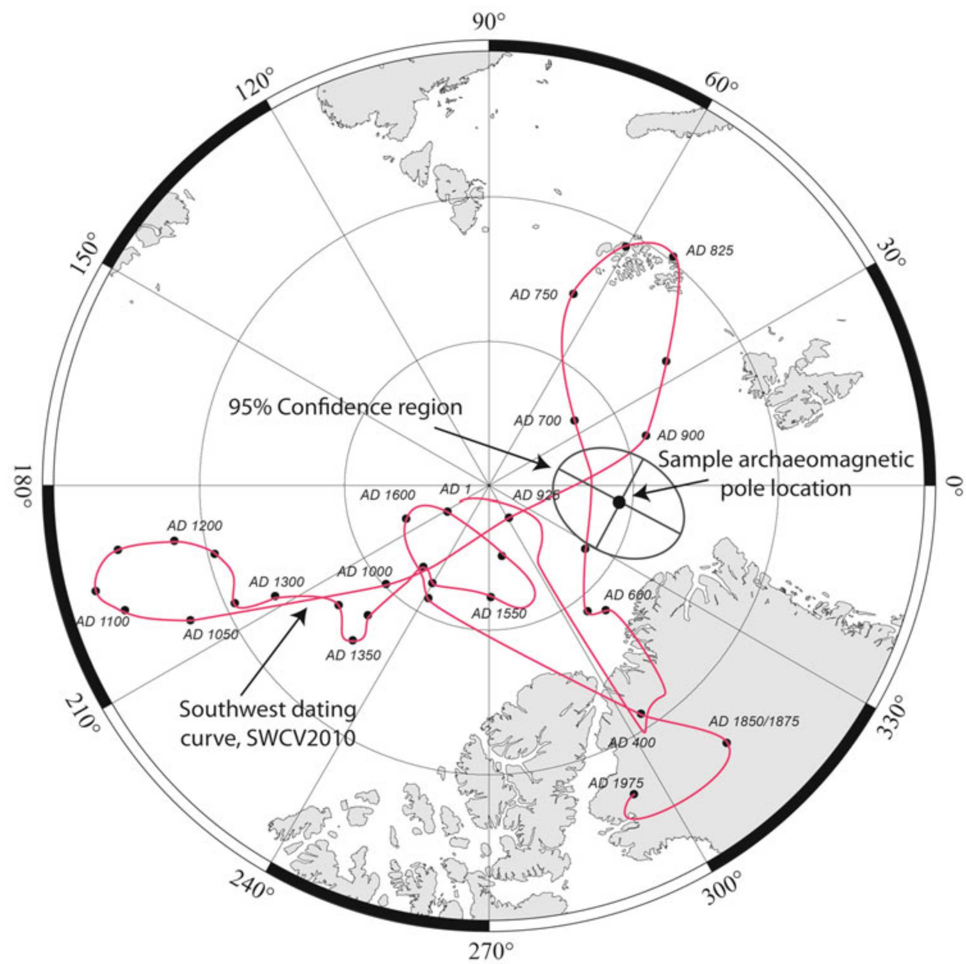
Archaeomagnetic laboratories have developed a number of techniques for isolating and measuring the characteristic remanent magnetization (ChRM) that is carried by archaeomagnetic samples. This is the primary magnetization that was acquired during the heating or depositional event of interest, and it is the information that must be retrieved in order to date the archaeological context. Over time, primary magnetization is overprinted with weaker and/or unstable secondary magnetic components that must be removed before the sample's ChRM can be determined. Typically, this is achieved by subjecting the individual specimens to sinusoidally decaying, weak alternating magnetic fields (AF demagnetization) or heating to low temperatures and then cooling within a zero magnetic field (thermal demagnetization). Both of these techniques have the effect of randomizing the magnetization of weak or unstable magnetic grains, effectively zeroing their contribution to the sample's overall magnetization. Most laboratories will measure the specimens prior to demagnetization in order to establish their baseline magnetization or natural remanent magnetization (NRM). Measurement is done with either a spinner or cryogenic magnetometer. Once the NRM is established, the demagnetization experiment begins by subjecting the specimen to low-level alternating fields, typically on the order to 5–10 mT (millitesla), or heating it to 50–100 °C. The specimen is then remeasured in the magnetometer, before being demagnetized at a higher temperature or peak field strength. Typically, labs will progressively demagnetize and remeasure specimens over a sequence of increasing temperatures or peak field strengths until the secondary components are removed. The changes in strength and direction that are measured over the course of demagnetization are statistically analyzed using principal component analysis (Kirschvink, 1980) to determine the specimen's primary direction of magnetization. Specimens that exhibit too much variation over the course of demagnetization are considered unstable and are excluded from further statistical analysis. Once the ChRM has been determined for each specimen, the results from all specimens are statistically averaged (Fisher, 1953) to calculate the mean direction of magnetic remanence, and associated error, for the sample. These values are then used to date the associated feature (see below).

Until recently, most labs routinely measured only the direction of the acquired magnetic remanence, due to the difficulties in reliably determining archaeointensities. However, the potential value of archaeointensity determinations, both for paleomagnetic field investigations (e.g., global field reconstructions) and archaeomagnetic dating purposes, has led several researchers to focus on improving the procedures used to determine these values (Le Goff and Gallet, 2004; Chauvin et al., 2005; Donadini et al., 2007, 2008; Ben-Yosef et al., 2008; Shaar et al., 2010). In theory, the strength of a sample's TRM (J) will be linearly proportional to the strength of the ancient geomagnetic field (H) that was present during cooling, such that $H = J/\chi_{TRM}$, where χ_{TRM} is a proportionality constant that indicates the material's susceptibility to TRM acquisition. Thus, by measuring the sample's intensity and then determining its proportionality constant by heating and cooling it within a known magnetic field, the intensity of the ancient geomagnetic field could be calculated. This straightforward approach presumes, however, that the sample retains a single magnetic component and that the magnetic mineralogy has remained unaltered since initial TRM acquisition, conditions that are rarely met in practice. Therefore, a much more complicated and time-consuming experiment is needed to establish the proportionality constant and estimate the paleointensity of the ancient field. Typically, researchers employ some form of the original experiment designed by Thellier (1938) and Thellier and Thellier (1959), in which individual specimens are repeatedly heated and cooled within a known field at increasing temperature intervals, twice at each temperature, in order to determine the range of temperatures over which the proportionality ratio remains constant. A variety of checks are employed throughout the experiment to monitor for laboratory-induced thermochemical alterations as well as the effects of nonideal magnetic grain sizes, cooling rates, and anisotropy of the specimen material (see Donadini et al., 2007). The experiment is repeated for all specimens in a sample, and a mean archaeointensity is calculated for the sample from a subset yielding statistically consistent results.

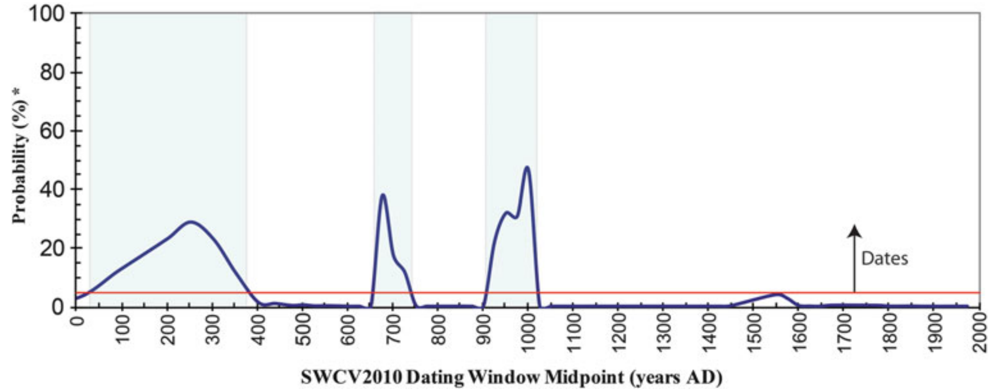
Secular variation curves

Archaeomagnetic data obtained from an archaeological feature can be used to estimate that feature's calendrical age by comparing the data to a calibrated reconstruction of secular variation, often referred to as an archaeomagnetic reference curve. The reference curve can be depicted either as changes in inclination (I), declination (D), and, if available, paleointensity through time (Schnepp and Lanos, 2005; Zananiri et al., 2007) or as changes in the location of the virtual geomagnetic pole through time (Lengyel, 2010). Because secular variation changes randomly and the geomagnetic pole appears to "wander" spatially over time, reference curves are created from sources such as historically recorded direct observations of the field (Barraclough, 1994; Jackson et al., 2000; Korte et al., 2009), archaeomagnetic measurements of independently dated archaeological features (LaBelle and Eighmy, 1997; Zananiri et al., 2007; Valet et al., 2008), paleomagnetic measurements of dated sediment deposits (Nilsson et al., 2010) or lava flows (Hagstrum and Champion, 2002), or some combination of the above (Lengyel, 2004; Finlay, 2008; Hagstrum and Blinman, 2010). Archaeomagnetic or paleomagnetic data included in these datasets must be dated independently through other techniques, such as dendrochronology or radiocarbon dating, and precision criteria often require these data to have independent date ranges of 200 years or less (e.g., LaBelle and Eighmy, 1997: 432).

Furthermore, these curves can be calculated from either a regional dataset (Zananiri et al., 2007) or directly from a global model (Lodge and Holme, 2009). Curves that are based on regional datasets are typically calculated by smoothing archaeomagnetic data from within a 1,000 km area through some form of running average (Sternberg and McGuire, 1990; Le Goff et al., 2002) or within a Bayesian statistical framework (Lanos et al., 2005). Each of these methods utilizes some form of the conversion-via-pole method (Noel and Batt, 1990), which allows researchers to relocate archaeomagnetic data recovered from localities scattered across a region to a single reference location, such as London in the UK or Paris in France. This is done for each pair of measured declination and inclination values by first calculating the virtual geomagnetic pole for that pair of values at the respective sampling site and then calculating the subsequent declination and inclination values for that same virtual geomagnetic pole from the reference locality. In some studies, particularly those in the USA, the regional archaeomagnetic data are simply converted to virtual geomagnetic poles, and subsequent calculations use these pole positions rather than the converted declination and inclination data. It has been shown, however, that the relocation of data to a central location introduces potentially significant geographic error (Casas and Incoronato, 2007). As has been demonstrated recently, this error can be avoided by calculating local reference curves directly from global models, a method that has the added benefit of producing reference curves for specific locations, such as an archaeological site (Lodge and Holme, 2009). Because data coverage varies between global models, it



Archaeomagnetic Dating, Figure 1 Archaeomagnetic sample data plotted against the American Southwest reference curve SWCV2010. This figure illustrates the regional secular variation curve for the American Southwest between AD 1 and AD 2000, and it depicts the virtual locations of the geomagnetic pole over that interval. Note the prominent loops in the curve at roughly AD 400, AD 825, AD 1125, and AD 1550. The sample data plots near a crossover in the curve at roughly AD 675 and AD 910, thereby intersecting more than one segment of the curve. This is a common situation in archaeomagnetic dating and results in more than one possible date range for the archaeomagnetic sample. Unlike radiocarbon date calibration, each archaeomagnetic date range obtained from the reference curve constitutes a unique 95 % probability range for that sample. Typically, other sources of chronometric data are consulted to determine which archaeomagnetic date range provides the best age estimate for the sampled archaeological context.



Archaeomagnetic Dating, Figure 2 Mathematically derived 95 percent probability curve for the archaeomagnetic sample data plotted in Fig. 1 when compared to the SWCV2010 reference curve data via Sternberg and McGuire's (1990) statistical method. Spikes in the probability curve above the 5 percent significance line indicate time periods during which there is no statistically measureable difference between the sample data and the curve data. In other words, these are the time periods during which the sample data is said to "date" against the reference curve. Each spike constitutes an individual 95 percent date range for the respective sample.

may be less robust for some areas and/or time periods than is currently available through regional datasets, limiting the application of this method.

Dating methodologies

The creation of archaeomagnetic reference curves and the dating of archaeomagnetic samples both rely on the underlying principle that archaeomagnetic materials that are the same age should exhibit similar geomagnetic characteristics. Thus, the data obtained from an archaeomagnetic sample can be compared to those of a calibrated reference curve for the region in question in order to ascertain the time periods during which both exhibit the same directional and/or intensity characteristics (Figure 1). This can be done visually or mathematically. The visual method is intuitively obvious and involves plotting the sample data and confidence limits against the regional reference curve. Visual inspection reveals the time period(s) during which the sample data were most similar to the magnetic field location and/or intensity, indicating the best-fit date range(s) for the associated archaeological feature. A greater variety of mathematical methods is available for estimating a sample's date range (Sternberg and McGuire, 1990; Le Goff et al., 2002; Lanos, 2004; Pavón-Carrasco et al., 2011; e.g., Figure 2), and in most cases these methods are preferred over the visual one due to their greater objectivity and the replicability of their results. However, the use of these methods is dependent on the availability of appropriately constructed reference curves with associated measures of uncertainty. Regardless which method is used, multiple dating solutions are often obtained because the path of secular variation loops back on itself through time, making it likely that sample data will match more than one segment of the reference curve. The use of the full magnetic vector for dating (i.e., both directional and intensity data) can alleviate this ambiguity, but the relatively limited spatial and temporal coverage of intensity curves currently restricts this approach to regions such as Central Europe (e.g., Kostadinova and Kovacheva, 2008). In most regions, researchers are advised simply to select the most likely dating option based on other archaeological evidence from the site.

Because archaeomagnetic data can be related directly to specific anthropogenic events, they lend themselves to addressing interesting archaeological dating questions. Typically, archaeomagnetic data are used to assess the age of individual archaeological features, such as kilns, furnaces, ovens, and hearths (Zhaoqin and Noel, 1989; Riisager et al., 2003; Jordanova et al., 2004; Casas et al., 2007), which have acquired the observed magnetic remanence during normal use. In some cases, archaeomagnetic data may provide one of the few methods for dating a specific context, such as unfired lime-plaster surfaces (Hueda-Tanabe et al., 2004) or hematite-pigment-painted murals (Zanella et al., 2000). Furthermore, archaeomagnetic data are especially well suited for reconstructing the use history of complex thermal sites such as glass-making installations (Linford and Welch, 2004), metallurgical workshops (Hus et al., 2004), and ceramic potteries (Kovacheva et al., 2004; De Marco et al., 2008), for which data from multiple features can be obtained and compared. Likewise, archaeomagnetic data recovered from multiple features at a single site can be used to resolve questions about a site's stratigraphy (Jordanova et al., 2004) or to address complex questions of site use through time (Donadini et al., 2012). In the American Southwest, in particular, it is not uncommon for extremely large suites of archaeomagnetic data to be recovered from numerous features ($N > 25$) across a single site for the express purpose of reconstructing the use history of the site, including the identification of different periods of occupation within a site's history and the ability to relate contemporaneous features across a large site (Sternberg et al., 1991; Chenault and Ahlstrom, 1993; Eighmy and Mitchell, 1994; Henderson, 2001; Deaver and Whittlesey, 2004; Lengyel, 2011). Finally, at even greater scales, archaeomagnetic data recovered from across archaeological culture areas may be used to assess and constrain cultural chronologies and the timing of archaeological phases within those chronologies. This has been particularly useful in the American Southwest, where archaeomagnetic data have played a key role in defining the Hohokam cultural chronology (Dean, 1991).

Summary

Archaeomagnetic dating uses changes in the Earth's magnetic field through time to date archaeological contexts such as kilns, fire pits, and canals. These contexts acquire a remanent magnetization parallel to the ambient geomagnetic field under conditions such as firing to relatively high temperatures or fluvial deposition, and the magnetization is retained unless the material is reheated or disturbed. The context is dated by comparing its remanent magnetization to a calibrated record of geomagnetic secular variation, using the principle that contemporary archaeomagnetic materials will share similar geomagnetic characteristics. Until recently, researchers typically used only the directional component of the remanent magnetization to date archaeological contexts. However, renewed recognition of the value of utilizing the full vector for dating, as well as for geomagnetic field reconstructions, has prompted several researchers to focus on improving the methodology used to determine paleointensity values and to advocate for expanding the spatial and temporal coverage of paleointensity records.

ARCHAEOMINERALOGY

George Rip Rapp
Department of Geological Sciences, University of Minnesota, Duluth, MN, USA

The term archaeomineralogy is relatively new. It was used by Mitchell (1985) for a brief bibliography, by Rapp (2002, 2009) for books, and by Kostov et al.,

(2008) and Rapp (2008) as part of the first international meeting on archaeomineralogy. This subdiscipline is quite distinct from the history of mineralogy. Archaeomineralogy is a subdiscipline of archaeology or geoarchaeology. It is the study of the exploitation of rocks and minerals by humans since prehistoric times for implements, ornaments, building materials, paints, and as raw material for metals, ceramics, and other processed products. Archaeomineralogy attempts to date, source, and characterize artifacts made from earth materials as well as put this information into geographic and historical contexts.

Scholars who could be called archaeomineralogists go back to ancient times and were located around the globe. Among the most prominent were the Hellenistic Greek philosopher Theophrastus (ca. 372–287 BCE), the Greek physician Dioscorides (ca. 40–90 CE), the Italian Pliny the Elder (ca. 23–79 CE), the Spaniard Isidore of Seville (ca. 560–636 CE), the Arab authors Al-Biruni (973–1048) and Avicenna (980–1037), the Chinese writer Su Song (1070), the Italian Albertus Magnus (ca. 1206–1280), and the German Georgius Agricola (1494–1555); various Sanskrit texts from India mention the use of a wide variety of minerals in medicine (Rapp, 2009).

The early Egyptians had one of the best understandings of mineralogy and lithology in the practice of medicine and the manufacture of monuments and ornaments (Lucas, 1989). Rock names such as basalt, syenite, porphyry, and alabaster have their origins in ancient Egypt. The igneous rock "basalt" appears to have the oldest roots, in use as early as 2000 BCE. The ancient Mesopotamians also had a well-developed understanding of rocks and minerals in industrial uses (Morrey, 1985).

In ancient times color was the most important character to classify rocks and minerals. Colors had significant symbolic attributes (mourning, purity, passion, danger) and minerals and rocks had medicinal and magic properties. Alchemists equated color with the essence or true nature of a substance. Modern understanding of the physical and chemical nature of mineral properties was established only in the early years of the nineteenth century by Joseph-Louis Proust's Law of Constant Composition in 1799 and John Dalton's Atomic Theory in 1805, and the development of accurate methods of chemical analysis.

It should be noted that early rock and mineral identification frequently was haphazard, often relying on color alone. The names given to many mineral species have changed over time and even today some minerals have a variety of names and synonyms (de Fourestier, 1999). Although there are more than a thousand names given to rock lithologies, sorting out what rocks were exploited in antiquity is somewhat easier than for minerals. An excellent guide to rock names is the "Glossary of Geology" (Neuendorf et al., 2005). This glossary presents historical definitions and obsolete variations in names and meanings.

ARCHAEOSEISMOLOGY

Tina M. Niemi
Department of Geosciences, University of Missouri-Kansas City, Kansas City, MO, USA

Synonyms

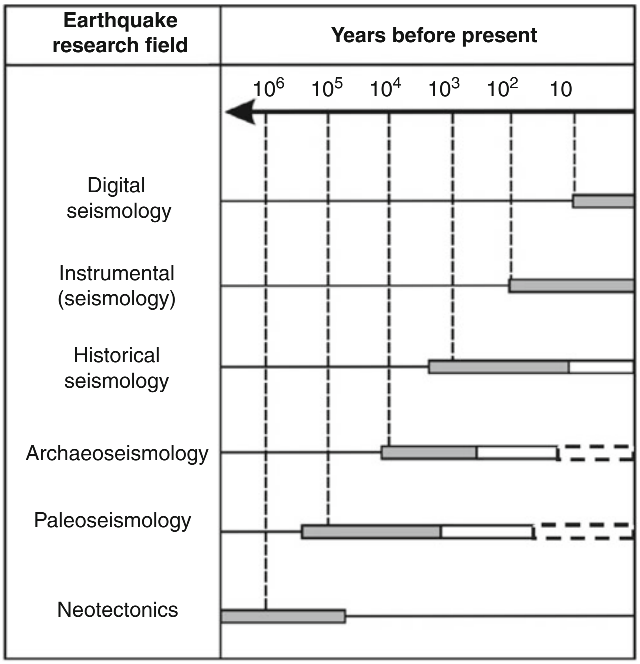
Earthquake archaeology; Seismic archaeology

Definition

The study of ancient earthquakes at archaeological sites.

Introduction

Earthquakes have disrupted human societies throughout history and prehistory. Whereas hunter-gatherer cultures may have been relatively little affected by seismic events, the built environment of sedentary societies can be quite vulnerable to collapse of structures by earthquake-induced ground motion. Understanding the severity and frequency of past earthquakes is important for understanding the history, consequences, and responses of past societies to these seismic disasters, as well as the hazards posed to modern populations. In many parts of the world, the recurrence of earthquakes is so infrequent that modern instrumental seismic data do not adequately represent the



Archaeoseismology, Figure 1 The study of instrumentally recorded earthquakes is the field of seismology. Pre-instrumental earthquakes are studied by other methods, including historical seismology that encompasses written history, archaeoseismology that documents earthquakes at archaeological sites, and the geologic studies of paleoseismology and neotectonics (Modified after Caputo and Helly, 2008).

earthquake potential. Therefore, other methods to document the history of earthquakes are needed.

Various sources of data provide evidence of earthquake occurrence and magnitude, albeit at varying resolutions and over different time scales. Seismology, or the study of earthquake data recorded on analog seismographs, and now digital seismometers, is a field that has documented the date, time, and other parameters of seismic events over the past century or so. Information on earthquakes prior to the late nineteenth century relies on other research fields, including historical seismology, archaeoseismology, paleoseismology, and neotectonics (Figure 1). The figure clearly shows that the time domain for each field of earthquake study overlaps, often significantly. In historical seismology, the record of written history varies across geographic regions, and only a few cultures in the Near and Far East have produced written accounts of earthquakes that extend as far back as two to four millennia. Furthermore, historical texts become increasingly incomplete with increasing antiquity, as well as in regions of sparse population or discontinuous habitation. In many areas, historical records are completely absent. The physical remains of complex societies extend thousands of years farther back in time, well beyond the earliest historical accounts, and they are distributed more widely over the globe. Thus, the evidence of earthquakes at archaeological sites revealed by archaeoseismology may potentially fill a much-needed void in the record of seismic events. Geologists have also studied faults, deformation, and ground rupture from modern, historical, and ancient earthquakes within the well-established fields of paleoseismology and neotectonics.

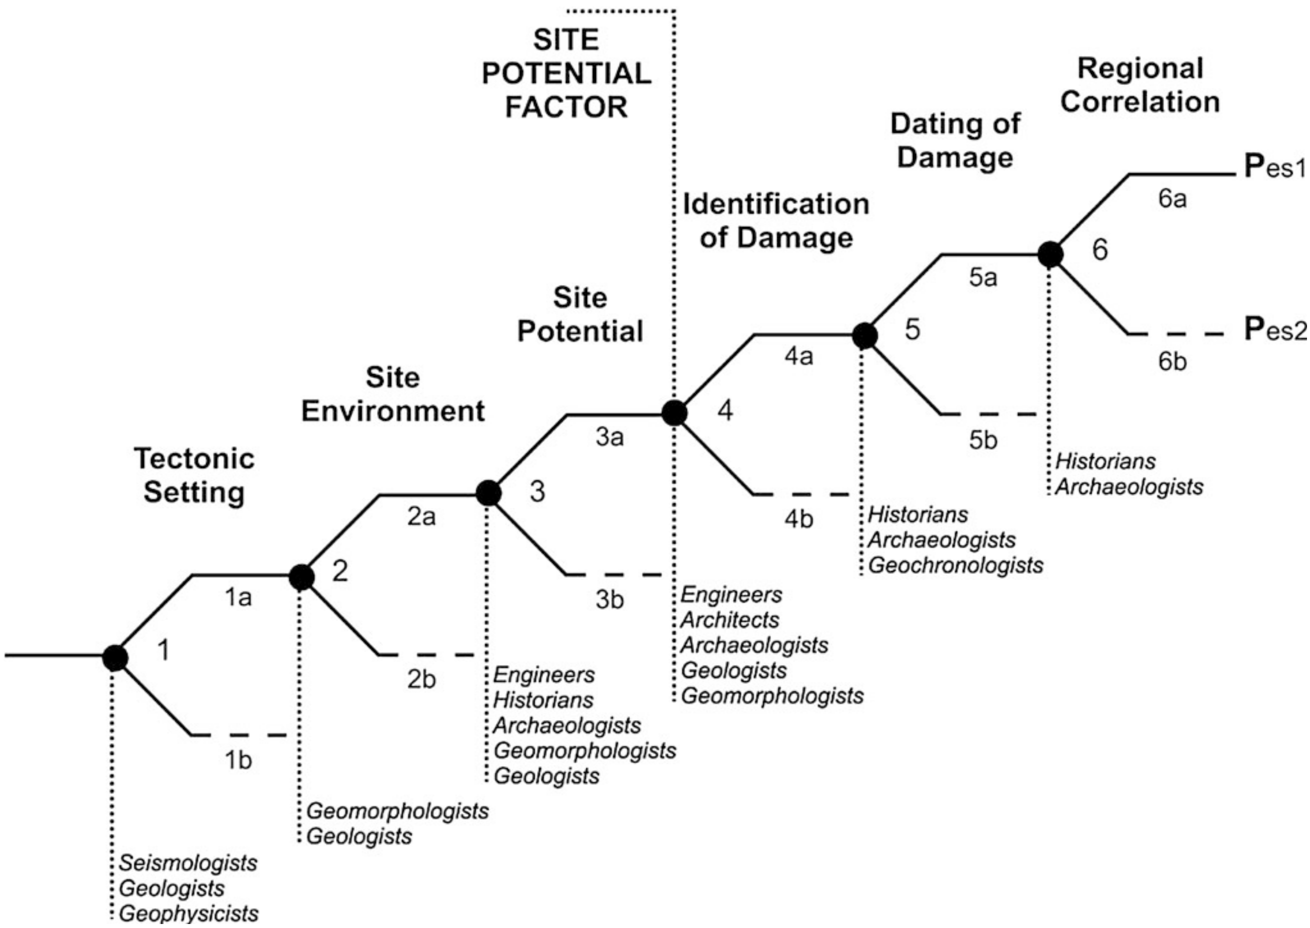
History of the field of archaeoseismology

Ambraseys (1971, 1973) was one of the first to advocate the modern use of archaeological data to help define a region's earthquake history and other seismic hazards. Deciphering and dating evidence of earthquake damage at archaeological sites is the goal of the modern field of "archaeoseismology" – a term first coined in the paper by Karcz and Kafri (1978). Several other terms have been used for this emerging field, including "seismic archaeology" (e.g., Guidoboni, 1996) and "earthquake archaeology" (e.g., Sbeinati et al., 2010).

Many archaeologists have documented "destruction horizons," i.e., stratigraphic layers that show signs of fire, instantaneous destruction, or massive structural collapse with evidence of smashed, in situ vessels on living surfaces, toppled masonry, or other catastrophic building failures. These destruction horizons have been interpreted as evidence for ancient earthquakes since the late 1890s and early 1900s, when large-scale excavations of sites across the Mediterranean and Near East were launched (e.g., Arthur Evans's excavations of the Minoan palace at Knossos on Crete). While outlining the clear benefits of archaeological data in earthquake research, Ambraseys (1971, 1973) also cautioned that modern structures respond differently from ancient buildings to ground shaking. Because some ancient structures are still standing, it should not be concluded that the hazard of future earthquakes is low. Further, he observed that earthquakes should not be indiscriminately used to explain a sudden abandonment or large changes in cultural history.

The field of archaeoseismology investigates both earthquake collapse horizons within archaeological stratigraphic contexts and damaged extant buildings and structures. Earthquake damage is, however, difficult to differentiate from other causes of building failures, including static collapse due to lack of maintenance and disrepair, slumping or gravitational sliding, foundation subsidence, and other geotechnical issues (e.g., Karcz and Kafri, 1978; Rapp, 1986; Stiros and Jones, 1996; Galadini et al., 2006; Marco, 2008). Buildings and monuments damaged in an ancient earthquake may also show signs of repair. But again, many authors have noted that reconstruction phases may relate to expansion due to population growth repairs after military conflict, or political, social, or religious reorganization (e.g., Guidoboni and Ebel, 2009), and they cannot be strictly interpreted as evidence for an earthquake.

Archaeological excavations have traditionally concentrated on monumental structures and cities. Therefore,



Archaeoseismology, Figure 2 Archaeoseismic quality factor (AQF) is a two-branch logic tree that can be utilized to evaluate whether an archaeological site is favorably located to record earthquake damage (site potential factor) and the extent to which features can be used as evidence for an earthquake based on the type of damage, its dating, and regional distribution (After Sintubin and Stewart, 2008).

the so-called hinterland or rural, agricultural villages and farmsteads have not received as much attention. The advent of survey archaeology, which systematically records sites and artifacts across the landscape, allows estimation of settlement patterns and population trends during different sequential periods of occupation. Guidoboni et al. (2000) analyzed the archaeological data around the area of southern Italy and Sicily that was affected by the 1908 M7 earthquake in the Strait of Messina; they concluded that evidence of earthquakes can be identified based on changes in habitation patterns. From the archaeological survey data, in conjunction with epigraphic, archaeological collapse horizons, reuse of inscribed blocks, and potential tsunami deposits, they suggest that contraction of settlements was a response to a large damaging earthquake circa 350–363 CE. Guidoboni et al. (2000, 45) call this method "territorial archaeoseismology."

Several papers have highlighted how earthquakes at archaeological sites, if not independently dated through artifactual or numismatic means, can lead to circular reasoning (e.g., Ambraseys, 2005, 2006; Rucker and Niemi, 2010). In such cases, historical earthquake catalogs are used to assign dates to archaeological collapse horizons, and then the evidence of collapse from the archaeological site is entered into the earthquake catalog as evidence for a particular seismic event. Because earthquake catalogs are inherently incomplete, this practice can lead to amalgamation and distortion of seismic event dates and locations. As is clear across all subdisciplines of geoarchaeology, interpretive problems can be avoided largely through direct field collaboration between archaeologists and earth scientists within an interdisciplinary or multidisciplinary approach to research (e.g., Guidoboni, 1996; Ambraseys, 2006).

Understanding the tectonic, geologic, and geomorphic setting of an archaeological site has long been recognized as fundamental to understanding archaeoseismic evidence (e.g., Karcz and Kafri, 1978; Rapp, 1986). Sintubin and Stewart (2008) proposed a two-branch logic tree that can

Archaeoseismology, Figure 3 (Continued) be utilized to evaluate whether an archaeological site is favorably located to record earthquake damage (site potential factor) and the extent to which features can be used as evidence for an earthquake based on the type of damage, its dating, and regional distribution (Figure 2). These authors introduce an archaeoseismic quality factor (AQF) as a numerical means to evaluate confidence levels for the archaeoseismic data. The AQF has been applied to a couple of sites, including Sagalassos in southwestern Turkey (Sintubin and Stewart, 2008) and Baelo Claudia in southern Spain (Grützner et al., 2010).

Archaeological evidence of past earthquakes

Earthquake damage to structures

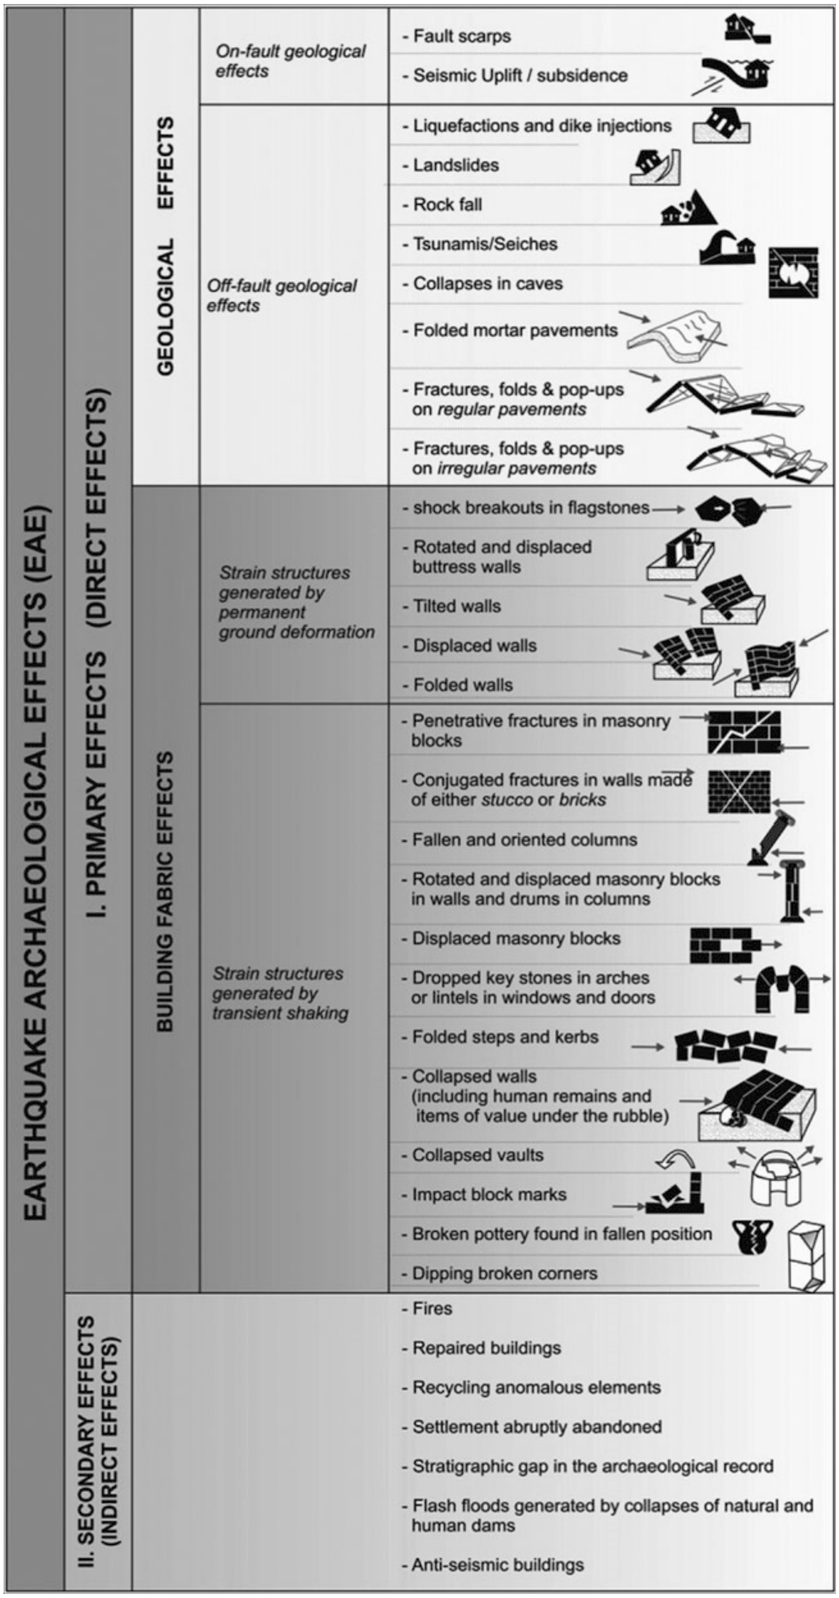
Stiros (1996) provided one of the first published lists of criteria to identify earthquake damage at an archaeological site. Buildings of blocks (brick or stone) and mortar behave differently from a building of large dimensional stones set on top of each other (dry masonry). Buildings of mudbrick or wood framing also have a specific response to seismic shaking. Much of what has been developed in archaeoseismology has focused on the Mediterranean region. Characteristic seismic damages to structures, here summarized from Stiros (1996), Galadini et al. (2006), and Hinzen (2009), include: (1) cross fissures in the vertical plane due to shear forces and diagonal cracks in rigid walls; (2) triangular corner expulsion due to orthogonal motion of walls; (3) lateral and rotational horizontal and independent motion of blocks within a wall, seen as open vertical fractures; (4) height reduction due to vertical crashing; (5) deformation of arch piers including collapse of keystones; (6) wall tilting and distortion; (7) rotation or toppling of pillars and column drums often aligned in a row or laid out "domino style"; and (8) impact of architectural elements on pavement. Photographic examples of these features are shown in Figure 3.

Scientific inquiry into the fall direction of monuments, statues, and structures largely began with Robert Mallet's (1862) investigation of the 1857 Naples earthquake in Italy. Numerous investigators have postulated that the fall direction of building columns or column drums and other architectural elements of a building has azimuthal relevance with respect to the causal earthquake. It should be evident, though not always acknowledged, that freestanding columns or monuments, such as an obelisk, will respond differently from a line of columns supporting a structure, such as a temple or church. A column that is carrying a load, like the superstructure of a building, is not free to fall in any direction. Numerical modeling of a single standing column using "input motion from 29 - strong-motion records indicates little correlation between downfall directions and back azimuth" (Hinzen, 2009, 2855). This study showed that, although columns often fall in a parallel alignment, the data cannot be used to determine the direction to the earthquake epicenter.

A variety of scales have been developed to quantify the intensity of ground shaking and the effects of an earthquake on people and animals, as well as damage to the built environment (e.g., the modified Mercalli scale). To measure earthquake intensity from seismically induced ground features recorded in the natural environment, the International Union for Quaternary Research (INQUA) developed the environmental seismic intensity (ESI) scale (Michetti et al., 2007). More recently, Rodríguez-Pascua et al. (2011) proposed an earthquake intensity scale for seismic damage at archaeological sites called the Earthquake Archaeological Effects (EAE), which is modeled after the ESI scale (Figure 4). The EAE scale divides earthquake damage into two categories: (1) those events affecting building fabric, either from seismic shaking of the superstructure or strain on the foundation, and (2) geologic effects on ancient buildings caused by faulting or other seismically induced ground failures. It is clear, however, that many of the features in the EAE scale (e.g., tilted or displaced walls, deformed or fractured pavement, cave or other structural collapses, among others) can occur under natural soil movement and gravitational conditions without invoking seismic excitation. Therefore, identification of one or two features in the EAE scale should not be interpreted as evidence for an earthquake without assessing the geological conditions of the site or performing something equivalent to the AQF test.

Quantification of earthquake damage at archaeological sites is complicated, as the conditions of the building before and after the earthquake in antiquity are not known. Extant buildings may have also experienced ground motion from multiple earthquakes originating from different source areas. Stiros (1996) cautions that recognition of earthquake damage can be assured only if other mechanisms of deformation such as differential ground subsidence, gravitational ground failures (i.e., slumps, landslides, rockfalls, etc.), shrinking and swelling soils, or poor construction, among other natural and structural engineering issues related to building collapse and failure, can be eliminated. Many fractures, warps, and collapses cannot unequivocally be designated as damage from an earthquake.

Archaeoseismology, Figure 3 Evidence of earthquakes at various archaeological sites: (**a**) destruction horizon at the Chalcolithic site of Hujereit al Ghuzlan in Aqaba, Jordan; (**b**) fallen columns at Petra, Jordan; (**c**) shifted keystone at the Crac des Chevaliers Crusader castle in Syria; (**d**) rotated, horizontally shifted blocks of gypsum at the Roman fortified city of Dura-Europos in Syria – in this case, the deformation is caused by military undermining of the wall during the siege of the city; (**e**) the collapsed wall of the city gate at Hierapolis, Turkey; (**f**) fracture crossing a stepped cistern at the Qumran site in Israel – the fracture is likely due to unstable lake marls beneath the reservoir rather than a through-going fault; and (**g**) impacted pavement at the Magnesia site, Turkey.



Archaeoseismology, Figure 4 The Earthquake Archaeology Effects seismic intensity scale divides earthquake damage into events affecting the building fabric, either from seismic shaking of the superstructure or strain on the foundation, or those geologic effects on ancient buildings caused by faulting or other seismically induced ground failures (After Rodríguez-Pascua et al., 2011).

Several studies have used detailed mapping of damage to extant archaeological structures to calculate ground motion that created the structural failures. Hinzen (2005) modeled the natural reactions of the soil under conditions of a local source earthquake and the resultant displacement to an ancient construction. He concluded that an earthquake caused the wall cracks, displacements, and rotations in the Roman fortifications at the Tolbiacum site in Germany. Kamai and Hatzor (2008) used the discontinuous deformation analysis method to calculate the peak ground acceleration that produced slipped keystones of arches at the Mamshit and Nimrod Fortress archaeological sites in Israel. These methods hold promise for quantifying earthquake parameters from archaeological data.

Coseismic offset at archaeological sites

One of the ways archaeological data can be used to quantify a seismic source is to define the amount of fault slip from a past earthquake (i.e., coseismic slip). Based on modern empirical relationships between earthquake magnitude and fault slip (e.g., Wells and Coppersmith, 1994), matching features that were offset across a fault, whether they are natural geologic (such as a riverbed) or cultural (such as a wall), can lead to estimation of the magnitude of an ancient earthquake. The advantage of utilizing archaeological piercing points (points that can be matched across a fault that have been displaced by an earthquake) is that they can often be more precisely dated than geologic deposits. The type of fault offset expected at an archaeological site depends on its tectonic setting. Thus, any number of deformations can be expected including strike slip (horizontal displacement), dip slip (vertical displacement), or oblique slip (both horizontal and vertical displacement), and land level changes due to tectonic uplift, subsidence, or folding. Offset archaeological data were summarized in Noller (2001), although additional work has clearly been conducted since his compilation.

The isolated observation of a single offset architectural feature from an archaeological site is not sufficient to differentiate between coseismic faulting and other shear plane failures, such as landslides. Landslide scarps, tensional fractures, and other features due to gravitational sliding can also produce offsets at an archaeological site. It is necessary to map the areal extent of fractures or offsets in order to interpret whether they represent an arcuate landslide scarp or a through-going fault rupture. Aseismic differential settling of a structure can also produce features that appear like fault offsets (e.g., Karcz and Kafri, 1978). Therefore, the interpretation of offset strata or structures at an archaeological site needs to be evaluated within the context of geologic and geomorphic site characterization.

Strike-slip faults laterally offset features either in a right- or left-shear sense across the fault or in a combined oblique slip. Perhaps one of the earliest and most spectacular documentations of offset is the three-meter right-lateral and two-meter horizontal displacement of the Great Wall of China in the 1739 earthquake (Zhang et al., 1986). A number of studies have documented strike-slip offset of ancient architectural features across the Dead Sea Transform (Figure 5). These include the fortification wall of the Crusader castle of Vadum Jacob (Ateret fortress) in northern Israel (Marco et al., 1997), the aqueduct and reservoir at Byzantine Qasr Tilah in Jordan in Figure 5a (Haynes et al., 2006), Neolithic tell and Roman road near Antakya, Turkey (Altunel et al., 2009), and the Al Harif Roman aqueduct in Syria (Meghraoui et al., 2003; Sbeinati et al., 2010). The last study clearly shows that after the first two fault ruptures, the aqueduct was repaired preserving a left-lateral bend. Archaeological sites that lack architecture can also be used to measure coseismic slip as is exemplified in the displacement of Native American middens along the San Andreas fault system in California (Noller and Lightfoot, 1997; Noller, 2001).

Extensional tectonic areas (regions where the continent is being stretched) are characterized by normal faults with steep triangular-faceted mountain fronts adjacent to linear valleys. Because of the abundance of normal faulting in Greece, western Turkey, and Italy and the extensive Bronze Age through Classical period archaeological excavations, many archaeoseismologic studies describing earthquake damage have been published from this region. However, few studies document direct normal-fault slip of archaeological remains, but rather show activity of normal faults adjacent to a site, as in the study of the Helike fault in Greece (Koukouvelas et al., 2001). The Helike fault study also suggested regional Gulf of Corinth tectonic subsidence to partially explain the burial of the Helike archaeological site. Hancock and Altunel (1997) report offset walls and water channels from the Roman to late Byzantine period at the site of Hierapolis in Turkey. Other examples of normal fault offset include a 4-m offset of a Roman aqueduct in southern Italy (Galli et al., 2010) and small offsets in Sicily (Barreca et al., 2010).

Tectonic geomorphological studies in convergent tectonic regions show that surface deformation in a compressive earthquake is complex. Depending on the specifics of the tectonic setting and the location of the archaeological site, an earthquake can produce fault rupture, or surface subsidence or uplift. Harbor sites are particularly good in recording deformation because sea level provides a datum for land level changes. The site of Phalasarna in western Crete was identified as early as the 1850s as an uplifted ancient harbor (Figure 5). Stefanakis (2010) summarizes the extensive research conducted into the great subduction zone earthquake of 365 CE that produced about eight to nine meters of coseismic uplift, leaving the ports of Phalasarna and Kissamos isolated. This earthquake also caused a devastating tsunami that crossed the eastern Mediterranean. Identification of tsunamis in archaeological context is discussed elsewhere in this book.

Archaeoseismology, Figure 5 An archaeological site that is located directly over an active fault may record offset of an architectural feature or other anthropogenic layer in an earthquake, including: (**a**) offset of the Al Harif Roman aqueduct in Syria, (**b**) offset of the aqueduct by about 2 m at the Qasr Tilah site in Jordan (Haynes et al., 2006), (**c**) the ancient harbor of Phalasarna in Western Crete was uplifted more than 8 m in the earthquake of 365 CE (e.g., Stefanakis, 2010), and (**d**) detail of the port boat ties.

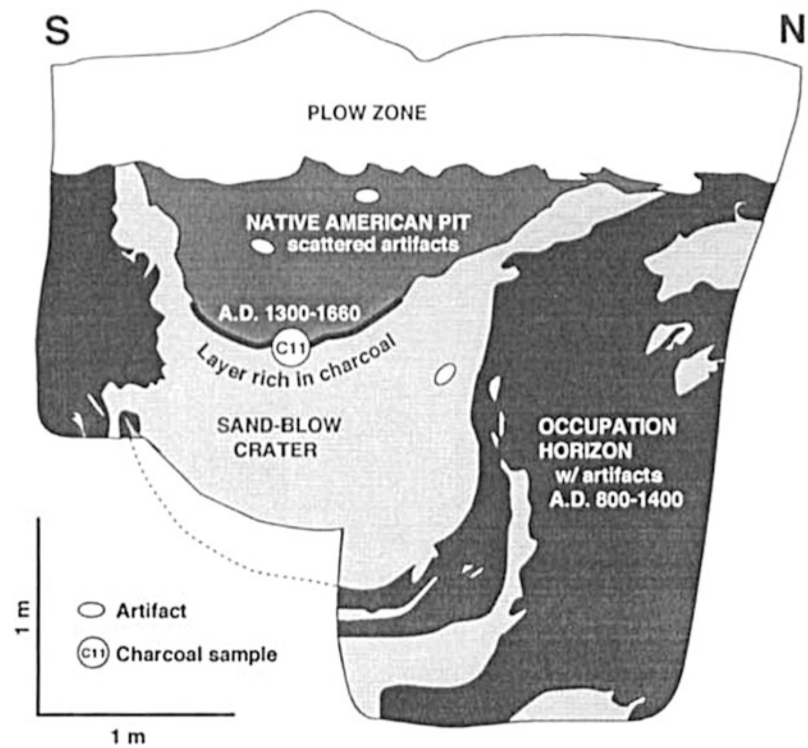
Liquefaction

In many areas of the world, the archaeological record does not include an abundance of monumental stone buildings. Consequently, methods to decipher earthquakes in the Mediterranean do not necessarily transfer readily to other regions of the world. In areas where the predominant building style is post and wall construction with organic materials, as is typical in many seminomadic cultures, or where building traditions preclude heavy masonry because of building tradition or lack of suitable resources, other methods of describing earthquake damage need to be devised. One successful method to document earthquakes in these regions is mapping and dating liquefaction features within archaeological sites.

Liquefaction occurs when shallow, saturated, loose sand loses strength and flows due to cyclical loading of seismic waves. Several features are diagnostic of liquefaction, including fluidized sedimentary structures, sand dikes, sand sills, sand blows and craters, land subsidence, and lateral movement (spread) of surface sediment toward topographically low areas. Native American occupation sites and artifacts buried or deformed by liquefaction (Figure 6) have been extensively used to date paleoearthquakes in the New Madrid seismic zone in the stable craton (interior) of North America (e.g., Tuttle et al., 1996, 2011). Other pioneering work utilizing liquefaction features to date earthquakes at archaeological sites has been conducted in Japan. Barnes (2010) provides a comprehensive summary of the Japanese archaeoseismologic studies.

Summary

The field of archaeoseismology developed out of dual needs: (1) to verify the historical record of earthquakes at sites and (2) to document earthquakes that are silent in the historical accounts but may have played a pivotal role in local and regional cultural history. Damage from earthquakes at archaeological sites has been widely observed in stratigraphic destruction horizons and in damaged architectural features and buildings. Cracks, fissures, tilted, distorted, and displaced walls, columns, floors, and pavements, slipped keystones, collapsed but aligned columns and walls, subsidence, slides, warping, and other deformations of the architectural elements of buildings and other



Archaeoseismology, Figure 6 Liquefaction features from the New Madrid seismic zone of the Central United States showing a sandblow crater formed in an earthquake that buries and deforms the lower occupation layer. Younger Native American deposits are found on top of the sandblow feature (After Tuttle et al., 1996).

structures have been cited as evidence of earthquake damage. This type of data cannot be interpreted as seismically induced until other causes have been eliminated.

In addition to dates of past earthquakes, archaeoseismic methods can provide either a measure of the amount of coseismic slip or the intensity of ground motion, both of which can be used to estimate the magnitude and epicenter of a paleoearthquake. In areas with a tradition of predominantly timber construction, the typical physical evidence of earthquake damage may be liquefaction. Working directly with the archaeologist in the field through an interdisciplinary approach or using unpublished original plans, maps, section drawings, and field notes is preferable to relying on published archaeological summaries. Archaeoseismology is a new and developing field that is evolving from its early focus on qualitative observations to more recent measurement of quantitative data to learn about past earthquakes.

ARCTIC GEOARCHAEOLOGY: SITE FORMATION PROCESSES

Kelly E. Graf
Department of Anthropology, Texas A&M University, College Station, TX, USA

Definition

Arctic geoarchaeology is concerned with how natural processes affect archaeological site formation in high-latitude northern environments. Perhaps the most significant site formation issue that produces the most serious problems in Arctic geoarchaeology is cryoturbation, which is the effect of repetitive freezing and thawing on sediment and soil. Frost heaving, gelifluction, and ice wedging are the most common cryoturbation processes that can significantly alter archaeological site matrices, disturbing stratigraphic order and displacing artifacts vertically and horizontally.

Frost heaving

Frost heaving results from upward movement of ground materials during freeze-thaw events (Taber, 1929). At archaeological sites, this process can reorient artifacts and ecofacts (Johnson and Hansen, 1974; Johnson et al., 1977). Much of the Arctic is underlain by permafrost, which is soil or other substrate that is permanently frozen, often to great depths. In the warm months, the upper, active layer of the ground thaws, but the still frozen base prevents drainage, leaving the surface generally covered by wet, hydromorphic soils. Winter brings freezing conditions and ice forms within the saturated, frost-susceptible sediment. As it does, it expands upward in the direction of heat loss (Konrad, 1999), which is the only direction in which it can expand as it is blocked by permafrost below. This upward movement squeezes large objects such as rocks and artifacts as freezing water expands in volume with great force, thrusting them upward as well (Bowers et al., 1983). Under certain conditions, frost heaving eventually produces patterned ground, where the repeated freeze-thaw cycles sort large stones and finer sediments into polygonal or linear geometrical shapes (Kessler and Werner, 2003). The longer an artifact is in the ground, the more it can be displaced (Johnson et al., 1977).

Telltale signs at sites affected by frost heaving include (1) large-sized artifacts found in on-surface or near-surface positions and (2) vertical orientation of buried, displaced artifacts (Schweger, 1985). Archaeological sites in areas of tundra, especially sites of greater age, can be completely unstratified through the effects of frost heaving acting over many centuries to move artifacts from initially layered deposits below ground to mostly near-surface positions (Thorson, 1990; Holliday, 2004, 279).

Gelifluction

The process of gelifluction occurs where snowfall accumulation is great, sediment overlying permafrost annually thaws and refreezes, and the ground surface is sloped. Rapid melting of snowfall in spring saturates the upper sediment zone. On a slope, saturated sediment succumbs to gravity, flowing or creeping downslope over the underlying impermeable permafrost zone. Displaced materials then refreeze in their new locations during autumn, creating ribbon-like involutions or folds of the upper sediment zone and displacing associated archaeological materials both vertically and laterally. As the lobes of gelifluctted sediment bulge downhill, they can attenuate upslope cultural deposits, thinning them sometimes to the point of leaving gaps as the mobile material bunches and folds over itself downslope (Hopkins and Giddings, 1953; Thorson and Hamilton, 1977; Holliday, 2004, 279–281).

Ice wedging

Ice wedges form when sediment overlying permafrost becomes freeze-dried, contracts, and cracks under the cold, winter conditions. Due to tensional forces acting on the sediment, these cracks form in a polygonal pattern on the ground surface (patterned ground), but below the surface, the cracks can penetrate to permafrost depth. During the summer months, snowmelt seeps into and fills the cracks and then refreezes during the subsequent winter months. As this water freezes, it expands to form an ice wedge. The following year, the cycle repeats as the ice wedge cracks and seepage fills it again. The process continues so that year after year this cycle of crack, thaw, and freeze widens and deepens the ice wedge. The implications for geoarchaeology are that surface sediment and artifacts can slip down into the cracks, entrained by meltwater seepage, as additional materials filling the ice wedges as they grow. As ice thaws, deformed fill features or ice-wedge pseudomorphs are left behind (Lachenbruch, 1962).

Pseudo-paleosols

A further behavior of soils in Arctic environments involves the concentration of fine particulate matter to form dark layers resembling buried paleosols. Under moist but not saturated soil conditions, thin layers of organic material, clays, and silts can be sorted by the freezing process seasonally, creating a layer that, in warmer months, traps downward moving illuvium, thereby producing color banding that appears to be a buried ancient soil (Thorson, 1990, 406; Holliday, 2004, 281).

Cryoturbation in pleistocene age sites

During the glacial advances of the Pleistocene epoch, Arctic-like conditions moved southward in step with the expanding ice sheets and down the slopes of high mountains carried by the ice flows emanating from upper elevations. Ancient sites dating to the last ice age can also display signs of cryoturbation given the extreme cold of the time. Lower and Middle Paleolithic remains in Britain are often found in alluvial terrace fill, which preserves the best record of such periods (Basell et al., 2011). Cryoturbation features illustrating the effects of frost heaving, gelifluction, and ice wedges have been found in such sites indicating periglacial or frost conditions (Basell et al., 2011, 29). Similarly, the effects of cold conditions due to the Last Glacial Maximum can be seen in the sediments and soils of Upper Paleolithic sites buried in alluvium in the Kostenki area along the Don River in southwest Russia (Holliday et al., 2007). On the Seward Peninsula of western Alaska, a fluted-point site dating to 12,400 calendar years ago shows evidence of cryoturbation in the form of frost-shattered grains and lenticular pores, suggesting the presence of ice in the soil (Goebel et al., 2013).

ARTIFACT CONSERVATION

Dennis Piechota
Department of Anthropology, Fiske Center for Archaeological Research, University of Massachusetts at Boston, Boston, MA, USA

Definition

Conservation of archaeological finds is a critical part of excavation and curation. It is the activity that assures the permanence of the physical artifacts and preservation of the information they contain, and it includes specific methods and standards for examination, documentation, treatment, and preventive care of archaeological materials. These activities are performed by specialists who belong to professional societies that promote education, research, and adherence among its practitioners to a code of ethics and standards of practice.

History

When an early human repaired or rejuvenated a stone tool to extend its working life, he was not engaged in conservation as we now understand the term since the preserving activity did not result from an academic tradition of research and education to explore and improve upon the suitability and compatibility of methods and materials. In Europe, it was not until the Renaissance when such an approach was applied to antiquities; sixteenth-century restoration practices were recorded by Benvenuto Cellini in his memoirs (Cellini, 1823). Subsequent discoveries of fragile finds at archaeological sites in Egypt, Italy, the Near East, and elsewhere showed the need for a disciplined approach to the development of preservation practices based on testable methods. In the eighteenth and nineteenth centuries, that need was met by the application of the scientific method in what would eventually become the field of materials science. Investigations of specific ancient materials began the process of consolidating the research and recommended methods of the previous century; these appeared in texts such as *The Preservation of Antiquities* by Friedrich Rathgen (1905) and a book of the same title by Harold Plenderleith (1934) which was subsequently expanded and updated as *The Conservation of Antiquities and Works of Art: Treatment, Repair and Restoration* until its final printing (1974). The discovery of Tutankhamen's tomb with its wealth and diversity of antiquities spurred research in archaeological materials science at the British Museum under Arthur Lucas (1926). These efforts together with those of other research centers formed the foundations of what would become academic postgraduate or certificate programs of study starting in the 1930s at Harvard's Fogg Art Museum and University College London's Institute for Archaeology. Today, universities and other cultural organizations throughout the world train conservators in graduate schools and certificate programs. Worldwide professional societies, such as the International Institute for Conservation (IIC) and the American Institute for Conservation of Historic and Artistic Works (AIC), support conservators by sponsoring journals and congress proceedings for the publication of juried research. UNESCO's International Council of Museums supports the Council for Conservation (ICOM-CC), which hosts a worldwide triennial congress of conservation.

Professional activities

This entry will introduce the professional activities of the conservator. Recent comprehensive studies can be found in *Conservation Treatment Methodology* (Appelbaum, 2007); *Conservation Skills: Judgement, Method, and Decision Making* (Caple, 2000); *Contemporary Theory of Conservation* (Muñoz Viñas, 2005); and *Conservation: Principles, Dilemmas and Uncomfortable Truths* (Richmond and Bracker, 2009).

Examination

Conservators examine artifacts to determine composition and condition prior to considering whether a treatment is needed. They approach every artifact individually and spend a considerable amount of time in this initial phase. Typical protocols for examination start with naked eye inspection under standard and raking visible light as well as ultraviolet light to detect common autofluorescent materials. Microscopic analysis often follows using a - low-power reflected light inspection microscope to begin characterizing minor components. Micro-sampling of these components may be done at this point and the samples mounted for polarizing transmitted light microscopy to further identify and describe the actual physical condition of the artifact. More technical examinations include x-ray fluorescence spectroscopy and x-ray diffraction to identify elemental and mineral components, respectively. Many other analytical methods are used as needed.

Though examinations are done in preparation for treatment, thorough explorations of artifacts whose construction is unfamiliar to specialists in the field can become ends in themselves, and they may be published without reference to any treatment phase under the rubric of technical studies. For example, in their paper "An Egyptian cartonnage of the Graeco-Roman period: Examination and discoveries," Scott et al. (2003) relate their discovery of unexpected pigments and construction techniques in a 350 BC coffin liner from ancient Egypt. Here, the conservators and conservation scientists brought together diverse technologies such as radiocarbon dating, x-ray diffraction analysis, energy-dispersive x-ray fluorescence, Fourier transform infrared spectroscopy (FTIR), thin-layer chromatography, and gas chromatography with mass spectrometry (GC-MS) to show the influence of contact with Roman culture on traditional Egyptian practices.

Documentation

The results of each artifact examination are recorded in a standardized treatment database along with other essential information, such as dimensions, detailed condition descriptions, and photo-documentation. The practice of photographing artifacts before and after treatment is a hallmark of conservation, as the appearance of artifacts can change due to the treatment. Care is taken to record accurately those characteristics of identification and condition such as color, surface condition, completeness, and size. Catalog numbers are always included in the frame of the photograph along with a color balance card and metric measurement scale. Typically, at least six overviews are taken of three-dimensional objects, four side views, a top view, and a bottom view. Additional close-ups or detail views are added as needed to document the pretreatment state. The importance of documentation and especially photo-documentation has caused these practices to be periodically codified through publication. See, for example, *The AIC Guide to Digital Photography and Conservation Documentation* (Warda, 2011).

Treatment

Proposed treatments are determined by the preceding examination. Because the artifacts are considered to contain archaeological data, the conservator generally limits treatment as much as possible to stabilization, and materials applied in this process should be removable, i.e., procedures should be reversible in the ideal. Waterlogged wood objects will crack when dried in air, so they receive treatments with intracellular bulking agents, such as polyethylene glycol, to maintain their dimensions after drying. Without such treatment, the wood might deform into a shape having no resemblance to either its original form or that which it had when recovered in the field. After recovery, some metal artifacts can begin to corrode rapidly in air; these will require treatments to remove the soluble salts that catalyze such corrosion. Textiles and other fibrous artifact fragments are among the most challenging to conserve. They can disintegrate during initial field inspection and, as a result, often require a method called blocklifting, wherein the artifact is kept encased in its surrounding soil or sediment and the entire sediment block is removed to a conservation laboratory where it can be micro-excavated under controlled conditions. Heavily corroded artifacts and complex composite artifacts can also require block retrieval. The care and ingenuity that such lifting techniques require in the field are described in Robert Payton's edited volume, *Retrieval of Objects from Archaeological Sites* (1992), including the recovery of 30 ton sculptures from Argo Island on the Nile and the extremely fragile human remains at Herculaneum.

Often excavations can be collaborative with the archaeologist and conservator listening closely to the wishes of the local community, including heritage groups and descendant groups. *Collaborating at the Trowel's Edge*, an edited volume by Steven Silliman (2008), and *Preserving What Is Valued*, by Miriam Clavir (2002), describe the breadth and complexity of the working relationships that result from community-based research. Such relationships can change the routine academic priorities of conservation performed simply as data preservation. Indigenous peoples are often collaborators with a strong concern for how the earth and its recovered artifacts are handled during and after an excavation. Sacred artifacts will usually receive no conservation treatment in order to preserve their unique unaltered state and avoid leaving preservative agents within the artifact that may be viewed as contaminants. Nonsacred artifacts having special significance to the local community will often receive extra conservation care as these objects often become symbols of local heritage.

Preventive care

Conservators limit the preservative chemicals they apply to all cultural objects. Archaeological collections that are curated primarily for their data require even greater attention because any resinous coating, consolidant, or other chemical can interfere with future chemical analyses. The archaeological conservator then attempts to provide preservation to control physical and environmental deterioration. These can include custom cushioned storage mounts that support weak areas and allow casual inspections without direct handling of the artifact. Termed housing or rehousing techniques, these supports can be enclosed to make passive microenvironmental control possible. Buffered or desiccating silica gel may be added to enclosed storage units or even to individual object housings to limit the range and rate of fluctuation in relative humidity. Instructions for preventive care are often included as part of the treatment database. See Carolyn Rose and Amparo Torres, *Storage of Natural History Collections*, for this aspect of preservation through environmental modification in the museum setting (Rose and de Torres, 1992). In the fieldwork setting, a recent offshoot of this focus on the modification of the environment is the movement toward *P*reservation of *A*rchaeological *R*emains In Situ (PARIS). In this application of preventive care, sites that cannot be excavated for some reason are remotely monitored to prevent damage from, for example, soil water table fluctuations, which could decrease the preservation of organics and metals in burials (Kars and van Heeringen, 2008).

Research

Besides their close work with archaeologists and curators, archaeological conservators also maintain a tradition of research and publication that is independent of the scholarship devoted to the interpretation of artifacts. It is in large measure practical research meant to develop new or improved methods for the examination, analysis, treatment, and care of artifacts. Most investigations of this kind focus on how to characterize the materials of which artifacts are made, how those materials degrade, and how to apply new materials and technologies to their preservation. The research is published mainly in journals of the conservation community's professional societies and institutions, including *Studies in Conservation* (the journal of the International Institute for Conservation), the *Journal of the American Institute for Conservation*, *The Conservator*, the *Journal of the Institute of Conservation* (London), and the Research and Conservation series of the Getty Conservation Institute.

Because conservation is highly interdisciplinary, it also gathers information from wide-ranging areas of research, including anything from the latest filling materials used in modern dentistry to the lives of subterranean termites and the damage they do to wood. Such data are best accessed through two custom online, searchable databases: the Conservation Information Network and Art and the Archaeology Technical Abstracts Online.

Other databases include those that evaluate the common properties of the chemicals and commercial materials used in the treatment of artifacts. They represent an essential resource to conservators because the formulas for commercial materials are changed by their manufacturers over time. Two of these databases are the Conservation and Art Materials Encyclopedia Online (CAMEO) and the Art Materials Information and Education Network (AMIEN). They are always consulted since every treatment requires its own research.

Education

Until the mid-twentieth century, conservation training took the form of apprenticeships under recognized conservators. Archaeological object conservation was a subdivision of museum objects conservation, which tended to concentrate on the aesthetic aspects of artifacts rather than on details such as use-related wear and accretions due to long intervals of surficial deposition or chemical alteration. As archaeological conservation developed, such details became a focus for study and preservation, as they contain information about the unique histories of individual artifacts. This approach is now central to the conservation of artifacts as archaeological data. For example, surface stains that would previously have been removed as disfigurements are now preserved for interpretation by the archaeologist. Ultimately, this trend toward viewing all aspects of an artifact as potential data has led to the current goal of preserving archaeological artifacts in ways that will make the least alteration and leave the fewest residues.

Since the mid-twentieth century, university-based graduate programs in art and historical artifact conservation have emerged around the world, and this is now the dominant way that new practitioners enter the field (though some internship programs continue to offer certificates in select specialties). Since the 1970s, graduate programs have recognized the trend toward specialization and started incorporating museum and field archaeological materials as areas of instruction and study; such programs exist at the University of California at Los Angeles, University College London, and the University of Applied Science in Berlin.

Ethics

Archaeological conservators are charged with recognizing, preserving, and enhancing the information potential of an artifact in ways that do not compromise future study, and they accomplish this without interpreting its meaning, characterizing its place of provenance, function, authorship, or date. This is analogous to preserving a book without commenting on its text. In this role, conservators approach their work very conservatively with respect to actions that change the artifact, even in small ways. For instance, routine artifact cleaning methods must be considered carefully since the wrong application could unintentionally strip off use-related substances or leave behind detergent residues that could confound future organic microanalyses. This position of advocacy for the uninterpreted artifact distinguishes the archaeological conservator from those disciplines that use the collections to reconstruct human behavior. Conservators can sometimes be so protective of cultural property that they seem to discourage any use of it for data acquisition, but, in fact, compromises are always reached that promote stable collections management while facilitating academic study and exhibition. Noninvasive analytical methods are usually promoted over those that require sampling of the artifact. Appropriate handling methods are routinely followed to lessen the wear and tear on artifacts during study. Recently, the issue of preservation sustainability has received increased attention as part of the mix of compromises that the ethical conservator must consider.

Geoarchaeological conservation

The act of unearthing an artifact can create physical and chemical instabilities that often lead to the artifact's deterioration with consequent loss of data. Prior to its excavation, the artifact lies in soil or other sediment, its weight supported by the matrix, and often at chemical and biological equilibrium with its surroundings. When it is first buried, the artifact becomes part of an evolving microenvironment that is related, but not identical, to the general sediment environments of the site. In practical terms, the artifact will either (1) decay, disintegrate, and disappear as an intact object within the site soil, or (2) it will develop a boundary layer at its surface brought about by local geochemical and biological conditions. Examples of these alteration boundaries include simple discolorations, corrosion layers on metal objects, or insoluble salt accretions on wood, ceramics, and other materials. The initial boundary, which can appear as a crust, a softened layer, or a discoloration, can be unstable and invasive, eventually destroying the artifact, or it can be stable and insulating, protecting the artifact from the surrounding sediment. Many materials form such boundary layers. Wooden artifacts, when degrading within wet sediments, will experience a buildup of toxic byproducts at their surfaces that gradually slow the rate of biodeterioration as the artifact – i.e., the food source – becomes less attractive to destructive bacteria and other organisms. Some metal artifacts form thin corrosion layers that transform the object's surface and prevent the underlying metal from further loss. Once formed, such layers must often be preserved along with the rest of the artifact because they may retain the original surface patterning; removing them in order to return the artifact to an unaltered appearance can actually strip away important surface detail. These boundary/alteration layers also yield clues to the geochemistry of the site soil or sediment, providing information that can be used to understand site formation processes. By focusing on preserving the artifact's surficial boundary layer, geoarchaeological evidence relevant to soil conditions, alteration, diagenesis, and other aspects of the burial environment may be conserved.

Summary

Artifact conservation is a young and rapidly developing field. Conservators continue the traditional activity of creating new and better methods of artifact treatment in order to safeguard the collections that form the basis of archaeological inference. At the same time, the conservation profession is evolving and expanding as an academic discipline, offering its own insights into artifact microanalysis and site development processes.

ATAPUERCA

Carolina Mallol
Departamento de Geografía e Historia, Universidad de La Laguna, La Laguna, Tenerife, Spain

Definition

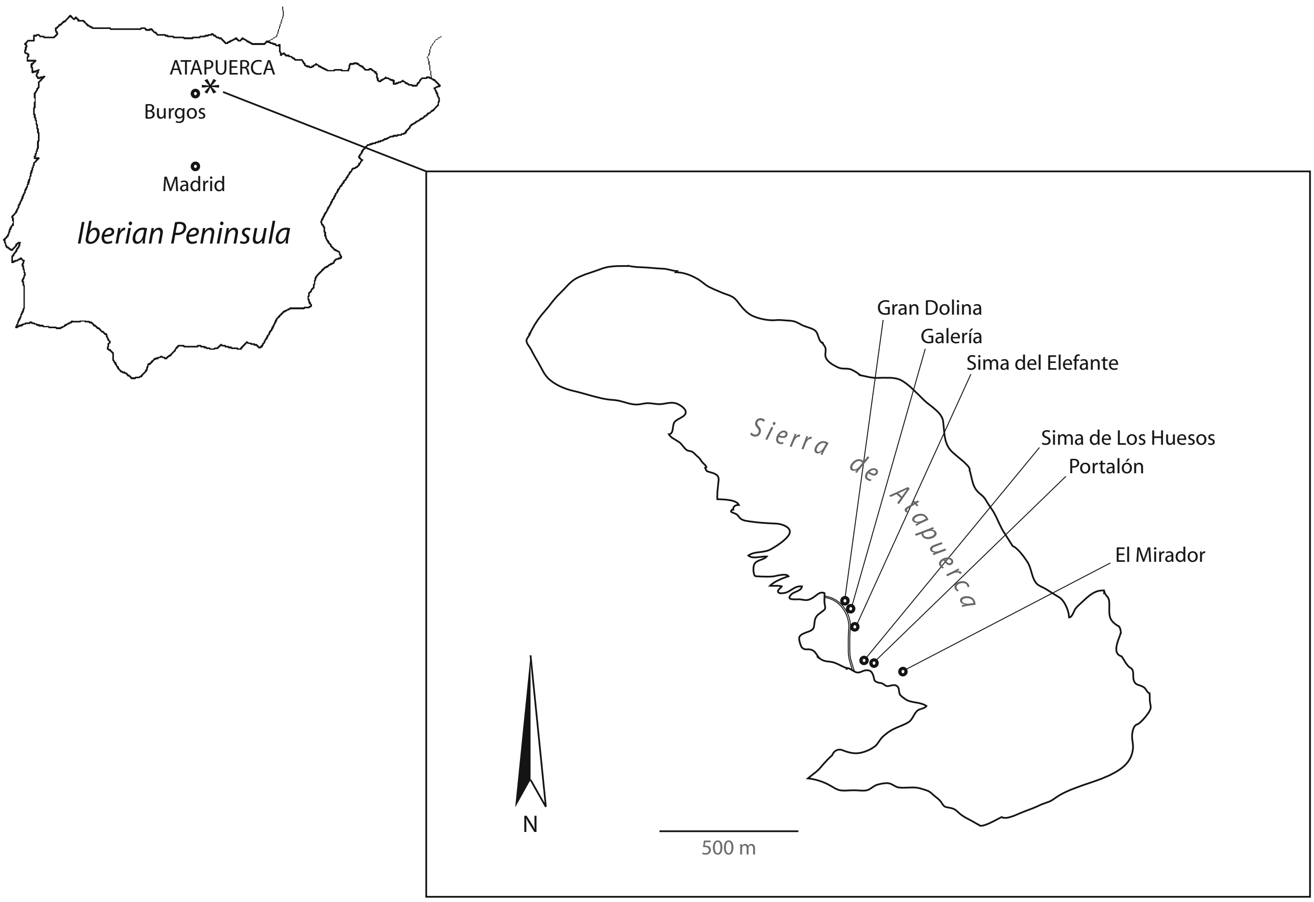
Atapuerca, or Sierra de Atapuerca, is a rich archaeological and paleontological site complex located 12 km east of the city of Burgos, in north central Spain (Figure 1). The sites consist of deeply stratified Lower Pleistocene to Holocene archaeo-sedimentary infills of different karstic caves and conduits within a Mesozoic limestone anticline at the boundary between the Tertiary basins of the Duero and Ebro rivers. Among the key sites, Gran Dolina, Galería, and Sima del Elefante (the railway trench sites) have yielded remains of Lower and early Middle Paleolithic occupations by different hominin species (Carbonell et al., 1999; Rosas et al., 2001; Carbonell et al., 2008). Sima de Los Huesos, a small, paleontologically rich gallery at the end of a 14-m deep sinkhole, has yielded a rich accumulation of hominin skeletal remains (Arsuaga et al., 1991, 1993, 1997, 1999). While the bulk of the Atapuerca sites span the Lower and Middle Pleistocene, two sites, El Mirador and Portalón, include Holocene deposits: Neolithic and Bronze Age remains have been explored in El Mirador (Vergès et al., 2002; Cáceres et al., 2007; Cabanes et al., 2009), and occupations from Upper Paleolithic to the Middle Ages have been found in Portalón (Carretero et al., 2008; Ortega et al., 2008).

All of the deposits are characteristic of cave entrance settings and consist of mixed quartz sand and sandy aggregates from nearby soils, red clay originating within the local karstic system, and limestone rubble from the immediate surroundings. The stratified sequences from the different sites each record a succession of high and low energy modes of gravitational deposition, including debris flows, runoff, and roof spall facies, as well as exokarstic stratified and microstratified waterlain deposits (Vallverdú 1999, 2001; Pérez-González et al., 2001; Mallol and Carbonell, 2008). None of the depositional sequences are continuous, and stratigraphic unconformities are frequent. The Holocene deposits from Portalón and El Mirador are primarily anthropogenic.

Postdepositional carbonate and phosphate diagenesis is prominent throughout the Pleistocene deposits. Overall preservation of bone is good, the smaller-than-2 cm fraction being most affected by diagenetic breakdown linked to decalcification. The Atapuerca flint comprises two geological types – one Neogene and the other Cretaceous in age. The former is highly susceptible to diagenesis due to its elevated percentage of moganite (a polymorph of quartz), and recovered artifacts made with this flint type are often found in poor states of preservation.

The Gran Dolina-TD6 deposit shows pedogenic evidence of calcareous brown soils suggestive of an Atlantic climate and sharp facies changes indicative of strong climatic fluctuations (Vallverdú et al., 2001). In contrast, the rest of the Gran Dolina and Galería deposits are weakly decalcified and bioturbated indicating a mixed Mediterranean/continental temperate climate (Pérez-González et al., 2001).

In-situ human occupation floors have been documented at Galería in layers GII and GIII, as well as in Gran Dolina layers TD10 and TD6, the latter in association with cut-marked human remains. No evidence of anthropogenic fire has been identified in any of the Pleistocene deposits. The Holocene sites, Mirador and Portalón, have yielded well-preserved combustion features and ashy



Atapuerca, Figure 1 Location of Sierra de Atapuerca and the main archaeological sites mentioned in the text. The curved line adjacent to the sites represents a railway trench that exposed the archaeological deposits.

anthropogenic deposits. Rich stabling deposits and human burials dating to the Bronze Age have also been documented at Mirador (Cáceres et al., 2007; Angelucci et al., 2009; Carrancho et al., 2009).

The Bering Land Bridge and Beringia: definitions and geography

The relatively shallow Bering Sea continental shelf lies between the Arctic and Pacific Oceans separating the coasts of Alaska and Siberia (Figure 1); it was exposed during periods of extensive continental glaciation, as moisture was locked up in the glaciers and sea level dropped about 100 m below modern levels. The exposure of this shelf established what is referred to as the Bering Land Bridge, a nearly 1,000 km wide land-based connection between northeastern Asia and northwestern North America. This area, when exposed, forms the once ∼34 million acre continental mass known as Beringia (Hopkins, 1959; Hultén, 1968; Barber, 2005). During the major episodes of glaciation of the Pleistocene, the extensive northern North American Laurentide and Cordilleran ice sheets coalesced in the region of Alberta, Canada, creating barriers for biotic migration to the east and south. During this period, Alaska and portions of far northwestern Canada were effectively part of northeastern Asia, permitting the exchange of animals, flora, and humans between the two continents and forming the unique blend of Asiatic and North American biotic and cultural systems (Hultén, 1968; Hopkins et al., 1982; Guthrie, 1990; Hoffecker and Elias, 2007).

Hultén (1968) first coined the term "Beringia" to refer to the Bering Land Bridge itself; however, its use has taken on a variety of geographic meanings. Others have broadened the geographic boundaries for the term to include extensive portions of unglaciated Northeast Asia, Alaska, and the Yukon and Northwest Territories of Canada (see Hopkins et al., 1982; Hoffecker and Elias, 2007; and Dixon, 2013 for excellent discussions on the history of the concepts of the Bering Land Bridge and Beringia).

Typically, Beringia has been subdivided into three regions: central, eastern, and western. The unglaciated areas of Northeast Asia, generally from the eastern Siberian Verkhoyansk Range to the western shores of the Bering Strait, comprise western Beringia, while those of Alaska, Yukon, and the Northwest Territories compose eastern Beringia. The area of the Bering Land Bridge itself is usually referred to as central Beringia (West, 1981; Hoffecker and Elias, 2007), consisting of the submerged lowlands of the Bering Sea continental shelf and the former highlands that are now the islands of the Bering and Chukchi Seas. Others have recently extended the definition of Beringia to include portions of southeastern Alaska and the northwestern coast of British Columbia that were once exposed unglaciated lands along coastlines during the Last Glacial Maximum (LGM: 23,000–19,000 cal BP; Dixon, 2013).

The exposure of the Bering Land Bridge forced the oceanic moisture sources of the Pacific and Arctic Oceans farther away from interior regions of Beringia. During the LGM, coastal air masses that currently provide moisture to eastern Siberia, Alaska, and northwestern Canada had to travel farther, and the large glacial masses in the mountain ranges became moisture barriers for the interior regions of Beringia (Manley, 2002; Brigham-Grette et al., 2004). This situation fostered periods of extreme continentality in the climate, exceptionally clear skies, and a remarkable environment that has no distinct modern analog (Guthrie, 1990, 2001; Anderson and Brubaker, 1994). Across the regions of Beringia, glaciated and

Beringia, Geoarchaeology, Figure 1 Map of Beringia showing exposed continental shelf and North American glacial extent at 14,000 cal BP, during the initial colonization of the Americas (Sea level and glacial ice distributions are derived from Manley (2002) and Dyke et al. (2003), respectively. Eastern Beringian archaeological site data are from Potter et al. (2013)).

periglacial environments provided the dominant geological processes that controlled depositional regimes, geomorphology, and pedogenic development. Beringian high latitude environments were some of the last Asian regions to be colonized by humans (Goebel, 1999; Hoffecker and Elias, 2007; but cf. Pitulko et al., 2004 and below), and the same adaptive strategies (high residential mobility, possibly microblade technology, and large mammal hunting) apparently enabled expansion into the Americas (Goebel et al., 2008).

Beringian paleoenvironments

The Last Glacial Maximum

There has been considerable discussion as to the general characteristics of the Beringian environment during the LGM, which is understandable given Beringia's vastness. In the 1980s and 1990s, two dichotomous views of the general Beringian environment colored most of this discussion: a barren polar desert versus relatively biologically diverse steppe tundra "grassland."

Glaciers and their associated outwash deposited an immense amount of silt and sand deposits into drainages; these deposits were subsequently redeposited across much of the Beringian landscapes through wind mobilization. Higher landforms nearest to glaciers were stripped of overlying unconsolidated sands and silts by high-energy katabatic winds creating ventifacted surfaces (Péwé, 1975, 1977). Landscapes farther away from glaciers developed sand sheets and extensive loess (wind-blown silt) deposits that capped hilltops, terraces, and fans.

Loessic and fluvial deposits across Beringia have yielded prodigious amounts of animal fossils dating to the LGM and earlier periods (Guthrie, 1990; Ukraintseva et al., 1996; Froese et al., 2009; Boeskorov et al., 2014). Steppe bison (*Bison priscus*), Yukon horse (*Equus lambei*), and woolly mammoth (*Mammuthus primigenius*), in that order, are the most prevalent species occurring in these deposits in eastern Beringia. Caribou (*Rangifer tarandus*), camel (*Camelops* sp.), musk ox (*Ovibos moschatus*), saiga antelope (*Saiga tatarica*), sheep (*Ovis* sp.), wapiti (elk; *Cervus canadensis*), and yak (*Bos* sp.) were present in lower numbers. Carnivores included short-faced bear (*Arctodus simus*), saber-toothed cat (*Smilodon* sp.), brown bear (*Ursus arctos*), wolf (*Canis lupus*), coyote (*Canis latrans*), and lion (*Felis* sp.). Megafauna were abundant and represented a larger amount of biomass on the Beringian landscape than any that exists in the northern hemisphere today. Many of these species did not survive in eastern Beringia much past the LGM; however, key subsistence species for early humans in the region did survive into the Late Glacial and early Holocene, including bison and caribou (Guthrie, 2006; Potter, 2011).

Based on small and large mammalian fossil assemblages recovered from loessic deposits in eastern Beringia, Guthrie (1968, 1990) proposed that a relatively homogeneous expanse of cold and arid steppe-like grassland, often referred to as the "mammoth steppe," extended east to west from the Yukon, Canada, to northern Europe. This grassland supported a diverse set of grazing megafauna with horse, bison, and mammoth as the dominant large mammal species. Some palynologists suggested, based on pollen influx analyses from lake cores, that the Beringian landscape was covered by sparse tundra during the LGM and could not have supported sizable populations of large mammals (Cwynar and Ritchie, 1980; Colinvaux and West, 1984).

More recent research on insect fossils and buried vegetation indicates that a geographically limited north-south mesic zone, possibly with more shrub tundra vegetation, was present on the exposed Bering Land Bridge (Höfle et al., 2000; Elias and Crocker, 2008). This more mesic zone may have prohibited some species (woolly rhinoceros, bonnet-horned musk ox, and North American camels) from migrating east or west over the land bridge (Guthrie, 2001; Elias and Crocker, 2008). Guthrie (2001) has referred to this mesic region as a north-south-trending "buckle" within the expansive mammoth steppe grasslands. This mesic buckle served as a refugium for mesic-adapted species and a barrier for several grassland-adapted North American and East Asian large mammal and insect species that never crossed the Bering Land Bridge, but inhabited adjacent arid environments (Guthrie, 2001; Elias and Crocker, 2008). Recent paleoecological studies have placed a wider emphasis on regional variation of tundra and shrub communities throughout Beringia with gradients of xero-, meso-, and hydrophytic plants depending on more local factors such as available moisture, evapotranspiration rates, soil temperatures, elevation, topography, and aspect (Anderson and Brubaker, 1994; Elias et al., 2000; Brigham-Grette et al., 2004; Zazula et al., 2006; Elias and Crocker, 2008). Thus, the current picture we have of the LGM Beringian climate and environment was highly continental, arid, and treeless across much of the Beringia, with shrubs likely occurring in lowland riparian zones of central Beringia.

During the LGM, central Beringia likely had a greater number of lakes than eastern Beringia (Ager, 2003), probably due to an east-west moisture gradient and potential difference in evapotranspiration rates (Guthrie, 2001). Many of the lakes in eastern Beringia were not initiated until after 15,000 cal BP as a consequence of the highly arid environment of the LGM (Shuman and Finney, 2007).

Late Glacial and Holocene

Around 18,000–16,000 cal BP, the climate began to ameliorate, and the extreme glacial conditions began to abate, which marks the beginning of the Late Glacial period. By 16,000 cal BP, shrub tundra vegetation with an increase in the presence of *Betula* (birch) expanded across many parts of eastern Beringia (Bigelow, 2007). *Populus* trees expanded northward beyond their current ranges by 12,900 cal BP (Mann et al., 2002). The expansion of shrub tundra caused widespread zonation of steppe tundra at higher elevations, thereby shrinking and fractionating the distribution of large mammal-grazing habitat (Guthrie, 1990). Humans, moose, and wapiti appear to have migrated into eastern Beringia at roughly the same time, coincident with the expansion of shrubs (Guthrie, 2006; Meiri et al., 2014). However, moose remained a very minor part of the overall subsistence economy throughout the late Pleistocene and Holocene (Yesner, 1989), while wapiti played a more prominent role (Potter, 2005, 2008).

Across Beringia, climatic fluctuation and ecological and landscape changes that were coincident with general hemispheric cooling during the Younger Dryas Chronozone (12,900–11,700 cal BP) seem to have been highly variable across and within regions (Kokorowski et al., 2008; Borzenkova et al., 2013). Several palynological records in western and eastern Beringia document the increase in herbaceous tundra taxa and decrease in woody vegetation (Mann et al., 2002; Kokorowski et al., 2008; Borzenkova et al., 2013), and localized glacial advances coincident with the Younger Dryas have been recorded in mountain ranges in interior, eastern Beringian regions (Briner et al., 2002; Reger et al., 2008). An increase in wind-blown sand deposition is recorded in a limited number of geologic sections in interior eastern Beringia implying localized sparse vegetation, exposed sediment sources, and increased wind intensity (Bigelow et al., 1990; Dilley, 1998). Other paleoenvironmental records, however, show increases in shrub tundra and deciduous species, soil formation, and continuing climatic amelioration (Carlson and Finney, 2004; Hoffecker and Elias, 2007).

Paleofaunal records show a substantial change in the character and distribution of large and small mammal communities that coincide with regional changes in climate, geological environments, and vegetative communities. Habitat reduction, decreases in belowground biomass, introduction of toxic plants, and increases in moisture and paludification have been put forward as some of the primary processes leading to changes in interior Alaskan mammalian biodiversity from the LGM to the Holocene (Guthrie, 1984, 1990, 2001). The distributions of small mammals, such as ground squirrels, large browsers and grazers, and smaller mammals, became more restricted from the Late Glacial into the early Holocene, with some species becoming locally extinct (Guthrie, 1990, 2006; Mann et al., 2013).

The inundation of the Bering shelf and separation of northeastern Asia and western Alaska occurred between 12,000 and 10,000 cal BP (Elias et al., 1996, 1997; Manley, 2002). This inundation reconnected the waters of the Chukchi Sea of the Arctic Ocean to the Bering Sea of the North Pacific Ocean. Air circulation patterns began to fluctuate regionally and seasonally as the heights of the large ice sheets were reduced. Coastal air masses were no longer blocked and bifurcated by the glaciers. The early Holocene maintained a general trend of increased warming and effective moisture. Multiple climate proxies indicate that summer insolation and July temperatures may have reached their maximum between 11,000 and 8,000 cal BP, a period referred to as the Holocene thermal maximum (Kaufman et al., 2004). Deciduous and coniferous forests expanded in many regions of Beringia, as well as paludification (Bigelow, 2007; Borzenkova et al., 2013). Sea-level rise began to stabilize around 6,000 cal BP, reaching modern levels at about 4,700 cal BP (Mason and Jordan, 1993; Mason et al., 1997), and the former highlands of central Beringia became islands and peninsulas.

Beringia: the georchaeological record

Western Beringia

The geoarchaeological record in Western Beringia exhibits considerable variability (see review in Brigham-Grette et al., 2004) and has affected archaeological research strategies. In much of Chukotka and Kamchatka with few exceptions (e.g., Ushki Lake, Kheta), sites have been discovered in areas with relatively little sediment deposition, and surficial (or near surficial) archaeology has largely limited analyses to typological approaches in the absence of deep stratigraphy and secure radiocarbon dating (Dikov, 1997; Slobodin, 1999). A more substantial record of stratified and generally well-dated Late Paleolithic sites (mainly post-LGM) has been discovered along the Lena River and tributaries such as the Aldan River, including Diuktai Cave, Verkhne-Troistakaya, and Ust-Mil 2 (summarized in Mochanov and Fedoseeva, 1996). The Yana RHS (Rhinoceros Horn Site) site (over 70° N. latitude), with an occupation dating to ~28,000 ^{14}C BP, pushes human occupation in Western Beringia to before the LGM (Pitulko et al., 2004; Nikolskiy and Pitulko, 2013).

Much archaeological research has focused on the earliest colonization of Northeast Asia, the presence/absence of humans during the LGM (Goebel, 2002 vs. Kuzmin and Keates, 2005; Kuzmin, 2008; and later papers by Kuzmin), and identifying the ancestors of the earliest Americans (see review in Hoffecker and Elias, 2007).

Many archaeologists have typically used culture history-based approaches to Siberian archaeology, and geology, where it is considered, has been focused on chronology (e.g., Okladnikov, Mochanov, Dikov), though there are examples of more geoarchaeologically informed approaches (e.g., Tseitlin, 1979; Waters et al., 1999; Buvit 2008, 2011). More recently, site-based and regional geoarchaeological approaches have become more common (Nikolskiy et al., 2010; Basilyan et al., 2011; Nikolskiy and Pitulko, 2013). New dating approaches such as OSL dating have been applied with varying success (e.g., Huntley and Richards, 1997; Waters et al., 1999).

The cultural chronology of Western Beringia has seen considerable debate, with various labels applied to the same materials – e.g., the Diuktai, Selemdzha, and Kamchatkan Paleolithic (Mochanov and Fedoseeva, 1996; Dikov, 2004; see Vasil'ev, 1993). The earliest undisputed occupation, at Yana RHS, is a Middle Upper Paleolithic site similar in certain respects to contemporaneous southern Siberian sites (e.g., Mal'ta) and unrelated to the later Diuktai culture, which is associated with widespread post-LGM expansion to into western and eastern Beringia (Yi and Clark, 1985; Goebel, 1999).

Central and eastern Beringia

Archaeological research in central Beringia concentrating on Late Glacial and early Holocene sites has been limited to identifying the potential for submerged landforms dating to these periods through geophysical remote sensing and coring. The only extensive archaeological excavations that have been conducted in central Beringia are on islands that were once the highlands of the Bering Land Bridge; no human occupations have been found that date older than 4,000 cal BP.

Eastern Beringia holds some of the oldest archaeological sites in North America and what has long been suggested as a unique record of technological variability during the Late Glacial and early Holocene that blends Old and New World technological traits (i.e., prismatic core and blade and bifacial projectile point technologies, respectively). The mechanisms that have led to variability in the eastern Beringian record have been highly debated with reasoning invoking stylistic and technological differences among cultural groups, differences in seasonal resource procurement strategies, and variation in raw material quality, abundance, and size and shape.

Many of the sites in the northern part of eastern Beringia (Seward Peninsula, the Brooks Range regions, and northern coastal plain) have been found on bedrock promontories and glacial outwash features. The overlying unconsolidated sediments are generally shallow (<1 m thick) and consist of eolian fine sands and silts and regolith (Reanier, 1982; Rasic, 2011; Goebel et al., 2013). Soils on these landforms above the Arctic Circle tend to cryic in nature and generally either gelisols or inceptisols that form under moist and wet tundra vegetation in cold, dry environments (Ugolini, 1986; Muhs et al., 2000). Podzolization in these regions primarily occurs under the presence of acidic tundra-heath vegetation and at the tree line of the coniferous forests.

The sites that have tended to garner the most attention are those that are associated with what has been termed the "Northern Paleo-Indian tradition" (Dixon, 1993; Reanier, 1995; Smith et al., 2013). Many of these assemblages contain distinctive styles of lanceolate and fluted projectile points that date between 12,900 and 11,200 cal BP and what may be regionally separated into three complexes: the Mesa, Northern Fluted Point, and Sluiceway complexes (Smith et al., 2013). The Mesa site is one of the more well known of these types dating to the Late Glacial and early Holocene and one of the type sites for the Mesa complex. A grouping of sites in the western Brooks Range has formed the basis of the Sluiceway complex (Rasic, 2011). Many sites containing so-called Northern Fluted Points have been used to define the Northern Fluted Point complex, and many of the finds have occurred on the surface of landforms or in very shallow undated contexts (Dixon, 1999). Recently, two sites were excavated in northwestern Alaska, Raven Bluff, and Serpentine Hot Springs that contain buried fluted point assemblages as well as relatively well-defined stratigraphy that has yielded age determinations from 12,400 to 11,200 cal BP (Goebel et al., 2013; Smith et al., 2013).

Microcore and blade technology has been recognized at several of these northern Beringian sites; however, they are generally assumed to have been produced by the later American Paleoarctic tradition or the Denbigh Flint complex (Giddings, 1964; Anderson, 1970) occupations of the region. The shallowness of the overlying unconsolidated sediments along with postdepositional disturbance of the deposits may have created a palimpsest and mixture of different occupations. However, several studies have been able to separate different components and occupations by fine-grained intrasite spatial analyses of activity areas (Bowers, 1982; Bever, 2000; Rasic, 2011). In addition, the lack of sufficient deposition over the archaeological materials makes for poor protection and increases the rate of degradation of organic materials at surface and near-surface sites. Well-preserved faunal remains associated with sites such as these are uncommon, with the exception of caribou at Raven Bluff (Smith et al., 2013).

Other depositional settings in which northern eastern Beringian sites occur are dunes (e.g., Nogahabara I: Odess and Rasic, 2007), caves (e.g., Trail Creek and Bluefish Caves: Larsen, 1968; Cinq-Mars, 1979), and alluvial terraces (e.g., Onion Portage: Anderson, 1988).

The earliest traces of humans in interior eastern Beringia appear to be associated with landscape stability and soil development. Human colonization of interior Alaska occurred during a period of the Late Glacial in which birch (*Betula* sp.) shrubs and likely willow (*Salix* sp.) expanded across the landscape (Bigelow and Powers, 2001; Hoffecker and Elias, 2007). Soil development intensified during the Late Glacial, likely associated with the expansion of shrubs and then dramatically increased throughout the early Holocene as forests began to expand.

In interior Alaska and the Yukon, Canada, relatively deep loess and eolian sand deposits (>1 m thick) contain excellent records of well-stratified soil sequences dating back to the Late Glacial – ~14,500 cal BP (Dilley, 1998; Hoffecker and Elias, 2007; Reuther, 2013), although some landforms in more wind intense environments were partially denuded of unconsolidated fine sediments. Surface and near-surface sites in these environments potentially suffer from similar multiple occupation palimpsest and preservation issues similar to those mentioned above at sites in northern eastern Beringia. In addition, postdepositional movement due to freeze-thaw of sediments (cryoturbation) and downslope movement (solifluction/gelifluction) can become a hindrance to deciphering potentially mixed occupations. Several sites that played a significant role in the development of eastern Beringian archaeology suffered from many of the issues outlined above, including many of those that were used initially to define the Denali Complex (West, 1967, 1975), e.g., the Campus site (Mobley, 1991) and sites around the Tangle Lakes region (West, 1996).

Extensive geological and geoarchaeological investigations have been conducted in two main river valleys in interior eastern Beringia: the Nenana and Tanana. Geoarchaeological studies during the North Alaska Range Early Man Project established a relatively consistent Late Glacial and early Holocene loess and sand sheet depositional sequence with intermittent soil development and landscape stability throughout the Nenana River Valley (Thorson and Hamilton, 1977; Powers and Hoffecker, 1989). Immature tundra soils (Cryothents) were widespread in the Nenana Valley during the Late Glacial and early Holocene occupations, while incipient forest soils (Cryochrepts) began developing later in the Holocene in areas where eolian deposition waned (Thorson and Hamilton, 1977; Power and Hoffecker, 1989). Geological work associated with the project also helped refine the glacial sequences and alluvial terrace development in the region (Ten Brink and Waythomas, 1985). Several important early sites in the Nenana Valley and adjacent valleys are situated on alluvial and outwash terraces and fans, including the Carlo Creek, Dry Creek, Eroadaway, Moose Creek, Owl Ridge, Panguingue Creek, Walker Road, and Teklanika West sites. Several of these sites helped to clarify the antiquity of the Denali Complex (West, 1967, 1975) dating it back to 13,000 cal BP, along with the recognition of an earlier regional and stratigraphically lower occupation, the Nenana Complex, dating back to 13,300 cal BP (Powers and Hoffecker, 1989; Goebel et al., 1991).

Several sites in the Tanana River Valley contain excellent organic preservation due to the rapid accumulation of, and calcareous nature of, the loess (Dilley, 1998; Reuther, 2013) and an incredible wealth of faunal assemblages that date to the Late Glacial and early Holocene. Like the Nenana Valley, immature soils (Cryothents) were widespread in the Tanana Valley during the Late Glacial and early Holocene occupations due to competing processes of soil formation and vegetation growth versus loess deposition. However, the Late Glacial and early Holocene Tanana Valley soils were likely associated with a shrub tundra and scattered open deciduous forest. Incipient forest soil (Cryochrepts) development began in the early part of the Holocene (Dilley, 1998; Potter, 2005; Reuther, 2013), likely associated with an open deciduous forest. As loess deposition decreased throughout the Holocene, coniferous forests and peats began to develop across the Tanana Valley, and landscapes became more stable.

Early sites in the middle and upper portions of the Tanana River Valley reveal a rich history of hunter-gatherer occupations that date back to 14,000 cal BP and the earliest unequivocal evidence for the settlement of northern North America (Holmes, 1996, 2011; Potter et al., 2013). Sites are generally situated on bedrock bluff edges and knolls (e.g., Bachner, Broken Mammoth, Chugwater, Gerstle River, Little John, Mead, McDonald Creek, Swan Point, the Healy Lake Village, and Linda's Point sites) and stabilized sand dunes (e.g., Upward Sun River and Keystone Dune sites) that were adjacent to wetlands during the time of the Late Glacial and early Holocene occupations, which allowed access to a wide diversity of animals, birds, and fish (Yesner, 2007; Potter et al., 2011, 2013). While many of the early sites in eastern Beringia are hunting and secondary processing camps, at least two sites in the middle Tanana Valley are base camps – the Upward Sun River and Mead sites – giving us a glimpse into more residential life, including mortuary practices (Potter et al., 2011, 2013, 2014).

In other regions of interior eastern Beringia, we are just beginning to get a glimpse of the Late Glacial and early Holocene records as more archaeological and geoarchaeological investigations are being conducted. Higher elevation landscapes in the central Alaska Range and the Talkeetna Mountains were used shortly after deglaciation as evident at 11,000–12,000 cal-year-old sites such as Bull River II, Jay Creek Ridge, and the Phipps sites (West et al., 1996; Dixon, 1999; Wygal, 2010).

Late Glacial and early Holocene cave archaeological sites are few in interior eastern Beringia, the most well documented being Lime Hills Cave I in southwestern Alaska with occupations that date back to 12,000 cal BP (Ackerman, 2011). Other caves have yielded important paleontological data dating back to 18,000 cal BP, but they have yet to yield early archaeological remains (Sattler et al., 2001).

The coastal zones of southern Alaska and northwestern British Columbia, beyond what is traditionally viewed as Beringia proper, contained areas that remained unglaciated during the LGM or were deglaciated very early in the Late Glacial period (Carrara et al., 2007; Misarti et al., 2012). These ice-free areas provided habitat for many terrestrial mammals (Heaton and Grady, 2003). Several early sites on raised terraces and in caves in southeastern Alaska and northwestern British Columbia (Dixon et al., 1997; Fedje et al., 2011; Carlson and Baichtal, 2015) date back to 12,000 cal BP. The earliest sites in the islands and peninsulas of the Bering Sea region date to no earlier than 9,500 cal BP (Davis and Knecht, 2010).

Summary

Beringia was a vast and geologically complex region no matter how its borders are defined by researchers. Past terrestrial mammalian diversity through the LGM and into the Late Glacial appears to have been much higher than many of the regions in northern Asia and northern North America today. The marginality of the interior northern environments that we see in these regions today may be more the product of Holocene changes in the climate and environment. During the Late Glacial and early Holocene interval, we see broad similarities in technology, subsistence, and settlement systems across many regions of Beringia. These systems became more regionalized into the Holocene with an adaptation to new changes in landscapes and the abundance and types of resources.

BIG EDDY SITE, MISSOURI

Edwin R. Hajic
GeoArc Research, Inc., Santa Fe, NM, USA

The Big Eddy site (23CE426) is located in the lower Sac River valley at the Plains-Eastern Woodlands boundary in southwest Missouri, USA (Hajic et al., 2007). It is a rare, documented site that contains distinctly stratified and radiocarbon-dated Early Paleoindian through Late Archaic cultural deposits. Early projectile points recovered from excavations at the site include Gainey, Sedgwick (Eastern Folsom), Dalton, and San Patrice (Hope and St. Johns varieties) (Lopinot et al., 1998, 2000). There is a scant and inconclusive evidence for a pre-Early Paleoindian cultural horizon, represented by a large possibly utilized flake, refit fragments of a possible anvilstone, and a poorly preserved bison-sized bone fragment.

Early cultural material is contained within alluvial deposits belonging to an early submember of the Rodgers Shelter Member (a series of alluvial fills) that span the metamorphosis from a braided to meandering regime in the Sac River valley. Alluvium in the lower and middle part of the early submember aggraded between ca. 15,300 and 13,250 cal year BP through a transition from braid-bar to upper point bar depositional environment at the site. Pre-Paleoindian-age material is contained in at least the uppermost 0.7 m of this sequence. Alluvium in the middle and upper part of the early submember that hosts the Paleoindian sequence is 0.7 m thick and aggraded between ca. 13,250 and 11,870 cal year BP through the transition from point bar to floodplain depositional environment. A complex buried soil altered deposits with Paleoindian and pre-Paleoindian material. The buried soil has a cumulic A horizon and is welded onto a paleogeomorphic surface at the top of Middle Paleoindian material that stabilized during the Younger Dryas (Hajic et al., 2007; Dorale et al., 2010).

Nearly 3 m of fine-grained floodplain alluvium, with a basal age of about 11,250 cal year BP, buries and preserves the Paleoindian record, and it contains stratified cultural material representing nearly the entire post-Paleoindian prehistoric cultural sequence as well. Post-Paleoindian alluvial stratification at the site resulted from lateral migration of the stream and aggradation of thick floodplain overbank and terrace veneer deposits of Early and Middle Holocene age, as well as a thin terrace veneer deposit of Late Holocene age at the top of the section. Overlying deposits are thick enough to mask completely the relief characterizing the buried Paleoindian alluvial landscape. At least seven distinctly stratified Early Archaic components are represented within the middle submember, including Breckenridge, Scottsbluff, Cache River, Graham Cave, Rice Lobed, and Hidden Valley. At least five later Archaic components are represented in both floodplain and terrace veneer deposits in different spatial locations at differing depths in association with a younger buried soil developed in the top of the middle submember. Minor Woodland and Mississippian components are within the uppermost increment of the late submember terrace veneer that is altered by the surface soil.

Big Eddy may not be a unique locality but rather part of a Paleoindian district in the lower Sac River valley. A cutbank survey along the steep eroding face of the river identified 22 Paleoindian sites, including at least one Clovis site, along 49 km of the lower Sac River (Ray and Lopinot, 2005). Valley geomorphic mapping and cutbank stratigraphy suggest other Paleoindian sites are likely associated with paleotopographic highs at the tops of former braid bars.

For further reading, see Lopinot and Ray (2007, 2010), Lopinot et al. (1998, 2000, 2005), and Ray et al. (1998, 2000, 2009) including papers within.

BLOMBOS CAVE

Magnus M. Haaland and Christopher S. Henshilwood
Department of Archaeology, History, Cultural Studies and Religion, University of Bergen, Bergen, Norway

Blombos Cave is located in Blombosfontein Nature Reserve on the southern Cape coastline of South Africa. The site is situated within a south-facing cliff on the upper part of a coastal slope, ca. 34.5 m above sea level, some 100 m from the present-day shoreline. The cave formed at the base of the sandy limestone bed of the Wankoe Formation (Mio-/Pliocene aeolianites) at its contact with the underlying Table Mountain Group (quartzitic Ordovician sandstones).

The outer talus is stabilized by large, semi-exposed blocks and presents a gently sloping platform that extends 4–5 m southward. The cave interior comprises a main chamber with an accessible surface area of ca. 40 m^2. Irregular cavities and smaller interconnected channels and chambers extend inwardly. The sediments at the base of the cave contain detrital particles of the substratum which are most likely related to the disaggregation of the limestone during the initial stage of cave formation. The seaward extension of the original limestone bedrock was at one stage truncated by marine erosion sometime during the Plio-Pleistocene, resulting in the opening of the cave. Following this exposure, infill sediments from the cave exterior accumulated and intermixed with limestone roof spalls.

In the excavated part of the cave, near the cave entrance, the sedimentary sequence is more than 3 m deep. It contains a well-stratified and unconsolidated deposit that is characterized by three major lithostratigraphic units. At the base is a layered and finely laminated sequence that contains Middle Stone Age (MSA) artifacts and anthropogenic material. In the middle, there is a coarse, sandy horizon representing an occupational hiatus, and on top lies a thin, silty, and sandy deposit that contains Later Stone Age (LSA) material. The hiatus, which can be found over more than 95 % of the excavated area, shows no major disturbance from the overlaying LSA deposit (Henshilwood, 2005). Decomposed marine and terrestrial faunal remains (fish, shellfish, and animal bones) and organic material are found within the sandy LSA and MSA layers. Larger combustion features, smaller hearths, and ash-rich horizons are also observed throughout the sequence.

The MSA sequence in Blombos Cave has been dated to ca. 101–70 ka using a number of methods, including thermoluminescence (TL), optically stimulated luminescence (OSL), uranium-thorium series (U/Th), and electron spin resonance (ESR). The occupational hiatus between 70 and 2 ka suggests that the cave was sealed off by aeolian dune sand during this period. The cave entrance may have reopened during the mid-Holocene transgression (ca. 4–3 ka), when high sea levels eroded away most of the nearby sand dune. Remnants of this eroded dune system are still visible in the surrounding coastal landscape. The LSA sequence is radiocarbon dated to 2000–290 years BP.

The most informative archaeological material – some of it ascribed to the Still Bay techno-complex – has been recovered from the MSA sequence and includes worked and engraved ocher, ocher processing kits, engraved bone, marine shell beads, polished bone tools, and bifacially worked stone tools (Henshilwood et al., 2002, 2004; Mourre et al., 2010; Henshilwood et al., 2011). The archaeological material recovered from Blombos Cave shows that, during the MSA, humans had developed a diverse set of subsistence and procurement strategies and were regularly manufacturing composite tools. The evidence for personal ornaments and abstract depictions represents some of the earliest occurrences of symbolically mediated behavior. The MSA sequence at Blombos Cave is thus central to our current understanding

Boxgrove, Figure 1 Panoramic view of Blombos Cave interior (Photo by Magnus M. Haaland).

of the behavioral, cognitive, and cultural development of early humans in southern Africa during the Late Pleistocene (Figure 1).

BOXGROVE

Richard I. Macphail
Institute of Archaeology, University College London, London, UK

The Lower Paleolithic site of Boxgrove, West Sussex, UK, is located 12 km north of the present day coastline of the English Channel, in a buried early Middle Pleistocene landscape that extends 26 km from east to west (Roberts and Pope, 2013). The area has had a long history of geological and archaeological investigation dating back to the nineteenth century. The main excavations were carried out in two gravel quarries that covered a 1 km stretch of paleocoastline (Roberts and Parfitt, 1999). A tibia and two teeth, probably from *Homo heidelbergensis* (Stringer et al., 1998), were recovered from a depositional sequence of marine followed by terrestrial sediments that were rich in artifacts and faunal remains.

The sediments record a change from interglacial/temperate (MIS 13) to glacial/cool conditions (MIS 12). Three marine cycles were found, with the highest point of marine transgression recorded at 43.5 m above sea level. However, this height is attributable to post-depositional neo-tectonics rather than a true eustatic rise in sea level only. Terminal marine regression led to the deposition of intertidal silts (Unit 4a/b) over nearshore sands (Unit 3) laid down during the transgression phase. Current date estimates for the warm-phase hominin occupation range between 500 and 478 ka. The lowermost major hominin occupation occurred in Unit 4b, with examples of large animal (e.g., horse) butchery and Acheulian hand axe manufacture preserved within laminated silt and chalky clay intertidal mudflat sediments as indicated by invertebrate microfossils (foraminifera and ostracods). The most extensive occupation, however, is recorded in Unit 4c, where concentrations of worked flint occur within a thin (now only ~40 mm in places) Aquic Udifluvent soil (calcaric-alluvial soil) formed by terrestrial ripening (weathering) of the uppermost Unit 4b. This process involved decalcification and a loss of mass (some 20–30 % by weight), which possibly developed briefly over ~100 years. Very few micro-pedological features (burrows and small invertebrate excrements) are preserved, but those present are consistent with small mammal fauna (voles and moles). This soil and overlying organic bed Unit 5a have now been mapped by boreholes across some 13 km of the full 26 km extent of the paleolandscape, outside the original quarry site. The sediments record the silting up and terrestrial landscape evolution of a large Middle Pleistocene marine embayment (Roberts and Pope, 2013). Uniquely at Quarry 1, a probable spring-fed freshwater pond was formed by eroding through Units 4a/b down into Unit 3, the freshwater event being coeval with the formation of Unit 4c elsewhere. Numerous hand axes, abundant bones of large fauna such as extinct rhinoceros, and preserved hominin remains were found here in calcareous sediments (Roberts et al., 2015). Anomalous inundation then affected the whole site, forming microlaminated and often ferruginous Unit 5a that likely originated as a carr (waterlogged woodland) colonized by alder. One borehole near Slindon, 5 km to the east, found a Unit 5a, in which both enigmatic coarse broad-leaved wood charcoal and remarkable examples of preserved, albeit degraded, wood occur (Macphail et al., 2010). Upward, the sequence eventually becomes dominated by cool-phase sediments, but even these include instances of refitting artifact scatters, i.e., lithic flakes that conjoin, or refit, back into parts of their original core, thereby giving evidence of undisturbed occupation residue and not simply reworked material displaced from earlier occupations. Both an occupied interstadial (within Unit 8) and cool, humid soliflual deposits (Unit 11) are recorded.

Acknowledgments

Mark Roberts is thanked for his contribution to this summary.

BUILT ENVIRONMENT

Joseph Schuldenrein
Geoarchaeology Research Associates, Yonkers, NY, USA

Synonyms

Cultural landscapes; Human-engineered cultural, social, and physical landscapes

Definition

The *built environment* refers to landscapes that are largely generated by people to sustain human activity. These settings include buildings, parks, and infrastructure facilities. They are viewed on a variety of scales ranging from neighborhoods to cities and surrounding municipalities that constitute "greater metropolitan areas." The archaeology of the built environment refers to the performance of survey, testing, and more extensive excavation of cultural or heritage resources. In the current age of sustainability, archaeology undertaken in urban settings assumes increased significance because space is confined, and the nearly continuous development intrudes upon older historic resources that represent actual archives of urban growth. Such intrusions are lateral, vertical, or both, and they impose complex stratigraphic disturbances upon remains that possess inherent archaeological importance. In fact, significant cultural resources are contained within the complicated accumulation of sediments laid down by natural and anthropogenic processes. These resources are subsequently disturbed or otherwise overridden by successive phases of development and landscaping.

There is a "top-down" bias in ranking the archaeological remains of the built environment. Traditional heuristic templates and theoretical models hold that stratified urban deposits assume increased importance with depth (i.e., age) and degree of preservation (i.e., retention of "archaeological integrity and context"). In the United States, for example, where the 50-year rule enacted under Section 106 of the National Historic Preservation Act (NHPA, 1966) determines the classification of a resource as formally significant (if it is older than 50 years), upper sediments in an urban sequence are considered to be "fill," or effectively undifferentiated depositional bodies. As the word "fill" implies, such sediments, with or without embedded cultural materials, are almost entirely dismissed out of hand archaeologically under the presumption that they carry no apparent worth other than functioning to level out a surface. However, older sediments, reconfigured for the same purpose as fill but 100–200 years earlier, may be deemed significant because they formed the foundation of a historic structure or municipal feature whose antiquity potentially affords it *archaeological significance*. The plethora of archaeological investigations in urban settings has called into question these traditional models, in step with the increasing acceptance of the concept of the *Anthropocene*, a "new human-dominated geological epoch" (Lewis and Maslin, 2015). This epoch is largely founded on the premise that human impacts account for the unique and dense deposits of an increasingly urbanized contemporary world. Within that context, it can be argued that the built environment will constitute a more prominent, even dominant, arena for archaeological exploration. For geoarchaeologists, today's land use patterns, and their present and evolving sedimentary and depositional contexts, are pivotal to the performance of "future archaeology." It follows that more sophisticated methods in geoarchaeology must be developed to analyze, for example, sediment bodies impacted by a broad range of anthropogenic inputs and residue disaggregation patterns that possess multiple origins, some never before encountered in the archaeological record.

Introduction

The built environment's boundaries and structural components are not easily charted geographically for a given metropolitan area. They will extend outward to suburban, exurban, and even rural areas in which support facilities for human activities have been constructed. This entry will consider modern built environments, but the analytical framework postulates that similar processes of anthropogenic construction and disturbance can be traced back in time to the earliest settlements comprising durable architecture. Modern infrastructure components considered here include the utility, supply, and distribution networks that allow built environments to function in maintaining contemporary lifeways. Major utilities encompass water and sewerage systems, electric and gas grids, fiber-optic lines, transportation networks, and energy facilities. A corollary to the function of the built environment is that the utilization of spaces by their occupying populations creates activity loci that record evidence of work and leisure time behaviors. Thus, this perspective of the built environment represents an anthropological approach to the continuity of patterned behavior. Its study implies that contemporary activities are the eventual archives of past human behavior as it will be seen in the future.

For archaeology, the built landscape may be viewed as composite and functional geographic settings wherein archaeology is performed – generally for legal and compliance purposes but also for research, the latter typically on a smaller scale. Archaeological work is legally mandated in settings that stand to be modified by construction and related activities. Firms contracting for these projects engage in what is called Cultural Resource Management (CRM), of which the charge is to mitigate the destruction of cultural remains, or remove them in a controlled, scientific manner, for the benefit of the citizenry. When development of these settings is undertaken, legally defined *adverse* effects may accrue to buried cultural resources (per NHPA, 1966). Accordingly, when project designs necessitate disturbances to lands that are both slated for development and funded by public monies, mitigation measures may be mandated by law. Empirically, this means that if (formally defined) *significant* archaeological resources are encountered, these must be documented, recovered, or bypassed depending upon projected impacts. It is stressed that decisions on mitigating impacts to cultural resources within the built environment require unique cooperative arrangements between regulators, stakeholders, developers, engineers, and planners, as well as the cultural resource teams implementing the work. Decision-making is driven by cost-benefit analyses and implemented by private contractors (e.g., for constructing housing complexes) and by public development agencies (e.g., for expanding subway lines). Ultimately, the performance of archaeology in urban settings must be meticulously coordinated by archaeological teams, construction engineers, and urban planners to guarantee that the activities of each do not delay or otherwise impede those of the other. Scheduling and use of space in these efforts is of paramount importance – see Carver (2013) for a discussion of logistics and planning in London's Crossrail project.

Geoarchaeologists are beginning to play a significant role in planning and applying mitigation strategies because of an increased emphasis on noninvasive data prospection and recovery in this "age of sustainability" (Brown et al., 2011). This approach is a practical result of limited accessibility (see below) to the urban substrate, which is packed with dense configurations of utilities as well as communication and resource networks.

The built environment in urban areas will typically preserve both discrete and disparate locations where much, if not all, of the surface and subsurface terrain has been previously disturbed, sometimes in the earlier historic past. Archaeological resources in such settings are often difficult to assess formally because, as noted above, sediment bodies currently classified as historically insignificant "fill" may extend to nineteenth- and eighteenth-century layers (or earlier) and thereby acquire increased importance because they bear on land use and discard practices of historic antiquity. Since these layers are often "stacked" (i.e., formally stratified), they effectively constitute successive occupations or multilevel archaeological sites. Paradoxically, while such buried pockets of cultural residues are dominated by "disturbance" activities that may compromise their archaeological integrity, the array of deposits and the artifacts within them preserve unique archaeological features (in the standard sense). Such deposits should not be dismissed as fill horizons since they represent historic practices that have changed through time. Moreover, deeper strata in the historic succession generally reflect lower-level "disturbances," since older technologies generally resulted in less disaggregation of primary occupation loci. One could contend, with reason, that systematic excavation of an urban footprint exposes strata within a single, multicomponent historic site, and that each and every horizon holds archaeological significance in documenting the evolution of the city.

Viewed from a contemporary perspective, in exurban and rural areas where less extensive and often shallower disturbance has taken place, elements of built environments may be anomalous and unique. Examples of limited impacts in rural areas are single-purpose constructions such as sewer lines and roadways. Rural areas are likely to have larger expanses of intact land, which may be more likely to contain undisturbed evidence for prehistoric cultural resources, while more urban tracts may preserve "palimpsests" or complex superpositions of archaeological remains representing occupations ranging from the prehistoric to historic. The upper limits of this time line extend to the subrecent and recent. Preliminary assessments of archaeological sensitivity are often the initial steps in the legal compliance process that provide both developers and cultural resource regulators with strategic guidelines for archaeological exploration. For geoarchaeologists, the key issues involve reconstructions of site formation processes indexed by chronologies. Such syntheses are often assembled by linking horizontally- and vertically-fragmentary natural stratigraphies with cultural residua that have often been displaced by earlier construction and secondary mobilization from their primary (in situ) activity areas. Stratigraphic taxonomies are critical for sequencing and codifying time-transgressive chronologies at historic sites. These may extend vertically from complex anthropogenic horizons (at the top of the sequence) to largely geogenic soils and sediments (at the bottom). At historic sites, and especially within the built environment, the "laws of superposition" become problematic and may require site-specific modification based on complex interfingerings of laterally- and vertically-compromised features and strata. The practitioner is advised to consult Harris (1989, Chaps. 5 and 6) as a baseline for developing an overarching sequence, in part grounded by the Harris Matrix.

When addressing issues attendant to the archaeology of the built environment, researchers must be focused on one of two specific objectives, both of which bear on geoarchaeological elements: (1) Is the goal to examine only targeted archaeological contexts beneath stratigraphic layers of extant and older (recent to subrecent) debris as probing proceeds through vestiges of present and former built environments? or (2) Must investigators concern themselves with vertical documentation of the entire stratigraphic complex of remains up through and including the time of interest? These questions are currently being framed by twenty-first-century archaeologists in conjunction with the general concern that even contemporary landfills and dumps – signature archaeological components of built environments – must be considered future archaeological features going forward. It can be argued, for example, that today's landfill sites and the processes that account for their accumulation reflect a technology and functional urban context that will provide clues for archaeologists of the twenty-second century; in short, they will help reconstruct the cultural lifeways of the present day. These questions characterize contemporary archaeological debate in conjunction with the controversial designation of the Anthropocene as a unique time-stratigraphic unit whose signature is the record of multiscalar events largely attributable to human interference.

In general, however, the focus of this entry is methodological, and concentrates on the first question: specifically the performance of archaeological work in complex, modern built environments. Here, the prevailing need is to extract maximum archaeological information in compromised (subsurface) stratigraphic contexts (although see the entry on "Dumps and Landfill" elsewhere in this volume).

Historic background

Updated concepts of the built environment have their roots in anthropological archaeology and were developed by scholars who explored the connection between environment and human behavior (Rapoport, 1990). In a broad sense, such theoretical foundations expand upon the theme of the symbiotic relationship between adaptive behaviors and changing landscapes, an idea initially pioneered by Karl Butzer (1964) and referenced as the "man/land relationship." The pace of landscape change accelerated in historic times, and patterns of cultural adaptation emerged in response to diverse landscape transformations that increasingly included humanly engineered physical geographic settings.

A recent review of heuristic trends in anthropological archaeology argued that one of the most pressing issues in twenty-first-century archaeology was to explore "...the ways in which the built environment, including the visible remnants of past settlements and monuments, has shaped patterns of culture change" (Rodning, 2010). Over the long term, the interdependence between the environment and culturally structured behavior systems provides for evolutionary changes in the human condition and accounts for the transition from foraging to farming, to cite just one pivotal example. Dynamic environmental zones are seen as accommodating different subsistence patterns, and, by extension, they can variously impact sociopolitical and economic systems. More recent scholarship implicitly links the built environment to the aforementioned Anthropocene (Lewis and Maslin, 2015) wherein the prevailing and accelerated impacts of human activity have left sedimentological and stratigraphic records attributed to products of both cultural activities and climate change (Ruddiman, 2013; Waters et al., 2014). Viewed through a human ecological lens, Butzer's "man/land relationship" has changed to a point where the evidence of that record is now dictated more by human impacts and less by landscape transformations generated by unimpeded ecological cycles.

A compelling case has been made that two dates, AD 1610 and AD 1964, should be considered as marking the beginning of the Anthropocene based on the global scale of such impacts – known as a Global Stratotype Section and Point, or GSSP (Lewis and Maslin, 2015, 173). In support of the earlier date, there is evidence (from the Greenland ice cores) that AD 1610 marked a low point in CO_2 emissions worldwide. The latter date (AD 1964) marks the initial global effects of ^{14}C peaks due to nuclear weapon detonation. Broader interpretations equate the onset of the Anthropocene to the immediate post-Pleistocene (ca. after 10,000 BP) and even turning points thereafter, based on expanding regionally derived patterns of cultural impact on landscapes. For example, both the Industrial Revolution and the expansion of Euroamerican culture within the New World have been invoked as changes that triggered the epoch (Nevle and Bird, 2008; Fischer-Kowalski et al., 2014). While the argument in support of a globally-based date for the Anthropocene is ongoing, and falls beyond the scope of this presentation, the concept of the built environment factors deeply into all considerations of archaeological practice in contemporary urban settings. It can be argued that once complex societies take root and city-states are functionally or structurally recognizable in the archaeological record, the built environment is effectively introduced. It constitutes a separate archaeological domain together with the methodological challenges attendant to maximizing systematic recovery and interpretive yield from that context. Accordingly, time ranges for the onset of the built environment can vary significantly, from the third millennium BC in the ancient Near East to the eighteenth- and even ninieteenth-century in many parts of contemporary North America. For present purposes, however, the use of the term should probably be confined to archaeological activities performed in and around urban centers where basal infrastructures are seen as the foundations of progressively more functional and efficient variants of those surviving at the tops of sequences in contemporary cities.

The need to understand the archaeology of the built environment is clear. Urban landscapes house archaeological records associated with prominent cultural remains and their distributions, and these remains increase in richness through time. On a global scale, dominant demographic shifts from rural- to urban-based lifeways strongly indicate that local and regional investigations exploring the dynamics and timing of such trends mirror the evolution of the urban human condition. Perhaps even more important is that when researchers infer advances in infrastructure technology (through material culture studies of the same), they are effectively in a position to help develop future urban planning strategies. The watchwords "the past is the key to the future" are nowhere more compelling than in urban centers in the age of sustainability, where the management of finite resources is key, and where the lessons of patterned urban growth are preserved in deep urban stratigraphies. The latter provide timelines, explanatory models of growth, and ultimately help furnish guidelines to assist planners in managing and calibrating urban growth without depleting limited resources.

For the geoarchaeologist, the built environment presents a vast array of quandaries. These vary from narrowing investigative efforts to target single components, expanding strategies to explain the broader processes of site formation, documenting burial and stratification of later archaeological components, or even articulating the characteristics of contemporary cover sediments (i.e., landfills) that would make them key to understanding future site formation trajectories under the 50-year rule. In most cases, development projects will center on delineated project footprints that will be exposed for limited duration, not to be exposed again in the short term. Within a CRM framework, formal research designs help structure investigations, but very often in the practice of excavation, and despite the limited size of the footprint, new finds are exposed often resulting in a restructuring of project objectives based on interim interpretations and the restricted access to stratigraphic sections. Experience shows that a range of evidentiary resources must be drawn upon when fieldwork is limited by access. To geoarchaeologists, this means that in-field strategies must focus on the exposures available at specific points in time and space. Models of site formation are then grounded on inductive and/or deductive projections of sequences based on background studies (i.e., landscape chronologies for prehistoric settings as well as maps and documented histories for historic components) and, of course, detailed microstratigraphies when these are available. A further corollary is that under most CRM and heritage-based protocols, the steps attendant to documentation and investigation center around a preference for preservation in place, and not disturbance. That said, the broader arena of the built environment is implicitly a disturbed context. The footprint of the planned impacts (i.e., apartment building complex, subway line, sewerage system) has already undergone initial vetting such that it is ultimately fixed and cannot be avoided, effectively rendering that footprint – and further disturbance to it – a foregone conclusion. In most cases, the archaeologist is called upon to salvage systematically the vestiges of features and intact components lying within the impact zone slated for development.

The archaeology of the built environment has risen to prominence over the past two decades for two main reasons: (1) climate change and new ideas emphasizing sustainability and (2) accelerated migrations to urban areas, often but not exclusively from Third World countries. In both cases, the need to reconfigure and modernize infrastructures has resulted in lateral expansion of city boundaries as well as pressure to reconfigure and expand existing urban facilities. In the case of the latter, ongoing updates to utility networks and transport systems (i.e., trains and highways) require episodic access to existing underground infrastructures and progressive disruptions to modern, historic, and even prehistoric geological and cultural sequences. In North America, a recent example is the "Big Dig" in Boston, a subsurface downtown highway expansion project where novel discoveries of early colonial architecture and land use were exposed (Lewis, 2001). In another example, an eighteenth-century sailing sloop was found in lower Manhattan (New York City) during construction for the Freedom Tower, a structure designed to replace the post-9/11 World Trade Center complex. A spate of books discussing the unique challenges confronting the practice of archaeology in North American cities has underscored the need to develop new methodological approaches in future urban excavations (e.g., Seasholes, 2003; Rothschild and diZerega Wall, 2014).

Globally, current high technology detection surveys and excavations associated with major transit projects have revamped the scale and scope of built environment research in unprecedented ways (see Hattam, 2015). In London, the long-standing Cross Rail project (Crossrail Project) has exposed deeply stratified geoarchaeological contexts for that city's human and landscape histories since the Upper Pleistocene. It has been uniquely informative for the record of the plague and the Great London Fire of 1666. In Istanbul, decade-long research at the site of a massive subway expansion has revealed one of the world's largest collections of Byzantine shipwrecks as well as burial structures and evidence of prehistoric activity. That work has revised the antiquity of the city's origins by 6000 years and has involved extensive cooperation in interdisciplinary work among underwater archaeologists and geologists (Perinçek, 2010; İstanbul Arkeoloji Müzeleri, 2012; Pulak et al., 2015). Since 2012, expansion of Rio de Janeiro's subway complex has produced one of the most telling treasure troves of seventeenth- to nineteenth-century trash from that city's aristocratic sector. In Rome, a Metro (railway) design project beneath the Piazza Venezia has disclosed a two-story cultural center built by Emperor Hadrian two millennia ago (Egidi et al., 2010). This discovery, together with evidence for farming complexes several kilometers outside of the former city center, attested to structural and economic relationships between the administrative center and exurban agricultural areas.

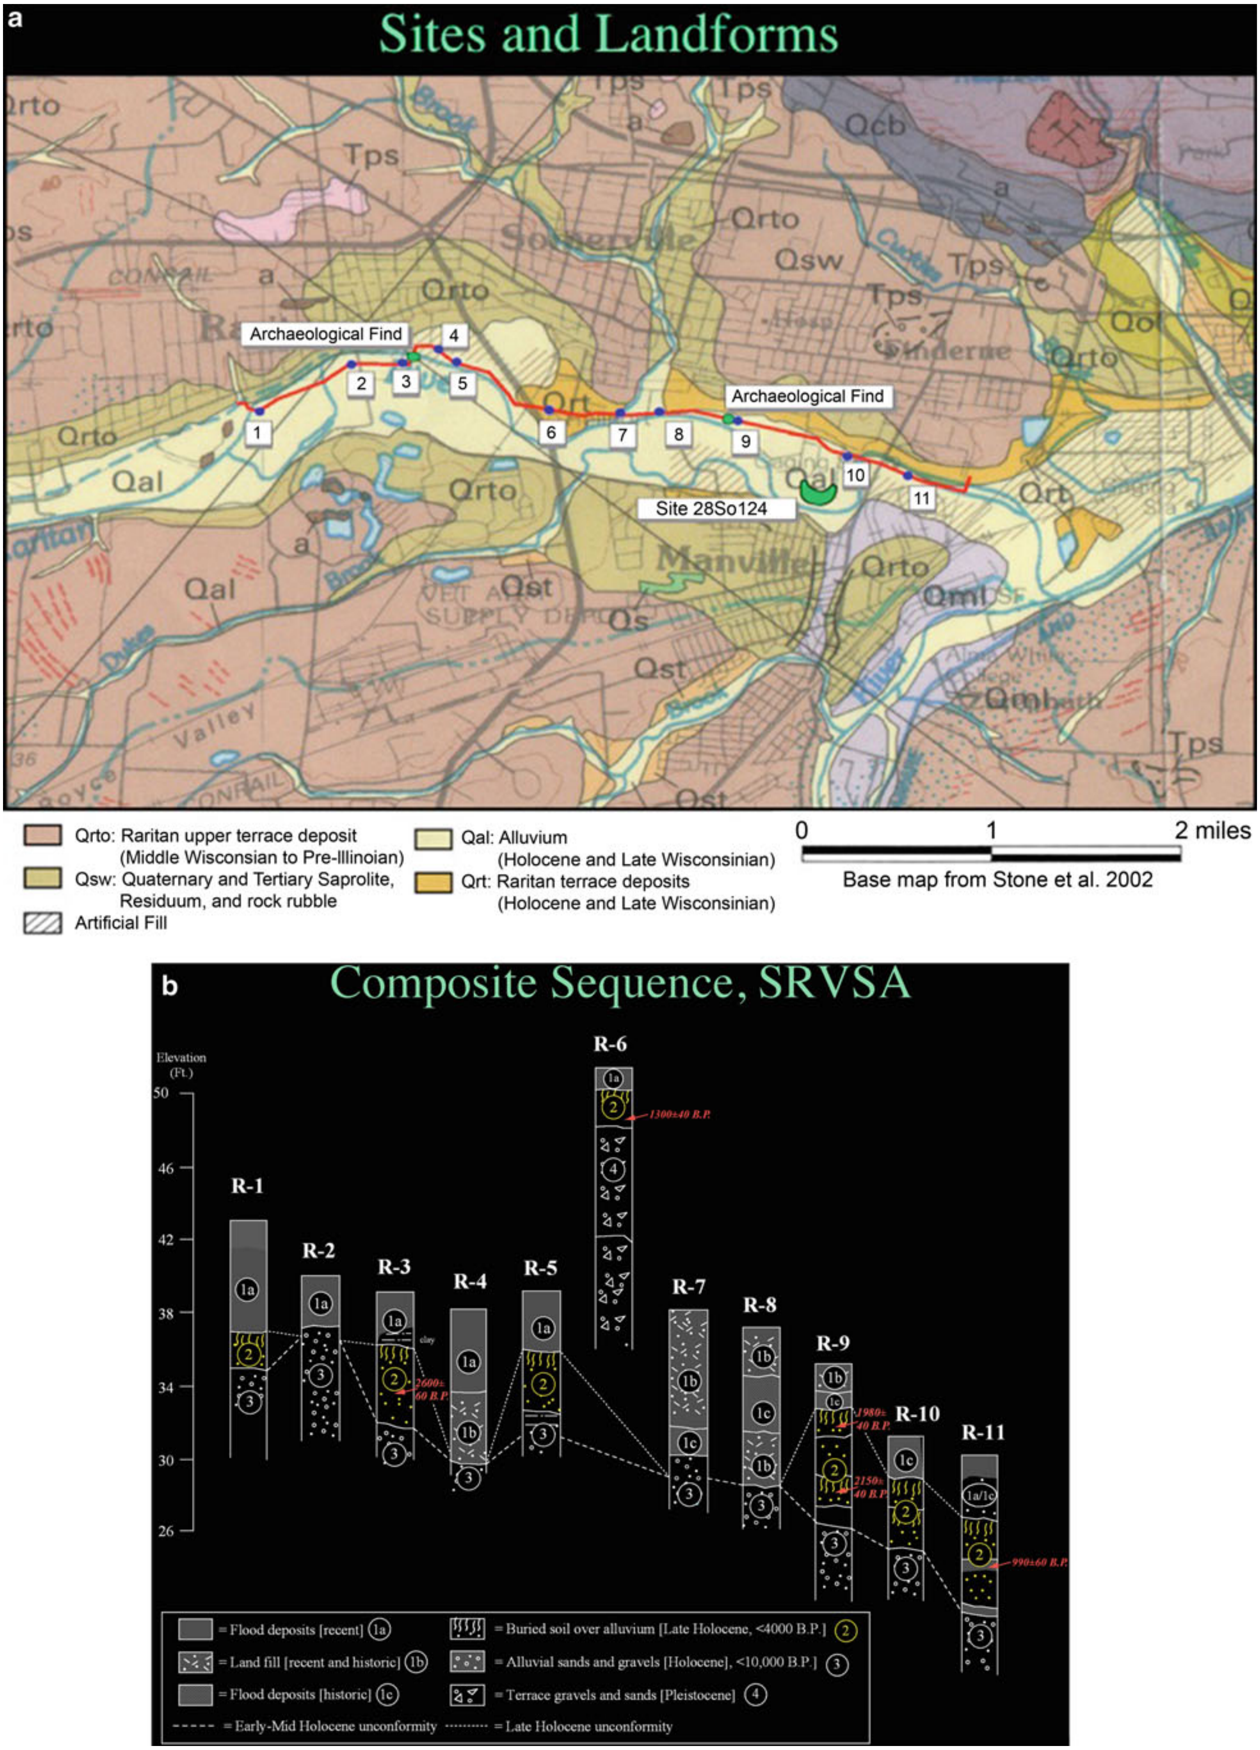
The nature of geoarchaeological exploration will vary depending on both the known archaeological potential of a location (based on previous exploration) and otherwise implicated potential. The latter refers to documented evidence of occupation or the presumption of such, either prehistoric or historic. Investigative methods and logistics are adjusted with respect to the origins and processes of subsurface disturbance, which may be broken down categorically according to developmental complexity. Categories range from minimal or single-source impacts in exurban to suburban locations to intensive and frequently multisource impacts in urban centers. Finally, levels of effort are formalized through memoranda of agreement (MOAs) dictated by planned impacts and agreed upon between developers, regulators, stakeholders, and the CRM teams with whom the geoarchaeologist coordinates in all phases of the endeavor.

Geoarchaeology in the exurban built environment (minimal disturbance)

Typically, exurban locales are affected by a single disturbance activity or several that are grouped together in order to minimize disruption and constrain construction footprints. The usual cases tend to include linear service routes such as pipeline corridors, water and sewer lines, and even roadways. Very often, such undertakings will not disturb laterally extensive swaths of land, and depths of disturbance may be shallow or minimal depending on the technologies applied for implementing construction. Construction of rights-of-way (ROWs) may also follow floodplains and river terraces, or parallel drainageways, as in the case of sewerage lines. Such settings are prime for containing stratified prehistoric sites.

For prehistoric projects in particular, it should be noted that landscape considerations factor significantly into research strategies. The geoarchaeologist will consult US Geological Survey (USGS) topographic maps to obtain broad guidelines for field relations – i.e., landforms and terrain gradients – and US Department of Agriculture (USDA)/Soil Conservation Service (SCS) county soil maps to obtain a preview of subsurface soil development, which provides a measure of subsurface stability along a floodplain. The latter is a predictor of prehistoric site preservation. For archaeological purposes, the question of buried soils is paramount. Equally significant are surficial geology maps, which present the distribution as well as the age of surface sediments. These maps are typically issued by state geological surveys and represent the collective mapping efforts of staff experts in regional Quaternary and bedrock geology. More recently LiDAR mapping has become available in many parts of North America, and such images enable researchers to discern landform and culturally based landscape disturbances beneath densely vegetated canopies or across otherwise obscured terrains. Expeditious application of map resources, together with a variety of historic documents and land use histories, provide the researcher with a preview of the antiquity and composition of the surface relations that his/her project is likely to encounter. Plans for systematic subsurface testing to locate cultural resources are refined on the strength of soil and sediment maps, their projected antiquity, and the known soil and landform associations of archaeological sites in the project area.

Figure 1a and b illustrates the application of this strategy to an extensive surface survey and subsurface testing



Built Environment, Figure 1 (Continued) program for a sewer line expansion project. The line spans a prehistorically sensitive terrace and more subtle alluvial features overlooking a tidal reach of the Raritan River in northern New Jersey. Simple shovel testing was deemed inappropriate by regulators because of obvious disturbance to upper deposits, which consisted of an undifferentiated organic fill clearly derived from localized swamp impoundments; the disturbed sediments were redistributed above an eroded soil cover (Schuldenrein, 2006). By superposing the footprint of the pipeline on the surface geology map (Stone et al., 2002), it was possible to identify areas of buried prehistoric potential that intersected with the line of impact. Sensitivity assessments were based on mapped distributions and ages of Late Quaternary deposits and landforms as well as the proximity of the line to a previously known archaeological site of Late Holocene age (Figure 1a).

The next step was systematic placement of geoprobe cores that ground-truthed the landform mapping units and isolated pristine alluvial deposits that were sampled for dating purposes (Figure 1b). Bulk organic determinations confirmed the age of the paleosol at < 4000 BP. It was possible to eliminate disturbed tracts from testing to confirm the antiquity of buried deposits corresponding to the known Late Archaic to Woodland occupations in the area, and to isolate the only intact buried segment of the landscape that could potentially preserve archaeological materials. The geoprobe sections were linked together across the length of the line, and they disclosed the prevalence of the paleosol (Bw horizon), albeit with pockets of disturbance (probably by land releveling activities along the western segment; Figure 1b). The fill-paleosol unconformity was the key to understanding the prominence of a buried but once stable surface. As a result of this testing, the sewer authority was able to determine if it wished to test for additional prehistoric site potential or to reroute a small segment of the line. They opted for the former, with the regulator's approval. The geoarchaeological survey and testing effort produced the baseline for a limited area-wide excavation that was both scientifically sound and cost effective (Schuldenrein, 2006).

Geoarchaeology of the urban built environment (significant disturbance)

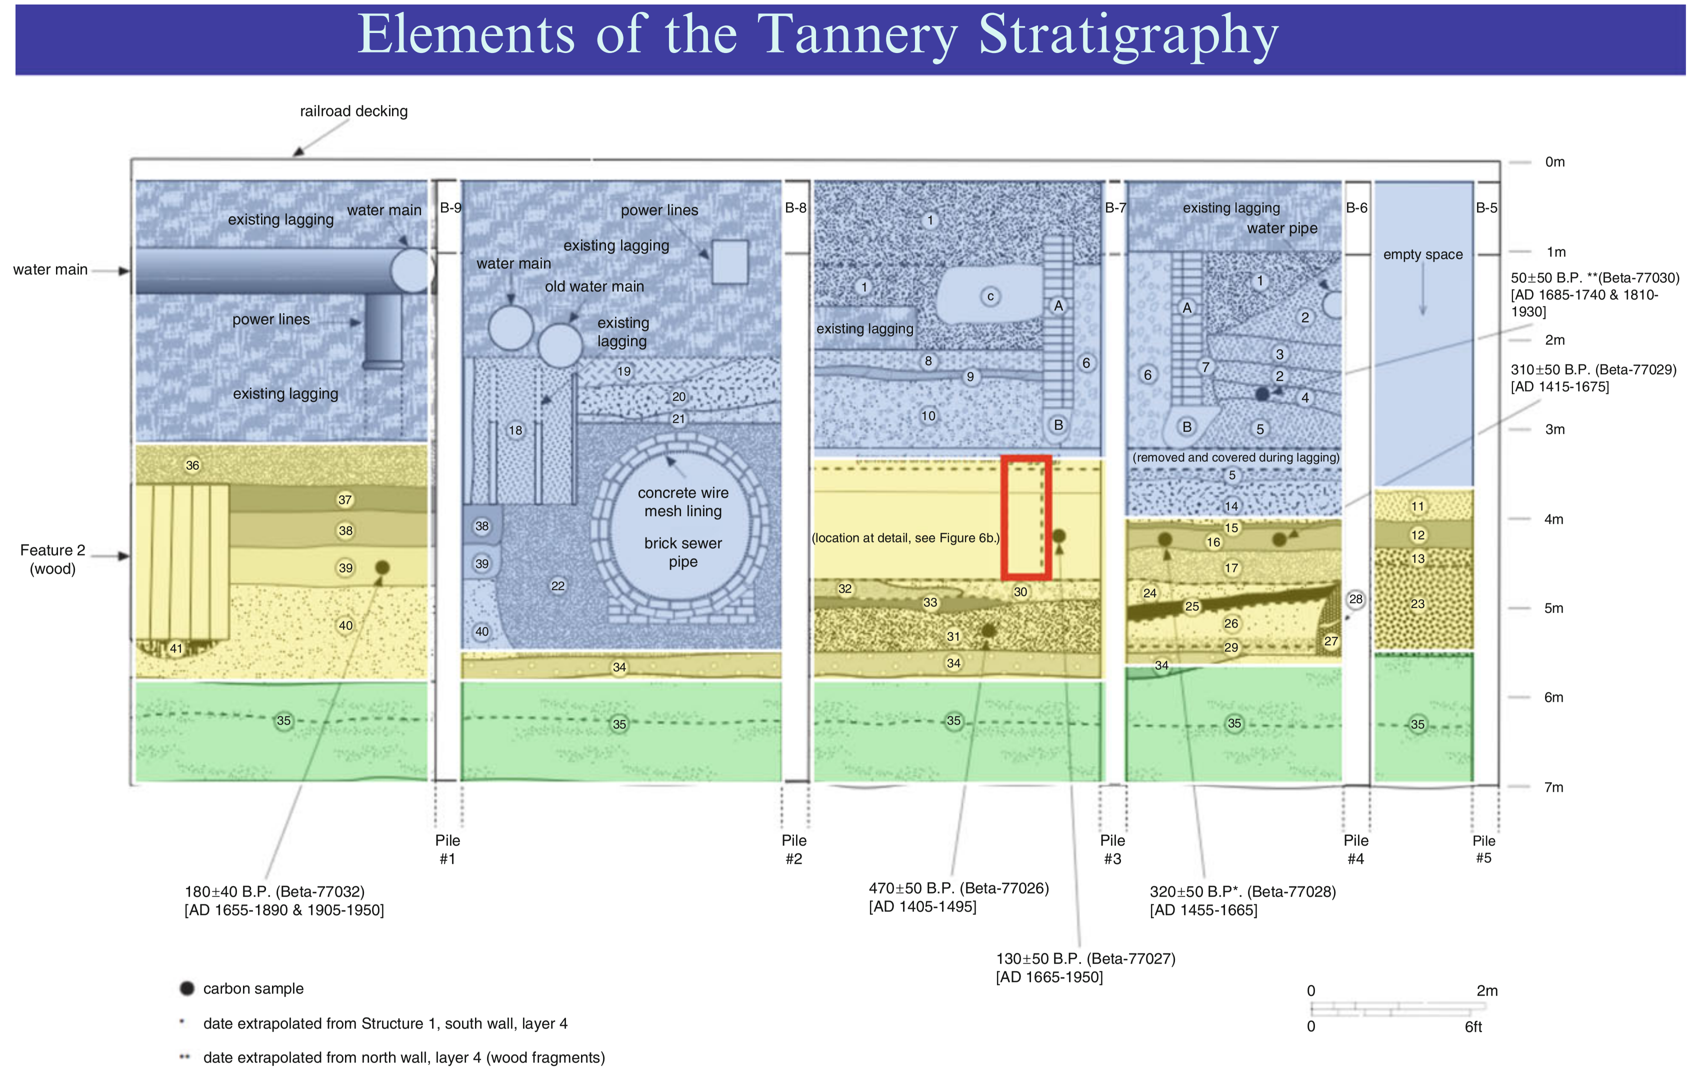
In heavily disrupted urban settings, performance of intensive background research is critical in developing research strategies for any project. The dimensions of a project's footprint become the target of any background research to be performed because the most direct disturbances will occur there and in the immediate vicinity. Since the construction or development will be made atop a previous substrate, recent maps and plans documenting previous building on the location may indicate the existence of earlier design maps and construction plans. These, in turn, could reference buried sediment types, architectural features, utility components, and fill elements that might inform about former site use and landscapes of historic and even prehistoric antiquity.

The density of cultural materials within a confined urban setting often precludes broad, bird's-eye perspectives on site stratigraphy and sedimentation patterns. In such cases, it is important that the geoarchaeologist be familiar with as much background history as possible. Excavations for a subsurface tunnel at the Metropolitan Corrections Center (MCC) in lower Manhattan, New York City, afforded stratigraphic inspections of a complex sequence during evening hours only. Further, such sections were accessible through minimal windows; here, wide exposure could not be provided because of the complex shoring structure needed to maintain on-site stability. A 7 m deep profile exposed a continuous sequence of three stratigraphic sets that facilitated a generic classification of the range of land use succession from later prehistory to the present (Yamin and Schuldenrein, 2007). Each stratigraphic set consisted of sequential depositional bodies that registered a common site formation history. The sets were unconformable (discontinuous) with respect to each other because each successive set marked a turning point in site formation history. Such a classification is useful for the built environment because it introduces a common denominator that helps to isolate patterns of site use and subsequent disturbance.

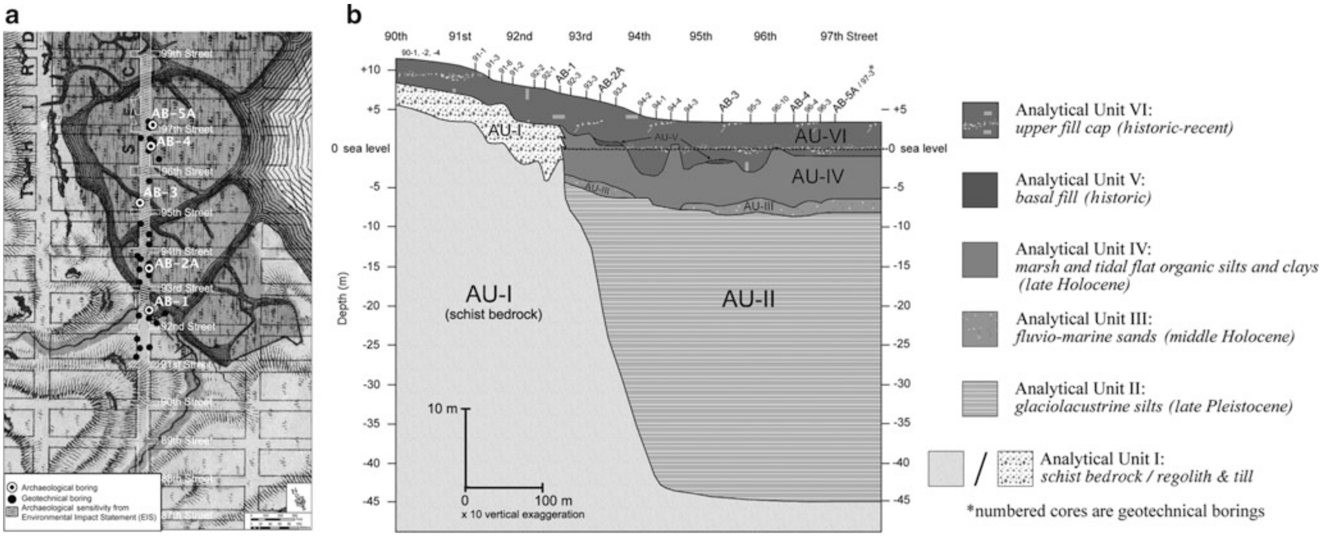
At MCC, the lowermost 1.5 m of sediments was considered a *geogenic set* (Figure 2) and comprised alluvium that was laid down before the first Euroamerican occupations on Manhattan Island. The matrix was largely a homogeneous silty sand capped by a thin, weathered soil (Bw horizon) that marked the uppermost level of the undisturbed river-laid flood material. Radiocarbon dates placed the age of the upper soil at ca. 500 BP. The set is referred to as geogenic because of its geological origins and the absence of any evidence of human impacts within the matrix. Significantly, however, the antiquity of the upper part of this basal profile was equivalent to the time of initial Euroamerican presence in the region.

The overlying 2 m contained evidence for approximately 200 years of historic activity and land use.

Built Environment, Figure 1 Distributions of late Quaternary landform-deposit complexes for geoarchaeological testing along planned sewer line route on the Raritan River, New Jersey. Ages of landforms are per Stone et al. (2002). (**a**) Numbered boxes denote Geoprobe stations selected for coring and analysis. Known archaeological sites are identified. (**b**) Composite stratigraphy of the sequence based on linked soil and sediment sequences. Radiocarbon dates of archaeological age signify tracts of prehistoric site potential. Segment R-9 to R-11 contains the most sensitive deposits.



Built Environment, Figure 2 Detailed stratigraphy of the MCC tunnel sequence, Manhattan, New York City. Three groups of strata are designated: the Built Environment (upper-set3), Historic Levels (middle-set2), and Geogenic components (lower-set1). Component microstrata for each group are based on Harris Matrix criteria. Radiocarbon determinations are presented, and key historic features are specified.



Built Environment, Figure 3 Geoarchaeological sediment stratigraphy for the Second Avenue subway project, Manhattan, New York. (**a**) Field core locations superposed on a historic landform map of the area (Viele, 1874). The tidal drainage net was reconfigured in the eighteenth and nineteenth centuries (From Schuldenrein and Aiuvalasit (2011: Fig. 3)). (**b**) Schematic stratigraphy across the seven-block-long project area. Analytical Units are identified by depositional origin and antiquity (From Schuldenrein and Aiuvalasit (2011: Fig. 9)).

Deposition was characterized by sequential accumulations of more intricate and thinner sediment bodies with primary clasts and finer-grained deposits intermixed with alluvium. The organic component of the matrix was not simply a vegetation mat but also included decayed finds from disaggregated animal parts as well as wood, organic mats, and various debris associated with hide-processing activities; by-products of the former tanneries that surrounded a water impoundment named the Collect Pond by the earliest Dutch settlers of Manhattan. Features of the tanneries were preserved intact – see the barrel identified as Feature 2 (lower left) in Figure 2. Component depositional bodies of this second set were poorly sorted and typically had no cohesive soil or sediment structures. Upon closer inspection and follow-up analyses, microstrata were separable from each other. Their common aspect was that they represented separate stages in a site formation record of eighteenth-century tanning activities, including hide preparation, processing, discard, and resultant sediment disaggregation. This second set preserved the historic levels (Figure 2) and represented the first sustained phases of Euroamerican occupation of the local landscape.

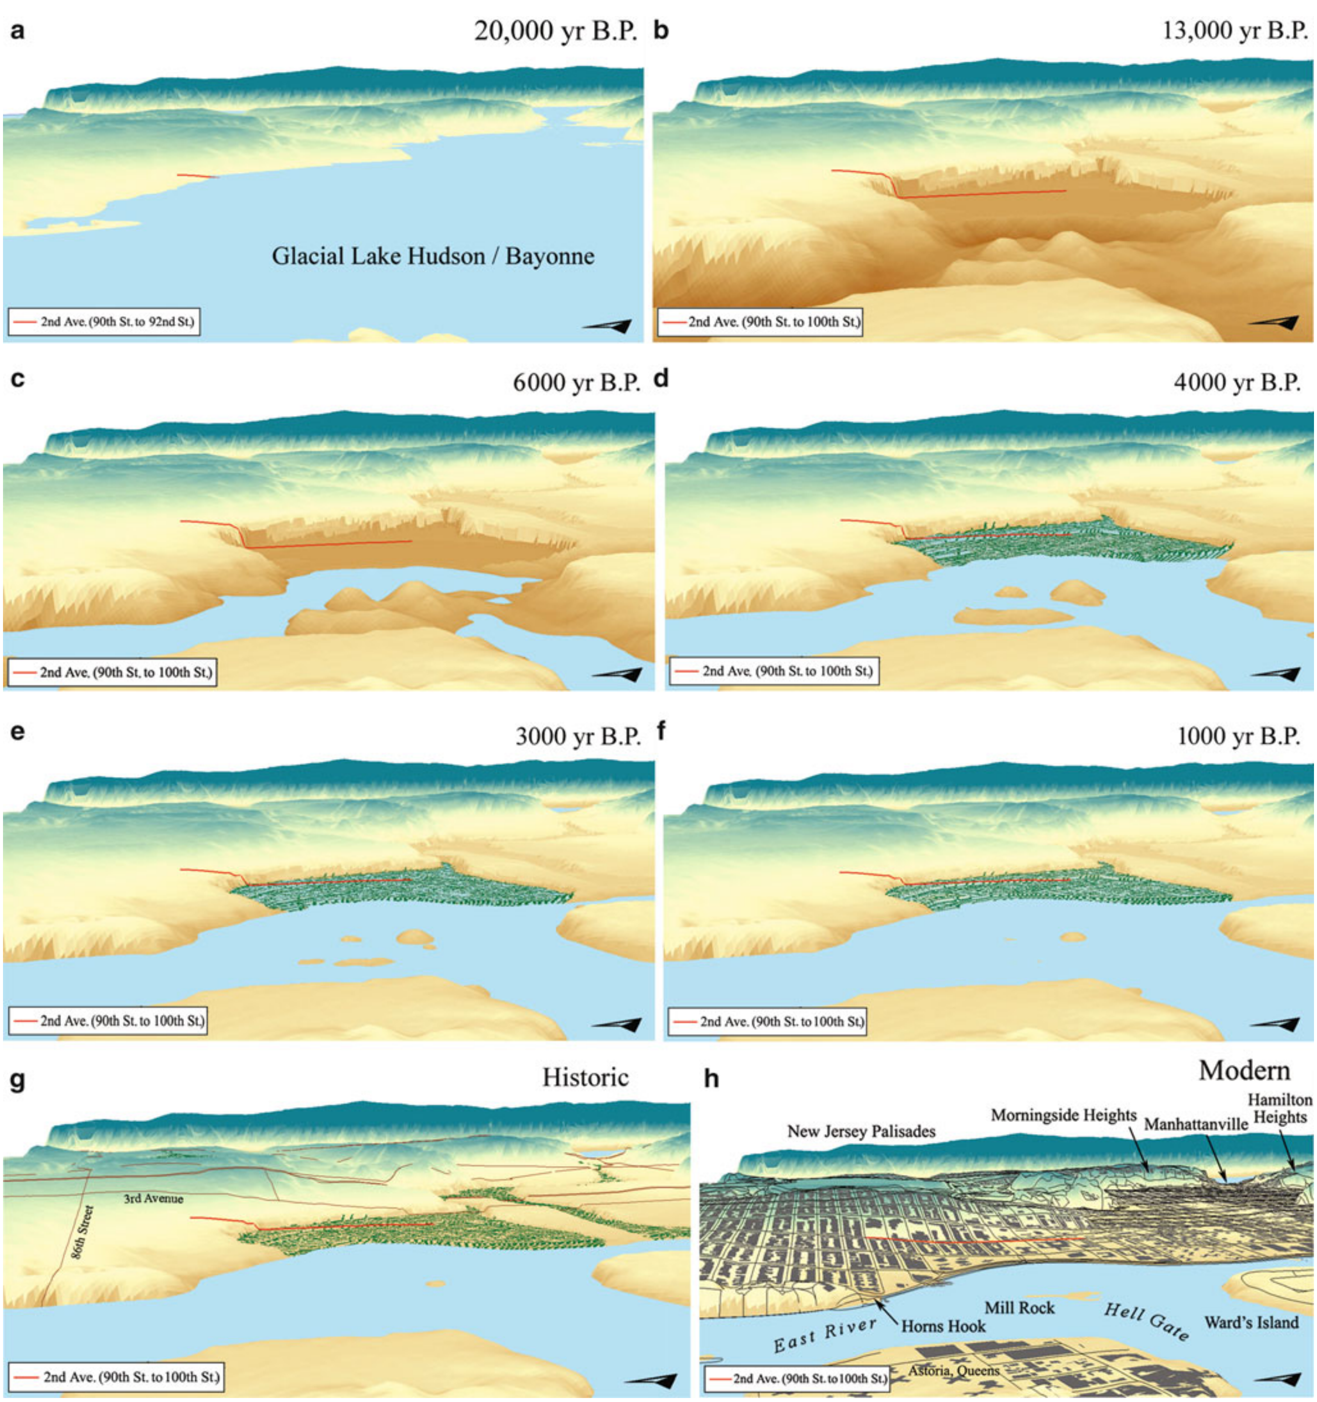
These historic levels were, in turn, overlain by 3 m or more of what would be currently recognized in any vertical exposure as the signature debris of the (late historic to contemporary periods) built environment (Figure 2). The parent matrix was a thick, poorly to nonsorted mass of "fill," very locally offset by pockets of a discrete sediment body. In general, the dominant sands of the parent matrix surround identifiable features of the present environment, specifically structural elements of the subsurface infrastructure (brick-sewer pipe was most prominent, as were water main segments). Within the generic "fill" were pockets of colluvium, debris flow, and even sections of floor that attest to the range of disturbance processes signaling the emergence of the built environment. Isolated archaeological features in this strata set were similar in type to those within the historic levels.

The three sets of strata distill a complex site stratigraphy into the primary phases of site formation history. The Late Holocene stream whose top formed the surface of a stable (probably) prehistoric landform (Set 1) was engineered and modified by the early Dutch and British colonists who utilized it to develop a tanning facility (Set 2). The latter gave way to leveling of the terrain, a sign of the emergence of New York City as a major administrative center in the New World, a position the city holds to this day.

Geoarchaeology of the urban built environment (future strategies)

As the previous example shows, there is an inverse relationship between advancing time and the availability of urban tracts for classic, large-scale, and area-wide archaeological excavations. Advances in remote sensing, GIS mapping, and the application of interdisciplinary methods in sediment analysis (e.g., pollen, microfauna, foraminifera, and malacology) allow geoarchaeologists to expand their interpretive domains as field working opportunities diminish. A major subfield that has emerged is paleoenvironmental reconstruction and, specifically, the ability to develop models of late Quaternary landscape history targeting urban areas. For New World cities, regional

Pleistocene chronologies (in glaciated and nonglaciated areas, shore, riverine, and estuarine environments) were typically unmodified anthropogenically until the Euroamerican arrivals 500 years ago. Colonial accounts coupled with detailed settlement and geological histories present excellent baseline referents for premodification terrain reconstructions. In the Old World, such chronologies are typically of late Holocene antiquity. For example, moderate to large-scale impacts can generally be dated to the Roman period in Europe, while in the Near East, they can extend back to the third millennium BCE. An idealized strategy for exploration in an urban setting is to probe to the contact of the initial natural/cultural-based interface. Very often coring can be applied within such settings, since the



Built Environment, Figure 4 (Continued) probing causes minimal disturbance, and recovery of buried sediments is often substantial enough to characterize the depositional context of the uppermost natural strata.

A major study of this type was performed in 2009 along the footprint of the proposed 2nd Avenue Subway line in New York City's Upper East Side (Schuldenrein and Aiuvalasit, 2011). Here, the density of the underlying utility network was such that a total of only five deep cores could be excavated to terminal Pleistocene levels over a distance of six city blocks (Figure 3a). Preliminary indications of the predisturbance landscape were afforded by historic maps. Moreover, nearly a century ago, an extensive series of nearly 100 borings was conducted in advance of the same subway line, and nearly complete core samples were housed in a storage facility maintained by the NYC Metropolitan Transportation Authority. Examination of these older core specimens allowed researchers to "retrofit" the stratigraphy of the older cores using the newly extracted cores as a stratigraphic baseline. Taken together, the refined 2009 descriptions coupled with the more aerially extensive subsurface mapping of the initial coring effort produced a comprehensive sediment stratigraphy, indexed by radiocarbon dates and broken down by six lithostrata that document the depositional chronology (Figure 3b).

The succession of events begins with the Late Pleistocene lake and upland tills; the subsequent disappearance of the lake and attendant erosion of the till margins; the emergence and sustained evolution of an estuary regulated by marine shoreline cycles during the Middle to Late Holocene; and finally the Euroamerican settlement and rapid modification of the natural shoreline during the industrial and commercial phases of neighborhood development. While the sequence is chronicled by unconsolidated sediments and the radiometric materials that date them, there are temporal gaps of equal or longer duration, attesting to extensive intervals of nondeposition.

Sustained erosion coupled with long-term edaphic adjustments probably account for the absence of early postglacial sediments, while the missing record of the pre-Euroamerican estuary is probably a function of intrusive and large-scale reclamation projects and relandscaping during the historic to recent periods. Additional concerns, for the estuary in particular, include changing sediment budgets (net accretion vs. loss) over the course of a particular geomorphic cycle.

The most detailed chronostratigraphies and reconstructions were developed for estuarine environments that evolved over the interval 4600–3200 BP based on earlier sea-level curves (see Schuldenrein et al., 2007). The significance of that time frame is that it is coincident with the Late Archaic to Woodland transition, which is a key adaptive phase in the regional prehistory of the northeastern coast.

The incorporation of project stratigraphies with regional landform histories permitted the generation of a diachronic model for the evolution of Hell Gate Bay. This is depicted in a time-transgressive, graphic representation of landscape form and process (Figure 4). The "time

Built Environment, Figure 4 GIS-based reconstruction of landscape history in the Second Avenue project area near Hell Gate. A thin line marks the later location of the subway jobsite under construction as of this writing (From Schuldenrein and Aiuvalasit (2011: Fig. 11)). (**a**) Pleistocene glacial Lake Hudson-Bayonne complex inundates most of the project area. Lake elevations are ~30 ft (9 m) higher than modern sea level. The terrain above 92nd street was submerged; the segment between 90th and 92nd streets was not. This is consistent with field results because lacustrine sediments were not identified between 90th and 92nd streets but were prominent in all cores to the north. (**b**) Drainage of the glacial lakes and incision of lacustrine deposits. By 13,000 year BP, the proglacial lakes had drained, and sea level was 22 m below modern levels. Exposed, steep-sided terraces flanked the ancestral trenches of the Harlem and East Rivers. The project area was perched above the floodplain. It is probable that small tributaries from Manhattan drained across the project area, although no evidence for these was observed in the cores. (**c**) Emerging nearshore environment. By 6000 year BP, sea level had risen to −11 m, and marine waters encroached onto the proximal edges of the lake terrace. During this very dynamic time, a complex of freshwater fluvial sands and transgressing marine deposits began aggrading atop the lacustrine terrace surface. (**d**) Estuarine formation. At 4000 year BP, the entire terrace surface was subject to tidal cycles, as sea level had risen to between −6 and −7 m. Organic muck and silts suggest the formation of marshes, which would have transgressed across the project area commensurate with rising sea level. The presence of freshwater pollen species indicates that, at these early stages of estuarine formation, the marsh still had a significant freshwater component. This would have been a habitat optimally suited for prehistoric (Late Archaic) activity, with convenient access to marine and terrestrial resources. (**e**) Zoned salt flats. Landward advance of mesohaline marshes (proximal) and subaqueous saline mud flats (distal). By 3000 year BP, fringing marsh biomes continued to develop, and the majority of the project terrain consisted of subaqueous mud flats. From 4000 to 3000 year BP, estuarine sedimentation is registered by mineral and organic sediment, reflecting pulses in sea-level rise. Shortly after 3000 year BP, the mud flats had stopped aggrading in response to general deceleration of sea-level rise. The environment would have remained attractive to later prehistoric groups (transitional Archaic to Woodland). (**f**) Stabilized subaqueous saline mud flat. At 1000 year BP, the landscapes reached a homeostatic state. This is signaled by the minimal accumulations of organic material on the mud flat bottoms. (**g**) Historic saline, thinly vegetated mud flat. The landform is referred to historically as a "meadowlands." During the early Euroamerican period, surfaces were level, subject only to tidal cycles. Thin and diffuse organic lenses and minor peats implicate changing (humanly influenced) edaphic conditions as subaqueous vegetation communities expanded across the landform. (**h**) Modern land surface built up by domestic debris, construction material, and fill. The infilling during the late nineteenth century reclaimed the major land segments of Hell Gate Bay. The landform was capped with ~3–6 m of fill material to raise shore elevations 4–4.5 m above sea level.

slices" were created using a combination of modern elevation data, historical bathymetry, historical landform maps, and projected sea-level information. A digital elevation model (DEM) for the Central Park Quadrangle (USGS 7.5 min series topographic maps) was used as the base, and it was modified within a Geographic Information System (GIS) to reflect the pre-landfill topography of parts of the Harlem plain. Bathymetry was digitized from a georeferenced digital image of the "Navigation Chart of Hell Gate and its approaches" (Survey of the Coast of the United States, 1851) retrieved from the image archives of the Historical Map and Chart Collection of the Office of Coast Survey, National Ocean Service, NOAA. This chart was considered more accurate than modern bathymetric data, as it predates most of the late nineteenth- and early twentieth-century dredging activities. The location and outline of the historic period's low-lying wetlands was digitized from a georeferenced image of the map "Sanitary & Topographical Map of the City and Island of New York" (Viele, 1874). The elevation of this wetland was lowered for older time periods in accordance with information generated in the course of this study's subsurface investigations.

This model generated eight temporal projections for landform evolution (Figure 4a–h). The temporal projections correspond to key occupation periods in the northeastern prehistoric chronology and afford a glimpse at the subsistence environments utilized during these time frames.

More challenging geoarchaeological issues await as the reach of historic site formation studies extends into the analyses of anthropogenic sediments. Accordingly, the multiple transformations of sediments and soils are just now being explored by specialists utilizing x-ray diffraction and florescence methods as well as elemental chemical assays using inductively coupled plasma-mass spectrometry (ICP-MS). While these approaches have been successfully applied to reconstructing land use practices in early complex settlements (i.e., Near Eastern tells, late prehistoric North American villages), the multiplicity of post-abandonment factors modifying historic sediments and artifact clusters are only now being explored – see Holliday (2004) and Howard et al. (2015).

Summary

The geoarchaeology of the built environment represents a new platform for research. Its development is intimately connected with the emerging template of a new geological epoch, the Anthropocene. Geoarchaeological work can and must be coupled with a changing archaeological practice, one that views opportunity through the prism of sustainability and research designs that are fashioned by the new imposed research universe. The archaeology of the built environment is guided by an almost "minimalist" approach wherein high data yield through science and technology is rapidly replacing labor-intensive strategies in large and expansive dig sites. Geoarchaeology will be undertaken across landscapes that are increasingly affected by human impacts. Since funding and opportunity will be generated by development interests, the methods and strategies applied by geoarchaeologists will be increasingly oriented toward urban environments where stratigraphies are complex and predominantly cultural. Within the built environment, natural processes of sedimentation will likely become less significant. These changing archaeological landscapes provide new and uncharted opportunities for geoarchaeologists to practice their craft.

BURNED-ROCK FEATURES

Alston V. Thoms
Department of Anthropology, Texas A&M University, College Station, TX, USA

Synonyms

Burnt-rock features; Fire-altered rock features; Fire-cracked rock features; Fire-modified rock features; Heat-retainer features; Thermally altered rock features

Definitions

Burned rock. Rock, commonly limestone, sandstone, quartzite, basalt, granodiorite, and metamorphic mudstone, that was purposefully heated to 500 °C or higher, resulting in discoloration, cracking, and fragmentation.

Burned-rock features. In situ concentrations of burned rocks representing the heating elements of thermal facilities as well as exhausted/discarded parts thereof. These features were most commonly used for baking, steaming, stone-boiling, and grilling food; also for hot-water and steam bathing; as flooring in metal-making furnaces, ceramic and charcoal kilns; and for other manufacturing purposes.

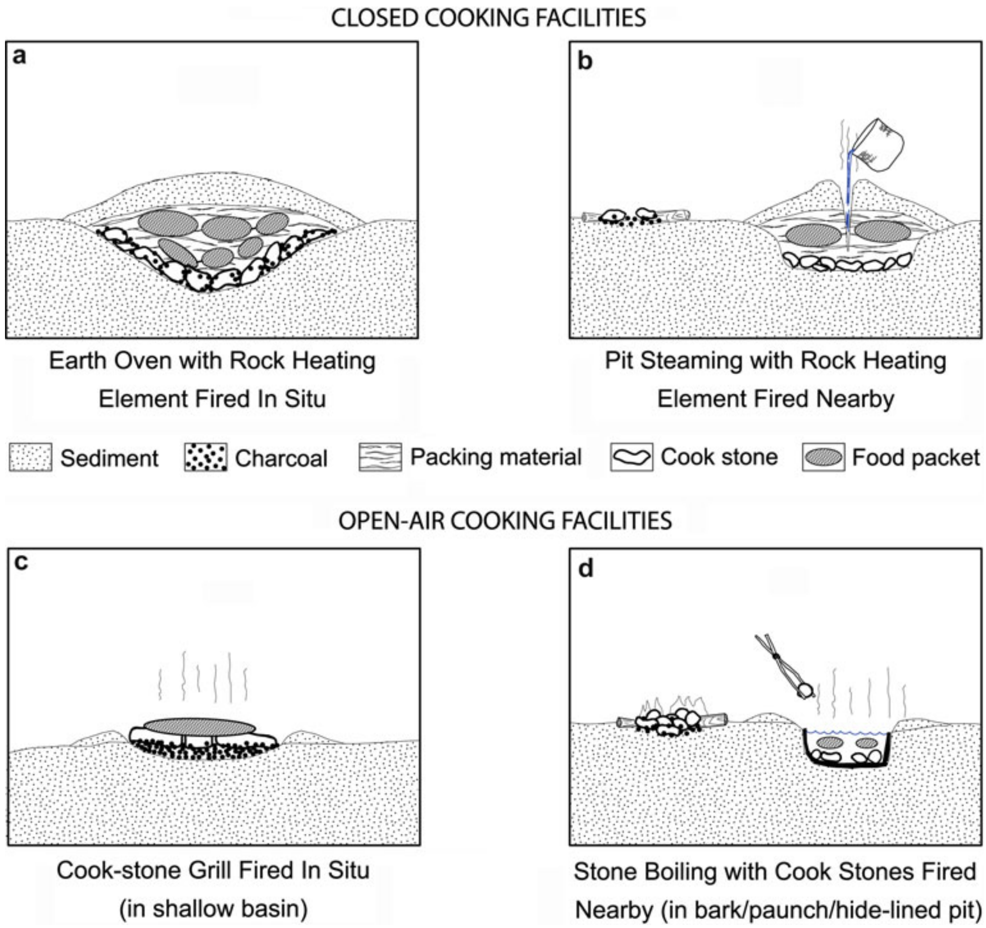
Cook-stone technology. Processes employed in the procurement, utilization, and discard of rocks that served as heating elements for cooking food; in regions where suitable rocks did not occur naturally, people often manufactured cooking stones by shaping and firing clay nodules.

Introduction

Burned-rock features are known worldwide from historical, ethnographic, and archaeological records. This entry focuses on cooking-related, burned-rock features, which account for the most common and ancient usage of heated stones from as early as ca. 32,000 years BP. Such stones are widely known archaeologically as fire-cracked rock (FCR). As products and byproducts of human activity, FCR from cooking features is among the most ubiquitous of artifacts. In behavioral realms, FCR served primarily as heating elements – cook-stones – in surface hearths, earth ovens, steaming pits, and for boiling. Composed mainly of cobble-size rocks (6.4–25.6 cm in maximum dimension), cook-stone features are structurally resistant to natural, soil/sediment-disturbance processes, and hence, they have considerable research value.

Research contexts and status

The human digestive tract requires consistent intake of cooked foods (Wrangham, 2009). Compared to short-term cooking over direct flames and on/in hot coals, prolonged baking and stone boiling render many foods more calorie-rich. Worldwide similarities in hot-rock cooking techniques and features result from the fact that plant and animal tissues with comparable biochemical properties



Burned-Rock Features, Figure 1 Four generic cook-stone feature types found in western North America: (**a**) earth oven; (**b**) steaming pit; (**c**) surface griddle; (**d**) stone boiling.

respond similarly to the application of heat and moisture (Wandsnider, 1997). The advent and proliferation of earth-oven and stone-boiling techniques have been identified as indicators of dietary changes and human evolution, notably smaller teeth, via increased consumption of fat, well-cooked meat, and complex carbohydrates (e.g., Brace, 2005; Thoms, 2008a). Integration of hot-rock cooking into subsistence strategies affords fuel-sparing and heat-conserving benefits that facilitate utilizing a greater proportion of a given region's food-resource potential (Thoms, 2009).

In North America (especially the south-central region), Europe, and Australia, cook-stone technology research is well developed, and it is increasingly underway elsewhere around the world (Driver and Massey, 1957; Doleman, 1996; Petraglia, 2002). Burned-rock features, nonetheless, remain under-studied. They lack a unifying nomenclature equivalent to lithic and ceramic technologies or soil-formation processes. Widely available syntheses tend be geographically limited, temporally restricted, or focused on specific hot-rock cooking techniques (e.g., Wandsnider, 1997; Odgaard, 2003; Straus, 2006; Thoms, 2008b; Nelson, 2010). Much of the relevant research remains obscure, presented in proceedings volumes (e.g., Buckley, 1990; Hodder and Barfield, 1991; Frère-Sautot, 2003), cultural resource management monographs (e.g., Schalk and Meatte, 1993; Black et al., 1997; Mehalchick et al., 2004), dissertations (e.g., Wolynec, 1977; Thoms, 1989; Soler Mayor 1996; Peacock, 1998; Stark, 2002; Yu, 2006; Lucquin, 2007; Graf, 2008), and theses (e.g., Jackson 1998; Clabaugh, 2002; Acuña, 2006).

Functional and morphological variation

Figure 1 illustrates four generic types of hot-rock cookery from western North America that are also common around the world. Each exhibits considerable variation in construction, size, morphology, and rock type(s), as demonstrated by varied descriptions of earth ovens and stone-boiling features (e.g., Thoms, 1989; Black et al., 1997; Wandsnider, 1997; Stark, 2002; Nelson, 2010). Figure 2 illustrates examples of cook-stone features from sites in western North America that are also exemplary of those

Burned-Rock Features, Figure 2 Examples of cook-stone features at archaeological sites in western North America: (**a**) small surface griddle in south-central Texas; (**b**) small earth oven exposed along a reservoir shoreline in east-central Texas; (**c**) plan view of a large earth oven in northeastern Washington; (**d**) cross section of another large earth oven at the same site in northeastern Washington; (**e**) cross section of burned-rock mound with embedded large earth ovens in central Texas; and (**f**) base of a large, slab-lined earth oven in the same mound at the same site in central Texas (various scales; author's photographs).

found in many other regions. Open-air/griddle hearths, earth ovens, steaming pits, and stone-boiling features 40–100 cm in diameter are suitable for family-size groups within or outside residential structures. Larger features, for example, earth ovens with heating elements 2–3 m in horizontal extent, are indicative of outdoor cooking exclusively. Most FCR mounds (ca. 6–15 m × 0.75–1.5 m) are accumulations – spanning decades, centuries, and, occasionally several millennia – of spent rocks from large ovens or from small cooking facilities at a nearby residential site.

Non-cooking activities also yield FCR. Ethnographic accounts of steam bathing in hot-rock saunas are common, but resulting features are underrepresented archaeologically (Barfield and Hodder, 1987). A few burned-rock mounds in Ireland and the United Kingdom are interpreted as the remains of hot-water or steam-bathing facilities. Other burned-rock features in Europe, and likely elsewhere, served as flooring in ceramic and charcoal kilns, metal-making furnaces, and for other manufacturing purposes (Buckley, 1990; Hodder and Barfield, 1991; Frère-Sautot, 2003).

Analytical methods

Ground-penetrating radar, magnetometry, and other remote sensing techniques are used to locate buried burned-rock features (e.g., Mehalchick et al., 2004). Geoarchaeological studies afford reliable measures of their structural integrity (e.g., Leigh 2001; Thoms, 2007). Paleomagnetic analysis can distinguish between rocks heated and cooled in place, as would be expected of earth ovens and griddles, and those heated in one place and cooled in another, as in stone boiling (Gose, 2000). Actualistic and laboratory cooking experiments suggest that rocks exhibit distinctive fracture patterns and other thermal weathering characteristics depending on whether they cooled slowly, as in earth ovens, or rapidly, as in stone boiling (e. g., House and Smith, 1975; McParland, 1977; Schalk and Meatte, 1993; Jackson, 1998). With varying degrees of success, gas chromatography, fatty acid, Fourier transform infrared spectroscopy (FTIR), and plant-microfossil analyses have been applied to FCR to determine what foods they cooked (e.g., Quigg et al., 2001; Buonasera, 2005; Lucquin, 2007; Cummings et al., 2011; Laurence et al., 2011; Malainey, 2011; Perry and Quigg, 2011). Luminescence dating has been done on FCR and fired clay nodules from earth ovens (Roberts, 1997). Distributions and ages of burned-rock features figure prominently in establishing geomorphic histories of landscapes (e.g., Mandel, 2000; Fanning et al., 2008).

Age and global distribution

Hot-rock cookery and, hence, formation of burned-rock features was underway 35,000–31,000 years ago in Europe (Movius, 1966; Straus, 2006), Japan (Dogome, 2000), Australia (Gillespie, 1997), and the Bismarck Archipelago (Torrence et al., 2004). It was evident by the terminal Pleistocene or early Holocene in Africa (e.g., Zerboni, 2011), the Middle East (McCorriston et al., 2002), India (e.g., Nambi and Murty, 1983), China (e.g., Madsen et al., 2006), Siberia (e.g., Graf, 2008), and North America (Homsey, 2009; Thoms, 2009). In Greenland, slab-lined, rock-filled heaths (i.e., box-hearths) were common in paleo-Eskimo houses by 4500–3900 BP (Odgaard, 2003). Earth ovens were in use by 6000 BP in South America (Stahl and Oyuela-Caycedo, 2007; Iriarte et al., 2008; van den Bel, 2010) and in Polynesian by 1000 BP (e.g., Carson, 2002). Most of the world's regions witnessed increases in diversity, density, and size of burned-rock features during the Holocene (e.g., Stark, 2002; Thoms, 2009).

Summary

Burned-rock features are known worldwide; most commonly they represent the remains of thermal facilities and exhausted/discarded parts of such installations that were used in baking, steaming, stone-boiling, and grilling food. Integration of cook-stone technology into land-use strategies, beginning ca. 32,000 BP, afforded an important means of utilizing a greater proportion of a given region's food resource potential and thereby contributed significantly to the long-term maintenance of our species. The information potential of cook-stone features, however, remains surprisingly under-studied, given that they are ubiquitous, often well preserved, and span tens of millennia of the human experience.

C

CACTUS HILL, VIRGINIA

Daniel P. Wagner
Geo-Sci Consultants LLC, University Park, MD, USA

Cactus Hill is an archaeologically stratified, multicomponent site discovered in 1993 on an interior coastal plain terrace adjacent to the Nottoway River in southeastern Virginia, USA. Utilized by humans over a period of many thousands of years, the site is most known for its buried Paleo-Indian occupations, one of which is indisputably of the Clovis culture and another, lying below the Clovis, interpreted to be of an origin predating Clovis. Several lines of evidence support a pre-Clovis component: (1) A sterile 7–20 cm zone of vertical separation lies between Clovis and underlying pre-Clovis materials; (2) different lithic assemblages are distinguished – imported cryptocrystalline rock types (such as chert and chalcedony) are exclusive to the Clovis level, while locally obtained quartzite was used by the pre-Clovis; (3) a distinctive core blade artifact technology for the pre-Clovis occupation; and (4) ^{14}C charcoal ages of 10,920 BP for the Clovis but as early as 16,670 BP for the pre-Clovis. The pre-Clovis component was subsequently referred to as Blade (McAvoy and McAvoy, 1997).

Because the above evidence argues against a long-held theory that Clovis people were the first inhabitants of the Americas, the Blade component became the focus of critical attention. Beyond the theoretical conception was a speculation that the sandy composition of Cactus Hill's dunal soil may have been too unstable to preserve very old cultural materials in an ordered stratified sequence. Multidisciplinary geoarchaeological investigations were employed to address this concern. Pedological investigations (Wagner and McAvoy, 2004) recognized episodic sand deposition but also identified preserved buried surface horizons both at the Clovis level and a deeper, much earlier one (19,540 ^{14}C BP) predating all site occupations. These surfaces and strongly developed, very old subsoil lamellae demonstrated intervals of prolonged stasis and soil formation as well as mostly protective burial during deposition events. Similarly, micromorphological examinations of soil matrices (Macphail and McAvoy, 2008) convincingly showed that Blade artifacts were unlikely to have been emplaced by a process of downdrift from the Clovis level. While relic surface horizon microaggregates were identified at both the Clovis and Blade levels, comparable surface indicators were not present within the intervening culturally sterile zone. In further support, luminescence dating (Feathers et al., 2006) of principal strata was in close agreement with radiocarbon ages and also verified an ordered vertical progression of increasing age with depth. Taken together, the above data indicate that natural soil disturbances such as deflation or mixing appear to have been relatively limited and not likely to have appreciably affected the long-term integrity of site stratigraphy.

CANALS AND AQUEDUCTS IN THE ANCIENT WORLD

Charles R. Ortloff
CFD Consultants International, Ltd., University of Chicago, Los Gatos, CA, USA

Introduction

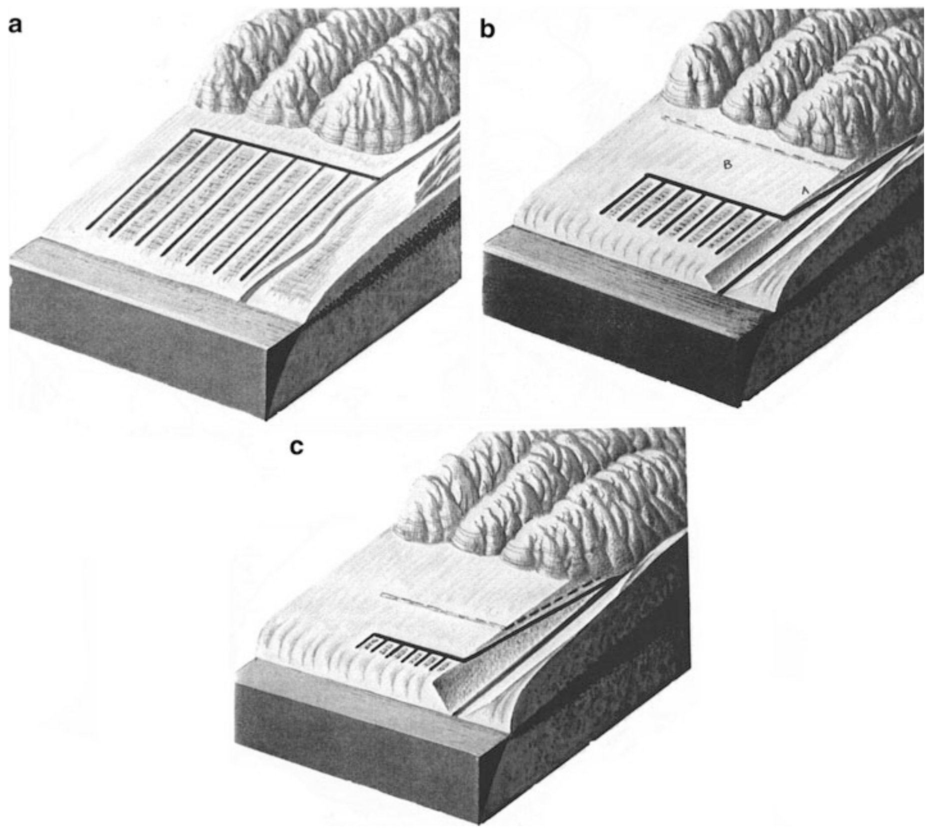
People of the ancient world understood that geophysical and climatic anomalies could alter the environments that permitted the growth of comestible agricultural resources for urban and rural populations. When their technical capability proved adequate, they were able to modify water supply systems to sustain agricultural productivity through times of environmental change. When technological solutions or adaptations to other resources were not possible, societal transformation and/or collapse followed, leaving archaeological remains that now testify to the lack of appropriate technology, management, or manpower to overcome the deteriorating resource base. Water for urban and agricultural use is vital to sustainability. When the collapse of agricultural systems is manifest in the archaeological record, remains of canals, aqueducts, water storage, and transport systems provide vital geoarchaeological clues detailing how and why failure occurred. These clues often point to long-term drought that limited water availability for farming, floods that incurred changes in agricultural landscapes through soil erosion or aggradation, seismic/tectonic effects that disrupted canal and aqueduct systems, river downcutting (rejuvenation) that stranded canal inlets, and aeolian soil transport that led to landscape inflation or deflation processes. The influence of these geoarchaeological processes on water supply and distribution systems is basic to (1) understanding the fate of ancient sites and cultures and (2) interpreting the processes of societal collapse and transformation.

Geoarchaeological effects on canals in ancient South America

Research on ancient canals of pre-Columbian Peru has shown the influence of seismic distortion and tectonic uplift on once-functional canals. Many ancient canals built during the Late Intermediate Period (LIP 800–1480 CE) Chimu occupation of North Coast Peru (Moseley, 2001) show layered silt deposits indicative of the functional, negative-declination slopes necessary to conduct water from rivers through irrigation canals onto field systems. Several major irrigation and water transport canals were subsequently rendered nonoperational by tectonic/seismic effects during the Chimu occupation within the Moche Valley heartland (Ortloff et al., 1985; Ortloff, 2009), thereby severely compromising the intravalley canal network supporting the agricultural field systems vital to maintaining large population centers. A further effect from tectonic uplift was incisive downcutting (rejuvenation) of the Moche River, the main water source for the Moche Valley irrigation network. In addition to uplift, erosion

Canals and Aqueducts in the Ancient World, Figure 1 Downcut riverbank sidewall from the effects of Moche River rejuvenation; the riverbank profile contains artifacts from the Early through Late Intermediate Period (300 BCE–1400 CE) (From Ortloff, 2009: Figure 1.1.12, p. 30).

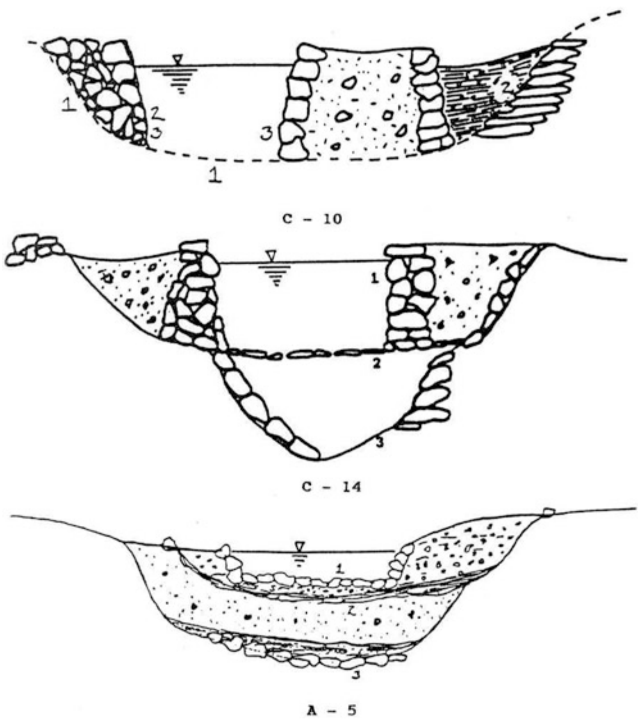
from torrential rains deriving from episodic El Niño events also accelerated the downcutting processes. The river gradually deepened its bed relative to the adjacent land surface that contained the agricultural field systems (Whitten and Brooks, 1982). Figure 1 shows the south-side riverbank of the steeply downcut Moche River layered with Early Intermediate Period (EIP 300 BCE–600 CE) cultural remains indicating the effects of river downcutting episodes that began in earlier EIP and continued through the later LIP Chimu occupation. Fed by flow from seasonal Andean mountain rainfall runoff, the Moche River deepened its bed in step with tectonic uplift, leading over time to lowered water levels and the stranding of inlets to irrigation canals originating in valley neck areas far from the coastline. These inlets served field systems on the coastal plains and were eventually abandoned when they became nonfunctional. As canals with valley neck inlets were abandoned, new canals were constructed further downriver toward the coast in places where downcutting was as yet minimal. These new constructions required short canals with shallow slopes that



Canals and Aqueducts in the Ancient World, Figure 2 Graphic representation of downcutting evolution in the Moche River: *frames A, B*, and *C* represent sequential riverbed lowering producing loss of agricultural land as canal inlets are stranded and tapping of river water progressively upriver limits the acreage that can be brought under cultivation (From Ortloff, 2009: Figure 1.1.13, p. 32).

were built into riverbank sidewalls to conduct water from the level of the river to slightly lower canal inlets serving lower elevation field systems. With ongoing tectonic uplift and river downcutting over many centuries, and with new canal inlets being constructed as higher elevation inlets were abandoned, agricultural field area was compressed into ever-decreasing areas downriver from the older abandoned inlets. This process is illustrated by the inlet/canal sequencing shown in Figure 2. Thus, geophysical processes acting on canal-based irrigation agriculture were a factor contributing to the ultimate collapse of the Chimu Moche Valley irrigation system in the tenth to eleventh centuries CE.

Coincident with these ongoing geophysical effects, long-term drought (Thompson et al., 1985, 1995) in Peru from ~1000 to 1300 CE lowered river flow rates and thereby compromised the water supply available for agriculture. A typical Chimu Moche Valley canal serving the Pampa Huanchaco field system (Ortloff, 2009) exhibited cross-section profiles that showed continual modification to accommodate decreasing water flow rates (Figure 3). Low Moche River water supplies impacted agricultural production severely, which then failed to support the large Chimu population at the Moche Valley Chimu capital city of Chan Chan. A remedial measure was attempted in order to overcome the decline in agricultural production: the 75 km Intervalley Canal was constructed prior to ~1000 CE to bring water from the higher flow rate river in the adjacent Chicama Valley to resuscitate failing Moche Valley field systems (Ortloff et al., 1982). Another remedial measure was the extensive excavation of deep pits dug to the phreatic zone of the water table near the Pacific coast margin of Chan Chan, also to maintain limited agricultural production. The Intervalley Canal's hydraulic design was ingeniously crafted to produce a maximum flow rate to match and reactivate the Moche Valley's main intravalley Vichansao distribution canal and provide water to field systems along its route to the Moche Valley (Ortloff et al., 1982; Ortloff, 2009); however, it stretched the drought-limited water supply of the Chicama River and ultimately provided only a short-lived solution to reactivate desiccated branch canals and maintain Moche Valley agriculture. Evidence of path modifications to restore functionality to the Intervalley Canal attest to seismically induced landscape distortions affecting canal slopes during its period of use; ultimately the combination of long-term drought and seismic distortions rendered the canal unusable. While the cumulative effects from



Canals and Aqueducts in the Ancient World, Figure 3 Cross-section profiles of a canal from the Pampa Huanchaco area of the Moche Valley; profiles indicate continuous infilling and contraction of cross sections as tenth- to eleventh-century drought reduced water supply to canals (From Ortloff, 2009: Figure 1.1.8, p. 25).

centuries of climatic and geomorphic change steadily contracted the heartland of Moche Valley agriculture, the Chimu expanded into north coast valleys with richer water and land resources in later times.

The Late Preceramic (2600–1800 BCE) society at Caral, located in the Supe Valley of coastal Peru, is a further example of geophysical landscape changes influencing both agricultural productivity and the marine resource base underwriting their economies. With intensifying ENSO (El Niño-Southern Oscillation) floods occurring at this time (Sandweiss et al., 2009), flood sediment transport produced large offshore beach ridges that trapped flood sediments, infilled bays with marshes, and prograded earlier shoreline locations by flood sediment deposition and aeolian sand transport (Ortloff, 2009; Sandweiss et al., 2009; Ortloff, 2012). These geophysical processes gradually buried extensive coastal agricultural field systems in the valley delta area and caused agriculture to be transferred to narrow and distant up-valley farming areas that were insufficient to support the large valley population. ^{14}C dating of near-shoreline-habitat mollusk deposits, now far inland from the present-day shoreline (Figure 4), indicates that large-scale sediment transport and littoral infilling had occurred over centuries (Ortloff, 2012). These episodes buried coastal agricultural fields beneath non-fertile sands and gravels that derived from concentrated ENSO flood events, preventing agriculture from being reestablished. Supe Valley excavation pits ~3 km inland reveal 4–5 m of sediment deposits covering what was previously Holocene beach sands. As sediment deposits and clay banks accumulated behind the beach ridges, decreased coastal zone hydraulic conductivity resulted, creating limited groundwater drainage. This caused the water table to back up and rise, producing up-valley bottomland springs in narrow valleys. These springs were canalized to support limited, narrow-valley bottomland field systems and ramped aqueduct canals built along the south-side Supe Valley canyon walls supplied by bottomland springs from far up-valley sources. The ramped canals led water to plateau field areas that added limited agricultural field acreage. Up-valley agricultural bottomlands were subject to episodic El Niño erosive flood events that reduced land areas suitable for agriculture and further destabilized the economic base of valley population centers. The major loss of large coastal fields buried by flood sediments, however, made it difficult to sustain all 19 Supe Valley sites, and their populations as geophysical landscape change progressed. Again, geophysical processes played a prominent role in influencing site abandonment of Preceramic societies in the Supe and adjacent coastal valleys. All sites were eventually abandoned by 1800 BCE, presumably due to the large-scale geophysical effects that compromised their economic base founded upon trade of marine resources from coastal sites for agricultural resources from inland sites (Shady Solís, 2000, 2007). As the marine resource base (primarily shellfish gathering) was compromised by bay infilling and the agricultural area underwent progressive contraction, the sustainability of coastal Late Preceramic society's economic base decreased.

The Middle Horizon (300 BCE–1100 CE) site of Tiwanaku (Bolivia) also underwent a collapse due to long-term drought in the tenth to eleventh centuries. A dropping water table and declining spring flow ultimately stranded 100,000 km^2 of raised field systems adjacent to Lake Titicaca that supported agriculture for the Tiwanaku capital city (Ortloff and Kolata, 1993); no ^{14}C dates indicating occupation after 1100 CE are recorded for the capital city or satellite centers.

Ancient South American societies experienced a variety of climatic effects that induced geophysical landscape changes affecting their agricultural and marine resource base. The disappearance and/or transformation of major societies, and their resurrection under different social structures in different areas when drought conditions relaxed in the twelfth to thirteenth centuries CE, depended largely upon exploitation of more sustainable agro-systems that benefitted from increasing water resources. Colonies and satellite settlements characterized many major Andean societies (Murra, 1962). This strategy expanded agriculture into different ecological zones and applied different farming techniques, employing local

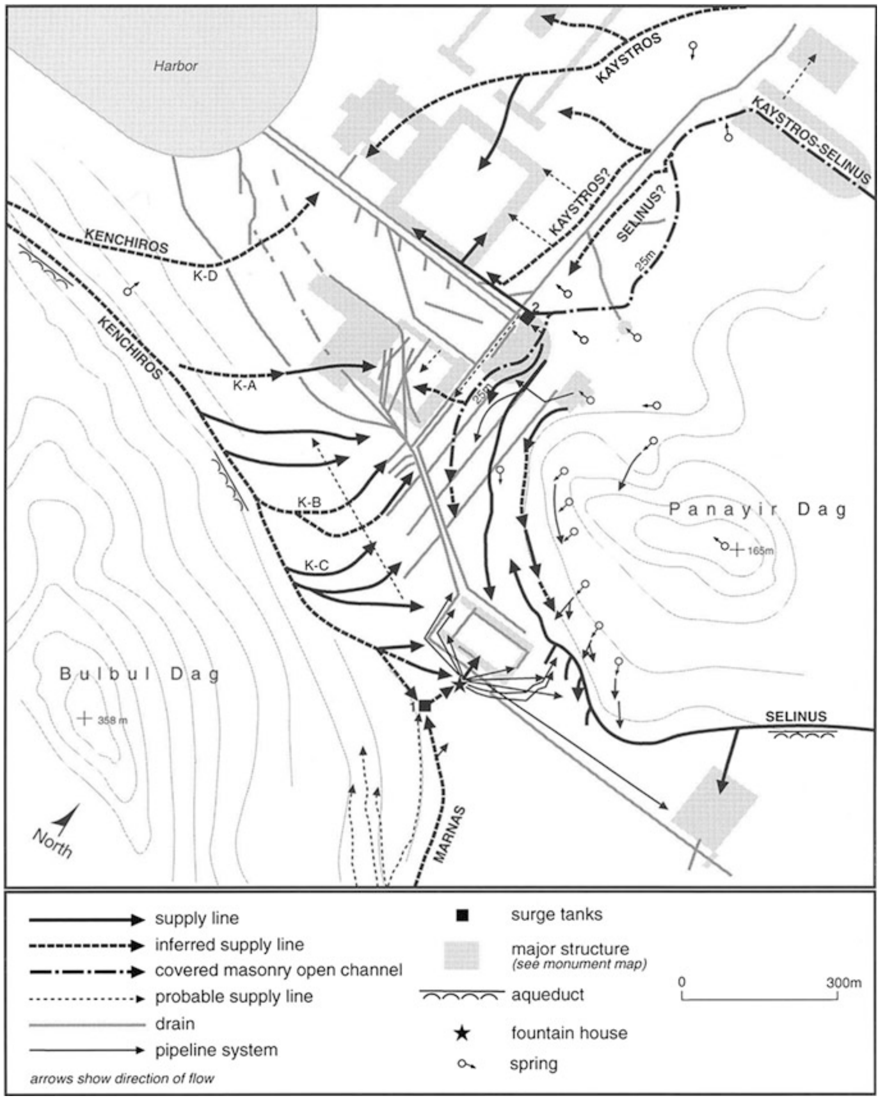
Canals and Aqueducts in the Ancient World, Figure 4 ^{14}C dates from mollusk layer concentrations far inland from the present-day Pacific Coast shoreline indicating aeolian/flood sediment transport producing coastal infilling over millennia; mollusk species sampled are known to thrive in ~1 m seawater. Samples obtained surrounding the salt pans of Salinas de Huacho, north of Lima, Peru.

water resources to lessen the dependence upon a single agro-system type. This approach proved valuable in diversifying the agricultural resource base of Andean societies.

Geoarchaeological effects on societies of the ancient Middle East

While climate change and severe weather events characterize coastal and highland societies of ancient (and modern) South America due to ENSO El Niño and La Niña drought and flood effects, ancient (and modern) Mediterranean societies had the advantage of milder climate and fewer significant weather fluctuations. For the most part, Roman, Greek, and Levantine civilizations experienced fewer climate-related environmental challenges than their South American counterparts. While drought and flood events certainly occurred, colonies and captive areas under central state authority that encompassed vastly different ecological zones guaranteed a resource base available through trade and tribute to sustain the large populations of capital cities. Under stable climate/weather conditions, canal and aqueduct construction exhibited a degree of permanence that reflected the monumental labor input dedicated to their construction. This is in contrast to ancient South American societies whose survival and continuity depended upon water transport and agricultural systems that had to be modified to accommodate changing ecological conditions.

As an example, consider the case of Roman Ephesus (Turkey) and the engineering that characterized the permanent water distribution structures constructed without major interferences from the effects of climate or other geophysical change (Bammer, 1988; Scherrer, 1995; Ortloff and Crouch, 2001; Crouch, 2004; Ortloff, 2009). Water supply to the city was by means of canals and aqueducts from distant spring systems (Figure 5); the terminal point for aqueduct flows was a multi-chambered holding tank structure (castellum), each of whose chambers held water at different depths, a condition that determined the hydraulic pressure and flow rate from each chamber into pipes that emerged from the base of individual chambers.



Canals and Aqueducts in the Ancient World, Figure 5 Water supply and drainage lines for Ephesus in the Roman occupation period (From Ortloff, 2009: Figure 2.3.8, p. 313).

The water distribution system consisted of joined segments of terracotta piping running from individual castellum chambers to city destination points, each with given water requirements. Other water distribution components consisted of open channels that led directly from a castellum to reservoirs and then to pipe systems that supplied baths, elite housing compounds, administrative structures, marketplace areas, fountains, and latrines within the city. When open channels were impractical due to access or unstable landscape paths, buried multiple pipeline bundles were used. Pipeline systems buried at shallow depths had the advantage of being conveniently reparable, as broken segments could easily be replaced. Open channels likewise had easy repair access. When earthquake damage occurred, repairs could be readily conducted. Thus, few elaborate renovation mechanisms were needed as repairs were made by virtue of the simplicity and accessibility of near-surface water piping networks. Drainage from built structures and baths was through subterranean channels that drained into the nearby bay. Rainfall runoff was collected through gaps in street paving slabs and conducted directly to the bay. Thus, both water supply and drainage facilities could be readily repaired due to the nature of the design. Large aqueduct structures were able to resist seismic loading pulses due to the flexibility provided by non-mortared, stone block construction that distributed and dissipated energy through sliding friction between the many individual blocks forming the aqueduct. While this type of construction limited earthquake damage, it is questionable whether this was a thoughtful consideration in Roman construction methodology. It produced a fortuitous outcome nonetheless. Redundancy was built into the water supply to the city by five different aqueducts from different springs (Figure 5). Although most components of the Ephesian water system were resistant to moderate seismic loading due to their flexibility and ease of repair, Ephesus nevertheless was vulnerable to some geophysical risk brought about by its location adjacent to major rivers that carried the large volumes of rainfall runoff (silt and sand) that are characteristic of the mountainous coastal zone of western Turkey. Silt from runoff erosion of mountain soils carried by the Meander (Büyük Menderes) River over many centuries gradually infilled the bay adjacent to the city (Kraft et al., 1999) and reduced the maritime trade and commercial importance of Ephesos. These river silts deposited ~10 m of sediments and engulfed an earlier Greek settlement below Roman Ephesus, thereby covering sacred processional paths associated with the earlier Greek settlement and burying springs at the base of the largely karst composition mountain (Crouch, 2004) adjacent to the Roman city precincts.

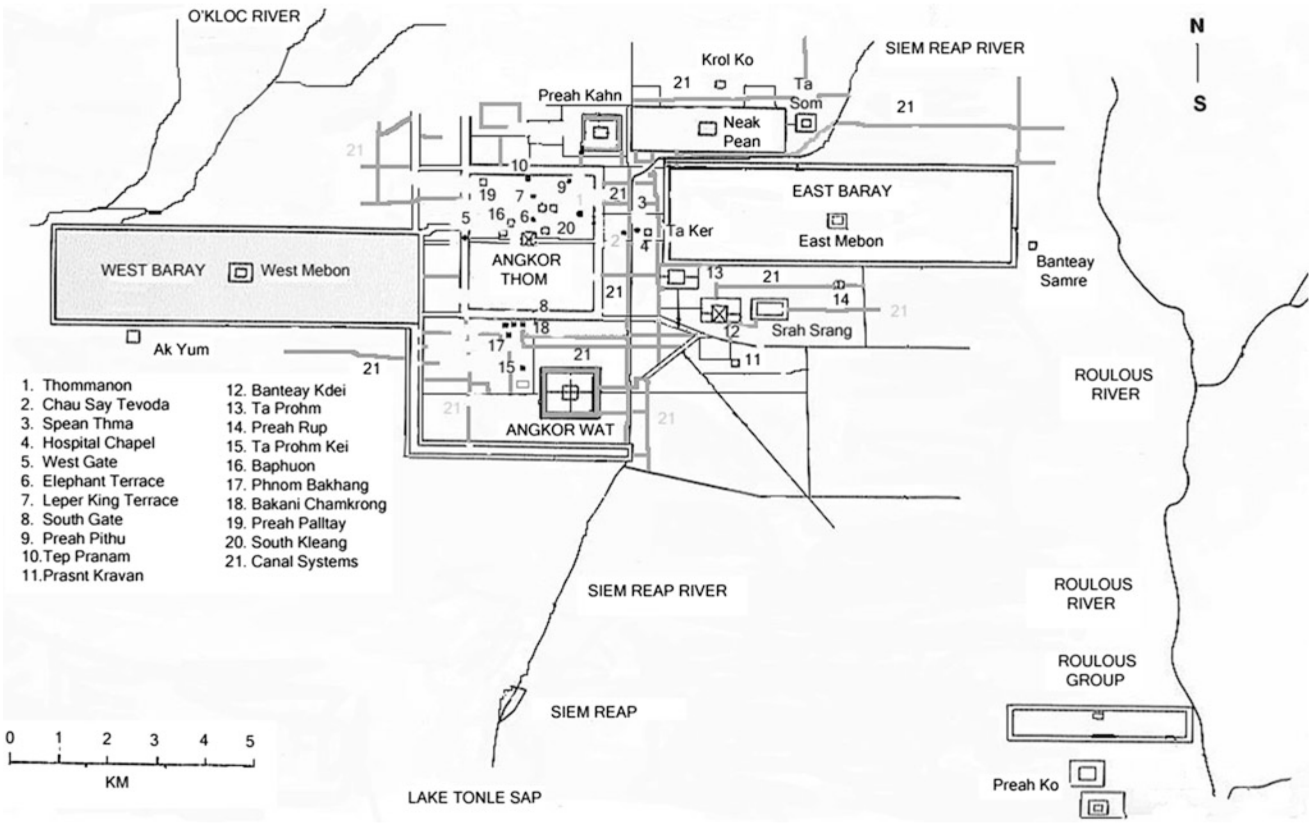
At Ephesus, canal and aqueduct systems leading from mountain spring sources distributed water into the urban core through complex pipeline systems that supplied water for 250,000 inhabitants at 150 gal/day/person, including baths, fountains, nymphea, latrines, elite housing compounds, public buildings, a coliseum, gymnasia, and a theater, all of which required a continuously running water supply (Figure 5). The nearby Temple of Artemis, originally ~3 km inland from the Mediterranean shoreline, was served by multiple underground pipelines of different designs for different ceremonial uses (Ortloff, 2009). This site, originating around 800 BCE, became inundated after many centuries of operation as a result of coastal subsidence and progradation, uplift of inland mountains, and sediment deposits interfering with springs that supplied water to the temple. Here, the geophysical effects were so gradual and subtle that compensatory structural engineering considerations made in advance of construction were apparently not a major concern.

The site of Petra in Jordan (Bourbon, 1999; Taylor, 2001; Guzzo and Schneider, 2002) is a further example of the creative use of intermittent water supplies from rainfall and springs to maintain city activities over centuries. Spring systems within tens of kilometers of Petra provided water to reservoirs from which terracotta pipes guided the flow to inner urban precincts for agoras, fountains, theater, water gardens, temples, public buildings, and domestic housing. Piping systems of different hydraulic designs were necessary given how distant these springs were from distribution hubs. Known from ancient times, and verifiable from modern computer calculations, is that a linear increase in supply hydraulic head does not result in a corresponding linear flow rate increase in long pipelines (Ortloff, 2009) due to nonlinear, cumulative water-internal pipe wall friction effects. This design constraint, together with how landscape-governed slope variations place constraints on pipe flow rate, results in a catalogue of hydraulic designs (Ortloff and Kassinos, 2003; Ortloff, 2009) that were utilized at Petra for the Siq, Jebel el Kubtha, and Zurraba water supply systems. Such urban core water supply systems possessing different hydraulic solutions for different geophysical constraints demonstrate that the ancient engineers possessed a wide knowledge base, approaching in many cases that of modern hydraulic design practice. Rainfall catchment basins and reservoirs provided additional water supplies and limited runoff into the urban center; some 250 such basins have been located in the mountainous areas surrounding Petra. The predictability of rainfall periods in this area of Jordan was well understood in antiquity and served to provide city reservoirs with water through many catchment basins and springs. Defensive water diversion channels and dams limited water damage to the urban core of Petra; here knowledge of water control was key to the permanence of the city for many centuries.

For the sites mentioned, the permanence of construction of fixed water supply elements (canals, pipelines, aqueducts, and reservoirs serving city and agricultural systems) indicates that geophysical threats were minimal outside of occasional, but reparable, earthquake damage. Thus, with regard to water supply systems, the advantage of the Mediterranean world with its stable climate and weather norms is apparent compared to New World cities and settlements.

Geophysical effects on the water systems of the Khmer Kingdom city of Angkor

The site of Angkor (800–1450 CE) in central Cambodia (Laur, 2002; Coe, 2003) reveals a long history of innovative water management that supported agricultural resources for a vast population centered about the central city core. A series of moats, channels, reservoirs, dams, and ritual water healing centers characterized the city's precincts (Figure 6). Of interest are two large reservoirs (*barays*), the largest of which is the West Baray with an 8×5 km footprint. A wide-barrier dike enclosed the baray on all sides, and water from monsoon rainfall and the Puok and Siem Reap rivers provided water to fill the reservoir during the rainy season. While some release points along the dike led to irrigation canals, the large reservoir had a profound reason for its existence. Groundwater flow modeling (Ortloff, 2009) indicates that water stored in the reservoir during dual monsoon seasons was slowly released by groundwater seepage during the dry season to maintain a constant groundwater height throughout the year in areas south and east of the baray. The area between the baray and the edge of Lake Tonlé Sap was primarily for rice cultivation in sunken pits dug below the water table. The East Baray served a similar function by maintaining groundwater height under the city's urban core and keeping the water level in moats and ceremonial pools constant year-round. Without dry season groundwater recharge from the barays, a permanent collapse in subsoil porosity would have occurred causing ground subsidence and structurally compromising the Angkor temples. Thus, two major barays, together with reservoirs,



Canals and Aqueducts in the Ancient World, Figure 6 Site feature map of Angkor (Cambodia) (From Ortloff, 2009: Figure 3.1.1, p. 359).

pools, and moats within city precincts, served to maintain the structural integrity of the many temples of Angkor, permitted extension of rice cropping on a year-round basis, and provided aesthetic embellishment to the Khmer version of the celestial capital of the gods. Through captured monsoon runoff, groundwater seepage systems, and surface transfer canals, an elaborate three-dimensional water control system (subsurface and surface) gave prosperity and continuity to Angkor over many centuries of occupation. Thus, Khmer knowledge of geophysical effects related to groundwater movement was a vital element in their city's prominence over many centuries.

Southwestern Native American societies: geophysics of canals and aqueducts

Over geologic epochs spanning millions of years, the Colorado Plateau has been etched by the deepening and headward extension of innumerable small valleys opened during periods of intermittent heavy rainfall. These valleys are characterized by floodplain incision from rain runoff producing areas of unconsolidated sediment deposits within the valleys that limit water control for irrigation agriculture (Longwell and Flint, 1962; Cooke and Reeves, 1976). Heavy rains lead to sediment deposition over bedrock, creating arable land for irrigation agriculture but not in areas prone to periodic erosion. Farther south in the Basin and Range country, deeper alluvial valleys containing sandy desert soils limit agricultural productivity due to limited moisture retention, as well as climate/weather conditions characterized by high desert temperatures and more frequent drought conditions. Across the Southwest, many alluvial valleys are prone to stream entrenchment (arroyo cutting) that lowers water tables and restricts the amount of arable land that can be irrigated (Cooke and Reeves, 1976). Thus, as a result of heavy flood runoff and periodic droughts, agriculture was limited by both climate and geomorphic processes that placed constraints on water control.

Yet despite difficulties with unstable farming terrains in these geographic zones, Spanish settlers coming into the area post-1540 CE found land being productively farmed by indigenous peoples (Doolittle, 2000) who ingeniously modified the landscape to capture and store intermittent rainfall and snowmelt to sustain crops (Anschuetz, 2001, 2006; Plog, 2008). On the Colorado Plateau, for example, most of the agriculture noted by the Spanish was floodwater farmed. Periods of drought that deteriorated grasslands and amplified erosion during heavy rainstorms, together with periods of light, but more frequent, rains caused continuous infilling of valleys with alluvium. Farming required adaptive responses to prehistoric climate variability influenced by El Niño and La Niña rainfall and drought periods, respectively (Dean and Robinson, 1977; Fish and Fish, 1984; Doolittle, 1992; Damp et al., 2002). Several of the major prehistoric (pre-Columbian) Indian societies of the Colorado Plateau (e.g., Anasazi and Mogollon) and southern Basin and Range areas outside of the Plateau (e.g., Hohokam and Patayan) farmed floodplains watered by melting winter snow and summer rains. Additional hill-slope terracing was used to stabilize planting surfaces, and flood diversion dams were built to limit erosional/depositional effects on field plots (Doolittle, 1992; Lightfoot and Eddy, 1995; Doolittle, 2000; Anschuetz, 2001).

Diverse technical innovations founded upon highly evolved indigenous cultural knowledge allowed for successful crop production in distinct geomorphic settings (Woosley, 1980; Doolittle, 1992, 2000). For example, the prehistoric Puebloans (Anasazi) located on Mesa Verde in Colorado (Ferguson, 1996) constructed a series of four reservoirs (Box Elder, Morefield, Far View, and Sagebrush) that were operational from 750 to 1180 CE and captured rainfall runoff to redistribute water for agricultural and domestic use (Leeper, 1986; Wilshusen et al., 1997; Wright, 2003). Ethnographically, the Tewa of north-central New Mexico employed bermed terraces to capture rainfall, together with stone-lined transport canals, dams, and spreaders to capture (or divert) runoff. The Tewa could exploit a combination of direct precipitation, intermittent runoff, groundwater, and canal extraction from springs and rivers to water their fields (Doolittle, 1992, 2000; Anschuetz, 2001, 2006). Stone-mulched and stone-bordered sunken pits were also used by Pueblo society to trap precipitation. Anschuetz (2001, 2006) describes anecdotal evidence that winter snow was rolled into balls and deposited in these pits in order to store water and amplify soil moisture for later agricultural use. The Hohokam (600–1350 CE) of south-central Arizona utilized extensive canal networks drawn from rivers and springs to irrigate vast field areas. The Salt River Valley contained as many as 400 km of main and distribution canals (Howard, 1987; Doolittle, 2000; Plog, 2008) with the Gila and Verde Valleys containing yet more irrigation canals estimated to be on the order of 600 km in cumulative length.

South-central Arizona employed the greatest extent of canal irrigation compared to all other southwestern indigenous societies. Aerial photography of these prehistoric canal and field system complexes taken 80 years ago (Judd, 1930) has proven indispensable in discovering and documenting trace canal, and field system remains now obliterated by erosion, sediment deposition overlays, and modern agriculture proceeding from urban expansion. Canal water transport technologies practiced by the Pima (Akimel O'odham) along the Gila River involved long, low-slope, open channels that supplied field systems. While similar water control systems were used elsewhere in the Southwest, canals originating from smaller river tributaries to major rivers were a preferred strategy due to easy water control practices. Other agricultural practices depended upon floodwater farming, especially in areas lacking large, perennial rivers. For example, the Papago (Tohono O'odham) were known for their *ak chin* (floodwater) farming along ephemeral streams, while the Navajo and Hopi planted fields in drainage areas where floods and runoff occurred during heavy rains (Plog, 2008). Further innovative indigenous agricultural strategies practiced in the Southwest are summarized by Doolittle (2000) and Plog (2008).

Modern scientific techniques integrated into archaeological studies add greatly to our understanding of complex geomorphologic processes and the response of indigenous societies to challenges posed by climate and landscape limitations. For example, ^{14}C and luminescence dating (Berger et al., 2009; Watkins et al., 2011), as well as pollen and biometric analysis of sediment layers in canals and reservoirs, provides insight into age, use history of water control features (Huckleberry, 1999; Wright, 2003; Wright et al., 2005; Wright, 2006), and an understanding of crop types farmed by different societies. Additionally, much has been learned about prehistoric canals and fields through analysis of the physical-mechanical properties of sediments and alluvial deposits (hydraulic conductivity, porosity, stratigraphy). These studies provide insight into rain infiltration and seepage rates, as well as details illuminating the formation processes of canals and reservoirs. For example, sedimentological and stratigraphic analyses of Anasazi mesa top and valley water storage reservoir systems and canals were essential to understanding their role in sustaining local farming communities (Rohn, 1977; Wright, 2003; Wright et al., 2005; Wright, 2006). Application of concepts from fluvial geomorphology (Knighton, 1998) (e.g., erosion initiation, sediment transport and deposition) has proven useful in recognizing the impacts of floods and climate change on indigenous farming in the American Southwest (Cooke and Reeves, 1976; Bettess and White, 1983; Abrahams, 1987), as well as post-abandonment weathering of agricultural landscapes. When combined with dendrohydrological studies (Dean and Robinson, 1977), fluvial geomorphic analysis provides insight into how indigenous Southwestern societies changed their irrigation strategies (which are detectable from archaeological studies) as an adaptation to climate and landscape changes.

Conclusions

A survey of urban/agricultural water supply systems of major New and Old World societies on four regions of the world reveals exploitation of different varieties of water sources available in different ecological zones. Dams, reservoirs, canals, aqueducts, pipelines, open channels, and groundwater resources served to collect, transport, and distribute water to urban centers and agricultural fields. Each water system type with its selection of water transport and storage systems exhibited vulnerabilities when subject to climate and geophysical landscape changes. When system modifications were not possible due to insufficient technology, labor shortage, or lack of management expertise, societies underwent collapse, transformation, and altered societal and cultural trajectories as observed in the archaeological record. Differences exist between water transport and distribution systems employing different construction techniques and materials by New and Old World societies. Where the effects of climate and geophysical landscape change were minimal over long time periods, construction was permanent and alterations remedial in nature; where climate and weather patterns were changeable and affected the stability of water transport systems, flexibility of design and modification is evident to guarantee sustained use of these water systems. Examples discussed reveal this basic strategy difference between Old and New World societies. The many different water usage strategies employed by these societies constitute a virtual library of solutions tailored to different ecological and geomorphic conditions and provide insight into the creativity and resourcefulness of ancient engineers to maintain their communities despite changes in environmental conditions affecting their agricultural resource base.

CASPER SITE, WYOMING

Vance T. Holliday
Anthropology and Departments Geosciences, University of Arizona, Tucson, AZ, USA

The Casper site was a bone bed from a bison kill near Casper, Wyoming. It was destroyed by construction activity shortly after excavations in 1971. The site is on the fourth terrace above the northern bank of the North Platte River and is located near the margin of an extensive dune field that follows the North Platte valley. Geoarchaeological research informed investigators about the setting at the time of occupation and also provided insights into human actions involved in creating the site.

The site was exposed in stratified sands resting on top of Pleistocene gravels that comprise most of the terrace fill. It consisted of the remains of ~100 extinct bison (*Bison antiquus*). Associated with the bones were 60 bifacial Hell Gap projectile points (one of a number of North American Paleoindian projectile point styles), along with unifacial cutting tools, resharpening flakes, and stream-worn cobbles likely used as hammerstones in the butchering process. The site is radiocarbon dated to ~10,000 ^{14}C years BP and is a classic example of a Paleoindian bison kill from the northern Great Plains of North America.

Based on the evidence of sedimentology, stratigraphy, and geomorphology at the site, the bison kill took place within a parabolic sand dune. Resting on the terrace is an older set of well-sorted medium sand dunes with low-angle cross bedding. This older set of sands and the upper terrace alluvium were truncated by erosion that formed a long trough that was minimally ~100 m long, ~25 m wide, and 2 m deep. Inset against this elongate depression was another set of medium sand dunes, similarly cross-bedded. The bone bed was in the younger sand deposit, scattered along the paleo-depression. The sedimentology and paleo-topography are essentially identical to the interior of parabolic dunes in the area, where the dune forms with its curved arms upwind and the windward face becomes concave as its surface sand is blown up and over the dune ridge. The interpretation is that bison were driven into the blowout of a parabolic dune. The steep blowout walls of the windward slope trapped or at least slowed the animals so they could be killed. The zooarchaeology combined with the microstratigraphy indicated that the site represented a single event and incorporated both a kill and a processing area.

Great Plains Geoarchaeology

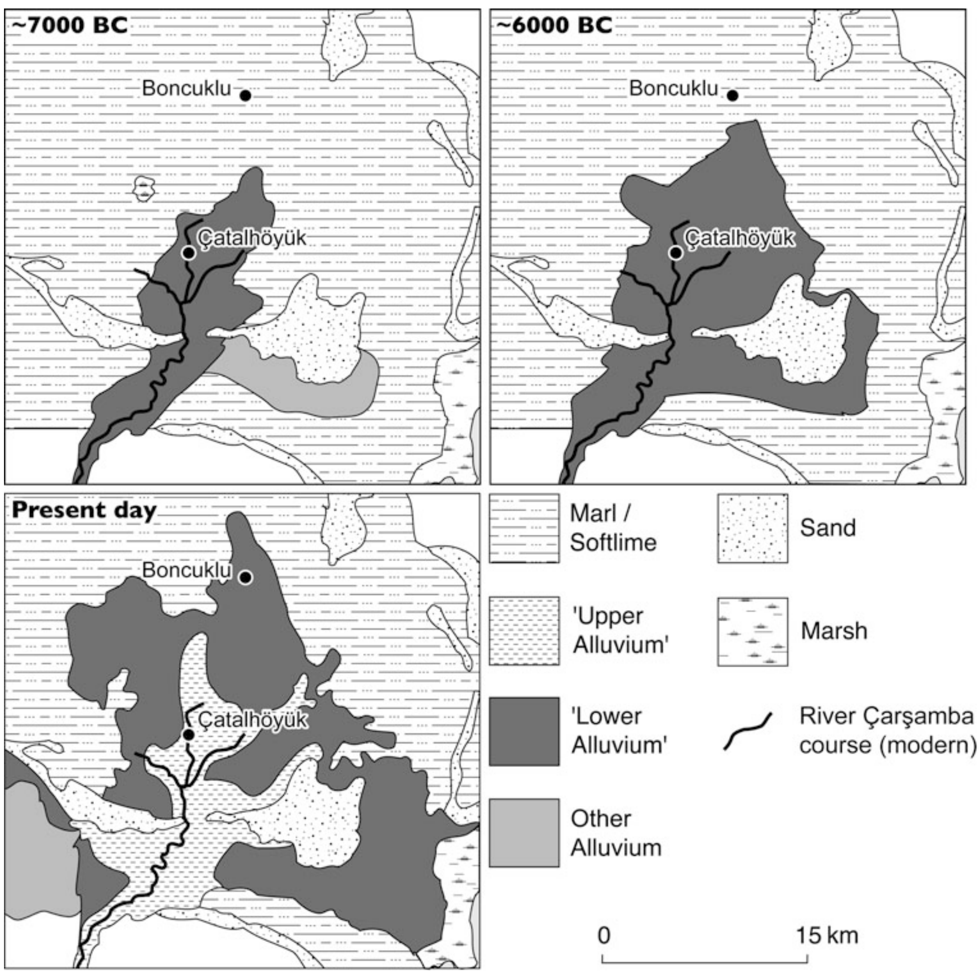
ÇATALHÖYÜK

Neil Roberts
School of Geography, Earth and Environmental Sciences, Faculty of Science and Environment, Plymouth University, Plymouth, Devon, UK

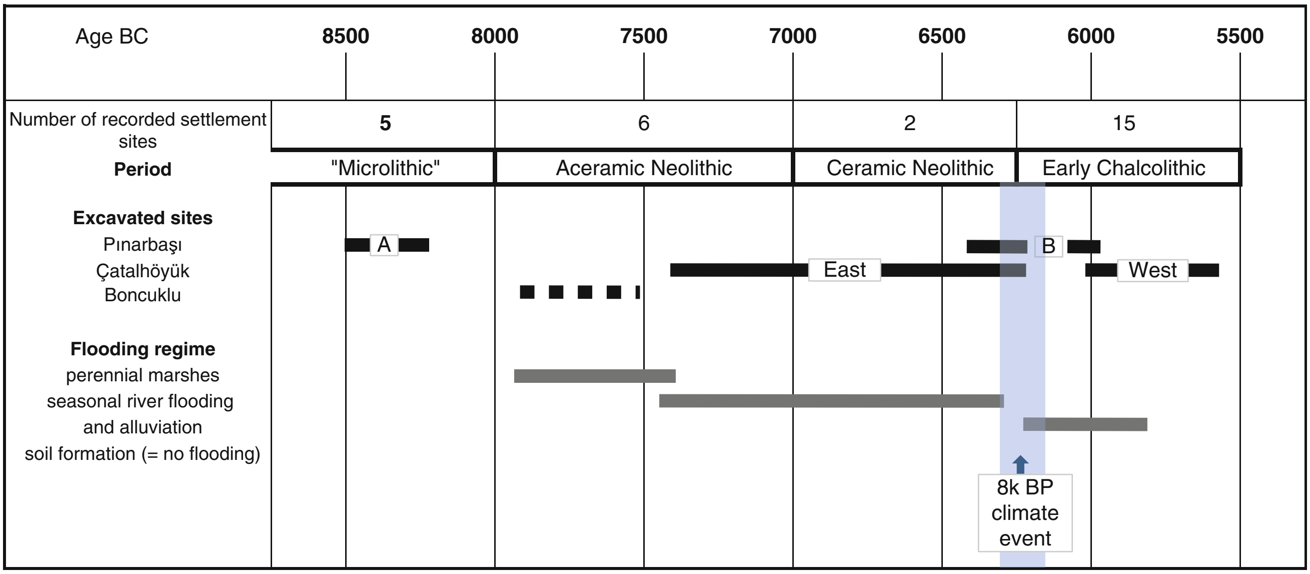
Çatalhöyük is a key Neolithic site located in south central Turkey. It is one of the largest and best studied early agricultural settlements in Southwest Asia, and it has also revealed a significant record of symbolic expression, such as wall paintings. Çatalhöyük, in fact, comprises two mounds, an East mound where most excavations have been focused and a smaller West mound of early Chalcolithic date. Çatalhöyük was originally excavated in the early 1960s by James Mellaart, but archaeological fieldwork subsequently stopped and recommenced only in 1993 under the overall direction of Ian Hodder – see Hodder (2006) for a summary.

Çatalhöyük is located on a gently sloping alluvial fan delta of the Çarşamba river, which has prograded across the bed of a large former lake that covered the Konya basin during the late Pleistocene (Figure 1). The plain lies at an elevation of ~1,000 m asl and lacks any surface outlet. Its climate is semiarid continental Mediterranean, in contrast to the surrounding well-watered mountain watershed. In contrast to initial speculations by Cohen (1970), studies by Roberts (1982) showed that (1) the main shrinkage of the Pleistocene Konya lake occurred prior to 16,000 BC, i.e., well before the first Neolithic occupation, and (2) significant post-occupation alluviation has occurred at Çatalhöyük. This continued deposition of alluvium means that modern soil type distributions (Driessen and de Meester, 1969) do not provide a reliable guide to those that existed around the site in prehistory. A comprehensive geoarchaeological field program took place between 1993 and 1999 linked to the current excavations at Çatalhöyük (Roberts et al., 1996; Roberts et al., 2007). This KOPAL (Konya basin Palaeoenvironment) project included vibrocoring, backhoe trenching, and study of off-site irrigation ditch sections, not only at Çatalhöyük but also at other archaeological sites located across the Çarşamba fan (Boyer et al., 2006).

Above pale gray marl deposited on the bed of the glacial-age lake, two principal alluvial units can be distinguished. A red-brown upper alluvial silt-clay dates from Bronze Age to post-Byzantine times. Beneath this lies a very dark gray lower alluvium comprising heavy, smectite-rich clay



Çatalhöyük, Figure 1 Maps showing the changing distribution of sediments around Çatalhöyük, near the start and end of the occupation of the East mound and at the present day (Modified from Boyer et al., 2006). At the microscale, this pattern would have been more spatially heterogeneous than shown here.



Çatalhöyük, Figure 2 Chronological chart showing recorded archaeological site numbers on or near the Çarşamba fan, individual site occupations, and changing flood regimes (From Roberts and Rosen, 2009).

that was laid down in a seasonally flooded backswamp environment. The top of the underlying marl is undulating due to Late Glacial eolian deflation, and as a result, the backswamp clay infill shows local-scale variations in thickness. Deposition of the backswamp clay at Çatalhöyük began ~7500 BC and ended by ~6000 BC with paleosol formation, and it coincides in time almost exactly with the Neolithic occupation (Figure 2). During the spring flood, much of the lower-lying land surrounding Neolithic Çatalhöyük would have been under water, which led Roberts and Rosen (2009) to propose that some cereal and pulse crops may have been grown on drier ground away from the alluvial fan.

In summer, the alluvial and marl plain dried out, and the Çarşamba river returned to its main channel, which ran next to Çatalhöyük. The strong wet-dry seasonal contrast in river and wetland hydrology has been confirmed by stable carbon and oxygen isotope analyses on samples taken across the surface of large *Unio* mollusk shells found on-site; the results for sequential samples showed isotopic variations explainable by seasonal fluctuations in local water levels as the bivalve's shell grew (Bar-Yosef Mayer et al., 2012). The river "flooding phase" at Çatalhöyük appears to have prompted a nucleated rather than dispersed settlement pattern on the Çarşamba fan, for only this single large site is known during the ceramic Neolithic, whereas several smaller settlements existed during both the preceding aceramic Neolithic and subsequent early Chalcolithic periods. The distinctive lifeways at Neolithic Çatalhöyük may, in consequence, have been partly an adaptation to specific hydro-environmental conditions.

The "flood phase" at Çatalhöyük can be linked to a period of wetter climate in the eastern Mediterranean during the early Holocene, and its ending coincides with the well-known 8.2 ka BP cold, dry climatic event. However, lake isotope data show that wetter climatic conditions in central Turkey had started by 9500 BC and continued until ~4500 BC, thus spanning a longer time period than the Çarşamba flood phase. Its timing must therefore have been affected by local factors, such as river avulsion and a changing depocenter, as well as regional climatic changes. Its onset, for example, would have been affected by a change in river course from an easterly to a northerly orientation when the Çarşamba broke through a sand spit of the former Konya lake (Figure 1).

More recent geoarchaeological fieldwork has been extended to include the nearby predecessor aceramic Neolithic site of Boncuklu, as well as further analysis of the sediment fill at and around Çatalhöyük, e.g., the sourcing of mudbricks and lime plasters (Love, 2012; Doherty, 2013). A new program of coring and ditch sectioning around the mounds took place in 2007–2009 in order to build a picture of the site environs at higher spatial resolution. At this fine spatial scale, the Neolithic landscape would have been a mosaic of upstanding marl hummocks, seasonally wet flood basins, and riparian zone river channels, some of which would have provided microhabitats suitable for more intensive "garden-scale" crop cultivation (Charles et al., 2014).

Çatalhöyük lies close to the volcanic terrain of Cappadocia, from where it obtained obsidian for lithic artifacts. A tephra layer found in eastern Mediterranean lake and marine cores has been linked geochemically to one of the Central Anatolian stratovolcanoes and dates to the ceramic Neolithic (Zanchetta et al., 2011; Schmitt et al., 2014). This may provide an explanation for an enigmatic wall painting at Çatalhöyük, which has been interpreted as showing a -twin-peaked volcano erupting above a settlement.

[2]Department of Archaeology, Emeritus at Boston University, Boston, MA, USA

Definitions

Cave: natural cavity in a rock which is enterable by people.

Karst: a terrain that is formed principally by the solution of the rock.

Introduction

Caves constitute a disproportionately large part of the surviving archaeological record for many prehistoric periods (Straus, 1997). Their stability in the landscape attracted humans in search of shelter early in the history of humankind, and at the same time, they facilitated the accumulation of sediment and cultural material. The lengthy geologic and archaeological record that has built up within some caves provides the basic data of prehistoric archaeology in many regions of the world. Caves are also parts of drainage systems as well as ground water flow paths, making them important water sources that may partly explain their early use. It has been suggested that caves provide ready-made natural structures without the need of any significant adaptation of human behavior, and in this way, they were convenient and useful for a variety of purposes (Skeates, 1997; Straus, 1997). Caves are an example of bounded space, and like architectural forms, they can be carefully manipulated to create inhabitable, delineated areas where such spaces do not exist in nature (Kent, 1990). As such, caves provide not only natural shelter and protection but also a memorable and confined living space with a sense of durability and familiarity, probably precursors of the modern idea of "home." Caves, therefore, have been considered to be the first "home base" sites during the late Middle Pleistocene (Rolland, 2004).

Caves have varying and changing uses across different cultures. Early in the evolution of humans, they were the focus of hominin occupation. Examples include the famous caves within the Cradle of Humankind in South Africa, where important early hominin fossils have been found (e.g., Pickering and Kramers, 2010). However, it is believed that widespread, regular cave occupation did not begin before later Acheulian horizons, and not until the Middle Paleolithic are caves more systematically exploited. The use of fire made deep caves available for specialized ritual functions, as is indicated by the Upper Paleolithic art caves of France and Spain. Later, during the Neolithic, an expansion of cave use is observed, as groups exploited cave spaces as part of a pastoral economy (Tolan-Smith and Bonsall, 1997). In addition to

Cave Settings, Figure 1 Photograph of the area around Klissoura Cave 1 (*arrow*) showing the typically rugged Mediterranean karstic terrain developed in limestone.

dwellings, caves have also been employed as storage sites, cooking places, cemeteries, and temples.

Cave formation

Most caves develop in limestone and similar carbonate rocks. Their formation is related to karst processes with the solution of rocks by meteoric (phreatic) water (Figure 1). Atmospheric carbon dioxide (CO_2) dissolved in rainwater becomes acidic and, as a consequence, is capable of dissolving carbonate rocks. Rainwater entering at the ground surface may be further enriched with CO_2 derived from decayed vegetal matter and fauna from the soil. Dissolution of carbonate rocks may follow changes in lithology, such as contacts between pure and impurelimestones and limestones and other non-carbonate rocks (including shales or various igneous rocks).

Water circulation is also greater near joints, bedding planes, and faults. Therefore, in the early stages of their formation, caves act as water conduits. When water-filled passages drain, hydrostatic support stops and breakdown commences. In any cave evolution sequence, the spalling of wall and ceiling surfaces is an inevitable phase that leads to partial or complete infilling but also to enlarging and generally changing the configuration of the cave (Gillieson, 1996). Other mechanisms of cave development in carbonate rocks include dissolution by sulfuric acid produced from upwelling thermal waters that oxidize sulfides present in the limestone or from oxidized hydrogen sulfide emanating from deep hydrocarbon sources. Sulfur-oxidizing and sulfur-reducing bacteria are involved in this type of speleogenesis (White, 2000).

Caves may occur in sandstones and quartzites, evaporates (e.g., gypsum), igneous rocks such as basalts and granites, as well as in ice. In some of these cases, dissolution is also the major factor of cave formation, particularly in sandstones and evaporitic rocks. In sandstones, if the cementing material is carbonate, then cave formation will proceed according to the karstification process described above. In quartzites and sandstones, silica cement dissolution is very slow, and mechanical removal of loosened grains by fast moving groundwater is an additional process leading to enlargement (Martini, 2000). Caves in basalt are often lava caves formed by the draining of lava tube feeding networks during the eruption period.

Along karstic coastal areas, caves develop where marine and fresh water meets (Mylroie and Carew, 2000). These shallow water occurrences are based on the same principle observed for the formation of deepwater karstic environments, where additional dissolution is achieved by mixing waters saturated with different amounts of carbon dioxide. Sea caves are formed by wave erosion during prolonged sea-level stands (Figure 2). They can develop in any kind of rock by mechanical weakening along rock discontinuities and the chemical action of saltwater (Mylroie, 2005). Sea caves can provide

Cave Settings, Figure 2 Photograph of two sea caves on the southern coast of South Africa, near Die Kelders Cave. Note the remnants of bedded aeolianites at the top (*arrow*) once covering and blocking the entrance to the caves.

useful information on the past sea-level fluctuations in relation to human occupation (e.g., Goldberg, 2000; Kuhn et al., 2009; Karkanas and Goldberg, 2010). Windblown sand can also scour relatively soft rocks and form aeolian caves of appreciable size (White and Culver, 2005).

Detailed study of the formation of caves, as well as their history prior to human occupation, is normally not undertaken in archaeological projects. Yet, such studies contribute significantly to our understanding of the paleoenvironment and evolution of the landscape, and they can reveal potential links to the eventual presence of humans. In addition, the processes responsible for a cave's formation are often ongoing, albeit at a slower rate, throughout its entire history, and consequently they affect or determine the type of deposits, structure, and location. For example, Qesem Cave in Israel was formed by a combination of processes that include subsidence and sagging of the bedrock into deeper voids formed by deep-seated dissolution (Frumkin et al., 2009). The gradual sagging of the basal bedrock layers also affected the overlying sediments such that the cemented parts of the cave deposits (indurated through hardening of the matrix) have fractured along the walls allowing the central area to sink through gravitational slumping. These processes have resulted in hanging ledges of cemented deposits clinging to the cave walls while the adjacent sunken area in the center subsequently filled in. Then everything was covered with new collapse material. Both the complex stratigraphy and the sedimentary character of the cave are better explained when the processes responsible for cave formation are clearly understood (Karkanas et al., 2007).

Cave sediments

Caves are often perfect sedimentary traps, accumulating and protecting the stratigraphic record from many postdepositional subaerial processes. Cave sedimentary facies are quite useful in interpreting and reconstructing depositional histories, which can track changes in earth system processes (Springer, 2012), thereby yielding insights into climate and landscape evolution within the area (Goldberg, 2000; Pickering et al., 2007; Karkanas et al., 2008; Kourampas et al. 2009). Sediments from different sources accumulate within caves, and thus complex stratigraphic sequences may result. At the same time, however, such instances provide some of the best cases for studying past human behavior (Macphail et al., 1997; Karkanas et al., 2007; Meignen et al., 2007; Goldberg et al., 2009).

Geogenic sediments

Caves are repositories of primary and secondary clastic sediments, but they also contain primary and secondary chemical sediments. Primary clastic sediments are derived from breakdown of the walls and ceiling of the cave (known as autochthonous or endogenous sediment). Cave mouths are more sensitive to surface weathering conditions, and, therefore, they can be dominated by processes not normally encountered in deeper passages. Since

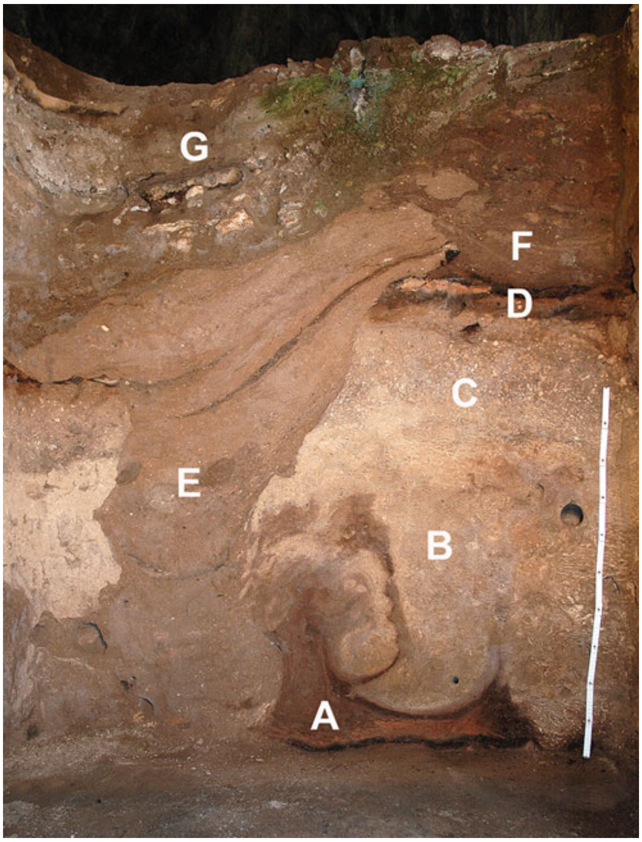
Cave Settings, Figure 3 Pile of breakdown material capped by brown infiltrated clay coming down a fracture in the bedrock (*arrow*). Unnamed cave in Israel, near Qesem Cave.

human occupation is typically restricted to the entrance area of caves (particularly the deeper ones), these entrance facies are most important from a geoarchaeological perspective. Breakdown is extremely common at the entrance area, and roof collapse produces talus cones marking the gradual retreat of the cave (Goldberg et al., 2007) (Figure 3). Therefore, slope processes often dominate the entrance area of caves occupied by humans (Karkanas et al., 2008). Frost action is also observed only in the entrance area of a cave. Cryoclastic sediments, the famous *éboulis* of the French literature, constitute a significant part of the sediments in present-day temperate environments. However, similar angular coarse particles can be produced by a variety of processes including hydration shuttering and seismic activity (for a review, see Woodward and Goldberg, 2001).

Secondary clastic sediments from the outside (allochthonous or exogenous) enter the cave through a variety of processes, such as fluvial deposition, aeolian activity, and mass movement (debris and mudflows, creep, falls, slumps, etc.). The main sources of this sediment are sinking streams carrying sediments from nearby drainage basins, soils, and weathering residuum from the ground surface that are flushed into caves through sinkholes and open fractures by storm runoff and sediment influxes from overlying rock formations through open fractures (Bosch and White, 2004).

Sediments deposited from high-energy water flow are not frequently encountered in archaeological cave sequences. However, fluvially transported endokarstic (subsurface) gravels often associated with bedded sands and silts have been reported in some archaeological caves (Macphail and Goldberg, 2003; Braillard et al., 2004). In some cases, invasive waters may enter caves through the karstic system, producing complex erosional features including irregular channels and underground tunnels (Karkanas, 2001). This often leads to a very complicated stratigraphy with several phases of sedimentation and erosion (Figure 4).

Low-energy water flow may transport material from outside and redistribute it toward the back of caves. Finely laminated, moderately sorted, fine-grained sediments deposited by sheetflow are frequently encountered in the entrance area (Karkanas, 2001; Goldberg et al., 2007). Debris flow and other types of deposit produced by mass movement are probably the most widespread sediments observed in archaeological sequences within caves. They appear in the form of sloping beds of angular to subrounded gravel, floating in unsorted fine-grained matrix. Gravel clustering, floating boulders, coarse "tails," and imbrication (overlapping) of coarser particles are indications of sediment gravity flows (Figure 5). They are formed when colluvium that has accumulated in the entrance is destabilized by water saturation and fails under the force of gravity (Karkanas et al., 2008; Mallol et al., 2009). Water saturation can also destabilize previously deposited sediments with substantial anthropogenic materials and redistribute them by the force of gravity, producing slumping and debris flows (Figure 4) (Karkanas and Goldberg, 2010). In cold climates, solifluction deposits



Cave Settings, Figure 4 Photograph of complex stratigraphy at Theopetra Cave, Greece. The lower sedimentary sequence, comprising cryoturbated burnt features (*A*) and in situ burnt remains (*D*), is truncated by a channel formed by invasive waters that was later filled with sediment (*E*). Slumping has reworked part of the fill, shown by whole pieces of the channel fill (*F*), and finally the sequence was capped by reworked burnt stabling remains (*G*).

occur widely in caves, where they are characterized by rounded aggregates and mineral grains coated by microlaminated silts due to the rotation they undergo during displacement (Goldberg 1979a; Courty and Vallverdú, 2001; Karkanas et al., 2008). Orientation of clasts provides useful information about the type and direction of flow (e.g., Bertran and Texier, 1999; Lenoble et al., 2008).

Another fine-grained sediment frequently observed in archaeological caves is infiltrated fine-grained sediment and soil flushed through joints, fractures, and generally thin discontinuities of the bedrock (Figure 3). This sediment is often deposited as hyperconcentrated slurries and mudflows producing cones where they exit from the joints. More diluted flows can slowly percolate inside coarser roofspall and accumulate within the voids, thereby creating secondary-filled, matrix-supported angular gravels. Piles of coarse breakdown deposits can be further redistributed by gravity when lubricated by infiltrated clay slurries (Karkanas et al., 2007).

In coastal areas, aeolian deposition is widespread. Several important sites along the coast of South Africa and the Mediterranean are dominated by windblown deposits of well-sorted sand interfingered with anthropogenic sediments (Figure 2) (Goldberg, 1973, Deacon and Geleijnse, 1988; Tsatskin et al., 1995; Goldberg 2000; Macphail and Goldberg, 2000; Jacobs et al., 2006; Karkanas and Goldberg, 2010). Aeolian silt (dust) is also an important component of cave sediments – particularly in the circum-Mediterranean zone – but due to its slow accumulation rate, it is often intermixed with coarser roofspall, aeolian sand, and other clastic or anthropogenic components, such as the similar-sized wood ash. These mixtures make the interpretation of such sediments very difficult in the field. In Dust Cave, Alabama, USA, original aeolian silts occur as rounded soil aggregates and are incorporated within the coarser deposits. Here, dust originated in the nearby floodplain of the Tennessee River and along the limestone bluffs above the cave, and it was transported directly and indirectly into the cave by different mechanisms (Sherwood et al., 2004; Goldberg and Sherwood, 2006). In general, aeolian deposits are quite loose and easily disturbed by secondary sedimentary processes. Water seeping from fractures in cave walls or flushed through conduits can redistribute aeolian sediment and produce finely laminated deposits (Goldberg, 2000).

Primary chemical sediments are mainly in the form of speleothems (stalagmites, stalactites, flowstones, etc.). They are deposited by carbonate-saturated dripping, seeping, or flowing waters on the surface of the caves. These sediments are suitable for high-resolution dating such as uranium-series techniques, and when intercalated with clastic sediments, they can provide secure stratigraphic and chronostratigraphic markers (Moriarty et al., 2000; Pickering et al., 2007).

Primary biogenic sediments are mainly represented by the accumulation of large amounts of bat guano but also excrements from other animals that occupy cave interiors (bears, hyenas, etc.). The decay of biogenic sediments leads to chemical alteration of all previously deposited sediments and the formation of a suite of authigenic phosphate minerals (Karkanas et al., 2000; Shahack-Gross et al., 2004). Diagenesis is often very aggressive in caves because they also contain an active and confined hydrologic regime (for the details of these diagenetic processes, see the entry on "Chemical Alteration"). As several studies in the Near East and Europe have shown, phosphate diagenesis can have a dramatic effect upon the preservation of archaeological materials, leading to complete dissolution of bones and all kinds of calcareous materials such as ash, shells, and limestone particles (Goldberg and Nathan, 1975; Weiner and Bar-Yosef, 1990; Weiner et al., 1993; Schiegl et al., 1996; Karkanas et al., 1999; Karkanas et al., 2000; Karkanas et al., 2002; Weiner et al., 2002).

Cave Settings, Figure 5 Debris flow deposits showing alternating finer and coarser debris sloping downward to the right. Also seen are floating boulders within a fine clayey matrix as well as clustering and imbrication of coarser clasts at Dadong Cave, China.

Anthropogenic sediments

Human activity in caves produces a variety of sediments, but burnt remains are often volumetrically the most significant. These deposits include ash, charcoal, and deposited sediments that were previously heated (see the entry on "Hearths and Combustion Features" for details). The use of fire in prehistoric times is of great interest because it is one the most important elements of human evolution (Rolland, 2004). Since burning produces abundant sediment in the form of calcitic wood ash and charred remains (Courty et al., 1989), such residues are generally preserved in the calcareous environments of limestone caves (Figure 6), and their volume, constituents, microstructure, geometry, and pattern can provide evidence relating to the intensity of occupation and organization of activities (e.g., Meignen et al., 2007). Note that the general structure of burnt remains survives even after severe phosphate alteration (Schiegl et al., 1996; Karkanas, 2001; Goldberg et al., 2007).

Although the hypothesis has been proposed only recently, it has been recognized that large amounts of organic matter were often introduced into some Stone Age caves by humans for subsistence and bedding (Figure 7), offering new dimensions for analysis and a more profound understanding of the behavioral complexity of humans (Goldberg et al., 2009; Cabanes et al., 2010; Wadley et al., 2011). Later, stabling activities in caves from the Neolithic onward deposited large quantities of dung. Studies on the composition, macro-, and microstructure of stable remains and their spatial organization have contributed to an improved understanding of the new economic conditions introduced with the advent of animal domestication (Courty et al., 1991; Macphail et al., 1997; Boschian and Montagnari-Kokelj, 2000; Karkanas, 2006) (see the entry on "Pastoral Sites" for more details).

Transported and introduced natural clastic sediments are also encountered in cave sequences. In several cases, prehistoric constructions such as clay hearths and platforms have been identified, representing outside materials accumulated and shaped into man-made structures (Karkanas et al., 2004; Goldberg and Sherwood, 2006). Nonetheless, one of the most important but also neglected aspects of human-induced sedimentary processes is the redistribution and general (often penecontemporaneous) reworking of previously deposited geogenic or anthropogenic sediments by human activities. The digging of pits, dumping of burnt remains and food refuse, sweeping or shoveling out of stable residues, and trampling are among the most common secondary anthropogenic processes that rearrange sediment (Goldberg and Sherwood, 2006). Since these processes alter primary sedimentary structures and tend to mix contents and textures, they are generally difficult to discern and interpret by eye in the field. These effects can be studied with the proper analytical tools, and the results of such examinations can considerably enhance our knowledge of human behavior.

Cave Settings, Figure 6 Stratigraphic section of overlapping, mostly in situ hearth structures from the Middle Paleolithic sequence at Theopetra Cave, Greece. Note the circular burrow perforating the upper hearth complex in the center of the photo.

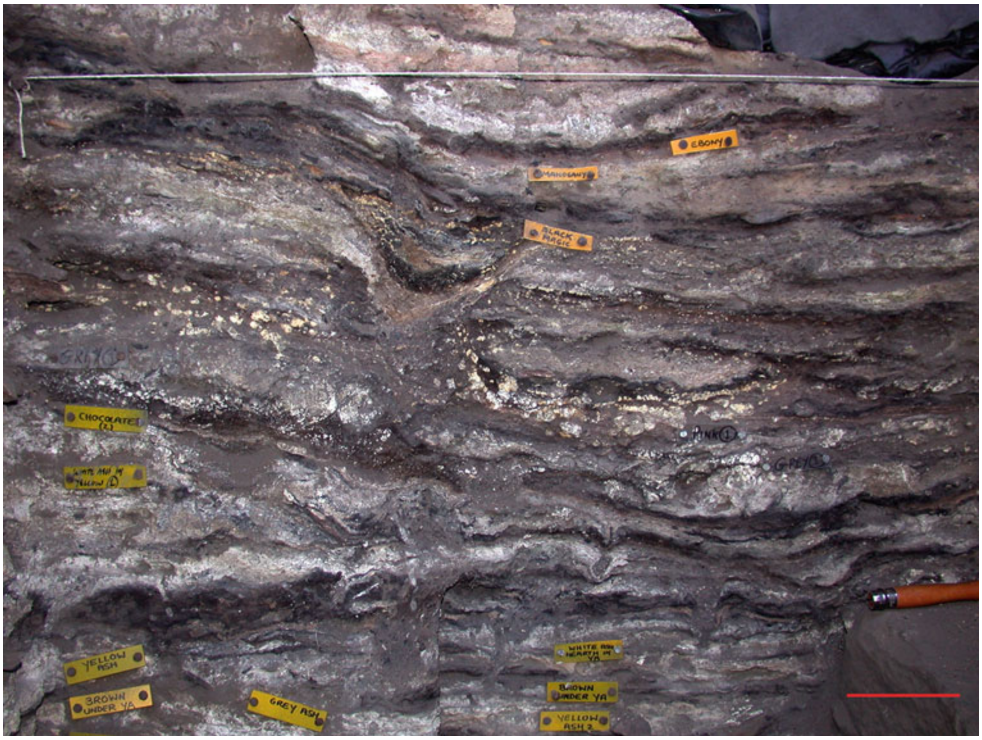
Methods of study

Caves were one of the first environments in which sedimentological techniques, such as grain-sized analysis, particle shape and composition, pH, and calcium carbonate and organic matter content, were applied to the study of archaeological deposits in order to interpret the depositional history of cave sediments (Bordes, 1972; Laville et al., 1980; Farrand, 2000). Although these data can provide useful quantitative information in some cases, they have mostly failed to (1) identify important anthropogenic components, such as calcareous ash, and (2) disentangle the complex syndepositional and postdepositional processes related to geogenic, biogenic, and anthropogenic activities. Indeed, as early as the 1970s, it was realized that classical sedimentological analyses did not reveal important postdepositional processes that constitute the basis of paleoclimatic interpretations (Goldberg, 1979a). Archaeological cave sediments were also the first to be studied by micromorphology, the study of intact sediments and soils under the microscope (Goldberg, 1979a; Goldberg, 1979b; Courty et al., 1989). Micromorphology is the best technique for unraveling such complex processes, and it provides the initial and basic framework for applying other techniques that can further elucidate details of both sedimentary accumulation and diagenetic changes. High-resolution approaches such as SEM, EDAX, XRD, and FTIR have been employed in the study of archaeological cave sediments along with micromorphology (Goldberg and Nathan, 1975; Bull and Goldberg, 1985; Weiner et al., 1993; Schiegl et al., 1996; Karkanas et al., 1999).

Cave sediments and environmental change

The usefulness of caves as archives of environmental change is controlled by the temporal resolution of the sedimentary record and the environmental sensitivity of the cave (Woodward and Goldberg, 2001). Studying caves as parts of the regional geomorphic system enables inferences relating to climatic and other changes in the regime of landscape processes for the entire area (Gillieson, 1996). There are, however, some limitations when trying to reconstruct paleoclimate using cave sediments. First, local factors govern the microclimate of the cave and may play a significant role in the way internal sedimentation occurs. Caves are complex settings with a unique microenvironment that is influenced by bedrock lithology, elevation, aspect, local drainage, internal configuration, and human activity (Goldberg and Sherwood, 2006). Second, caves are parts of larger karstic systems where sediments are circulating and stored for considerable periods of time before ultimately being deposited within the cave under study. This lag effect hampers easy interpretations based on weathering indices of external soil sources of the surrounding area. Fortunately in many regions, caves preserve distinct suites of sedimentary features that can provide the best available terrestrial record when combined with detailed stratigraphic analysis and comprehensive field observations, then corroborated by instrumental laboratory analysis.

The earliest micromorphological studies conducted on cave sediments in the Dordogne region of France clearly demonstrated episodes of colluviation, flowstone, and



Cave Settings, Figure 7 Field view of the profile along B4/B5 at Sibudu Cave, South Africa, showing the superposition of numerous combustion features. Whereas these features appear similar in the field, in thin section, cm-thick differences in composition can be observed, reflecting different materials (e.g., sedge phytolith remains of bedding) and activities (e.g., burning and trampling) (see Goldberg et al., 2009; Wadley et al., 2011). Scale bar = 10 cm.

stalactite formation, alternating with ice lensing and cryoclastism (Goldberg, 1979a; Courty, 1989). Frost-related processes affecting fine-grained sediments, such as cryoturbation and ice lensing, are particularly informative about climatic changes in caves (van Vliet-Lanoë, 1985) (Figure 4). Clastic deposits showing evidence of frost action may alternate with non-affected sediment or flowstones, which generally form during warmer climatic conditions. However, even in these cases, prior to a final interpretation, other environmental indices should be considered, such as phytoliths, charcoal, and macrobotanical remains, along with a thorough micromorphological analysis of the deposits. For example, flowstones intercalating with frost-affected sediments would be typically considered to be an indicator of warmer climate intervals. However, there are cases where flowstones can also be deposited under cold climate regimes (Bar-Matthews and Ayalon, 2011), and they themselves can also be affected by frost action (Courty et al., 1989; Karkanas et al., 2008). It should be remembered that sediments affected by frost action may have been deposited already and were not necessarily formed during a cold climate. In the end, it is the association and spatial distribution of all sedimentary features, both primary deposits and secondary disturbances, that ultimately lead to a thorough understanding of the sedimentary processes and stratigraphy of a cave site.

Finally, recent advances in dating techniques and isotopic analyses have made speleothem records the key proxy in reconstructing paleoclimatic change (e.g., Cheng et al., 2009). Highly detailed analysis of speleothem laminae can produce a yearly or even seasonal climatic record, and these complete climatic records can be compared to the archaeological record. Important inferences about cultural transitions, social changes, and even the collapse of civilizations (Bar-Matthews and Ayalon, 2011) can be made, though the exact role played by these detailed climatic changes in influencing human behavior must still be demonstrated with further evidence.

Cave sediments and human behavior

As mentioned above, the use of fire is of major importance to understanding human behavior in prehistory. Claims for early control of fire have been challenged by studies of cave sediments using micromorphology and FTIR. In Zhoukoudian, China, the purported burnt features were found to consist of dark brown and reddish-brown, finely laminated silts and clays interbedded with decayed fragments of organic matter. The sediments were therefore not the result of in situ burning as was previously interpreted based on field observations, but they were instead deposited in standing or slow-flowing water

(Goldberg et al., 2001). In contrast, the Middle Pleistocene cave of Qesem, Israel, contains sediments that appear in the field as a light reddish-brown, strongly lithified, and mostly massive deposit that archaeologists recognize as a common fill of angular rock fragments and matrix called "cave breccia." Based on micromorphological observations as well as mineralogical and isotopic analysis, however, it was discovered that a considerable part of these sediments in fact consist of recrystallized wood ash, indicating the presence of fire in antiquity (Karkanas et al., 2007).

In caves, combustion features can be well preserved, thus offering a clear picture of the burning activities related to them. In Kebara Cave, Israel, field observations and micromorphology revealed a variety of features including massive accumulations and small patches of charcoal and ashes, intact hearth structures, and diffuse ashy lenses. The geometry, composition, and microstructure of each of these types of deposits provided information on specific fire-related activities and events such as dumping, trampling, and cleaning that can place other archaeological materials into the context of a living settlement (Goldberg et al., 2007; Meignen et al., 2007).

In Dust Cave, Alabama, USA, prepared thin clay constructions were identified within Paleo-Indian strata based on field and micromorphological observations. As these features preserved intact lenses of ash, they provided data on fuel, feature type, and function. It was thus suggested that these flat clay structures were used as special heated cooking surfaces for roasting or specialized food processing (Sherwood and Chapman, 2005). Similar structures have been also identified in the Aurignacian sequence of Klissoura Cave 1, Greece. Here, micromorphology corroborated by FTIR and differential thermal analyses (DTA) revealed that the clay structures were heated in place at relatively low temperatures (400–600 °C), implying that they were also used as hearths for special cooking activities (Karkanas et al., 2004).

Study of cave sediments from later periods has offered insights into questions related to the nature of cave occupation, their monofunctional or polyfunctional uses, differences in the exploitation of site space, and the seasonality of occupation (Courty et al., 1991; Boschian and Montagnari-Kokelj, 2000; Angelucci et al., 2009). Several studies have shown that that during the Neolithic, caves were used both for herbivore stabling and for domestic occupation and that different areas within the caves were used for each purpose (Macphail et al., 1997; Karkanas, 2006).

Summary

Caves occupy an important place in archaeology and environmental studies. As unique landforms within the earth, they act as sediment repositories preserving detailed records of human activities and paleoenvironmental changes. Sedimentary sequences within caves comprise not only a suite of primary and secondary clastic sediments but also primary chemical and biogenic sediments, as well as secondary alteration deposits. Human activities add to the complexity of the sedimentary processes by adding organic-rich deposits, combustion features, and the reworking of previously deposited sediments. Despite these complications, detailed sedimentological studies at the microscopic scale supplemented by high-resolution instrumental techniques can untangle these complex processes, offering some of the best opportunities to study early human behavior.

CERAMICS

Charles C. Kolb
Vienna, VA, USA
National Endowment for the Humanities, Washington, DC, USA

Introduction

Ceramics are among the tangible products of human culture that are relatively widespread among societies across the world. The innovation or adoption of ceramic objects provides significant and compelling questions for scholars, and ceramics, especially fragments of pottery called potsherds (sherds or shards), are one of the most common material objects that archaeologists encounter on surveys or excavations of Holocene archaeological sites, particularly over the past six millennia. In materials science, "ceramic" includes any solid made of inorganic compounds combining metallic and nonmetallic elements and generally possessing refractory and nonconducting properties, while "ceramics" in a nontechnical sense include varieties of fired-clay and siliceous bodies, such as earthenwares, stonewares, terra-cottas, china, and porcelain (Rice, 1987, 2015). Ceramic artifacts include many types and classes of object: domestic/utilitarian and ritual pottery containers; cooking, serving, and food storage vessels; figurines, spindle whorls, earspools, lamps, smoking pipes, tokens, medicinal pastilles, female pubic coverings, beehives, coffins, and other objects. The definition also embraces glass, bricks, ovens, architectural decorations (roof and floor tiles, cast sculptural forms), vitreous plumbing fixtures, sewer pipe, and molds (Matson, 1965; Kolb, 1989b, 2001, 2011).

The study of ceramics is a broad, highly diverse topic, and it is the subject of numerous scientific and popular books as well as journal articles. This contribution focuses initially on the relationships of geoarchaeology to clay and ceramic materials, then it summarizes the literature on archaeological ceramics, provides distinctions between ceramics and pottery, and reviews analytical methods used to interpret technological variables.

The importance of ceramic products

Potsherds are likely the most abundant macro-artifacts recovered archaeologically during the later periods of human existence, and in the main, they tend to be preserved almost as well as stone or lithic tools and their debris. Yet, it can be challenging to date ceramic materials accurately, determine their provenance or location of manufacture, and discern their intended original and subsequent uses. Fired and unfired clay figurines, not vessels made of clay, are the oldest known ceramic artifacts attributed to human fabrication; such small sculptures were created over 25,000 years ago in Eastern Europe according to current evidence (Vandiver et al., 1989; Farbstein et al., 2012). Nonetheless, pottery making is one of the oldest crafts known to humankind and was invented independently in different parts of the world, at different times, and within extremely diverse sociopolitical, economic, and ecological settings (Shelach, 2012; Wu et al., 2012). Scientific analysis of ceramic materials can inform us about technological changes that vary across space (synchronic) and through time (diachronic), craft specialization, and sociocultural, behavioral, economic, religious, and ideological roles and relationships within and between human societies. Hence, banal and unassuming ceramic artifacts such as potsherds provide a wealth of scientific and cultural information if the relevant data can be extracted and interpreted.

Geoarchaeology and ceramics

The term "geoarchaeology" was apparently coined by Karl Butzer in 1973, and it was a foundational component of his influential book *Archaeology as Human Ecology* (Butzer, 1982). Davidson and Shackley (1976) provided a traditional approach to the topic, while Waters (1996) documented the foundations of geoarchaeology in North America, emphasizing archaeological site matrices, alluvial environments and fluvial landscapes, glaciers, and cave and rock shelter formation. Rapp and Hill's *Geoarchaeology: The Earth-Science Approach to Archaeological Interpretation* (1998, 2006) was among the first textbooks to offer an integrated approach to geoarchaeology and focused on the direct use of geologic concepts and methods to solve archaeological problems and interpret archaeological records. Goldberg et al. (2001) and Goldberg and Macphail (2006) assessed geology and archaeology and provided case studies. In most other treatises on geoarchaeology, however, ceramics were subsidiary to ecological and site formation processes. A truly earth-science approach focused specifically upon ceramics began earlier, in the 1930s, with geologist Anna O. Shepard's research (1965), which integrated geology and archaeological ceramic data for the American Southwest and Mesoamerica. Scientific approaches to ceramic analysis encompassed a finer examination of the composition of ceramic artifacts and sherds to determine the source of the material and, through this, the possible location of manufacture. Major criteria that were examined included the composition of the clays and tempers (aplastics) used in the fabrication of the artifact being analyzed. Temper is an organic or inorganic material added to the clay during the production stage to achieve a particular quality in the paste (plastic, or malleable, material to be formed into a desired object) such as workability, drying and firing characteristics, and intended use, such as a cooking vessel that would undergo thermal stress.

Sources of information

Potters who fashion objects from clay are faced with technological choices throughout the fabrication process. These choices involve selection of clays and tempers, techniques of raw material preparation, forming methods and equipment, diversities of surface treatment, varieties of graphic and plastic decoration, as well as drying and firing procedures. The choices and selections that a potter makes are limited by environmental parameters, technological options, subsistence and economic factors, sociocultural contexts, political forms, religious and belief systems, as well as individual and group psychological or behavioral variables. These parameters are examined through methodological paradigms of ceramic ecology (Matson, 1965; Arnold, 1985; Rice, 1987, 2015) and the concept of *chaîne opératoire* wherein archaeological finds are understood as products of sequential processes of manufacture, use, and disposal (Scarcella, 2011). Matson's (1965) concept of ceramic ecology emphasizes a holistic assessment of pottery, beginning with the selection of raw materials, the fabrication of products and their distribution, the final uses, modifications, and discards of the ceramic object. The method and theory of ceramic studies has been expanded and enhanced (Arnold, 1985, 1993; Kolb, 1989a, 1997; Rice 1987, 2015) and extended in a revised form into the ethnographic literature through ceramic ethnoarchaeology (Kramer, 1985; Longacre, 1991). The relationships among these factors have been the subject of much discussion in the anthropological and archaeological literature, and they have led to the publication of voluminous numbers of books and journal articles in what is termed archaeological ceramics and ceramic ethnoarchaeology.

A recent examination of the scientific and anthropological periodical literature that focuses on ceramic studies illustrates the major journals that contain articles on the subject. The information (up to 2015) is summarized in Table 1. The publication of reports on ceramic analysis commenced early in the twentieth century with a concern for typology and classification, and the scientific analysis of ceramics began in the 1930s with thin-section petrography (TSP), expanding greatly with the advent of new physicochemical techniques following the development of radiocarbon dating in the late 1950s. Chemical and radiometric analyses of all forms of material culture in the 1970s and 1980s led to the creation of new journals for the publication of analytical results.

The data also indicate that two science-oriented journals, *Archaeometry* and the *Journal of Archaeological Science*, consistently publish contributions on ceramics in each issue, while *Geoarchaeology: An International Journal* reveals surprisingly fewer than might be expected. Other periodicals that occasionally publish ceramic studies include the *Journal of Archaeological Method and Theory* and the *Journal of Field Archaeology*. Relatively few journals are devoted exclusively to ceramic studies; the notable exceptions are the *Journal of Roman Pottery Studies* and the *Leiden Journal of Pottery Studies*. Two primary archaeological journals, the venerable *American Journal of Archaeology* of the American Institute of Archaeology and the British journal *Antiquity*, published a few scientific studies on ceramic materials beginning in the 1950s and more during the past two decades. Periodicals published by professional archaeological societies often contain articles on pottery analysis; these include *American Antiquity* and its newer sister journal, *Latin American Antiquity*, affiliated with the Society for American Archaeology, and the Society for Historical Archaeology's *Historical Archaeology*. The regionally oriented *North American Archaeologist* and *Midcontinental Journal of Archaeology*, as well as *World Archaeology*, occasionally present contributions on ceramic studies. Among other major professional organizations, the American Chemical Society, American Ceramic Society, and Materials Research Society, each have a publication series that focuses on archaeological ceramics.

Ceramics, Table 1 Ceramic studies in the major journals

Journal/publication (dates reviewed)[a]	Volume numbers	Ceramic articles n =
Archaeological and Anthropological Sciences (2009–2015)	1(1)–7(2)	4
Archaeomaterials (1986–1993) [ceased publication]	1(1)–7(3)	26
Archaeometry (1957–2015)	1(1)–57(3)	444
Geoarchaeology: An International Journal (1986–2015)	1(1)–30(3)	64
Journal of Anthropological Archaeology (1981–2015)	1(1)–40	34
Southwestern Journal of Anthropology (1945–1972)	1(1)–28(4)	8
Journal of Anthropological Research (1973–2015)	1(1)–71(2)	25
Journal of Archaeological Method and Theory (1994–2015)	1(1)–22(2)	26
Journal of Archaeological Research (1993–2015)	1(1)–23(2)	8
Journal of Archaeological Science (1974–2015)	1(1)–60	385
Journal of Archaeological Science: Reports (2015)	1–4	8
Journal of Field Archaeology (1974–2015)	1(1)–40(2)	90
Journal of Roman Pottery Studies (1986–2012)[b]	1–15	132
Newsletter of the Department of Pottery Technology		
[Leiden University] (1983–2002)	1–19	94
Leiden Journal of Pottery Studies (2004–2010) [ceased publication]	20–26	57
American Anthropologist (1888–2015)	1(1)–117(2)	33
American Antiquity (1935–2015)	1(1)–80(2)	196
Advances in Archaeological Practice: A Journal of the SAA (2013–2015)	1(1)–3(2)	5
American Journal of Archaeology (1897–2015)	1(1)–119(2)	284
Antiquity (1927–2015)	1(1)–89(345)	59
Bulletin of the American Schools of Oriental Research (1919–2015)	1–373	83
Historical Archaeology (1967–2015)	1–48(1)	86
International Journal of Historical Archaeology (1997–2015)	1(1)–19(2)	20
Latin American Antiquity (1990–2015)	1(1)–26(2)	49
Midcontinental Journal of Archaeology (1975–2015)	1(1)–40(2)	25
North American Archaeologist (1980–2015)	1(1)–36(3)	22
World Archaeology (1970–2014)	1(1)–47(3)	58
American Chemical Society: Advances in Chemistry Series		
Archaeological Chemistry (1974–2007)[b]	8 volumes	39
American Ceramic Society		
Ceramics and Civilization (1985–1998)[b, c]	8 volumes	101
Materials Research Society		
Materials Issues in Art and Archaeology (1988–2014)	10 volumes	115

[a]Data collected through June 2015
[b]Latest issue published
[c]Volume 8 (1998) is on glassmaking (the 16 articles are not included)

While Anna Shepard's *Ceramics for the Archaeologist* (1965) was the foundational handbook, Prudence Rice's *Pottery Analysis: A Sourcebook* (1987, 2015) still remains the most comprehensive volume yet available covering all aspects of ceramic materials, including raw materials, the properties of clays, pottery manufacture and use, and characterization studies.

For a materials science and engineering perspective, Carter and Norton's *Ceramic Materials: Science and Engineering* (2007) is invaluable.

The most recent reviews of the status of archaeological ceramic studies are by Tite (1999) and Kolb (1989b, 2001, 2011). Over the past four decades, there have been three distinct, discernible, but overlapping chronological phases of archaeological ceramic research: (1) an initial phase concerned predominantly with the documentation of variables of pottery manufacture, provenance, and physicochemical characterization; (2) a phase, derived in part from economic anthropology, with particular emphasis on the distribution and consumption of the finished products; and (3) a trend, building on the second phase, toward behavioral analyses and psychological meanings reflecting upon the potters and their products. Through all three phases, there has been a dynamic growth in the application of methods derived from the physical and biological sciences, so that the archaeometric toolkit has expanded dramatically in our ability, for example, to determine provenance and vessel contents. With few exceptions, the literature on archaeological pottery is particularistic, or narrowly focused, rather than holistic in that published reports provide in-depth assessments of production but lack consideration of consumption and distribution, and they rarely concern group or individual behaviors and sociocultural meanings (Lemonnier, 1993). The major compendia on archaeological ceramics consider raw materials selection and preparation, methods of pottery fabrication and surface treatments, and drying and firing procedures (Shepard, 1965; Rye, 1981; Rice, 1987, 2015; Sinopoli, 1991; Orton et al., 1993; Gibson and Woods, 1997; Orton and Hughes, 2013) but provide minimal or no discussion of pottery distribution, consumption, and the ultimate disposition of the artifacts.

There are substantial scientific studies of ceramic materials ranging from general treatments (Lambert, 1997) to handbooks or encyclopedic compendia (Ellis, 2000; Brothwell and Pollard, 2001; Maschner and Chippindale, 2005) and substantive assessments, some now dated (Rice, 1987; Henderson, 2000; Biswas, 2005). Recent volumes designed as an introduction to the breadth of archaeological chemistry include major works by Goffer (2007), Pollard et al. (2007), Pollard and Heron (2008), and Price and Burton (2011); see comparative reviews by Kolb (2009). Velde and Druc (1999) authored *Archaeological Ceramic Materials*, one of the few focusing on ancient ceramics. There are also a number of recently edited volumes on pottery analyses (Druc, 2001; Glascock, 2002; Glowacki and Neff, 2002; Jakes, 2002; Martinón-Torres and Rehren, 2008; Shortland et al., 2009). Rice (1987, 1996a, 1996b, 2015) provides a valuable review of the literature, while Neff's (1992) edited volume contains specific, in-depth views of the applications of a variety of these analyses. Materials science approaches also play a significant role in this phase and include "cautionary tales" about archaeological ceramic research (Bronitsky, 1986; Kolb, 1997). Pottery function is also a trait of this phase (Skibo, 1992, 2013; Rice 1996a) as is specialization and standardization (Rice, 1987, 1996b; Costin, 1991, 2005). Archaeometry and materials science are foci of edited works by Martinón-Torres and Rehren (2008), Quinn (2009), and Shortland et al. (2009).

Clay, ceramics, pottery, and other distinctions

The nature of clay

The distinctions between these terms are drawn primarily from Carter and Norton (2007), Goffer (2007), Pollard and Heron (2008), and Rice (1987). The word "clay" derives from the Old English *clǣġ* ("stiff, sticky earth"), from the Proto-Germanic *klajjaz* or *kli* ("to stick"), and from Proto-Indo-European *glei* ("to glue or stick together") and is ultimately related to the Greek word *gloios* ("sticky matter"), the Latin *glus* and *gluten* ("sticky matter"), and the Old Slavic *glina* ("clay") (Harper, 2015). "Clay" is effectively a generic term referring to a substance that incorporates one or more clay minerals in many combinations with traces of metallic oxides and organic matter. Clay is a naturally occurring material, and its constituent clay minerals are composed predominantly of fine-grained sheet silicates (or phyllosilicates) with grain sizes <2 μm that are chemically classified as hydrous aluminosilicates. All silicate minerals contain silicon and oxygen, and they comprise the largest and most significant class of rock-forming minerals, constituting about 90 % of the Earth's crust. Silicate minerals are classified on the basis of the structure of the silicate group and the strength of the Si–O bond. In the case of clay minerals, the structure is sheet-like, yet the extremely thin sheets several atoms thick break up into very small, submicroscopic crystals.

The introduction of water to a clay body provides sufficient lubrication to impart plasticity, which is defined as the ability of a material to deform under pressure yet maintain the new deformed shape when the pressure is released. As long as the plastic limit is reached for the particular clay mineral or admixture of minerals by the introduction of sufficient water, the platy clay crystals slide by one another and hold the position into which they are forced. Additional water will lower the yield strength, so that less force is required to deform the mass, until the liquid limit is reached and the clay begins to behave as a liquid.

The moisture required to reach the plastic limit and produce a plastic body is referred to as the "water of plasticity." When a clay object has been fashioned and left to dry, this water of plasticity evaporates in large measure, causing the paste to lose its plastic nature and become hard. When fired to a sufficiently high temperature, the crystal structure of the clay minerals making up such a hardened clay object breaks down, and the hydrous component of its mineral composition is driven off. The loss of this "water of crystallization" transforms the formerly clay object into an essentially artificial ceramic one that will no longer return to a plastic state with the addition of water (Rice, 2015).

Unlike stone sources, clay is a complex erosional product of rocks that were subjected to gradual chemical weathering over long periods of time. Because clays are widely distributed, they are relatively easy to find, extract, and process; their abundance also explains why earthenware products are found in nearly every part of the world. Clay deposits are generally made up of tiny clay mineral crystals (plus extraneous fine materials) that settled out of suspension in low-energy bodies of water such as lakes and rivers. Higher-energy flows and internal thermal currents tend to keep clays in suspension.

Clays are differentiated from other fine-grained soil substances based on grain size and mineralogy. Silts are fine-grained materials that do not include clay minerals. They generally have larger particle sizes than clays, but there is some overlap in particle size as well as other physical properties, so many natural deposits can include both silts and clays. Primary clays are located at the site of formation, while secondary clay deposits have been relocated by erosion and possibly lengthy transport by natural processes from their primary location. There are approximately 30 different types of "pure" clay minerals in these categories (Moore and Reynolds, 1997), but most "natural" clay deposits are mixtures of these types, with additions of other weathered minerals (Rice, 2015).

The distinctions between silt and clay and between the different types of clay vary by academic discipline. Geologists and soil scientists consider the separation between clay and silt to occur at a particle size of 2 μm (clays being finer than silts), sedimentologists often use 4–5 μm, and colloid chemists use 1 μm. Materials scientists and geotechnical engineers distinguish between silts and clays based on soil plasticity properties. Categorized by their atomic composition and molecular structure, there are three or four main groups of clays: kaolinite, montmorillonite-smectite, illite, and chlorite. Chlorites are not always considered clay, sometimes being classified as a separate group within the phyllosilicates. Other names for clay sediments exist in common usage. "Kaolin" is sometimes referred to as China clay because it was initially identified in China; "ball clay" is an extremely plastic, fine-grained sedimentary clay, which is largely composed of the clay mineral kaolinite and may contain some organic matter; "bentonite" is a highly plastic clay composed mostly of the clay mineral montmorillonite that absorbs water and is used as a mold binder in the manufacture of sand castings; "fire clay" differs from kaolin in having a slightly higher percentage of fluxes (components that promote melting at lower temperatures than the pure material), is quite plastic, and is highly heat resistant. "Stoneware clay" is fine grained and used to create a ceramic with characteristics lying between fire clay and ball clay and is heat resistant in order to produce the hard and watertight ceramic called stoneware (Rice, 1987; Guggenheim and Martin, 1995; Kolb, 2011; ASTM, 2015). Clays, the raw materials of pottery making, chemical and mineralogical definitions, and the clay/water system are further elaborated by Rice (1987, 2015).

The word "ceramic" comes from the Greek word *κεραμικός*, keramikos ("of pottery" or "for pottery") and from *κέραμος*, keramos ("potter's clay, tile, pottery") (Harper, 2015). It is an "artificial stone" created by humans that combines earth/clay, water, fire, and air – the four basic elements identified by the ancient Greeks. The terms ceramics, pottery, and earthenware are sometimes interchangeable, but although these are all synthetic materials, there are important distinctions and discrete definitions that require explanation. A ceramic is an inorganic, nonmetallic solid prepared by the action of heat and subsequent cooling. Ceramic materials may have a crystalline or partly crystalline structure, or they may be amorphous (e.g., a glass). Because most common ceramics are crystalline, the definition of ceramic is often restricted to inorganic crystalline materials, as opposed to the noncrystalline glasses. Pottery as a generic term includes earthenware, stoneware, and porcelain. ASTM Standard C 242-01: "Standard Terminology of Ceramic Whitewares and Related Products" (ASTM, 2015) defines pottery as "all fired ceramic wares that contain clay when formed, except technical, structural, and refractory products." There are four major types of pottery:

- *Terra-cotta* is a very porous, lightweight pottery developed in Southwest Asia ca. 6000 BP and fired to <850 °C.
- *Earthenware* has a continuous history from the Neolithic period to the present and was made from clays that were fired at temperatures >950 °C in open bonfires or pits. Majolica and faience are glazed earthenwares (Tite and Shortland, 2008).
- *Stoneware* was created beginning as early as the fifteenth century BCE in China, and especially since the seventh century CE, and coincides with the innovation of kilns that could be fired at higher temperatures, 1200–1300 °C.
- *Porcelain* is made from "China clay" and fired at 1300 °C. It was first made in China during the Tang Dynasty (618–906 CE).

"Greenware" refers to unfired objects in a soft and malleable "plastic" form. "Leather-hard" refers to a partially dry, pliable clay body that has approximately 15 % moisture content and represents the ideal stage for trimming and handle attachment. "Bone-dry" refers to clay bodies after glaze or biscuit firing with moisture content near 0 %. "Biscuit" connotes a shaped object that has been fired in the kiln for the first time. "Glost fired" is the final stage when a glaze may be applied.

Ceramic research

Research on ceramics has, in the main, four goals: (1) description and characterization; (2) provenance; (3) ascertaining chronology; and (4) explanation, inference, and/or the testing of hypotheses.

Materials scientists and archaeologists are concerned with research design parameters, such as sampling and analytical or statistical procedures. Likewise, they expend time and effort in characterization studies of the physical properties of pottery (examining color, texture/microstructure, porosity/permeability, luster, density, mechanical and thermal properties), mineralogical composition (using petrography and X-ray diffraction), chemical content (using spectroscopy and microprobe analysis), structural characteristics (using electron microscopy and radiography), and contents and residues (using scanning electron microscopy and varied chemical analyses). Aspects of manufacturing/forming methods include tool use, form/shape analyses, surface modifications and drying, prefired and/or postfired decoration, and firing. Quantification of dimensions, volume, shape, function/use analyses, and contexts/associations is also of great cultural significance. Most archaeologists must work in some way with ceramic relative chronology, as it is essential to chronological control in many archaeological sites, but some specialists are particularly focused upon "absolute" or chronometric techniques of dating (archaeomagnetic, thermoluminescence, and radiocarbon analyses) or the use of varied methods in the authentication of objects.

Description and characterization

The process of pottery manufacture, from obtaining raw materials through firing and uses, is detailed by Rice (1987, 2015) and summarized by Tite (1999). The former author also reviews the important concepts of firing loss rates and fuel consumption and costs. Sheehy (1988) is among the few scholars to have examined clay/fuel ratios from archaeological and ethnoarchaeological perspectives. Vessel forms, technologies, and properties related to fabrication and the identification of use are well documented by Rice (1987), who also has summarized decorative styles and stylistic analyses (see also Cumberpatch and Blinkhorn, 1997). Use alteration, mentioned by Tite (1999), has been detailed by Skibo (2013). An assessment of residue analysis is also provided by Rice (1987) and Skibo (1992, 2013). Organic residue analysis (ORA) involves biomolecular studies, notably employing gas chromatography (GC), gas chromatography-mass spectrometry (GC-MS), and gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) as methods of extraction to evaluate lipids and other residues.

Colors of ceramic materials are normally described in the Munsell Color System (2009); for an historical assessment, see also Nickerson (1976) and Kuehni (2002). Clay identification is sometimes determined by a process of refiring the ceramic and assigning a color to it using Munsell Soil Color notation.

By estimating both the clay and temper compositions, and locating a region where both are known to occur, an assignment of the materials' origin can be made, leading to the identification of potential sites of manufacture. This process is referred to as sourcing, and the location of raw material extraction and/or production of the ceramic object is called its provenance. Mechanical and thermal properties and the mineralogical and chemical characterization of ceramic materials can also be determined (Rapp, 2002; Carter and Norton, 2007; ASTM, 2015). The varied types of physicochemical characterization studies conducted on ceramics have been summarized by Rice (1987, 1996b) and Kolb (2014), while Neff's (1992) edited volume provides specific, in-depth views of the applications of a variety of these analyses. Pottery function and use analyses are added to the bibliography (Skibo 1992, 2013; Rice 1996a), as is specialization and standardization (Rice, 1987, 1996b; Costin, 1991, 2005).

Thin-section studies (TSP: thin-section petrography) in archaeology, also termed optical mineralogy or optical petrography, date to the 1930s with Shepard's research (1965). It is the "classic" approach and, although tedious and time consuming, provides data on specimen compositions that bulk analyses such as INAA cannot provide. There is a voluminous literature (Philpotts, 1989; Humphries, 1992; Glazner et al., 1997; Tite, 1999; Clarke and Eberhardt, 2002; Reedy, 2008; Quinn, 2009). Kolb provides examples of analyses and cautionary tales (1997, 2001, 2008), while Reedy's current research focuses on digital and 3D imaging of ceramic thin sections (2012); radiographic procedures are summarized by Lang and Middleton (2005).

The primary physicochemical methods used in ceramic analysis include:

AAS: atomic absorption spectroscopy – superseded in the last decade by XRF
EPMA: electron probe microanalysis
INAA/NAA: instrumental neutron activation analysis
M/S: Mössbauer (German: Mößbauer) spectroscopy
TSEM: transmission scanning electron microscopy
X-ray milliprobe
X-ray radiography
XRF: X-ray fluorescence

A persistent difficulty within archaeological ceramic analysis is the study of whole assemblages from both a compositional and technological perspective. Existing techniques, such as TSP microscopy, ICP-MS, and INAA, "struggle" to integrate compositional datasets with the textural information that is crucial for reconstructing technological choices. The latter two provide chemical compositions, while TSP shows structural/textural evidence. However, advances in automated scanning electron microscopy with linked energy-dispersive spectrometers (SEM-EDS) create the potential to offer a seamless combination of textural and mineralogical data in which textural information can be accompanied by the acquisition of energy-dispersive elemental spectra. Mineral quantification using QEMSCAN® (quantitative evaluation of minerals by scanning electron microscopy) technology and compositional mapping allows standardized comparison of diverse datasets to address wider issues of social interaction within the ancient world. A typical analysis involves the collection of more than 500,000 individual points on a sample surface. For ceramic materials, this method offers an attractive visual representation of the texture as well as the mineralogical components. The components of the matrix and temper are commonly recognizable, and the analysis can reveal fine structures that are not visible by the naked eye. Automated SEM-EDS refines petrographic descriptions but also provides unique insight into clay mineral composition and clay mixing; mixtures of different clays combined to achieve specific working properties represent a traditionally difficult behavior on the part of potters to identify analytically (Hilditch et al., 2012).

Methods of determining provenance

Provenance studies have been conducted on earthenware, stoneware, protoporcelain, and porcelain, but few chemical studies have directly linked pottery vessels with specific clay sources. Clays may be transported long distances from sources to distant production workshops, making those sources difficult to trace. They may contain naturally occurring organic or inorganic aplastics that were removed prior to use through levigation (the separation of coarse matter by suspending the fine fraction in water), and organic or inorganic materials may be introduced purposefully as temper or unintentionally during the preparation of the clay. Heterogeneous clays from different sources may also be brought together to achieve specific properties and thoroughly mixed during the wedging process wherein air is forced out of the clay prior to forming. The size and complexity of the manufacturing process may vary – from simple contexts such as household production by one potter to larger group efforts by multiple artisans, each responsible for one step in a multiphase process, to the most complicated situations presented by a factory or industrial level of fabrication – and these variations pose challenges to one's ability to define ceramic provenance precisely (Rice, 1987, 2015; Neff, 2002; Goldstein et al., 2003; Pollard and Heron, 2008; Shackley, 2011; Kolb, 2014). The following list of methods that have been used to determine provenance derives from a review of the volumes and journal literature in Table 1. As in physicochemical analyses (discussed above), each method has advantages and disadvantages.

AAS: Atomic absorption spectroscopy: Superseded in the last decade by XRF.
EPMA: Electron probe microanalysis: Similar to SEM which has a higher sensitivity.
FTIR: Fourier transform infrared spectrometry.
GC: Gas chromatography, HT-GC (high-temperature GC), HT-GC-MS (HT-GC with mass spectrometry): Residues on or in ceramics.
ICP-AES: Inductively coupled plasma (spectroscopy)-atomic emission spectroscopy.
INAA/NAA: Instrumental neutron activation analysis.
ICP-MS: Inductively coupled plasma-mass spectroscopy: It is replacing INAA (Speakman and Neff, 2005).
ICP-OES: Inductively coupled plasma-optical emission spectrometry.
LA-ICP-MS: Laser ablation-inductively coupled plasma (spectroscopy)-mass spectrometry, TOF-LA-ICP-MS (time-of-flight LA-ICP-MS).
LC: Liquid chromatography, LC-MS (LC with mass spectrometry): Residues on ceramics.
M/S: Mössbauer (German: Mößbauer) spectroscopy.
OCL: Optical cathodoluminescence.
PIXE/PIGME: Proton-induced X-ray emission/proton-induced gamma ray emission.
R/S: Raman spectroscopy.
SEM: Scanning electron microscopy, SEM-EDS (SEM with energy-dispersive spectrometers), SEM-WDS (SEM with wavelength-dispersive X-ray spectroscopy).
TSP: Thin-section petrography, OM (optical mineralogy), and OP (optical petrography).
XRD: X-ray diffraction.
XRF: X-ray fluorescence, ED-XRF (energy-dispersive-XRF): Portable (or hand-held) X-ray fluorescence (pXRF) spectrometry has become common for the geochemical characterization of ceramics.
XRPD: X-ray powder diffraction.

Methods of ascertaining chronology

Chronology is a fundamental component of scientific and humanistic inquiry. There are two ways to establish chronology: methods of *relative dating* (ascertaining the correct order of the events) and *absolute or chronometric dating* (quantifying the measurement of time in terms of years or other fixed units). Relative dating may be determined from (1) sequence dating through seriation (changes in artifact form, function, or style through time), (2) stratigraphic analysis (geological stratigraphy based upon the "Law of Superposition"), and (3) cross-dating. Chronometric dating may rely upon (1) historic or written records, (2) non-radiometric scientific studies (such as dendrochronology, thermoluminescence, or obsidian hydration dating techniques), (3) radiometric analyses (radiocarbon and uranium series dating, e.g., which rely upon the decay of unstable parent isotopes into stable daughter forms), and (4) biochemical analyses (notably by amino acid racemization). Chronometric dating that assigns specific dates or date ranges in calendar years to artifacts and other archaeological finds is critical to ceramic studies. Most of the chronometric dating methods above do not date ceramics directly; however, they provide an age for other materials that must be recovered in close temporal association with the ceramics. Since the 1950s, radiocarbon dating has been the most significant and commonly employed chronometric method in archaeology, but ceramic materials must be associated with appropriately datable samples in order to be assigned the same age. The analysis of carbonaceous residues adhering to ceramic cooking pots has been used to some advantage.

There are two types of luminescence dating techniques: optical dating (notably optically stimulated luminescence or OSL) used on sediments and thermoluminescence (TL) which can be employed on a variety of burned materials including heat-treated flint, sediments, and pottery. Thermoluminescence is now commonly used in the authentication of old ceramic wares, for which it gives the approximate date of the last firing (Aitken, 1990; Taylor and Aitken, 1997). When a small sample of ancient pottery is heated, it glows with a faint blue light, called thermoluminescence. During its lifetime, the pottery absorbs radiation from its environment as well as internal radiation sources, and this radiation causes an increase in energy within the fabric of the ceramic due to electrons trapped at higher-energy states after having been displaced from their regular atomic orbits by the radiation. The older the pottery, the more radiation it has absorbed, and the brighter the pottery sample glows when reheated in the laboratory. By measuring the TL, it is possible to calculate how much radiation has been absorbed. This information can then be used to compute the approximate age of the pottery.

Rehydroxylation (RHX) dating has been proposed as a new chronometric dating tool for use on archaeological fired-clay ceramics (Wilson et al., 2009, 2014). The technique relies upon the propensity of reheated porous ceramic objects to regain water through a two-stage process (rehydration and RHX), where the kinetics of the second stage have been shown to follow a $(\text{time})^{1/4}$ power law at temperatures of 13–50 °C. RHX is self-calibrating, so the reaction rate adjusts according to differences in firing temperature, mineralogy, and microstructure. An empirical equation accounting for the effects of burial in archaeological sites and temperature history has been developed to describe the observed ceramic's rehydration and RHX behavior. RHX can provide a date of manufacture for archaeological ceramics by measuring the lifetime mass gain. The technique shows great promise, and after additional research, it could become an important archaeometric tool.

Emerging analytical techniques

Close-range digital photogrammetry is applicable to pottery (Matthews, 2008). The technique is used to derive 3D measurements from stereoscopic image overlap and has been shown to have extensive applications (Verhoeven, 2011). Close-range photogrammetry (CRP) refers to the collection of photography from a lesser distance than traditional aerial photogrammetry. It is similar to 3D scanning, in that both techniques are noncontact, fast, and accurate methods for recording objects in three dimensions. Images captured from a distance of 0.5–2 m will have a pixel resolution of 60–250 μm and will potentially produce a 3D model with a point spacing of approximately 0.5–1 mm.

Reflectance transformation imaging (RTI) (Webb and Wachowiak, 2011) is a relatively new method of digital documentation being increasingly utilized as an effective means of object documentation, and it is ideal for ceramic vessels. The process consists of capturing multiple digital images (typically between 40 and 64) of a stationary object from a fixed camera position. For each image captured, the object is illuminated using a single light source at a fixed distance and luminance. Employing a "stack" of images, each with a different but known light position, a per-pixel reflectance function can be mathematically estimated using a method known as polynomial texture mapping (PTM).

Experimental archaeology

Experimental archaeology and ceramic replication (Mathieu, 2002) are well-known methods designed to generate and test hypotheses based upon archaeological source material, the goal being to replicate past processes. The branch has four categories: (1) controlled replication of recovered artifacts or the reconstruction of known activities; (2) testing the validity of methodological assumptions by applying them to known data; (3) contextual experimentation, such as burying modern replicas and/or ecofacts for varying lengths of time to assess postdepositional effects on them; and (4) ceramic ethnographic or ethnoarchaeological data. Closely related is "reverse engineering," exemplified by Vandiver (2005), which links archaeological materials research and conservation science.

Databases

Digital data analysis and the creation of data bases often involve a transition from analog to searchable digital formats (Levy, 2012).

POTSHERD: Atlas of Roman Pottery (Tyers, 2012) is a collection of Web pages on archaeological pottery principally of the Roman period (first century BCE to fifth century CE) in Britain and Western Europe. The database includes an introductory atlas containing descriptions and distribution maps of types of Roman ceramics, lists of wares by class (tablewares, cooking wares, transport amphorae, etc.), and source (Roman province of origin).

The *Pottery Informatics Query Database* (PIQD) (Levy, 2012) provides for the digital preservation and analysis of ceramic collections, including 2D and 3D data. The initial focus is on the Iron Age Levant, 1200–500 BCE.

The *Diyala Database* (Oriental Institute, 2012) has published all archaeological materials from the Diyala Expedition in ancient Mesopotamia (modern Iraq). More than 15,000 artifacts including pottery and cuneiform tablets, as well as archival materials, object registers, field diaries, photographs, site plans, and correspondence were scanned, object descriptions entered into database tables, and new images of artifacts taken at the Oriental Institute Museum were inserted. The searchable Web-accessible database integrates all of these data formats. Employing high-resolution three-dimensional scans (up to 60 µm resolution) may allow many future projects to proceed by manipulating the digital rather than physical versions of ceramic objects.

CERÉN

Payson Sheets
Department of Anthropology, University of Colorado, Boulder, CO, USA

The Cerén archaeological site, sometimes called "Joya de Cerén" in Spanish, was a small Maya village in what is now El Salvador (Sheets, 2006). It was founded by immigrants from the north as part of the recovery from the cataclysmic disaster of the Ilopango volcanic eruption (Dull et al., 2001) that probably occurred in AD 536 (Dull et al., 2010). The immigrants settled on the bank of the Rio Sucio and began farming maize, beans, squash, chiles (Lentz et al., 1996), and manioc (Sheets et al., 2007). About 200 people lived there until a nearby volcanic vent erupted – the Loma Caldera event of ca. AD 660 – and buried it deeply under layers of volcanic ash.

Four households have been at least partially excavated, and each household built three separate structures: a domicile for sleeping and daytime activities, a storehouse (Figure 1), and a kitchen (Sheets, 2006), all built of wattle-and-daub, a highly earthquake-resistant architecture. Each household possessed about 70 complete pottery vessels (Beaudry-Corbett, 2002) and, in order to be agriculturally self-sufficient, grew food in gardens, in corn-bean fields located around the

Cerén, Figure 1 The "bodega" structure at the buried village of Cerén, occupied by Maya after the Ilopango volcanic eruption of ca. AD 536. The building was the storehouse for a family, where pottery vessels, food, clothing, grinding stones, and knives of obsidian were kept. The village was buried by volcanic ash from the nearby Loma Caldera volcanic vent, ca. AD 660, during which alternating layers of white fine-grained and dark coarse ash were deposited. The fine-grained layers were created by steam explosions when the erupting magma came into contact with river water. The steam explosions were violent enough to blast away the water, resulting in a subsequent dry phase that allowed the coarse layers to fall through the air as lapilli and volcanic bombs.

households (Sheets and Woodward, 2002), and in abundant manioc planting beds on sloping terrain outside the village. Each household had a part-time specialization and exchanged what it produced with other households. Such traded items included grinding stones (manos, metates, and perforated mortars), painted gourds, agave plants for fiber to make twine and rope, chilies, and canes to reinforce the walls of their buildings. Each household building had an incense burner to produce copal smoke for communicating with the supernatural domain (Sheets, 2006).

A civic center was established in the center of the village (Gerstle, 2002) consisting of a large plaza with special buildings facing it. In contrast to the household structures, these public buildings were constructed of massive, solid earthen walls. One building suggests an authority function, with two large benches in its front room, probably seats of power for the village elders to make decisions and adjudicate disputes. Another has been only partially excavated, and it is filled with artifacts, including a turtle shell drum. Two others have been detected only with geophysical instruments and await verification and excavation.

A functional-religious building, a sauna, was maintained by Household 2. It was used for physical and spiritual cleansing and curing respiratory ailments (Sheets, 2006).

Two overtly religious buildings were sited at the highest elevation in the area, overlooking the river (Sheets, 2006). Each had multiple floor levels, from the secular outside to the highest innermost room, and each had complex floor and wall plans with white and red painted walls. One was for village ceremonies; a harvest ritual was underway when the volcano erupted. The ritual focused on deer ceremonialism, a powerful symbol of the fertility of nature for the Maya. The other building was erected for a shaman/diviner, who kept collections of minerals and beans inside to help predict the future. As all the gender-associated artifacts left to pay for services rendered were used primarily by women, it appears the diviner was female. People would approach the structure, communicate with her through a lattice window, leave an offering, and proceed to the back to hear the result through another lattice window.

Cerén is a World Heritage site, maintained by UNESCO, the United Nations Educational, Scientific, and Cultural Organization.

CHEMICAL ALTERATION

Panagiotis Karkanas
Ephoreia of Palaeoanthropology & Speleology of Southern Greece, Athens, Greece

Definitions

Authigenic minerals: Minerals forming in situ within sediments.

Chemical equilibrium: The state of a chemical reaction where the concentration of reactants and products is constant.

Cementation: Formation of new minerals that fill the pore spaces within a sediment.

Diagenesis: All of the processes that act to modify sediments after deposition.

Dissolution: Removal in solution of all or part of previously existing mineral.

Oxidation-reduction (redox): All reactions that involve changes in the oxidation number. Some oxidation reactions can be described as the combination of a substance with oxygen.

pH: A measure of the acidity or basicity of an aqueous solution. The mathematical definition of this is the negative decimal logarithm of the concentration of the hydronium cation (H_3O^+) in a solution.

Recrystallization: Change in size or shape of a crystal of a given mineral with no change in its chemical composition or mineralogy.

Saturation: The point at which a solution of a substance can dissolve no more of that substance.

Solubility: The maximum amount of a substance that can dissolve in a solvent.

Introduction

Archaeological sediments are modified after their deposition, and this has potentially serious implications for interpreting the archaeological record. Physical diagenetic modifications such as those of faunal activity (bioturbation) and compaction tend to change the original position of archaeological finds; however, chemical diagenetic modifications are major agents of alteration and destruction, yet they are often less obvious to the naked eye.

All natural environments have particular preservation characteristics. Factors such as climate, activities of organisms, and geomorphic processes play primary roles in regulating these conditions (Retallack, 2001), including the chemical nature of a burial context, which can affect the degree and bias of preservation for many objects contained within a deposit. Environmental changes are directly or indirectly related to human biological and cultural evolution, and thus, chemical alteration in natural sediments and soils is also of major importance for archaeology.

Chemical reactions at normal temperatures are basically simple; the main chemical processes involve solution, hydration, acid attack, and oxidation. In nature, practically all reactions take place simultaneously, and they tend to change the composition of the archaeological deposits, eventually moving incompatible assemblages of materials toward conditions of chemical equilibrium with the burial environment that are more adjusted to the conditions that prevailed in the sediment postdepositionally. Unfortunately, materials of direct archaeological interest can be altered or even completely dissolved. This is particularly important, for it can obscure the critical determination of whether or not the distributions of recovered archaeological materials – such as bones, teeth, plant phytoliths, charcoal, and ash – reflect their original burial distributions or new configurations and forms that came to be as a result of secondary diagenetic processes. Furthermore, chemical reactions in archaeological deposits produce alterations that may distort the original stratigraphic context. They produce volume changes, assimilate layers or create secondary layering, destroy interfaces, and change the original locations of artifacts and the relationships between artifacts. Identifying these processes is crucial if one is to interpret the recorded contexts of human activities within the precise radiometric time scale.

Method strategy

Studying chemical alteration in archaeological sites is not an easy task. It starts in the field with careful observations and stratigraphic analysis and ends in the laboratory where a set of instrumental techniques are employed (XRD, FTIR and micro-FTIR, SEM, EDS, etc.). A detailed description of these methods can be found in the relevant entries of this volume. Different types of sampling are necessary, including point and bulk sampling and removal of intact blocks of sediment for micromorphological analysis (see review in Courty et al., 1989). In most cases, a combination of techniques is used because it is impossible to control simultaneously the context of alteration features at all scales while precisely describing the chemistry of these alterations. Micromorphological analysis is used to define the relation between the different mineralogical features at the microscopic scale. At the same time, instrumental mineralogical techniques are employed to describe the mineralogy and chemistry of the defined features. Nevertheless, the base strategy of all analyses should be to understand the spatial relationships of features covering all scales of observation. This is mainly based on the sequence of disappearance and/or appearance of certain minerals and features in space as crossing alteration zones (Karkanas, 2010). This is the only way to record the sequence of events, define what is missing and what is introduced, and therefore assess the preservation conditions (see discussion below).

Agents of chemical alteration

A fundamental precondition of chemical reactions is the presence of water and/or free oxygen. This is because a fluid medium is needed for transport and exchange of chemical compounds. For example, it would be meaningless to define the acidity or alkalinity (pH) of a material in the absence of water. Free oxygen is important in the decay of all materials containing oxidizable materials, such as iron and organic matter. However, at the surface temperatures of the Earth, oxidation reactions are very slow in the absence of water. The role of water is largely that of a catalyst because it provides a favorable environment for the oxidation reaction to proceed (Krauskopf, 1979, 85). Water is equally important in biochemical reactions because all organisms that degrade organic matter need some water, even as a vapor phase, for their survival (cf. Weiner, 2010, 51). Water that is in contact with sediments carries various amounts of dissolved or particulate material that initiate chemical reactions. The chemical composition of water changes after reaction with the sediment, and therefore, static pore water very quickly attains equilibrium with the sediment; then, it becomes inactive, and no further reaction takes place until the water in the pore space is replaced by new water that has the capability of again reacting with the sediment. It follows that the amount and flow rate of water into sediment pores dictate the rate of chemical reactions. Consequently, highly altered sediment implies that substantial amounts of water have passed through its pore spaces. Note that clay sediments absorb large quantities of water but do not allow the water to pass through, mainly because their pores are not interconnected. It is thus expected that materials of archaeological interest will be better preserved in clay-rich sediment (e.g., Weiner and Bar-Yosef, 1990).

Temperature is also an important factor in speeding up reactions. An increase in temperature of 10 °C can double or triple the reaction rate (Krauskopf, 1979, 8). Therefore, in warm climates, weathering and consequential chemical alteration proceed faster in the presence of water. Hence, soil profiles in areas with tropical climates show deep chemical alteration (Nahon, 1991).

Carbon dioxide readily dissolves in water producing carbonic acid, and the increased acidity of this water makes it a better solvent. All natural waters exposed to air become dilute solutions of carbonic acid, and in the absence of other acid sources, the pH of rainwater is about 5.7. Other dissolved components, such as nitrogen and sulfur, also increase the acidity of water. The significance of these acids is only locally important, however, and in most cases, the acidity of water is due to elevated concentrations of CO_2 released by the decay of organic matter. In the presence of oxygen, soil organisms oxidize organic matter and convert it into carbon dioxide, water, organic acids, and other compounds. Again, an important factor in determining the rate of oxidation of organic matter is the extent of water flow that replenishes oxygen. In the absence of oxygen, anaerobic processes result in the formation of other acidic products (Weiner, 2010).

In summary, the fluid medium and its capacity of reacting with the sediment are what makes reactions proceed beneath the earth's surface. Although this is quite apparent, we tend to forget its implications. The mere existence of an alteration implies some kind of reaction with a fluid possessing certain characteristics, and this information alone already determines something about past environmental conditions.

Major chemical diagenetic processes

The most important chemical processes affecting archaeological deposits are also simple; they include dissolution, recrystallization, authigenesis, cementation, and oxidation.

Dissolution

Dissolution occurs when the solubility of a particular mineral is exceeded under a given set of environmental conditions that are normally defined by pH, oxidation conditions, temperature, and the amount of soluble salts. The stability of the most important carbonate minerals (calcite, aragonite) increases with decreasing temperature. However, the most decisive agent of dissolution of carbonate minerals is pH. Calcite ($CaCO_3$) is stable at pH values above about 8, but it undergoes solution under acidic conditions. Therefore, carbonate materials of archaeological importance, such as calcareous shells, are not stable under acidic conditions.

An important but generally neglected carbonate component of archaeological sites is calcitic ash. During combustion of wood, CaO oxide is formed from the oxidation of calcium oxalate crystals that are commonly found in wood. Upon cooling, the CaO will absorb CO_2 from the atmosphere and react to form $CaCO_3$ in the form of calcite. Due to its fine texture and high porosity, ash readily reacts with acidic rainwater or humic acids in some soils and dissolves. It is obvious that decalcified sediments would not preserve ash or any other calcareous material of archaeological interest; however, if the groundwater equilibrates in calcareous environments, it will become alkaline with a pH close to 8.2, and as a result, further dissolution of calcite will be prevented. This is known as the buffer capacity of calcite. It follows that wood ash will be preserved in sites where calcite is found in large quantities, such as in a limestone (e.g., karstic) environment. Furthermore, in sites possessing large amounts of calcitic ash, the pH of the groundwater will be buffered by the ash even if it is relatively acidic; in this way, much of the archaeologically deposited ash will be preserved (see Weiner, 2010, 77). Of course, this will be dictated by the rate of ash input and generally the sedimentation rate in relation to the rate of water flow (see above). As already stated, degradation of organic matter can also produce acidity, which can reduce the pH of the groundwater leading to ash dissolution. Another environment where ash is often preserved is caves. Caves are formed mainly in carbonate rocks (limestone and dolomite), and therefore, waters flowing within their environment are usually alkaline. Impressive well-preserved ashy sequences are known from several Paleolithic caves, e.g., Kebara Cave (Goldberg et al., 2007).

Dung spherulites are another form of calcium carbonate found in archaeological sites that contain stabling remains. They appear to be formed in the ruminants' gut and consist of microscopic radial masses forming an approximately spherical aggregate (Canti, 1997). They also survive burning and are often found in large quantities in ashed dung. It has been shown experimentally that dung spherulites do not survive in sediments with a pH lower than approximately 7.7 and that they are more soluble than geogenic calcite (Canti, 1999), something that has been also observed in archaeological sediments (e.g., Albert et al., 2008). Conditions of preservation affecting dung spherulites are broadly similar to those of wood ash.

Bone is another material of archaeological interest that can dissolve. The mineral component of bone is a biogenic variant of the phosphate mineral apatite. Berna et al. (2004) were able to show experimentally that bone is stable in sediments with pH above 8.1. In more acidic environments and particularly at pH values below 7, bone will rapidly dissolve depending on the water flow (Hedges and Millard, 1995). Berna et al. (2004) also confirmed that, in the presence of calcite, bone is stable due to the buffering capacity of a calcitic environment – a process that is predictable based on the discussion above and demonstrated already in case studies (Weiner et al., 1993).

Phytoliths are a biogenic form of opal and another primary material of archaeological interest. They are produced by many plants as a siliceous packing deposited within varied anatomical components using hydrous silica taken up through the roots. These mineralized parts of plants are considered relatively stable in most sedimentary environments, and they survive burning or oxidation well. However, opal is a hydrous, amorphous silica polymorph and has a constant solubility of up to 8.5 pH; solubility increases rapidly above pH 9 (Krauskopf, 1979). Therefore, dissolution of phytoliths to fluctuating degrees can be assumed if calcite is present, calcite being an indicator of a generally alkaline environment (Piperno, 1988). Nonetheless, the solubility of amorphous silica and phytoliths is almost an order of magnitude higher than that of the most stable silicate mineral, quartz (Fraysse et al., 2009). As a consequence, the solubility of phytoliths is high enough that they can dissolve in the normal pH range (4–8) of the soil environment, assuming a high rate of water flow through the sediment (Fraysse et al., 2009).

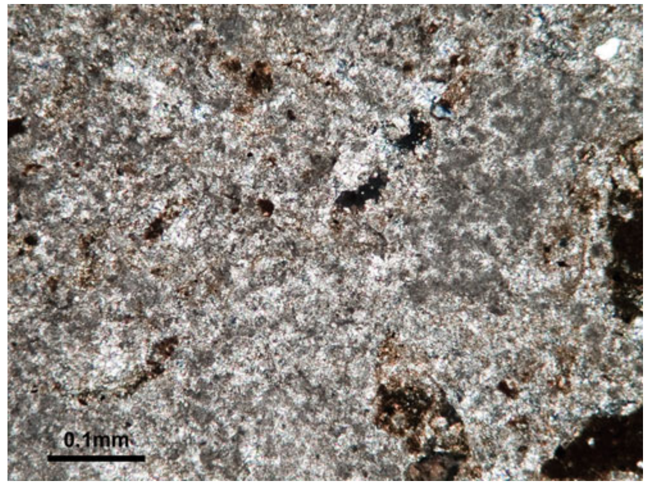
Silica artifacts such as chert and flint are usually composed of micro-quartz with variable amounts of other silica minerals, mainly chalcedony and opal (Luedtke, 1992). Quartz is practically non-soluble below pH 9, but opal and the structurally disordered chalcedony are much more soluble than quartz (Krauskopf, 1979; Sheppard and Pavlish, 1992; Burroni et al., 2002). Therefore, the silica mineral composition of artifacts will determine the dissolution rate, which also depends on the amount of water flow through the sediment. Silica artifacts usually contain mineral impurities that possess different solubilities. In particular, calcite is a frequent minor constituent of chert artifacts. Therefore, dissolution of artifacts is expected to vary not only under different pH regimes but also according to local raw materials (cf. Sheppard and Pavlish, 1992; Burroni et al., 2002). For example, calcite inclusions may dissolve or transform to phosphate minerals (see below).

As already stated in the description of the agents of chemical alteration, it appears that, given sufficient time, the dissolution of several materials of archaeological importance is largely dictated by the amount and flow rate of water. Therefore, not just climatic conditions but also localized hydrological configurations determine the fate of many archaeological materials.

Recrystallization

Recrystallization implies a change from a more soluble to a less soluble substance. Usually, small crystals recrystallize into bigger crystals. Recrystallization is very important in carbonate sediments. In particular, calcitic ash crystals due to their very small size are readily recrystallized to form indurated sediments that resemble natural carbonate rocks (Karkanas et al., 2007). However, the presence of pseudomorphs of the calcium oxalate crystals associated with charcoal or fine charred material can differentiate recrystallized ash from natural geogenic calcite (Figure 1). Furthermore, charcoal, oxidized (burnt) soil aggregates, as well as a close association with burnt bone and other burnt archaeological materials are further indications.

Bone can also recrystallize. After death, crystals of bone mineral continue to grow and increase their size and order. Berna et al. (2004) showed experimentally that buried bone in deposits between pH 8.1 and 7.4 will undergo recrystallization and be replaced by more stable



Chemical Alteration, Figure 1 Photomicrograph of light gray sparitic calcite replacing dark gray micritic aggregates in a sample from Qesem Cave, Israel. Some of the micritic aggregates reveal the remnant rhombic shapes of the original ash crystals (especially in the *upper right* quarter of the image). *PPL* plane polarized light.

forms of apatite. This is a significant observation because it shows that bone becomes more stable with time and that it attains greater stability when authigenic apatite is forming in the sediments (see below).

Authigenesis and cementation

Precipitation of new minerals into pore spaces results in cementation of the sediment and production of an indurated deposit that will eventually become rock. Cementation differs from recrystallization in that it refers to the formation of new minerals (authigenesis) inside the sediment. Each mineral forms under a specific set of conditions, and hence, its presence is indicative of the conditions that prevailed at the time of formation. Thus, the formation of an authigenic mineral can be regarded as the product resulting from changes in specific environmental parameters. These parameters define the stability field of the authigenic mineral under consideration.

Waters that are saturated with bicarbonate will precipitate calcite with the release of carbonate gas and water, but different forms will result depending on the mechanism of precipitation and the local environmental conditions. Direct evaporation will bring about saturation of the solution and precipitation when the solubility is exceeded. Release of carbonate gas (degassing) will also lead to supersaturation and precipitation of calcite, and this process is more common in the formation of cave speleothems. Percolating waters rich in carbon dioxide deriving from the soil enter the cave interior through fissures in the rock. These waters will equilibrate with the new cave environment, which is relatively depleted in carbon dioxide; under such conditions, carbon dioxide will be lost from solution through degassing, and dissolved carbonate will precipitate as a solid mineral (Gillieson, 1996, 116–120). Dripping, seeping, or flowing water on the surface of caves produces a variety of forms known as stalactites, stalagmites, flowstones, and others named according to their morphologies (Hill and Forti, 1997). Due to their incremental development, speleothems are proving to be the best records of the history of climate in an area. The isotopic analysis of oxygen and carbon in the calcite of each lamina or ring reveals the chemistry of waters that precipitated it, and this in turn reveals something about the climatic and local environmental conditions that produced these waters (Ford, 1997). The same waters percolating within the cave sediment will also precipitate calcite, thereby cementing the sediments and producing a hard rock known as cave breccia. Often, cave breccias seal and preserve bones dating to millions of years ago, like the famous caves within the Cradle of Humankind in South Africa, where important early hominin fossils have been found (e.g., Pickering and Kramer, 2010).

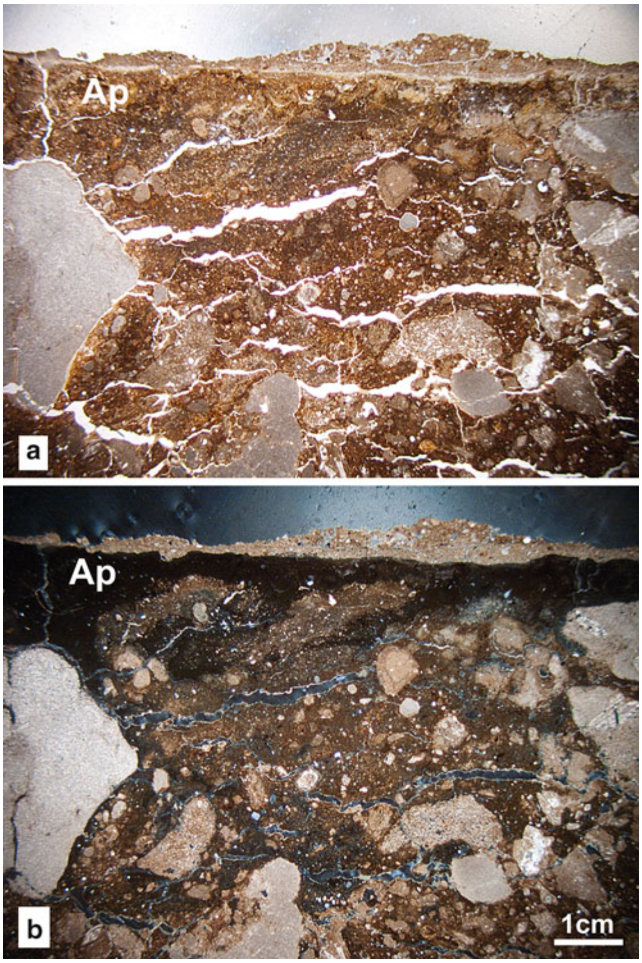
In soil environments, biological activity is an additional factor that controls the precipitation of carbonates. Root evapotranspiration is another mechanism that removes water from solution. Evapotranspiration is considered to be a major cause of rhizocretion (calcified root) formation (Wright and Tucker, 1991). Organic processes regulate the carbon dioxide budget in soils but also induce carbonate precipitation by direct uptake of CO_2 or other mechanisms that trigger its precipitation. Nevertheless, evaporation, evapotranspiration, and probably degassing are climatically controlled, and numerous studies suggest that calcareous soils are formed in arid to subhumid environments (e.g., Zhou and Chafetz, 2009). The isotopic profiles of calcitic nodules that formed in well-developed calcareous soils (calcrete or caliche) have also been used to reconstruct ancient environments. The carbon isotopic composition of pedogenic carbonate is related to the soil CO_2, which in turn is correlated with the proportion of plants employing C3 and C4 photosynthetic pathways. The carbon isotopic composition of plants reflects the climate and the environment in which they grow and is, therefore, a powerful tool in paleoecological reconstruction. This information has been used to estimate rates of erosion, alluviation, and archaeological site preservation potentials (Nordt, 2001) as well as explain the context of human subsistence and evolution, (e.g., Cerling et al., 2011).

Authigenic gypsum is frequently reported in archaeological sites. It is related to the degradation of organic matter (Shahack-Gross et al., 2004; Cabanes and Albert, 2011) and is also found in areas with stabling remains and dry conditions (Figure 2). In the initial stages of degradation, sulfate accumulates due to microbial activity. Increased acidity and sulfate concentration favor the formation of gypsum at the expense of calcite (Donner and Lynn, 1989). An interesting observation is the hydration of anhydrite ash ($CaSO_4$) to produce gypsum ($CaSO_4 \cdot 2H_2O$). Anhydrite is formed during the burning of gypsum-bearing plants such as tamarisk (Shahack-Gross and Finkelstein, 2008).

Chemical Alteration, Figure 2 Banded concentration of gypsum nodules (indicated by an *arrow*) in the historical deposits of Drakaina Rockshelter, Greece. The association of gypsum with dung spherulites identified microscopically suggests that the cave was used as a pen.

Formation of gypsum in soil environments is also favored by the presence of organic matter at high pH (Poch et al., 2010, and references therein). However, most soil gypsum formations are found in well-drained soils under dry conditions. Soil parent material and aeolian dust are the most important factors in gypsum distribution. Gypsum is more soluble than the carbonates, and therefore, gypsic horizons normally do not coexist with calcic horizons (Amit et al., 2011). When gypsum is found in calcrete profiles, its distribution is a useful guide to soil hydrology and precipitation (<250 mm/year).

Degradation of organic matter also releases chemical compounds such as phosphates. In all occupational sites, anthropogenic inputs of human waste and organic residues add phosphates to the sediment in the form of animal stabling, manuring, fertilizing, and privy accumulations (Goldberg and Macphail, 2006; Karkanas and Goldberg, 2010). The major source of phosphate, however, is not directly the original vegetal remains but their reprocessed, phosphate-rich contributions derived from animal excrements (e.g., horses, cattle, goats, and sheep; see, e.g., Macphail et al., 2004). Human activities related to preparation of animal food or processed foods such as oil and fat are probably additional contributors after their degradation (Figure 3). As phosphate is relatively insoluble, it tends to remain in the area where it was originally deposited. Depending on the pH and the availability of other chemical elements, a variety of authigenic phosphate minerals can be formed. In alkaline environments and in the presence of calcium, the calcium phosphate mineral apatite is formed; bone mineral is a variant of the same mineral. In more acidic environments, i.e., at a pH below



Chemical Alteration, Figure 3 Photomicrograph of apatite (*Ap*) (confirmed by FTIR: Karkanas and Stratouli, 2008) altering the surface of a lime floor in a sample from Drakaina Rockshelter, Greece. In PPL (**a**), apatite is *yellowish*. In XPL, or crossed polarized light (**b**), apatite shows optically isotropic behavior and becomes *dark*, blocking transmitted light.

ca. 7, apatite is transformed into a series of complex aluminum-rich phosphate minerals (Karkanas et al., 2000). Obviously, bone is not stable in such environments. Authigenic phosphates can be formed in large amounts and eventually cement the sediment (Figure 4). This has often been observed in caves where the existence of substantial deposits of bat guano provides the necessary phosphorus for the reactions to take place (Shahack-Gross et al., 2004).

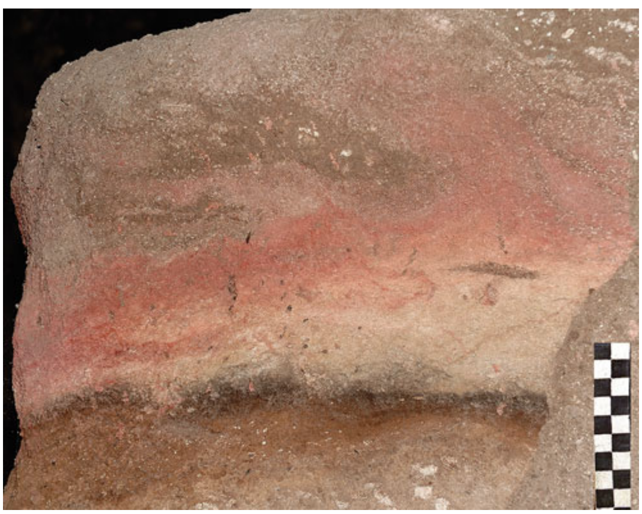
In the presence of phosphorus, calcareous materials are not stable and are readily transformed to phosphates. The reaction is one of dissolution and precipitation; hence, a new mineral is formed. Authigenic apatite can replace calcitic ash and calcareous shells, and it can alter limestone to the point where it is no longer recognizable. Phosphate-rich solutions from the degradation of food products have also been reported to alter lime floors and form apatite alteration surfaces (Figure 3) (Karkanas and Stratouli, 2008; Regev et al., 2010). In the case of ash, the general structure of the burnt layer, i.e., ashes overlying an organic/charcoal-rich or fire-reddened substrate, can still be recognized after alteration to apatite. As phosphate reactions proceed, these apatite formations are also transformed to aluminum-rich phosphates.

Oxidation

Among the products of chemical alteration, iron oxides are the most conspicuous because of their bright colors. Iron oxides that formed in contact with air are in an oxidative state (ferric iron). The color of the simple oxides, such as hematite, is red and that of the hydrates, such as goethite, is yellow to brown. Iron-rich minerals in a reduced state (ferrous iron), such as siderite, have a gray color, and a variety of authigenic ferrous iron-rich clays show green and gray colors. Indeed, the rank of hues in the Munsell soil color chart follows this trend. That is, colors in reducing waterlogged environments are bluish or greenish to olive yellow (hues of PB, BG, G, GY, and 10Y–5Y); aerated, slightly oxidized sediments are yellowish to reddish brown (hues of 2.5Y–2.5YR); and fully oxidized sediments are red (hue of R). Oxidation reactions are mainly observed in well-drained soils and in warm climates with contrasting wet and dry seasons (Courty et al., 1989, 165–167). Therefore, iron-containing authigenic minerals can, in principle, be used to reconstruct past oxidation conditions. It is important to note here that reddening can be produced by high temperatures associated with human activities such as fireplaces and other pyrotechnological processes; however, it has been observed that that fire reddening always affects the substrate of the burning feature and that certain microscopic features differentiate it from pedological processes (see Courty et al., 1989, 169).

Many of the primary constituents of the sediments that are most important archaeologically consist of organic matter (pollen, charcoal, and other botanical remains), and they may be destroyed under oxidizing conditions. The oxidation of organic matter produces reducing conditions because oxygen is consumed by the reaction. Iron oxides are very insoluble under oxidation conditions, but when very little or no oxygen is present, they will readily dissolve. Dissolved reduced iron will diffuse away until it encounters oxygen. It will then reoxidize, and in so doing, it will again become insoluble and precipitate as ferric iron oxides such as hematite (Figure 5). Thus, an observation that iron oxide minerals have been redistributed is an indication of past reducing conditions. This, in turn, can be used to suggest that organic matter was initially present but it decayed postdepositionally. Oxidation over long periods of time has been found to affect buried charcoal, and this has serious implications for radiocarbon dating (Cohen-Ofri et al., 2006).

Chemical Alteration, Figure 4 Phosphate cementing fissures (*white-filled crevices*) produced by freeze-thaw activity in Theopetra Cave, Greece.



Chemical Alteration, Figure 5 Bright red, hematite-rich sediments above oxidized burnt remains from Theopetra Cave, Greece.

Similar conditions have been observed for the precipitation of manganese oxides in archaeological sites (Marín Arroyo et al., 2008). Manganese is released during the decomposition of organic matter accumulated by anthropogenic activities. Then, pH increase leads to manganese precipitation in insoluble oxidative forms. Black coloring and encrustations on bones are often the result of this process (Shahack-Gross et al., 1997).

The oxidation conditions of sediments favor the formation of several other iron-rich minerals as well. In waterlogged sediments, vivianite, an iron-rich phosphate mineral, is formed under reducing conditions. These occurrences have been related to the degrading of human and animal waste (Bertran and Raynal, 1991; Gebhardt and Langohr, 1999; McGowan and Prangnell, 2006).

Apparently, oxidation and reduction reactions in archaeological sites are directly related to the breakdown of organic matter, and since most anthropogenic activities result in the accumulation of organic matter, minerals that are favored by these conditions will be preferably formed.

Broader archaeological implications

As discussed above, the study of chemical alterations in geoarchaeological contexts can provide valuable information for paleoenvironmental reconstruction and for assessing the integrity of the archaeological record. Knowing the mineral that was replaced as well as the mineral that replaced it allows us also to reconstruct the trends in changing paleoenvironmental conditions. This, in turn, can be used to determine whether the archaeological materials of interest were likely to have been stable under such assumed preexisting conditions – providing that we know the nature of their stability (how they react) under these conditions. Retallack (2001) has constructed a diagram with the theoretical Eh-pH stability fields of common kinds of terrestrial fossils preserved in paleosols. For example, based on phosphate mineral stabilities, we can predict when bone mineral can be expected to be preserved in the archaeological record. As already discussed above, the formation of authigenic apatite in sediments is not accompanied by bone dissolution. Therefore, the phosphate source of newly formed apatite cannot be the bones themselves. Bone will be unstable in a chemical environment in which the mineral apatite is not stable. Accordingly, an indication of the instability of apatite will

Chemical Alteration, Figure 6 Dissolution of ash in a pit at the Kolona Bronze Age site, Aegina Island, Greece, has resulted in considerable subsidence and disruption of the continuation of the burnt layer that was covering the pit. *White pins* mark the burnt layer and its original surface at the *left*, *red pins* mark the outline of the pit, and *yellow pins* mark the burnt layer covering the pit where it now lies approximately 20 cm below its former level.

be the presence within sediments of aluminum-rich phosphate minerals, which are more stable than apatite (Karkanas et al., 2000; Karkanas, 2010).

Chemical reactions also involve changes in volume. During the transformation of one mineral type to another, volume can increase or decrease depending upon the specific transformation. The more important volume change is, however, due to loss of material during the dissolution stage. This is most pronounced in the case of wood ash (Figure 6), which on average contains about 98 vol.% calcite, which is soluble in normal rainwater. If all the calcite is lost, the volume decrease could be 50 times (Karkanas et al., 2000). However, dissolution of mineral phases may not necessarily result in a volume change, but only in an increase in porosity. Volume changes due to diagenesis affect calculations of the density of bones as well as lithic and pottery artifact distributions within the archaeological deposit, a measure that is often used to assess "intensity" of occupation.

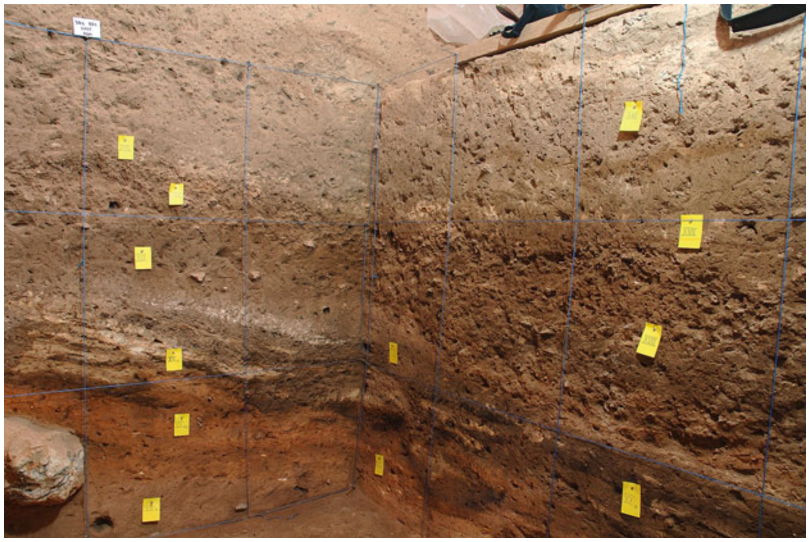
Volume changes are also accompanied by changes in the mineral assemblages. The differing assemblages, in turn, have different contents of the elements uranium, thorium, and potassium, which are the major sources of the radiation that affects dating by thermoluminescence and electron spin resonance (Mercier et al., 1995).

Chemical alteration can be also used to define major stratigraphic changes. Dissolution is not likely to be uniform over the whole sedimentary layer; thinning can occur in some areas and not in others. Therefore, differential dissolution can produce changes in the inclination of the layers. Such changes produce unconformities inside the archaeological sequence, which can translate into considerable time gaps before the new layers that are not affected by diagenesis are deposited horizontally (Figure 7). Nevertheless, even in cases where considerable volume changes are not involved or dissolution is uniform, direct contact between altered and unaltered sediments or sediments showing different chemical alterations often imply major changes in paleoenvironmental conditions (e.g., Goldberg and Berna, 2010). The reasons for this change could involve climate, occupational intensity, site abandonment, or local changes in the landscape.

Most of the impressive alteration features in archaeology have been described from cave sequences. Caves were used preferentially during prehistory, and being perfect sedimentary traps, they preserve long occupational sequences. They are also characterized by an active but confined hydrologic regime and accumulation of large amounts of organic matter, usually in the form of bat and other types of guano or dung from animals that were penned within the cave. Therefore, diagenesis is often very aggressive with obvious consequences for the preservation of archaeological materials. However, more recent and open-air sites also show alteration features, such as volume changes in tell sediments (Albert et al., 2008), authigenic phosphate minerals in medieval sites (Bertran and Raynal, 1991; Gebhardt and Langohr, 1999), and bone alteration features associated with food processing in open-air environments (Simpson et al., 2000). Unfortunately, the lack of systematic studies in such sites enhances the bias in favor of caves.

Summary

Chemical alteration affects the bulk of the sediments that contain materials of archaeological importance.



Chemical Alteration, Figure 7 Photograph of a strongly inclined altered ash layer at the *bottom* overlain by subhorizontal deposits (*left side* section) at Klissoura Cave 1, Greece.

Understanding the chemical processes responsible for these alterations will usually facilitate an assessment of the completeness of archaeological record. Materials of direct or indirect archaeological importance recrystallize or completely dissolve and oxidize, thereby seriously affecting the recoverable evidence and subsequent interpretation of past human activities. Newly formed minerals or minerals that remain stable under changing chemical conditions can be used to deduce prior states of preservation. Moreover, cementation, dissolution, and oxidation processes are environmentally controlled and therefore can be used to reconstruct ancient environments.

Definition

In earth science, chronostratigraphy defines rock strata by their temporal relations, reconciling stratigraphy with relative and chronometric dating in the historical discipline of geology. Relative dating by stratigraphic correlations, employing bio-, magneto-, or isotope-stratigraphy, provides a relative time scale between specific events in the geologic record. Thus, chronostratigraphic unit definitions are based on age relations, which are referred to on a relative linear time scale and preferably fixed in time by chronometric (often wrongly termed *absolute*) dating. With some differences in scale and evidence, chronostratigraphy is also applied to cultural material left by humans.

Chronostratigraphy

In the original geological definition, the temporal sequence of rock strata in more than one *lithostratigraphy* provides the framework for the interpretation of geological history, together with relative or chronometric age determinations. Lithostratigraphy refers to sequences of lithological units (see Figure 1). In archaeology, the "rock strata" are instead layers containing cultural remains, which are assumed to represent meaningful entities, often referred to as cultures, cultural traditions, cultural facies, industries, etc. (Clark, 1991). While the geological use of chronostratigraphy is aimed at validating synchronicity and sequences in worldwide systems, the term is only regionally applicable in archaeology because human cultural entities are not worldwide in extent. However, if contemporaneous cultural units from different regions are regarded as facies, it is possible to construct chronostratigraphies on a coarse scale. Even though chronostratigraphies of human cultural history can also be event based, the recognizable results of events are neither as universal nor contemporaneous as they can be in geology, where such events are especially exploited in the construction of chronostratigraphies.

In either case, the scale in time and/or space determines the validity (and construction) of any given chronostratigraphy, because geological and archaeological phenomena operate at different scales (Dean, 1993). The scales are mainly dictated by the nature of the record; they vary with time but are also different between disciplines (Stein, 1993), especially in archaeology, where change over time can be rapid (Blackwell and Schwarcz, 1993). Chronostratigraphies should be based on several independent lines of evidence for time sequences, such as the use of various relative stratigraphies (e.g., lithostratigraphic, magnetic, or biological) combined with chronometric age estimates developed through multiple dating techniques. Lithostratigraphic and biostratigraphic units can have diachronous or time-transgressive boundaries – i.e., variable lower starting points and upper ending points – but chronostratigraphic units always (by definition) have synchronous boundaries – i.e., start and end points are globally coeval (Holliday, 1993).

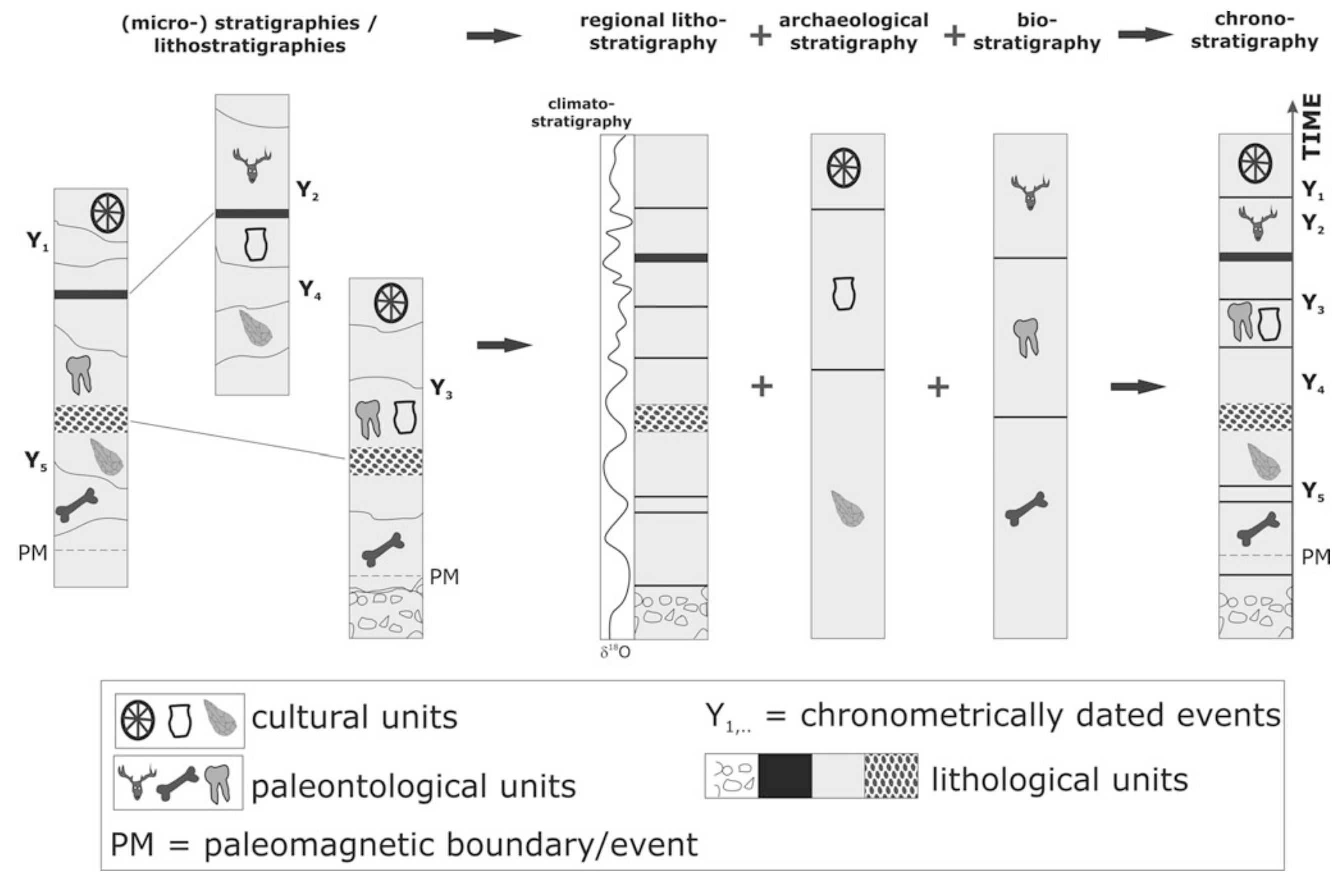
Geological chronostratigraphy

Geological chronostratigraphy is based on lithostratigraphies (Figure 1), and in contrast to archaeology, they are formalized and aimed toward global applicability (Miall, 2010). Global Boundary Stratotype Sections and Points (GSSP) are defined through internationally agreed upon stratigraphic sections or marker horizons, which are governed by international bodies (see http://www.stratigraphy.org and Remane, 1997, 2003). Such boundaries on the geologic time scale are based on paleontological changes (*biostratigraphy* as in the relative sequences of bone –tooth – antler in Figure 1), isotopic marker horizons (as in *climatostratigraphy*), or magnetic events (as in *paleomagnetic dating*), which can be traced over large geographical areas (Rey and Galeotti, 2008). The base of a chronostratigraphic unit is identified in a certain stratigraphic section, while the end of that unit is defined as the base of the following chronostratigraphic unit, which can be defined from evidence in a different section at some distance from the first. Such units are isochronous bodies that are bound by synchronous surfaces and formed during a single span of time (Cremeens and Hart, 1995).

Specific chronostratigraphies, like isotope chronostratigraphy (*climostratigraphy*; Baskaran, 2011; Bowen, 2011), *biostratigraphy* (Palombo and Sardella, 2007), or magneto-chronostratigraphy/*paleomagnetic dating* (Opdyke and Channell, 1996), refer to the construction of a time series using one specific method (i.e., analysis of isotopic chemistry, biota, or magnetism) to provide relative age information.

Archaeological chronostratigraphy

Chronostratigraphy in archaeology follows the same general principles as in geology (Lyman and O'Brien, 2000), but it is less strict and less formalized, given the impossibility of a worldwide application because human culture is so diverse, and there is great potential for large time gaps and sparseness of available data. *Archaeological stratigraphies* are constructed from the time series provided by their own lithostratigraphies, in which specific features related to cultural remains (like stone tools, ceramics, etc.), or the typological/technological compositions of the cultural remains, are repeatedly observed in strata within stratigraphies. Such entities are defined and assumed to represent meaningful units of human cultural history in space and time (cultural traditions, cultural facies, industries, horizon style, etc.), reflecting normative



Chronostratigraphy, Figure 1 Schematic representation of the construction of chronostratigraphies. The cultural units for archaeological stratigraphies are represented by hand axes, pots, and wheels; the lithological units are depicted as having different signatures (bones, teeth, and antlers) representing biostratigraphical units. Chronometric age estimates are marked by "Y" (based on specific dating methods) and paleomagnetic events by "PM." A regional lithostratigraphy is first constructed on the basis of the lithological units combined with climatostratigaphy ($\delta^{18}O$ curve). By combining the archaeological and biological stratigraphies, together with chronometric ages and the paleomagnetic event, a chronostratigraphy is established, which serves archaeology, geology, and paleontology.

ideas and mental templates of extinct people (Clark, 1991). An unspecified number of archaeological assemblages showing more or less identical patterns are necessary to define such a cultural unit, which is understood to demonstrate the shared behavior reflected by a human society and, thus, a socioeconomically meaningful unit (as represented by the hand axe, pot, and wheel in Figure 1). However, any chronostratigraphic marker or event concept in geology is widespread, whereas the definitions of specific features/items of cultural remains are often based on typology (chronotypology after Clark, 1991), which can be quite localized and of limited regional extent.

The resulting cultural units provide the basic relative stratigraphic framework (e.g., the relative sequence of hand axe–pot–wheel in Figure 1), similar to *lithostratigraphy* and *biostratigraphy* (e.g., the relative sequence of bone–tooth–antler in Figure 1), sometimes sharing the type fossil (O'Brien and Lyman, 1999) or the assemblage (Clarke and Chapman, 1978) approach with paleontology. By incorporation of other relative (paleomagnetic event "PM" in Figure 1), as well as chronometric data (Y in Figure 1), chronostratigraphies are constructed on variable scales in time and geography. Linking the archaeological remains of formerly occupied sites to the paleoclimatic record ($\delta^{18}O$ curve in Figure 1) allows more precise age estimates than would be obtainable by many chronometric dating methods, subsequently increasing the precision of the chronostratigraphies.

The resulting regional archaeological chronostratigraphies can overlap and do not necessarily correspond in time, number, or definition of units. Furthermore, archaeological chronostratigraphic units are sometimes blurred by imprecise definitions and by circular logic, e.g., when the supposed age, not the actual cultural remains themselves, is used as an argument for the attribution of an archaeological assemblage to a cultural unit. Archaeological chronostratigraphic units (sometime called phases) can have boundaries coincident with the bases of geological ones, or they can overlap. Obviously, geological and archaeological chronostratigraphic units do not have to correspond, especially as the relationship of cultural remains and geological/sedimentological processes are not always clearly defined. Such specificities like pedostratigraphy and related chronostratigraphies, especially with reference to archaeology, are discussed in detail in Cremeens and Hart (1995).

CLIMATOSTRATIGRAPHY

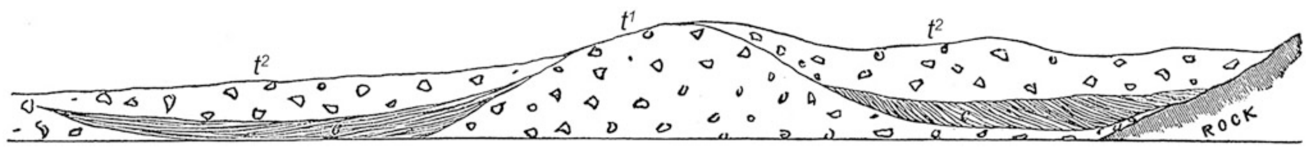
Philip L. Gibbard
Cambridge Quaternary, Department of Geography, University of Cambridge, Cambridge, UK

Definition and introduction

That part of geological time most germane in archaeology, the Quaternary Period, has long been subdivided on the basis of represented climatic changes. The overriding influence of climatic change on geological processes in the Quaternary has meant that climate-based classification (referred to as climatostratigraphy or climostratigraphy) has remained central to the subdivision of the succession. This entry discusses the role of climatostratigraphy (geologic-climate classification) and its relation to chronostratigraphy for the division of the Quaternary sequence.

Climatostratigraphy ("climostratigraphy")

Since the middle of the nineteenth century, Quaternary sediment sequences, and therefore the chronology of human activity and evolution, have traditionally been divided on the basis of the climatic changes they represent, particularly sequences based on glacial deposits in central Europe and mid-latitude North America. This approach was adopted by early workers for terrestrial sequences because it seemed logical to divide glacial diamicton (unconsolidated, poorly sorted sediments) and non-glacial deposits found in stratigraphic sequences into *glacial* (*glaciation*) and *interglacial* periods, respectively (cf. West, 1968, 1977; Bowen, 1978). In other words, the divisions were fundamentally lithological (Figure 1). The overriding influence of climatic change on sedimentation and erosion during the Quaternary has meant that, despite the enormous advances in knowledge during the



Climatostratigraphy, Figure 1 Fossiliferous sand deposits (shown by diagonal cross hatching) between tills (shown by angular symbols) exposed in the Cowden Burn railway cutting at Neilston in Renfrewshire, Scotland, reproduced from Geikie (1874, Figure 27).

last 150 years, climate-based classification has remained central to the subdivision of the succession. Indeed, the subdivision of the modern isotope (e.g., Railsback et al., 2015) stage sequence of ocean sediments is itself based on the same basic concept (e.g., Railsback et al. 2015). It is this approach which has brought Quaternary geology so far, but at the same time, it causes considerable confusion to workers attempting to correlate sequences from enormously differing geographical, and thus environmental, settings. This is because of the great complexity of climatic change and the very variable effects these changes impose upon natural systems, including humans.

The recognition of past climatic events based on environmental indicators within sediments is an inferential method and by no means straightforward. Sediments are not unambiguous indicators of contemporaneous climate, so that other evidence – such as fossil assemblages, characteristic sedimentary structures (including periglacial structures) or textures, soil development, etc. – must be relied upon wherever possible to determine the origin and climatic affinities of a particular unit. Local and regional variability of climate complicates this approach because particular sequences are always the result of local climatic and environmental conditions, yet there remains the need and desire to equate them to a global scale. For at least the first half of the twentieth century, the preferred scale was that developed for the Alps at the turn of the twentieth century by Penck and Brückner (1909) (Table 1).

Since the mid-twentieth century, a comparable scheme developed in northern Europe has been dominant, at least in Europe, but similar schemes have also been established elsewhere, such as in North America or the former USSR. More recently, these schemes have tended to be replaced by the marine- or ice-core oxygen isotope records. Today, the burden of correlation lies in equating local, highly fragmentary, yet high-resolution terrestrial and shallow marine sediment records on the one hand, with the potentially continuous, yet comparatively lower resolution isotope sequence from oceanic sediments on the other (cf. Gibbard and van Kolfschoten, 2005).

Terminology

Before the impact of the ocean-core isotope sequences, an attempt was made to formalize the climate-based stratigraphic terminology in the American Code of

Climatostratigraphy, Table 1 The Alpine sequence in increasing age, as proposed by Penck and Brückner (1909), with later additions from Doppler et al. (2011). Transition dates provided where they are known

Stratigraphic Nomenclature (American Commission on Stratigraphic Nomenclature, 1961), where the so-called geologic-climate units were proposed. Here, a geologic-climate unit was based on an inferred widespread climatic episode defined from a subdivision of Quaternary rocks. Several synonyms for this category of unit have been suggested, the most recent being climatostratigraphical units (Mangerud et al., 1974) in which an hierarchy of terms is proposed. In subsequent stratigraphic codes, however (see Hedberg, 1976; North American Commission on Stratigraphic Nomenclature, 1983; Salvador, 1994), the climatostratigraphic approach has been discontinued since it was considered that for most of the geological column, "inferences regarding climate are subjective and too tenuous a basis for the definition of formal geologic units" (North American Commission on Stratigraphic Nomenclature, 1983, 849). This view has not found favor with Quaternary scientists, however, since it is difficult to envisage a scheme of stratigraphic subdivision for recent earth history that does not specifically acknowledge the climate change factor (Lowe and Walker, 1997). Accordingly, Quaternary stratigraphic sequences continue to be divided into geologic-climatic units based on proxy climatic indicators, and hence, following this approach, the Pleistocene-Holocene boundary (the base of the Holocene series/epoch), for example, is defined on the basis of the inferred climatic record (cf. below). Boundaries between geologic-climate units were placed at the transitions between those the stratigraphic units on which they were based.

The American Code (1961) defines the fundamental units of the geologic-climate classification as follows:

A *glaciation* is a climatic episode during which extensive glaciers developed, attained a maximum extent, and receded. A *stadial* ("stade") is a climatic episode, representing a subdivision of a glaciation, during which a secondary advance of glaciers took place. An *interstadial* ("interstade") is a climatic episode within a glaciation during which a secondary recession or standstill of glaciers took place.

An *interglacial* ("interglaciation") is an episode during which the climate was incompatible with the wide extent of glaciers that characterize a glaciation.

In Europe, following the work of Jessen and Milthers (1928), it is customary to use the terms interglacial and interstadial to define characteristic types of non-glacial climatic conditions indicated by vegetational changes. Interglacial describes a temperate period with a climatic optimum at least as warm as the present interglacial (Holocene, Flandrian: see below) in the same region, and interstadial describes a period that was either too short or too cold to allow the development of temperate deciduous forest or the equivalent of interglacial type in the same region (West, 1977, 1984).

In North America, mainly in the USA, the term *interglaciation* is occasionally used for interglacial (cf. American Code, 1961). Likewise, the terms *stade* and *interstade* may be used instead of stadial and interstadial, respectively (cf. American Code, 1961). The origin of these terms is not certain, but the latter almost certainly derive from the French language word *stade* (m), which is unfortunate since in French, *stade* means (chronostratigraphical) stage (cf. Michel et al., 1997), e.g., *stade isotopique marin* = marine isotope stage.

It will be readily apparent that, although in longstanding usage, the glacially based terms are very difficult to apply outside glaciated regions. Moreover, as Suggate and West (1969) recognized, the term glaciation or glacial is particularly inappropriate since modern knowledge indicates that cold rather than glacial climates have tended to characterize the periods intervening between interglacial events over most of the earth. They therefore proposed that the term "cold" stage (chronostratigraphy) be adopted for "glacial" or "glaciation." Likewise, they proposed the use of the term "warm" or "temperate" stage for interglacial, both being based on regional stratotypes. Lüttig (1965) also recognized this problem and attempted to avoid the glacial connotations by proposing the terms *cryomer* and *thermomer* for cold and warm periods, respectively. These terms have found little acceptance, however. The local nature of these definitions indicates that they cannot necessarily be used inclusively over great distances or between different climatic provinces (Suggate and West, 1969; Suggate, 1974; West, 1977, 1984) or indeed across the terrestrial/marine facies boundary (see below). In addition, it is worth noting that the subdivision into glacial and interglacial is mainly applied to the Middle and Late Pleistocene (i.e., the last 0.78 Ma).

Boundaries

Perhaps the biggest problem with climate-based nomenclature is where the boundaries should be drawn. Ideally, they should be placed at the climate change, but since the events are recognized only through the responses they initiate in depositional or biological systems, a compromise must be agreed upon. As Bowen (1978) emphasizes, there are many places at which boundaries could be drawn, but in principle, they are generally placed at midpoints between temperature maxima and minima, e.g., in ocean-sediment sequences. This positioning is arbitrary but is necessary because of the complexity of climatic changes. Problems may arise, however, when attempts are made to determine the chronological relationship of boundaries drawn in sequences that possess differing temporal resolution, show different sediment facies, or originate through the use of differing proxies. By contrast, in temperate northwest Europe, the base of an interglacial or interstadial is very precisely defined. It is placed at the point where herb-dominated (cold climate) vegetation is replaced by forest. The top (i.e., the base of the subsequent glaciation or cold stage) is drawn where the reversal occurs (Jessen and Milthers, 1928; Turner and West, 1968). It is unclear, however, how this relates to the timing of the actual climate change recorded, or how this is recorded by other proxies.

Climatostratigraphic units are not chronostratigraphic units

By the second half of the twentieth century, it was realized that Quaternary time should be subdivided as far as possible in keeping with the rest of the geological column – using time, or chronostratigraphy, as the basic criterion (e.g., van der Vlerk, 1959; Gibbard and West, 2000). Because stages are the fundamental working units in chronostratigraphy, they are considered appropriate in scope and rank for practical intraregional classification (Hedberg, 1976). However, the definition of chronostratigraphical units at the status of stage, with their time-parallel boundaries placed in continuous successions wherever possible, is a serious challenge especially in terrestrial Quaternary climate-dominated sequences. In these situations, boundaries in a region may be time parallel, but over greater distances, problems may arise as a result of diachroneity. It is probably correct to say that only in continuous sequences which span entire interglacial-glacial-interglacial climatic cycles can an unequivocal basis for the establishment of stage events using climatic criteria be truly successfully achieved. There are the additional problems which accompany such a definition of a stage, including the question of diachroneity of climate changes themselves and the detectable responses to those changes.

For example, it is well known that there are various "lag" times of geological, biological, and human responses to climatic stimuli. Thus, in short, climate-based units cannot be the direct equivalents of chronostratigraphical units because of the time-transgressive nature of the former. This distinction of a stage in a terrestrial sequence from that in a marine sequence should be remembered when correlation is attempted.

In general practice today, these climatic subdivisions have been used interchangeably with chronostratigraphical stages by the majority of workers. While this approach, which gives rise to alternating "cold" and "warm" or "temperate" stages, has been advocated for 50 years, there remains considerable confusion about the precise distinction between the schemes, particularly among non-geologists. In Europe, many of the terms in current use, perhaps surprisingly, do not have defined boundary or unit stratotypes. This problem has been recognized, and steps are now being taken to define units formally through the work of the INQUA Subcommission on European Quaternary Stratigraphy (SEQS). Many fail to see the need for this, however, especially those who rely on geochronology, particularly radiocarbon, for correlation. For example, despite repeated attempts to propose a GSSP boundary stratotype for the base of the Holocene Series – i.e., the Pleistocene-Holocene (Weichselian-"Flandrian") boundary (Olausson, 1982) – in the past, only recently has a universally acceptable boundary been defined (Walker et al., 2008).

Nomenclatural complexities

As already stated, the situation is more confused in languages other than English. For example, in German the terms *glazial* and *interglazial* are used as equivalents to the English stage. Such an approach, on the face of it, seems expedient until one considers certain stages that have been correctly, formally defined in the Middle and Early Pleistocene of the Netherlands, which are commonly used throughout Europe. Here the Bavelian Stage includes two interglacials and two glacials; likewise the Tiglian Stage comprises at least three interglacials and two glacials (de Jong, 1988; Zagwijn, 1992). Each of these interglacials is comparable in their characteristics to the last interglacial or Eemian, which is a discrete stage, which is also defined in the Netherlands. In these cases, workers have fallen back on the noncommittal term *complex*. One example is the Saalian of Germany, originally defined as a glaciation. This chronostratigraphical stage includes at least one interglacial and potentially a second, as currently defined (Litt and Turner, 1993). Attempts to circumvent the nomenclatural problem by defining a "Saalian Complex" are a fudge at best but one that is occasioned by linguistic and long-term historical precedent, as much as by geological needs.

Global correlation

The original intention was that "cold" or "warm" or "temperate" stages should represent the first-rank climate oscillations recognized in the geological record, although it has since been realized that some, if not all, are internally complex. Subdivision of these stages into substages or zones was to be based, in the case of temperate stages, on biostratigraphy, and in the case of cold stages principally on lithostratigraphy and or pedostratigraphy. Within the range of radiocarbon dating (ca. 30 ka), the most satisfactory form of subdivision is frequently that based on radiocarbon years (cf. Shotton and West, 1969); however, high-resolution investigations, such as the ice-core investigations, have allowed the recognition of ever more climatic oscillations of decreasing intensity or wavelength within the first-rank time divisions. These events are stretching the ability of the stratigraphical terminology to cope with the escalating numbers of names they generate. Terms such as "event," "oscillation," or "phase" are currently in use to refer to short or small-scale climatic events (often referred to as "sub-Milankovitch oscillations"). Clear hierarchical patterns are becoming blurred, but perhaps this should be seen as a positive development since the system must reflect the need to classify events that are recognized. Moreover, as our ability to resolve increasingly smaller-scale oscillations improves, a more detailed nomenclature will inevitably emerge. One possible approach is to avoid attempted chronostratigraphical classification in favor of an event scheme based on the recognition of "diachronic units" (e.g., Curry et al., 2011) or event stratigraphy, but in practice this differs little from that based on climate.

Therefore, for many geologists and archaeologists, chrono- and climatostratigraphical terminology are interchangeable. Although realistically, this situation is clearly unsatisfactory because of the imprecision that it may bring to interregional and ultimately to global correlation, it is likely to continue for the foreseeable future. The long-term goal should be to clarify the situation by continuing to develop a formally defined, chronostratigraphically based system that is fully compatible with the rest of the geological column, supported by reliable geochronology.

Definition

Within at least the last 70,000 years of human history, coasts have been favored increasingly as places for people to settle, typically in order to take advantage of coastal foods, as well as places from which to interact readily with other human groups (Bailey and Parkington, 1988). Long-standing claims that coasts stimulated the development of agriculture by allowing *Homo sapiens* a unique opportunity to domesticate plants (Sauer, 1962; Binford, 1968) remain credible. Yet it is also apparent that "many of the world's coastlines that have the most productive environmental conditions for heavy dependence on marine and intertidal resources . . . were only colonised by human populations relatively recently" (Bailey, 2004, 41). Coastal food exploitation was so important to some societies that it came to define them (Szabó and Amesbury, 2011; Jew et al., 2013), whereas for others it was less important, something that might feature in societal subsistence only during periods when preferred options were unavailable (Holdaway et al., 2002; Cleuziou and Tosi, 2007).

Food was only one reason why humans have been attracted to coasts throughout the past 100,000 years. The relative ease of movement along coastal strips, where intervening barriers like mountain ranges are less common than in inland areas, meant that the main movements of many early human groups were along continental coasts (Davidson, 2013). Later, as maritime networks became important for trade, coasts were increasingly settled, a major factor in explaining the subsequent concentration of people in coastal cities (von Glasow et al., 2013).

Owing to their location at the nexus of the lithosphere, hydrosphere, and atmosphere, coasts are among the most changeable of Earth's landscapes and have long posed unique challenges to people who sought to locate their permanent settlements there. Foremost among these challenges are changes to coastal landforms and (food-producing) ecosystems resulting from changes, typically gradual, in the level of the land-sea interface caused by relative sea-level change. More localized changes may result from abrupt tectonic change, the impacts of large waves, and by changes in coastal topography as might be driven by the development of offshore reefs or by changes in process regime such as nearshore sedimentation.

It is important on one hand to understand that coastal settings occupied by humans were and still are invariably dynamic, yet it is also important to appreciate that the present is not necessarily a helpful guide to the past. The processes that control the form of a modern coastline are not always those that existed in the past. Further, many ancient coastal occupation sites are now often far from the modern shoreline, perhaps inland or underwater, emphasizing the susceptibility of coasts to change.

This entry looks first at the most common coastal settings occupied by humans, describing examples from different parts of the world, before discussing the coevolution of coastal environments and coastal societies, illustrating the complexities of this with various examples. Finally there is discussion of several key issues in the contemporary understanding of coastal settings for past human activities.

Common coastal settings

Coastal peoples of the past occupied the full range of coastal settings, but in most parts of the world, they favored a few that – at least at the time of their initial occupation – maximized livelihood opportunities, particularly for subsistence. This means that there are few cliff-top or hinterland locations that were intentionally selected in preference to adjacent coastal lowlands. Exceptions are found on high cliffed oceanic islands such as Rurutu (French Polynesia) and many of those in the Marianas Archipelago (northwest Pacific), either because of the difficulties of occupying the shoreline or because of the impoverished resources it contained compared to elsewhere (Weisler et al., 2010; Amesbury, 2013). Three of the most common coastal settings that became sites for permanent human settlement in almost every part of the world are coastal plains, river mouths, and islands, each of which is discussed separately below.

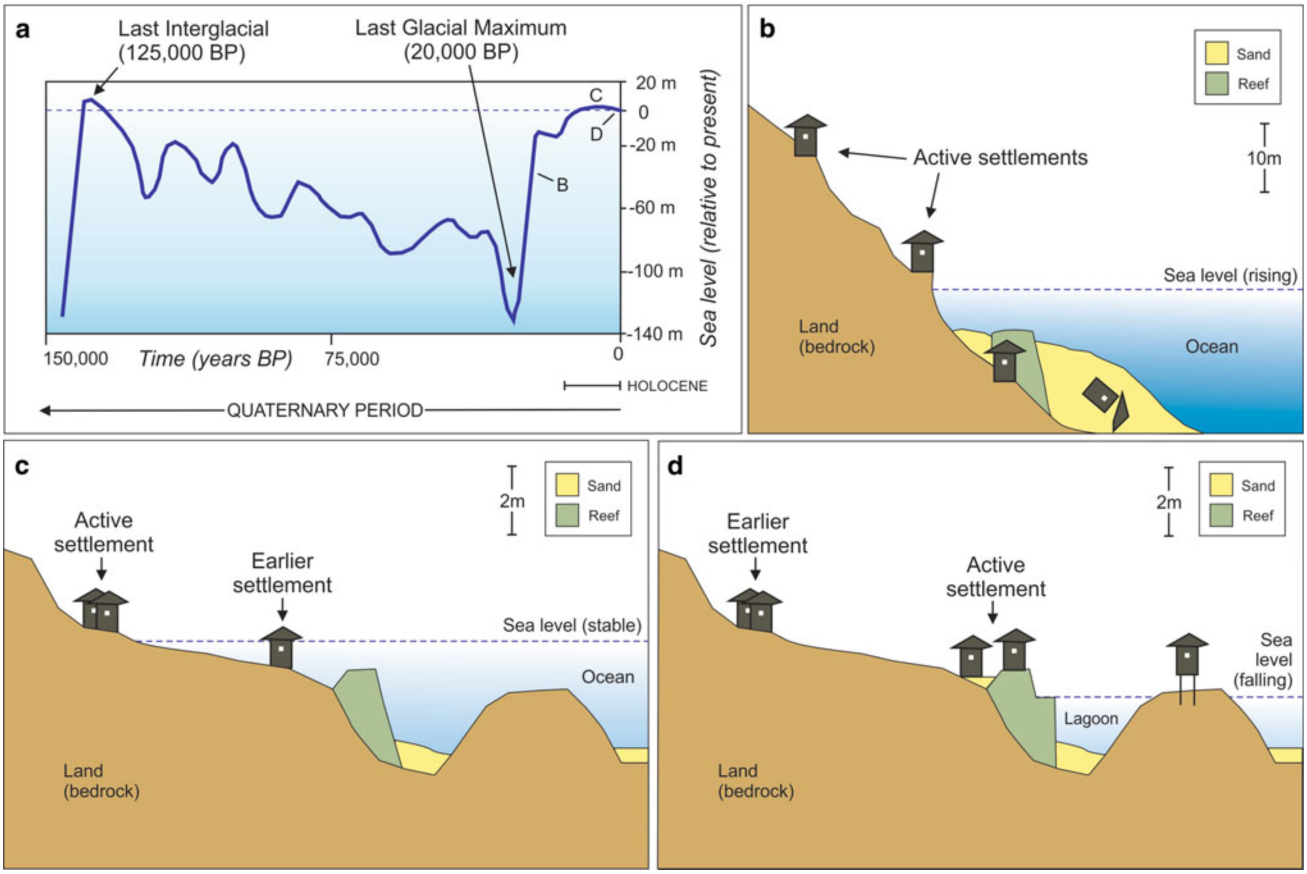
Coastal plains

Varying in breadth from perhaps a few tens of meters, as often found around the fringes of high oceanic islands, to several hundred kilometers, such as were available for human use along many continental margins during the low sea levels of the last glacial period, coastal plains have long attracted humans much as they do today. It can be demonstrated that, at times when population densities were comparatively low, human interest in such coastal plains was proportional to the width of the plain (Lowery et al., 2012).

Human uses of coastal plains more than 4–5 ka ago are invariably difficult to reconstruct because the original environments have disappeared as a result of coastal changes linked to regular (glacial-eustatic) sea-level fluctuations that have characterized the past 2–3 Ma (Figure 1). For this reason, it is challenging to understand, for example, the nature of Pleistocene human occupation on the Australian (Sahul) coastal shelf (O'Connell and Allen, 2012) and that of Doggerland, which linked Britain to continental Europe more than 10,000 years ago (Gaffney et al., 2009).

In many places today, coastal plains represent features created only after sea level fell from its mid-Holocene maximum at 4–6 ka BP (typically 1–2 m above present; see Figure 1d); for this reason, they are found today along most parts of the world's coastline after having become available for human settlement only in the later Holocene (i.e., after 4000 years BP). For example, it has been argued that the initial colonization of the tropical Pacific Islands was controlled by regionally variable sea-level fall in the late Holocene (Dickinson, 2003). More commonly, coastal plains, or at least their younger parts, were occupied progressively as sea level fell during the late Holocene. Haifa Bay and the Zevulun Valley Plain in the eastern Mediterranean exemplify this situation (Porat et al., 2008). As these coastal plains grew seaward with gradual sea-level decline, they were sometimes extended by the accumulation along the coast of sediments derived both from land and shallow offshore (underwater) shelves, particularly those on which (coral-) reef-fringed lagoons had developed. The interplay of erosion and sedimentation accounts for many of the variations in coastal landscapes found along coastal plains. Human manipulation of coastal landscapes sometimes produced unanticipated effects. Examples include the harbors constructed by trading peoples along the coasts of the Mediterranean and Red Sea that subsequently started to infill and, despite ingenious attempts to prevent this, invariably fell into disuse with often profound societal consequences (Marriner and Morhange, 2007; Hein et al., 2011).

Landscape elements of coastal plains are numerous, but those that appear key for most settlers in such settings include sheltered sites, on straight coasts typically behind dunes/berms, beach ridges, or around the fringes of coastal lagoons and wetlands. Examples of back-dune occupations may be found in Fiji and Oman, where they were established by many seasonally transient groups (Anderson et al., 2006; Cavulli and Scaruffi, 2013), and coastal-lagoon occupations were a critical step in the emergence of modern societies along the northeastern New Guinea coast (Terrell, 2002). Occupation sites in



Coastal Settings, Figure 1 Coastal settings influenced by late Quaternary sea-level change. Note that tectonic stability is assumed. (**a**) Global sea-level changes within the last 150,000 years (After Nunn, 1999). (**b**) Coastal environments during the early Holocene at a time of rapid sea-level rise (see (**a**) for timing). Many coasts at this time would have been steep with fewer possibilities for settlement than today. Note the drowned settlements, both buried by sediment and overgrown by reef and those that have been fragmented and dispersed. (**c**) Coastal environments during the middle Holocene at a time when sea level had stabilized at a level 1–2 m higher than today (see (**a**) for timing) resulting in the development of coastal plains and other types of attractive settings for humans. Note how settlements have moved landward as sea level rose toward its maximum and how reefs – along most tropical coasts – have not yet reached the ocean surface. (**d**) Coastal environments during the late Holocene when sea level had fallen to near its present level (see (**a**) for timing) extending low coastal settings seaward and even creating new lands for settlement offshore. Along tropical coasts, some reefs emerged and were used for settlement, while other reefs grew laterally, creating unique ecosystems.

coastal wetlands were generally situated at higher locations where crops might be cultivated to supplement foods obtained from surrounding areas. Lakes were important components of many wetlands. One example is Šventoji (western Lithuania), where the role of late Holocene sea-level oscillations is clear in transforming coastal environments and influencing human lifeways, particularly through the successive creation and infilling of coastal lagoons (Stančikaitė et al., 2009).

Along embayed coasts, it was possible for humans to live directly on the shore in places sheltered from dominant winds and waves. The founder settlement in the Tonga archipelago (southwest Pacific) at Nukuleka was located in the lee of a sand spit at the entrance to the Fanga 'Uta lagoon on the leeward side of Tongatapu Island (Burley and Dickinson, 2001). Spatial and temporal variations in human occupations along the coasts of the sinuous Limfjord (Denmark) were regulated by various physical factors, including salinity and sedimentation (Lewis et al., 2013).

Where a particular coast is fringed by an offshore reef, which reduces the size of waves reaching the shore, shelter was a less important concern, and early settlers sometimes even built stilt-house settlements over shallow water. For example, the use of such settlements is a defining feature of early Lapita colonizers in the southwest Pacific (Green, 2003).

River mouths

River mouths are attractive to humans because of the access both to inland areas and freshwater resources, as well as many coastal resources. Well-documented examples of river-mouth cultures include those around the estuaries of the Irrawaddy (Myanmar), Sông Hồng or Red River (Vietnam), as well as many smaller ones (Stark, 2006). River mouths are often more dynamic environments than coastal plains or most parts of islands, requiring more frequent adjustments by their occupants. A study of archaeological sites at the mouth of the Santa River (Peru) was one of the first to show the dynamic nature of settlement patterns in such places (Wells, 1992: see Figure 4).

Highly valued for their fertile, well-watered soils as well as ready access to aquatic food resources, river deltas are highly dynamic river-mouth environments, and their coastal fringes especially so. Some of the most profound changes have involved abrupt shifts in river mouths that forced changes in the locations of human activities in the past, leading in some cases to migrations and cultural shifts. Examples come from the Huanghe (Yellow) and Yangtze River deltas in coastal China (Chen et al., 2008) and from the Danube Delta in southeastern Europe (Romanescu, 2013). Deltas are especially prone to flooding, yet there are several studies showing how people in the past continued to utilize these areas during wetter periods. An example comes from the Sông Hồng, or Red River, Delta (Vietnam) (Funabiki et al., 2012).

In the past few centuries or more, the dynamics of environmental changes in deltas elsewhere have been so marked that delta cities, well known in antiquity, have proved controversial to rediscover. A good example is Vineta, which was considered to be "the greatest of all cities in Europe" by the traveler Ibrahim Ibn Yaqub in AD 970; it was probably located on a marshy island in the Oder River Delta (Poland) (Brysac, 2003). The city of Herakleion in the Nile Delta (Egypt) likewise disappeared into the realm of myth for several centuries after its abandonment in the first century AD following river-channel shifts and subsidence (Stanley et al., 2004).

Outgrowth of river deltas – a result of both sea-level fall and (accelerated) terrestrial sediment delivery to river mouths – has led to the creation of new areas for coastal settlement that grew in importance in many places. The progradation of the Grijalva Delta (Mexico) witnessed the embryonic emergence of maize cultivation in Mesoamerica, as the first farmers in the region occupied its fertile fringes (Pope et al., 2001).

Islands

Smaller islands may be effectively coastal in their entirety (or very nearly so), and they often exhibit the full range of coastal settings found along the fringes of larger landmasses. Yet on such islands, owing to a lack of large rivers, coasts may feature less dynamic, more resource-rich ecosystems of the kind that perhaps drove, or at least sustained, the successive eastward colonization of tropical Pacific islands (Kennett et al., 2006). At population densities below carrying capacity, islands provided attractive environments for potential settlers because of this resource richness, but also perhaps because their restricted areas made them easier to manage than more diverse landmasses. For example, critical to traditional food production in prehistoric Hawaii was the *ahupua'a* system that involved the vertical integrated management of food systems from the highland island centers downslope, across the coast, and into the deep ocean (Kagawa and Vitousek, 2012).

Yet precisely because of their circumscribed nature, such islands were also susceptible to abandonment by prehistoric populations when resources were no longer sufficient to sustain them. Illustrations of this include the Line Islands (central Pacific) and the Pitcairn Island group (southeast Pacific), both of which were abandoned several hundred years ago (Weisler, 1996; Di Piazza and Pearthree, 2001).

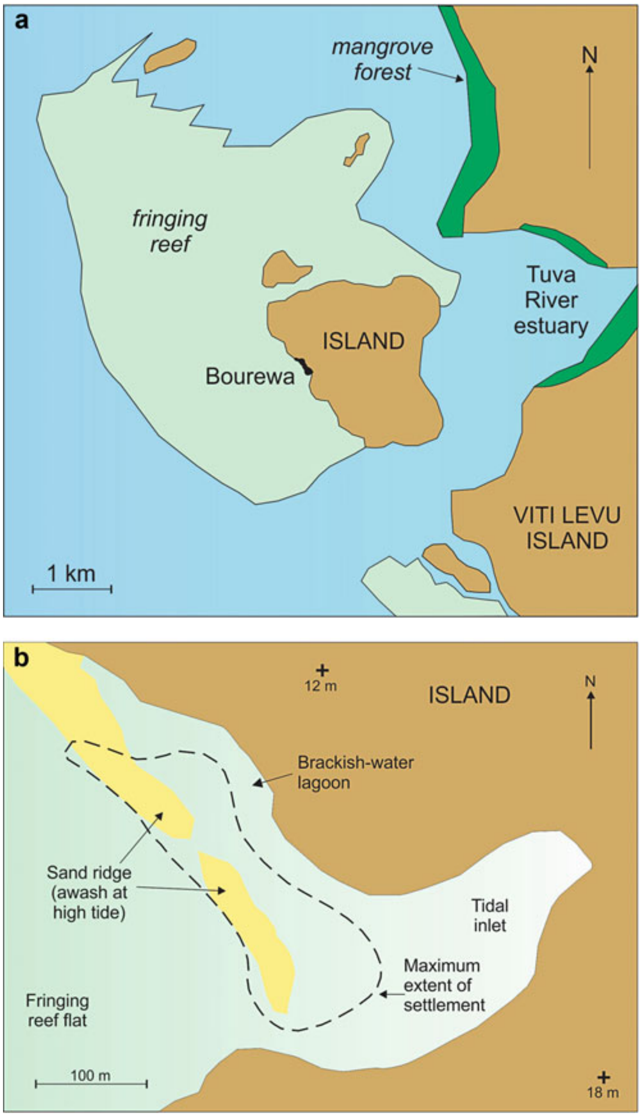
Coastal settings on islands vary largely according to the composition and form of the island in question. Older volcanic islands tend to have irregular coasts with numerous indentations marking drowned river valleys, while younger volcanic islands may have more regular coasts. There is no tradition of coastal settlement along the "iron-bound" (fringed by young, hard lava rock) coasts of young Savai'i Island (Samoa), for example. Most limestone islands are similar, and many of those that have emerged recently possess comparatively little coastal lowland. One example is Niue Island (central Pacific), where most settlement is along a 23-m-high cliff-top terrace (Nunn and Britton, 2004).

There is evidence that the earliest occupants of islands in the southwest Pacific targeted smaller islands intentionally (Specht, 2007), perhaps because these islands tended to be surrounded by more pristine reefs (Figure 2a). Within such islands, the earliest sites were often built on stilt houses across shallow-water flats, which became dry land as sea level fell and as the middens below the houses gradually built upward (Kirch, 2001). One such occupation in Fiji occurred on a sand spit separating a brackish coastal lagoon from a fringing reef flat (Figure 2b).

Atolls are types of low (wholly coastal) island that, in parts of the northwest Pacific, have been occupied continuously for around 2000 years. Their restricted terrestrial biota meant that subsistence was dominated by food acquisition within shallow-water reefs and lagoons, although this came to be supplemented by novel techniques of onshore production (Kayanne et al., 2011).

Changing coastal settings and their effects on coastal societies

As coastal environments were transformed by climate-driven (especially sea-level) and tectonic changes, their



Coastal Settings, Figure 2 Occupation of island fringes illustrated by the (Lapita-age) Bourewa settlement, perhaps the earliest in the Fiji archipelago (southwest Pacific) (After Nunn, 2009a). (**a**) The Lapita peoples were the first to colonize most island coasts in the southwest Pacific. Their earliest settlements were commonly on smaller islands lying off the coast of larger ones, as is the case with Bourewa that was located on an island which is now, owing to sea-level fall, part of the larger Viti Levu Island. It is thought that smaller islands were favored by Lapita people because of their often broad reef flats from which ample foods could be readily obtained. (**b**) The original settlement at Bourewa was a series of stilt-house complexes built over water along the axis of a sand ridge. As sea level fell, this sand ridge emerged to create a partial barrier between the fringing reef on the southwest and a brackish lagoon on the northwest, both environments of which were exploited by the Lapita settlers here.

human occupants were often forced to adapt. Yet humans sometimes altered the coastal landscapes they inhabited, and these modifications often brought about unanticipated responses that also required adaptation.

In earlier societies, adaptation commonly required refocusing subsistence strategies, particularly as food-producing ecosystems changed. In more recent times, owing to the greater potential impacts of humans, it is often more difficult to separate the anthropogenic effects from environmental changes driven by natural causes (see below). The present section illustrates these points by looking at the parallel evolution of coastal environments and societies during specific periods of prehistory. Since the potential for tectonic disruption of coastal sites is not time dependent in the way that climate-driven changes have invariably been, coastal sites affected by tectonism are considered in a separate section.

Pleistocene times (>10,000 years ago)

Some of the first forays out of Africa by *Homo sapiens* may have intentionally followed coastal routes because of the availability of coastal resources (Bailey, 2009). A particular case in point is the southern dispersal route that early humans are thought to have taken from Africa to Southeast Asia (Field et al., 2007), which may have initially involved crossing the Red Sea at a time when sea level was lower and the Bab al-Mandab Straits were relatively easy to cross (Bailey et al., 2007). At such times, presently arid coasts like those of the Farasan Islands and mainland Arabia may have received more rainfall than today, permitting contemporary occupation of a number of coastal settings. There are indications that early humans in this area also targeted nearshore marine resources; some giant clam species show signs of having been overharvested here as much as 125,000 years ago (Richter et al., 2008).

Implicit in the crossing of the Wallace Line from Sunda to Sahul (Southeast Asia to Australia) perhaps 60,000 years ago is a familiarity with tropical coasts that included a degree of maritime technology sufficient to permit the successful crossing of ocean gaps as much as 70 km wide. Most likely, the sites occupied by such humans were on coastal plains fringed by broad reefs or around river mouths where coastal inhabitants depended largely on intertidal and reef-flat food resources but also pelagic resources (Balme, 2013). It is possible that coastal environmental changes, perhaps driven by last glacial sea-level fluctuations, stimulated pioneer occupations of offshore islands in Sunda, leading eventually to the first colonization of Australia and New Guinea (Sahul).

A final example of Pleistocene human interaction with coasts is that involving initial human arrival in the Americas ca. 16,000 BP from the western Pacific Rim, perhaps along a shoreline that is now largely invisible due to submergence by later sea-level rise and fragmentation by differential tectonics (Erlandson and Braje, 2011). These authors note that, at the time, this former shoreline would have been associated with "rich and diverse resources from both marine and terrestrial ecosystems" (p. 28), perhaps a "kelp highway" that could have sustained migrants from Japan through the Kuril Islands to Kamchatka, the southern shores of Beringia, and thence along the ice-free coastal fringe of glacier-covered North America to the California coast from where migrants began to settle onshore and inland (Erlandson et al., 2007).

Early Holocene times (10,000–6000 years ago)

Postglacial sea-level rise drowned ice-age coasts in almost every part of the world, causing their inhabitants to move either inland and upslope or offshore. Along many coasts during the early Holocene, sea-level rise was accompanied by broadening of the diet range of their human inhabitants (Marín-Arroyo, 2013). This diet change may have been a response to changes in productive coastal environments and ecosystems associated with sea-level rise in addition to economic intensification linked to increases in coastal populations.

During the early Holocene, accompanied by climate changes, sea level rose about 60 m but this rise was neither monotonic nor regionally uniform (Smith et al., 2011). Sea-level transgression was instead oscillatory; there were periods of rapid rise and periods of temporary fall. For example, sea level rose about 3 m in 200 years during the 8200 BP Event (Hijma and Cohen, 2010). In coastal Portugal, this led to rapid submergence of the lower Tagus Valley that was accompanied by a massive decrease in the availability of coastal foods that forced an inland shift of coastal people who had previously occupied now-drowned coastal plains (Bicho et al., 2010). Similar events at the same time may have displaced coastal people occupying parts of the western Pacific Rim leading them to undertake deliberate voyages to settle lands beyond development of the horizon, something that may have led eventually to the maritime traditions that involved the earliest occupations of Pacific oceanic islands (Nunn, 2007b).

Middle Holocene times (6000–3000 years ago)

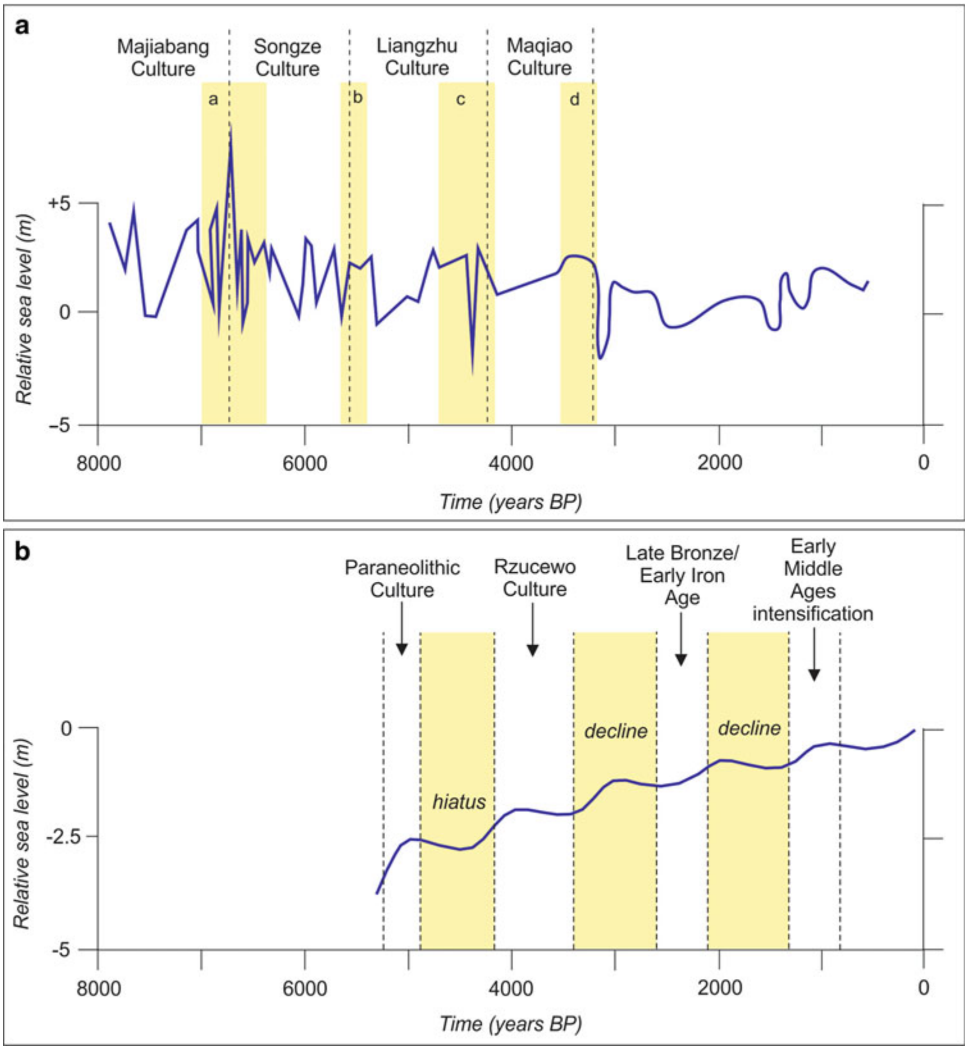
After global sea level stabilized along most coasts around 7000–5000 BP, the bioproductivity of nearshore coastal ecosystems increased sharply leading to the comparatively rapid occupation of many coasts by humans during the middle Holocene (Day et al., 2012). An example comes from the northern shoreline of New Guinea, today the largest Pacific "island" but until about 7500 years ago a promontory of Australia. Except in a few places, coastal settlement during the terminal Pleistocene and early Holocene was not possible in this part of New Guinea because of its fringe of steep cliffs plunging into deep water, but by about 6000 BP, when sea level had reached close to its present level, many of these coasts "started to evolve into rich floodplains, river deltas and lagoons" (Terrell, 2004, 605). People began to settle these areas and establish trade networks.

During the middle Holocene, sea-level fluctuations of shorter periodicity affected coastal societies in many places. Some of the most notable effects were recorded by delta communities. In the Yangtze Delta (China), mid-Holocene sea-level changes transformed coastal environments in ways that influenced wetland rice cultivation, a key driver of increasing societal complexity. A study from Tianluoshan found that, following a sea-level maximum around 7000 years ago, sea level fell and created wetlands in which Hemudu farmers could cultivate rice. Subsequent transgressions flooded these wetlands causing a drop in rice production and a consequent increase in hunting and gathering (Zheng et al., 2012). Sea-level fluctuations in this region have been linked to successive cultural collapses; larger settlements with more complex interactions were sustained at times of lower sea level but failed when the sea level rose subsequently (Figure 3a). A comparable situation has been found in the Vistula Delta (northern Europe) where four cultural phases involving changes in human lifeways that are attributable to sea-level fluctuations have been recognized in the Gdańsk area (Miotk-Szpiganowicz et al., 2010). Here, changes in the delta landscape associated with sea-level fluctuations and the alternate development/breaching of offshore barriers (protecting lowlands) saw the area utilized by agriculturalists when it was dry (often when sea level was comparatively stable) but abandoned by many people when it became flooded, those remaining being focused on fishing, sealing, and amber working (Figure 3b).

While coastal societies often respond to climate-driven sea-level changes, there are also instances where these societies have had to respond to climate changes alone. One example comes from coastal Syria where separate periods of increased aridity in the mid-late Holocene transformed productive coastal plains into hot desert (Kaniewski et al., 2008). A comparable study of the southwest coast of the Barents Sea (Norway) found that alternating warm and cool climates during the last 2000 years could be correlated with economies based mainly on cereal agriculture and fisheries, respectively (Sjögren, 2009).

Late Holocene times (<3000 years ago)

Along most of the world's coasts during the late Holocene, sea level dropped 1–2 m from its mid-Holocene high stage, causing many coastal plains and deltas to accrete and offering an advantage to resident coastal peoples. This process can be calibrated by tracing the effects on human settlements, which either remained in situ and adapted their activities to a prograding shoreline or moved as the land surface expanded. The process was never simple or easy to predict, as illustrated by an example from coastal



Coastal Settings, Figure 3 Relationship between sea-level change and cultural change. (**a**) The Yangtze Delta, eastern China (After Zhang et al., 2005; Nunn, 2007a). The Majiabang culture collapsed when high sea level caused groundwater flooding (*shaded zone a*). The Songze culture declined because of increased sea-level variability and flooding (*shaded zone b*). The Liangzhu culture collapsed as a result of sea-level increase which caused a rise in water tables and expansion of the Taihu Lakes (*shaded zone c*). Flooding linked to a high sea-level phase is also implicated in the collapse of the Maqiao culture (*shaded zone d*). (**b**) The Gulf of Gdańsk, northern Poland (After Miotk-Szpiganowicz et al., 2010), showing the variations in human occupation of the Vistula Delta that coincide with local sea-level oscillations during the later Holocene. Through creation of coastal wetlands, rising sea level is implicated in the initiation of the Paraneolithic. A later phase of sea-level rise created a large inland lagoon and extended the delta front, both of which attracted people to the area and underpinned the Rzucewo culture which later declined as sea level rose and displaced many of those people. An influx of people to the area occurred during the Late Bronze/Early Iron Age as the development of offshore barriers opened up land in the Delta that had previously been waterlogged but this land was subsequently inundated when sea level rose again. Only in the Early Middle Ages when barriers developed off the front of the Delta and large amounts of land became dry did the area rapidly become repopulated.

Peru (Figure 4). The changing resource base associated with shoreline migration during the late Holocene can also be documented in changing patterns of coastal subsistence. For example, the "mega-midden" period approximately 2000–3000 years ago along the west coast of South Africa may have been linked to environmental changes (Jerardino, 2012).

Along Mediterranean coasts, the sea-level rise of the earlier Holocene continued into the late Holocene, so that the coasts in this area show signs of continued transgression. In western Greece, for example, people at the start of the late Holocene settled close to the shore of the salt-water Messolonghi Lagoon and the adjoining freshwater Etoliko Lagoon, exploiting these diverse environments until about AD 1350 when continuing sea-level rise breached the isthmus joining both lagoons (Haenssler et al., 2013).

Within the last millennium in many parts of the world's coasts, minor perturbations of sea level occurred that in some cases led to significant responses from coastal-dwelling humans. Some of the most notable occurred as a result of rapid sea-level fall of as much as 80 cm during the AD 1300 Event (approximately AD 1250–1350) along many Pacific island coasts. This sea-level fall led to the rapid depletion of coastal foods, both onshore as a result of water-table lowering and offshore as a result of reef-surface exposure and increased lagoon turbidity. In turn, this led to conflict and, along many island coasts, the abandonment of coastal settlements in favor of others in fortifiable positions, typically upslope. Examples are known from most tropical Pacific island groups (Nunn, 2007a) with more recent work reported from Fiji and Timor (Nunn, 2012; O'Connor et al., 2012). In addition to having direct impacts on human settlement, the AD 1300 sea-level fall also caused changes to coastal landscapes that are implicated in coeval cultural changes. These include the infilling of coastal embayments and the emergence of offshore reef flats on which islands grew or could be built. Examples of the former include Tikopia (Solomon Islands) and Kawai Nui Marsh on O'ahu Island in Hawaii (USA), while the latter is exemplified by fortified Lelu Island off the coast of Kosrae (Federated States of Micronesia) and perhaps some of the artificial islands off the coast of Malaita (Solomon Islands) (Nunn, 2007a).

Tectonic disruption of coastal sites

Tectonic activity has significantly impacted the activities of coastal populations, particularly along coasts adjoining convergent lithospheric-plate boundaries. The most disruptive types of tectonic change are usually those that are abrupt and involve rapid uplift or subsidence of as much as several meters. The impacts of (associated) tsunamis often cause major problems.

The ancient Achaean city of Helike (Greece), located on a delta of the Gulf of Corinth coast, was abruptly submerged during an earthquake-tsunami in 373 BC but was subsequently uplifted, and its remains now lie buried beneath post-earthquake delta sediments (Soter and Katsonopoulou, 2011). Seismic subsidence accompanied by liquefaction caused major disruptions on at least two occasions to inhabitants of the port city of Ayla (now Aqaba, Jordan) (Al-Tarazi and Korjenkov, 2007). In the tectonically active island arcs of the southwest Pacific Ocean, many similar instances are known, the most extreme being ones where entire inhabited islands abruptly sank, in most cases probably due to an earthquake-triggered landslide along an adjoining ocean trench. Examples include the "vanished" islands of Teonimanu (Solomon Islands) and Malveveng and Tolamp (Vanuatu) (Nunn, 2009b).

Away from plate boundaries, some of the most marked coastal changes have occurred in places like Scandinavia where the land is rising as a result of isostatic rebound. The Viking-era shoreline (AD 800–1050) on the Estonian coast, for example, is now known to be 3–4 m above present sea level, emphasizing the importance in such places of understanding "the relation between a given site and the shoreline at the time when the site was used" (Ilves and Darmark, 2011, 147–148).

Conclusions and key issues

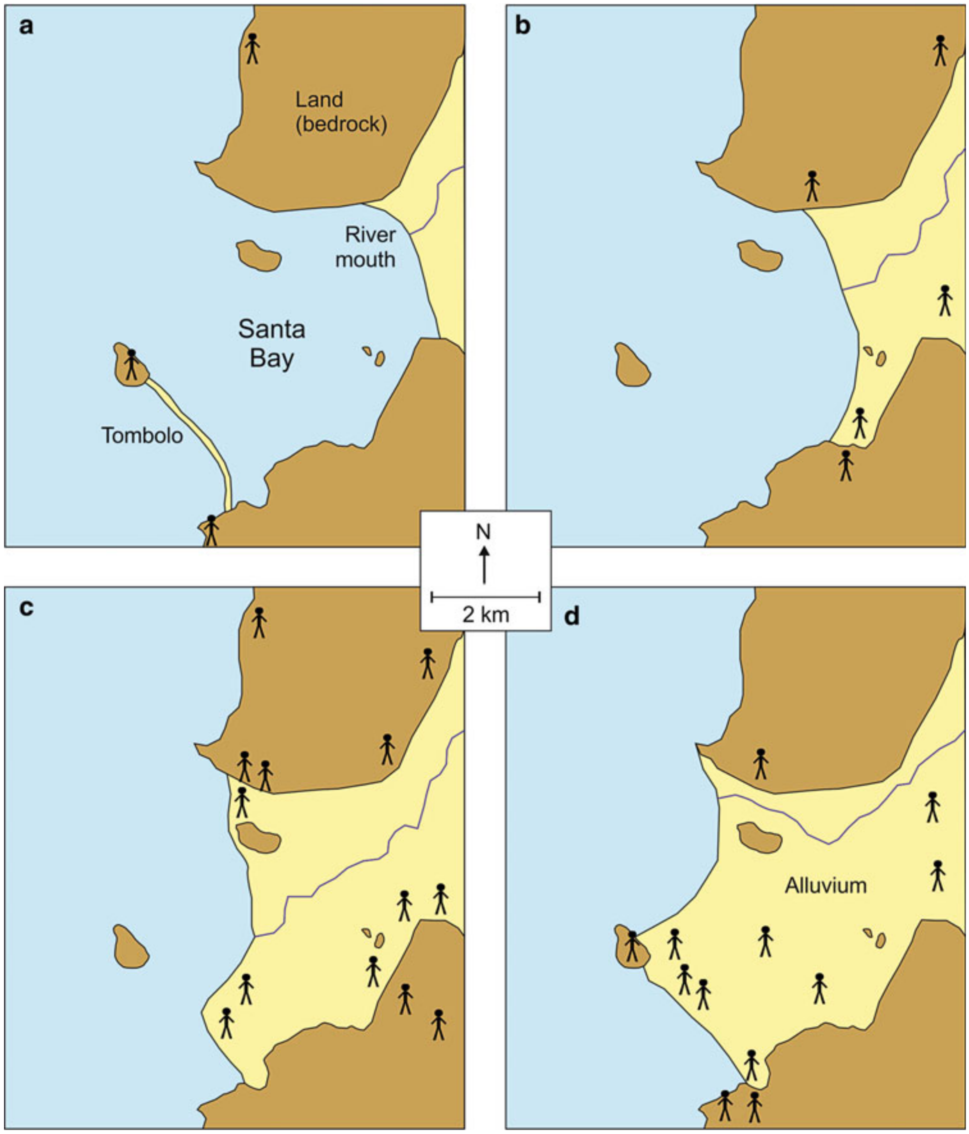
When considering the relationship between coastal settings and past human societies, there are a number of issues that remain insufficiently understood or acknowledged by many researchers. Three such issues are discussed below.

The importance of understanding coastal paleoenvironments

Despite calls to consider the effects of postglacial sea-level rise on coastal archaeological records, "many archaeologists working in coastal areas . . . have ignored such warnings" (Erlandson and Braje, 2011, 34) and continue to interpret past human-environment interactions in terms of the landscape configurations and landscape-forming processes they observe today. Such comments also extend to dynamic river deltas, such as the tendency of Egyptologists to plot the present-day rivers of the Nile Delta onto maps of the valley in the past, something that may have "misled interpretations of ancient monuments and settlements" (Hillier et al., 2007, 1011). This is hard to justify in an age when the understanding of (coastal) landscape change is so far advanced, and there are numerous examples of how this understanding can provide insights into the development of ancient societies.

Examples are illustrated above. The Lapita-age settlement at Bourewa (Fiji) was reconstructed using observations of settlement character (particularly the extent of postholes that once supported over-reef stilt houses), reef configuration, and an understanding of sea-level change to demonstrate that this settlement had extended along a submerged sand spit which emerged subsequently (see Figure 2), changing the possibilities for coastal subsistence (Nunn, 2009a). Morphological changes at the mouth of the Santa River (Peru) linked to sea-level changes explain the changes in settlement pattern shown in Figure 4 (Wells, 1992).

The locations of ancient shell middens can plot out coeval shorelines, assuming that shellfish gatherers processed their harvest just beyond the reach of high tide rather than carrying it whole back to their communities. There is no single answer. In some places, the former appears true – most shell middens (*Køkkenmødding*) in Denmark are situated along former shorelines which have been reconstructed using midden locations (Gutiérrez-Zugasti et al., 2011). In contrast, marine shell concentrations that differ little from those in coastal middens have been found 23 km inland in the Norte



Coastal Settings, Figure 4 Late Holocene growth of the Santa River Delta (Peru) showing changes in coastal settlement pattern associated with changes in shoreline configuration during the middle and late Holocene (After Wells, 1992; Nunn, 1999). Person symbol represents an archaeological site inhabited at that time. (**a**) Las Salinas Period (7000–3750 BP) shows that early settlers avoided the river valley. (**b**) Early Suchimancillo Period (1950–1750 BP) shows the initial occupation of the river mouth, targeting places where marine resources were most plentiful. (**c**) Guadalupito Period (1550–1300 BP) shows deliberate occupation of the prograding delta fringe. (**d**) Early Tambo Real Period (800–600 BP) shows more intense occupation of the delta fringe.

Chico region (coastal Peru) and 10 km inland on northern Viti Levu Island (Fiji) (Creamer et al., 2011; Robb and Nunn, 2014).

The identification of ancient shorelines and the signs of their human usage (such as boat landings) is particularly difficult in places where the Earth's crust is rebounding isostatically because this movement tends to be monotonic (only one direction: upward) rather than episodic. One approach in such places has been to use phosphate mapping to identify former shorelines, the assumption being that the human occupation of these localities resulted in an increase in surficial phosphate concentrations (from the butchering of game, the gutting of fish, human waste, burning); such a study resulted in the mapping of Österby Harbor (northwest Estonia) (Ilves and Darmark, 2011).

Imperatives for underwater archaeology

Understanding how shoreline emergence might affect coastal settings occupied by ancient humans can be obtained by investigating the sites on dry land, but the effects of shoreline submergence generally represent greater challenges. It is not simply an issue of former settlement sites being underwater but also that the material evidence associated with these sites may have been fragmented and dispersed as a result of submergence, first by the encroaching swash and backwash of wave action as the sea slowly enveloped the sites and then by further deterioration as the sites slowly sank into deeper water. For this reason, it is easier to reconstruct those sites that have been submerged only a few meters relatively recently rather than those that may be lying at water depths of 100 m or more over a lengthy interval, as is the case for most Last Glacial Maximum sites (dating from 22 to 18 ka BP) that now lie in offshore continental shelf locations. It is also important to appreciate that, once submerged, coastal settlements may become buried by sediments and even overgrown by reefs, which makes these settlements difficult to identify in many places. The danger is that they will be assumed to have been absent at a particular time, and erroneous chronologies of human history constructed as a result.

Since so much of the evidence is underwater, there are understandably few data-rich case studies of coastal societies affected by early Holocene sea-level rise. Some of the most compelling of these depend on data gathered through techniques of underwater archaeology. Underwater archaeological investigations have the potential not only to provide contexts for inferences from on-land sites (Bailey and King, 2011), but they can also demonstrate the existence of unsuspected coastal settings at particular times which in turn inform regional settlement models. An example comes from the Gulf of Maine (USA) where a slowing of postglacial sea-level rise 11,500–7500 years ago allowed development of coastal barriers and wetlands that may have attracted settlers, a finding contrary to earlier assumptions about the habitability of such formerly ice-covered coasts (Kelley et al., 2010). Perhaps the most comprehensive survey of now-submerged coastal settings occupied by a maritime society during the early Holocene comes from Doggerland (North Sea, between Britain and continental Europe) where a low-relief landscape of marshes, lakes, and wetlands dissected by rivers, now buried under marine sands, can been traced (Gaffney et al., 2009).

Debating the relative roles of natural and human processes in prehistoric coastal change

The inherent natural dynamism of coastal settings has not deterred them from being, through much of human existence, favored places for people to live, and as a result, it is not always easy to retrospectively distinguish the effects of natural and anthropogenic actions. There are many well-documented examples of ways in which humans modified coastal environments as well as examples of how coastal environmental change, linked to extraneous climate-driven changes, forced coastal dwellers to change the ways in which they lived. To judge which cause (natural or human) of an observed change in coastal societies was dominant, it is necessary to compare chronologies of both. If societal change was clearly not synchronous with possible (natural) forcing variables, then the latter is unlikely to have played a role in causing the former. But if there is demonstrable synchronicity, then a role for natural forcing should be considered possible.

Relative sea-level change is a major mechanism that could have forced adaptive change in coastal societies, and several examples were described above (see also Figure 3). Over the past decade, there has been an increasing number of case studies in which relative sea-level migration is cited as a major cause of change among coastal societies; these include tropical Pacific islands (Nunn, 2007a) and the coasts of Italy (Romano et al., 2013) and Portugal (Bicho and Haws, 2008). In many cases, the separation of natural and human causes of societal change appears almost impossible to achieve (e.g., Marín-Arroyo, 2013) given the paucity of available data.

COLLUVIAL SETTINGS

Charles A. I. French
Department of Archaeology and Anthropology,
University of Cambridge, Cambridge, UK

Introduction

Colluvium, or hillwash, is both an erosive deposit and a preserving medium for buried surfaces. The term encompasses slope deposits moved by shallow surface flow (or slope wash) or by mass movement (or creep or slide). Colluvium is soil- and/or sediment-derived material that accumulates on lower slopes. It is poorly sorted and heterogeneous, composed of any size grade from clay to coarse sand plus rock rubble, and can be up to several meters thick (Waters, 1992, 230–232; Selby, 1993, 243). Bedding and stratification are often poor and particularly hard to identify in the field (as opposed to in thin section), and colluvium may also contain a variety of artifact inclusions brought down from upslope. Colluvium may occur any place that possesses more than two degrees of slope, even beneath woodland (Imeson et al., 1980).

Hillwash can be generated by a variety of processes, of which devegetation and agriculture are two of the main instigators. Consequently, colluvial sequences frequently contain a record of human activities and reflect anthropogenic impacts on landscapes. Colluvium also has the ability to distort, bury, and preserve past landscapes, especially over the last 10,000 years. How and why deposits are laid down and subsequently modified, and at what rate, are central issues in geoarchaeology. Detailed information can be gleaned from colluvial sequences through the use of good field recording, particle size analysis, associated soil micromorphological and molluscan studies, and appropriate use of dating techniques. Thus, hillwash is a valuable resource in archaeology and geoarchaeology, but an understanding of its formation, depositional processes, and chronology is required.

This entry examines and illustrates the formation and depositional factors causing hillwash in a variety of landscape settings in order to demonstrate its importance in the interpretation of past land use and human activities and exemplify these through a number of case studies from around the world.

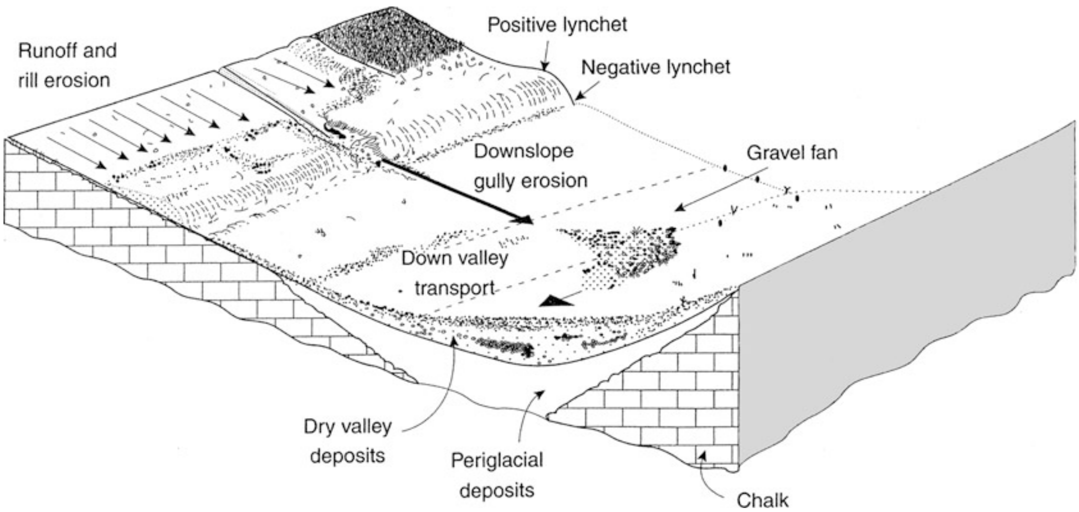
Formation of hillwash

Slope processes regularly lead to soil erosion, transport, and redeposition of soils and sediments in valley situations (Figure 1), and they are therefore involved in both the alteration and the preservation of archaeological sites and landscapes. Soil/sediment movement may range from rapid to slow and intermittent to gradual. Every situation is exacerbated by the degree and character of the slope, topography, hydrology, vegetation cover, rainfall amounts and frequencies, and the nature of human activities on the land.

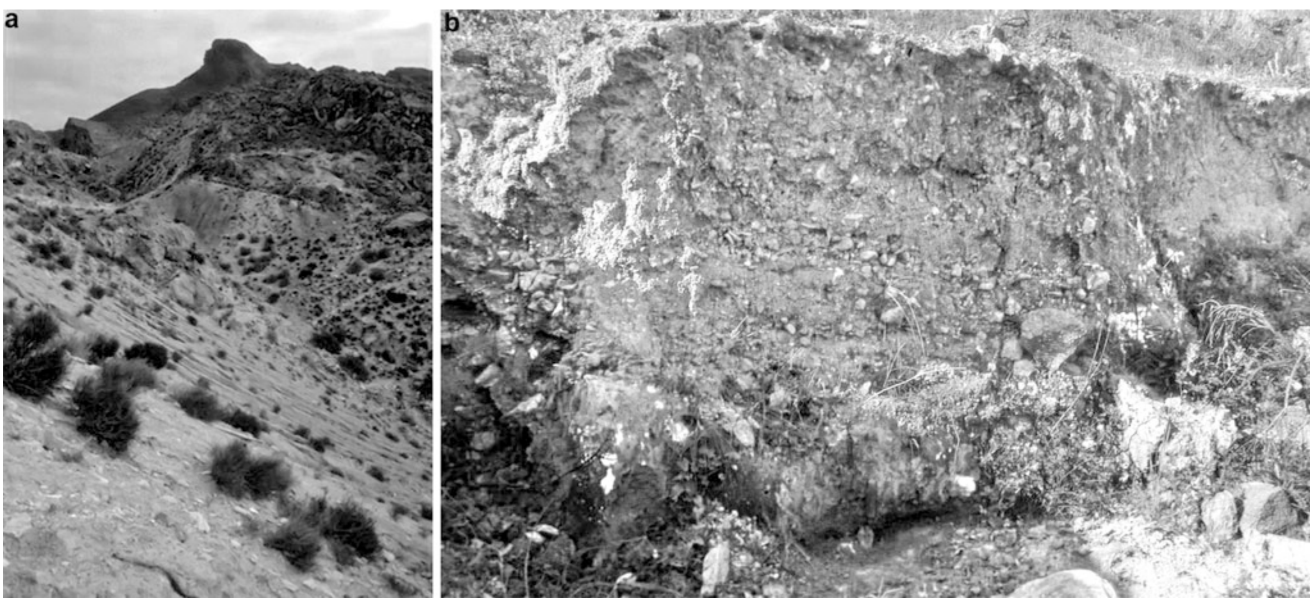
There are two major types of soil/sediment movement on slopes related to process: (1) slope, hill, and rainwash and (2) mass wasting. The former group generates colluvial deposits, and the latter group is associated more with solifluction and debris flow deposits. Mass movement involves the rapid downslope movement of rock and soil debris from a rupture surface and/or shear plane, which is usually controlled by the intact strength of the soil and/or subsoil (Statham, 1979; Statham, 1990). It is a fast movement, often as a single erosive event, with stability quickly returning. A rockfall after a freeze-thaw episode and slab failure on a rock face are typical examples. In the Sierra Cabrera mountains of southeastern Spain, for example, rock debris and gully erosion regularly shear off material from the upper slopes above the Barranco de Gatas, which falls onto the first agricultural terraces below as rubbly fans (French et al., 1998) (Figure 2a, b).

Slow and/or seasonal slope processes produce slow downslope translocations of soil debris as soil creep or colluviation (Statham, 1979; Statham, 1990). These can be near continuous, seasonal, or random in occurrence, they can affect small or large areas of slope, and they can occur anywhere. This type of movement can result from frost heave in soils, periglacial conditions and solifluction, rainsplash impact, and saturation and/or waterlogging, often aggravated in arable areas by the farming regime. For example, massive soil creep can result from the saturation and cultivation of bare slopes, as is seen in Bosnia today (Figure 3a), or in sandy hillwash deposits accumulating at the base of slopes in later prehistoric to historic times adjacent to the grand Saxon burials at Sutton Hoo, Suffolk (Carver, 1998; French, 2005) (Figure 3b). Often, such areas of eroded soil accumulation are easily mapped from the air and ground-truthed through auger survey and test pitting, as exemplified by the mapping of later Holocene hillwash deposits in the dry valleys of the upper Allen valley of Dorset (French et al., 2007, 23–35) (Figure 4).

Slide or water flow processes such as overland flow on slopes and alluviation in floodplains produce variable rates of deposition. Overland flow is particularly influenced by slope angle, soil, and vegetation type and in turn by the amount of rainwater splash impact (Selby, 1993), as well as human impacts. During flow, the sediment load tends to decrease with time. Overland flow occurs when either the infiltration capacity of the soil is exceeded either during high intensity rainfall or during the rapid melting of snow. Grains of c. 0.5 mm in diameter are the most easily moved, whereas smaller and larger grains require a much higher threshold velocity. Grains are not redeposited until very low flow velocities are reached (Morgan, 1979). With reference to the Spanish example, past and recent colluvial fans and overland flow deposits comprising meters of coarse silt and very fine sand-size, calcitic marl material were regularly observed in out-of-use agricultural terraces and dry valleys of the Barranco de Gatas (French et al., 1998) (Figure 5a). Moreover, the removal of natural vegetation, the presence of



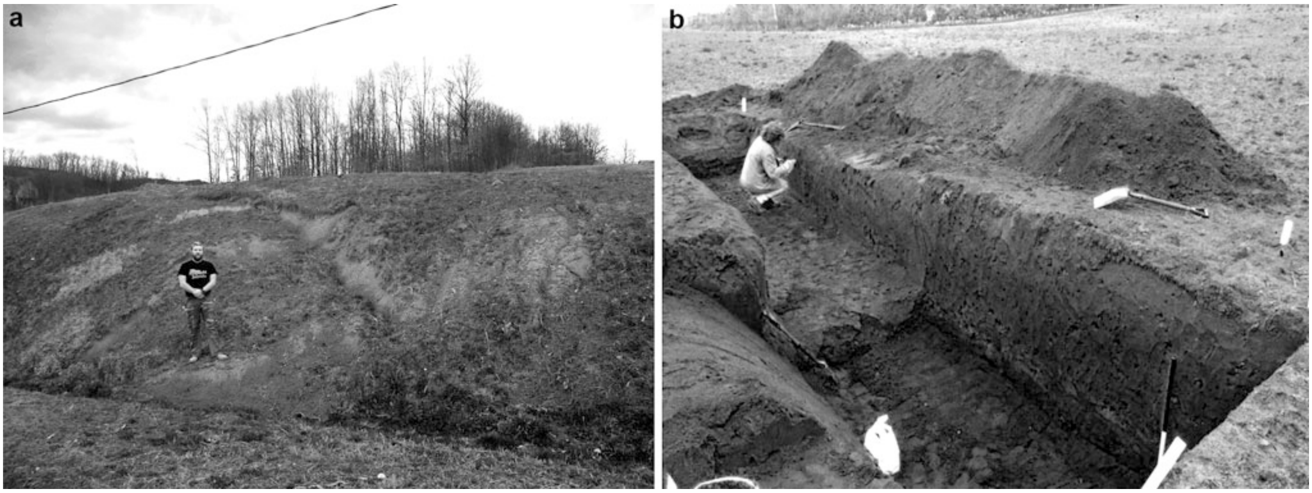
Colluvial Settings, Figure 1 Schematic cross section of a colluviated valley landscape (After Allen, 1988; Goldberg and Macphail, 2006: Figure 4.4).



Colluvial Settings, Figure 2 (**a**) Gully erosion on steep, bare slopes above Fuente Alamo, southern Spain. (**b**) Soil and rock debris accumulation in an abandoned agricultural terrace in the Barranco de Gatas, Sierra Cabrera, southern Spain.

steep slopes, and extensive past agricultural exploitation for wheat crops, coupled with increasing aridification since the second millennium BC, have exacerbated the susceptibility of soils and subsoils of this region to erode downslope (Castro et al., 1999).

The presence of colluvium is often directly related to human activities in the landscape and particularly to arable agriculture. Bare arable land and ongoing cultivation regularly result in the direct displacement of soil downslope and its redeposition at the base of the slope as colluvium or within the adjacent floodplain as alluvium (Figure 1). The exposure of soil/sediment particles and aggregates to the elements leads to further physical breakup of soil structure. Add water and a slope angle of greater than two degrees, and soil movement downslope can take place; if vegetation cover is removed, even greater soil erosion may occur (Figures 2a and 5b) more quickly and more often (Mücher, 1974; Kwaad and Mücher, 1979; Selby, 1993, 106–122). Disturbances due to people or animals can easily produce gullying and soil erosion as well



Colluvial Settings, Figure 3 (**a**) Recent colluvial slumping near Prijedor, in central Bosnia. (**b**) Historic and later prehistoric sand hillwash overlying a disturbed acidic sandy brown earth in the Deben valley associated with the Bronze Age settlement site and Saxon ship burials at Sutton Hoo, Suffolk, England.

as the accumulation of eroded soil/sediment downslope, often against boundaries (such as field banks and hedges) to form lynchets. For example, browsing of pigs in present-day cork oak woodland in northern Sicily has led to gully erosion and soil transport downslope within a few months (Figure 5b). Evidence of past soil erosion and accumulation is often seen associated with prehistoric field boundaries such as the later prehistoric "Celtic" fields and lynchets on the chalk downlands of southern England (Evans, 1972, 316; Limbrey, 1975, 188–189) (Figure 6), or at the base of slopes in the Aguas valley of southern Spain associated with the Bronze Age settlement and agriculture upslope of Las Pilas (French et al., 1998: Figure 13.5).

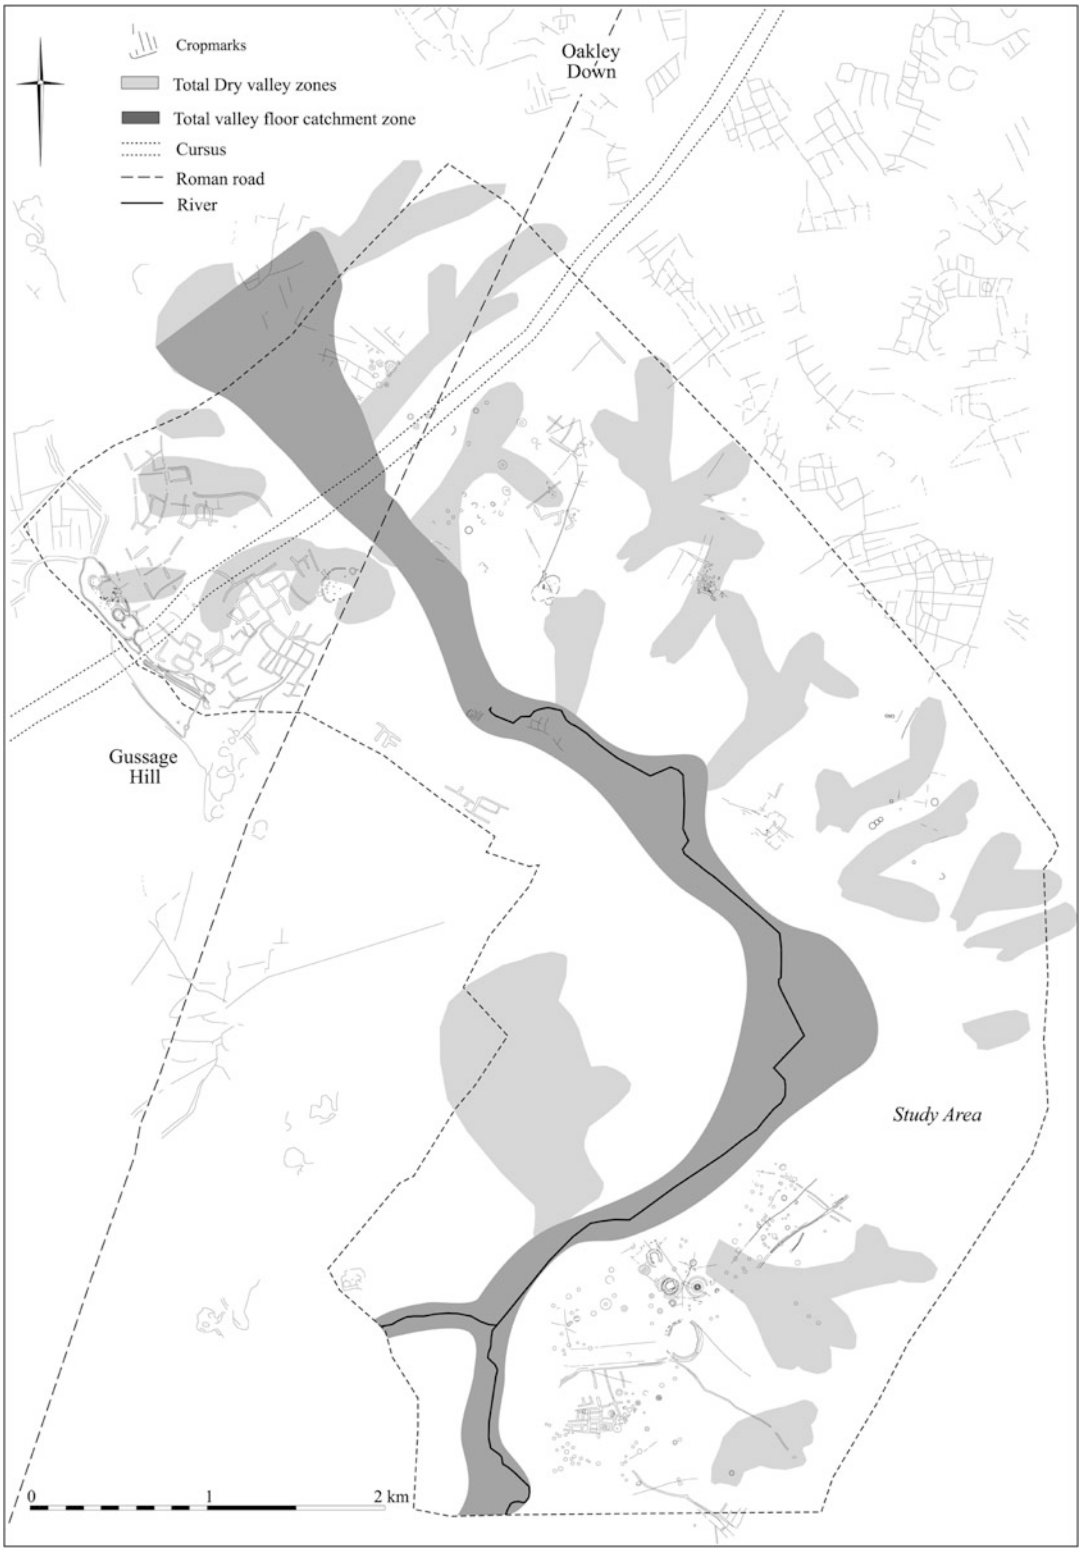
Different amounts and rates of saturation will also affect the threshold at which soil movement occurs as well as the speed and distance of travel. For example, if a soil requires only 50 % saturation to become mobile (or plastic), shear will occur more quickly and more often, dependent, of course, on the nature of the vegetation cover and degree of slope; if a soil becomes saturated at 90 % moisture content, however, it will be less susceptible to shear and colluvial displacement downslope (Selby, 1993, 56–63). Plowing and overcropping can lead to the depletion of not just essential minerals for plant or crop growth, but the destruction of soil structure, thus making a soil more prone to destabilization and downslope movement. Soil texture also affects its movement, with fine sandy and coarse silty soils being much more susceptible to destabilization than well-structured silty clay loam soils (Selby, 1993, 106–122). This will be compounded when vegetative cover is removed or the soil is physically disturbed by plowing or animal trampling.

In addition to these formation factors, it is also worth considering the ecological concepts of thresholds of stability/instability (Butzer, 1982; Allen, 1992). Change in just one factor in a landscape, or a combination of several factors, might be sufficient to cause instability in a soil system. This could be as simple as an individual thunderstorm event on a dry, bare soil, or it could be a combination of factors, such as an unstructured sandy soil fabric on overgrazed and degraded grassland with 20° of slope and a prolonged rainy spell that causes a catastrophic shear and slumping of soil downslope. Each response will be governed partly by climatic, environmental, human, and land-use factors as much as the diverse pattern and different magnitudes of individual valley responses.

Rates of colluvial movement

Rates of soil/sediment movement downslope can vary enormously over time, and modern experimental observations are often the only real analogue providing indications of the volume of soil moved versus soil texture, time, slope, vegetation, and land use (Table 1). For example, debris flow in southern Spain can produce up to several meters of accumulation in one event such as from a single thunderstorm (French, 2003, p. 207, Figure 13.7). This is because there is (1) almost no moisture infiltration into the soil/substrate, (2) a high erodibility index, and (3) a lack of vegetative cover, all leading to very high rates of runoff (Thornes and Gilman, 1983). Colluvial soil creep can be continuous, seasonal, or random. Its formation can be exacerbated by steeper slope gradients, bare soil surfaces, soil moisture exceeding its infiltration capacity, soil/sediment texture, rainfall and temperature regime, and human activities such as plowing.

Rates of colluviation have been observed in many modern landscapes, and these data provide a good idea of the



Colluvial Settings, Figure 4 Colluvial accumulations in the upper Allen valley mapped against the terrain and archaeological record.

Colluvial Settings, Figure 5 (**a**) Overland flow colluvial soil creep and gullying of unmaintained terrace systems in the Barranco de Gatas, Sierra Cabrera, southern Spain. (**b**) Soil slumping and wastage in open cork oak woodland caused by pigs, near Troina in north-central Sicily.

Colluvial Settings, Figure 6 Later prehistoric field system banks or lynchets (raised former field boundaries consequent upon colluvial accumulation against hedgerows) at Abbotsbury, Dorset, England.

speed and volumes of material that can be moved downslope under particular conditions. For example, under coppiced oak/beech woodland on loessic (or windblown) soils in Luxembourg, as much as 6 cm of soil per 100 years had accumulated (Kwaad and Mücher, 1979; Imeson et al., 1980). Observed rates of soil loss can vary from 0.0045 g per square meter per year for areas of moderate relief under natural conditions to 0.045 kg per square meter per year for steep relief and rates of 4.5–45 kg per square meter per year on agricultural land (Young, 1969). A major controlling factor is the angle of slope; the total transport caused by sheet erosion has been observed to increase sixfold as the slope angle increased from flat to 25° (Moseley, 1973).

Factors that influence soil erosion and its severity are rainfall, runoff, wind, soil type, slope angle, and the amount of vegetative cover, both on localized and regional scales. Erosion tends to reach a maximum in temperate,

Colluvial Settings, Table 1 Examples of measured rates of soil erosion from experimental plots in the southeastern United States (After Kirkby, 1969)

Type of vegetation cover	% runoff	Soil loss (mm per year)
Oak forest	0.8	0.008
Grass pasture	3.8	0.03
Oak woodland	7.9	0.1
Bare abandoned land	48.7	24.4
Cultivated, with rows along the contour	47.0	10.6
Cultivated, with rows downslope	58.2	29.8

semiarid areas with a mean annual rainfall of c. 250–350 mm per year (Langbein and Schumm, 1958). In more humid areas, and as one moves from drier to wetter environments, rates of erosion initially decrease rapidly to the point (at c. 600 mm per year) at which total vegetation cover is established; rates change little thereafter. For example, in the northern Cambridgeshire region, where the annual rainfall varies between 500 and 600 mm (Burton, 1981), the greater vegetative cover tends to counteract the erosive effect of greater rainfall. In contrast, the Rio Puerco of New Mexico experiences very low rainfall of 200 mm per year that occurs during thunderstorms; land use associated with intensive livestock grazing has contributed to conditions resulting in massive river incision of up to 11–12 m over approximately the past 120 years (French et al., 2009).

Rainsplash is probably the most important detaching agent and contributes considerably to runoff. Splash back following raindrop impact on a level surface has been observed to move stones 4 mm in diameter up to 20 cm, while 2 mm sized stones can be displaced up to 40 cm, and even smaller stones up to 150 cm (Kirkby, 1969). Short-lived, intense, and prolonged storms of low intensity have the greatest erosive effect (Morgan, 1979; French et al., 2009).

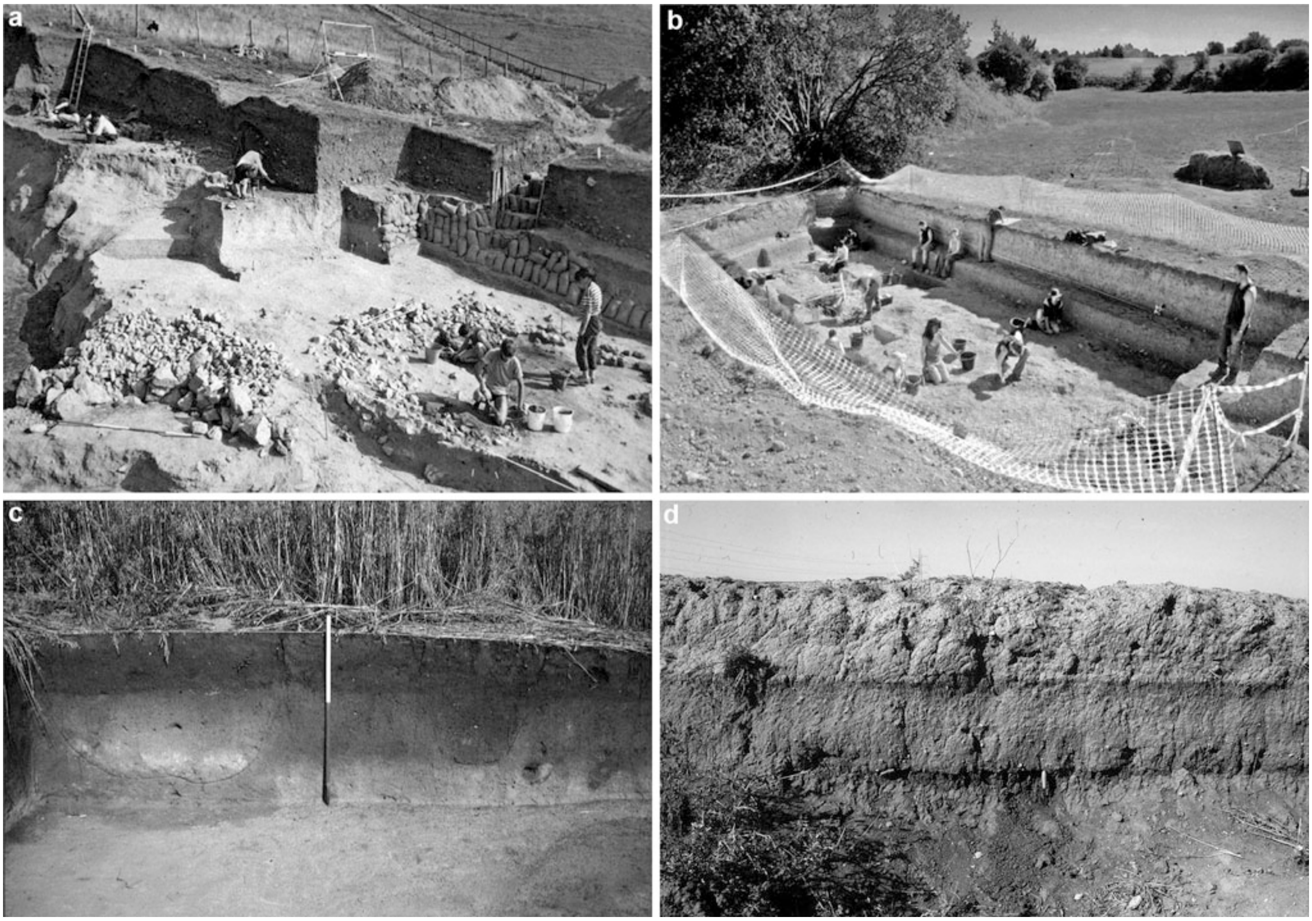
Surface runoff or overland flow occurs on slopes when the soil's infiltration capacity is exceeded (Kirkby, 1969). Overland flow transports soil particles detached by rainsplash, often creating distinct gullies or channels (Figure 2a). It has been suggested that overland flow covers two-thirds or more of hillsides in a drainage basin during the peak period of a storm (Horton, 1945). Grains of c. 0.5 mm in diameter (coarse silt or very fine- and fine-sized sand) are most easily moved, whereas both smaller and larger grains require a much higher threshold velocity. Clay tends to resist detachment (Farmer, 1973). Grains are not redeposited until very low flow velocities are reached (Morgan, 1979). Subsurface soil water flow erodes possibly only 1 % of the total material from a hillside (Roose, 1970).

The resistance of soil to detachment and transport depends on the steepness of slope, vegetative cover, and disturbance by humans. It also varies with soil texture, aggregate stability, shear strength, infiltration capacity, and the organic and chemical components (Selby, 1993, 106–122). The least resistant particles are silts and fine sands. Soils with a low shear strength or low cohesiveness are susceptible to mass movement, as are those with a low infiltration rate and low organic matter content (Morgan, 1979).

The effect of slope is to increase erosion with increasing slope angle (Kirkby, 1969). Numerous forces such as gravity, frost heave, rainsplash, soil texture, and the lack of vegetative cover all help to produce erosion on slopes. The amount of vegetative cover has a considerable effect on the susceptibility of soil to erosion. Its effectiveness in reducing downslope erosion depends on the height, density, and continuity of the canopy or ground/root cover. Both forest and dense grass are more or less equally effective at reducing erosion. Vegetation intercepts rainfall and reduces the velocity of runoff. Mean annual soil loss on bare ground can be as much as 100 times the volume of loss from dense grass-covered ground under the same environmental conditions (Morgan, 1979), and soil loss on vegetated slopes can be reduced by 10–30 % (Horton, 1945). Moreover, conversion of forest to arable land will dramatically increase erosion by up to 200-fold (Wolman, 1967). Thus, vegetation is a critical factor, and the removal of plant cover especially on slopes can considerably enhance the potential for erosion by overland flow, slope wash, or some other mode of transport.

Hillwash deposition may frequently be discontinuous, with many pauses in the gradual sediment buildup. These episodic sequences are not always easily detectable in the field, but they may exhibit "standstill" horizons that usually show some organic accumulation and a degree of soil formation if the hiatus was of sufficient duration to allow some pedogenesis to occur. A good example of this is at Brean Down, Somerset, where a basal Neolithic paleosol was buried by a sequence of hillwash and blown sand episodes that were interrupted by standstill phases with turf development and several later prehistoric, Bronze Age occupations (Bell, 1990) (Figure 7a). This type of sequence lends itself to good dating through both archaeological and artifact associations as well as radiocarbon and/or luminescence techniques (see below).

Variable hillwash accumulations are common. For example, Bronze Age settlement and agriculture on the sand-dominated soils at Sutton Hoo have led to over 1.5 m of undifferentiated soil hillwash accumulation downslope in the adjacent Deben valley (Figure 3b). In contrast, two major episodes of hillwash accumulation, one predating and the other postdating the Romano-British period, were found within the center of the late Neolithic henge at Durrington Walls, Wiltshire (Figure 7b). Associated with this was a major erosive interval affecting the calcitic rendzina soil material that was found in old paleochannels of the Avon valley at Durrington Walls (French et al., 2012). Also, a mixture of thick deposits of soil and rock debris is known to

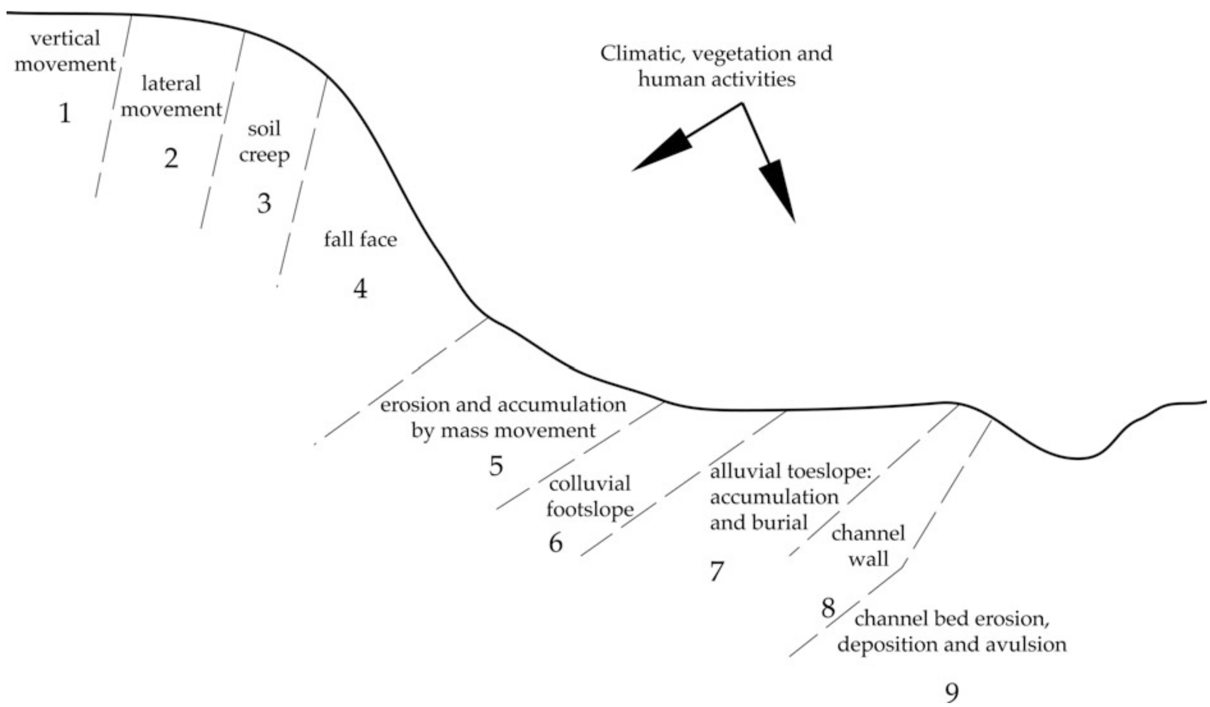


Colluvial Settings, Figure 7 (**a**) Repeated paleosol, hillwash, and blown sand deposits of Bronze Age to medieval times at Brean Down, Somerset, England (Bell, 1990: Figure 32). (**b**) Two major episodes of rendzina soil erosion and colluvial accumulation bracketing an incipient rendzina soil of the Roman period (at the level of the tape measure) within the interior of the late Neolithic henge at Durrington Walls, Wiltshire, England. (**c**) Episodic pre-Roman loessic soil erosion and paleosol formation at Erd in the Benta valley, central Hungary. (**d**) Two phases of soil development in post-Neolithic hillwash deposits at Bet el-Kowmani in the Dhamar highlands of Yemen.

aggrade episodically as colluvium in dry valleys of Sussex in southeastern England from at least the Beaker period, e.g., at Newbarn Combe on the Isle of Wight (Allen, 1992: Figure 4.2; Bell, 1992: Figure 3.3; Boardman, 1992). Near Szazhalombatta in the lower Benta tributary of the Danube, there were three episodic periods of hillwash accumulation – in the Bronze Age, Iron Age, and medieval times – each on an old land surface represented by a paleosol indicating a lengthy period of stability (French, 2010a) (Figure 7c). Several episodic phases of hillwash accumulation were also observed burying Neolithic paleosols in the Dhamar highlands of Yemen (French, 2003, 224–234; Wilkinson, 2005) (Figure 7d).

Nine-unit land-surface erosion model and catena sequence

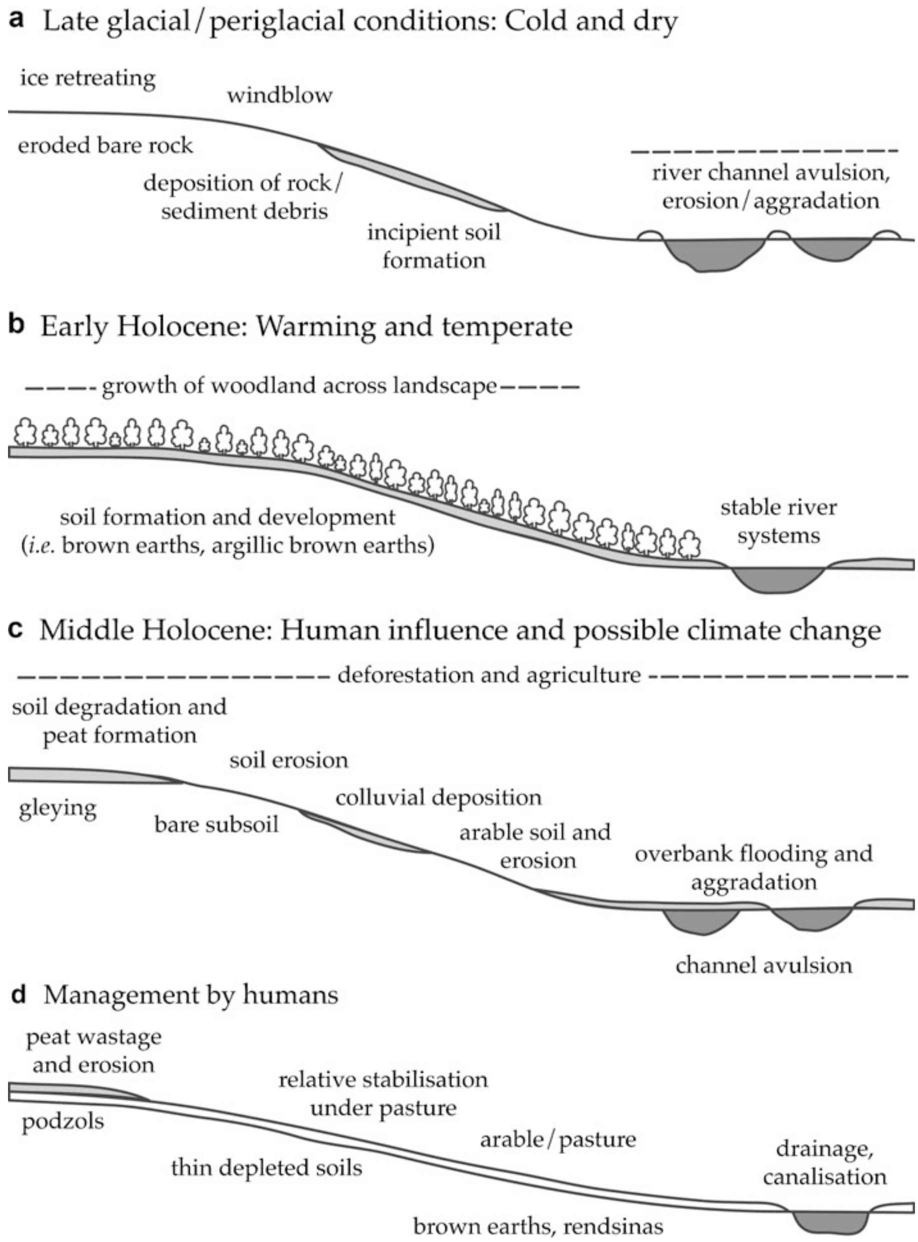
The use of Dalrymple et al.'s (1968) nine-unit land-surface erosion model (Figure 8) is a good way of envisaging erosion and landscape change both across and within a valley landscape. It allows the visualization of every part of a landscape at whatever scale of investigation is being used. This model creates an idealized cross section through one-half of a valley, from the watershed boundary at the highest point of the valley to the river channel below. If this model is then combined with the catena concept (see below), both geomorphological processes and soil formation and change can be seen in combination. When archaeological distributions by time period are overlaid and related to these geomorphological contours, they form the beginnings of a two-dimensional model of landscape development, which when extended and viewed in plan allows the use of digital terrain and geographical information system models to analyze landscape change in three dimensions through time. A case study of this type of work in the upper Allen valley of the chalk downlands of southern England (French et al., 2007) is discussed below.



Colluvial Settings, Figure 8 Dalrymple's nine-unit land-surface model (After Dalrymple et al., 1968).

A catena (based on the Latin word for chain) is a sequence of soils that forms along the course of a particular slope, usually over one parent material (Limbrey, 1975, 83; Goldberg and Macphail, 2006, 63). The differences between the soils that form a catena are generally related to their varied positions on the slope and their drainage characteristics. These factors produce changes in soil properties from the upper elevation members to the lower elevation members of the catena, and they can also create a sequence of modifications to catenas through time – i.e., a paleo-catena (Figure 9). Thus, a catena is a sequence of soil profiles appearing in regular succession with similar and differing morphological features over a uniform lithology.

The nine-unit land-surface model combines slope aspect, degree of slope, erosion, and soil forming processes (Dalrymple et al., 1968) (Figure 8). The uppermost unit (1) exhibits less than 1° of slope; it is characterized by pedogenic processes with vertical subsurface movement and is often associated with waterlogging or severe denudation. Below that, unit 2 exhibits 2–4° of slope, with both chemical and mechanical eluviation (or removal) by lateral subsurface water movement. Unit 3 is the upper part of the fall face with 35–45° of slope, and it is characterized by bare rock surfaces, sheet erosion, soil creep, and terracette formation. Unit 4 is the lower and steeper part of the fall face with 45–64+ degrees of slope, which is characterized by physical and chemical erosion leading to much bare rock, rock falls, and slides. Unit 5 is the mid-slope zone with 26–35° of slope, surface and subsurface water action, transport by mass movement, terracette formation, and both the removal and accumulation of soil and sediment material. Unit 6 is effectively the colluvial footslope zone, where there is subsurface water action, redeposition of material by mass movement, and some surface wash as colluvium, as well as transport further downslope in the form of hillwash and down valley in the form of alluvium. This colluvium may be laminated, nonlaminated, or massive, and it often accumulates on a buried soil that may or may not be truncated. Unit 7 in the floodplain is characterized by alluvial deposition as well as downstream water movement containing colluvially derived material as alluvium. Unit 8 in the active floodplain exhibits channel avulsion and erosion, bank slump, and fall. Unit 9 is the active channel itself, with bed transport down valley, as well as periodic aggradation and erosion. Obviously, not all units and slope angles will be applicable to every landscape encountered during fieldwork, but the model gives foreknowledge as to where areas of denudation, transformation, and burial may be occurring within a valley complex. As a corollary, it will also provide a good indicator of where buried soils and land surfaces may survive and where buried waterlogged deposits may be found intact for paleo-vegetational and land-use reconstruction. These data can also be used to inform a universal soil loss equation (USLE) to model landscape change through time (Wischmeier et al., 1971; Wischmeier and Smith, 1978; Ayala and French, 2005; French, 2010b) (see below).



Colluvial Settings, Figure 9 Hypothetical series of paleo-catena sequences for southern England in the late glacial-Holocene.

Methods of analysis

Two main approaches have been used to study colluvial processes, namely, (1) observation and recording in the field backed up by (2) experimental studies in the field and laboratory. More recently, a much wider repertoire of techniques has emerged for routine use. Good field description and mapping of soil and colluvial deposits is an essential starting point for appraising soil erosion in any landscape. Aerial photography and remote sensing methods such as LIDAR are essential tools (Wilson, 2000; Donoghue, 2001; Bewley et al., 2005), perhaps even geophysical survey and the use of ground-penetrating radar (GPR) to determine sediment thicknesses (Clark, 2000; Gaffney and Gator, 2003) accompanied by systematic augering profiles and test pitting to ascertain depths and characteristics of the erosion/soil complex (French, 2003; French et al., 2007). Test pitting allows bulk sampling from the section face for molluscan studies (Allen, 1992). It also permits block samples to be taken for soil micromorphological analysis (Courty et al., 1989; French, 2003), as well as small bulk sampling for particle size analysis, pH, carbonates, loss on ignition, and magnetic susceptibility (Allen and Macphail, 1987; Canti, 1995; Bertran and Texier, 1999; English Heritage, 2004;

Goldberg and Macphail, 2006), while permitting the recording of stone content and its orientation, recovery of artifacts for relative dating, and sampling and sieving to retrieve charcoal for radiocarbon assay (French, 2003; Goldberg and Macphail, 2006). If any clear horizon differences exist, or there are perceptible old land surfaces in evidence, optically stimulated luminescence (or OSL) dating can also be used effectively to provide sequence dating (Grün, 2001). Finally, both laboratory and field experimental data from known present-day landscape scenarios on different soil and geological types need to be compiled and used for comparison as analogues for potential rates of slope erosion under known conditions (Kwaad and Mücher, 1979; Evans, 1992).

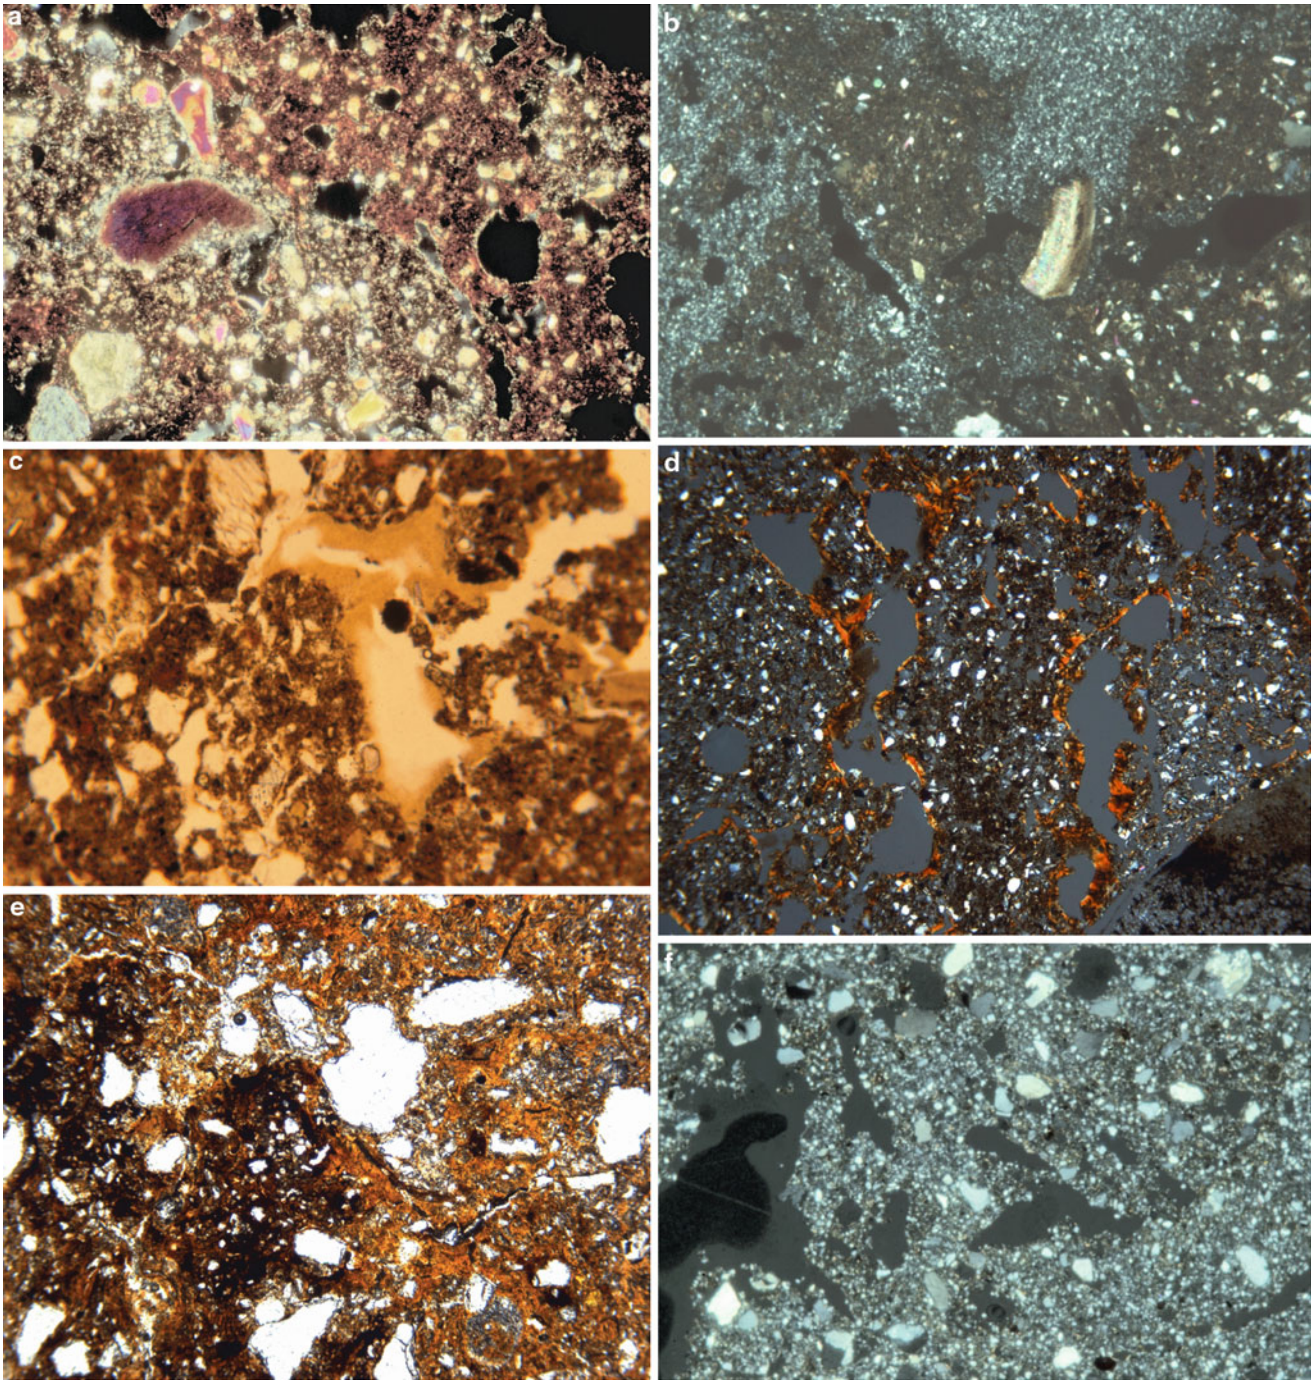
Once hillwash has been recognized and recorded in the field as a deposit, micromorphological analysis can then play a role in providing corroborative evidence as part of a mixed method approach (Courty et al., 1989; Canti, 1995; English Heritage, 2004). Different slope processes may generate similar types of micromorphological features, and consequently, it is essential to use a suite of criteria and methodological approaches as itemized above, including macromorphological features and granulometry, for corroboration and a more reliable interpretation (Mücher et al., 2010, p. 37). Moreover, there has not been a large amount of micromorphological research work done on slope deposits (Mücher, 1974; Mücher and Morozova, 1983; Bertran and Texier, 1999). Nonetheless, features such as (1) mixed, juxtaposed, and heterogeneous fabrics (Figure 10a, b), often as pedo-relict aggregates; (2) fresh and/or unoriented subrounded rock fragments; (3) sharply bounded nodules; (4) surface or mud crusts, often fragmented and in all orientations; (5) silty clay coatings; (6) infillings and intercalations in the void/channel space between soil peds (Figure 10c–e); (7) fabrics depleted of fine material (Figure 10f); and (8) anthropogenic inclusions are all common indicators of colluvial deposits (Mücher, 1974; Goldberg and Macphail, 2006, 44–45; Fedoroff et al., 2010, 641–645; Kuhn et al., 2010, 228–230; Mücher et al., 2010). Micromorphology can also distinguish quite well between in situ soils and redeposited soils/sediments, and it will recognize fine laminations in colluvial deposits as well as various postdepositional processes. Crucially, micromorphology can identify different types of clay coatings, which can be associated with hillwash processes, often the result of rainsplash impact on bare soil surfaces, such as oriented pure clays (Figure 10c), dusty impure silty clay coatings with weak to moderate striae (Figure 10d), silty clay intercalations (Figure 10e), and dirty or very speckled clay coatings with weak orientation (Bolt et al., 1980; Goldberg and Macphail, 2006, 44–45; Kuhn et al., 2010).

Studies of molluscan assemblages may also be used to help define different localized environments within a valley catchment and to recognize cyclical land-use regimes (Allen, 1988; Allen, 1992). Usually, the molluscan faunas in hillwash reflect arable activity and are generally depleted assemblages with a narrow species range (Bell, 1983). Any temporary hiatuses or standstill horizons can reflect grassland or incipient soil formation (Kerney et al., 1964; Allen, 1992). Occasionally palynological (Scaife, 1984) and micromorphological analyses (Macphail et al., 1990; Macphail, 1992) can aid in the interpretation of land use and activities represented in the colluvial stratigraphy.

Once the formation, age, depths, and spatial extent of colluvial deposits have been determined, and the deposits have been mapped and set within their geological, soil, and vegetational contexts, it then becomes possible to model past and present landscape change. This involves using the tools of geographical information system (GIS) and the universal soil loss equation (USLE) and erodibility factor (K) (Wischmeier et al., 1971; Wischmeier and Smith, 1978) to model erosion in a landscape, as well as dynamic people-landscape interactions in the archaeological record (Kwan and Lee, 2004; Conolly and Lake, 2006; Wainwright, 2008; French, 2010b). For example, in the Troina valley of north-central Sicily, USLE and GIS modeling techniques were used to model the potential impact of Roman agriculture on the erosion record (Ayala and French, 2005). The study suggested that greater clearance for winter pasture land may have been the major driving force causing intensified soil erosion. Other recent studies (Barton et al., 2004; Barton et al.,2010) have effectively employed both computational applications (USLE and GIS) and developed them further using a Geographic Resource Analysis and Support System (GRASS) to model socio-ecological interactions. This type of approach will not only enable visualization of a landscape's erosion record, but it will also allow (1) comparisons to be made between long-term landscape dynamics and the archaeological record as well as (2) further testing using different landscape settings and different scales of human activity.

Dating

Dating of colluvial sequences is rarely easy. Artifacts such as pottery and lithics are often included in eroded soils as hillwash deposits, but of course, they may be inverted or mixed in depositional terms, making them unreliable indicators of the age of any slope deposit. They should certainly not be used on their own without other corroborative data and dating methods. But, it is a different matter if standstill zones with in situ archaeological materials are found within a colluvial sequence, such as the Bronze Age and later sequence at Brean Down (Bell, 1990) (Figure 7a). This type of episodic deposition and standstill sequence allows dates "after which" (*terminus post quem*) and relative dating of the main phases in the profile based on their archaeological components. In addition, it is sometimes possible to make



Colluvial Settings, Figure 10 Photomicrographs of colluvial features in thin section: (**a**) Juxtaposed fabrics from the Neolithic paleosol at the Etton causewayed enclosure, Cambridgeshire, England (frame width = 4.5 mm; cross-polarized light). (**b**) Fine calcitic sandy clay loam with calcitic/gypsic infills from Gatas, Spain (frame width = 4.5 mm; cross-polarized light). (**c**) Pure clay as channel infills/linings in a pre-Iron Age paleosol under hillwash at Ribat Amran, Yemen (frame width = 4.5 mm; plane-polarized light). (**d**) Pure to dusty clay linings of the soil fabric of barrow mound 41, Wyke Down, Dorset, England (frame width = 4.5 mm; cross-polarized light). (**e**) Clay intercalations in a pre-Bronze Age paleosol under hillwash near Stonehenge, Wiltshire, England (frame width = 4.5 mm; plane-polarized light). (**f**) Bronze Age, depleted, poorly sorted, fine sandy loam hillwash fabric, Barranco de Gatas, Spain (frame width = 4.5 mm; cross-polarized light).

relative linkages to other regional events recorded in associated environmental, archaeological, and/or historical records that are already dated. For example, Nile flood records in pharaonic Egypt (Adamson et al., 1980; Brown, 1997, 6–7), extreme weather conditions such as those occurring during the Little Ice Age of northwestern Europe in the AD 1500s (Lamb, 1979), the huge eruption of Santorini in the Bronze Age (*c*. 1625–1645) (Aitken et al., 1988), biostratigraphic correlation with well-dated pollen records in the study area (Brown 1997, 47), and tree-ring series and ice core sequences can provide proxy dated records of major erosive and climatic events for some parts of the world.

Radiocarbon dating is an ideal method (Taylor, 2001), but it depends upon an organic component – such as charcoal, wood, bone, or other humic substance – being incorporated within the eroded material or stratified within any standstill horizons. There might nevertheless still be problems related to how the organic matter selected for dating was introduced into the eroded sediments, and uncontrolled taphonomic processes could produce inverted or otherwise erroneous dates. The reliability of any dated sequence is improved by obtaining numerous dates. For example, in the Dhamar Highlands of Yemen, sets of radiocarbon dates from the fifth millennium BC were obtained from the humic content of buried soils associated with several pre- and post-Neolithic hillwash sequences (Wilkinson, 2005), and in the central Rio Puerco valley of New Mexico, some 125 radiocarbon dates were obtained from charcoal in one reach of the Rio Puerco and its associated tributary Arroyo Tapia in order to date the 11 m thick colluvial/alluvial/buried soil sequence from about 5750 BC to the present (French et al., 2009).

Luminescence dating is another excellent technique, now increasingly being used because it yields much better accuracy than it has previously and is widely applicable (Aitken, 1997; Grün, 2001). Thermoluminescence dating (or TL) may be used on pottery and burnt flint, and optically stimulated luminescence (or OSL) works well for sedimentary sequences, especially where there are clear contacts of eroded material with buried land surfaces. For example, early Neolithic TL dates were obtained from pottery in hillwash deposits associated with two Neolithic sites in the Troina valley of north-central Sicily, and Bronze Age, Roman, and late medieval OSL dates were determined from the various stop/start alluvial profiles in the associated river floodplain (Ayala and French, 2005; R. Bailey, pers. comm.). Recent work on the Channel Island of Herm has successfully employed OSL dating techniques to chart the episodic deposition of windblown sands between about 1200 BC and AD 1600 on buried soils of Neolithic age (Bailiff et al., 2014; Scarre and French 2013).

In sum, the combination of dated archaeological associations and environmental sequences and the use of radiocarbon and/or OSL techniques are essential tools with which to date colluvial sequences. OSL dating should revolutionize future understanding of dynamic landscape change where there are repeated episodes of soil erosion and deposition.

Importance and conclusion

Colluvial deposits and the land surfaces and paleosols that they bury represent valuable resources for archaeological, paleoenvironmental, and landscape interpretation. They inform us not only about landscape development and land use in the past but also (1) the variability of human and natural impacts on valley systems, (2) the links between past and current processes of land degradation, and (3) possibly even associated climate change. The use of new techniques, such as micromorphology, OSL dating, and GIS-based modeling tools, is beginning to transform our understanding of the chronology of many colluvial sequences, as well as our ability to relate these deposits to human-land interactions through time.

Acknowledgments

I would like to thank Drs Mike Allen and Richard Macphail and Professor Paul Goldberg for permission to use Figure 1 and Professor Martin Bell for Figure 7a.

COSMOGENIC ISOTOPIC DATING

Ari Matmon
The Institute of Earth Sciences, The Hebrew University, Jerusalem, Israel

Definition

Calculating the age of rock and sediment surfaces according to their concentration of cosmogenic isotopes.

Cosmogenic isotopes, such as ^{26}Al, ^{10}Be, ^{21}Ne, ^{36}Cl, ^{14}C, and ^{3}H, are produced in the atmosphere as *meteoric nuclides* and at the surface of the Earth as in situ *terrestrial cosmogenic nuclides*, or TCNs, by interaction between cosmic particles and target atoms (Gosse and Phillips, 2001; Dunai, 2010). The production of TCN depends on geographic location and altitude.

Cosmic particles are attenuated so that they produce cosmogenic isotopes only within the upper several meters of the Earth's crust. Therefore, the concentration of TCN in rock or sediment is a good indication that it spent time close to or at the surface.

The concentration of TCN in a sample can be interpreted in two end-member ways (Bierman, 1994):

1. Representing a constant erosion rate (E) over a long time ($t \approx \infty$)

$$N = \frac{P}{\lambda + \frac{E}{\Lambda/\rho}} \tag{1}$$

2. Representing exposure time at the surface and assuming $E \approx 0$

$$N = \frac{P}{\lambda}\left(1 - e^{-\lambda t}\right) \tag{2}$$

where
N = concentration in atoms g^{-1} quartz
t = exposure time in years
λ = decay constant (yr^{-1})
E = erosion rate in cm yr^{-1}
P = production rate at depth in atoms $year^{-1}$ g^{-1} quartz
Λ = attenuation length (g cm^{-2})
ρ = overburden rock density (g cm^{-3})

The choice of calculating an erosion rate or exposure age depends on the context. Relevant examples are the calculation of exposure ages of relict surfaces, such as glacially carved surfaces, or of boulders that have experienced very little erosion. On the other hand, erosion rate calculations are suitable for landforms that are continuously being eroded due to tectonic uplift.

Quartz is commonly used in TCN dating. It is widely available in rocks and sediments, its chemistry is simple, and the analytical extraction of TCN is relatively straightforward.

Cosmogenic isotopes can also be used to date the age at which a sediment was buried, for example, in an alluvial terrace, glacial till, or in caves (Granger, 2006). The $^{26}Al/^{10}Be$ ratio in buried quartz grains, which were previously exposed, will decrease at an exponential rate due to the different half-lives of the two isotopes:

$$\frac{N_{26}}{N_{10}} = \left(\frac{N_{26}}{N_{10}}\right)_0 e^{-t_{burial}\left(\frac{1}{\tau_{26}} - \frac{1}{\tau_{10}}\right)} \tag{3}$$

where

N_{26}, N_{10} = measured concentrations of ^{26}Al and ^{10}Be (atoms g^{-1} quartz)
$(N_{26}/N_{10})_0$ = initial $^{26}Al/^{10}Be$ at burial
t_{burial} = time since burial
τ_{26}, τ_{10} = mean lives of ^{26}Al and ^{10}Be (year) ($\tau = t_{1/2}/\ln 2$)

This application of cosmogenic isotopic dating has been used to date buried sediments and artifacts in prehistoric sites such as Sterkfontein (Partridge et al., 2003) and Wonderwerk Cave (Matmon et al., 2012) in South Africa.

Definition

Data visualization. Pictorial representations that are derived from qualitative or quantitative raw data to infer process or patterns in phenomena. Data visualization is closely linked to *informatics*, the collection, indexing, storage, retrieval, analysis, synthesis, and dissemination of data (He, 2003) and *graphic design*, which is the study of the technology, implementation, and social impact on human visual communication (Frascara, 1988).

Introduction

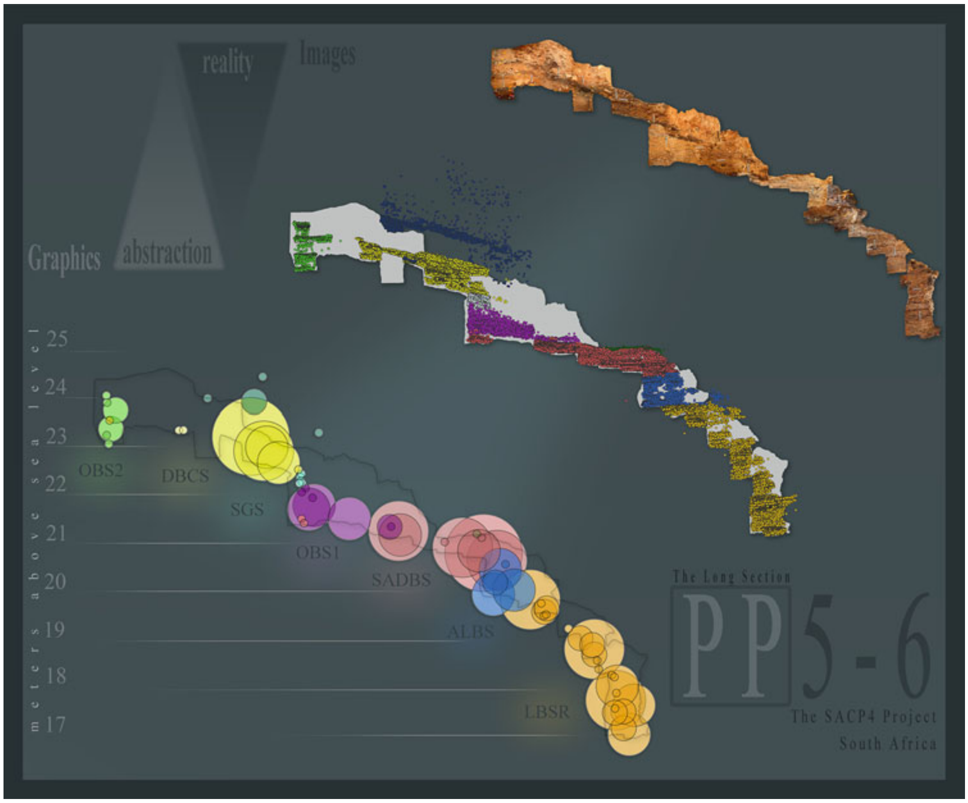
Multimedia learning theory posits that the human brain creates dynamic associations between words, pictures, and auditory information to maximize learning capability (Mayer, 2001). Sociological studies of scientific practices have also showed that visualizations are a key part of the discovery process and the transmission of information among individuals (Lynch and Woolgar, 1990; Dibiase et al., 1992; Suárez, 2010; Allamel-Raffin, 2011; Gelfert, 2011). While words alone are an effective medium to transmit complex information, they may be less effective than when they are paired with pictures. Thus, one needs only to look at the myriad of papers, presentations, or field books to see that visualization is innate to scientific practice regardless of time period, theme, scale, or methods.

Visualizations are versatile tools because they work as a heuristic device capable of distilling real-world experiences and phenomena into simplified abstractions that can convey specific ideas, meanings, or knowledge (Gooding, 2008; Wang and Shen, 2011). The abstraction of visual representations is graded. At one end of the spectrum are *images,* like photographs, which mimic the real world and whose internal elements have no inherent meaning. On the other end of the spectrum are *graphics*, like maps, which are abstracted representations of the real world that are used to convey specific meaning through their symbolic representations. The level of abstraction and inherent meaning between images and graphics thus creates a fundamental difference in how these visualizations are used (MacEachren, 1994): *images* lead one to question the picture itself, whereas *graphics* lead one to question the relationship between what is being symbolized within the picture. These concepts are represented in Figure 1, which shows how a photographic image can be progressively simplified and abstracted to convey only specific information. By abstracting the image, it is much easier to analyze the relationships between the symbols.

Visualizations can also be used to describe empirical observations and to develop hypotheses. As visual *models*, they can also be tested and refined themselves. Thus, everything from informal field sketches (sometimes of dubious quality) to formalized maps, graphs, charts, figures, photographs, and animations all serve the same purpose. They allow the geoarchaeologist to conceptualize complex ideas,

Electronic Supplementary Material The online version of this chapter (doi:10.1007/978-1-4020-4409-0_56) contains supplementary material, which is available to authorized users.

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,



Data Visualization, Figure 1 Differences between graphics and images. This figure shows the PP5-6 long section at varying levels of abstraction to illustrate the difference between images and graphics. The photomosaic of the long section in the *upper right* corner most closely approaches reality, and interpretation is centered on the image itself. In the center, the image has been abstracted as a silhouette overlaid by points representing archaeological plotted finds color-coded to major stratigraphic groups. The interpretation is now shifted to the relationships between the elements within the graphic and not the long section. In the *lower left*, the graphic is abstracted further to control what information is conveyed to the observer: in this case, the density of plotted finds within sub-stratigraphic groups.

organize when and how to test ideas, develop new ideas, and describe and disseminate results.

This contribution will review how new digital technologies are changing the way data are visualized. Several common applications of data visualization within geoarchaeology and the broader archaeological sciences are presented, with critiques regarding how some visualization methods are used in the process. Effective integration of a wide diversity of disciplines is crucial to archaeological research. Data visualization can assist this, so a brief example is offered to show how multi-proxy datasets derived from artifact plots, micromorphology, stratigraphy, and optically stimulated luminescence (OSL) data are currently being integrated into empirical 3D models with the intention of testing hypotheses about site formation and human occupation at the site of Pinnacle Point 5-6 (PP5-6), near Mossel Bay, South Africa.

Georchaeological visualization in the digital age

Only a few years ago, the production of visualizations was a specialized and typically non-digital affair. Today, the visualization process – from field data collection to final image production – is nearly or entirely digital. This change can be attributed to exponential increases in computing power over the past three decades alongside the concomitant decrease in computer price/performance ratios (Moore, 1975; Dongarra et al., 2010; Fuller and Millett, 2011). Simultaneously, newer software and digital input devices like cameras, scanners, and measurement tools are now more commonly available and affordable.

The plethora of new software has firmly shifted the creation of data visualizations from specialists to the end user. On the one hand, this is beneficial to researchers, who are now empowered to create visualizations that suit their needs. On the other hand, empowering end users who may have little or no specialized training in GIS, cartography, graphics design, or even statistics (to name but a few) emphasizes their commonsense intuitions that may run counter to established expert knowledge. This phenomenon is variably described in cognitive science as *naïve* "geography" (Egenhofer and Mark, 1995), "realism" (Smallman and Cook, 2011), "cartography" (Hegarty et al., 2009), and "statistics" (Trumpower and Fellus, 2008).

One example of data visualization naïvety is that realism increases performance. Yet, Hegarty et al. (2009) found that increasing map realism also increased a person's data extraction time by ~10 %. Another example (which happens also to be common among archaeologists) is that small-scale maps equate to small areas, and vice versa. In fact, the opposite is true (Harris, 2006): small geographic areas have larger representative fractions (e.g., 1:5) than small-scale maps (e.g., 1:250,000) that represent larger areas. Furthermore, there is abundant research on the mechanics, cognition, and psychology underlying our ability to see and understand visualizations, yet this information may be unknown to nonspecialists (Ware, 2013). This includes the numerous optical illusions, biases, and limitations that influence how people subjectively perceive space, depth, color, and movement.

Color, for example, is perceived in context, so that the same color can appear differently based on its surroundings within an image (Ware, 1988). Chromatic aberration and insensitivity of the human eye to short-wavelength light also makes the color blue a poor choice for fine details that might appear fuzzy, especially on black backgrounds (Jackson et al., 1994).

The take-home message is that while we may all be able to create detailed and complex data visualizations, it is still prudent to work within a multidisciplinary framework with specialists in each respective field who may be able to provide expert knowledge to optimize the data visualization task at hand. Otherwise, simple mistakes may lead to significant problems in the way the visualization is seen and understood.

Application of data visualization within geoarchaeology

The use of data visualizations within geoarchaeology and the broader archaeological sciences is also changing as digital technologies become more common. By far the most frequent application of data visualizations has been what we refer to here as *visual aids*, which supplement analyses, discussions, or presentations. Visual aids can be static imagery, graphics, or animations, but they share the underlying commonality of being generalizations derived from particular observations, thus making them inductively based.

Maps are among the commonest examples of visual aids, and multiple studies have shown that the usefulness of maps lies in their generalizing capabilities to develop ideas or hypotheses from complex real-world phenomena (MacEachren and Ganter, 1990; Fisher et al., 1993; MacEachren, 1995; Häberling et al., 2008; Hegarty et al., 2009). Similarly, scientific visualization methods for exploratory and summary data analysis, like diagrams, flow charts, and graphs, are also visual aids. A good example of visual aids in geoarchaeology is Hassan's (1978) well-illustrated discussion on the contributions of sedimentological analysis within archaeology, which included flow charts, a Sankey flow diagram, oblique 3D cross sections, stratigraphic profiles, ternary diagrams, thematic illustrations, and even a stacked, shaded line graph. Visual aids can also be interactive, as shown by Entwistle et al. (2009), who used 3D images to study soil chemical distributions at an archaeological site in the Scottish central highlands. The similarities between visual aids, as a class of data visualization, are thus not within the technical complexity or type of visualization rather than in their application as a multimedia supplement.

Site prospection methods have also been applied largely as visual aids independently of the method being used (e.g., radar or aerial imagery). Here, the focus is on condensing large amounts of data to identify specific features that can then be analyzed in more detail. Wynn's (1986) review of remote sensing methods in archaeology clearly emphasized their data collection capabilities as a way to survey and summarize large areas rapidly. Conyers (2004) also highlighted the exploratory role of ground penetrating radar (GPR) as a rapid and noninvasive method. Dalan (2008) further suggested that archaeogeophysics remained limited to a "confirmatory method." Meanwhile, Gaffney's (2008) updated review on archaeological geophysical techniques similarly emphasized their prospection and 3D modeling capabilities, but he stopped short of articulating how the datasets could be applied empirically. More recently, however, Conyers (2010) and Conyers and Leckebusch (2010) have suggested that the application of GPR is moving from prospection to being a primary and empirical data source.

The widespread application of visual aids has thus proved to be a useful tool for research and data dissemination. But, focusing only on the acquisition and summary of data in a visual manner potentially hobbles scientific progress toward also using data visualization as an empirical tool. Perhaps this is why Llobera (2011, 194) has noted that:

> Archaeological visualization has not developed much since the introduction of stratigraphic sketches by Boucher de Perthes (1847) and distribution maps by O. G. S. Crawford during the early twentieth century. Even with the incorporation of advanced tools such as GIS, the use and production of forms of visual communication remain painfully narrow. . . . For the most part, the role of visual output is restricted to legitimizing our output rather than as an active element within the archaeological reasoning machinery.

3D, VR, and animations

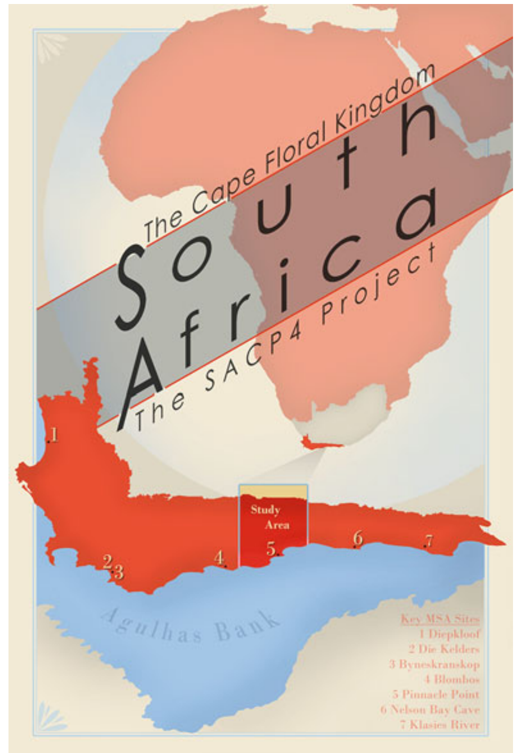
3D and virtual reality (VR) are broadly seen as a superior way to visualize data (Barceló et al., 2000; Gillings, 2005). Multidimensionality provides an immersive and interactive experience that augments learning in users with already high spatial abilities as well as providing a compensatory effect in learners with low spatial abilities (Höffler, 2010). Kumar and Benbasat (2004) even found that 3D graphs outperform 2D graphs overall in data extraction exercises, whereas Wickens et al. (1994) found that 3D representations of surfaces were more easily understood than 2D representations.

3D, VR, and animation appear to be the data analysis and dissemination models of the future, as recognized in the many software packages that now offer native 3D manipulation of data. ESRI ArcGIS, for example, supports multidimensional rendering and analysis of raster and vector datasets via ArcScene and ArcGlobe. GRASS GIS supports volumetric modeling as well as advanced spatial analysis capabilities. The stereo analyst extension for ERDAS Imagine 2011 allows users to extract 3D data from digital stereo models. GPR-SLICE provides detailed 3D (i.e., volumetric) and 2.5D (i.e., non-volumetric depth of field) rendering of ground penetrating radar data. Statistical software packages like SYSTAT, PASW/SPSS, and SAS, as well as add-ins to Microsoft Excel like XLSTAT, allow the user to generate 3D graphs and charts from tabular datasets. Image creation and processing software like Adobe Photoshop and Illustrator CS5 also offer 3D design utilities. The industry standard format for publications, Adobe PDF, also now natively supports 30 different 3D model formats including VRML (for web-based 3D) and KMZ (Google Earth). Lastly, many scientific journals now accept animations and 3D models within PDFs or as supplementary online materials.

Curiously though, most applications of 3D data visualization seem to conform to Llobera's (2011) observation that they are used only to legitimize what we already know, thus being merely *visual aids*. Within the archaeological sciences, this narrow application may be due to the developmental history of 3D and VR, which has been largely unorthodox and haphazard (Gillings, 2000, 2002). Most software is not written for an archaeological audience or its scales of interest. ESRI ArcGIS, for example, is progressively being tailored toward small-scale 3D geographic applications like urban planning (ESRI, 2011). This may aid regional geomorphological studies and archaeological surveys, but it could inhibit large-scale site-based 3D studies. The same can be said of the immensely popular Google Earth, which is also designed for regional applications.

The realism inherent within 3D and VR models may also be a limiting factor in their current application. 3D and VR models are becoming almost too convincing, which, at least, inhibits critical questioning and, at most, can imbue these visualizations with a false sense of authority (Lock, 2003). This, and their esoteric development, has led Gillings (2005) to suggest that 3D and VR models are seen to be self-evident, so they are developed ex post facto without any hypotheses leading to the model development and testing process. The end result is that these showy visualizations are thus often dismissed because they are seen to be "pseudoscientific" (see also McCoy and Ladefoged, 2009).

Conventional use is changing, however. Barceló (2001) argued that VR needs to move away from presentation toward explanation, where the digital environments become testable visual models in their own right. Herries and Fisher (2010) tested 3D models of mineral magnetic data against micromorphological, geochronological, and stratigraphic observations to illustrate complex

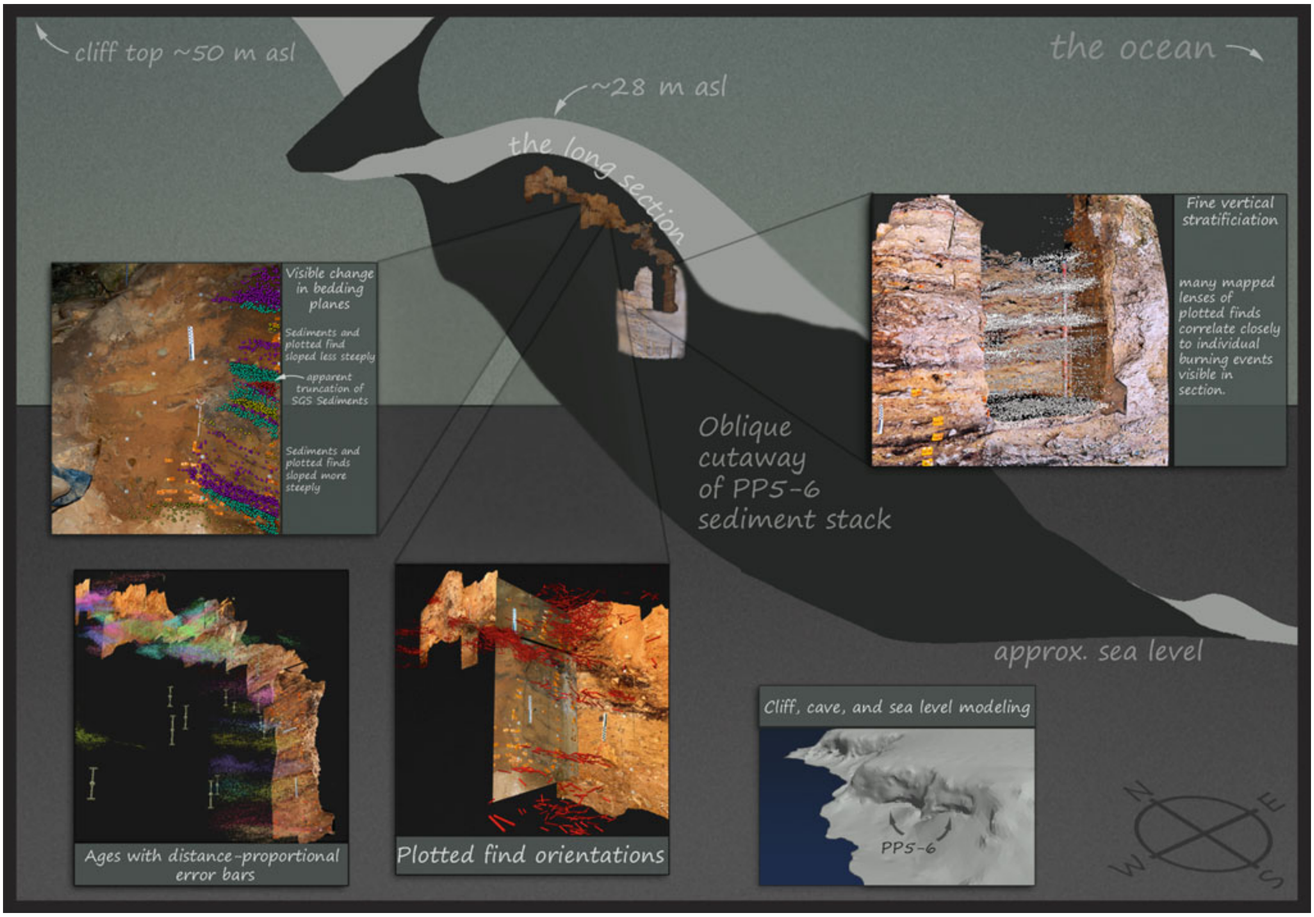


Data Visualization, Figure 2 The SACP4 project study area within the Cape Floral Region of South Africa. Many sea caves on the south coast of South Africa preserve paleoenvironmental, paleoclimatic, and paleoanthropological records from the Middle and Late Pleistocene. SACP4 is studying a series of caves at Pinnacle Point in the heart of the Cape Floral Region.

spatiotemporal patterning in fire use at cave PP13B in South Africa. Fisher et al. (2010) tested 3D spatiotemporal models of coastline changes across the south coast of South Africa using geochronological, strontium isotope, and archaeological datasets. In both examples, the 3D models were used as a primary, independent, and testable dataset that was governed by underlying hypotheses. Furthermore, to communicate more effectively the complex 3D patterning, both papers integrated static imagery and narrated 3D animations. Lastly, Fisher et al. (2010) provided detailed metadata on the methodology, computer scripting, and model parameters that enable the duplication of the results. Drawing upon the theme of building and using empirical 3D GIS models of geoarchaeological data, the following section will present a brief case study focused on site PP5-6 in South Africa.

The PP5-6 3D GIS

Pinnacle Point is located within the Cape Floral Region on the south coast of South Africa. Similar to other sites along the south coast, a series of sea caves at Pinnacle Point preserve long sedimentary records of climate, environment, and human evolution (Marean et al., 2007; Marean, 2010) (Figure 2). Since 2006, researchers from the SACP4



Data Visualization, Figure 3 The SACP4 3D GIS: This image provides an overview of the PP5-6 3D GIS and how multi-proxy datasets have been integrated in the framework to tackle complex archaeological and geoarchaeological questions.

project led by Marean have focused on site PP5-6, a >100 m long cavity that was incised into the cliff face by multiple past high sea stands. Sediments incrementally built up in front of the cavity since the last interglacial high stand (~125,000 years ago), providing the substrate for past human occupations at the site.

Overviews of SACP4 excavation methods can be found in Marean et al. (2007) and Marean et al. (2010). Excavations at PP5-6 have been conducted over a 30 m long distance roughly north-south, spanning over 14 vertical meters. The broad spatial extent has required detailed analysis to understand the complex history of site formation. These ongoing studies have included geochronology, micromorphology, magnetic susceptibility, on-site macrostratigraphic characterizations, and mapping.

All excavation coordinate data and imagery are integrated into a 3D GIS model using ESRI ArcGIS 10. Nearly 250,000 total station plotted finds have been mapped to date. These plotted finds represent, among other things, archaeological stone, ochre, or ostrich eggshell artifacts, as well as faunal remains (mollusks, mammals, etc.). Section imagery was captured using Nikon digital SLR cameras under consistent camera orientation, lighting, focal length, aperture, and sediment moisture conditions. All images were post-processed for geometric distortion in Adobe Photoshop CS5 using unique camera model/lens correction profiles. Photographic mosaics were created using PTGui v.9 and Adobe Photoshop before being geo-rectified using ArcGIS. Additional details on integrating the photography into ArcScene will be made available in forthcoming publications.

Integrating the plotted finds and the geometrically rectified section photography in 3D allows unprecedented recognition of vertical and lateral patterning in the plotted finds. The resolution of the 3D plotted finds is so fine that empirical observations of features like changes in bedding planes can be identified independently from other data sources or methods where they would be otherwise invisible (Figure 3). Many small lenses of plotted finds also correlate closely with discrete burning events seen in the sections, which represent individual hearths that were likely

Data Visualization, Video 1 The PP5-6 3D GIS supplementary video was produced using a combination of software. ArcGIS 10 ArcScene and ArcGlobe were used to develop the 3D GIS and subsequent animation sequences. Adobe Photoshop CS5 was used to create other still graphics. Audio files were recorded using a Samson S11 cardioid microphone and Olympus WS-210S digital recorder. Audacity 1.3 was used to remove background noise, sound normalization and compression, and equalization using the EMI 78 standard. The video was produced using Corel VideoStudio Pro ×4. The aspect ratio was set to 16:9 widescreen format. The final movie was exported using the H.264 codec.

used for only a limited time. Plotted find orientation is also recorded, and it can be used to test for postdepositional disturbances (Bernatchez, 2010) and to create directional flow models to study erosional patterns at the site.

The 3D plotted find point data was analyzed and grouped based on the structure (e.g., laminations, clusters, absences, etc.) visible within the dataset. To minimize preexisting bias, these points were analyzed using a single point color. Thereafter, the groupings were tested against infield stratigraphic observations, thereby allowing simultaneous testing of field assignments and the 3D analysis. The final stratigraphic groupings are represented in Figure 1. When micromorphology and OSL age estimates are also integrated into the 3D GIS, a third invaluable and independent test of the stratigraphic models is created.

The result is a comprehensive characterization of the PP5-6 stratigraphy derived from multiple, independent datasets (Figure 3). The PP5-6 3D GIS has thus proved to be a valuable *visual aid* and *empirical* model. As a visual aid, it provides unprecedented access into the archaeological deposits, allowing researchers to see and check the accuracy of new data and spot new and interesting features for future study. The 3D framework is also an invaluable tool to show and explain complex ideas using animations and still imagery within and outside the main research group. To showcase the animated capabilities of the PP5-6 3D GIS, and similar kinds of datasets, a brief supplementary movie is provided with this entry (Video 1). But when used as a deductive reasoning tool, the PP5-6 3D GIS also allows SACP4 researchers to test observations and hypotheses relating to the archaeological and sedimentological records. 3D visualization may not be necessary to address each research question, but on the whole it provides an immersive, dynamic, and multi-local experience that is lacking in 2D imagery. Contrary to Llobera's perspective (2011), the state of data visualization within geoarchaeological and the broader archaeological sciences is actually quite positive. Newer software, faster computers, and flexible solutions to tackle complex problems will ultimately provide innovative and better ways to visually observe and test scientific data.

Synonyms

Tree-ring dating

Definition

The word dendrochronology comprises three parts, originating from Greek "dendron" (tree), "chronos" (time), and -ology (study of), and is defined as "the science of dating tree rings" (Kaennel and Schweingruber, 1995, 65). It is a chronometric ("absolute") dating technique that employs records of annual growth increments in trees to establish the calendar age of wood samples taken from living or nonliving trees and from wood that has been used by humans.

History

Interest in tree growth and the rings produced by this phenomenon has its origin in fifteenth century AD and possibly before. Leonardo da Vinci is often cited as the first notable scientist not only to write about tree growth but also to speculate that tree rings and environmental parameters (rainfall) in the growing season might be linked (Schweingruber, 1988; Speer, 2010). In the seventeenth century, the invention of the microscope paved the way for wood anatomical studies, and by the mid-eighteenth century, an understanding of tree-ring development had emerged from the work of Theodor Hartig and others (Schweingruber, 1988). It was not until the early twentieth century that the principle of cross dating was fully established and consistently applied by Andrew Ellicott Douglass (1867–1962), who is universally acknowledged as the "father of dendrochronology" (Schweingruber, 1988, 257). Douglass and a team of co-workers applied the newly emerging technique of dendrochronology to date archaeological sites in the American Southwest. In 1923, the National Geographic Society sponsored a "Beam Expedition" (Nash, 1999), which led to the sampling of numerous timbers and the establishment of the first long tree-ring chronology back to AD 1280, as well as a 585-year floating chronology (not tied to the ring sequence ending in modern time) (Schweingruber, 1988). Douglass founded the first laboratory dedicated to dendrochronological research in 1937, the Laboratory of Tree-Ring Research (Tuscon, Arizona), which has remained a center of excellence in teaching and research and has contributed significantly, although not in isolation, to the current large global network of tree-ring laboratories (Grissino-Mayer, 2014).

Since the early twentieth century, dendrochronologists have produced records of chronometrically dated tree-ring patterns, i.e., tree-ring chronologies, stretching further and further back in time. In North America, two key species in this chronology development have been the giant sequoia (*Sequoiadendron giganteum*) and bristlecone pine (*Pinus longaeva*). The latter is particularly useful in dendrochronology, being very long lived, as its Latin name suggests, with some individual trees living in excess of 5,000 years (Rocky Mountain Tree-Ring Research, 2013) and a continuous master chronology extending back 8,681 years put in place by the early 1980s (Ferguson and Graybill, 1983). Their high-altitude habitat, in areas such as the White Mountains in California, makes bristlecone pines sensitive to temperature and precipitation. As a result, this species has been important in the development of long-term climate reconstructions (Scuderi, 1993; Woodhouse et al., 2011), in determining the global effects of volcanic eruptions on ecosystems (LaMarche and Hirschboeck, 1984), and in calibrating the radiocarbon timescale (Walker, 2005, 32–33).

In western Europe, the key species for dendrochronology are both oaks (*Quercus patrea* and *Q. robur*) due to their consistent growth patterns that rarely exhibit missing or false rings and their widespread occurrence both in natural environments and those associated with human activity, e.g., building timbers. Work began on producing long oak chronologies in the 1960s and 1970s, mainly in Germany and Ireland, but it was not until the early 1980s that the first long European oak chronologies were finalized (Pilcher et al., 1984; Baillie, 1995). A large network of local and regional chronologies has now been developed, providing the basis for routine dating of archaeological timbers (Haneca et al., 2009), as well as applications in climate and other reconstructions (Rinne et al., 2013). Oak is a much shorter-lived species than bristlecone pine, and most specimens rarely exceed an age of 200 years. Therefore, chronology building in western Europe has been based on cross dating of many samples from living trees, buildings, and trunks preserved within peat bogs.

Tree-ring chronologies now stretch back into the last ice age based on trees that grew in areas less influenced by the immediate effects of ice advances. German oak chronologies now cover the Holocene (Becker, 1993), and they have been extended back into the last glacial period using a floating Preboreal Pine Chronology of previously unknown age (Friedrich et al., 1998, 1999). This dating is based on dendrochronological cross matching (see "Cross-dating and chronology building") and on radiocarbon wiggle matching (Baillie, 1995, 69–72). Although chronometric dating cannot at present be guaranteed, sites from southern and central Europe have produced tree-ring records that date to around 14,300 years BP (Kaiser et al., 2012). A BP date indicates years "before present," where the present is set at AD 1950 as the baseline standard for radiocarbon dating. Future sampling in these geographical areas and the extension of chronologies may well lead to a chronometric late-glacial growth record with significant implications for advancements in radiocarbon calibration and for improved understanding of past climate change.

In the southern hemisphere, there are also significant subfossil (the preserved remains of a living organism that has undergone limited physical and chemical change) tree-ring records forming floating chronologies potentially as far back as 45,000–25,000 years BP (Turney et al., 2010). These have been created following the sampling of subfossil Kauri (*Agathis australis*) buried in bogs in New Zealand. This long-lived species produces annual tree rings that reveal a marked sensitivity to climate (Hogg et al., 2012). Turney et al. (2010) highlight the possibility that further "harvesting" of these trees and associated sampling for dendrochronology could have significant implications for radiocarbon calibration (see "Pollution: air and soil (dendrochemistry)"), possibly as far back as 60,000 BP.

Long tree-ring chronologies have now been constructed for many areas across the globe, with their extent limited only by the availability of wood of appropriate age. Dendrochronology has developed in midlatitude areas, where tree growth is governed by seasonal weather patterns that produce distinct annual growth increments. Lack of distinct seasonality in the tropics initially made dendrochronology challenging (Worbes, 2002), but ring width and isotopic measurements have isolated annual growth responses permitting the identification of annual signals in wood and assessments of species suitability for dendrochronology and chronology building. Tropical dendrochronology is now an important emerging area within the subject (cf. Robertson et al., 2004; Wils et al., 2011; De Ridder et al., 2013).

Two major traditions emerged in dendrochronology during the twentieth century that have been key to its growth: the North American tradition with notable academics who continued the work of Douglass, including Schulman, Smiley, Hawley, Giddings, Haury, and Fritts; and the European tradition, led among others by Huber, Liese, Becker, Eckstein, Schweingruber, and Baillie.

Journals	*Tree-Ring Research*, formerly *Tree-Ring Bulletin* (North American) *Dendrochronologia* (European)

Dendrochronologists now comprise a global community brought together by similar research interests, international training, research collaborations, and conferences. Tree-ring analyses have a wide range of applications (see below) that are reflected in the vast array of journals in which dendrochronological research is now published, although the subject's roots and traditions are still clearly evident in the two main tree-ring specific journals and in the regular regional meetings held in both North America and Europe (Table 1). Tree-ring research is now well established or becoming established in other areas, notably South America, Africa, and throughout Asia, as exemplified by the growth of new organizations such as the Asian Dendrochronology Association (ADA). For extended coverage of the history of dendrochronology, see Schweingruber (1988, 255–261), Baillie (1995), Nash (1999), and Speer (2010, 28–42).

Field sampling

Samples for dendrochronological analysis can emanate from a number of sources, including timbers that form part of standing buildings, wood from archaeological sites, trees preserved in peat bogs or other natural environments, and from living trees. A general rule at the outset of all tree-ring projects is to ensure that written permission is

Dendrochronology, Figure 1 Sampling a roof timber (rafter) using a power increment borer, Salisbury Cathedral, UK (Image: J. Lageard).

gained for sample retrieval from appropriate land or property owners.

Standing buildings

Dendrochronology has dealt primarily with dating wood from standing buildings. Some of these may be private homes or public buildings, but many can be under renovation or in varying states of disrepair. It is therefore imperative that insurance is sought, safe access is carefully considered, and all relevant health and safety procedures are followed at all times (English Heritage, 1998). Initially, a trained dendrochronologist should make a building assessment to judge suitability for tree-ring dating. This should include establishing the number of building phases present, type of wood used, presence of sapwood and bark, whether there are sufficient rings, and whether there is evidence of seasoning or timber reuse (English Heritage, 1998).

Samples (ca. 50–150 mm thick) can be taken using a hand or chain saw, but when such access is unavailable, timbers are cored in situ using a powered coring device. This consists of a hollow metal tube sharpened at one end (with saw teeth) which is attached to an electric drill (see Figure 1). Core removal is a skilled operation that aims to extract a cylinder of wood parallel to the medullary rays of the timber, ensuring tree rings are sampled at right angles to their original growth positions, with a goal to sample the maximum number of rings. Training is highly recommended from an experienced dendrochronologist to avoid unnecessary damage to buildings and to avoid problems such as core overheating.

Archaeological and natural environment sites

In archaeological and natural environment sites, sampling wood for tree-ring analysis should follow the good practice outlined for standing buildings, but there are other important considerations.

Field locations should be carefully recorded and can also be contextualized within geomorphological maps. Disc samples from trunk sections should be cut at right angles to the bark, ensuring later ring measurements are not distorted. Research focusing on subfossil wood can involve techniques other than dendrochronology, and it is therefore prudent to consider the collection of samples other than wood concurrently, for example, adjacent peat or other sedimentary deposits for the purpose of pollen analysis (cf. Lageard and Ryan, 2013).

Archaeological sites frequently contain only small quantities of wood, often unsuitable for tree-ring dating (e.g., Timberlake and Prag, 2005). At some sites, however, impeded drainage can lead to the preservation of large quantities of timber. Preparation of land for new housing at Kingsley Fields (Cheshire, UK) led to the discovery of a significant Roman industrial site that had engaged in salt production. A total of 355 oak structural timbers were recovered and recorded, including those comprising a substantial wood-lined brine tank. In commercial archaeology, it is rarely possible to date large wood assemblages in their entirety, and a spot dating approach is recommended whereby a small sample is analyzed to better assess dating potential (English Heritage, 1998). At Kingsley Fields, seven samples were initially analyzed in 2002 and a further 34 in 2004 in the post-excavation phase of the project (Tyers, 2012), providing an excellent basis for dating. A large quantity of timbers and their subsamples raises important questions in terms of storage, conservation, and later display, especially with limited local museum space and resources.

Living trees

Deciding which trees to core depends on the nature of the research project. As a rule, dendrochronologists seek trees that demonstrate sensitive growth responses, as these contain more climatic information and are more likely to cross-date (see "Cross-dating and chronology building"). Conversely, complacent growth (low variability among consecutive tree-ring parameters) should be avoided where possible.

The choice of sampling sites can be guided by this distinction, as trees located centrally within the geographical range of a species are more likely to produce complacent ring series, while trees growing in more marginal conditions at altitudinal or latitudinal limits generally exhibit sensitive growth responses (see "Climate reconstruction (dendroclimatology)"). Trees with sensitive ring series can also be found where other limiting factors are present, for instance, pollution, geomorphological processes, and flooding (see "Pollution: air and soil (dendrochemistry)," "Climate reconstruction (dendroclimatology)," and "Impact of water (dendrohydrology)").

Particularly where specific phenomena such as flooding or pollution are being studied, it is important to establish a secondary field site (control site) where trees of the same species are not being influenced by the variable under investigation. The use of control sites is exemplified by Pelfini et al. (2007) in a study of ice movement reflected in larch (*Larix decidua*) growing in debris on top of a small glacier in the western Italian Alps and also in a study of water-table fluctuations caused by solution mining in Cheshire, UK (Lageard and Drew, 2008).

Once a field site has been selected, it is important to collect a representative sample of the trees present. A number of different approaches can be employed; two of the most widely used techniques are (1) defining a specific sampling area and (2) sampling along a transect. The former is often utilized when investigating stand dynamics and the latter in studies involving ecological gradients of elevation, moisture, temperature, or pollution (Watmough, 1999; Lageard et al., 2008).

The approach to coring an individual tree depends largely on the nature of the research project. For example, if the tree is growing on a slope, the force of gravity and the weight of the tree mean the trunk will start to lean downslope. As long as the tree remains securely rooted, it will compensate for this downslope force by bending the base of the trunk with the growth of reaction wood to allow the upper part of the trunk to grow vertically (saber or geotropic growth). In conifers, such compensation causes the formation of a type of reaction wood called compression wood (larger rings with thicker individual cell walls) on the downslope side of the tree, since this side of the trunk is being compressed by the downslope pull of gravity. Compression wood therefore braces the trunk against further bending, enabling it to grow upward. Hardwood trees compensate differently, and the larger rings of reaction wood in this case are called tension wood, which develops on the upslope side to counter and reinforce the stretching caused by gravity pulling in the opposite direction. So if the research aims to date the year in which a slope became unstable, then trees should be sampled from either an upslope or a downslope direction. If, however, the research is trying to understand tree response to meteorological variables, coring parallel to the contour is advisable.

Powered corers can be used, but these are cumbersome, intrusive, and potentially dangerous (Speer, 2010, 77–78), so it is more common to employ a manual Pressler-type increment borer (lengths 100–1,000 mm; diameters normally 5 or 12 mm) to retrieve a cylindrical core from the tree (see Figure 2). If properly maintained, borers may take several hundred cores during their lifetime.

When coring, careful consideration should be given to a range of issues, including sampling height (Brown, 2007), avoiding branches or injuries, aiming for the pith, the number of cores per tree, the number of cores per sample site (Speer, 2010, 176), engaging the borer, and knowing when to stop coring to avoid borer loss. For more extensive advice on borer usage and increment core retrieval, see Grissino-Mayer (2003), Speer (2010, 77–87), and Haglöf (2014). There is little research that investigates tree mortality resulting from increment boring, although Wunder et al. (2011) support general impressions of minimal impacts.

Dendrochronology, Figure 2 Extracting a 5 mm core from a cedar tree (*Cedrus libani*) in Morocco using a manual increment borer (Image: J. Lageard).

Waterlogged wood

Waterlogged wood can provide key dating control at archaeological sites, but mishandling can lead to sample deterioration and loss. As a consequence, guidelines (English Heritage, 2010) have been made available to assist archaeologists. Waterlogged wood is often by its nature very fragile, so great care should be exercised to prevent damage to samples. In particular, attention should be given to the preservation of sapwood and/or bark if present, as these can be crucial in producing precise felling or mortality dates. Increment cores and V-shaped wedges can also be taken where wood is being conserved as part of archaeological investigations (cf. Bridge, 2011), but coring is problematic when weaker sapwood is present (English Heritage, 2010). In many cases, samples can be sawn by hand, but larger timbers may require the use of a chainsaw. Ideally, an experienced dendrochronologist or wood technologist would be involved in collecting samples as part of archaeological investigations and to advise on the suitability of samples for tree-ring dating (English Heritage, 2010).

Laboratory preparation

Increment cores should be processed ideally at the end of each field day. If left too long in enclosed spaces, cores can become moldy, causing problems particularly if dendrochemistry is being investigated. Processing can involve sticking cores with wood glue into grooved wooden channels, ensuring that the rings are correctly oriented according to their growth positions within the tree. Alternatively, in dendrochemical studies, cores can be held in place on the wooden channels using string or elastic bands.

Increment cores and robust samples can be left to air dry. Once dry, samples are sanded in order to differentiate wood structure clearly, particularly ring boundaries, to facilitate subsequent ring-width measurements. Because saw dust is carcinogenic, sanding should occur in well-ventilated facilities, where dust extraction systems are in operation. Powered sanders, with vibrating plates or rotating belts, are best employed using progressively finer sandpaper (Speer, 2010, 92–95).

Waterlogged archaeological samples can be soaked in, or sprayed with, PEG (polyethylene glycol) in order to preserve the integrity of the wood structure, as demonstrated in the conservation of the Tudor battleship Mary Rose and as a precursor to freeze-drying smaller samples before measurement (Babiński, 2011). Wet wood samples are sometimes prepared using a scalpel or a sharp blade in order to differentiate the wood structure clearly (Nayling and Susperregi, 2014).

Measurement

Once wood samples have been collected and prepared, patterns of tree-ring widths or tree-ring series are measured. This process normally deals with rings starting from the oldest, ideally from the center of the tree or pith, and finishing with the most recently formed, located immediately underneath the bark of living trees.

Records of ring-width patterns can be made using the skeleton plot method traditionally employed in North America (Schweingruber, 1988, 47–50; Cook and Kairiukstis, 1990, 43–44; Speer, 2010, 96–100). This technique is still widely employed today and is particularly useful as a training tool (Sheppard, 2014), but ring-width measurements are now more frequently made using computer-based systems capable of an accuracy of 0.01 mm that employ specialized software, measuring stages, and binocular microscopes (Tyers, 1999; Speer, 2010, 102–103). Standard practice is to make consecutive ring-width measurements along at least two radii per sample. Once verified by cross matching, these are combined to make a sample mean.

Other measurement systems use high-resolution flatbed scanners to produce digital images, which can then be manipulated using specialist software such as WinDENDRO (Regent Instruments Inc., 2014) to produce ring-width measurements or to assess other parameters such as blue light reflectance (McCarroll et al., 2002).

Where subsampling of wood and preparation by sanding is impossible, such as for a valuable musical instrument, more sophisticated measuring techniques have been developed based on techniques such as computer tomography (CT). Bill et al. (2012) tested scanners used for medical and industrial purposes on air-dried archaeological oak samples and found that CT scanning was as effective in dating archaeological objects as using conventional techniques, although more time consuming. Bernabei et al. (2010) successfully employed a "Video Time Table," a portable measuring device and high-resolution video camera (VIAS, 2005), to assist in the dating of stringed instruments from the Cherubini Conservatory Collection in Florence, Italy. This system also has the advantages of being noninvasive and deployable on site with minimal disturbance to museums or curators. Similar success was reported by Okochi et al. (2007), who clearly demonstrated that an X-ray CT method could be used for the nondestructive measurement of ring widths from wooden artifacts made of ring-porous Japanese oak (*Quercus mongolica*) and diffuse-porous Japanese beech (*Fagus crenata*).

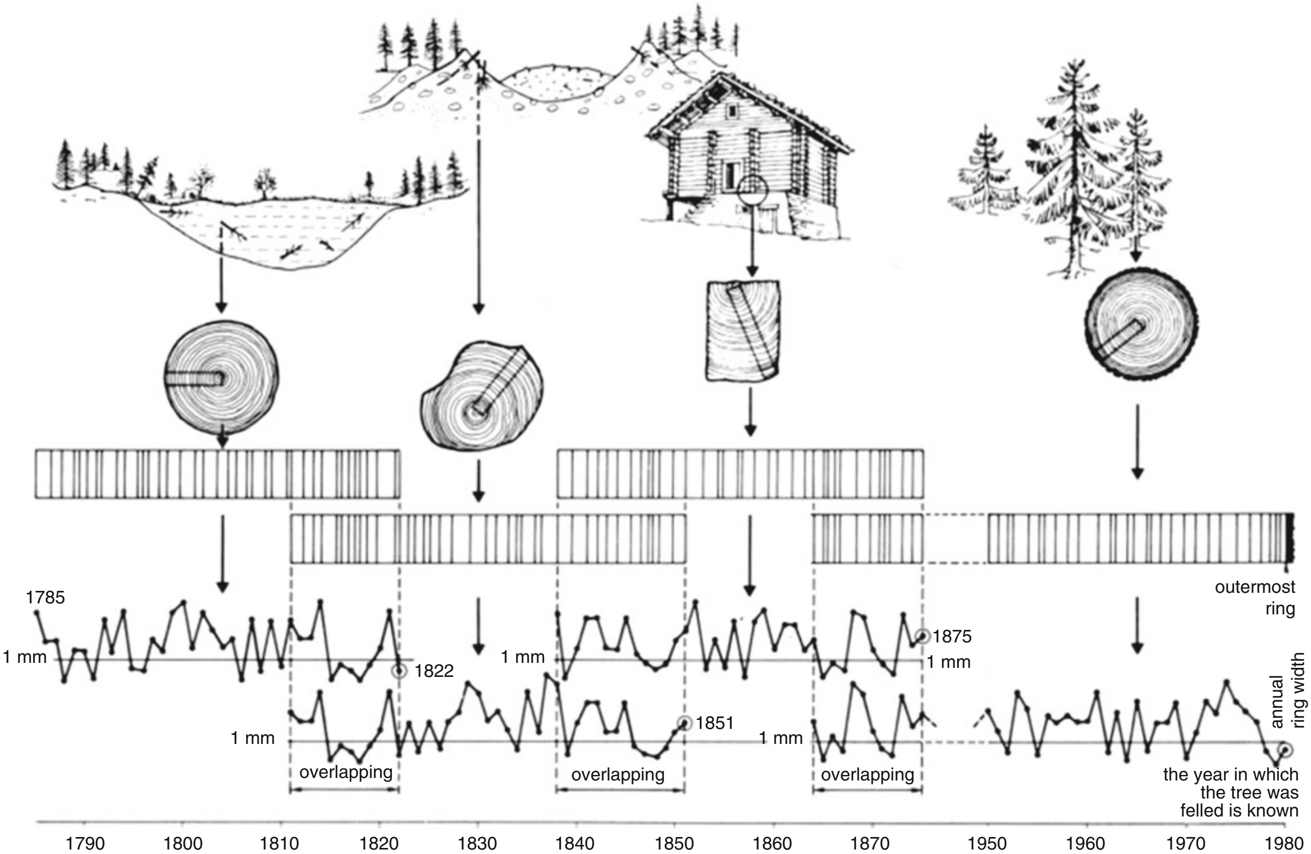
Measurements of tree-ring variables other than ring width are now common in dendrochronological research. Dendrochemistry (see section below), for example, can be employed to monitor historical changes in trace metal deposition. Once ring-width patterns are synchronized using standard dendrochronological techniques, cores can then be subsampled. These wood samples can then be digested in acid, and the resultant solutions are filtered and analyzed using techniques such as inductively coupled mass spectrometry (ICP-MS) (Watmough, 1999; Lageard et al., 2008). These additional analyses are costly in terms of time, money, and facilities. Tree-ring density has been identified as a surrogate for summer temperatures; hence, it is widely used in climatic reconstructions (see "Climate reconstruction (dendroclimatology)"). Density data can require complex sample preparation and costly measuring equipment (Schweingruber, 1988, 64–71), but image analysis and blue light reflectance are now thought to be a low-cost surrogate for ring density (McCarroll et al., 2002).

A rapidly expanding area within dendrochronology is the use of the isotopic composition of wood to reconstruct past climate. Physiological processes governing, for instance, oxygen isotope composition ($\delta^{18}O$) in wood are now generally well understood (McCarroll and Loader, 2004), and the widely acknowledged correlation between wood $\delta^{18}O$ and precipitation has driven reconstructions as far back as AD 1697 (Rinne et al., 2013).

Cross dating and chronology building

Tree-ring series from wood samples thought to have grown contemporaneously are compared using a technique known as cross dating – sometimes also referred to as cross matching. This is the procedure "for matching variations in ring-width or other ring characteristics among several tree ring series, allowing the identification of the exact year in which each tree ring was formed. . ." (Kaennel and Schweingruber, 1995, 81).

Matching tree-ring series can be achieved manually using skeleton plots (see "Measurement") or by comparing ring widths plotted on a semilogarithmic scale. Both methods place emphasis on narrow rings to aid

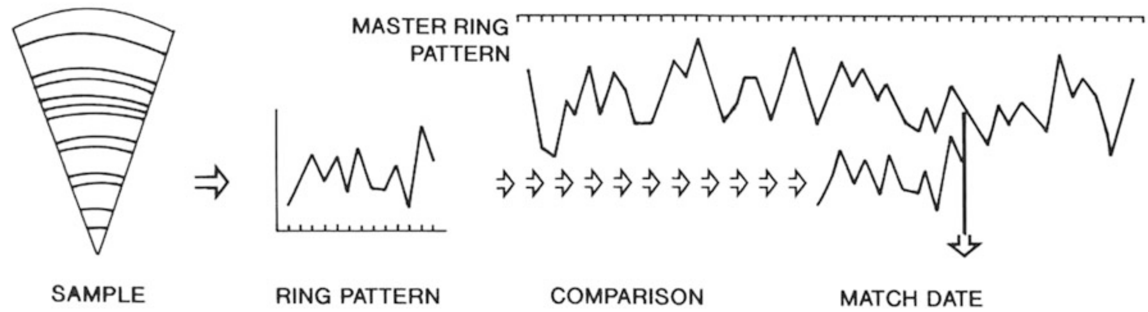


Dendrochronology, Figure 3 A visual representation of how tree-ring samples are cross-dated using the bridging technique (Reproduced from Schweingruber, 1983, 51 with permission).

comparisons. Due to the volume of data in modern research, mean ring-width measurements from individual trees or timbers are more frequently compared using specialist cross-matching software such as COFECHA (Holmes, 1983; Speer, 2010, 115–133) or DENDRO (Tyers, 1999). Cross-matching software contains routines that calculate statistically the strength of correlation between two ring-width series for a set of consecutive positions at which the two data sets could overlap. For instance, DENDRO utilizes t-value calculations based on routines published by Baillie and Pilcher (1973) and Munro (1983) to highlight positions where the two ring series might match. If the t-values exceed specified criteria, for example, $t > 3.5$, they are listed and form the basis for checking the reliability of correlations. Cross matching between two samples should always be verified by visual comparison of ring-width plots, as relatively high t-values (e.g., $t \geq 6.0$) can give spurious results.

Once exact contemporaneity between samples is established, sample means can be combined to produce an averaged tree-ring record or a tree-ring chronology. Chronologies are produced for living trees in a specific geographical or ecologically defined area, and they can be assigned calendar (chronometric) ages if careful note is made of the sampling dates of living trees. Chronologies from living trees can then be extended further back in time using wood that has been preserved in buildings or within preservative natural environments (e.g., anaerobic peat deposits). Tree-ring series from older sources of wood can be cross-dated with younger chronometrically dated records, extending the chronology of tree growth further back in time using the bridging technique illustrated in Figure 3. Tree-ring chronologies are normally made from wood samples of a single species. They can be created using several different parameters, such as ring width, maximum ring density, vessel size, or isotopic composition.

Once a chronology has been built, further statistical manipulation is possible. Such calculations include the expressed population signal (EPS), which measures the strength of common variability among the component records making up the chronology, and standardization, which maintains low-frequency variability within the data while removing age-related growth trends (Speer, 2010,



Dendrochronology, Figure 4 A schematic representation of the process leading to a dendro- or match date (From Baillie, (1995, 17) with permission).

141–142). Both EPS and standardization are considered essential in climate-related studies (see "Pollution: air and soil (dendrochemistry)").

Establishing a dendrodate

Over the last few decades, the work of dendrochronologists has been instrumental in creating a large geographical network of master chronologies largely based on ring-width measurements (Haneca et al., 2009). These master chronologies have then been used to date wood samples from natural and built environments using the software outlined above (as illustrated in Figure 4). This process seems straightforward, but there are a number of factors including minimum sample requirements, complacent growth, and irregular growth patterns (Cherubini et al., 2013) that can obviate a dendrodate.

Where an exact calendar age is assigned to a tree-ring series, different dating scenarios can arise, providing important distinctions in archaeological and other interpretations. The presence of bark can provide an exact year, and sometimes even season, in which felling or mortality occurred (Hillam et al., 1990). If bark is lacking but some sapwood rings are present, an estimated felling date or mortality date can be calculated (English Heritage, 1998). Samples lacking bark and sapwood can provide only a terminus post quem (date after which death occurred).

Applications

Tree-ring chronologies facilitate dating of wood sampled in natural and anthropogenic contexts, but dendrochronology has much more to offer than simply the calendrical dating of building timbers. Dendrochronology has now been applied in a number of subfields, from tracing movements of timber to studying the timing and impacts of past volcanic eruptions.

Archaeological dating (dendroarchaeology)

Dendrochronology is a widely used and accurate dating tool employed as an integral part of archaeological investigations (Baillie, 1982). In the American Southwest, dating both charcoal samples and beams used in building construction have provided a detailed understanding of the development of native Pueblo cultures (Nash, 1999; Speer, 2010). Recent developments in archaeological dating include chronology development from salvaged river logs (Dick et al., 2014).

Haneca et al. (2009) list some important European archaeological sites that have benefitted from routine tree-ring dating yet have also been instrumental in the development of the method. These include the Viking settlement of Haithabu (Hedeby, Germany; Eckstein, 1969; Eckstein and Wrobel, 2007), prehistoric lake shore settlements (pile dwellings) in the area surrounding the Alps (Billamboz, 1996, 2008), and the Neolithic Sweet Track in the UK dated to 3807/3806 BC (Hillam et al., 1990). Haneca et al. (2009) also note the success of routine dating for archaeological samples based on a dense network of chronologies that has been created in northern and western Europe following the development of long chronologies and the proliferation of dendrochronology laboratories, particularly since the 1990s. Tree-ring dating remains difficult in some areas, particularly southeast of the Alps (Italy, Slovenia, Austria), due to a lack of prehistoric chronologies (Haneca et al., 2009).

Widespread dating of both vernacular and more prestigious buildings (e.g., castles and cathedrals) during the historic period has revealed progression in architectural styles over time, unknown construction or repair phases, and the stockpiling of wood for prestigious building projects (Hillam and Groves, 1996; Hoffsummer, 2002; Miles, 2006).

Exciting developments related to the use of dendrochronology in archaeological dating are the dating and provenancing of shipwrecks (cf. Čufar et al., 2014; Nayling and Susperregi, 2014) and the reconstruction of past forest management practices.

Sourcing timber (dendroprovenancing)

Dendrochronology in Europe has developed regionally with chronologies being constructed and wood dated at local and regional levels. As the geographical coverage of chronologies expanded, cross matching and cross dating of wood became possible over greater distances, but there were still limits to this based on the fact that tree growth responses are governed by regional climates and environmental conditions. For example, cross matching is often possible between England and Ireland, but not between Ireland and Germany or between England and Poland. Haneca et al. (2009, 6) capture the essence of these relationships in their definition of dendroprovenancing:

> Trees experiencing similar growth conditions are expected to develop a comparable ring-width pattern. This is one of the basic principles of dendrochronology. Trees from distant geographical locations will develop growth ring patterns with different characteristics, driven by discrepancies in the local climate and site conditions. This supports the assumption that a tree-ring pattern contains information related to the location at which the tree grew. Comparison of individual tree-ring series with chronologies that reflect the average growth conditions for specific regions allows the sourcing of the origin of the timber, i.e., dendro-provenancing.

The proliferation of European oak chronologies in the 1980s opened up the possibility of unraveling significant problems that had previously been encountered in tree-ring dating. Cases in point were the art-historical oak chronologies created in the 1970s. Medieval paintings were often made on thin oak boards or panels. Attempts to date these by measuring oak ring-width series and comparing them to oak chronologies constructed from local timber sources often failed. It was suspected that the oak boards may have come from more distant locations (Baillie, 1995; Eckstein and Wrobel, 2007). Creation of a Gdańsk-Pomerania chronology by Wazny (Eckstein et al., 1986) was key to dating wood used in creating Dutch paintings and also wooden artifacts from Lübeck Cathedral, separating German timber from Baltic timber sources (Eckstein and Wrobel, 2007). The medieval Baltic timber trade has also been revealed in imports of wood used for construction purposes in the British Isles, as at Stirling Castle, Scotland (Crone and Fawcett, 1998; Mills and Crone, 2012). Art-historical oak wood in Europe is now routinely dated using Polish and Baltic reference chronologies (Haneca et al., 2005).

Perhaps the most often quoted example of dendroprovenancing is the case of the Skuldelev ships, which were excavated in a Danish fjord between AD 1958 and 1962. These included warship, trading, and fishing vessels that were clearly of Viking age in their construction, yet their oak tree-ring series did not cross-match against any German or Scandinavian chronologies. Some aspects of their design hinted at a possible British origin of the wood, and subsequent comparisons with English and Irish chronologies showed highest correlations with a chronology constructed from trees that had grown in the Dublin area (Ireland). This led to the conclusion that Vikings who had settled in Ireland constructed the ships from Irish oak around AD 1060, before sailing them back to Denmark (Bonde and Crumlin-Pedersen, 1990; Baillie, 1995).

Tree-ring chronologies now form a dense geographical coverage, particularly in northern Europe, affording the possibilities of high-resolution dendroprovenancing (e.g., Daly and Nymoen, 2008). Such studies may, however, suggest more than one possible timber origin, so the results of attempted dendroprovenancing are not always easily interpreted (Bridge, 2011, 2012). Nevertheless, tree-ring research focusing on dendroprovenancing is an increasingly important area within dendrochronology.

Sources of wood transported by rafting on rivers in central and northern Europe (for charcoal used in the production of iron) have been traced by Grabner et al. (2004). In southern Germany, the altitudinal sensitivity of growth in spruce (*Picea abies*) and fir (*Abies alba*) has permitted the provenancing of rafted logs to specific mountain areas (Dittmar et al., 2012). Dendroprovenancing can also play a critical role in evaluating the relative integrity of historic buildings (Sass-Klaassen et al., 2008). In addition to ring-width measurement, elemental and isotopic analyses of tree rings have added important new dimensions in dendroprovenancing (Durand et al., 1999; Reynolds et al., 2005; Kagawa and Leavitt, 2010).

Dendroecology

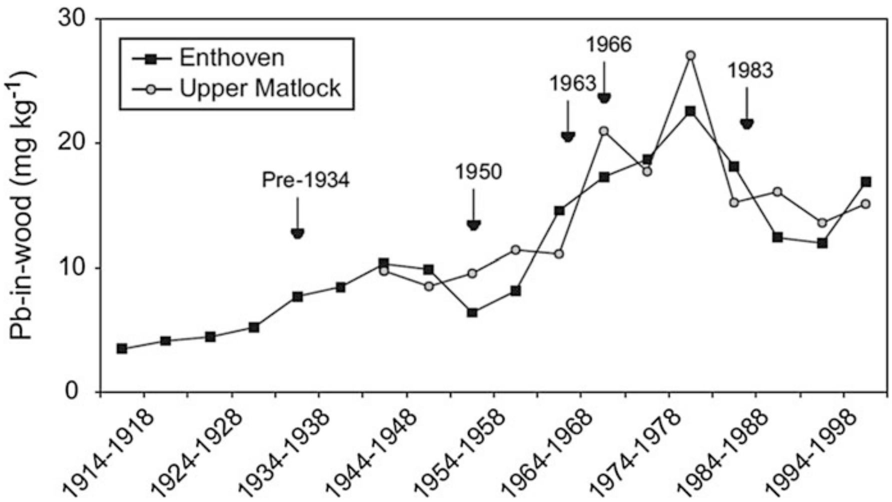
Dendroecology is a subfield of dendrochronology and encompasses all the other subfields that use dated tree rings to study ecological problems and the environment (Kaennel and Schweingruber, 1995). Examples of other subfields include dendrochemistry, dendroclimatology, dendrogeomorphology, dendrohydrology, dendroglaciology, dendrovolcanology, and a number of subfields that assist informed forest management – all covered in the sections below.

Pollution: air and soil (dendrochemistry)

Dendrochemistry has been defined as "…the use of tree rings as indicators of past chemical fluctuations in the environment" (Cutter and Guyette, 1993, 612). It has been widely employed in attempts to reconstruct pollution histories and also in the calibration of the radiocarbon (^{14}C) timescale.

Pollution directly resulting from human activities is known to have a detrimental impact on trees, causing tree mortality especially for those growing in close proximity to industrial plants (Schweingruber, 1996). The key question is whether dendrochronology can be used to reconstruct annual fluctuations in pollutants accurately.

A number of issues and potential problems exist in dendrochemical research, including (1) species suitability, (2) pollution pathways (leaves, needles, bark, or roots), (3) the effects of soil acidity on elemental uptake (cf. Guyette et al., 1991), (4) elements essential or nonessential for growth, (5) radial translocation within wood (cf. Watmough and Hutchinson, 2002), (6) tree age, (7) variations in elemental concentrations in trees sampled close together, and (8) potential chemical contamination of increment cores. These difficulties led Smith and



Dendrochronology, Figure 5 Dendrochemical records from Scots pine (*Pinus sylvestris*) sampled near a lead smelter (*black squares*) and trees from a sampling site 9 km distant (*gray circles*) in the Peak District, Derbyshire, UK (From Lageard et al., 2008, with permission).

Shortle (1996, 633) to write "...radial trends of chemical data are not good places to 'go fishing' for research topics."

Nevertheless, if careful consideration is given to potential shortfalls in designing research projects (Watmough, 1999), successful pollution reconstructions are thought to be possible (Lageard et al., 2008), and these can shed light on the scale of human impacts upon the environment in industrial archaeology. Figure 5 shows dendrochemical records obtained from Scots pine (*Pinus sylvestris*) growing adjacent to, and at 9 km distant from, a lead smelter in Derbyshire, UK. These records mirrored anticipated pollution trends based on industrial output and on increasing use of mitigation technologies. Other studies have concluded that accurate pollution reconstructions were impossible for combinations of the factors listed above (e.g., Patrick and Farmer, 2006).

Measurements of isotopic variations in wood that has been used in the construction of long chronometrically dated tree-ring chronologies in Europe and North America have also provided records of natural variations in the production of radiocarbon (^{14}C) that are now routinely applied in the calibration of radiocarbon dates (Walker, 2005, 32–36).

Climate reconstruction (dendroclimatology)

Climate is "...one of the main controlling factors of most tree-ring growth across all spatial and temporal scales" (Speer, 2010, 174). Several approaches have been adopted in order to reconstruct past climate and its effects on trees and their spatial distributions. These include (1) calibrating growth responses with meteorological data and (2) studying growth responses or the presence/absence of trees related to present-day latitudinal and altitudinal growth limits.

Dendroclimatic reconstructions seek to establish a link between specific climatic variables and tree growth, usually through statistical comparisons of tree-ring and meteorological data. Generally, standard field and laboratory methods are employed, but careful attention is required for climatically sensitive site selection, tree age, number of samples (Speer, 2010), and the need for removal of age-related growth trends (standardization). The climate response of trees is achieved using a correlation matrix, or response function analysis, to compare the master chronology with monthly climate data to identify months or seasons that correlate with ring-width data. Calibration then occurs as a transfer function (Fritts, 1976), describing the relationship between the tree rings and climate variables using linear regression analysis. Transfer function coefficients are used to transform, or rescale, the tree-ring sequence into a new sequence of meteorological estimates that can be extended back in time for the whole length of the tree-ring sequence (Schweingruber, 1988). The final stage is verification, when the validity of the model is tested by comparing reconstructed climatic data with real data that have not been used in the calibration.

Examples of dendroclimatic reconstructions based on different tree-ring parameters include Briffa et al. (2001), who reconstructed summer temperatures for the northern boreal forest over the previous 600 years based on ring density, and Rinne et al. (2013), who utilized $\delta^{18}O$ isotope measurements to reconstruct precipitation back to AD 1697.

Climatic reconstructions can also be achieved using routine dendrochronological techniques. For example, Shumilov et al. (2007) studied juniper (*Juniperus sibirica*) on the Kola Peninsula, Russia, using ring-width analyses, establishing a 676-year chronology. This record correlated well with known periods of reduced solar radiation (Sporer, Maunder, and Dalton minima) and associated decreases in hemispheric temperatures. Subfossil larch (*Larix sibirica*) has also been used in latitudinal reconstruction of climatically induced latitudinal fluctuations in the northern boreal tree line (Hantemirov and Shiyatov, 2002), and the altitudinal limit of stone pine (*Pinus cembra*) was reconstructed by Nicolussi et al. (2005) in the Austrian Alps, during the last ca. 9,000 years using living trees and subfossil samples retrieved from till in glacier forefields. Neuwirth et al. (2007) employed the more traditional pointer year approach (Schweingruber et al., 1990) in conjunction with GIS to identify spatial patterns in positive and negative growth anomalies evident in 377 ring-width chronologies from central Europe. Pointer years are cross-dated years in which the majority of trees investigated have responded simultaneously to events such as the Europe-wide drought experienced in AD 1976.

As climatic reconstructions have become more widespread, it is now possible to map the effects of specific climatic variables across regions and continents to create dendroclimatological networks (cf. Fritts, 1976). Esper et al. (2009) used 53 ring width and 31 maximum latewood density chronologies across Northern Eurasia to establish an east-west climatic gradient and a correlation between larch (*Larix decidua*) and temperature. D'Arrigo and Jacoby (1991) found links between El Niño and climate in the Southwestern United States. North Atlantic Oscillation sea surface temperature signatures are also apparent in tree-ring records of Scandinavian pine (*Pinus sylvestris*) chronologies (D'Arrigo et al., 1993).

The impacts of major climatic events on human populations have been clarified through tree-ring-based reconstructions (Jacoby et al., 1999; Stahle et al., 2000). Chronology building itself has also encountered periods where few dated samples are available (Baillie, 1995), thought originally to be artifacts of sampling strategies. These may, in fact, be genuine "gaps" related to climatic downturns or other factors such as disease that have impacted human populations as well as trees (Brown and Baillie, 2012).

Application of dendrochronology to climate has been "One of the most publically debated applications of dendrochronology" (Speer, 2010, 174). This statement referred primarily to the controversial "hockey stick" multi-proxy climate reconstruction of Mann et al. (1998) that provided early scientific evidence in support of global warming exacerbated by human industrial activity (IPCC, 2007). Dendroclimatology and its statistical methods again came under international scrutiny in 2009 with "Climategate" (Carrington, 2011) in which hacked email messages of the Climate Research Unit at the University of East Anglia, UK, were exploited to cast doubt on the human agency behind climate change.

Recent dendroclimatological research has identified hydroclimatic events of great magnitude and duration in central Europe that may have had significant past political consequences. Büntgen et al. (2011) argue that these should serve as historical justification for expenditure in advance of currently projected climate change.

Slope instability (dendrogeomorphology)

This subfield of dendrogeomorphology has been defined as "The use of tree rings to date geological [sic geomorphological] processes that affect tree growth" (Speer, 2010, 219). Its significance in geoarchaeology is that it can help in developing an understanding of how natural processes can influence human activities, notably settlements, and how natural processes can also affect archaeological sites, particularly those that were abandoned and then colonized by trees. Schweingruber (1996, 272) noted that dendrochronology had rarely been considered in mountain forests where geomorphological processes are common and stated that "only dendrochronology is able to provide information about the frequency and extent of past events."

Trees react in a number of ways to the onset of slope instability or instability caused by other processes, for example, advancing ice ("Impact of ice (dendroglaciology)," see below). Onset dates, years, or sometimes seasons can be identified from a variety of evidence preserved in tree-ring records such as: the formation of reaction wood (see "Living trees") in response to trees starting to lean; scars left following damage to the bark and cambium; root exposure; tree mortality, and tree establishment germination dates (ecesis, or colonization of a new habitat by a species). Although the principles of dendrogeomorphology were established in the 1970s (Alestalo, 1971; Shroder, 1978), research in this area has only recently proliferated, benefitting from advances in dendrochronological techniques and computer technology. For instance, Stoffel et al. (2005) made detailed analyses of the impacts of rock falls in the Swiss Alps on European larch (*Larix decidua*). In addition to dendrochronological dating, the authors used GIS software to visualize the spatial extent, as well as the timing of events. Such studies have important implications for reconstructing past mass movement activity and are key tools in hazard mapping and hazard mitigation. Similar research has been undertaken for different types of mass movement, such as debris flows (Bollschweiler et al., 2008; Sorg et al., 2010).

Dendrogeomorphology also includes research with the goals of dating lakeshore erosion (Fantucci, 2007), tectonic movements such as earthquakes (Jacoby et al., 1997), and the buildup of coarse wood debris (Campbell and Laroque, 2007).

Impact of water (dendrohydrology)

"Dendrohydrology uses dated tree rings to study and date hydrologic phenomena, such as river flow, lake level changes and flooding history" (Kaennel and Schweingruber, 1995, 71). Trees growing in a variety of landscapes from upland to lowland can be affected by hydrological events. For instance, trees bordering streams and rivers can be uprooted by flood events, tilted as soils and banks are washed away, or scarred by debris carried by flood water. Subfossil trees preserved in sediments marking old river courses in central Europe have been a key resource in building long master chronologies (Becker, 1993).

Dating scars and abrupt growth changes allow a temporal and spatial assessment of the disturbance regime. Zielonka et al. (2008) reconstructed flood history in the Tatra Mountains, Poland, using cross-dated scars from trunks of Norway spruce (*Picea abies*). Flood events identified in the tree-ring sequence were compared to meteorological data, and although no one variable could be held responsible for all the flooding, the dendrochronological approach identified otherwise invisible flood events. Trees can also be defoliated during flooding, which can affect wood structure as demonstrated for young ring-porous ash trees (*Fraxinus americana* and *F. pennsylvanica*) by Yanosky (1983). Erosion during flood events can cause sediment loss and root exposure, leading to growth reductions, tree destabilization, and the formation of compression and tension wood. In riverbeds, undermined trees often lean in the direction of water flow. Sediment deposited by floods can lead to the growth of adventitious roots and shoots (the development of secondary cambium on older stems, branches, and roots), both of which can be dated to establish timing of their response to flood events. As flows subside, trees germinate in locations protected from water flow, for example, on the downstream side of boulders. Riverbed trees can provide minimum ages since the last major flood event (Schweingruber, 1996, 133).

In colder climates, ice can scar trees on river banks (Payette and Delwaide, 1991) and lakeshores. Research focused on the latter has used combinations of ice scars and tension wood resulting from tree tilting by waves to reconstruct higher water levels and to make inferences about increased flooding events and climate change (Bégin, 2001). In more arid areas, tree rings of bristlecone pine at lower elevations have been shown to be sensitive to the combined effects of precipitation and evapotranspiration. In a hydroclimatic reconstruction, Woodhouse et al. (2011) were able to estimate water flow in the Arkansas River (USA) from AD 1275 to 2002.

Génova et al. (2011) investigated small wooden "canals" used to channel river flow and to drive machinery of the sixteenth-century Old Mint in Segovia, Spain. Dendrochronology was used to date timbers used in repairs following flood events, and these data were compared to documentary records to confirm the timing of flood events, to assess their relative magnitude, and also to identify undocumented floods. Dean (1993), studying canyon terraces in Arizona, USA, successfully employed geological and archaeological analyses together with tree-ring dating to reconstruct landscape history.

Groundwater levels can have significant effects on trees. Although species demonstrate different tolerances to water in soil (cf. Vreugdenhil et al., 2006), prolonged waterlogging will often lead to significant growth reductions and eventually tree mortality.

Peat bogs are naturally wet places, but during drier periods, they can be colonized by trees. Layers of mire-rooting woodland have been uncovered, usually during commercial peat extraction, and dendrochronological investigations have now produced chronometrically dated ring-width sequences that demonstrate distinct periods of germination (ecesis) and mortality during the Holocene associated with climate-driven hydrological variations on bog surfaces (cf. Eckstein et al., 2010). In coastal areas, often rich in archaeology, salt water incursions caused by postglacial sea-level rise have been responsible for woodland mortality of submerged coastal forests on the Dutch coast (Munaut, 1966) and of the intertidal woodland and associated Mesolithic and Neolithic archaeology of the Gwent Levels, South Wales (Bell et al., 2001).

Deliberate human interventions in the landscape can improve conditions for tree growth through drainage (Schulthess, 1990). Conversely, artificial aridity can be detrimental to tree growth as exemplified by solution mining. In the hydrogeological research documented by Lageard and Drew (2008), the growth responses of oak (*Quercus robur*) were shown to be governed by water-table variations resulting from brine pumping in the Cheshire Saltfield, UK (Figure 6). Significant reductions in ring widths could be related to the construction of brine processing sites in the 1920s and precisely to the cessation of all pumping activities in AD 1977.

Impact of ice (dendroglaciology)

Dendroglaciology is the use of tree-ring series to date and plot the extent of past glacier movements, defined by relic landscape features such as moraines and trimlines. This subfield has close affinities to dendroecology and dendrogeomorphology, as trees react to ice advances and retreats in forested areas by (1) being scarred or killed by ice advances, (2) tilting under the impact of ice advance, and (3) colonizing glacier forefields upon ice retreat. In Europe, the rate at which different species colonize freshly de-glaciated land (ecesis) has been studied in localities such as the Aletsch Glacier in Switzerland, where colonization by spruce (*Picea abies*) and larch (*Larix decidua*) took on average 20 years, whereas stone pine (*Pinus cembra*) took 45–85 years (Schweingruber, 1988).

Classic dendroglaciological research has mapped the maximum extent of Little Ice Age outlet glaciers emanating from the Columbia Icefield in the Canadian Rockies (Luckman, 1988). It has also reconstructed glacial mass balance (inputs and outputs to glacial systems), for example, a 600-year reconstruction in the Austrian Tyrol (Nicolussi and Patzelt, 1996) and a 400-year reconstruction using hemlock (*Tsuga mertensiana*) for two glaciers on Vancouver Island, western Canada (Lewis and Smith, 2004). Further information on the history of, and techniques employed in, dendroglaciology is available in Smith and Lewis (2007).

Dendrochronology, Figure 6 Surface depressions resulting from uncontrolled solution mining of salt and the collapse of underground cavities in Cheshire, UK: (**a**) subsidence lake or "flash" and (**b**) a possible "brine run" resulting from solution of salt beds at depths of ca. 30–40 m. Such landscape features as in (**a**) document hydrological change that can impact tree growth, while the latter (**b**) can document the environmental impacts of industry (Images: J. Lageard).

Volcanic impacts (dendrovolcanology)

There are a number of ways in which volcanic eruptions/ episodes can affect tree growth. Tree mortality can be caused by shock or heat waves, by hydrological change (as volcanic sediments can cause prolonged flooding), or through natural pollution (SO_2, fumaroles). Growth suppression can result from the proximity to lava flow causing tree tilting, scorched crowns, dust-reducing photosynthesis, responses to burial by volcanic sediments, and volcaniclastic sediment preventing germination. Volcanic impacts can conversely improve tree growth when the death of emergent trees leads to subsequent growth release in trees of the previously suppressed understory. Fine volcanic ash, in contrast to coarser volcaniclastics, promotes rapid seed germination (Schweingruber, 1996).

Dendrochronology can therefore be used to study the environmental impacts of volcanism and also to date specific events during the historic period when documentary evidence does not exist. For example, Yamaguchi et al. (1990) dated the extrusion of the large andesite "Floating Island" lava flow at Mount St. Helens, USA, to late AD 1799 or early AD 1800 using living trees, and Yadav (1992) reconstructed regional volcanism on the Kamchatka Peninsula, Russia. Jacoby et al. (1999) demonstrated major human impacts on the Alaskan Inuit following the eruption of Laki in AD 1783.

Volcanic events can also be dated by sudden growth reductions preserved in timber, such as a beam from Wupatki, Arizona (USA), thought to date an eruption of Sunset Crater to AD 1064 (Smiley, 1958). Similar growth reductions can also appear within subfossil tree-ring series from prehistory. Contemporaneous narrow ring events (NREs), found in bog oaks preserved in natural environments such as peat bogs throughout northern and western Europe, are thought to indicate long-term climatic cooling, so-called volcanic winters, caused by the prolonged presence of volcanic aerosols in the atmosphere (Baillie, 1995). Chronologies based on ring density have also clearly demonstrated the climatic impacts of volcanism on summer temperatures during the historic period (Briffa, 2000).

Dendrovolcanology is, however, not without its controversy. Narrow rings in European bog oaks supported by the simultaneous appearance of frost rings in bristlecone pines (LaMarche and Hirschboeck, 1984) have provided a chronometric date for the catastrophic Bronze Age eruption of the Greek Island of Santorini, 1628 BC (Baillie and Munro, 1988; Baillie, 1995). This date depends upon the Santorini eruption having had global climate effects. Problems have occurred with attempts to correlate a tree-ring date such as this with loosely dated environmental evidence, for instance, acidity layers preserved within ice cores (Baillie, 1991). The 1628 BC date continues to generate controversy (Zielinski and Germani, 1998), not due to the emotive links made by some to the legend of Atlantis but because varied specialists still find it challenging to link tree ring and ^{14}C determinations that indicate a date in the seventeenth century BC with the associated artifacts that appear to belong to a period over 100 years later. Similar debates have arisen concerning other notable prehistoric eruptions, such as Hekla 3 in Iceland with a dendrodate of 1159 BC, when scientists try to make links with other paleoecological records loosely dated by radiocarbon, such as those obtained from pollen analysis (Payne et al., 2013).

Volcanoes are not the only environmental mechanism capable of causing sudden climate change and prolonged growth reductions in trees. The AD 540 NRE has been linked to the effects of specific volcanoes, but the dating evidence (^{14}C) is inconclusive, and it is possible that a meteorite strike similar or greater than that experienced at Tunguska (Siberia) in AD 1908 could have caused significant disruption to the Earth's atmosphere over a number of years (Baillie, 1995, 91–107).

Forest management

Dendrochronological research has been used increasingly by foresters in the management of woodland resources, for instance, in assessing the role of fire in the landscape (dendropyrochronology), damage caused by insects (dendroentomology), and also changes in species composition. Humans are key agents of change in forests and woodlands, and as such, dendrochronological reconstructions of the extent and composition of forested areas are of relevance to archaeology, particularly in understanding the evolution of cultural landscapes.

Schöne and Schweinguber (2001) used dendrochronological techniques to reconstruct the history of natural reforestation in the Inn Valley, Switzerland, since World War II following land abandonment in response to changing management practices and rural-urban migration. Such abandonment often results in reduced biodiversity, as highlighted in Sweden when traditional medieval farming practices lapsed (Hayashida, 2005). In these abandoned landscapes, older trees, originally retained for practical, cultural, and aesthetic reasons, often remain concentrated around villages as relict features. Combinations of dendrochronological data and information gleaned from other sources, such as forest management records (Müllerová et al., 2014) and livestock inventories (Genries et al., 2009), can be used to reconstruct land use history and also to make informed choices regarding conservation management. There is also potential for similar dendrochronologically informed reconstructions in former industrial landscapes and in relict battlefield landscapes, for example, in parts of the European Alps fought over in the First World War (Thompson, 2008). In the future, dendrochronology could play an important role in multi-proxy archaeo-environmental studies attempting to shed more precise light on significant military deforestations already apparent in palynological (Dumayne and Barber, 1994; Dumayne-Peaty, 1998) and documentary research (Pluskowski et al., 2011).

Trees can be affected by fire of both natural and human origin. Tree mortality will result if the bark and cambium are killed around the full circumference of the trunk, but some tree species, notably pines (Richardson, 2000; Lageard et al., 2000), have developed resistance to fire and protect damaged areas of the trunk by producing callus tissue and forming a scar (Schweingruber, 1988, 206). In fire-prone regions, a series of fires can burn into a tree leaving a set of overlapping scars and sometimes a large triangular scarred area at the base of the trunk known as a catface (Speer 2010, 197). In some species, the impacts of fire may be more subtle and noted only by carefully documenting anomalous wood structure, for instance, in black ash *Fraxinus nigra* (Kames et al., 2011). Scars can be sampled from living and dead trees by cutting discs or partial sections using a chainsaw (Arno and Sneck, 1977). Once prepared using standard techniques, these samples can be dated by dendrochronology to calendar years, seasons, or even parts of seasons – as illustrated by Swetnam and Baisan (1996). Records of fire scars in individual trees can be synchronized in fire history charts to document regional fires over prolonged periods (Swetnam et al., 1999) and the calculation of fire return intervals. The latter can be related to human interventions, and the significance of fire as a management tool can be seen, for instance, in its use by Native Americans to favor mast-producing trees (those yielding edible nuts) such as oak, hickory, chestnut, and walnut. These management practices are thought to have had a major impact on the distributions of present-day forest and grassland ecosystems of the eastern USA (Abrams and Nowacki, 2008). Dendrochronology now also provides the scientific basis for fire suppression policies in the USA that became prevalent in the later twentieth century, as foresters and politicians struggled to combat the effects of fire on humans and their habitations (Speer, 2010).

Summary and future directions

Dendrochronology is a powerful chronometric dating technique that has been employed in many research projects that can be linked directly or indirectly to geoarchaeology. The technique has its limitations in terms of suitability of tree species, suitability of sampling sites, and minimum sample requirements for computer-assisted cross matching. That said, the technique has been applied in numerous environments, both natural and those affected by humans.

Traditionally, dendrochronology has been applied in the dating of wood from archaeological sites and from standing buildings, but the technique has much wider application and also potential. Of particular relevance to geoarchaeology is the use of dendroprovenancing that can reconstruct historic and potentially prehistoric movements of timber from forest source regions, reconstruction of past land use, industrial and pollution histories, and climatic reconstructions that can be used to assess climatic/environmental impacts on past and future human population.

Baillie (1995, 32) sums up the significance of the technique: “The power of dendrochronology to date things precisely opens up a whole new window into the past. . ..” The utility and future directions of the technique are often discussed at conferences (Baillie, 2002; Sass-Klaassen, 2002). Some important themes in this respect have included the handling and storage of increasingly large quantities of data (Jansma et al., 2012); improving dendrochronological coverage, spatially and temporally; dendroprovenancing; the use of tree rings as sources of environmental data; funding for academic and private laboratories; cooperation between dendrochronology and other disciplines; and also the need for dendrochronology to receive proper recognition as an interdisciplinary subject in academia.

DMANISI

C. Reid Ferring
Department of Geography, University of North Texas, Denton, TX, USA

Dmanisi is an Early Pleistocene hominin-bearing archaeological site located 65 km southwest of Tbilisi in the Republic of Georgia (41°20′10″N, 44°20′38″E; elevation: 910 m msl). Situated on a promontory at the confluence of the Masavera and Pinasaouri rivers, the site preserves up to 6.5 m of stratified ashfall and colluvial deposits conformably overlying the 1.85 Ma Masavera Basalt (Gabunia et al., 2000; Ferring et al., 2011). Dating by $^{40}Ar/^{39}Ar$ and paleomagnetism shows the site was occupied repeatedly from ca. 1.85 to 1.76 Ma, with rapid accumulation of hominin fossils during a brief interval ca. 1.77 Ma (Lordkipanidze et al., 2007; Messager et al., 2011).

Sediments are divided into nine major strata, separated by minor erosional surfaces; soils reveal periods of slow deposition and/or stability following episodes of ashfall or colluvial deposition. These deposits contain stratified occupation surfaces, with lithic artifacts and associated faunas. In the main excavation areas, extensive piping (shallow tunnellike features created by corrosion of the underlying deposits), pipe collapse, and gullying have led to rapid burial and superb preservation of both hominin fossils and thousands of large mammal bones. Over 40 taxa of Eurasian large mammals are dominated by cervids, bovids, and carnivores; some of these have cut marks and percussion blows indicating butchery (Lordkipanidze et al., 2007). Thousands of lithic artifacts of a Mode I (core-flake) industry are associated with the faunal remains (Mgeladze et al., 2011).

Dmanisi is the oldest archaeological site outside of Africa (and in the temperate zone), preserving the largest and most complete sample of hominin fossils in the Lower Pleistocene record. The rich archaeological and paleontological materials are being studied in concert with formation analyses to document patterns of site occupation, faunal exploitation, and lithic technology.

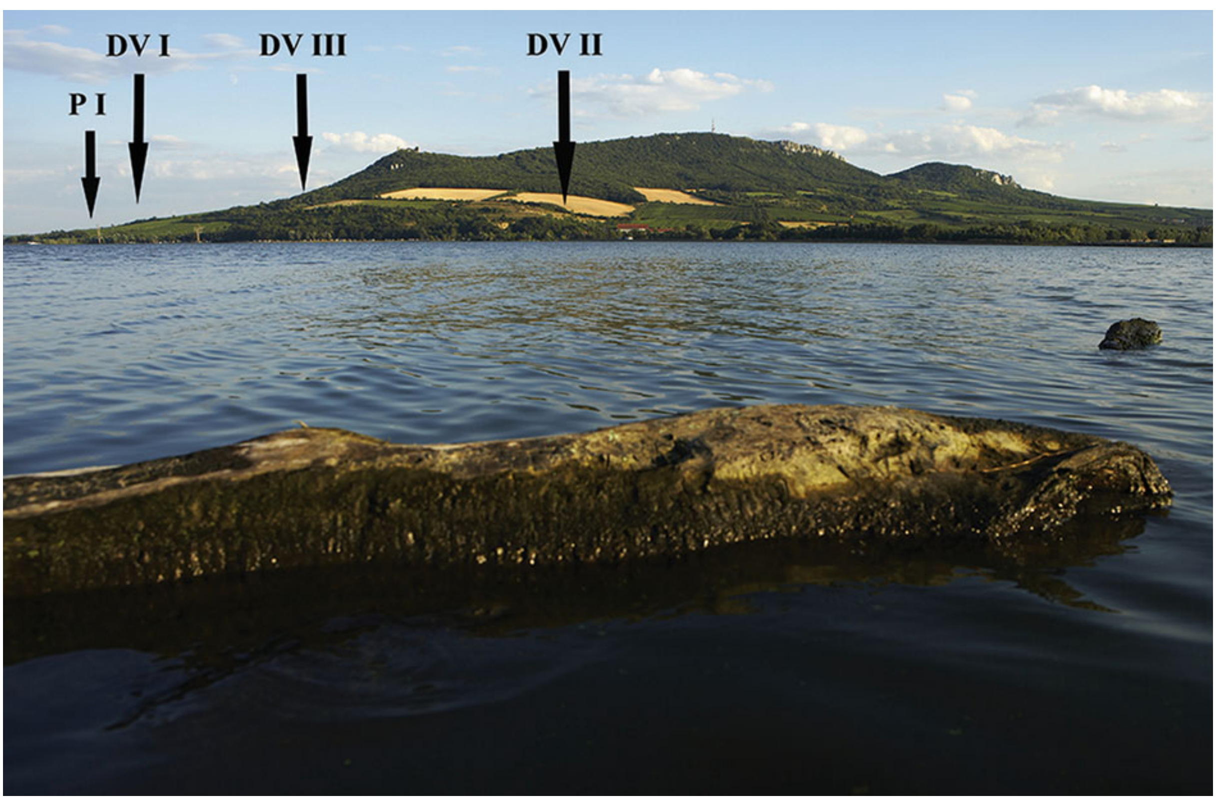
DOLNÍ VĚSTONICE, PAVLOV, MILOVICE

Jiří Svoboda
Insitute of Archaeology, Academy of Sciences of the Czech Republic, Dolní Věstonice, Czech Republic
Department of Anthropology, Faculty of Science, Masaryk University, Brno, Czech Republic

Introduction

These locations form a cluster of Gravettian (Pavlovian) sites on the northeastern slopes of the Pavlov Hills



Dolní Věstonice, Pavlov, Milovice, Figure 1 The Pavlovské Hills with sites of the Dolní Věstonice-Pavlov-Milovice area.

(550 m a.s.l.) in southern Moravia, Czech Republic. As a whole, the sites create an almost regular chain about 7 km long at elevations above 200 m a.s.l., which allowed an overview of the Dyje River Valley lying 30–40 m lower. The individual sites have been excavated since 1924 by Absolon (site DV I), Bohmers (DV I), Klíma (DV I–III, Pavlov I–III), Oliva (Milovice I), Svoboda (DV I–II, Pavlov II–II and VI, Milovice IV), and other excavators (Figure 1).

Stratigraphy and dating

A complete stratigraphic sequence of the last climatic cycle recorded at site DV II (bricketerry section) includes paleosols of the Last Interglacial and Early Glacial at the base (OSL dated to 110–70 ka), followed by laminated sandy loess (MIS 4) and a brown soil complex (MIS 3) and covered by a thick body of laminated sandy loess (mostly of MIS 2). The Gravettian (Pavlovian) occupation layer, located at the stratigraphic boundary between the brown MIS 3 soil complex and the above loess, is characterized by the expansion of parkland steppe (majority of ^{14}C dates between 32 and 29 cal ka).

Archaeology

These sites display a hierarchy ranging from large semi-permanent settlements with complex hearths, domestic constructions, and evidence of various activities, creating extensive clusters or palimpsests (DV I or Pavlov I), to smaller sites of seasonal and episodic character. The subsistence system seems to have been complex and labor-intensive. Although discussions are ongoing about intentionality of mammoth hunting, this animal played a key role in the human economy, accompanied by smaller animals such as reindeer, hares, a variety of carnivores, birds, fish, and plants (evidence of ground plant tissues and starch grains). Extensive mammoth bone deposits were located either inside the settlements or separately, in the adjacent gullies or on the slopes. Sophisticated blade and microblade technologies were based on siliceous rocks imported from distances of hundreds of kilometers. A variable industry of bone, ivory, and antler served as weapons and domestic tools. These sites have world primacy in the production of the earliest known ceramic figurines, textile structures, and cordage (recorded as imprints on the surface of burnt clay pieces). Besides zoomorphic and anthropomorphic figurines modeled in clay, these sites also provided delicate carvings in ivory and a variety of items for bodily decoration.

Physical anthropology

The sites of DV I, DV II, and Pavlov I provided a sample of early modern human skeletons from ritual burials, including four adult males (DV 13,14, and 16, Pavlov 1), one female (DV 3), one sexually undetermined individual (DV 15), and a large number of human skeletal fragments and teeth dispersed within the cultural layers.

DUMPS AND LANDFILL

Joseph Schuldenrein
Geoarchaeology Research Associates, Yonkers, NY, USA

Synonyms

Areas of designated waste management; Designated discard or refuse zones (public or private); Managed sites for waste processing and/or surface construction

Definition

Landfills are designed and modified sites for recycling postconsumer waste. They are regulated depositories whose function is dictated by statutes. Regulation is concerned with issues of contamination and groundwater. Refuse must be buried. Landfills can also be considered structural features of the terrain as their design is aimed to level or reconfigure topography of a landform or landscape.

Dumps are unregulated loci for discard on a variety of scales. They may be open facilities initially and become landfills when regulatory mechanisms are imposed and implemented. Dumps are initially proposed as sites for refuse deposition, and they may be considered activity areas in an archaeological sense.

Since landfills are the products of relatively recent and large sediment redeposition (often with the use of heavy equipment), they are not commonly traced to historic-age activities thereby minimizing their archaeological significance. As discussed below, the scale and extent of the twentieth century and subsequent landscape development is of such magnitude that future archaeologists will necessarily examine landfill contents and processes of formation when reconstructing the functional landscapes of the modern era (now referred to as the "Anthropocene").

Introduction

The terms "dumps" and "landfills" connote elements of the landscape that are unnatural and, per the definitions above, they are dominated by sediments that may be contaminated, polluted, and otherwise infested with waste remains that should not be handled without prescribed protocols and protection. Contemporary archaeological practice in most countries prohibits excavation through landfills without formal protective measures. In a preponderance of cases, landfills represent bodies of sediment that may have to be penetrated or removed to gain access to pristine surfaces that potentially contain sites or artifact assemblages in "primary context" (locations of original use). Paradoxically, those ostensibly pristine surfaces can themselves be sheet middens, which are essentially ancient discard surfaces and, in places, localized "dumps." Methodological advances in the study of the dumps of antiquity are at the heuristic core of advances in archaeological site formation studies. Yet, archaeologists either deliberately or circumstantially avoid collecting data on what the pioneering scholar of cultural landfills, W. Rathje, called "the archaeology of us" (Rathje et al., 1992; Shanks et al., 2004). Archaeologists who work in historic periods are increasingly drawn to studying older dumps and landfills since they represent early phases of large-scale discard in the case of the earliest municipalities. In addition to documenting historic patterns of land use, dumps and landfills also inform on land management strategies applied by the predecessors of today's city planners. The development of zoning and building codes is directly linked to the use of space for accommodating the various activities attendant to urban life; the discard footprints and processing activities of waste staging areas explain changing urban layouts, infrastructure configurations, and the legalities governing the patterned growth of cities. It is ultimately short-sighted to evade studies of contemporary landfills especially since, in the United States and elsewhere, formally designated landfills are in excess of 50 years old and may qualify for assessments of integrity according to the statutes of Section 106 of the National Historic Preservation Act guidelines (King, 2013).

Geoarchaeological approaches have been widely utilized in urban archaeological studies because they explain changing stratigraphies beginning at the general unconformity between "natural" and "cultural" sequences and progressing through various phases of anthropogenic landscape modification. Landfills and dumps pose unique taxonomic problems stratigraphically, because they may defy the laws of geological stratigraphy, which are based on "superposition" and "strata identified by fossils" (Rowe, 1961). Harris (1989: 29) calls attention to potential conflicts in projecting archaeological sequencing on formal geological stratification. Theoretically, each (archaeological) level or stratum is dated to a time *after* the date of manufacture of the most recent artifact found in it. Not so in the case of dumps and landfills where, in many cases, episodic recycling and remobilization of artifact-enriched discard sediments may produce inverted stratigraphies, or completely jumbled collections, depending on the objectives of landscape reconfigurations and reclamation goals.

Decay of historic features, historic drainage technologies, historic surface recontouring, and geochemical enrichments to natural sediment complexes are only some of the problems geoarchaeologists are called upon to solve. Varied techniques are applied to reconstruct site formation chronologies and processes at urban sites with landfill complexes in which the dominant sediment type in upper horizons is generally referred to as "fill." The entire question of designating a sediment as "fill" may now be called into question insofar as both ancient and modern dumps and landfills must be considered both as access nodes to archaeological exploration, as well as features that preserve the record of ancient and contemporary discard strategies.

Emergence of dumps and landfills in the archaeological record

Humans have discarded debris since the earliest hominins populated the earth. It is arguable that the study of debris and refuse comprises the core of archaeology, generally, as the residua of human activity accounts for a preponderance of interpretations bearing on the earliest human lifeways. Paleolithic archaeology, for example, is concerned with the analysis of nonperishable refuse in the form of waste flakes produced during stone tool manufacture and perishable remains such as charred or burnt organic matter in hearths. Those features ultimately represent the discard of food processing activities. Subsequent periods (i.e., Neolithic and onward) register progressively larger scales of discard reflective of the growing magnitude of human activity as social, political, and economic organizations became expansive and extended across the landscape. Near Eastern tells and Archaic or later shell mounds (see Stein, 1992), to cite classic examples, represent successive stages of occupation that incorporate abundant waste remains (middens) that can be considered the largest and most diagnostic features of the human imprint on the landscape. With time, the signatures of such discard features became progressively larger, more complex, and multifaceted even as discrete disposal loci were exposed to the ravages of erosion and landscaping. In such cases original discard loci often lost their integrity over the course of post-site abandonment and, in many cases, reoccupation. The earlier complex societies (i.e., third millennium BCE) witnessed large-scale terrain resculpting because of changing land use strategies (i.e., herding, agriculture), and these are often manifest in collapsed debris from structural features intermixed with pockets of deliberate human discard (the latter may retain primary integrity). Episodic erosion was a dominant formation process as well. Accordingly, there is clear evidence of deliberate leveling as land use and utilization changed. In the case of Archaic shell mounds, stratified accumulations of discrete shell types provide the evidence for reconstructions of ancient subsistence patterns bearing on both paleoenvironmental conditions and deliberate subsistence strategies. Those features are functionally akin to dumps.

Thus, the study of these most ancient of dumps and landfills is central to the study of archaeology in a variety of settings, scales, and contexts.

Viewed in a developmental context, the emergence and proliferation of complex societies have been accompanied by increasingly broader and deeper "discard" footprints as urban centers expanded outward and grew in size and frequency across global landscapes. Neolithic villages in Europe and Asia eventually gave way to medieval cities, while urban-like complexes in Mesoamerica and South and North America witnessed more punctuated and sporadic growth in later prehistoric times before giving way to the Euro-American expansions in the seventeenth century. Discard features changed in size, shape, and function in response to all of these changes in human socialization, commerce, and administrative organization.

The role of landfills and dumps is of great importance and will continue to assume an immediate and compelling role in archaeological investigations as these features become more prominent structural and functional components of the twenty-first-century landscape. Moreover, these features are global, serving populations in First, Second, and Third World economies. Urban and "central places" – in the classic sense of Christaller (1933) – require the large-scale creation of features and even "networks" of disposal loci that are tied to municipal and even regional waste disposal facilities and practices. In the developed world, dumps and landfills are usually zoned and monitored with city planning agencies regulating their utility, safety, and longevity. In nineteenth-century New York City, for example, 30 feet of "fill" was deliberately laid down around the perimeters of Lower Manhattan to impede shoreline erosion and to allow economic life to proceed despite frequent flooding (Cantwell and Wall, 2001). Geoarchaeological studies in and around New York City have demonstrated that this fill served to seal in evidence of prehistoric landscapes (see Schuldenrein and Aiuvalasit, 2011). In many parts of the Third World, more intermittent regulation, both historically and in the present day, accounts for longer and sustained "upbuilding" of dumps and landfills so that generations of residents live on the pure discard of their predecessors, often irrespective of health and safety concerns. Archaeologically, the "fill" components tell a multifaceted story of urban growth, development, and decay, allowing social scientists to reconstruct patterned occupation of the city and its supporting network of ancillary sites and rural landscapes.

A rethinking of the role of landfills and dumps is necessitated by contemporary concerns in environmental archaeology and geology, which consider questions of sustainability both within the archaeological record and across broader, more pressing, contemporary contexts of dramatic ecological change (Butzer, 2011). The "discard" component of the urban landscape is both deep and increasingly expansive. The "depth" dimension requires geoarchaeologists to examine tight stratigraphic "windows," or narrow exposures, in the substrate where classic archaeological excavations would be obviated by active subsurface infrastructures (i.e., gas and sewage lines). Also, because urban excavations are mostly conducted within the framework of cultural resource management (CRM), investigations are constrained by the guidelines of particular contracted questions that define and confine the limits of archaeological exploration spatially.

The prominence of what may be called "dump and landfill archaeology" is magnified further by the recent push to recalibrate and redefine geological epochs in the wake of humanly induced climate change and impact on ecological systems. Many scientists are now accepting the designation *Anthropocene* as a formal geological epoch based on climatic and geomorphic changes that have been either initiated or catalyzed by large-scale human impacts (Ruddiman, 2003; Price et al., 2011; Zalasiewicz et al., 2011; Brown et al., 2013). Amid considerable debate, the start of this Anthropocene epoch has been variously dated to the age of the European Industrial Revolution (ca. AD 1850). Among the significant adaptive strategies attendant to that initial date, many consider land-use changes in agricultural practice, the proliferation of extractive activities (i.e., mining and industrial production), and the growth of the urban landscape to have imposed the greatest influences.

Under these criteria, the emergence of large-scale dump and landfill features marks a categorical change in the material culture landscape as well as in the archaeological indicators that inform about the changing functions of such prominent discard features across time and space. Time-stratigraphic criteria are still not uniformly accepted by professionals, and research into the dating, utility, and archaeological signatures of the Anthropocene remains an ongoing focus of academic investigation.

Distinguishing archaeological landfills and dumps: a geoarchaeological question

It is widely accepted that the archaeological record is one of the most informative barometers of change in the evolution of the human condition, and some propose that it is the single best indicator. It certainly provides the most tangible evidence in the form of the material cultural record. Patterns of waste discard, which are ubiquitous archaeologically for nearly all prehistoric and historic time frames, may therefore be viewed as one of the most reliable parameters in explaining such change (Rathje et al., 1992).

That said, many archaeologists nevertheless look for primary evidence of human behavior beneath the deep and complex caps of recent to subrecent discard matrices. The objective is to reach the intact, or in situ, remains left by human activity in the same locations where those behaviors were conducted, i.e., not yet introduced into the trajectory of purposeful discard and disposal. The primary kind of setting informs only about a specific episode of past human action as it can be tied directly to a principal site and/or time frame under investigation. In traditional archaeological parlance, in situ context remains the measure of site integrity and the baseline from which artifact associations retain meaning for interpretive purposes.

Such pristine in situ contexts tend to be preserved under variable thicknesses of deposits (also referred to as "fill caps") whose integrity, or internal structure, has been variably compromised either geomorphically by surface or near-surface processes or functionally by repeated remobilization. Mobilized sediment, moved and redeposited through numerous agencies, has been considered, until recently, contextually meaningless. In urban areas, for example, massive earthmoving equipment is typically employed to re-level surfaces in preparation for new development projects, such as residential or commercial quarters. Why would the "fill cap" be useful for landscape reconstruction? In exurban zones, where historic manufacturing and industrial areas are being reclaimed for revived urban infrastructures, contaminated, polluted, and toxic subsurfaces are paved over and treated with neutralizing chemicals in the interests of "green development" and urban renewal. In this case, the compromised sediment is not even available for analysis, which further compounds the futility of addressing its primary source and formation history. These "fill caps" are thus typically viewed as "sealants" to enclose the primary evidence of historic events and land use. In the case of the buried city, minimal to modest disturbance by burial and recontouring of overlying fill does not damage the primary evidence of infrastructure formerly associated with earlier city function. Polluted exurban locales will almost certainly preserve the evidence of earlier manufacturing and refining technologies, if only because these facilities cannot be removed, given the risk of toxicity. In both scenarios, the buried landscapes become eligible for listing on the National Register of Historic Places if they meet the criteria of uniqueness mandated by the National Historic Preservation Act of 1966 (King, 2013).

And yet, forward-thinking archaeologists are now considering formation processes of the "fill cap" to provide insights into the logistics of modern landscape development. There is no doubt that changing configurations of massive bodies of recycled sediment reflect efficient strategies for land reclamation and systematic land-use transformations. Staged, flexible, and deliberate engineering designs have been increasingly integrated into urban planning schemes especially in the modern age (twenty-first century) of sustainability and conservation. In addition to the term "fill caps," the sediments that have been mobilized to bury relict features and recontour the landscape are also now referred to as "debris" and "rubble" (more generic classifications for the separate dump and landfill definitions described above). In cases where sediments from geological sources clearly formed the primary matrix and/or bulk of artificially tainted cultural deposits, the "fill cap" includes a prefix, i.e., "artificial fill in estuarine matrix" (Stone et al., 2002). For public and professional archaeologists alike, these terms carry no sense of context, and the terms themselves have negative or neutral connotations archaeologically. In Europe, stratified archaeological sites in urban areas may be separated by intervals of sedimentation laid down over historic neighborhoods that are centuries or even millennia in age. That sediment, if predating the era of heavy equipment, may incorporate ostensibly heterogeneous admixtures of locally remobilized rubble from the Roman and Greek periods. In most cases, those deposits are demonstrably devoid of any integrity, but there are situations wherein wholesale redeposition of matrix results in at least semi-primary retention of archaeological context. An example is when homogeneous pottery sherds and brick fragments have been displaced locally and form a "fill pocket" that preserves evidence for a specific object's use and function or, on a larger scale, for house architecture. It is noteworthy that the longevity and range of Europe's material culture record within sealed urban contexts have resulted in archaeologists often overlooking displaced objects whose internal structure is only minimally disturbed even though there is no in situ primary provenience in a "fill context." A common explanation is that the exponential growth of urban centers over the past 600 years has created a sedimentary context, with consequent loss of provenience, in which the most available "filling material" is Byzantine-age rubbles that were widely mobilized to modify early urban tracts for lot leveling and building construction. The long history of urban development in Europe (and elsewhere in the Old World) is such that priorities must be assigned to those archaeological components and contexts deemed most worthy of greater study. An implicit assumption here is that compromised spatiotemporal settings fall on the lower end of the preferred research spectrum even if such features may inform on, for example, ancient landscaping technology (see Harris, 1989: 48). An example here is the selection of specific sediment fabric ("fill derived") to form the substrate for well-trafficked Byzantine roads. Design plans for landscaping of similar features, with a concomitant dependence on "fill" materials, have been documented as early as the Roman period (Parker, 1874), but it has been registered much more extensively for the post-Byzantine.

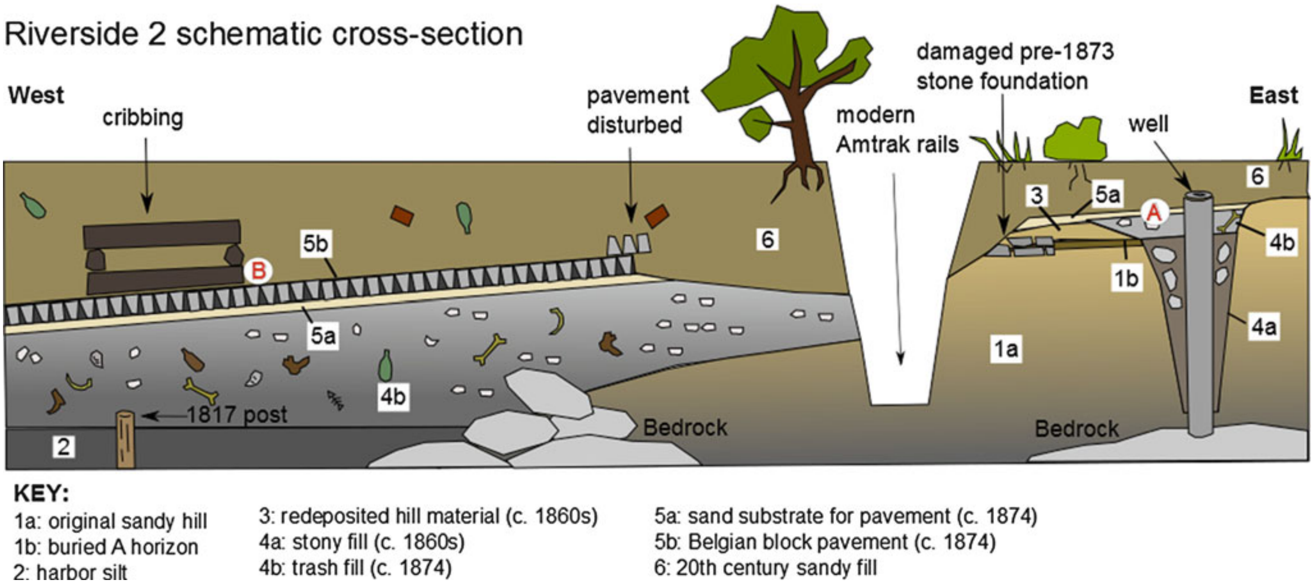
The situation is different in North America. The application of the "50-year rule" – the minimal wait time for designation to the National Register of Historic places, barring special eligibility circumstances (King, 2013) – coupled with the short duration (about 400 years) of the Euro-American occupation, and sparser population densities and settlement distributions, accounts for a scarcity of urban areas possessing deep archaeological successions. Multicomponent historic sites dating to the seventeenth and even early eighteenth century are comparatively rare. Patterns of urban redesign were also highly variable, given the diverse natural environments in the eastern, central, and western parts of the North American continent. Here, the disposition of "fill" across buried urban neighborhoods generates considerable interest and provides new information on site formation chronologies across time and in connection with changing historic settlement geography.

It can be argued, sensu lato, that today's fill is tomorrow's archaeological sediment because the former sediment bodies in fact reflect previous fill functions (i.e., relandscaping, recontouring). In many cases, their disposition, textural and compositional properties, and patterned redeposition may be associated with properties linked to the process of site burial and subsequent land use. For example, lime-rich sediment is often used to neutralize acidic and corrosive impacts in modern tank farms (oil depots). Accordingly, it is questionable as to whether or not those sediments should be designated as fill or more accurately "historic sediment." The former term is generic, implying undifferentiated and unsourced depositional complexes, while the latter is suggestive of primary, semi-primary, or displaced contexts linked to demonstrable functions and known periods. Given the growing acceptance of the Anthropocene concept and advances in site formation reconstructions (facilitated by high-technology applications), the latter designation of "historic sediment" should emerge as an umbrella for a nascent taxonomy centered on historic-age processes of site emergence, florescence, and abandonment. The use of the latter classificatory scheme would then restrict the term "fill" to situations wherein human engineering of the terrain produces artificially constructed or degraded landforms whose functions are mapped out in advance. That definition is more consistent with the growth of scientific methodologies, and it focuses on the dynamism of landscape archaeology and an overarching geoarchaeological perspective.

Stratigraphy and sedimentation at "landfill" sites: a case study from New York City

At complex archaeological sites, and specifically at urban centers preserving past and present architectural and landscape features (either humanly or naturally engineered), it is a challenging exercise to determine when a mappable sediment body is more appropriately classified a "fill" or an "occupational matrix." To distinguish these two deposits, a very loose identifying criterion would be whether or not the matrix was used to prepare and/or bury a former building to provide a new and currently usable lot or whether the deposit is a product of the degradation and collapse of nearby in situ locations and thus represents discrete human activities. As discussed earlier, there are gradations – for example, natural processes can embed and preserve re-transported anthropogenic components, and thus "occupational matrix" can be mobilized by natural forces eventually to create what appears to be fill. Generally, the modification of drainage grades by erosional processes is an indirect effect, but conversely, if a drainage landscape was explicitly designed to manage water flow, as in the canals of historic Dutch New York, that landform - component is legitimately categorized as an archaeological feature. The gradations between these two extremes are subtle, at the very least.

The subtleties of these distinctions are best demonstrated in a case study of a complex, stratified site on Manhattan's Upper West Side, which provides a semicontinuous, 4.5–5 m thick, record of human occupation from middle to later prehistoric times (6000–3000 BP) through the present (Figure 1) (Schuldenrein and Hulse, 2013). The schematic section illustrates the emergence of a complex landscape beginning with diagnostic sediments and soils of pre-Euro-American times. Strata 1a, 1b, and 2 register the pre-cultural ground surface of an elevated late glacial kettle moraine landscape (1a) sealed by a preserved (Holocene) soil (1b) and overlooking the postglacial estuary (2) of the Hudson River. The estuarine shoreline was utilized over the course of earlier Euro-American settlement. By the mid-nineteenth century, the natural landscape was impacted by initial urban settlement, originally activated by accelerated slope erosion (3) and subsequently by a growing population that constructed facilities, leveled land, and ultimately disposed of debris in several discrete locations, both locally (4a) and more extensively in designated waste discard locales (4b) (Figure 2a). The size and extent of the latter is a measure of the intensification of settlement and the emergence of ethnic neighborhoods. By the 1870s, a road network was designed that necessitated construction of a base with a pure sandy "fill" (in the formal sense of the term) to sustain a stable cobblestone roadway for horse and carriage and early automobile use (5b) (Figure 2a). The uppermost 2 m of the profile represents a complex of sediment bodies, poorly sorted and laterally and vertically variable in terms of sediment type and consistency (6). The construction of midtown Manhattan's twentieth-century (and now twenty-first) infrastructure is preserved within that complex of sediment. Isolated features were constructed within the matrices (e.g., a well, railroad tracks, and supporting railway station facilities); discrete features such as crib structures and paved segments were also found within that accumulation of sediment.



Dumps and Landfill, Figure 1 Schematic stratigraphy for Riverside 2 archaeological site, Manhattan, New York. Various historic landfilling units are labeled stratigraphically (marked 2 through 6) above the prehistoric strata (units 1a and 1b). Historic landfilling units date from Euro-American contact when the site marked the Dutch shoreline of early Manhattan Island (unit 2) through the twentieth-century "capping fill" (unit 6) which leveled off the contemporary site surface.

Dumps and Landfill, Figure 2 Discrete nineteenth-century landfilling units by type and age (see Figure 1 for location). (**a**) Excavation and landfilling activities associated with construction of a civil war era well (units 4a and 4b). (**b**) Preparations and construction of a cobblestone roadway, 1870s (units 5a and 5b).

Summarily, the "fill" designation can be applied to two functional deposit types: waste discard loci (Figures 1, 2: units 4a, 4b) attendant to mid-nineteenth-century neighborhood growth and an elevated base for a late nineteenth-century roadway (Figures 1, 2: units 5a, 5b). As the city expanded, both labor and heavy machinery were brought in to construct, deconstruct, and remake the infrastructure of the modern city. The multipurpose and remobilized sediment is essentially a third fill-type: collective residua whose sources are multiple. Those sediments and the feature elements found within it preserve a variable record of complex and penecontemporaneous activities over a century in the making. They include anthropogenic and displaced sediment contributions through erosional process.

Conclusion

Landfills and dumps are contemporary features of increasingly dense, complex, and human-engineered landscapes. They are critical archaeologically because contemporary research and cultural resource investigations often require that they be explored for subsurface structure if their footprints are slated for development. Since these landscapes are often polluted and toxic, noninvasive, and exploratory, high-technology strategies are often used to detect the archaeologically significant targets beneath them. Those strategies are often the venue for "beta-testing" of new methods designed to improve the yield of information. Landfills and dumps are also critical as artifacts and landscape archives themselves. They preserve a long history of industrial development that extends well into medieval times in Europe and Asia and over 300 years in North America. On a heuristic level, investigations of contemporary landscapes and dumps underscore one of the most pervasive themes of archaeological inquiry: the study of waste and discard. For earlier prehistory, that theme is all consuming, since the remains of human activity may represent the full extent of the archaeological record of the Paleolithic. With the passage of time, the archaeology of complex societies and cities is encapsulated, to a large degree, in the examination of discard facilities, which form key elements in infrastructure emergence and growth. The current debates over the legitimacy of a new geologic epoch, the Anthropocene, recast the significance of anthropogenic activities as measures of human impacts on the landscape. That thematic inquiry requires geoarchaeologists to develop new approaches to the study of "historic sediments." Those sediment bodies can no longer be generically dismissed as "fills" since sophisticated analytic and provenancing techniques allow for reconstructions of depositional origins and taphonomies. The ability to reconstruct and date site formation vectors and chronologies is an emerging tool in the interpretation of the human-engineered environment.

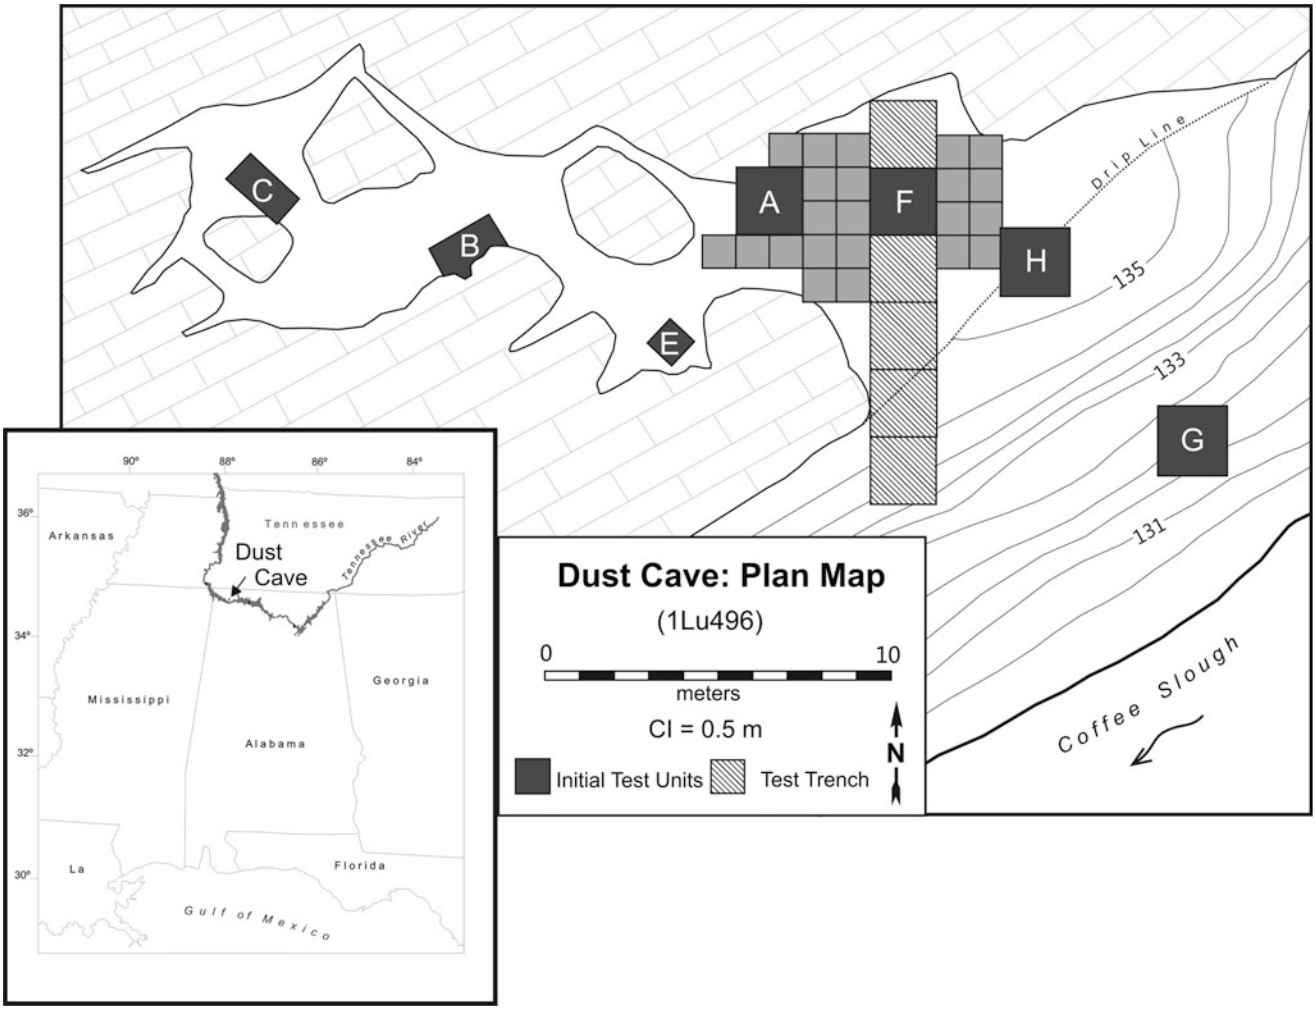
DUST CAVE, ALABAMA

Sarah C. Sherwood
Environmental Studies, The University of the South, Sewanee, TN, USA

Dust Cave (1Lu492) is a habitation site located within a karstic vestibule in the middle Tennessee River Valley of northern Alabama (Figure 1). The cave entrance contains over 4 vertical meters of sediment generated through various processes (Figure 2), with human occupation



Dust Cave, Alabama, Figure 1 The location of Dust Cave and plan of the excavations.

being the primary source (Sherwood et al., 2004). This segment of the Tennessee River is generally considered a migration route and staging area for the colonization of eastern North America based primarily on the high concentration of fluted points found in the area (Anderson, 1996; Anderson and Sassaman, 1996; Anderson and Gillam, 2000; Anderson et al., 2010). Periodically occupied over 7,000 years, the cave contains well-preserved bone and botanical materials and exhibits microstratigraphy and intact occupation surfaces that provide insights into forager adaptations in the Midsouth from the end of the Pleistocene through the first half of the Holocene. The chronostratigraphic framework for Dust Cave is based on 43 ^{14}C dates, temporally diagnostic artifacts, and detailed geoarchaeological analysis that defines five cultural components designated: Quad/Beaver Lake/Dalton (10650–9200 cal BC), Early Side Notched (10000–9000 cal BC), Kirk Stemmed (8200–5800 cal BC), Eva/Morrow Mountain (6400–4000 cal BC), and Benton (4500–3600 cal BC) (Sherwood et al., 2004). Microstratigraphic and artifact analyses indicate that the primary differences in the deposits over time connect to the intensity of activity and spatial organization as it relates to changing conditions in the cave, not to the types of activities. Geomorphic transformations influenced the timing of the occupation at Dust Cave, especially the initial occupation in relation to the fluvial history of the Tennessee River at the Pleistocene/Holocene transition (Sherwood, 2009). This site is best known for the interdisciplinary research on subsistence (Walker et al., 2001; Hollenbach, 2007; Walker, 2007; Hollenbach, 2009; Hollenbach and Walker, 2010; Homsey et al., 2010; Carmody, 2012), and the geoarchaeological study of anthropogenic deposits within the cave (Sherwood et al., 2004; Sherwood and Chapman, 2005; Homsey and Capo, 2006; Sherwood, 2008; Homsey, 2010; Homsey and Sherwood, 2010).

E

EASTERN SAHARA: COMBINED PREHISTORIC EXPEDITION

Christopher L. Hill
Graduate College, Boise State University, Boise, ID, USA

Geoarchaeological studies conducted by the Combined Prehistoric Expedition (CPE) in the Eastern Sahara focused on stratigraphic sequences and paleolandscapes associated with Acheulian, Middle Paleolithic, Late Paleolithic, and Neolithic archaeological sites. Significant regions of study included Bir Sahara-Bir Tarfawi, Wadi Kubbaniya, and Nabta, all situated west of the Nile in southern Egypt. From its inception in 1962 until 1999, Fred Wendorf served as Director of the CPE, with Romuald Schild serving as Associate Director beginning in 1972 and as Director after 1999. After Schild's retirement in 2007 the CPE was led by Jacek Kabacinski. Schild was responsible for the geologic mapping and stratigraphic studies, although an impressive list of geologists and geoarchaeologists were members of, or collaborated with, the expedition.

The CPE first conducted research along the Nubian region of the Nile Valley as part of the construction of the Aswan High Dam (Wendorf, 1968). The study region extended from south of Aswan in Egypt to Wadi Halfa in Sudan, and it included Dungul Oasis and Kurkur Oasis. During the late 1960s, field studies were conducted primarily along the Nile Valley, but they included also the Western Desert's Fayum depression in 1969 (Wendorf and Schild, 1976). In 1972, the major focus of research became the Eastern Sahara (Wendorf and Schild, 1980).

Bir Sahara became a significant region for the CPE when, in 1971, Bahay Issawi discovered the stratigraphic exposures about 350 km south of Kharga (Schild and Wendorf, 1981). In 1972, spring vents west of Kharga at Balat (Dakhla) containing Acheulian bifaces were studied (Schild and Wendorf, 1977). Bir Sahara and nearby Bir Tarfawi were investigated in 1973 and 1974 and in three seasons from 1986 to 1988 (Wendorf et al., 1993). Although the Sahara-Tarfawi area contains some Neolithic scatters, the primary focus was on spring and pond deposits associated with Acheulian artifacts and a series of important Middle Paleolithic localities associated with either year-round lakes or playas. The Acheulian deposits may date to about 500,000 years ago, while the Middle Paleolithic localities range from before 200,000 to after 100,000 years ago. They reveal Middle and Late Pleistocene environments linked to fluctuating wetter and drier climates during the evolutionary transition to anatomically modern *Homo sapiens*.

The discovery of channel-like features in 1981 by space shuttle imaging radar (McCauley et al., 1982) prompted the CPE to conduct a systematic archaeological survey of the region south of Bir Tarfawi in 1984 (Wendorf et al., 1987). Hundreds of archaeological sites were found in the region of the radar channels. Most were assigned to the Neolithic, although several interesting Acheulian localities were also studied. Satellite images show a paleodrainage system extending from the highlands in southwestern Egypt towards the Bir Tarfawi region (Ghoneim and El-Baz, 2007), and it has also been suggested that water from the Nile flowed into the region during the Pleistocene (Maxwell et al., 2010).

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

Wadi Kubbaniya, located in the region northwest of Aswan, revealed the presence of Late Paleolithic sites, discovered in a 1977 CPE survey. These sites were the subject of excavations in 1978 and from 1981 to 1984 (Close, 1989) and again in 2011–2012. The stratigraphic sequence at Kubbaniya shows the interplay between aggrading Nilotic alluvium and dunes and the presence of a lake, formed when the wadi was blocked by dunes from about 23,000 to 12,000 ^{14}C years BP. The stratigraphic sequence extends back to the Middle Paleolithic.

Nabta was discovered by the CPE in 1974. Neolithic sites from Nabta were studied in the 1970s, 1990s, and 2000s (Wendorf et al., 2001). The stratigraphy revealed a sequence of episodic climate changes dating from about 10,000 to 4,000 ^{14}C years BP. Wet episodes resulted in the formation of seasonal lakes, although at times small, permanent bodies of water may have persisted. An ecological argument has been put forward that the early bovid remains present at Nabta are domesticated cattle. During the late and final Neolithic, Nabta appears to have been a ceremonial center; pottery from this time is similar to that of the predynastic in the Nile Valley.

EL MIRÓN CAVE

Lawrence Guy Straus[1,2] and Manuel R. González Morales[2]
[1]Department of Anthropology, University of New Mexico, Albuquerque, NM, USA
[2]Instituto Internacional de Investigaciones Prehistóricas, Universidad de Cantabria, Santander, Spain

El Mirón is a large cave near Ramales de la Victoria in the Cantabrian Cordillera, roughly equidistant between the cities of Santander and Bilbao, about 20 km from the present shore at the mouth of the Asón River. Its coordinates are 43°14′48″ N × 3°27′5″ W × 260 m a.s.l. It is surrounded by mountains ≥1,000 m a.s.l. and, facing due west, dominates the upper valley of the Asón at a strategic crossroads of natural routes linking the Cantabrian coast with the Castilian *meseta* (N-S) and the Basque Country with Cantabria and Asturias (E-W). Discovered scientifically in 1903 by H. Alcalde del Río and L. Sierra, it was never systematically excavated until the present authors began their research in 1996 (e.g., Courty and Vallverdú, 2001; Straus et al., 2001; Cuenca-Bescós et al., 2009; González Morales and Straus, 2009; Straus et al., 2011; Straus and González Morales, 2012; Straus et al., 2014a; Straus et al., 2014b). The main excavations are in the spacious cave vestibule (30 m deep × 8–16 wide × 13 m high) and consist of two 9–10-m^2 blocks connected by a 9 × 1-m trench. The inner of the two blocks has a connected 3 × 1-m test pit excavated down from the base of a large crater dug by looters, plus a 4-m^2 area excavated to recover a Lower Magdalenian burial at the rear of the vestibule.

Sediments in the vestibule are of several sources; most are limestone debris from the cave ceiling and walls and colluvial silts and cobbles derived from the ancient alluvial infilling of the >100-m-long inner cave that had undergone numerous fill-and-cut episodes. There are also fine aeolian silt and organic materials derived from long-term occupations of the cave by humans, birds, and other animals. Sedimentology was done by the late William Farrand, micromorphology by Marie-Agnès Courty, and magnetic susceptibility by Brooks Ellwood. An aggregate total of ca. 5 m of deposit have been sampled by the excavations, but geophysical prospection shows a total depth of ca. 9 m to bedrock in the vestibule. The climatic and vegetational changes of the late Upper Pleistocene and early Holocene are documented by micromammalian remains, pollen, wood charcoal, seeds, and phytoliths studied, respectively, by Gloria Cuenca, Maria Jose Iriarte, Lydia Zapata, Leonor Peña, and Debora Zurro. The mammalian fauna from the post-Paleolithic and Magdalenian levels has been analyzed, respectively, by Jesús Altuna, Koro Mariezkurrena, and Manuel Pérez Ripoll and by Ana Belen Marín.

Eighty-four radiocarbon assays date the excavated layers between ca. 41,000 BP and AD 1400 (all dates uncal). Documented cultural occupations pertain to the late Mousterian, Gravettian, Solutrean, Initial, Lower, Middle, Upper, and Final Magdalenian, Azilian, Mesolithic, Neolithic, Chalcolithic, and Bronze Ages, with traces of Medieval visits, as well as modern use of the cave by both humans and livestock. There are significant depositional hiatuses in the early Holocene part of the sequence. The Mousterian, Gravettian, Azilian, and Mesolithic occupations are minor, but the other periods are represented by important residues of human utilization, from specialized hunting camps in the Solutrean (ca. 19,000–17,000) to major, long-term, complex, multifunctional residential base camps in the Lower Magdalenian (ca. 16,000–14,000 BP) to mini-village settlements with pit structures in the Neolithic (one of the oldest in northern Atlantic Spain at ca. 5800–4500 BP), Chalcolithic, and Bronze Age (ca. 4500–3200 BP), with abundant ceramic technology, wheat grains, domesticated ovicaprines, cattle, and pigs and, in the latter, evidence of metallurgy.

The Magdalenian sequence is one of the longest and most complete in Spain, and it shows continuity from the preceding Solutrean and into the succeeding Azilian. Pollen and micromammal evidence in particular point to cold, but more or less humid climatic conditions, with open landscapes dotted with pines and junipers during much of the Upper Paleolithic sequence, until the Late Glacial Interstadial, when woods began to recolonize the area. The Initial (17,000–16,000 BP) and Lower Magdalenian levels have numerous hearths with abundant fire-cracked rocks; masses of red deer (DNA analyzed by X. L. Hermoso-Buxán and Rhiannon Stevens) and ibex remains; salmon and other fish bones (DNA analyzed by Sonia Consuegra and Carlos García Leaniz); vast quantities of stone, antler, and bone tools and weapons; objects of personal adornment (perforated shells and teeth); and works of mobile art (notably a red deer stag scapula engraved with the image of a hind and a slate pendant engraved with the image of a horse). The Lower Magdalenian was the setting of the only human burial yet to be found in the Late Glacial of the Iberian Peninsula: an interment of a short, apparently healthy, middle-aged woman now represented by over half her bones,(but the cranium and most long bones were missing). The bones are stained with red ocher and deposited in sediments also stained with red ocher and sparkling with hematite crystals. The remains are currently under study by a team led by J. M. Carretero, and whose mtDNA and nDNA are being analyzed by a team led by S. Pääbo. The corpse, which (once skeletonized) was slightly disturbed by a carnivore, had been placed within a narrow space between a large fallen block and the rear vestibule wall, partly atop the bedrock ledge and partly in a pit dug into a preexisting Magdalenian level upon which the block had fallen. Subsequent to its fall, the block was engraved in late Lower-Middle Magdalenian times on its outward-oriented (west) surface and painted red on its inward-facing side (east). The rear vestibule wall is also covered with fine engravings, mainly lines, but also one horse and a possible bison.

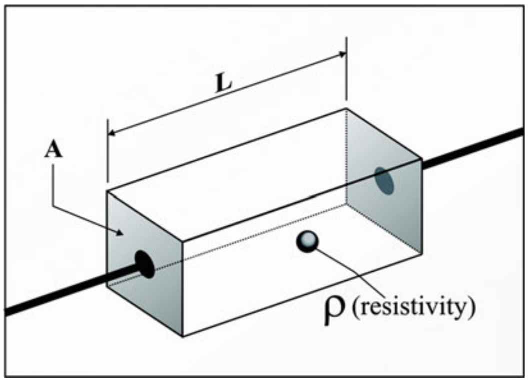
ELECTRICAL RESISTIVITY AND ELECTROMAGNETISM

Alain Tabbagh
Université Pierre et Marie Curie, Paris, France

Introduction

Resistivity and electromagnetic prospecting are two methods by which the electrical resistivity of the ground can be measured. This property of resistivity quantifies the difficulty experienced by electrical currents in passing through the soil. As an example, most stones resist the flow of an electrical current. Clay is the opposite, and current readily flows through it. By using these geophysical methods, one attempts to describe the three-dimensional structure of the ground (Clark, 1996) without the intrusiveness and destruction of an excavation. Such information can be useful in evaluating the buried archaeological remains of a site. The quality of such information is



Electrical Resistivity and Electromagnetism, Figure 1 Definition of the resistivity of a prismatic body.

limited, however, first by the physical principle of the methods and second by the chosen spatial sampling interval. Nevertheless, one of these methods can probably be successful at a greater variety of sites than any other geophysical technique.

The ideas and procedures of resistivity surveys will be described first. The lesser known and more complex procedures of electrostatic and electromagnetic surveys will be discussed later. All of these very different techniques allow the measurement of the same parameter, the electrical resistivity of the soil. While the many different procedures may seem unusual, there are also many different types of magnetometers and several different types of ground-penetrating radars. Each has advantages.

Electrical resistivity

Electrical resistivity is indicated with the symbol ρ and is quantified with a unit called the ohm · meter ($\Omega \cdot$ m). If a resistance of R (in ohms) is measured between the ends of the rectangular prism shown in Figure 1, the resistivity of the medium contained within the prism will be $\rho = R\frac{A}{L}$, where A is the area of the cross-section of the medium, and L is the distance that electricity must cross along the length of the prism. For convenience, one may also talk about the conductivity (indicated by the symbol σ) of the medium, which is simply the reciprocal of resistivity: $\sigma = 1/\rho$.

In natural, earthen materials, this property of resistivity exhibits a broad range of variation (a wide dynamic range) from less than 1 $\Omega \cdot$ m to more than 10,000 $\Omega \cdot$ m. In soils and rocks, ions are the moving electric charges. Depending upon their location within the three phases of the subsurface medium (solids, liquids, and gases), these mobile ions fall into two categories: (1) ions dissolved in pore water that generate *volume conductivity* and (2) counter ions that can slide at the surface of clay platelets and generate *surface conductivity.* Counter ions are positively charged cations that adsorb onto the generally negatively charged surfaces of clay platelets, and thus, interpretation of conductivity/resistivity values becomes a matter of distinguishing between materials that contain clay and those that do not contain clay.

Materials without clay

Here, one observes a direct proportionality between the bulk resistivity, ρ_b, and the resistivity of the pore-filling water, ρ_w. The ratio between them, $F = \frac{\rho_b}{\rho_w}$, is called the formation factor. Consequently, one may assume that both solid and gas fractions can be considered in isolation and that all the electrical current circulates only through the pore water. For moist, porous soils, F can be as low as 4, while for stones, it can reach 100. If the porosity were to be constituted solely by a bundle of straight channels filled with water, F would be inversely proportional to the porosity, φ. In reality, however, the channels are not straight but tortuous because of the irregularity of structure and packing within the ground subsurface, and their sections as well as the length along their path may vary. Experiments conducted with saturated media have led to the formulation of Archie's law, which states: $F = \varphi^{-m}$, where φ is the porosity and the parameter m is not far from 2. In unsaturated media, this law behaves differently: $F = \theta^{-m}$, where θ is the volume water content.

Materials with clay

In fine-grained materials, volume conductivity is present, but surface conductivity also exists. The relationship that corresponds best with experiments is the simple addition of these two types of conductivity:

$$\sigma = \sigma_v + \sigma_s,$$

where σ_s is the surface conductivity and σ_v is the volume conductivity. However, except in areas of saline soils, surface conductivity plays the major role; a conductive soil must be interpreted as one containing a significant clay component, while a resistive soil is usually one with lower clay content. For all soils, an increase in water content will correspond to an increase in conductivity.

Consequences for archaeological prospection

The significance of these two different processes of electrical charge transport for archaeological prospection is twofold: (1) resistivity informs about the character of the natural substrate in which the archaeological remains are buried, and (2) one can assess the contrast that exists between a given archaeological feature and its surrounding medium depending upon their respective clay content. For instance, a ditch infilled with superficial soil of 70 $\Omega \cdot$ m resistivity that was originally dug into 30 $\Omega \cdot$ m loess will be imaged as a resistive feature, while the same infilled ditch dug into alluvial gravel of 300 $\Omega \cdot$ m resistivity will be imaged as a conductive feature.

It should be noted that the resistivity of sedimentary rocks may vary due to the influence of their clay fraction; even a wall built using solid limestone blocks can have a moderate resistivity of 100 $\Omega \cdot$ m if it contains several percent of clay, while another, clay-free, limestone may

Electrical Resistivity and Electromagnetism, Table 1 Electrical resistivity of layers that can be encountered in archaeological sites.

Subsurface medium	$\Omega \cdot$ m
Superficial clayey layer	15
Loess	30
Typical cultivated layer	70
Chalk	100
Sand, moist	200
Limestone	100–2,000
Sand (dry)	3,000
Crystalline stone	5,000

have a much higher resistivity of 2,000 $\Omega \cdot$ m. Some reference values and a few general rules of thumb are as follows. (1) The resistivity of water varies linearly with salt content from 0.25 $\Omega \cdot$ m for seawater to 20 or 100 $\Omega \cdot$ m for soft waters (containing little dissolved mineral content). (2) Clays in superficial formations show a narrow range of resistivity from 5 to 15 $\Omega \cdot$ m. (3) Sedimentary rocks exhibit a wide range in resistivity, from 20 $\Omega \cdot$ m for marl to 5,000 $\Omega \cdot$ m for sandstones. (4) Unweathered crystalline rocks and permafrost are both very resistive. (5) Generally, stones or fired bricks from building remains are more resistive than their surroundings, while earthen features, pits, pit-house fills, and ditches are more conductive. (6) In alluvial contexts, the sign of the contrasts can change abruptly when passing from gravel or sand to clay. Table 1 summarizes the order of magnitude in resistivity for different materials commonly encountered in an archaeological context.

Physical principles underlying the different techniques

The discussion of electrical current flowing though resistors (or soils) has so far assumed that these are steady currents that do not change with time. If, however, these are alternating currents, the applications become more complex, but also more valuable. The increased complexity occurs because two additional properties of soils can now affect the measurements. The first property is the *magnetic susceptibility* (κ) of the soil, a dimensionless constant; iron-containing minerals in the soil have the greatest effect on its magnetic susceptibility. The second property of soils is the *dielectric permittivity* (ε), measured in farads per meter (F/m); while this term is less familiar, this property controls the velocity of a radar pulse in the soil. Fortunately, the applications become more informative when these two additional properties of soils are measured, for they allow greater distinctions to be made between different soils and archaeological features.

Ground-penetrating radars work at a higher frequency; their operation is controlled by the conductivity (σ, which is the reciprocal of resistivity, ρ) and the dielectric permittivity of the soil. If the frequency is lower than 30 kHz, the dielectric property of the soil has little effect on measurements, leaving the other two properties, conductivity and susceptibility. Most electromagnetic (EM) instruments operate at this lower range of frequencies, and they can measure both the conductivity and the susceptibility of the soil, independently, with a single instrument.

These EM instruments will be described in greater detail later, but an important aspect will be introduced here. Many of them operate by sending an oscillating magnetic field from one coil of wire (the transmitter) through the soil to another coil (the receiver). This magnetic field is increasingly attenuated, the deeper it descends into the earth. However, a greater depth is possible if the soil is resistive or if the frequency of oscillation is lower. If the magnetic field is able to penetrate deeply into the soil (deep relative to the spacing between the two coils), then the EM instrument can follow the low induction number (LIN) approximation. This LIN approximation means that the coupling of the magnetic field from the transmitter to the receiver coil is directly proportional to the conductivity of the soil. These instruments are often called conductivity meters, and they are widely used in archaeology.

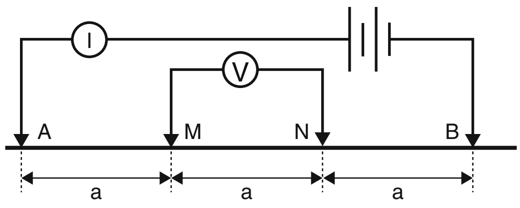
Direct current electrical prospecting (static approximation case)

To inject an electrical current into the soil, two electrodes (e.g., two metal stakes) are enough. It is impossible, however, to deduce the resistivity of the soil from the voltage difference between these two stakes and from the delivered current intensity. One can obtain only the sum of the two earth resistances at each stake. Fortunately, the voltage at locations other than the injection points is dependent on soil resistivity, and thus arrays of four electrodes – two electrodes for current injection and two others for the measurement of voltage differences – represent an effective solution for resistivity determination. Direct current (DC) electrical prospecting is achieved by using a quadrupole, which is often called "the resistivity method."

If one considers a homogeneous half-space of resistivity, ρ, and a direct current, $+I$, is injected with an electrode at a point A on its surface, the current density will be isotropically distributed (equal in all directions) and is expressed at a distance r from A by: $i_r = \frac{1}{2\pi r^2}$. By applying Ohm's law, the electric field is expressed by: $E_r = \frac{\rho I}{2\pi r^2}$, and the electrical potential by $V = \frac{\rho I}{2\pi r}$ (if the potential is 0 at infinity). If one considers a second electrode at a point B on the same surface, where the injected current emerges and is $-I$, it becomes possible to determine the voltage difference between two other electrodes serving as measurement points, M and N, yielding the following:

$$V_M - V_N = \Delta V = \frac{\rho I}{2\pi}\left[\frac{1}{MA} - \frac{1}{MB} - \frac{1}{NA} + \frac{1}{NB}\right],$$

where AM is the distance between electrodes A and M, BN is the distance between electrodes B and N, etc.

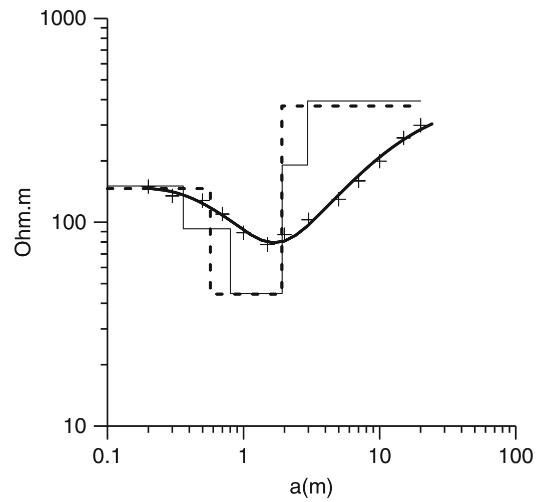


Electrical Resistivity and Electromagnetism, Figure 2 Schematic diagram of the Wenner α array.

The measurement of $\Delta V/I$ is proportional to ρ but also depends on the geometry of the four-electrode array, that is, on how the electrodes are arranged spatially. The apparent resistivity concept can express the measurement with one parameter, and it also compares the results obtained with different array geometries. The apparent resistivity, ρ_a, is the resistivity of a homogeneous ground that would give the same value of $\Delta V/I$ as the array that was used. It is thus expressed by using a geometrical coefficient K (in meters): $K = \frac{2\pi}{\frac{1}{AM} - \frac{1}{BM} - \frac{1}{AN} + \frac{1}{BN}}$ and $\rho_a = \frac{\Delta V}{I} K$. The apparent resistivity can be considered as a sort of global average value of the electrical resistivity of the soil volume that influences the measurement.

There exist an infinite number of ways to deploy the four electrodes over a ground surface, and therefore, some arbitrary procedures have been adopted that are advantageous from either a practical point of view, a theoretical one, or both. The first is the Schlumberger array where the four electrodes are placed along a straight line in a symmetrical disposition with MN ≪ AB; here $K = \frac{\pi AB^2}{4MN}$. For this array, all electrodes lie along the same line, but the inner ones that measure voltage (M and N) are separated by a much shorter distance than that separating them from the outer current electrodes (A and B). In the Wenner array, presented in Figure 2, the four electrodes are aligned but separated by the same distance, a, so that $K = 2\pi a$ for the A,M,N,B configuration (called Wenner α). Additionally, the electrode arrangement can be modified to yield $K = 6\pi a$ for the A,B,N,M configuration (called Wenner β, or Wenner dipole-dipole) and $K = 3\pi a$ for the A,M,B,N configuration (called Wenner γ). The electrodes can also be located at the four corners of a square, in which case $K = 10.72a$, where a is the side of the square. This holds true if electrodes A and B are adjacent; if they are located at the diagonally opposite corners of the square, then $K = 0$.

In the process of surveying, the electrodes are moved in order to measure a different spot in one's area of investigation or probe deeper into the subsurface. It is possible to limit the number of electrodes that must be moved for each voltage measurement by fixing one of them, for example, B, at a great distance (infinity), so that $K = 4\pi a$ if the three others stay aligned and separated by a. This array is called "pole-dipole." One voltage electrode and

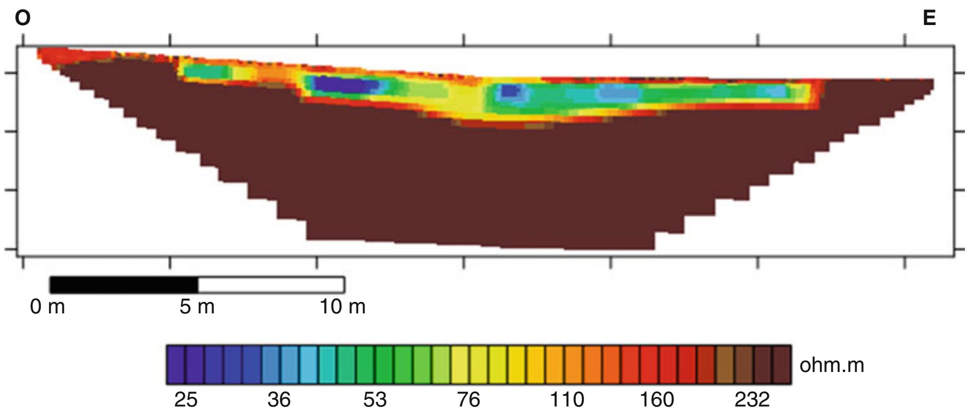


Electrical Resistivity and Electromagnetism, Figure 3 An example of a VES using the Wenner α configuration (in which the a spacing is gradually increased to deepen the sounding progressively. A log-log display is used to show the apparent resistivity measurements (+). A calculated curve (*black continuous line*) is the same for two different models of stratification, one with three layers (*dotted line*) and the other with five layers (*continuous thin line*), giving the same level of fitness between experimental and theoretical values. The thicknesses of the layers can be read on the horizontal axis and the resistivities on the vertical axis. For both scenarios, the dip in the curve reveals the conductive layer of clay at a depth of about 1 m.

one injection electrode can also be fixed at great distances from the moving electrodes to obtain the so-called pole-pole configuration where $K = 2\pi a$; here, only two electrodes are moved.

Historically, the resistivity method allows one to explore both the vertical and lateral distribution of resistivity. Vertical changes in resistivity (at one location) are revealed by increasing the electrode separation and sending the current deeper into the ground; lateral variations (at a constant depth) are detected by moving a quadrupole that has a fixed geometry around a wide area. The first type has been called "electrical sounding" (or vertical electrical sounding, VES). The second type has been called "resistivity profiling." In archaeological prospecting, one always makes a series of parallel profiles to get a map of apparent resistivity variations across a ground surface (see Figures 5 and 6). Both types of resistivity survey require an understanding of the effective depth of a measurement, as it is determined by the resistivity stratification of the soil and the electrode separation. As an approximation, the depth of investigation, that is, the soil thickness averaged by a measurement, is generally somewhat smaller than the smallest distance between one current-injection electrode and the closest voltage electrode.

As an example of the information provided by a VES, Figure 3 shows the result of an electrical sounding



Electrical Resistivity and Electromagnetism, Figure 4 Example of electrical resistivity tomography done at the archaeological site of La Citerne (Grand, Vosges, France). It shows a section perpendicular to a linear drainage depression cut into the underlying limestone; the drain was about 20 m wide and up to 1.2 m deep (Courtesy of C. Brinon). The drain is filled with conductive sediments, and the resistive limestone is underneath (Brinon, 2012, 146).

performed with a Wenner α configuration. The measurement was located where the soil contained planar strata and where, between a resistive limestone base and the moderately resistive topsoil, there was a conductive clayey layer resulting from the weathering of the limestone. Unfortunately, infinitely many different resistivity stratifications within the soil could yield the measurements that were obtained; there is no one-to-one relationship between a resulting curve and a specific sequence of strata. Two of the possible solutions are drawn in Figure 3, one with three layers (dotted line), the other with five (continuous thin line). Even though these solutions differ, both reveal the presence of the conductive layer of clay, and its approximate depth of around one meter is readily established on the horizontal axis of the graph.

It has been also recognized that both sounding and profiling can be combined by using multipole arrays, whether one opts for a mobile process wherein electrodes are moved or an immobile one (a stationary switched array). The two-dimensional (2D) switched array is also called "electrical resistivity tomography," or ERT. It allows a simultaneous measurement of resistivity variations in both the horizontal and the vertical dimension, generating what is called a resistivity pseudosection. It is achieved by placing a long line of n equidistant electrodes separated by the same distance, a. One first chooses the normal quadrupole configuration, for example, the Wenner array. The first measurement is made using electrodes 1, 2, 3, and 4; one then switches to electrodes 2, 3, 4, and 5 and repeats this operation down the line of electrodes until electrode n is reached. In this way, a first profile corresponding to the a-spacing is performed, generating a resistivity cross section at a uniform depth. Additional, deeper profiles are then produced by using electrodes 1, 3, 5, and 7, followed by switching to electrodes 2, 4, 6, and 8 and so on; this will yield a second profiling that reaches to a depth of approximately 2a due to the 2a spacing. All the possible successive spacings are then done the same way to a maximum spacing of (n–3)a. 2D interpretation transforms the pseudosection into vertical sections of resistivity variations. This 2D exploration process can be expanded into a 3D one by using a grid of electrodes that extend in two horizontal directions. An example of an interpretation of a 2D ERT is shown in Figure 4; this resistivity section reveals a low resistivity stratum caused by soil-filled drains above limestone bedrock.

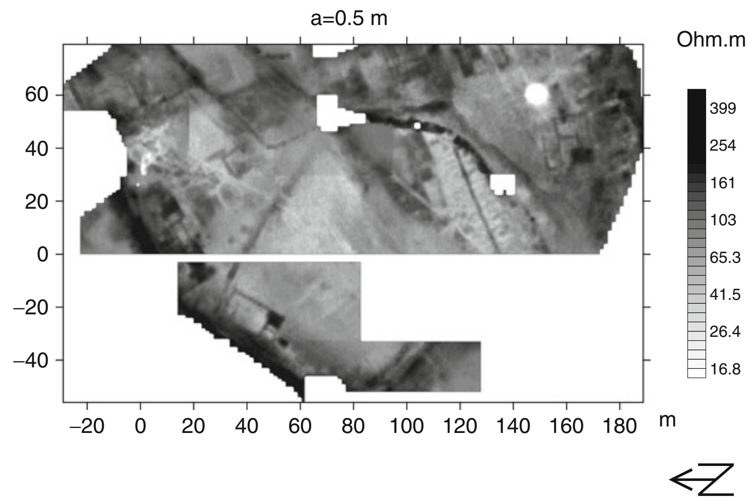
A substantial amount of equipment is needed to measure a pseudosection, and the survey is quite slow because of the greater number of electrodes that must be inserted into the soil before beginning to record measurements. A simplification for purposes of archaeological prospection has involved the development of moving multielectrode systems. Two different types, one hand held, and one mechanically towed, are described next.

Handheld devices

The best compromise between lightweight equipment and high data quality led to the adoption of the pole-pole array; several different depths can be explored by using moving in-line arrays of electrodes fixed to a rigid frame (Gaffney and Gater, 2003). With the RM15 from Geoscan Research Ltd., a set of four electrodes separated by 50 cm allows the sequential determination of a number of pole-pole measurements for each setting of the electrode array: three at a spacing of 0.5 m, two measurements with electrodes spaced by 1 m, and one measurement with a spacing of 1.5 m. Figure 5 is a resistivity map that was prepared with this procedure inside the small town of Grand (Vosges, France), an area of over 2 ha was mapped, and a series of gardens were revealed.

Mechanically towed systems

The device above is suitable for the survey of limited-size parcels, but for larger areas, this type of survey is still



Electrical Resistivity and Electromagnetism, Figure 5 An apparent resistivity map measured at 'le Pré Laguerre' (Grand, Vosges, France) using a pole-pole array with an electrode spacing of 0.5 m. Measurements were ended at the edges of the garden. The apparent resistivity was found to decrease as the depth of investigation increased due to the presence of a conductive substratum. The Gallo-Roman features are clearer on this shallow (a = 0.5 m) map, which proves that their depth is limited (Brinon, 2012, 224).

Electrical Resistivity and Electromagnetism, Figure 6 An automatic resistivity profiling (ARP©) instrument with a differential GPS positioning antenna, that is towed by a light, all-terrain vehicle (courtesy of Geocarta SA). The current is injected at poles A and B, while the voltages are measured at the three pairs of electrodes M and N.

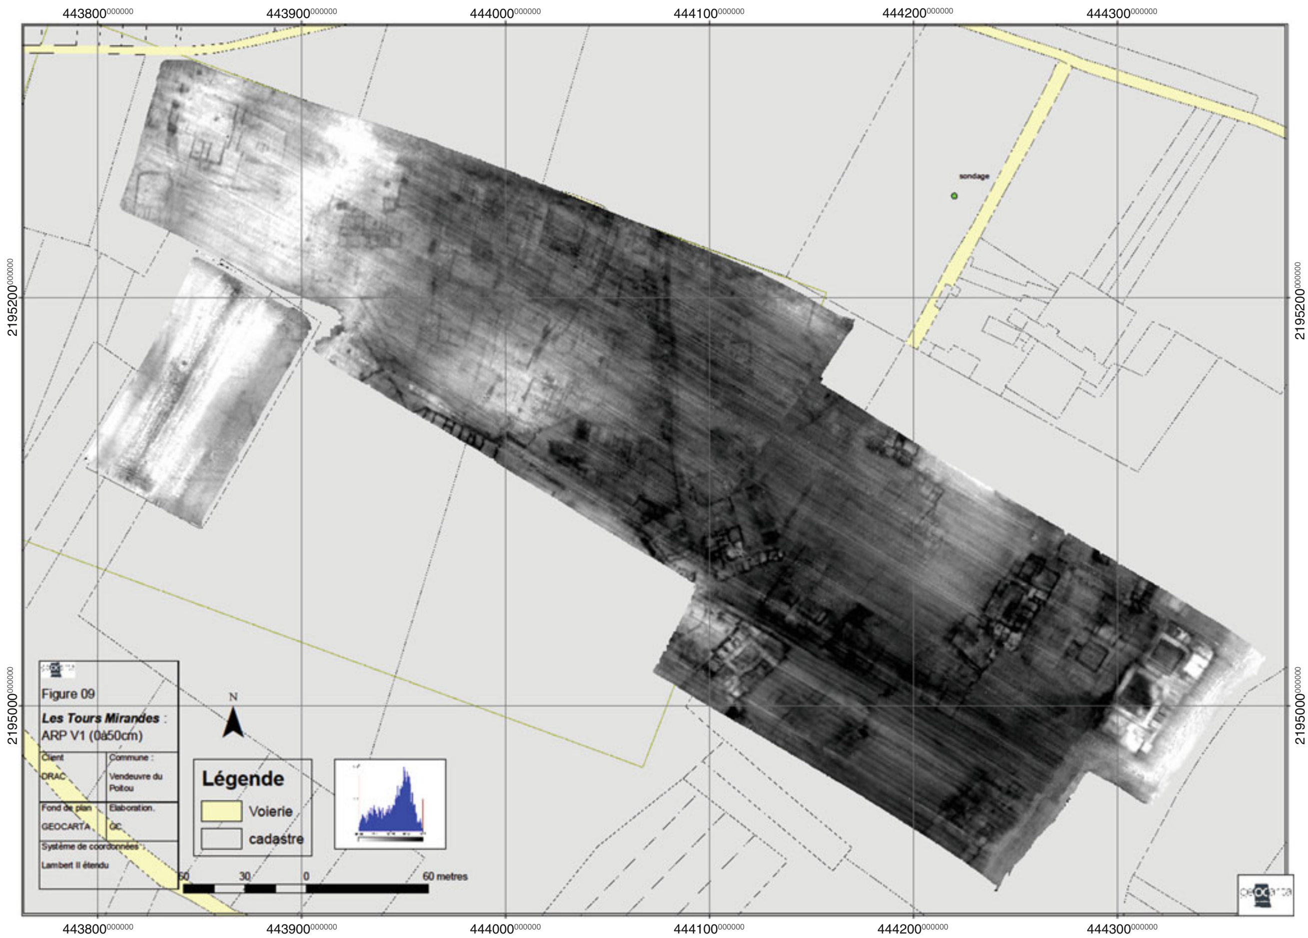
tedious and slow, and therefore expensive. For more extensive surveys, mechanically towed systems should be considered (Campana and Piro, 2009).

For such systems, two main problems need to be overcome: the measurement speed must be fast, and the electrical contact between each electrode and the soil must be good. Stable measurements of resistivity can be made in a few microseconds; therefore, resistivity meters have been designed to overcome the first limitation. The second problem is more difficult; the most effective solution has been to use heavy spiked wheels (weighing about 20 kg). A good instrument for archaeological prospection (Panissod et al., 1998) is a multipole system with one pair of current-injection wheels and three different pairs of voltage-measuring wheels, as illustrated in Figure 6. This is called a MUCEP (Multi-pole Continuous Electrical Profiling) or an ARP© (Automatic Resistivity Profiling) instrument. Simultaneous measurements can be taken with several depths of investigation afforded by the differently spaced voltage electrodes (Brinon et al., 2012).

The example shown in Figure 7 is a resistivity map of a 4-ha area at Tours Mirandes (Vendeuvre du Poitou, Vienne, France) from Caraire et al. (2011). Roads and stone foundations are revealed in this map; the resistivity of the surrounding soil varied from 15 Ω·m (clayey soils) to 120 Ω·m (at limestone outcrops).

Electrostatic prospecting

The DC electrical method has a major weakness in that it requires a good galvanic contact between the electrodes and the ground. This is not too difficult on cultivated soil in temperate climates, but it can be very difficult in arid areas and impossible on tarmacs and other hard layers.



Electrical Resistivity and Electromagnetism, Figure 7 An apparent resistivity map with a depth of investigation of 1 m that was measured at the Gallo-Roman city of Tours Mirandes (Vendeuvre du Poitou, Vienne, France). This map is superimposed onto a historical property map (Courtesy of Geocarta and Johan Durand, HERMA, Poitiers University).

In such challenging situations, one can generate an electric field by applying electrostatic charges and then measuring voltage differences in the air, and not in the ground itself. If an electric charge is located in the air just above the ground, and both low frequency and *LIN* assumptions are valid, then the electric potential at another point can be approximated by the same formula that is applied to DC prospection: $V = \frac{\rho I}{2\pi r}$. Thus, the electrostatic method is a generalization of the DC electrical one, where the source of the electric field is a pair of electrical charges, $+Q$ and $-Q$, that constitute an open capacitor. It can be called a "capacity-coupled resistivity method" or "capacitive resistivity method." This method has the same capabilities as the DC electrical resistivity method, and it can be used for both vertical and lateral investigations with simple quadrupole or multipole arrays. The required assumptions can be met, for typical values of soil resistivity, by using a frequency between 3 and 300 kHz and by limiting the depth of exploration to at most 10–20 m, which is suitable for archaeological prospection. The advantages that result from the absence of galvanic contacts are important: (1) one can survey over insulating surfaces and also delicate surfaces, for example, painted walls, and (2) it is easy to move a quadrupole (or a multipole) continuously over a surface without significant changes in the impedance of the poles (Panissod et al., 1998; Souffaché et al., 2010).

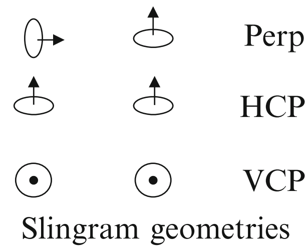
Electromagnetic prospecting, Slingram EMI

Another way of avoiding electrical contact with the soil is with the application of a time-varying magnetic field. In a conductive medium, this time variation causes eddy currents to flow, which in turn generate secondary magnetic fields that can be measured with receiving coils. Several different sources for the primary magnetic field can be applied: one can use low-frequency radio broadcasting transmitters, the magnetic field from large or small loops or coils, or a long wire lying on the ground surface. For archaeological prospection, a suitable combination of the correct depths of investigation and good lateral resolution is achieved with instruments that have a pair of small coils. One is a transmitting coil that emits a continuous monofrequency magnetic field, and the other, or companion, receiving coil measures, the resulting secondary magnetic field. The suitability of this instrument was recognized after a series of test studies begun in the mid-1960s (Scollar et al., 1990). The coils may have orientations that differ from each other; it is also possible to use several receivers or transmitters, but the distances, L, between the coils should not significantly exceed the lateral and vertical size of the features that are sought. This type of instrument has several names; the name slingram EMI indicates that the measurements are based on electromagnetic induction from coils (slingram is a Swedish word roughly meaning "loop frame").

For practical reasons, these EM instruments measure the electrical conductivity of the soil. Electrical conductivity, σ, is defined by Ohm's law, $i = \sigma E$ where i is the current density, i.e., the sum of electrical charges crossing the surface during some unit of time, and E is the electric field. Conductivity is expressed in Sm^{-1} (siemens per meter) and is dependent on the material through which the current passes. Conductivity is just the reciprocal of resistivity, that is $\sigma = 1/\rho$. With normal soils and typical frequencies of excitation, the low induction number (*LIN*) approximation will be valid. Then, the field at the secondary coil is directly proportional to the *IN* and thus proportional to the conductivity of the soil.

Most, if not all, electromagnetic instruments can measure either the electrical conductivity or the magnetic susceptibility of the soil, simply by changing a switch. This distinction is possible because of the phase, or time lag, of the oscillating magnetic field that is received from the soil by the instrument. The soil's susceptibility creates a magnetic field that oscillates exactly in synchronism with the field that is transmitted into the soil; this is called the "in-phase component" of the field. However, conductive strata in the soil generate a magnetic field that is delayed relative to the transmitted field; this is called the "quadrature component" of the field. Electronic circuitry in the EM instrument allows these two components to be separated. Finally, these instruments can also detect metallic objects, so they are excellent tools for archaeological prospection.

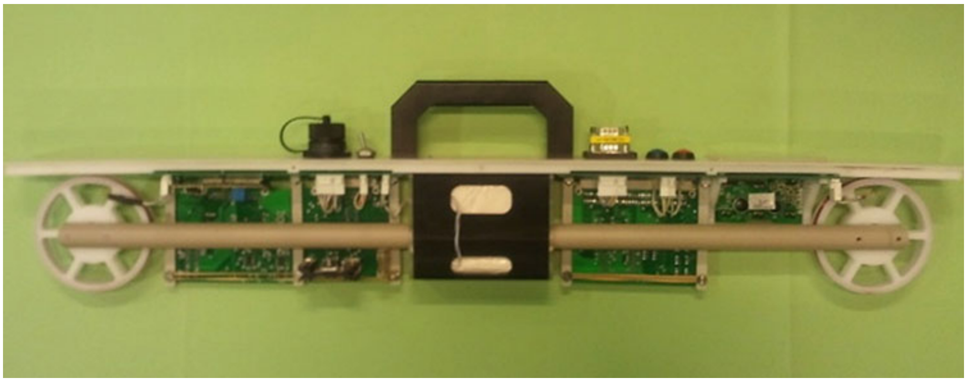
The relative orientation of the coils must be considered. First, some orientations will yield no response over a homogeneous, or planar-stratified ground, and this creates a disadvantage because the configuration yields no absolute values of conductivity or magnetic susceptibility, which are important for characterizing below-ground archaeological features and their host medium. The three relative orientations of a pair of coils that have been found to be most suitable for near-surface prospection are shown in Figure 8. In the HCP (horizontal coplanar) configuration, the two coils are on the same horizontal plane, their axes being vertical. In the VCP (vertical coplanar) configuration, the two coils are on the same vertical plane, and their axes are both horizontal. In the Perp (perpendicular) configuration, the two coils are in perpendicular planes, one having a vertical axis, the horizontal axis of the second being 90° from this axis. The same instrument can be used in both HCP and VCP orientations by a simple rotation of both coils; it can also be used in the vertical position (with the line between the transmitter and receiver coils vertical) (Thiesson et al., 2011). While the HCP configuration has the greatest sensitivity to deep conductive layers, it has two major faults: (1) the in-phase response of a magnetic layer exhibits a sign change at a depth of $z = 0.38\,L$, and (2) small conductive features yield readings of apparent conductivity that are less than that of the feature.



Electrical Resistivity and Electromagnetism, Figure 8 Different configurations (orientations) of the coils that are applied to near-surface prospection. In HCP, two coils lie in one horizontal plane but with vertical axes; in VCP, two coils lie in one vertical plane but with horizontal axes; in Perp, two coils lie in perpendicular planes, one with its axis vertical, the other with its axis horizontal and oriented 90° from that of the first.

The most suitable orientations for archaeological prospection are VCP and Perp, with Perp having a greater sensitivity to soil contrasts (Scollar et al., 1990). When comparing the relative advantages of the DC electrical method and the slingram EMI method in terms of feature detection, two points must be emphasized. First, with EMI, the detection of conductive features is easier than the detection of resistive features (Thiesson et al., 2009), and with the electrical method, the study of resistive targets is more reliable. Second, there is a question regarding their respective depths of investigation: in other words, which array size for a DC resistivity survey would give the same exploration depth as an L-spacing between coils of an EMI instrument? This question has neither a simple nor a general answer, but for an elongated resistive body of width L, a coil separation of L in the VCP configuration gives an anomaly whose width (measured at full-width half maximum) is about the same as an L-sided square array, although its anomaly is smaller in amplitude.

EM prospecting has the major advantage of allowing magnetic susceptibility measurements to be combined with magnetic field data in an interpretation (Pétronille et al., 2010). A picture of a small slingram EMI instrument, the CS60, is shown in Figure 9. In the field, it can be used in both the HCP and VCP orientations. It can also take its measurements while being pulled continuously on a sledge, or measurements can be made point by point.



Electron Probe Microanalyzer, Figure 9 The CS60 instrument without its casing. This instrument measures conductivity and susceptibility with a 60 cm inter-coil spacing in the VCP configuration (Courtesy of UMR Métis, UPMC; instrument designed by S. Flageul and J. P. Pencolé).

Conclusion

Electrical resistivity is the most variable parameter among those used in geophysical prospection; it allows the detection of a wide variety of archaeological features using quite simple (and inexpensive) measurement techniques. The DC electrical resistivity method allows a rapid approximation of the three-dimensional shapes of different archaeological targets, and it can be operated in small areas as well as large, open areas where mechanized techniques can be employed. Where the application of DC methods is difficult due to insufficient galvanic contacts, the electrostatic or electromagnetic methods can substitute; the EM technique has the advantage of simultaneously measuring conductivity and magnetic susceptibility.

ELECTRON PROBE MICROANALYZER

J. Victor Owen
Department of Geology, Saint Mary's University, Halifax, NS, Canada

Synonyms

Electron microprobe (EMP); Microprobe; Probe

Definition

Electron probe microanalyzer: a microbeam instrument primarily used for in situ, generally nondestructive, chemical analysis and imaging of minute (micron scale) parts of solid media, including minerals, ceramics, glass, metals, and alloys, and biological materials (e.g., biopolymers such as chitin, cellulose, and encapsulating agents, especially those containing metals).

Introduction

The electron probe microanalyzer (henceforth "EPMA") essentially is a scanning electron microscope (SEM) equipped with wavelength (WDS)- and/or energy (EDS)-dispersive spectrometers. Thus, it provides high-resolution images of the medium being analyzed, as well as precise, quantitative, analytical data on a micrometer scale. As its name implies, the EPMA makes use of a tightly focused electron beam – as little as 1 micrometer (μm) or 1×10^{-6} m – to irradiate samples being investigated. The principal advantage of the EPMA is that it can be used to analyze samples of minute volumes in situ, so textural and microstructural features are preserved. Furthermore, the small "spot" size of the electron beam ensures that individual phases in extremely fine-grained materials can be analyzed and compositional zoning in larger grains can be quantified. The EPMA can also be used to generate elemental X-ray images (concentration maps), as well as bulk compositional data for extremely fine-grained samples.

If suitable standards are available, the EPMA can provide reproducible analytical data for elements heavier than lithium (i.e., atomic number (Z) > 3) at concentrations as low as ~100 parts per million (ppm). Where equipped with appropriate software, the instrument can be used to collect images of domains being analyzed. These images can then be subjected to quantitative image analysis to determine, for example, the proportion of phases (modal composition) in polymineralic materials. The same approach can be used to determine the modal composition of individual grains in a crystalline rock that contain an immiscible phase, so that the composition of the exsolved mineral can be numerically reintegrated back into its host. This is a first step in the application of some mineral thermometers (wherein mineral compositions are used to determine paleotemperatures). A more time-consuming approach involves rastering grains containing the exsolved phase (e.g., Bohlen and Essene, 1977).

Not all solids can be easily analyzed by the EPMA. Materials containing abundant volatiles can be unstable at the high-vacuum (~$2\text{–}5 \times 10^{-6}$ Torr) conditions in the microprobe chamber. Volatile components tend to decompress explosively when subjected to heating by the electron beam, thus potentially resulting in irreparable damage to the specimen. Strongly insulating materials can be damaged because they cannot quickly dissipate heat produced during irradiation by the electron beam, although this effect can be mitigated by coating in a highly conductive medium such as Al. Similarly, hydrocarbon-based media should not be analyzed because they are readily damaged by the electron beam, and they can contaminate the instrument.

Principle

The fundamental principle on which EMP analysis operates was discovered by H. G. J. Moseley (1887–1915), one of the leading young British physicists of his era. Moseley demonstrated that the frequencies of characteristic X-rays generated by particular elements vary linearly with the square root of the atomic numbers of those elements. This discovery, known as Moseley's law, supported models of the atom that had been proposed by Niels Bohr and A. J. van den Broek, and it showed that the atomic numbers of the elements are not arbitrary but are based on measureable attributes. Moseley recognized the potential of his discovery for analytical chemistry and for predicting elements missing (at the time) from the periodic table.

With regard to EPM analysis, the most important of the interactions between the electron beam and the sample occurs when incident beam electrons cause one or more inner shell electrons to be ejected from irradiated atoms. These inner shell vacancies leave atoms in a high-energy excited state. This excess energy is dissipated as (1) an outer shell electron fills the inner shell vacancy or (2) an outer shell (Auger) electron is ejected. The first mechanism releases an X-ray photon with energy equal to the difference in energy between the inner and outer shell electrons involved in this process. This is usually on the order of 0.1–15 keV. For specified inner/outer shell electrons, the energy of the emitted X-ray photon increases with atomic number (Z) because the higher positive charge of the atomic nucleus (i.e., number of protons) causes the electrons in all shells to be tightly bound, and this influences the energy of the emitted X-ray photons. Thus, each element produces X-rays with a characteristic energy or wavelength as they are irradiated. This phenomenon is exploited by the EPMA. The two characteristic X-ray lines most commonly used in microprobe analysis are $K\alpha$ and $L\alpha$, where, by X-ray notation, shells are labeled K, L, M, N, and O (from the lowest ground-state energy to the innermost shell outward). Electrons in the innermost shells have the highest ionization energies, and, in general, K X-rays have higher energies than L X-rays, and L X-rays have higher energies than M X-rays for any given element.

How it works

Electron microprobe analysis is based on the effects that a tightly focused and accelerated electron beam (5–30 keV) has on solid media. These include the generation of heat, secondary and backscattered electrons, continuum X-ray radiation (bremsstrahlung: German for "braking radiation"), cathodoluminescence, and, significantly, characteristic X-ray radiation. The emitted X-rays are counted by wavelength- and/or energy-dispersive spectrometers and compared with the intensity of characteristic X-rays generated during the analysis of standards (materials of known composition). Each wavelength-dispersive spectrometer contains specifically oriented diffraction crystals of known d-spacing that are sequentially positioned at angles determined by Bragg's law to diffract the X-ray wavelengths specific to particular elements toward a detector. WDS typically uses several gas-flow or sealed proportional detectors to count specific wavelengths; EDS uses a single solid-state semiconductor detector to accumulate X-rays of all energies (wavelengths) generated by the sample. Thus, EDS generates information about all elements in the analyzed sample simultaneously, whereas WDS will determine the concentration of only those elements selected by the user for analysis. Because of its superior X-ray peak resolution, the precision of WDS data is better than EDS data.

In WDS, the X-ray photons released by each element are counted for a length of time specified by the user. No single crystal satisfies Bragg's equation for all wavelengths, so most instruments have several spectrometers. Since the concentrations of elements sought by individual crystals are determined sequentially, WDS analysis is relatively slow compared to EDS. Depending on the number of elements being sought and count times, individual spot analyses determined by WDS typically take between 2 and 20 min to complete. Count data must be corrected for matrix effects (absorption and secondary fluorescence) to yield reliable quantitative analyses.

History

Moseley's experiments made use of an electron gun housed in a vacuum. Characteristic X-ray lines emitted by the irradiated samples were measured photographically. This apparatus has been described (Malissa, 1970) as the first EPMA. Subsequently, Manfred von Ardenne (1907–1997) measured backscattered electrons generated by a focused electron beam. In 1947, James Hiller (1915–2007), one of Canada's most distinguished scientists, patented the idea of using a focused electron beam as the basis for generating characteristic X-ray lines as an analytical tool. Shortly thereafter, Raimond Castaing (1921–1999), a French Ph.D. student, and his supervisor, Robert Guinier, constructed two prototypes, one for their own use and the other for a metallurgical laboratory (Grillon and Philibert, 2002). This equipment used a quartz crystal fitted to a Geiger counter to discriminate the wavelengths of secondary X-rays generated by particular elements (Newbury, 2001). In his Ph.D. thesis, Castaing reported both practical and theoretical aspects of the instrument, including a discussion of matrix corrections, and its applications to crystallography and metallurgy. Because of their contributions, Castaing and Guinier are generally considered to be the fathers of the modern EPMA.

A more complete history of the EPMA is provided by Mulvey (1983).

The instrument

The modern EPMA consists of four main components: a source of electrons (a tungsten or lanthanum boride filament), an electron-optic focusing system comprising electromagnetic lenses, a sample chamber that houses a stage that can be manipulated by the analyst using a joystick, and one or more wavelength- and/or energy-dispersive spectrometers. The sample chamber and electron-optic system are held to a high vacuum, so samples are loaded and removed via an external housing (air lock) that can also have its atmosphere evacuated. This procedure takes several minutes. Depending on its design, the turret holding samples and standards can usually accommodate several thin sections or grain mounts. These are viewed either directly with an optical-fiber-equipped optical microscope or using the instrument's electron imaging system, in which case the sample appears on computer monitors.

Use of the EPMA

In preparation for analysis, the instrument is calibrated (either by a technician or an experienced operator) for the elements to be sought. The appropriate operating conditions (e.g., beam current and accelerating voltage) are set, as is the electron beam diameter.

Samples are loaded onto a sample holder (turret), which is then inserted into an interlock chamber from which the air is then evacuated. A standard usually accompanies the "unknown" samples for quality control purposes. The turret is then loaded into the main chamber of the microprobe and positioned for analysis using a joystick to adjust X-Y coordinates. To assist with positioning, it is helpful to have a sketch map of the turret and the samples it holds and to have marked (where appropriate) individual points on the samples that have been selected for analysis. Once a spot to be analyzed has been found, the surface of the sample must be focused (by adjusting the Z coordinate, again using the joystick) to ensure that the Bragg's condition for diffraction is satisfied. Depending on the type of instrument, the operator views the sample either as an optical or an electronic image (i.e., a backscattered electron or secondary electron image). For operators accustomed to petrographic microscopes, the electronic images can be problematic because their gray tones are based on mean atomic weight and will initially be unfamiliar compared to optical images of the same material. It also takes some time for inexperienced operators to adjust to the small field of view (typically $\sim 3 \times 3$ mm at minimum magnification). Thus, the operator must be well prepared before commencing a session on the microprobe; otherwise, he or she will waste machine time seeking the intended points to be analyzed.

Depending on the type of data to be acquired, individual points can be selected and stored in a stage file (which records their X-Y-Z coordinates), or, for raster-type analysis (e.g., for documenting zoning in individual crystals or for determining the bulk composition of fine-grained media), the end points of a line or grid pattern can be selected, along with the number or spacing of intermediate points. Inevitably, some individual rastered analyses will have to be rejected because, by happenstance, spot analyses will have overlapped a pore or a region from which material to be analyzed has been plucked during the sample preparation process, resulting in a low analysis total.

Advantages and disadvantages

The main advantage of the EPMA is that samples can be analyzed and imaged in situ at a micrometer scale. Imaging detectors include backscattered electron, secondary electron, and, in some instruments, cathodoluminescence. Precision and accuracy can be assessed through the repeated analysis of suitable standards. All but the lightest elements (H, He, and Li) can be detected and analyzed quantitatively.

The principal disadvantage of the EPMA concerns overlapping peaks of X-rays generated by some elements (e.g., $Ba[L_\alpha]$ and $Ti[K_\alpha]$). These overlapping peaks must be separated in order to distinguish between these particular elements. The valence of iron is another concern. The EPMA cannot distinguish different valence states of iron. The operator of the EPMA can choose to have total iron expressed as a particular valence state, but only one valence state at a time. Generally, total iron is expressed as Fe^{2+}. Regardless, oxidation ratios ($X_{Fe3+} = Fe^{3+}/(Fe^{2+} + Fe^{3+})$) cannot be directly determined. Consequently, X_{Fe3+} must be determined independently (e.g., by Mossbauer spectrometry) or, in the case of ferromagnesian minerals, calculated using crystal-chemical constraints. Not all such minerals are well suited to this procedure, however (e.g., Droop, 1987), and even where they are, the reliability of the calculated oxidation ratio will be strongly dependent on the quality of the analysis; inaccuracies in the determination of other components (notably Si in the case of silicate minerals) will directly affect the calculated oxidation ratio. The EPMA cannot distinguish polymorphs; distinction between such minerals can be achieved using a petrographic microscope or by X-ray diffraction. Neither can the EPMA be used to determine isotopic ratios, but it has been used to date minerals such as monazite that do not initially contain appreciable amounts of daughter elements (e.g., Scherrer et al., 2000).

Sample preparation

Samples to be analyzed by EPMA are usually prepared as polished thin sections or grain mounts. The mirrorlike, flat, polished surface of the prepared sample optimizes interaction between the electron beam and the sample and minimizes the likelihood that surface imperfections will scatter X-rays generated by the electron beam.

The polished samples should be thoroughly cleaned with a suitable solvent to remove oils that can lead to charging (a buildup of excess, static electron density) of the sample. Electrically insulating media such as silicate minerals need to be coated with a conductive material such as graphite prior to analysis, again to minimize charging. The charge is dissipated by connecting the surface of the sample to the sample holder with a metal (typically copper) tape or conductive paint (generally carbon or silver).

Applications to geoarchaeology

The EPMA is principally used by geologists and materials scientists. As such, it also has geoarchaeological applications, and a wide range of archaeological materials can be analyzed by this method. These include lithic artifacts, ceramics, glass, metals, and alloys.

In terms of raw materials, lithic artifacts can be subdivided into two categories: those consisting of volcanic glass (obsidian) and those consisting of crystalline rock. The use of lithic materials in geoarchaeological studies, however, is not confined to artifacts shaped by humans; it also includes volcanic ash deposits (tuff; tephra) used in constraining the absolute age of stratigraphic layers containing evidence of human activity (i.e., tephrochronology). This involves identifying on compositional grounds volcaniclastic deposits related to specific eruptions that have been independently isotopically dated (e.g., Tryon and McBrearty, 2002) or, in the case of more recent volcanic events, whose age is known from historical records. To be effective, individual deposits must be sufficiently distinctive that the geochemistry of their constituents (e.g., volcanic ash) can be distinguished from those comprising tephra deposits related to the same or other volcanic centers that were active at different times. Although usually applied to proximal deposits, the method can also be applied to relatively fine-grained, distal deposits (cryptotephra; Balascio et al., 2011). Case studies involving the EPMA tend to focus on the major and minor elements to characterize tephra geochemically (e.g., Tryon and McBrearty, 2002; Balascio et al., 2011) as well as obsidian artifacts (e.g., Rosen et al., 2005), but trace element concentrations can also be acquired using this method by employing longer count times. Substantially more precise trace element data with much lower detection limits can be determined for tephra by other methods – notably LAM-ICP-MS (laser ablation microprobe-inductively coupled plasma-mass spectrometry) – applicable to fine-grained media.

Analysis of crystalline rock artifacts using the EPMA focuses on determining mineral compositions. These data can be coupled with bulk compositional analyses of the same artifacts (generally acquired by other methods) for use in provenance studies, but a bulk compositional analysis may not always be required. In the case of lithic artifacts made from geochemically unusual rocks (e.g., alkali basalt), the compositions of their constituent minerals can be sufficient on their own to track down the source of the rocks from which they were made. For example, Mallory-Greenough et al. (1999) were able to trace the source of alkali basalt used to make some Egyptian vessels to a specific lava flow by comparing the compositions of pyroxenes, plagioclase, and other minerals as determined by EPM analysis.

Archaeological ceramics are well suited for analysis by the EPMA, but the specific type of data to be gathered for these materials depends in large part on their grain size. Bulk, major, and minor element compositions can be reliably determined only for the body of those ceramics with average grain sizes smaller than the diameter of the defocused electron beam used during analysis. Typically, this is in the order of a few tens of micrometers. So, reproducible bulk compositional data can be determined only for porcelains and fine earthenwares such as creamware. The bulk compositions of coarse earthenware (e.g., most red-colored earthenware) should be determined by other methods (e.g., XRF or ICP-MS). Of course, the compositions of glazes and of minerals in the body of both fine and coarse earthenwares can be determined using the EPMA.

The acquisition by EPM analysis of bulk compositional data for porcelain and fine earthenware involves rastering using a defocused electron beam; bulk analysis of coarse wares (i.e., with average grain sizes exceeding a few tens of micrometers) is not practical with this method. The minimum number of spot analyses required to ensure that the resulting data are reproducible can be assessed statistically (e.g., DeJong and Owen, 1999). The finer grained and more homogeneous the ceramic medium, the fewer will be the number of spot analyses required to generate reproducible major and minor element bulk compositions. Many such wares are slip cast, ensuring more homogeneous compositions than coarse wares whose pastes are mechanically mixed. However, some elements are preferentially partitioned into accessory minerals (notably heavy minerals such as Fe(Ti) oxides, zircon, and apatite) that, even if homogeneously distributed in the ware, they are, by definition, present only in very low concentrations. The low concentration of these phases presents a serious challenge in the acquisition of reproducible data for the concentrations of elements tied to these minerals, and a greater number of domains must be rastered to improve the precision and accuracy of these analyses.

A similar problem is encountered during the analysis of glazes containing refractory opacifiers and whiteners such as tin. Being refractory, such grains are incompletely resorbed by the glaze as it melts in the glost kiln. As with accessory minerals in the body of the ware, refractory minerals in the glaze tend to be present in low concentrations and may be inhomogeneously distributed. Moreover, the element(s) they contain may be confined to these grains. So, determining the concentration of these components in the glaze will require multiple spot analyses, the number of which must be assessed statistically. One solution to both of these problems lies in using a scanning electron microscope equipped with electron-dispersive spectrometer (e.g., a silicon drift detector) that allows a larger area to be scanned during each analysis. Count time can be increased accordingly. Recent work has shown that SEM/EDS (SDD) analysis can produce results comparable to those of EPMA/WDS analysis (Owen, 2012; Ritchie et al., 2012) for major and minor elements. Moreover, the software controlling this equipment can allow the operator to outline in detail the areas to be rastered, even if irregular in shape. EPMA/WDS analysis, however, still generates more accurate and precise data for components present only in trace concentrations.

Microprobe analysis has also revealed that the lead-rich glazes commonly found on archaeological ceramics can be compositionally zoned. Typically, the zoning is dominated by an increase in lead and a decrease in silica content outward toward the glaze surface. The investigator must decide how best to present these data. One approach is to report the compositions of the outer surficial, middle, and inner parts of the glaze and perhaps supplement these data with a more detailed compositional profile for a representative sample (e.g., Owen and Barkla, 1997). Alternatively, space restraints might require that measurements for several such profiles be collected and the data averaged. The fact that the glaze is zoned should nonetheless be reported to facilitate comparison of data acquired by other methods. This issue will become increasingly acute given the popularity of methods that analyze only the surfaces of artifacts. Chief among these is portable XRF, which is relatively inexpensive and simple to operate and can generate data consistent with other analytical methods (e.g., traditional XRF and INAA; see Millhauser et al., 2011).

The imaging capability of the EPMA is particularly advantageous in the study of archaeological ceramics. For example, an investigation of the microstructure and composition of phosphate phases in the eighteenth century, variably vitrified, phosphatic porcelain sherds, suggested the recycling of overfired wasters (Owen et al., 2011a). The same approach can be used to compare distinctive accessory minerals (e.g., titania polymorphs) in early ceramics and their suspected clay or temper sources (e.g., Owen et al., 2011b).

The EPMA is also well suited to the analysis of metals and alloys. Microprobe data have been used to confirm sampling procedures involved in the analysis of metal artifacts by other methods (e.g., INAA; Gordus et al., 1996), but they also have formed the basis for archaeometric/geoarchaeological studies. Owing to the importance of isotopic data (e.g., particularly lead isotopes) in provenance studies involving alloys, other analytical methods are commonly used in addition to the EPMA. For example, Dorais and Hart (2006) used microprobe data supplemented by lead isotopes determined by mass spectrometry to characterize the composition of a Roman bronze artifact and assess the likely source of metals used in its manufacture. Increasingly, however, other methods with lower detection limits than EPM analysis are presently being used to analyze archaeological metals and alloys (e.g., Guerra and Calligaro, 2003; Cooper et al., 2008).

Electron paramagnetic resonance (EPR) dating

Introduction

Electron spin resonance (ESR) dating is a chronometric dating method, but depending on the author, it may also be classified as a radiation exposure, a trapped charge, a paleodosimetric, or a radiometric method. Like other methods that use luminescence phenomena, ESR is based on an evaluation of the exposure of some materials to natural radioactivity. This expsoure is expressed as an absorbed radiation dose, which corresponds to the energy deposited in the matter by ionizing radiation. Such materials can acquire or develop a paramagnetic behavior under the effect of natural radioactivity, which can be later detected and quantified by means of ESR spectroscopy.

Use of this technique for dating purposes was first suggested by Ikeya (1975) based on the study of stalactites from caves in Japan. Since then, numerous applications to a wide range of materials have been to varying degrees successfully attempted (see the extensive reviews in Grün, 1989; Rink, 1997), so that ESR dating has become a landmark in *Quaternary Geochronology*.

Basic principles

ESR spectroscopy is a technique based on the detection of unpaired electrons. Materials possessing unpaired electrons are paramagnetic. As a result, they can be affected by an externally applied magnetic field, which induces an alignment in the spin of some unpaired electrons and, consequently, in their magnetic dipoles. When the external magnetic field is removed, the alignment is not retained. To measure unpaired electrons, the sample to be tested is placed in a magnetic field and exposed to microwaves of a fixed frequency (Figure. 1a). At a given magnetic field value corresponding to specific conditions of resonance, the microwaves are absorbed by the unpaired electrons, and an ESR signal is detected (Ikeya, 1993). ESR spectroscopy is used in many scientific fields like biology, physics, chemistry, medicine, earth sciences, and archaeology, and it is now considered a key tool for studies dealing with biological and retrospective dosimetry (Regulla, 2005; Fattibene and Callens, 2010). Its application for dating purposes is directly derived from that branch of investigation. Indeed, in ESR dating, the sample acts as a dosimeter, i.e., a material that is able to register accurately the energy absorbed when exposed to natural radioactivity over geological time. The interaction of the sample with ionizing radiation (alpha and beta particles plus gamma and cosmic rays) emitted from the radioelements (mainly U, Th, and K) located within the sample and in its surrounding environment induces changes in the electronic structure of the material. Some electric charges (electrons or holes) become trapped in the crystalline network by lattice defects (impurities or vacancies in the solid material), producing radiation-induced paramagnetic species (i.e., free radicals or paramagnetic centers possessing unpaired electrons) which build up a characteristic signal that can be detected by ESR spectroscopy. The intensity of the ESR signal is proportional to the amount of trapped charges. The latter depends on three main parameters: the strength of the natural radioactivity in the sample and its surroundings, the duration of exposure to radiation, and the total number of traps available in the sample. An ESR age is derived from the following equation:

$$D_E = \int_0^T D(t)dt \tag{1}$$

In (1), D_E is the equivalent dose, or paleodose – expressed by the dosimetric unit Gray or Gy (which represents the absorption of 1 J of ionizing radiation per kilogram of matter) – i.e., the total dose absorbed by the sample during the time elapsed between the zeroing of the ESR clock ($t = 0$) and the sampling (t = T). D(t) is the dose rate (usually in Gy/ka or μGy/a), or annual dose, which is the average dose absorbed by the sample in 1 year. When the dose rate is constant over time, (1) may then be simplified as follows:

$$T = \frac{D_E}{D} \tag{2}$$

where T is the age of the sample.

Four main processes may lead to the elimination of paramagnetic species and then to the zeroing of the ESR clock (i.e., removal of accumulated charges by releasing the trapped electrons): (1) crystallization, (2) heat, (3) optical bleaching, and (4) mechanical stress (Ikeya, 1993). Depending on the kind of sample analyzed, the events that can be dated are consequently quite diverse, for example, death of an animal, a crystallization process, the last exposure to sunlight, or the last time a material was heated. Further details about the basic principles of the dating methods can be found in Grün (2007) and Ikeya (1993).

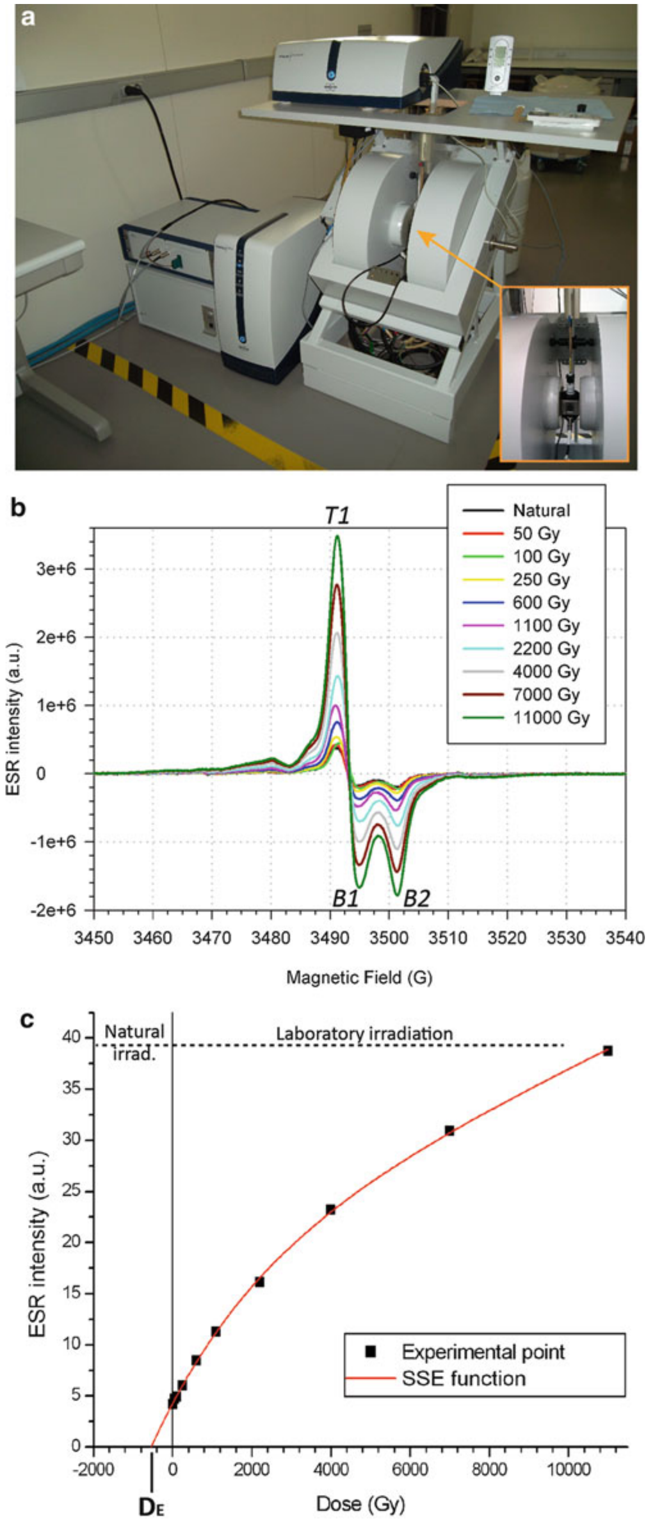
ESR age determination

An ESR age estimate is basically derived from the combination of two principal parameters: (1) the equivalent dose and (2) the dose rate. Nevertheless, to obtain these two parameters one must follow a long and complex analytical process made of several steps involving both field and laboratory procedures.

Sampling

Fieldwork is the first step of the dating process. It consists not only of the sampling but also in the collecting of all relevant information that may be useful at the time of data analysis and interpretation: stratigraphic and spatial location of the sample, sedimentary context, homogeneity, texture and composition of the sediment, depth of the sample, etc. Sampling itself can take many forms, depending on the kind of material to be analyzed (Grün, 1989). For example, it is important to minimize the exposure of raw sediment to sunlight when sampling for ESR dating of quartz grains. To accomplish this, several tactics can be employed: inserting a PVC tube into an outcrop or section, extracting an intact block of sediment for further preparation under stricter light conditions in the laboratory, or collecting the sediment under an opaque cover. For the dating of teeth, samples have usually already been recovered during an archeological or paleontological excavation and are thus chosen from collections. In that case, it is important to make sure that the selected tooth is well preserved and its findspot within the site is well known in order to avoid future problems during subsequent sample preparation and environmental dose rate reconstruction.

In addition, it is also advisable to carry out in situ measurements of the natural radioactivity at the place where the sample was collected, or the closest possible locality, in order to get an accurate estimation of the gamma dose rate. This is usually done using either synthetic TL dosimeters (e.g., $CaSO_4$:Dy, Al_2O_3:C) registering a total gamma dose rate over a long period (up to several months, e.g., Miallier et al., 2009 and references therein), or a portable gamma spectrometer with NaI or LaBr scintillation probes



Electron Spin Resonance (ESR) in Archaeological Context, Figure 1 (Continued)

(Arnold et al., 2012), which can identify the specific activities of each radioelement (energy windows technique Arnold et al., 2012) or provide a total gamma dose rate (threshold technique: Duval and Arnold, 2013) in a short amount of time (<30 min). Additional small bags of sediment are also usually collected for future laboratory analysis, in order to determine the water content or the radioelement concentration of the sediment surrounding the sample.

Sample preparation

The main goal of sample preparation always remains the same, whatever kind of sample is to be analyzed: to extract "pure" material (a few grams) with no contamination that would interfere with the intended analysis (ESR, U-series, etc.). The examples described by Grün (1989) show the wide range of tools and processes that may be employed (e.g., dentist drill, sieving, crushing, removal by chemical attack, etc.). In addition, preparation is often the opportune time to remove as much of the outer parts of the sample as possible in order to minimize or even eliminate the contribution of the external alpha and beta particles (see Dose rate assessment). Sample preparation usually ends when the sample is reduced to a powder prior to gamma irradiations (see later).

D_E reconstruction by ESR spectrometry

ESR spectrometry (equipment shown in Figure 1a) is used as a dosimetric tool to assess the DE value absorbed by the sample. The standard procedure involves artificially "aging" the sample by irradiating one or several subsample aliquots (single aliquot or multiple aliquot techniques) at various doses (additive dose method) in order to study the behavior of the ESR signal with increasing dose values (Figure 1b). A variant of this procedure is to reset the ESR signal to zero in the natural sample prior to any laboratory irradiation (regenerative dose method). The ESR intensity is extracted from the spectrum obtained for each aliquot (Figure 1b), and paired data (dose; intensity) are plotted as shown in Figure 1c. Then, a curve may be fitted to the experimental data points in order to describe the growth behavior of the samples versus absorbed dose. Further details about this fitting procedure may be found in Duval et al. (2009) and references therein. Assuming that the ESR intensity was null at $t = 0$, i.e., usually at the moment of formation or burial of the sample, the extrapolation of the curve to the abscissa axis ($Y = 0$) leads to the D_E value accumulated in the sample since $t = 0$ (Ikeya, 1993) (Figure 1c).

ESR measurements are usually carried out with an X-band spectrometer (microwave frequency ~9.8 GHz) on a powdered sample (with grain size between 50 and 500 μm) in order to remove, or at least minimize, the angular dependence of the ESR signal within the cavity (see Figure 1a) and to improve sample homogeneity and thus data reproducibility. Nevertheless, some efforts have been made in the past 20 years to reduce the destructive aspect of the dating method and to minimize the amount of material needed (e.g., by using the regenerative dose technique, a single aliquot procedure, carrying out ESR measurements on single crystals, or using Q-band spectrometers). For example, the combination of ESR measurements on enamel fragments with laser ablation ICP-MS U-series analysis allows determinations to be conducted on fossil human teeth without causing any visible damage (Grün et al., 2006).

Dose rate assessment

Dose rate is obtained from the assessment of the natural radioactivity of the sample itself (internal dose) and its surrounding environment (external dose + cosmic dose) (see Figure 5 from Grün, 2007). It may be expressed as follows:

$$D = D_{int.} + D_{ext.} + D_{cos.} = D_\alpha + D_\beta + D_\gamma + D_{cos.} \quad (3)$$

where $D_{int.}$, $D_{ext.}$, and $D_{cos.}$ are the internal, external, and cosmic dose rate, and D_α, D_β, D_γ are the alpha-particle, beta-particle, and gamma-ray contributions to the total dose rate (D), respectively. Depending on the size and the geometry of the dated sample, however, some specificities need to be carefully considered. Indeed, the weighting of the contribution of each component may vary greatly, given the ranges of alpha (~20–40 μm) and beta particles (~2 mm) and gamma rays (~30 cm) in matter such as sediment (see Grün, 1992 for further details).

Usually, the dose rate is derived from the activities, expressed in becquerels (Bq/kg), or disintegrations per minute per gram (dpm/g), or concentrations, expressed in parts per million (ppm) or percentage (%) of the radioactive elements (U, Th, and K) present in the sample and its surroundings. Those values may be obtained in the laboratory using different techniques (Goldstein and Stirling, 2003, and references therein), such as measuring either the

Electron Spin Resonance (ESR) in Archaeological Context, Figure 1 ESR dose reconstruction (**a**) EMXmicro-6/1 (X-band) Bruker ESR spectrometer. *Bottom right*: zoom on the cavity (or ESR resonator) located between the magnets and where the tube containing the sample is inserted for ESR measurements. (**b**) Evolution of the ESR spectra of tooth enamel with the irradiation dose (the magnetic field is expressed in Gauss). The ESR intensities are extracted from each ESR spectrum by measuring peak-to-peak amplitudes between T1 and B2 peaks. (**c**) D_E determination involves the following steps: (i) ESR intensities (experimental points) are plotted versus the irradiation doses, (ii) a single saturating exponential (*SSE*) function is fitted through the experimental data points, and (iii) the curve is extrapolated to $Y = 0$ in order to get the D_E value. Graph c is usually defined as a dose response curve (*DRC*).

emitted energy derived from the disintegrations (e.g., α-spectrometry and γ-spectrometry) or directly from the isotopes using mass spectrometry (e.g., TIMS, ICP-MS) (Figure 2). Then, these data are converted into dose values with published factors (Guérin et al., 2011, and references therein). Another way of proceeding is to obtain a total beta or gamma dose rate value directly by using a beta counter (see, e.g., Ankjærgaard and Murray, 2007). In addition, as previously explained, the external dose due to sediment resting adjacent to the sample can also be assessed in situ (Figure 2). Then, the data characteristics of the sample and its surrounding environment have to be adjusted using various correction factors relating to parameters such as water content, the geometry of the sample, its thickness and density (α-attenuation, β-attenuation, and γ-attenuation), and the alpha efficiency (α-particles are high-energy particles that are less effective in producing an ESR signal than beta particles or gamma rays, and thus the alpha efficiency must be estimated as the fraction of an equivalent beta or gamma dose that would yield the same ESR intensity) (Aitken, 1985; Grün, 1989; Ikeya, 1993). Similarly, the cosmic dose has to be adjusted according to various factors, like the ground density, depth of the sample, elevation, and latitude (Prescott and Hutton, 1994, and references therein). In addition, it is known that some materials (e.g., fossil teeth, corals, mollusk shells) behave as open systems for uranium, which means that U may be incorporated or leached at any time. In that case, U-uptake needs to be modeled by using, for example, both U-series and ESR data to get a combined U-series/ESR age estimate (Grün, 2009a). U-series disequilibrium in sediment may also be detected and have a significant impact on the dose rate estimate (Olley et al., 1996).

Evaluation of the dose rate is based on the analysis of present-day data extracted from the sample and its surrounding environment, and such data are considered as representative of the past history; either they are assumed to have been constant over time or following a trend that can be accurately assessed. Otherwise, if not detected, any substantial modification of the sample or its surroundings by diagenetic processes (e.g., dissolution/recrystallization processes, recent U-mobilization, water circulation, reworked sediment, etc.) can introduce a bias into the dose rate assessment. Careful sampling is therefore an important starting point in the analytical process, as it can help to minimize future potential uncertainties that may affect the ESR age estimation.

ESR age estimate

Once all the above data have been collected, the age calculation may be processed by simply dividing the equivalent dose value by the dose rate. Some guidelines about the error assessment may be found in Aitken (1985); however, for samples that require modeling (e.g., for uranium uptake in dental tissues), the age calculation becomes more complicated, and some iterative computations are necessary. Noncommercial programs for ESR age calculation are available on request from the scientists who developed them. For example, the DATA program (Grün, 2009b) and its Matlab equivalent USESR (Shao et al., 2014) permit combined U-series/ESR age calculation for teeth (Grün, 2009b) and also for coral or mollusks, as soon as the alpha efficiency is adjusted. The ROSY software is another program option (Brennan et al., 1999).

ESR ages are usually quoted at 1-sigma, and final errors are rarely <10 % (Rink, 1997) – more likely, they lie between 10 % and 20 %. This is mainly due to the numerous parameters (sometimes more than 20) that must be considered and adjusted for the age calculation process (among others: D_E, water content, radioelement content, alpha efficiency, density, cosmic dose, gamma dose). Reviews may be found in Grün (1989, 1992).

Potential of ESR dating

ESR dating shows great potential for *Quaternary Geochronology*, since it can theoretically cover the last 2.6 Ma in any geological context. One of the major strengths of ESR dating is the wide range of materials that can potentially be dated with it (Ikeya, 1993). Such materials include, among others, carbonates (e.g., speleothems, coral, shell, foraminifera), sulfates (e.g., gypsum), phosphates (e.g., fossil tooth), silica (e.g., quartz extracted from sediment, volcanic rock, or geological faults – to date the tectonic event based on zeroing of the ESR clock due to mechanical stress reset), or other silicates (e.g., clay minerals, feldspars). Every material with dosimetric properties, i.e., showing the creation of paramagnetic centers under the effect of natural radioactivity, may potentially be used for ESR dating if it fulfills the six criteria (Grün, 1989, 2007):

1. The selected ESR signal is equal or (re)set to 0 at $t = 0$;
2. Its intensity increases proportionally with the absorbed dose (radiation sensitivity);
3. The ESR signal has a lifetime at least one order of magnitude higher than the age of the sample;
4. The number of traps remains constant over time (i.e., no dissolution, recrystallization, or crystal growth processes have occurred);
5. The selected ESR signal does not show anomalous decay over time (fading) under normal conditions of measurement and storage;
6. The ESR signal is not influenced by sample preparation, unless the impact can be controlled and quantified.

With relatively modern samples, the dating limits for the most recent $t = 0$ are mainly driven by: (i) the radiation sensitivity of the material, and (ii) the sensitivity of the instrumentation employed for dose reconstruction, including the ESR spectrometer. As an example, for tooth enamel samples, the smallest dose value ever detected was of ~0.46 mGy (lower detection limit) (Romanyukha et al., 2005), suggesting a possible dating application up to and including even present-day materials. For speleothems, an older dating limit around 2 ka (Bassiakos, 2001) or even less (Grün, 1989) has been determined.

In contrast, the upper dating limit is mainly constrained by two parameters. The first one is the saturation of the ESR signal with the absorbed dose. Depending on the number of traps available in the crystal lattice and the nature of the paramagnetic center that is analyzed, the intensity of the ESR signal will saturate more or less quickly when the material is absorbing ionizing radiations. The second parameter is the thermal stability of the paramagnetic centers, which describes the mean life of a trapped electron at a lattice defect site. In general, one considers that the ESR signal must have a mean life at least one order of magnitude higher than the age of the sample dated (Grün, 2007). As an example, Schwarcz (1985) assessed the lifetime of the ESR signal of tooth enamel to ~1 Ga at 25 °C, suggesting a possible application over a few million years. In quartz, the ESR signal associated with the aluminum (Al) paramagnetic center, the most widely used in geochronology, shows almost no saturation with doses up to 60 kGy (Lin et al., 2006) and stability over ~7.4 Ga at 27 °C (Toyoda and Ikeya, 1991) making it potentially useful for the entire Quaternary.

Examples of applications in archaeology

ESR is probably the only chronometric dating method that can be potentially used in almost any geological context. It may take over from some chronometric methods, like OSL dating, for alluvial terrace deposits older than ~200–300 ka or from U-series dating of carbonates in karstic environments over ~600 ka. Direct dating of hominin remains beyond the range of radiocarbon is also possible (Grün et al., 2010). As an example, in Europe, most archeological sites are not found in volcanic contexts, but either in karstic or alluvial environments where the use of a chronometric method like Ar-Ar is impossible because of the lack of coeval volcanic materials. For occupations older than mid-Middle Pleistocene (>500 ka), ESR is definitely the most widely used method, in particular for dating the first hominin settlements in Europe. The development of the method for Early Pleistocene times offers perhaps one of the most interesting perspectives (Duval et al., 2012), since this is a period when the number of chronometric dating methods is very limited, and those that exist are highly dependent on the geological context (Falguères, 2003).

There is a large and diverse list of published ESR dating applications in archeological contexts over the last ~20 years, most of which lie within the 50–500 ka time range. These dating studies are based principally on three kinds of materials that come from either open-air sites or caves: carbonates, phosphates, and silicates. Examples of applications are given hereafter, and the strengths and weaknesses of the most common ones, are detailed in Table 1.

ESR dating of speleothems is the oldest application of the method (Ikeya, 1975). As an example of a recent application, Valladas et al. (2008) obtained ESR age estimates using stalagmitic formations from the Neanderthal Payre Cave in France. The late Middle Pleistocene age results (<300 ka) were consistent with the corresponding U-series ages performed on the same unit. At Treugolnaya Cave in Russia, Molodkov (2001) dated several terrestrial shell samples from deposits associated with Early Acheulean lithic artifacts. They yielded an ESR chronology older than 350 ka. Similarly, Blackwell et al. (2012) dated mollusk shells correlated with Late Pleistocene archeological evidence in the Western Desert of Egypt. Such applications may potentially cover a time range from as recent as 5 ka to as old as >2 Ma (Molodkov, 2001; Blackwell et al., 2012), even if their reliability mainly depends on the accuracy of the U-uptake modeling.

ESR dating of fossil teeth (hydroxyapatite mineral) is surely the most famous application of the ESR method. It allows direct dating of animal and hominin occupations from the Early to Late Pleistocene time range (Table 1). Although the fossil teeth of large mammals are typically dated (e.g., Falguères et al., 2010), human teeth may be analyzed as well (e.g., Grün et al., 2006). One can consider the work of Torres et al. (2010) as an example. Part of a study combining various chronometric dating methods included the dating of a fragment of human incisor from El Sidrón Cave in Spain; the tooth material was dated by a semi-destructive analytical procedure based on the combination of ESR analysis with LA-ICP-MS U-series analysis. The ESR age estimate of 38.5 ± 4.5 ka was found to be in good agreement with the results derived from the other methods, like radiocarbon, U-series, OSL, and amino acid racemization, which ranged from 30 to 50 ka for the archeological unit (see further details in Torres et al., 2010). Geological occurrences of hydroxyapatite can also be dated, as illustrated by the work performed on authigenic terrestrial apatite veins at Tabun Cave in Israel, which provided useful information about the diagenetic processes that had occurred in the deposits (Rink et al., 2003).

Silicates, and especially quartz minerals, are also widely used for ESR dating. As with OSL dating, ESR can date optically bleached quartz grains extracted from sediments (Table 1). Quartz is a ubiquitous mineral that is found in almost any geological context. Because many Pleistocene archeological sites are situated in fluvial contexts (Mishra et al., 2007), ESR is often employed to date whole terrace systems where hominin occupation has been documented. As an example, Voinchet et al. (2010) dated several fluvial systems from central France between ~130 to ~1700 ka. As previously detailed, ESR is one of the few dating methods that can be applied to Early Pleistocene sites. For example, at the archeological site of Vallparadís in Spain, ESR was not only applied to quartz grains but also to fossil teeth (Duval et al., 2015, and references therein); both applications yielded consistent results around 0.8 Ma for the main archeological level. The resulting mean ESR age of 858 ± 87 ka was found to be in excellent agreement with the results derived from paleomagnetism and biochronology, which suggested a Matuyama age for the deposits, and more precisely between the Brunhes chron and the Jaramillo subchron (i.e., 0.99–0.78 Ma). Other applications to silicates are also documented. At the lower paleolithic site of Menez Dregan in France, Monnier et al. (1994) published an ESR chronology of ~350–400 ka based on heated quartz grains extracted from fireplace sediments and a burnt quartzite pebble. Similarly, ESR dating of burnt flint has also been studied. Porat and Schwarcz (1991) showed the potential of this application by dating some samples from Middle Eastern archeological sites. In addition, similarly to the thermoluminescence (TL) method, ESR may be used to date pottery firing. Bartoll and Ikeya (1997) analyzed fragments from a Neolithic vessel excavated in Rohrback, Germany: ESR age estimates of ~5 ka were in agreement with the TL ages obtained on the same fragments, even if they showed larger errors than the TL age results.

Summary

ESR dating is a paleodosimetric method based on the detection and quantification of the trapped charges accumulated over time in the crystal lattice of some materials due to their exposure to natural radioactivity. Perhaps more than any other chronometric method, ESR can be used in a very broad variety of archeological applications covering almost any geological context during the last 2.6 Ma. Among them, ESR dating of fossil tooth enamel, sedimentary quartz grains, and speleothems are probably the most promising, since these materials are commonly found in association with archeologically significant remains.

Electron Spin Resonance (ESR) in Archaeological Context, Table 1 Summary of the potential and limitations of the three main ESR dating applications in archeological contexts: fossil teeth, optically bleached quartz grains extracted from sediment, and speleothems. Key: *LLD* lower limit of detection, i.e., the minimum dose that can be assessed by ESR.

	Fossil tooth enamel	Optically bleached quartz grains extracted from sediment	Speleothem (stalagmite, stalactite, flowstones)
Dated event	Death of the animal/burial of the fossil tooth	Last sunlight exposure of the sediment	Formation of the speleothem
Main specificity of the application	Dental tissues are open systems for U: U-uptake needs to be modeled	Optical dating method (same basic principles as OSL dating)	Speleothems are usually closed systems for U: no specific U-uptake has to be modeled
		Presence of a residual (non-bleachable) ESR intensity for the Al -center	
Lower dating range	Present-day (LLD = 0.46 mGy; Romanyukha et al., 2005)	~10 ka (Ti-center; Beerten et al., 2003) (LLD = a few tens of Gy, Ti-center; Beerten and Stesmans, 2005)	~500–2,000 a (LLD = 1.6–1.8 Gy; Bassiakos, 2001)
Upper dating range	Early Pleistocene (e.g., Duval et al., 2012)	Miocene (Al-center) (e.g., Laurent et al., 1998)	~1–2 Ma (e.g., Yokoyama et al., 1988)
Strengths of the application	Fossil teeth are frequently found in archeological contexts	Quartz mineral is found in almost any geological context	Material frequently found in caves
	ESR dosimetry of tooth enamel is now international reference method (Fattibene and Callens, 2010)	Great potential in fluvial contexts, where bleaching conditions are usually optimum (e.g., Voinchet et al., 2007), and evidence of human occupation are frequent (Mishra et al., 2007)	Can date beyond the U-series dating time range
	Direct dating of hominin and animal fossil remains	May date beyond the OSL dating time range	
	Can date beyond the C-14 and U-series dating time range (Grün et al., 2010)	Several paramagnetic centers may be used for geochronology (see Ikeya, 1993): Al, Ti, E′, etc.	
	Semi-destructive method, when combining ESR on enamel fragment with LA-ICP-MS U-series analysis (Torres et al., 2010)		
Weaknesses of the application	Complexity of the analytical process (e.g., U-series analysis is needed for each dental tissue)	Technological limitations: Single-grain ESR measurements are complicated (e.g., Beerten et al., 2003); ESR data are not as reproducible as those obtained for enamel samples (e.g., quite strong angular dependence of the ESR signal in the cavity)	Debate about the choice of a reliable and stable ESR signal (e.g., Grün, 1989)
	Difficulty to locate precisely (geographically and stratigraphically) the sample's origin in case of old excavations		Compared with ESR, U-series dating offers several advantages: a relatively fast and standardized analytical procedure leading to the production of more precise age results.
	Quite low precision (standard errors are usually >10 %) in comparison with other chronometric methods like C-14, Ar-Ar and U-series (e.g., Ludwig and Renne, 2000)	Quite low precision (standard errors are usually >10 %) in comparison with other chronometric methods like C-14, Ar-Ar and U-series (e.g., Ludwig and Renne, 2000)	Quite low precision (standard errors are usually >10 %) in comparison with other chronometric methods like C-14, Ar-Ar and U-series (e.g., Ludwig and Renne, 2000)

EOLIAN SETTINGS: LOESS

Marcelo A. Zárate
INCITAP (Institute of Earth and Environmental Sciences of La Pampa), CONICET/National University of La Pampa, Santa Rosa, La Pampa, Argentina

Definition

The term loess comes from the German word *Löss*, meaning loose, which is reported to have been first used to describe friable, silty deposits along the Rhine Valley near Heidelberg (Pye, 1995). Loess is a fine-grained sedimentary material resulting from the deposition of eolian dust, which extensively accumulated in some areas of the world during the Quaternary; it is also recorded in older geologic intervals (e.g., Soreghan et al., 2008). Loess is defined as a sediment composed predominantly of silt-sized particles (50–2 μm) with subordinated amounts of clay (<2 μm) and sand (>50 μm) that has been entrained, transported, and accumulated by the wind (Muhs, 2007). A more restrictive definition of loess, still regarded by some researchers, considers that loess is not simply eolian dust but the result of weathering and soil formation, a process called loessification (Pécsi, 1990; Smalley et al., 2011). If primary loess has been modified by weathering, soil formation, and diagenesis, it is called "weathered loess," while "reworked loess" has been eroded and redeposited by fluvial and/or slope processes. The term "loess-like deposit" refers to sediments with lithological properties similar to loess that have been transported by fluvial, lacustrine, or mass movement processes (Pye, 1987, 1995).

Geographical distribution

Loess and loess-like deposits cover approximately 10 % of the world (Pye, 1987; Pécsi, 1990). In the northern hemisphere, loess is extensive across the North American Great Plains, the northwestern USA, and Alaska (Figure 1a–c) (Roberts et al., 2007), Europe (northwestern France, south central Europe, Ukraine, Russia) (Rousseau et al., 2007), Central Asia (Tadjikistan, Uzbekistan, Kazakhstan, Yakutia, the Lake Baikal area) (Dodonov, 2007), and China (Figure 1h) (Porter, 2007). Geographically limited areas of loess deposits have been reported in Africa (Tunisia, Libya, Nigeria, and Namibia) and the Middle East (Figure 1i) (Israel, Yemen, and the UAE) (Coudé-Gaussen and Rognon, 1988; Brunotte et al., 2009; Crouvi et al., 2010). In the southern hemisphere, loess occurs over much of New Zealand, while loess and loess-like deposits are particularly extensive across the eastern Pampas (Figure 1d–g) and the Chaco Plain of Argentina along with areas of Bolivia, Paraguay, Brazil, and Uruguay (Zárate, 2007). Loess is mostly absent in Australia (Pye, 1987, 1995; Muhs, 2007).

Loess characteristics and composition

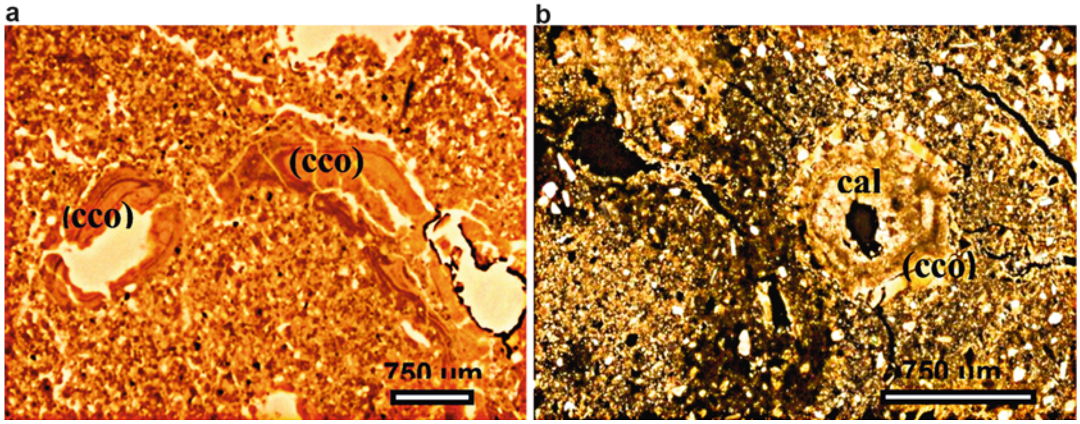
Loess is a friable and porous deposit of very variable thickness ranging from a few centimeters to hundreds of meters (Figure 1).

Usually unstratified or showing only a subtle structure, loess deposits exhibit a generally massive and homogeneous aspect (Figure 1a–e) (Pye, 1995; Smalley, 2004; Muhs, 2007). Although in general they are described as characteristically light yellowish or creamy brown calcareous deposits (Figure 1g), the color varies considerably, and loess is not always calcareous (calcareous nodules can be of either pedogenetic or groundwater origin). Secondary structures resulting from mammal (Figure 1f) and invertebrate activity are commonly present. Geotechnically, loess is characterized by high tensile strength resulting from interparticle bonding by clays and/or carbonates; the deposit is able to form vertical faces several meters high along natural or artificial exposures (Figure 1a, b, d); however, loess collapses if it is wetted or sheared (Derbyshire et al., 1994). Erodibility of loess

Eolian Settings: Loess, Figure 1 (**a**) Last Glacial age loess south of the Yukon River, central Alaska; (**b**) Bignell Hill, Nebraska, alternating sequence of Last Glacial (Peoria) loess, Brady paleosol, Holocene (Bignell) loess; (**c**) Last Glacial (Peoria) loess, southern (Mississippi) Mississippi River Valley (Photographs **a**, **b**, and **c**, courtesy of Daniel Muhs); (**d**) early to late Pleistocene loess/loess-like deposits with paleosol (15 m thick), northern Pampas, Buenos Aires, Argentina; (**e**) Last Glacial loess mantle and present soil, northern Pampas, Buenos Aires, Argentina; (**f**) loess section, *upper* part modified by present soil formation and burrows of fossorial rodents, a common bioturbation process in Pampean archaeological sites, southern Pampas, Buenos Aires, Argentina; (**g**) Last Glacial loess, upper ~1 m decalcified by pedogenesis, *lower* part (*whitish color* marked by **w**) unleached loess, northern Pampas, Buenos Aires, Argentina (Photos **d**, **e**, **f**, and **g** by Marcelo Zárate); (**h**) panoramic view of the ~200-m-thick Wuhan loess-paleosol section near Xian, China – paleosols are the darker layers (Photograph courtesy of the Chinese Academy of Sciences); (**i**) primary loess on top of a mountain summit (Mt. Harif) in central-western Negev (Photograph courtesy of Onn Crouvi).

deposits is usually very high, and severe soil erosion affects many of the loess areas of the world; the Chinese loess plateau is one of the most seriously eroded (e.g., Xinbao et al., 1990).

Loess stratigraphic sections are characterized by the occurrence of paleosols that record intervals of landscape stability, during which rates of loess accumulation and erosion were very low. During these intervals, soil-



Eolian Settings: Loess, Figure 2 Photomicrographs of thin sections from Pleistocene loess and loess-like deposits modified by pedogenesis, northern Pampas of Buenos Aires, Argentina (Gorina locality): (**a**) clay coatings (*cco*) around channels; (**b**) calcitic coating (*cal*) postdating (accumulating on top of) a clay coating (*cco*) (Photographs by Rob Kemp).

forming processes prevailed, and over several such cycles, noteworthy loess-paleosol sequences were produced (Figure 1b, d, h). Following the approach of soil micromorphology, the analysis of loess thin sections provides detailed insights into diagenetic changes and the interaction between sedimentation and pedogenesis during and after loess accumulation (Figure 2) (e.g., Kemp et al., 1995, 2006). The paleontological record of loess deposits may consist of fossil mammal remains and mollusk shells that are powerful paleoenvironmental and paleoclimatic indicators (Rousseau et al., 2007; Li et al., 2008). In addition, the analysis of recovered pollen and phytoliths provides information on the vegetation cover during loess accumulation and intervals of soil formation (e.g., Blinnikov et al., 2002; Komar et al., 2009). Commonly interstratified with eolian dust and paleosol sequences are tephra layers as well as non-eolian silty sediments (e.g., alluvium, colluvium, and mass movement deposits) that may include reworked loess (Mücher and Vreeken, 1981; Huang et al., 2006). Loess deposition can be dated by optical dating (Stevens et al., 2007; Roberts, 2008; Fuchs et al., 2013). Indirectly, chronology can be calibrated by means of magnetostratigraphy along with amino acid racemization on mollusk shells (e.g., Oches and McCoy, 1995).

The mineralogical composition of North American and Eurasian loess includes a prevailing amount of quartz, on the average 60–70 %, with a subordinated fraction of plagioclase, K-feldspar, mica, calcite, and small amounts of heavy minerals; illite and montmorillonite dominate among the clay minerals (Muhs, 2007; Smalley et al., 2011). The Argentine Pampean loess (Figure 2) is of volcaniclastic composition, with a dominant fraction of volcanic shards, volcanic lithic fragments, and lesser amounts of quartz grains (Zárate, 2007). Due to its characteristics and mineralogical composition, loess and loess soils have been the raw material for manufacturing ceramics, with examples reported from northern China since the early Neolithic (Needham et al., 2004), Europe (Vandiver et al., 1989), Israel (e.g., Goren, 1995), and Argentina (Frère et al., 2012).

Origin and source areas of loess particles

Two genetic models have been proposed to explain the origin of loess particles. The glacial loess model classically considered that silt size particles are produced by glacial grinding of crystalline rocks deposited in till that are later reworked by fluvial processes as outwash and finally entrained, transported, and deposited by wind (Muhs, 2013). In the desert loess model – for example, the loess of Israel (Figure 1i) – particles are the result of physical and chemical weathering, eolian abrasion, and ballistic impacts in dune fields (e.g., Crouvi et al., 2010; Muhs, 2013). The source areas of the particles forming loess deposits can be any of several environments characterized by high availability of sediments potentially deflated by the wind. They could be formerly extensive glacial outwash plains, floodplains of ephemeral streams in desert areas, dry lake and playa sediments, alluvial fans, stony desert surfaces, and weathered rock sections in formerly extensive deserts (Pye, 1995; Smalley, 2004; Muhs, 2007).

Geomorphological distribution

Loess geomorphology is an important source of information in geoarchaeology, as, for instance, in the search for archaeological sites, the geographical distribution of sedimentary settings, and paleolandscapes. Loess forms a blanket of variable thickness over preexisting landscapes and covers a wide range of landforms (e.g., fluvial terraces, moraines, alluvial fan surfaces, interfluvial areas) contributing also to the filling of rock-shelters and caves (Figure 3a, b) (Zárate and Flegenheimer, 1991; Woodward and Bailey, 2000; Cremaschi and Negrino, 2005).

Eolian Settings: Loess, Figure 3 Tandilia ranges of Buenos Aires, Argentina: (**a**) quartzitic rock-shelter Sierra Larga with loess mantle in the foreground modified by pedogenesis; (**b**) loess filling (70 cm) of rock-shelter modified by pedogenesis (*arrow* indicates archaeological level); (**c**) thin loess layer covering the quartzitic surface of a butte (Cerro El Sombrero) (the deposit that contains archaeological lithic remains is modified by present soil formation); (**d**) detailed view of a section of the pedogenized loess layer (a soil horizon) with a stem of a Fishtail projectile point (Photographs **c** and **d** courtesy of Nora Flegenheimer).

In geomorphological settings such as plains, loess forms mantles of relatively uniform thickness and low relief (Figure 1e). In contrast, on steep slopes, loess mantles may be thin, with increasing thickness in the downslope direction. The potential preservation of archaeological remains will vary according to the geomorphological setting of the loess deposit. Holding other controlling factors constant, a very low gradient landform (e.g., terrace tread, flat interfluvial surface) will be more stable than a hillslope setting, which is more subject to fluvial or mass movement processes, erosion, and the potential reworking and redeposition of archaeological remains embedded in the former loess deposit. In addition, the pattern of loess distribution, particularly in desert margin settings, is controlled by the extension and development of the vegetation cover that generally plays an important role in trapping eolian dust (Pye, 1995). Loess can bury partially or completely a ground surface and then smooth and mask previous topographies. In this respect, the landscape history of a loess area contributes to the interpretation of the archaeological record (e.g., Waters and Kuehn, 1996).

Loess-paleosol sequences and paleoclimatic significance

Loess-paleosol sequences are an excellent source of information in archaeological research. They constitute archives of past climatic and environmental conditions during intervals of human occupations and provide a valuable framework to analyze the stratigraphy and chronostratigraphy of archaeological records. During the Quaternary, loess was predominantly deposited during periods of cold and relatively dry conditions (Bordes, 1954; Kukla, 1977; Juvigne et al., 1996; Haesaerts and Mestdagh, 2000; van der Plicht et al., 2003; Fuchs et al., 2013) corresponding to glacial intervals, while paleosols formed under more humid and warmer conditions, which correlate with interglacial or interstadial intervals. The alternation of loess and paleosols thus becomes a useful tool in climostratigraphy.

The Chinese loess-paleosol sequence (Figure 1h) spanning the last 2.6 Ma is the most complete Quaternary continental archive of paleoclimatic conditions (Porter, 2007) and shows a good correlation with deep-sea records (Ding et al., 1994). Lu et al. (2011)

have illustrated the significance of a Chinese loess-paleosol sequence as a source of stratigraphic and paleoenvironmental information in Paleolithic archaeology.

Site formation processes in loess

Archaeological sites in loess deposits are generally better preserved in comparison with other eolian settings, such as dune fields, since they represent low-energy sedimentary environments. In general, archaeological remains show a relatively higher visibility in loess as a result of its homogeneous aspect, which makes the occurrence of exotic remains more obvious in comparison with other non-eolian sedimentary settings (Figure 3c, d). Bone remains show fairly good preservation due to the general dominance of alkaline conditions (e.g., Händel et al., 2009). Groundwater table oscillation and perched water tables may potentially affect the preservation of different remains, a factor still not fully analyzed. Post-burial transformation will depend on the environmental conditions that prevail in the loess area under study; a wide range of turbation processes may disturb and alter the archaeological context.

The rate of loess accumulation after sites are abandoned is crucial because it will determine how fast the burial occurs. Periods of higher loess accumulation rates will favor a more rapid burial and better preservation (e.g., Händel et al., 2009). Conversely, if human occupation occurs when loess surfaces are stable and affected by pedogenesis, which means very low rates of loess accumulation and higher rates of soil formation, archaeological remains will be subject to more dispersal and poorer preservation. In addition, on a stable loess soil surface, several successive occupations will be mixed, disturbed, and altered by pedoturbation, faunalturbation (Johnson, 2002), and also repetitive human occupations, resulting in the formation of palimpsests (cf. Ferring, 1986). The resulting archaeological layer will be composed of material from different occupation events that are not stratigraphically separated.

Loess and early agriculture

Loess is the parent material of very productive agricultural soils due to its particle size distribution, workability, mineralogical composition, good drainage conditions, soil aeration, and extensive penetration by roots. Loess soils yield nutrients such as K and N, which are of key importance for cereal growth without the need to add fertilizers (Catt, 2001). As a result, the inherent fertility of loess soils has played a crucial role in the development of Neolithic farming and agriculture in Europe (Bakels, 2009) and China (Ho, 1969). Renfrew and Bahn (2004) estimated that at least 70 % of the Linearbandkeramik (LBK) Culture sites of central and western Europe are found on loess areas.

Summary

Loess is a fine-grained eolian deposit that usually alternates with paleosols and covers wide areas of the northern hemisphere and to a lesser degree the southern hemisphere. Loess-paleosol sequences represent powerful archaeological tools that can help to reconstruct paleoclimatic and paleoenvironmental conditions, providing stratigraphic and chronostratigraphic context for archaeological sites. Loess settings are low-energy sedimentary environments favoring the preservation of archaeological remains in comparison with other settings. Site formation processes are mainly controlled by the balance between active loess sedimentation and soil formation along with the environmental and geomorphological conditions of the loess area.

Definition

Dunes and other sand depositional settings.

Introduction

Large numbers of important archaeological sites have been identified in areas with sand dunes and eolian sand deposits: on ocean coasts (Erlandson et al., 2005; Winterbottom and Dawson, 2005; Anderson et al., 2006) where middens are often abundant, on lake shores such as those of Lake Michigan (Lovis et al., 2012), and in the world's dry lands (which will be the main focus of this entry). Dunes provide an environment of accumulation in which (1) artifacts may be preserved (e.g., Fuchs et al., 2008); (2) indications of former climatic and other environmental conditions may be buried in temporal sequences, such as paleosols (Butzer, 2004) and phytoliths (Boyd, 2005); (3) lake deposits (Parker and Goudie, 2008), fluvial gravels (Atkinson et al., 2013), and other indicators of humidity may be interspersed within the sand; and (4) strata or levels within the accumulation may be susceptible to dating by techniques such as optical dating, including OSL (optically stimulated luminescence). There may, however, be problems of artifact displacement in dune situations (Rick, 2002; Mayer, 2003).

Dune types

There is now a huge literature on dunes and various excellent recent texts, including those by Lancaster (1995) and Warren (2013). Good introductions to the physics of sand movement are provided by Sherman and Li (2012), but the classic work remains that by Bagnold (1941).

Dune forms are diverse and vary between and across dune fields. Moreover, one form may be superimposed upon another. Many classification schemes for dune morphology have been developed, and it is recognized that there are a number of possible controls on the development of different dune types in different areas. Factors include the amount and grain size of available sand (Eastwood et al., 2011), the transport capacity and directional variability of wind (Fryberger and Dean, 1979), the vegetation cover, the evolutionary stage that the dunes have reached, the presence of bedrock highs, the position of the dunes within a sand sea, whether or not sand budgets are positive or negative (Mainguet and Chemin, 1990), the presence of high groundwater levels (which may favor the formation of parabolic forms), and the areal extent of the dune field.

There are, however, some basic dune types that have widespread expression in many of the world's deserts. Tsoar et al. (2004) proposed a threefold classification: *migrating* dunes (exemplified by transverse forms, such as barchans), *elongating* dunes (exemplified by linear dunes), and *accumulating* dunes (exemplified by star dunes).

In addition to these free forms, there are also dunes that are fixed or anchored in the landscape by topographic features or vegetation. Some of these features have been called *sand ramps*, which are sloping sand forms blown against the front of elevated terrain and within which multiple generations built up over time can be identified. They often are contaminated by talus, stone horizons, and colluvium derived from the slopes which they abut, and they may contain paleosols (Bateman et al., 2012), thus making them excellent repositories of climate and local environmental information.

Another type of topographic dune is the lunette: a roughly crescentic eolian accumulation that occurs on the downwind margins of closed basins (pans) (Figure 1). They may be several kilometers long and may attain heights in excess of 60 m in exceptional cases. They tend to occur in areas where present-day precipitation levels are between about 100 and 700 mm, but their stratigraphy can yield good indications of past changes in climate and hydrological conditions (Lawson and Thomas, 2002). They are also landforms within which archaeological sites may occur, as in the Willandra Lakes of Australia (Fitzsimmons et al., 2014) and the High Plains of the USA (Rich, 2013).

Lunettes may accumulate rapidly, with rates in the Kalahari reaching 10 m in 1,000 years (Telfer and Thomas, 2006), and some basins may have multiple lunettes on their lee sides (Harper and Gilkes, 2004). Various hypotheses have been put forward to explain differences in lunette composition. Campbell (1968) believed that deflation from a lake bed could account for many lunette features; however, she also recognized that some of the material could be derived from wave-generated beaches and so could be analogous to primary coastal foredunes. This concept was developed for Lake Mungo by Bowler (1973), who saw sandy lunette facies as being associated with a beach provenance at times of relatively high water levels, whereas clay and evaporite-rich facies formed during drier phases when deflation of the desiccated lake floor was possible.

Eolian Settings: Sand, Figure 1 A major lunette dune from Kelbia, Tunisia. The salt lake from which it is derived is visible in the background.

Parabolic dunes occur in areas with vegetation cover and/or high groundwater levels. The importance of vegetation cover in areas with parabolic dunes, such as the Canadian prairies or the US High Plains, suggests that such factors as droughts and human disturbance may cause rapid changes of state to occur (Hugenholtz et al., 2010). Clear stratigraphic evidence indicates that parabolic dunes have undergone repeated phases of activity and stability at different points throughout the Holocene in response to cycles of drought (Forman et al., 2009).

One often finds that at any one location, different dune types may be superimposed upon each other, as the following examples show. In the Gran Desierto of Mexico, for example, Beveridge et al. (2006) found five different patterns dating to different ages. The oldest pattern consisted of linear dunes believed to have formed between 26 and 12 ka. This was followed by the construction of three sequential phases of crescentic dunes. Finally, in the last few thousands of years, star dunes and a sand sheet formed. These different patterns can be related to changes in aridity, wind direction, and sediment supply in the Late Quaternary. Equally, in the Algodones dune field of California, Derickson et al. (2008) found five dune types showing varying degrees of superimposition. In the northeastern Rub' al Khali in the United Arab Emirates, large linear dunes trend from approximately southwest to northeast, and they are overlain by much smaller linear ridges that trend from northwest to southeast (Atkinson et al., 2013). In the Badain Jaran Desert of China, Dong et al. (2009) identified three dune generations.

Dunes as paleoenvironmental indicators

The former extent of major tropical and subtropical sand seas (called ergs from the Arabic term for a dune field) gives an indication of former dry conditions. That some dunes are relict rather than active is indicated by deep weathering and intense iron-oxide staining, clay and humus development, silica or carbonate accumulation, stabilization by vegetation, gullying by fluvial action, and degradation to angles considerably below that of the angle of repose of sand – normally ca. 32–33° on lee slopes. Sometimes, archaeological evidence can be used to show that sand deposition is no longer progressing, while elsewhere dunes have been found to be flooded by lakes.

Sand movement will generally be restricted so long as there is good vegetation cover, though small parabolic dunes are probably more tolerant in this respect than the more massive linear dunes and barchans. Indeed, dunes can develop where there is limited vegetation cover, and vegetation may contribute to their development. Sediment availability is also an important factor in determining dune mobility. It is, therefore, difficult to provide very precise rainfall limits to dune development. Nevertheless, studies where dunes are currently moving and developing suggest that vegetation becomes effective in restricting dune movement only where annual precipitation totals exceed about 100–300 mm. These figures apply for warm, non-coastal areas. Fossil dunes typically occur in areas with 600–1,200 mm of mean annual rainfall (see Anderson et al., 2013; Table 4.1).

Eolian Settings: Sand, Figure 2 A series of dunes of different ages and colors that have accumulated in the Budha Pushkar basin, Rajasthan, India. Stone tools have been recovered from surfaces between the different dune types.

In India, fossil dunes have been identified in Gujarat and Rajasthan (Allchin et al., 1978) where they have been sites of Paleolithic occupation (Blinkhorn, 2013) (Figure 2). They occupy zones where the annual rainfall is now as high as 750–900 mm.

In southern Africa, the Kalahari is dominantly a fossil desert, now covered by a dense mixture of woodland, grassland, and shrubs. Relict dunes are widespread in Botswana, Angola, Zimbabwe, and Zambia and may extend as far north as the Congo rainforest zone (Shaw and Goudie, 2002). North of the equator, fossil dune fields extend south into the savannah and forest of West Africa. The "Ancient Erg of Hausaland" (Grove, 1958) occurs where present rainfall is as high as 1,000 mm per annum. Further east, in the Sudan, a series of fixed dunes, called *Qoz*, extend as far south as 10° N lat. and merge northward, locally, with mobile dunes at about 16° N. lat. (Grove and Warren, 1968).

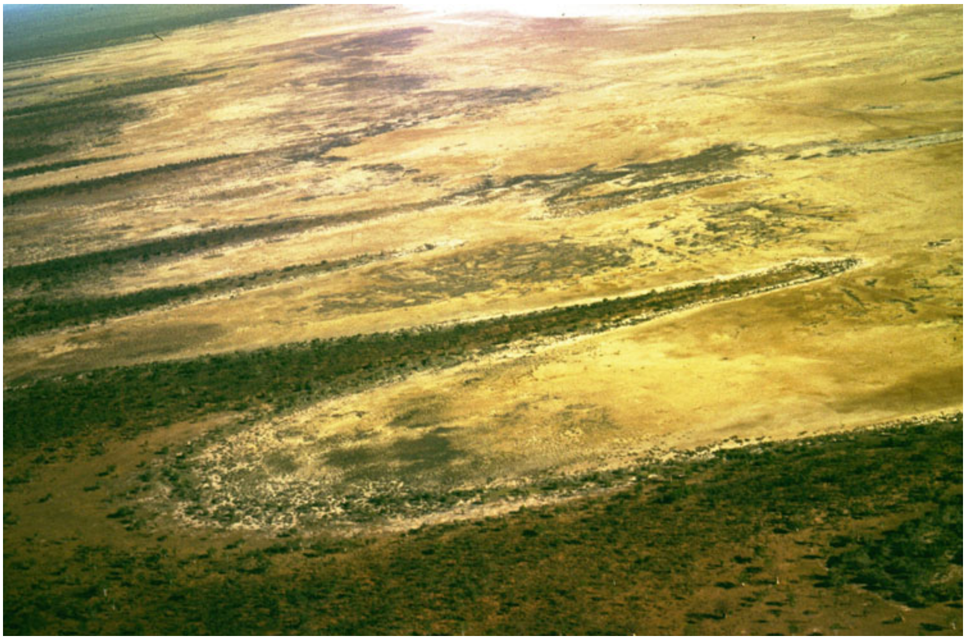
In the USA, parts of the High Plains were formerly covered by large dune fields. Substantial dune development took place in the Late Pleistocene and during the drier portions of the Holocene (Halfen et al., 2012). Relict Quaternary dunes also occur in South Carolina and elsewhere along the eastern seaboard of the USA (Swezey et al., 2013). The American dunes contain many important archaeological sites, and these are found from Texas in the south (e.g., Holliday, 2000, 2001; Hall et al., 2010) to Wyoming in the north (Mayer, 2002).

In South America, in the Llanos, fossil dunes underlying the Venezuelan savannah region extend southward as far as 5°20′ N lat. Other dunes occur in northern Amazonia and the Roraima-Guyana (Latrubesse and Nelson, 2001). Another erg was in the valley of the São Francisco in Bahia State, Brazil. In addition, it is likely that eolian activity was much more extensive in the Pantanal, the Pampas, and other parts of Argentina (Tripaldi and Forman, 2007), including the steppes of Tierra del Fuego (Coronato et al., 2011).

In Australia, fossil dunes are developed over wide areas (Wasson et al. 1988; Nanson et al., 1995). They occur from Tasmania (Sigleo and Colhoun, 1982) in the south to the Fitzroy plains of north Western Australia, where they pass under (and thus predate) the Holocene alluvium of King Sound (Jennings, 1975) (Figure 3). In the country to the south of the Barkly Tableland, they probably indicate a decrease of annual rainfall in that area to between 150 and 500 mm, indicating an equatorward shift of the isohyets by about 8° of latitude, or around 900 km. Lunette dunes on the lee sides of closed depressions have also had a lengthy history and provide many details about both dune and lake evolution (see, e.g., Chen et al., 1995), in addition to being sites where human remains and artifacts occur (Fitzsimmons et al. 2014), as at Lake Mungo.

Thus, as this brief review shows, large swathes of low latitudes possess dunes that currently have limited or negligible eolian activity (Telfer and Hesse, 2013). Although precipitation amounts may have been a major controlling factor in their former activity, there are other factors that must be considered, including changes in wind energy and sand supply (Chase, 2009; Roskin et al., 2011).

There is evidence that the strength of the trade winds may have intensified during particular phases of the



Eolian Settings: Sand, Figure 3 Relict linear dunes, of probable Late Pleistocene age, that were flooded by the postglacial rise of sea level in the King Sound area, near Derby, West Kimberley, Australia.

Pleistocene, causing increased eolian activity. Northeasterly trade wind velocities were higher during glacials, probably because of an intensified atmospheric circulation; this intensity was caused by the increased temperature gradient between the North Pole and the equator due to the presence of an extended Northern Hemisphere ice cap (Ruddiman, 1997; Broecker, 2002).

Sand supply is another major control influencing dune formation. In this connection, rivers may be an important source of sand, so that their state is important (Londoño et al., 2012). Broad, sandy channels that dry out seasonally may provide ample sand for dune construction, while perennially wet or deeply incised channels may provide little (Wright et al., 2011). It is also possible that, in some cases, increased fluvial sediment transport could have led to a much greater sand supply to river channels so that dune accretion may have been greater even if the climate was moister than today (Ellwein et al., 2011). In very arid areas, moist phases may have been required to create aggradation of fans and alluvial washes through increased erosion; with the onset of drier conditions, the accumulated sand could then be deflated, enabling dune accretion to occur (Lancaster and Mahan, 2012).

Sea-level changes may control the availability of sand supply in coastal environments as seems to have been the case in the lands bordering the Arabian/Persian Gulf and on the coast of the southern Levant. On one hand, at times of low sea level, large expanses of former seafloor would be dry land, making it a source of sand (Goring-Morris and Goldberg, 1990), while on the other, rising sea levels would comb up large quantities of material which could then be blown inland (Teller et al., 2000). Even the quite modest sea-level changes of the Holocene may have affected dune accumulation (Compton and Franceschini, 2005). Moreover, sea-level changes may also have influenced dunes through control of groundwater levels in near coastal environments (Carr et al., 2006).

Dating of sand dunes

The development of optically stimulated luminescence (OSL) dating has provided the means for determining dune ages, and there are now many dates for periods of dune accumulation (e.g., Fitzsimmons et al., 2012; Stone and Thomas, 2012) (Figure 4). When conditions are favorable for the application of such dating methods, results can yield ages in the hundreds of thousands of years. It is important to point out, however, that the dates are generally for periods of sand accumulation and stabilization rather than being for periods of actual dune movement during which the sand is repeatedly being exposed to light in the process of moving (Lu et al., 2011; Thomas, 2013). In many areas, dune activity appears to have been considerable in the period between the Last Glacial Maximum and the early Holocene wet phase.

There are numerous problems in interpreting OSL dates on dunes, including the fact that erosional phases may cause the record to be incomplete (Telfer et al., 2010), and bioturbation can lead to mixing and displacement (Bateman et al., 2007). Moreover, the record obtained from dunes in close proximity to each other may not always be the same, and as more and more dates are

Eolian Settings: Sand, Figure 4 Linear dunes in the United Arab Emirates being sampled for OSL dating after face clearance.

obtained from an area, some of the supposed intervals of non-accumulation of sand may turn out not to be as static as once thought. Equally, a more intensive vertical sampling strategy may have a similar outcome (Stone and Thomas, 2008).

Site formation processes in dunes

Although dunes can be a treasure house of archaeological materials embedded within them, care needs to be taken in their interpretation. For example, deflation of dunes may lead to preferential removal of fine materials, such as small fish bones, while other susceptible materials may be destroyed by eolian abrasion (Rick, 2002). Artifacts can also be vertically displaced as a result of post-occupational erosion and deflation (Mayer, 2002). In addition, bioturbation and other processes may lead to upward or downward movement of artifacts from their original level of deposition, and inverted clast stratigraphy has been reported (Buck et al., 2002).

Summary

Areas of eolian sand deposition have often proven to be the locations of major archaeological sites. In the last half century or so, many relict dunes have been identified in low- and mid-latitude locations, indicating by their presence former periods of aridity. We now recognize, however, that other factors may also have played a role, including changes in windiness, sand supply, and sea levels. Another important development has been the application of optical dating for establishing chronologies of dune accumulation. The presence of archaeological materials in dunes needs to be interpreted with care, because site formation processes may not be readily apparent, making accurate conclusions over their age and relationship with human exploitation challenging.

Definition

Ethnogeoarchaeology: Geological methods and observations that address archaeological questions and are applied in an ethnographic context/environment.

Ethnographic environment: Extant traditional societies that preserve traditional ways of living and subsistence strategies.

Essential concepts of ethnogeoarchaeology and historical perspective

Geoarchaeology refers to any earth-science concept, technique, or knowledge base applicable to the study of artifacts and processes involved in the creation of the archaeological record (Rapp and Hill 1998, 1–2). Ethnoarchaeology is the study of extant societies with the goal of answering archaeological questions about site and artifact formation that can be applied to the interpretation of archaeological sites. The combination of the two fields – geoarchaeology and ethnoarchaeology – leads to ethnogeoarchaeology, which can be defined as the conduct of geoarchaeological research in societies that preserve traditional ways of living in order to use such observations and analytical results to gain insights into the structure of ancient societies and their subsistence strategies.

The first geoarchaeological studies conducted in ethnographic environments intended to make geological observations of ongoing phenomena that were related to archaeological problems being encountered at nearby sites. Such a study was pioneered by McIntosh (1974) and was focused on mud wall decay in Hani, a modern village of western Ghana, in order to learn about the deterioration process as it occurs in modern time so that the ideas could be applied to the study of an archaeological site in the vicinity at Begho. The ethnographic research was aimed at describing and understanding the processes of decay and the subsequent rearrangement of altered material during all phases of deterioration in order to recognize former walls in an archaeological context. The modern structures under study were built of unfired courses of puddle mud (terre pisé) or of wattle and daub, both roofed with thatch. It was seen that both the puddle mud and wattle-and-daub walls decayed readily and that the process continued until the wall remains were protected by overlying deposits of previously intact wall material. Within the archaeological site, environmental factors (such as humidity and acidity of the local soil as well as animal and root activity) plus the use of local soils for construction had made the identification of decayed walls almost impossible. The results of ethnogeoarchaeological observation helped in recognizing the remains of former buildings within the archaeological site. The excavators also determined that, in almost all cases, it was impossible to distinguish archaeologically between terre pisé and wattle and daub.

Another pioneering study based on geoarchaeological observations was conducted by Gifford and Behrensmeyer (1977) on the northeastern shore of Lake Turkana, Kenya. They were investigating site formation processes, specifically the interplay of geological factors and human activities at a recent hunting/gathering campsite established by a small group of Daasanach people. The goal was to investigate, among several matters, the sedimentation rate and resultant sedimentary structures, the bone taphonomy and preservation, and the identification of subsistence activities in a controlled, well-described, temporal geomorphic context (see also below).

Subsequent ethnogeoarchaeological studies employed geologic methods and scientific techniques that sought to detect anthropogenic traces left in the sediments. These studies included micromorphology, analysis of mineral components (phytoliths and spherulites), soil mineralogical analyses, and organic residues of the sediments (phosphorus concentrations, heavy mineral identifications, etc.). Research conducted to date has been directed largely toward understanding the microscopic record, and new developments are still taking place.

Most recently, the study of site formation processes has emerged as the newest field of ethnogeoarchaeological research. It involves studies on both macroscopic and microscopic scales (Schiffer, 1987) that investigate the accumulation, abandonment, and degradation of sites (Shahack-Gross, 2007). Accumulation and abandonment have been studied through ethnographic and archaeological research (Shahack-Gross, 2007). Accumulation processes include those of site buildup, such as construction of architectural features (e.g., houses, hearths) and disposal activities (e.g., knapping waste, dumping patterns) (see Hayden and Cannon, 1983). Abandonment processes affect patterning in the archaeological record and involve regional as well as site-specific studies in ethnographic and archaeological contexts (Cameron and Tomka, 1993). Degradation processes occur throughout the life history of settlements as well as after their abandonment. These are usually referred to as taphonomic and diagenetic processes, and they are studied mostly using natural science approaches emphasizing biological, chemical, and physical methods and techniques (Schiffer, 1987).

Applications: in greater detail

Micro-artifacts

A definition of size that differentiates micro-artifacts from macro-artifacts has been proposed by S. Weiner, a pioneer in the application of scientific methods to deciphering the archaeological record. In his definition, “one millimeter or so is the cutoff between fragments that can be discerned by the naked eye and those that cannot” (Weiner, 2010, 229). The small artifacts (e.g., bone fragments, lithics, charcoal pieces) enter into the substrate by trampling, and they therefore have a better chance of being preserved than larger artifacts (Gifford, 1978). They also have a better chance of being recovered close to the location where they were produced (O’Connell, 1987), that is, as part of a primary deposit.

A pioneer study of micro-artifact assemblages was conducted by Gifford (1978), who examined a Daasanach hunter/gatherer site on the shore of Lake Turkana that was occupied by a small group for four days. She observed a size-dependent sorting of micro-artifacts, and she recorded nine times the number of bone fragments recovered from the subsurface than had been visible on the ground.

A later study conducted in Israel by Rosen (1986) investigated micro-artifact assemblages from the floors of tells; this information was combined with site formation research in order to identify activity areas. Rosen included aspects of accretion and erosion in tell sites to show the landscape formation processes that affect mounds and how humans influence this environment. This and later research conducted by Rosen was inspired by several ethnoarchaeological studies dealing with micro-artifact accumulation on earth floors conducted mostly in Central American contexts (Hayden and Cannon, 1983). The basic finding of those New World studies was that small fragments trampled into floors during the course of specific activities (e.g., flint, pottery, bones, and charcoal) represent clearer evidence for those activities than that available from the macroscopic artifactual record (Hayden and Cannon, 1983). Rosen developed a procedure to obtain data on micro-artifacts within tell sites (Rosen, 1989, 1993), and she applied it at sites such as Tell Miqne, Tell Batash, Tell Halif, Lachish, and Shiqmim.

Biological material

Phytoliths are microscopic mineral forms produced by certain plants within their tissues. The best-preserved ones

Ethnogeoarchaeology, Figure 1 Photograph showing a section dug into the clay floor of an abandoned house at Sarakini, Greece. Thick oak beams forming the base are covered by a mud mixture and then overlain by successive clay laminae that represent floor replasterings. The loose sediment on the floor reflects debris accumulated after abandonment as well as secondary use remains (rye straw).

Ethnogeoarchaeology, Figure 2 Photograph showing a section dug into the floor of an abandoned barn at Sarakini, Greece. Bedrock is overlain by thin, compacted layers of decayed straw and soil. Fallen thatch covers the barn floor.

are composed of hydrated silica (opal), and they remain in the soil of archaeological sites as phytolith concentrations resulting from dissolution or degradation of plant organic matter. They are usually trampled into floors, thereby providing evidence of human activities involving the plants identifiable by their phytoliths.

A recent ethnogeoarchaeological study of abandoned structures conducted at a Greek village in Thrace, northern Greece (Tsartsidou et al., 2008), looked into phytoliths as indicators of activity areas within an agropastoral community. The structures analyzed had been abandoned for more than 30 years, and therefore, the transformation of the organic remains had already led to complete decay, leaving the place much like an archaeological site. The buildings and village layout were still preserved, and a local informant verified their functional uses. Sediment samples were collected from diverse locations and analyzed (Figures 1 and 2). The results demonstrated the value of phytoliths as a useful tool for identifying some activity areas (e.g., barns, Figure 2) while indicating the difficulties of recognizing others. For example, the living floors of houses, made of clay (Figure 1), were devoid of phytoliths, whereas the clay floors of storage areas had more phytoliths. The rich phytolith concentrations of the ground floor stables (originating from residual dung) contrasted markedly with the paucity of phytoliths associated with the living areas of the second story floor above. Stabling areas of seasonal sites were sometimes cleaned and the dung used as fertilizer; in such cases, there was no evidence of stabling activities based on phytoliths, thereby demonstrating the difficulty of recognizing such an activity area in an archaeological context – but offering a clue to the possible presence of an agropastoral community that exploited the dung for the fields. The threshing floors were also not easily identified since most of them were devoid of phytoliths, and the phytoliths that were found originated from the hard layer of dung often used to coat the floor.

The results of these ethnogeoarchaeological observations were applied to a pottery Neolithic site at Makri in the broader geographical area (Tsartsidou et al., 2009). Aspects of construction practices and use of space were identified through the analysis of phytolith assemblages from the floors of the site. A possible change in the use of space was also identified in a sequence of superposed floors, where one of them lacked the consistent presence of dung phytoliths and incorporated an assemblage related more to straw used in construction. Finally, the rich husk phytolith remains from wheat and barley seeds that accumulated significantly in a certain area of the site pointed to a central storage facility, probably of communal character.

Phytolith analyses have proven very useful for the identification of dung remains (Shahack-Gross et al., 2003; Tsartsidou et al., 2008). Dung may have been used in the past for several purposes, including as building material, fuel, fertilizer, etc. It can therefore be found in various contexts within archaeological sites, such as enclosures, middens, trash pits, floors, walls, and other deposits. Various geoarchaeological studies have been conducted in ethnographic environments all over the world in order to learn about the ways dung has been used as well as the diagenetic processes it undergoes after deposition (Brochier et al., 1992; Canti, 1997). Laboratory studies of fresh ovicaprine droppings and comparative explorations of four Neolithic sites from France and Greece conducted by Brochier (1983) showed that prehistoric herding could be identified by the occurrence of spherulites, i.e., microscopic crystals of calcium salt formed in the animals' guts (Canti, 1999) that are frequently found in association with grass phytoliths. The encouraging results of this initial study led Brochier et al. (1992) to study modern stock pen deposits, combining sedimentology, archaeology, and ethnography in order to identify traces of past herding and isolate variables that affect the preservation of dung in archaeological sites. The study was conducted in open-air sites, caves, and rock shelters of Sicily, where traditional herding was still performed. The results verified that spherulites, phytoliths, layers of burnt manure, and rock polish in caves are diagnostic indicators of herding, and these indicators are preserved in open-air sites and beneath roofed structures under conditions of rapid burial. Diagenetic gypsum has been also identified as an indicator of the former presence of quantities of vegetal matter.

Apart from phytoliths and spherulites, researchers have reported other characteristic features that constitute evidence of decayed dung: unique, undulating, microlaminated structures in sediments associated with substantial amounts of phytoliths identified by thin section analysis (Shahack-Gross et al., 2003) and the presence of phosphate concentrations (Macphail et al., 2004) and organic residues. High $\delta\ ^{15}N$ values point to preserved organic matter in degraded livestock dung, and $\delta\ ^{13}N$ values proved to be helpful for distinguishing grazing from browsing animals (Codron et al., 2005).

Shahack-Gross et al. (2003, 2004) carried out studies in Kenya among Maasai pastoralists, where the basic approach was to follow the accumulation and degradation processes related to the formation of livestock enclosures by sampling sediments along a taphonomic sequence of abandoned Maasai settlements. Sediments were sampled not only from enclosures but also from houses, hearths, gate areas, and trash pits; formation processes were monitored for over 40 years after abandonment using geoarchaeological techniques that included infrared spectroscopy for bulk mineral identifications, micromorphology for sediment microstructure attributes, and quantitative phytolith analyses for differentiating enclosures from other sediments within and around the settlements. The methods developed by Shahack-Gross et al. (2003, 2004) have been applied to archaeological sites in Israel and are most useful for inferring subsistence practices and activity areas (Shahack-Gross et al., 2005). Furthermore, pastoral practices and the use of dung as fuel in Bronze Age and Iron Age sites of Israel have been tested (Katz et al., 2007; Albert et al., 2008; Shahack-Gross and Finkelstein, 2008).

Finally, an ethnogeoarchaeological study of accumulation processes in Bedouin camps in southern Israel conducted by Shahack-Gross and Finkelstein (2008) has shown that livestock dung in the desert ecosystem differs from that in the Mediterranean ecosystem by having much lower phytolith concentrations. In addition, they showed that seasonality of herding camps in the desert might be discerned by phytolith analysis. They also discovered that spherulites are better preserved in arid contexts than in the moister Mediterranean zone. Shahack-Gross and Finkelstein (2008) applied these results to the study of sediments from Atar Haroa, an Iron Age site in the Negev Highlands near Sde Boqer, and proposed that the economic base of this site was centered on pure pastoralism rather than agropastoralism.

Micromorphology

Micromorphology is the study of undisturbed soils and soft sediments using petrographic thin sections (Goldberg and Whitbread, 1993). It has been applied to numerous archaeological problems since it can identify anthropogenic impacts by recognizing effects of very small scale within sediments (Courty et al., 1989) and therefore help to diagnose otherwise invisible human and natural activities.

Goldberg and Whitbread (1993) pioneered a study that investigated the formation of floors in an abandoned Bedouin camp near Be'er Sheva in Israel; the goal was to define the living floor using micromorphological analysis (both qualitative observations and quantitative image analysis). They showed that the living floor could be identified based on its relatively higher compactness and subhorizontal, parallel-elongated voids. They highlighted the problem of identifying earthen floors in archaeological sites and stressed that microscopic features are more reliable than macroscopic ones when dealing with "dirt," rather than plastered or paved floors (see also Gé et al., 1993). Goldberg and Whitbread (1993) also reported that living floor features are more easily identifiable in clayey sediments because they are more easily compacted than sandy sediments and develop the characteristic subhorizontal voids more readily. Later studies have indeed identified these micromorphological features in archaeological sites (Shahack-Gross et al., 2003, 2005; Berna et al., 2007; Shahack-Gross and Finkelstein, 2008).

In order to achieve greater interpretative detail from the repeated fine plastering events observed in the structures at the Neolithic site of Çatalhöyük in central Turkey, Boivin (2000) investigated a modern rural community in Rajasthan, northwestern India. The occupants of the village repeatedly replastered rooms in their houses following various rules of hygiene as well as major social events on the calendar, religious or civil (births, deaths, marriages, etc.). Replastering was not related to some constructional method or necessity. Temporal cycles were identified in the floor sequence of Rajasthani houses, with repeated replasterings involving variations in materials used depending upon the occasion. These ethnoarchaeological observations were compared to the repeated replasterings of floors and walls at the Neolithic site of Çatalhöyük. Archaeological study of these floors and wall sequences suggests in their cyclical pattern involving techniques and materials a possibly similar temporal rhythm of associated rituals.

Another ethnogeoarchaeological study was conducted at nineteenth- and early twentieth-century turf houses on a farm in Iceland (Milek, 2006). The research included observations regarding the physical properties of turf as a building material, the techniques used in construction and maintenance, as well as the collapse and decay of the buildings. The floors of a residential building and a sheep stable were analyzed, the activities performed were investigated, and samples for micromorphological analysis were collected from trenches excavated into the floors. The results determined again that the study of micro-artifacts shows greater potential in recognizing activity areas than macro-artifact analysis, and combining this with micromorphology provides strong evidence of floor formation processes and the human actions conducted on them. The results were then applied to archaeological sites of the Viking Age in Iceland in order to explore the use of space and understand the depositional history of the archaeological floors.

Micromorphological analysis of five different types of fires (sleeping fires, communal cooking fires, etc.) was conducted among the Hadza, hunting and gathering people of Tanzania, in order to identify the anthropogenic nature of the fires, the burning intensity, and the type of fuel used (Mallol et al., 2007). The results show that micromorphology can be helpful in distinguishing between natural and anthropogenic fires as well as detecting the burning intensity; it can thus serve as a tool for distinguishing among different types of fires, e.g., telling cooking fires apart from sleeping fires. Implications of such research include greater understanding of how and when such combustion features are preserved archaeologically and signs that bear upon interpretation of their function.

Goodman-Elgar (2008) studied the formation of archaeological deposits through ethnogeoarchaeological research into highly weathered contemporary adobe structures of an abandoned domestic compound on the Taraco Peninsula, Bolivia. The intent was to use thin section micromorphology to ascertain the composition of construction materials and their sources, identify features associated with the use of the structures, and characterize the processes by which they deteriorated over time. The ethnographic site was composed of rooms for different functions that had been uninhabited for over 50 years. Geoarchaeological samples were collected from intact and weathered adobes, earthen hearths, mud plaster, and floors. Conclusions from analysis showed that (1) organic material (e.g., reed thatch of roof fall) attracted soil fauna leading to bioturbation of floor layers (beaten earth), (2) the most stable indicators of anthropogenic activities were the reddened adobes and earth patches ("rubified peds") associated with hearths, and (3) based on general observations, a devolutionary sequence could be constructed for the progressive degradation of adobe architecture and redeposition of its erosional materials. The results were compared with data from prehistoric sites excavated on the Taraco Peninsula (Chiripa, Kala Uyuni, and Sonaji). The comparison showed both parallel and significant differences in the construction materials and techniques used.

Research carried out in shell middens of Tierra del Fuego followed an ethnoarchaeological approach to test new developments in archaeology (Godino et al., 2011). The archaeological sites of this area (Beagle Channel) are shell middens formed by multiple episodes of shell deposition mixed with the remains from diverse production and consumption activities. The ethnographic research was conducted among the Yamanas, a hunter-fisher-gatherer society with a high level of marine resources management. The lines of evidence examined were micromorphology, phytolith analysis, and functional lithic analysis in order to identify different occupation episodes and unravel the spatial organization of the daily activities aiming at understanding social dynamics in hunter-fisher-gatherer societies. The results have been applied to two archaeological sites of the Beagle Channel: Tùnel VII and Lanashuaia I. Micromorphological analysis proved helpful in interpretations relative to site function and intensity of frequentation. The application of micromorphology together with phytolith analysis allowed greater stratigraphic definition as well as evaluation of the effects of taphonomic processes on the transformation of buried materials into the final archaeological record. Finally, it successfully recognized specific spatial patterns inside the dwellings and defined the actual function of anthropic features such as fireplaces.

Soil chemical analysis

Soil chemical analysis is based on the premise that activities performed in the same place over a long period of time leave behind distinct chemical signatures in the form of residues that are trapped in the soil where they remain relatively unaffected over time (Barba and Ortiz, 1992; Parnell et al., 2002a, b). Although soil chemical analysis in archaeology encompasses a wide range of procedures, some of the most promising signatures come from analyses of phosphorus and heavy metals, e.g., copper, iron, mercury, manganese, lead, and zinc (Wells et al., 2000; Parnell et al., 2002a).

Ethnographic studies have been conducted in order to demonstrate the interpretive value of chemical analysis (Hayden and Cannon, 1983; Smyth, 1990; Barba and Ortiz, 1992; Manzanilla, 1996; Middleton and Price 1996; Fernández et al., 2002; Parnell et al., 2002a, b). Some exemplary research has been done in Guatemala. Phosphate analysis of sediments was conducted at the contemporary Qéqchi Maya village in order to investigate household activities and establish their soil chemical signatures (Terry et al., 2004). The results were then applied at the archaeological site of Aguateca. The study showed high concentrations of phosphorus in the kitchen, the refuse dump, and the runoff area from the refuse dump.

Similarly, ethnogeoarchaeological work by Barba and Ortiz (1992) demonstrated that phosphorus levels correlate with known activities; high concentrations were found in the kitchen floors and eating areas, whereas soils of the discard area for water used in maize soaking showed moderate levels and walkway soils exhibited low concentrations.

Finally, a study of two fish processing sites used by Cupiit Eskimos in southwestern Alaska revealed high phosphorus and other element concentrations in specific locations, such as fish drying racks (Knudson et al., 2004).

Summary

Ethnogeoarchaeology is the application of geologically based techniques to the study of sediments as well as the cultural traces within them in extant societies in order to gain ideas about the structure of ancient societies and their activities. These techniques have included granulometry, phosphorus concentrations, heavy mineral identifications, mineral component analysis, study of micro-artifacts, and micromorphology. To this end, ethnographic sites have been explored all over the world, and the results have been applied in archaeological sites of the same geographic area.

Although the results from applications of geoscience methods have been encouraging, further work on new samples obtained under controlled ethnogeoarchaeological conditions is nevertheless needed to corroborate and enhance these initial insights into human dynamics. One problem is that, with few exceptions, most studies are of local importance and focused on specific materials and processes. In so doing, they provide only a limited part of what should be a coherent set of characteristics leading to a better understanding of archaeological site formation. It is therefore necessary to design more holistic and multidisciplinary approaches to conducting ethnographic explorations using the prism of geoarchaeology.

Definition

Experiments in archaeology that further our understanding of geoarchaeology in its broadest sense.

Introduction

Experimental geoarchaeology has been practiced systematically at least since the 1960s in the UK (Bell, 2009), with particularly active times for reconstructions and experiments occurring during the 1970s and 1980s in Europe and North America. The last decade has also seen a renewal of interest universally. Originally, earth science experiments attempted to replicate natural processes (e.g., with the use of flume tanks) and then expanded into studying human activities (constructions, farming, and artifact manufacturing) and postdepositional effects on soils and sediments and the artifacts within them (cf. taphonomy). In addition, archaeological "farms" and open-air museums have also been seen as opportunities to infer past uses of space and activities and to learn how these can be identified from the geoarchaeological record – e.g., "Viking" L'Anse aux Meadows, Newfoundland, Canada, "seventeenth century" Plymouth Plantation, Massachusetts, USA, and (see below) Butser Ancient Farm, Lejre Museum, and West Stow Anglo-Saxon Village. Lastly, individual or small study groups have conducted numerous small experiments and produced their own reference data; this kind of research is often unpublished, however. Compared to some short-lived (~3 year) research projects, and serendipitous analyses of material from open-air museums, only a few well-constructed research studies have been substantially longitudinal; the best examples are the Experimental Earthworks which have a planned monitored life of 128 years.

Care has been taken in this entry not to include within experimental geoarchaeology ethnographic observations sensu stricto or information stemming from archaeological site studies in general, although these are both crucial parallel sources of information. In addition, such data contribute to the construction of experiments and the testing of experimental results – the last a very necessary step. Finally, it should be noted that some overlap with experimental archaeometry, geomorphology, soil science, and agronomy is inevitable, along with an often essential holistic paleoenvironmental pluri-disciplinary approach.

This entry selectively examines experimental geoarchaeology from the perspective of:

Natural processes: examples of slope processes and colluvium and marine inundation
Constructions: examples of turf structures and earthworks, lime plaster, and disuse and destruction features
Activities: examples of fires, ovens and furnaces, animal management, and cultivation
Occupation floors and use of internal space: comparison of domestic and stabling space

Natural processes

Some of the classic studies of slope deposits (which aid the understanding of Quaternary sediments, for example) were carried out on the redeposition of aeolian loess in Europe using flumes and soil micromorphology (Mücher and Morozova, 1983). These studies were able to differentiate between loess redeposited simply by (1) rainsplash (e.g., unsorted and unlaminated), (2) rainwash (overland flow with raindrop impact and laminated sediments with some mineral and size sorting), and (3) flow without splash ("after-rain flow" or meltwater flow) leading to some very well-laminated and sorted deposits, which were also mineralogically differentiated. In addition, when freezing and thawing factors are added, bare soil erosion increases in direct proportion to soil moisture (Ferrick and Gatto, 2004). These findings are directly relevant to understanding the supposed cold and humid sedimentary conditions associated with hominin occupation (artifact concentrations) in the upper deposits at Lower Paleolithic Boxgrove, UK. Experiments related to agronomy and soil erosion have also found that rainsplash disrupts soil aggregates and aids soil slope movement and that soil aggregate types from different land uses vary from the most stable to the least stable as follows: pasture→woodland→arable. Resulting hillwash colluvia develop as waterlain sediments, and this is suggested not only by modeling (Farres et al., 1992), but it is also found in reality. Such findings have been applied to both environmental and land-use history reconstructions, for instance, plough/bare ground-induced soil erosion.

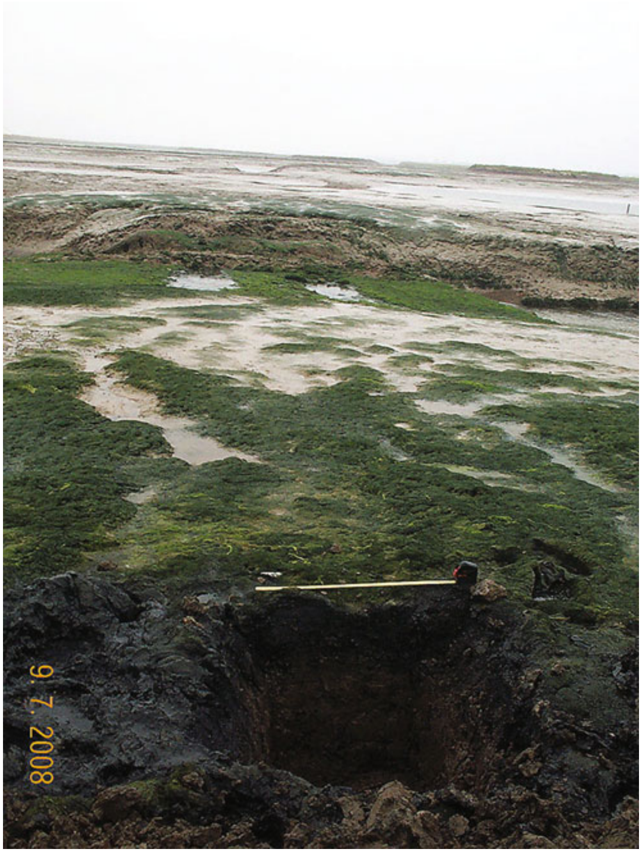
More recently, the modern effects of sea-level rise on coastal archaeology have begun to be of concern. Effects of past marine inundation on low-lying early Holocene sites as sea levels rose (i.e., as ice sheets retreated) have already been observed from excavated intertidal sites, but the monitored effects of flooding are only now being recorded. As a way of mitigating the future effects of marine flooding, "planned retreat" has led to the experimental establishment of salt marsh when the sea wall around reclaimed land was breached on purpose at Wallasea Island, Essex, UK (Macphail et al., 2010). The area was originally medieval reclaimed land. Control profiles from the current sea wall-protected arable fields and grassland were compared to a 2-year-old marine-flooded grassland soil (Figures 1, 2, and 3). The chief results were:

- The rise in base level causes the onset of hydromorphic conditions.
- A strongly marked rise in saturation extract conductivity ("salinity") by 20–60 times due to marine inundation (hence soil dispersion by Na^+ in ancient flooded soils).
- Terrestrial surfaces become sealed by microlaminated salt marsh sediments, with marine alluvium also washing down profile.
- At low tide, sediments undergo rapid ripening (subaerial weathering) over a 2-year experimental timescale, with detrital organic matter (e.g., seaweed) becoming oxidized and ferruginized.
- Biostratigraphy becomes salt marsh and tidal flat in character (e.g., foraminifera); pollen spectra change from local (arable) to regional/extra-regional with the North Sea being the potential catchment area (anomalously high tree pollen concentrations).

Constructions

Turf structures and earthworks

The first 1960s experimental earthworks in the UK were linear bank and ditch constructions designed to study buried artifact taphonomy, but which also supplied information on the changing morphology of the bank and ditch fill, as monitored over 1, 2, 4, 8, 16, and 32 years, with future recording scheduled for 64 and 128 years (Bell et al., 1996). The 1960 Overton Down earthwork (Wiltshire, UK) on chalk was most recently studied in 1992 (after 32 years). Turf bank- and chalk bank-buried rendzina soils (rendols) were compared to nearby control profiles. Field observations showed a decrease in thickness in the Ah horizon, from ~180 mm to 90–100 mm, in part because of organic matter loss (from ~11.0 % to 7.59–7.88 % organic C); acidity also increased under the

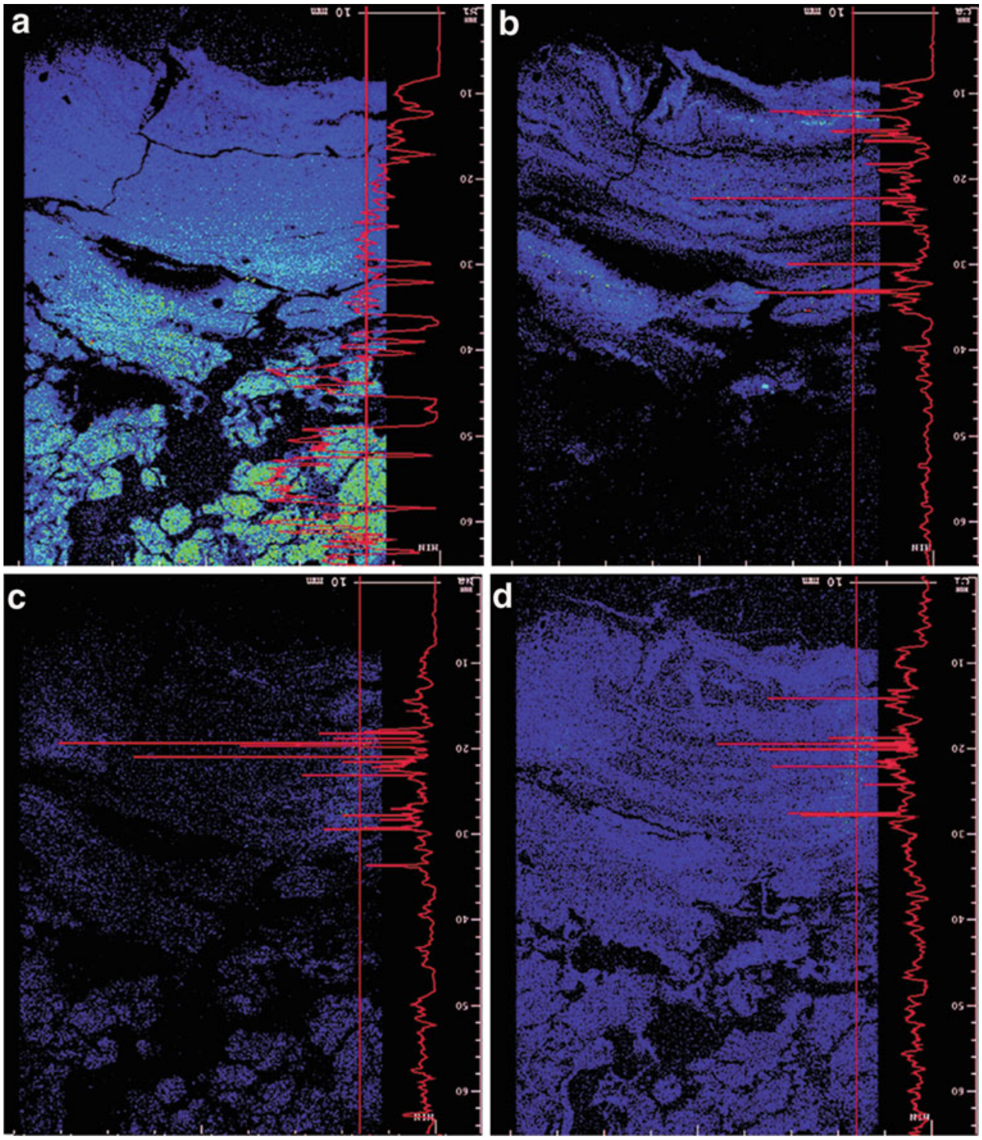


Experimental Geoarchaeology, Figure 1 Wallasea Island, River Crouch, Essex: field photo of Profile 3 dug into a newly marine-flooded grassland soil (after 2 years). Note in the distance the 1953 repaired sea wall breached in 2006 to create new marine wetland. Salt marsh/salt flat sediments are covered in detrital seaweed (see Figure 2).

Experimental Geoarchaeology, Figure 2 Wallasea Island, River Crouch, Essex; flooded Grassland Profile 3; scan of ~11 cm-long resin-impregnated block, showing algae (*A*) coated estuarine clay laminae (*Est*) over buried Ahg and Bg horizons (See Figure 3). (Estuarine clay: 8,950 μmho (micromhos per centimeter) specific conductance: *bAhg*: 4,750 μmho specific conductance).

turf bank from pH 6.9–5.6 (Crowther et al., 1996). The open microfabric (55 % voids) has also diminished to a minimum of 14 % voids at the junction zone between the buried soil and the overlying turf bank, partially through compaction. There was also a change to a spongy microfabric, and broad mammillated earthworm excrements became thinner and more evident of an acidophile mesofauna (soil invertebrates ranging in size between 0.1 mm and 2.0 mm). Less well-drained conditions also developed with the formation of fine ferromanganese nodules, which partially reflected the original humic character of the topsoil. Under the chalk bank, the original decalcified buried soil became biologically mixed with chalk; here, pH rose to 7.9. Bone was patchily preserved in the buried soil, and phosphate migration away from weathering bone was demonstrated. Partially stratified ditch accumulations of chalk and humic soil were presumed to reflect weathering cycles: winter giving rise to stony layers and summer producing fine biologically worked soil. Soil formation on the bank eventually stabilized the bank profile.

The parallel experiment at Wareham, Dorset, (1963) was carried out on acid sandy podzols (typic humod). In the field, the bank remained unstable and rapidly diminished in height, producing berm colluvia, also with infilling of the ditch including turf fragments that had become undercut by ditch side instability. Comparison to control profiles showed no obvious topsoil compaction. The most marked micromorphological change to the buried soil is the thinning of the superficial humus layer (referred to as LFH for litter, fermentation, and humus) from a presumed 70 mm in 1963 to an apparent 50 mm in 1972, which in thin section measurements was found to be 2 mm in 1981 and 1–2 mm in 1996 (Macphail et al., 2003). Oxidation had the effect of "artificially" concentrating the least decomposable organic matter in this buried humus horizon, mainly lignin and charcoal. The lower turf stack held water, and hydromorphic (e.g., iron



Experimental Geoarchaeology, Figure 3 Wallasea Island, River Crouch, Essex; flooded Grassland Profile 3; microprobe maps of Ca, Cl, Na, and Si of thin section across estuarine sediments (marine alluvium) and buried terrestrial soil. This shows the distribution of (**a**) Si, (**b**) Ca, (**c**) Na (which occurs both as saline NaCl salts and as sodium carbonate); and (**d**) Cl. Also note that the terrestrial buried soil is relatively quartz rich (Si), compared to the overlying estuarine alluvium which is more calcitic (Ca). Width of thin section is ~50 mm.

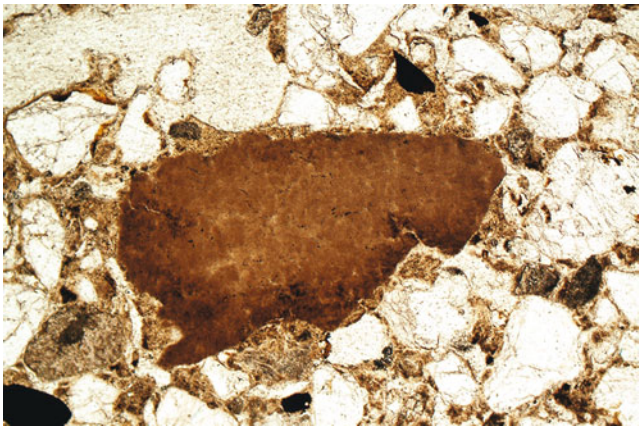
pan) features formed, including the ferrugination of roots, although continued podzolization could also be shown by the marked loss of K but increase in alkali soluble humus and pyrophosphate extractable C. It can also be noted that, at Lejre, Denmark, sandy sods were employed to replicate Iron Age barrow-buried inhumations and were artificially compacted to develop anaerobic conditions; meat, replicating an inhumation, was found to be well preserved over the short term of 3 years (Breuning-Madsen et al., 2001). Other earthwork studies include a series of four octagonal earthworks on four different soil types, instigated by Peter Reynolds (see Butser, below) to monitor bank weathering, ditch infilling, and vegetation invasion as affected by eight different aspects (north facing, south facing, etc.). Recently, the buried soils from Little Butser, Wroughton, Bascomb, and Fishbourne have been examined by Reading University. Fishbourne is on brick earth (loess) over gravels and was 22 years old when excavated (Bell, 2009). As at Overton Down, earthworms had been active in the 16-year-old buried soil on Lower Chalk at Wroughton. All these experimental earthwork findings aid our use of archaeologically buried soils for reconstructing past landscapes and demonstrate how quickly soils may be altered after burial (Crowther et al., 1996; Macphail et al., 2003). Mounds and other earthworks are a universal phenomenon and a global archaeological resource.

In Scandinavia, turf was used for both walls and roofs. At Umeå (Bagböle ancient farm), north Sweden, a 140 mm thick turf roof was made up of two turves upon a roof over a birch bark layer; the basal turf was facedown and the upper turf was faceup, revealing a living grass sward (Macphail and Goldberg, 2010: 279–281). A grass turf (mull Ah horizon/Ap pasture) roof, held together by its root mat, works well if gently pitched, whereas Peter Reynolds at Butser found that a steeply pitched turf roof failed (Reynolds, 1979: 42–43). Moreover, moder (LF), mor (LFH), or peat (histic A) turf roofs do not last, mainly because of organic matter oxidation and lack of living vegetation holding it together (R. Englemark, Umeå, pers. comm.). Pollen and organic matter concentrations show the original way up of turf in mounds (i.e., how it was laid during construction: faceup, facedown, or face-to-face), but at Umeå the topmost, right way up turf (i.e., grassy side upwards) has also the character of a living A1h horizon, with concentrated living roots and excrements of the extant mesofauna. Lime plaster constructions often use calcareous building materials, which are not lime based. Chalk-based cob (a form of daub) on wattle walls, rammed chalk floors, and clunch (crushed chalk adobe-like walls) all show weak cementation of the matrix due to localized recrystallization of calcite, as shown from a clunch-built structure at Butser. In addition to this and "native" British round houses built at Butser, a typical Romano-British villa was reconstructed, based on the Sparsholt Villa, near Winchester. After this building work was completed, heaps of unused constructional materials, including tesserae and mortar, were widespread (Figures 4, 5, 6, and 7). In ancient structures, such spreads may resemble "floors" but are simply constructional waste (Goldberg and Macphail, 2006: Figure 10.4c–d). In experiments, lime plaster and natural calcareous sediments were compared (Karkanas, 2007). Useful ways to identify lime were the recognition of transitional textures of partially carbonized slaked lime (categorized as poorly crystallized portlandite and mixtures of cryptocrystalline calcite). These are found in lime lumps and the matrix cement. A well-developed calcitic groundmass and shrinkage cracks are also possible indicators of lime plasters being present (Karkanas, 2007).

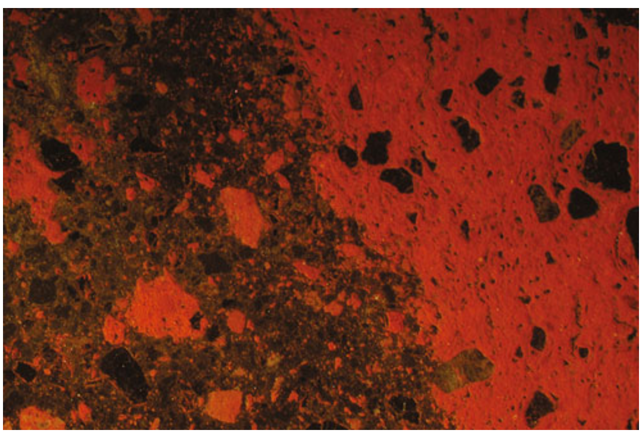
Experimental Geoarchaeology, Figure 4 Butser Experimental Romano-British Farm, Hampshire, UK; reconstructed Roman villa (designed from Sparsholt, near Winchester); a two-storied structure with load-bearing lime mortared flint walls and an upper story which is timber-framed with wattle and daub panels. Walls were lime plastered, floors were either mortared or made up of *opus signinum* to be more hard wearing; here crushed brick or terra-cotta was added to the mortar (see Figures 5, 6, and 7). (http://www.butser.org.uk/bulletin30.html; Christine Shaw, pers. comm).

Disuse and destruction features

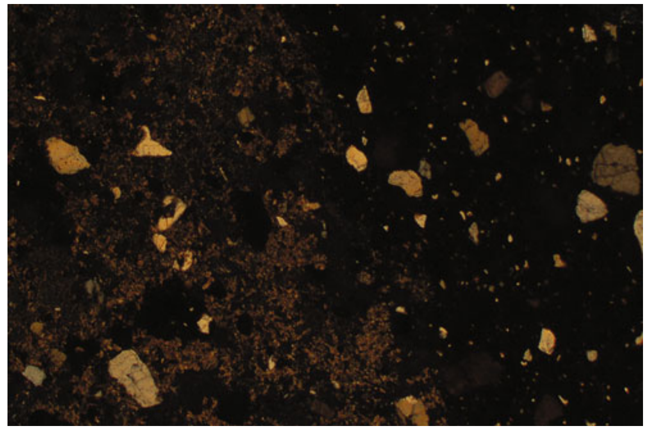
In some cases, it has been possible to see what happens to an "ancient' structure after it has been razed (burned down), a common occurrence in "clay and timber" settlements. At Romano-British Butser Ancient Farm, Hampshire, the thatched *Moel-y-Gaer* roundhouse, which has been used as a stable/byre (see below), was intentionally burned down in 1990, which took only 20 min, as video recorded by Peter Reynolds. The fire generated the highest temperatures by the door lintel, where clay daub was reddened and developed the most enhanced magnetic susceptibility values (Macphail et al., 2004; and P. Reynolds, pers. comm.). Heat from the fire mainly went upwards, and the stable floor showed few effects of heating. Almost immediately afterwards, the daub walls of the house were piled over the old stable floor to attempt to replicate the collapse of walls onto a floor after a fire. A re-excavation in 1995 found the stable floor to be clearly recognizable in terms of its micromorphology and pollen spectrum but that only traces of blue light autofluorescent hydroxyapatite remained (see occupation surfaces, below). In the case of a "pit house" structure at West Stow Anglo-Saxon Village, Suffolk, UK, a likely case of arson(?) led to the "cellar" receiving burned wood debris from the collapsed plank floor, etc., which formed a marked layer in the fill. Constructions of roundhouses at Butser and their dismantlement and reconstruction, during the period ~1975–2010, also showed that so-called drip gullies in the archaeological record could be small mammal runs along the base of the wattle and daub wall and that posts rotted quickly in the ground providing voids into which fills began to develop that reflected roundhouse use (Reynolds, 1995). Use of space studies in longhouses, employing both geoarchaeological and macrobotanical methods, is often based upon the theory that fills are contemporary with the life of the house (Viklund, 1998), as implied at Butser. An experimental house has also been constructed within the site of Çatalhöyük, Turkey (Bell, 2009).



Experimental Geoarchaeology, Figure 5 Butser Experimental Romano-British Farm, Hampshire, UK; reconstructed Sparsholt Roman villa; photomicrograph of constructional debris spreads: mortar. Here, a lime mortar binder has been tempered with medium sand (used to cement coarse flint walls in the villa); mortar includes incompletely burned chalk ($CaCO_3$), as a residue from lime (quicklime CaO) making in a kiln at ~1,000 °C (Reference material kindly supplied by Christine Shaw) Plane polarized light, frame width is ~2.38 mm.



Experimental Geoarchaeology, Figure 6 Butser Experimental Romano-British Farm, Hampshire, UK; reconstructed Sparsholt Roman villa; photomicrograph of constructional debris spreads: *opus signinum*. In order to produce a hard-wearing mortar, crushed brick (*red material*) was added to mortar; the precipitation of aluminum silicates from the brick into the mortar binder creates a more robust mortar. Note coarse and finely fragmented red brick material (Reference material kindly supplied by Christine Shaw) Oblique incident light, frame width is ~4.62 mm.



Experimental Geoarchaeology, Figure 7 Butser Experimental Romano-British Farm, Hampshire, UK; reconstructed Sparsholt Roman villa; photomicrograph of constructional debris spreads: *opus signinum*. Same as Figure 6, now under cross-polarized light (XPL). Brick is isotropic (appears dark) under XPL, whereas the calcium carbonate lime mortar is birefringent (transmits double refracted light).

Activities, features, and materials

Fires, ovens, and furnaces

Many experiments have been undertaken to replicate activities, such as surface camp fires (Linford and Canti, 2001), iron working, and smithing in the field of experimental archaeometry. Some diagnostic mineral magnetic properties develop in the soils and ash of camp fires, but they vary according to depth, nature of the substrate, and length of heating time. A few studies have been focused upon the geoarchaeology of ovens, hearths, and furnaces. The large ("Pimperne") roundhouse at Butser has a clay oven constructed from daub (straw and dung-tempered clay loam soil). In thin section, some iron clays had become rubified (reddened) while organic materials had often become lost (oxidized) or blackened. In a straw-tempered, rubified chalky clay oven replicating Roman and Saxon installations at West Heslerton, North Yorkshire, the presence of blackened straw sections suggests that temperatures remained moderately low (~<400 °C), because barley straw has been found to oxidize around this temperature (Dammers and Joergensen, 1996; Macphail, 2002; Macphail and Goldberg, 2010: Figure 6). Another effect is the shrinking of the fine matrix around the straw, and fissuring in general, due to loss of water from the clay. At higher temperatures, mineralogical changes identified by FTIR (fourier transform infrared) spectrometry have been found in experimental furnaces using bellows (Berna et al., 2007) (Table 1).

When such transformed minerals are found in archaeological deposits, it is therefore logical to infer that they arise from local "industrial" activities.

Animal management

A classic experiment in soil science concerning the compacting effects of animal trampling was carried out using a mechanical foot loaded to 138 kPa (~1.45 psi) in Queensland, Australia, to examine changes in rainfall acceptance by different soil types and how trampling

Experimental Geoarchaeology, Table 1 The effect of increasing temperature on minerogenic materials in ovens and furnaces (From Berna et al., 2007)

Temperature	Effect
Up to 400 °C	Reddened sediment with unaltered clay components
500–700 °C	Loss of kaolinite, dehydroxylation, and partial vitrification of smectite
800–900 °C	Quartz with residual altered clay minerals
1,000–1,200 °C	"Altered quartz," opal, tridymite
1,300 °C and above	Glaze-like phase, cristobalite

Experimental Geoarchaeology, Figure 8 Butser Experimental Romano-British Farm, Hampshire, UK; field photo of the Reynolds team using two Dexter cattle to pull an Iron Age replica ard (scratch plough) in one of the arable fields in the "old demonstration area" (1972–1990) (Photo kindly supplied by Peter Reynolds).

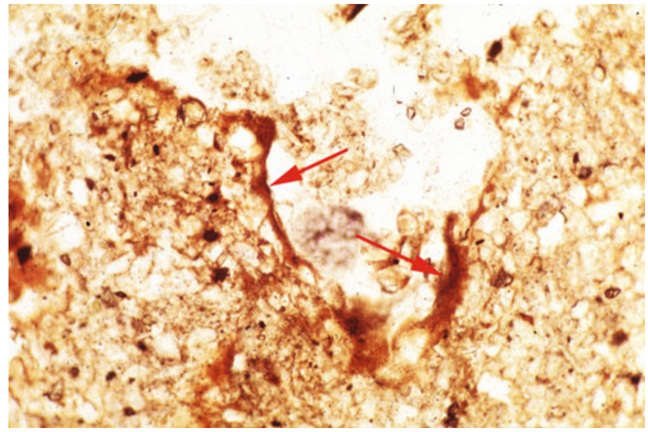
altered this (Beckman and Smith, 1974). All soil types lost structure, with even clayey, stable well-structured soil suffering surface collapse and development of a comparatively impermeable "skin." Aggregates in soils that began as apedal and massive in character totally collapsed and developed densely packed surface layers, and additional wetting and trampling had no further effect. This is the kind of phenomenon found in muddy trackways, for example. Pounding or stocking of domestic animals can have the same effects, although pig husbandry (below) is a special case which has been investigated.

An experimental "pig pasture" at the Lann-Gouh "medieval" farm near Melrand, Morbihan, Brittany, in northwestern France was investigated (Gebhardt, 1995). Here, pigs ("Porcs de Bayeaux") quickly disturbed soil surfaces and uprooted some small trees in an open-forested area. The chief result of pig action was to create a 150 m-thick compacted colluvium composed of mixed Ao and A1 soil and fragments of B horizon. This buried the in situ forest soil formed on a granitic parent material. This study was followed up in the UK (Macphail and Crowther, 2011) by examining both the "pig pasture" and small adjoining pig enclosure area at West Stow Anglo-Saxon Village, Suffolk, UK, on Breckland sands (see below for stabling of cattle, sheep, and goats). In 2008, two pigs (cross-bred Tamworths) occupied a small enclosure where their pathways to drinking water showed concentrations of fecal remains. The "pig pasture" showed churning and mixing of the sandy Ah and clean sands from the A2 horizon. Bulk sample chemistry located the highest concentrations of organic matter and phosphate in an example of the pig-trampled and dung-enriched crust of the pathway surface in the small enclosure. The surface crust was compact and composed of a concentration of sub-horizontally layered, partially digested, cereal husk remains and amorphous organic matter (pig fecal waste). Scanning electron microscope/energy-dispersive spectrometry analyses found the phosphate to be concentrated in these fecal remains, alongside iron, calcium, and sulfur. Below this crust layer, nodules of amorphous iron, phosphorus, and calcium were present and logically so are neo-formed features of pig slurry origin developed over several years of keeping pigs here. The concept of equifinality has always to be borne in mind, however, similar results can emerge from several possible scenarios in such experiments, which are not laboratory controlled.

Cultivation

Much of our understanding of ancient cultivation has been achieved by extrapolating findings from modern agronomy. This database, however, has not always been sufficient because modern cultivation regimes and heavy machinery are so unlike past methods. Still, it has been useful, for example, in the study of crusts forming on bare arable soils due to rainsplash (McIntyre, 1958; Boiffin and Bresson, 1987). Experiments in *ancient* agriculture have been criticized on the basis that they have taken place on modern soils and even in "soil bins" (Silsoe Agricultural College, Bedfordshire, UK; Lewis, 2012), but to find a *totally* undisturbed soil of early Holocene origin may be impossible. Like any experiment, constraints have to be built into the interpretation of the resulting data. An interesting suite of soil types and cultivation methods was analyzed during the late 1980s from two French (Déherain and Grignon experimental farms), one German (Hambacher Forst), and one UK site (Butser) and then compared to supposed archaeological examples (Macphail et al., 1990; Gebhardt, 1992) (Figures 8, 9, and 10). At Hambacher Forst, a replica Neolithic ard plough was used to cultivate between trees on loess soils (Meurers-Balke, 1985). In all cases, cultivation led to soils becoming looser through an "explosion" of fine structures, which was believed to relate to the inherent weakness of soil structures caused by wetting and drying. These weaknesses fractured under tool impact, a phenomenon known from modern plowing – in part carried out to develop a fine tilth suitable for rooting. Gebhardt found that

Experimental Geoarchaeology, Figure 9 Hambacher Forst, Rhinelands, Germany; field photo of "Neolithic" ard plowing by Meurers-Balke and her team (Cologne University) during 1985; they carried out cross plowing in woodland on loess soils. (Photo kindly supplied by Anne Gebhardt).



Experimental Geoarchaeology, Figure 10 Hambacher Forst, Rhinelands, Germany, "Neolithic" ard-plowed loess soil; photomicrograph of junction between newly formed Ap topsoil and subsoil A2 horizon formed in loess silt. Note dusty clay void coatings and concentrations (*arrows*), which may possibly direct result from this plowing experiment. (Thin section kindly loaned by Anne Gebhardt) Plane polarized light, frame width is ~3.3 mm.

resulting ped size could be associated with tool type, with medium angular peds at Butser (ard) and coarse angular peds at Déherain (spade). At all sites, the nature of the uncultivated soil could be ascertained from the inclusion of recognizable humic soil within the clods, and numbers of peds increased, although at Hambacher Forest this was less obvious because of poor structural stability. Soil horizon mixing (topsoil and subsoil) was, however, clearly obvious here. Peds were also compacted into loose soil in this weakly structured soil, with a 1 cm thick silt pan forming at a depth of ~6 cm, and at 12–14 cm some dusty clay had accumulated over a limpid clay of assumed woodland soil origin that had presumably formed earlier. Excessive watering at Grignon Forest caused structural collapse and the formation of bird's foot-/star-shaped voids (cf. polyconcave voids) as evidence of this. Further sampling of Butser manured and non-manured arable soils and control, non-cultivated surface horizons, was carried out in 1990; organic matter and phosphate were also measured (Macphail, et al., 2004). Structural stability was well maintained here (the 1990 Old Demonstration Area) because of the high base status of the soils (calcareous colluvium) and high organic content; organic matter levels actually rose despite cropping, and although no erosion was noted, fields became dish shaped (Reynolds, 1987; Reynolds, pers. comm.).

Anne Gebhardt's studies were followed up by those of Helen Lewis who, for example, examined experimentally cultivated soils from the Little Butser downland site and Lejre Museum (west of Copenhagen, Denmark). In addition, Neolithic (Donneruplund) ard cultivation was carried out on artificial fine sandy loams in soil bins at Silsoe, Bedfordshire, UK (Lewis, 2012). Some results are:

- The shape of the furrow varies according the share used; the arrow-shaped share produced a wide V-shaped furrow; a rounded U-shaped furrow was made when only the main straight share was employed.
- Furrows were 60–70 to 120–150 mm in depth and 210–220 mm wide.

A number of zones were identified in the plough soil, with different characteristics; these are:

- "Ridge" (e.g., blocks and aggregates formed from the original apedal soil)
- Furrow upper fills (e.g., rolled aggregates over apedal soil)
- Furrow basal fills (e.g., lines of fine soil and fine aggregates follow line of cut)
- Furrow cut (e.g., arrow-shaped share produces stepped profile with changes in soil density, becoming more compact downwards)
- Furrow compaction/impact zone (e.g., planar voids run-off at 90°; dense soil zone 10 mm under furrow)
- Sub-furrow compaction/impact zone (e.g., planar voids mirror base of furrow for 10–40 mm)

These soil bin experiments were protected from the weather, but at Lejre and Butser, textural pedofeatures had formed due to soil water dispersion.

As at Butser, where the chief aim was to grow ancient crops (and associated weeds), cultivation of Boreal podzols (ferrods) at Baggböle Farm, Umeå (north Sweden), tested the sustainability of slash-and-burn versus manured cultivation for the growing of barley during the Iron Age (Viklund, 1998). Slash and burn had a very ephemeral effect on pine woodland, with the surface 30 mm becoming characterized by an "anomalous" concentration of fine to coarse pine wood charcoal and by the presence of thin to

Experimental Geoarchaeology, Table 2 Experimental floors, stables, and domestic space: a summary of characteristics at Butser Ancient Farm 1975–1990 (After Goldberg and Macphail, 2006, Tables 12.2–12.3)

Stable floors	Typically homogeneous where high concentrations of organic matter, phosphate, and pollen grains may be preserved. Organic matter occurs in the form of layered plant fragments which, depending on pH, are either cemented (e.g., hydroxyapatite) or stained by phosphate. If preservation conditions permit the survival of pollen grains, they are likely to be abundant and possibly highly anomalous with respect to the surrounding area	Butser surface crust: 40.9 % LOI (loss on ignition), 5,960 ppm P, $\chi = 27\ (\times 10^{-8}\ m^3\ kg^{-1})$
Domestic floors	Typically heterogeneous; floor deposits are comparatively mineralogenic, massive structured, and contain abundant anthropogenic and allocthonous inclusions, such as burned soil, charcoal, and ash. Plant fragments are less common and may occur in single layers of organic mat remains. The palynology of domestic floors is an under-investigated subject, but available data suggest the likelihood of far more diverse weed pollen assemblages (reflective of settlement flora), lower concentrations and poorer preservation than in stabling deposits. Magnetic susceptibility is likely to be enhanced and P and LOI will reflect in situ activities and trampled-in materials	Butser beaten surface: 20.2 % LOI, 2,430 ppm P, $\chi = 47\ (\times 10^{-8}\ m^3\ kg^{-1})$

moderately broad (200–1,000 μm) mesoaggregated excrements of invertebrate mesofauna (Macphail, 1998). These occur in addition to the very thin and moderately thin (50–200 μm) excrements that dominate the L/F and Ah horizons of the local pine-covered podzols. This larger-size excrement type reflects the, albeit short lived, improved fertility of the slash-and-burn podzol. The chief characteristic of the permanently manured cultivated soil, which had the highest concentrations of organic matter and phosphate at the Baggböle Farm (Goldberg and Macphail, 2006: Table 12.4), was the total homogenization of the L, F, Ah, and A2 horizons into an Ap horizon that reached as far as the Bs horizon (these near coastal soils are shallow because of recent exposure ~2,000 bp due to postglacial uplift). Charcoal and other anthropogenic inclusions and exotic materials (e.g., limestone, pottery) were present throughout, along with individual fragments of dung, up to ~5 mm in size. The occurrence of iron pan fragments testified to cultivation affecting the spodic subsoil. Levels of biological activity were enhanced with thin to moderately broad organo-mineral excrements throughout. This is consistent with the transformation of superficial humus (L, F, H), Ah, and A2 horizons of podzols into overdeepened Ap horizons of plaggen soils which are characterized by a "moder" humus.

Occupation Floors and Use of Internal Space

The chief studies of how experimental domestic and stabling (byre) floors differ, again, took place at Butser. They first involved the 1975–1990 sites: the small *Moel-y-Gaer* roundhouse used to house stock over the winter and the large domestic *Pimperne* roundhouse, as reconstructed from Iron Age archaeological site evidence (Reynolds, 1979). The large roundhouse was built in 1992 as a Longbridge-Deverel (Cowdown, Wiltshire) reconstruction. As soon as the roof went on, the grass died, and the formation of a "beaten floor" commenced (Reynolds, pers. comm.). Chemical, pollen, and micromorphological analyses were carried out on the Moel-y-Gaer and Pimperne floors in order to see how the very different functions of space were represented by the resulting floor accumulations (Tables 2 and 3) (Macphail and Cruise, 2001; Macphail et al., 2004).

Comparisons to numerous occupation floor deposits in archaeological sites are consistent with these experimental findings, although domestic floors can show higher phosphate concentrations because of food disposal and latrine waste spillage, something not conducive to modern "health and safety" at open-air museums. Nevertheless, the results from the Pimperne house floor demonstrate traffic within the house and traffic into the house, bringing in soil and organic matter from outside. Such cyclical deposition is common to beaten floors. It can be noted that when the 1992 Longbridge-Deverel house floor was sampled in 1994, both locations (rear and main area) showed immaturity of development compared to the much longer lived Pimperne house, for instance, with only 12 % LOI (loss on ignition) and 1360–1880 ppm P % levels (Macphail et al., 2006). Further floor samples were collected from the next domestic roundhouse incarnation in ~2005, but floor deposits were no longer accumulating through traffic but being lost because pathways had now been graveled (unlike ancient conditions). Floor soil now had to be replaced and compacted as a repair and thus no longer reflected an actual traffic-accumulated beaten floor.

Summary

This entry provides some examples of geoarchaeological experiments sensu lato; these, together with ethnographic and archaeological case studies, have successfully advanced our understanding of cultures as found in the soil and sediment record at archaeological sites. First, experiments involving pedology, geomorphology, and the biological sciences have aided our understanding of natural processes. Constructions, settlement morphology, and use of space, however, cannot be understood properly by simply relying on the natural sciences. Instead, specific experiments (turf-based earthworks, lime making, ovens) have had to be carried out. In addition, many advances have been made from the careful use of material from open-air museums and ancient farm and settlement

Experimental Geoarchaeology, Table 3 Immature beaten domestic floor soils; Butser Longbridge Deverel roundhouse 1992–1994

Depth (m)	LOI (%)	P (ppm)
Beaten floor (main area)		
0–0.005 m	12.0	1,360
0.005–0.04 m	8.5	1,220
0.04–0.08 m	8.1	1,240
Beaten floor (wall corridor)		
0–0.005 m	12.0	1,880
0.005–0.04 m	8.7	1,270
0.04–0.08 m	8.1	1,290

reconstructions. Management of these institutions, however, governs how useful these can be for replicating archaeological site formation processes. Notably, the regime at Butser Ancient Farm under Peter Reynolds during the period 1972–1990 produced an unrivalled environment for studying "Iron Age" cultivated soils and domestic and stabling floors formed in roundhouses.

Definition

Geochemical analysis: The chemical analysis of elements associated with soils, rocks, and minerals.

Ethnoarchaeology: The application of archaeological techniques to elucidate contemporary human activities.

Chelate: Complex organic molecules that surround metallic ions to hold them in solution and prevent their chemical precipitation.

Introduction

Examinations of the physical and chemical properties of soils produce data that augment archaeological information on the structures and artifacts left behind by ancient peoples. In fact, the soil is a *palimpsest* of the physical changes and chemical residues associated with both ancient and contemporary human activities on the land surface. The origin of the term palimpsest dates to classical times, but it commonly refers to medieval manuscripts on parchment that were reused, because the medium was valuable and more durable than papyrus or paper. The old ink was partially effaced to clear the sheet for new writing, and in most cases, vestiges of the previous text, though faded and indistinct, could still be discerned. This aptly describes the soil medium as a cumulative recorder of human activities from ancient to contemporary times (Bailey, 2007; Dore and López Varela, 2010). Soils can store pollen, phytoliths, bones, architectural components, and nonperishable artifacts over sequential occupations; however, perishable organic implements and food that are readily decomposed and seldom survive to become part of the artifactual record may have initially accounted for as much as 90 % of an ancient household's artifact inventory (Cavanagh et al., 1988; Dahlin et al., 2007). Such organic materials associated with food preparation and consumption can lose their carbon and nitrogen components, which decompose to gaseous and soluble substances, yet phosphorus (P) and certain trace nutrients – including iron (Fe), copper (Cu), manganese (Mn), and zinc (Zn) – are adsorbed onto soil particles or are precipitated as insoluble compounds and remain for centuries at the location of ancient use. These and other geochemical residues of human activities serve as invisible artifacts.

Nonperishable artifacts associated with abandoned habitations and public structures were often picked up and moved and then reused at distant locations. In most cases, the soils and earthen floors of former landscapes are not transported, and thus the geochemical residues within soils provide excellent in situ evidence of ancient use (Barba et al., 1996; Wells et al., 2000; Parnell et al., 2001; Parnell et al., 2002; Barba, 2007). Geochemical analyses of soils and floors have become established archaeological methods for locating ancient sites. The results further define the types and extent of human activities within those sites and help in the interpretation of those activities (see reviews by Wilson et al., 2005; Wilson et al., 2006; Holliday and Gartner, 2007; Walkington, 2010).

Anthropogenic chemical residues in soils

Phosphorus (P)

The application of phosphate analysis in archaeology was first developed in Europe in the 1930s, where pioneering efforts by Arrhenius (1931) and Lorch (1940) indicated that areas of ancient occupation contained elevated

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

concentrations of soil P. Ethnographic studies likewise illustrated the relationship of P concentration with domestic activities (Barba and Ortiz, 1992; Middleton and Price, 1996; Fernández et al., 2002; Terry et al., 2004). Phosphorus is used by plant and animal cells in plasma membranes, nucleic acids, and other organic molecules. When ancient plant and animal foodstuffs were harvested and brought into dwelling places, the P contained in the food was also introduced into the settlement. As the food waste decomposed, the mineralized P was readily fixed onto the surface of soil particles and remained stable for long periods of time (Barba and Ortiz, 1992; Holliday and Gartner, 2007). Activities such as preparation, storage, and disposal of food as well as the fertilizing of soil for agriculture have left distinct chemical residues that remain relatively in their original place within the soil for centuries.

Soil samples collected prior to excavation can be analyzed and their chemical patterns determined and mapped, in order to prospect for archaeological features of interest. For instance, Parnell et al. (2001) reported a significant positive correlation between sherd density discovered within test pits and surface soil P concentrations. An area that contains elevated soil P near architectural structures may indicate locations of residential middens.

Floors with elevated P concentrations may indicate kitchen and food consumption areas. Ethnoarchaeological studies of indigenous households have demonstrated that activities associated with high soil P concentrations include gardening, food preparation, waste disposal, and sweeping that pushes organic material to the peripheries of patios and high-traffic areas (Barba and Ortiz, 1992; Fernández et al., 2002). Combined with other lines of evidence, geochemical data have helped identify areas used as sleeping quarters and spaces in which ritual and funerary activities were conducted (Barba et al., 1995; de Pierrebourg, 1999). Thus, extraordinarily high P concentrations in soils and on floors can be associated with prehistoric food preparation, consumption, storage, and disposal. Very low levels of P could indicate high-traffic areas such as pathways and patio centers, as movement and sweeping push organic debris to the outer margins.

Several methods of P extraction have been used in geochemical studies of ancient activity areas. Dilute acid extraction procedures remove a portion of the P adsorbed onto the surfaces of soil particles (e.g., Mehlich, 1978; Middleton and Price, 1996; Terry et al., 2000; Rypkema et al., 2007). The concentrations of extracted P vary with the type and strength of the acid. In each extraction procedure, the portion of P analyzed is affected by soil acidity or alkalinity, percentage of organic matter, clay content and mineralogy, and other physical and chemical properties of the soil. For these reasons, the magnitude of extracted P concentration differs with the extraction procedure, with the type of soil, and with the geographic origin of the soil.

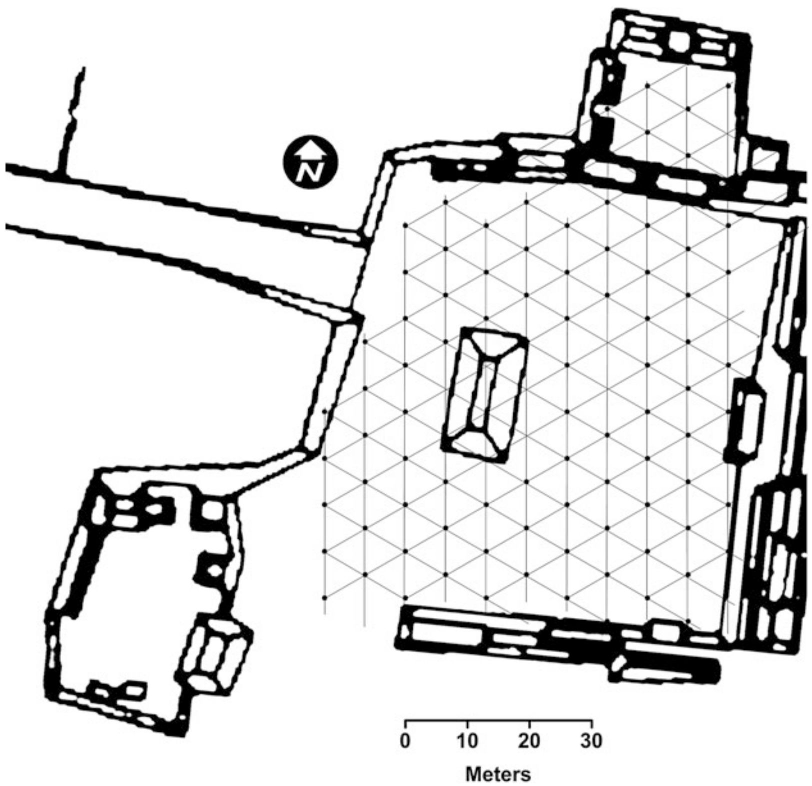
Trace elements

Anthropogenic metal and trace element residues have proven useful in the identification of ancient activities. Much of this work has focused on Cu, Fe, Mn, lead (Pb), and Zn (Bintliff et al., 1990; Entwistle and Abrahams, 1997; Entwistle et al., 1998; Entwistle et al., 2000; Parnell et al., 2002; Terry et al., 2004). Many of the metallic ions remain stable in soils for long periods, as their ions are readily adsorbed and precipitated onto clay surfaces, and they can form insoluble oxides, sulfates, or carbonates (Lindsay, 1979; Wells et al., 2000). Some pigments and paints used by the pre-Hispanic Maya contained metallic bases, such as hematite and cinnabar (Goffer, 1980; Vázquez Negrete and Velázquez, 1996a; Vázquez Negrete and Velázquez, 1996b), and thus, elevated values of trace metals in soils may help to identify areas where pigments were processed or applied and where craft workshops were located (Terry et al., 2004). For example, evidence of workshop activities was provided by trace metal extraction and inductively coupled plasma mass spectrometry (ICP/MS) or atomic emission spectroscopy (ICP-AES) analyses of soil and floor samples at Cancuén (Cook et al., 2006), Piedras Negras, and Aguateca, Guatemala (Parnell et al., 2002; Terry et al., 2004). Multivariate analysis of P and several trace metals has also proven useful (Parnell et al., 2002; Abrahams et al., 2010; López Varela and Dore, 2010).

Geochemical analysis in the field

Two problems arise when samples must be delivered from the field to a distant formal laboratory setting with the attendant lengthy wait for chemical analysis and data processing. First, the process of moving samples from field to laboratory and the analytical time required at a busy soil laboratory mean that geochemical data are usually not available before the end of the field season. Second, the permitting process for carrying soil samples across international borders is time-consuming and often both difficult and expensive. For these reasons, archaeological prospection benefits greatly from more rapidly obtained results from analyses conducted in situ and in a field laboratory. As geochemical techniques in archaeological research have developed and as analytical capabilities have advanced, the demand has grown for relatively quick data obtained at the time of excavation or at least in a field laboratory so that within minutes or a couple of days, results can be available to guide archaeological investigations and to target features of interest.

Simple spot tests for soil P, amino acids, and lipids have been developed (Eidt, 1973; Barba et al., 1991) for in situ use. In the field laboratory, extractable P tests can be conducted with relatively inexpensive equipment and chemicals. Both Terry et al. (2000) and Rypkema et al. (2007) have described such tests and equipment. Much of the equipment needed for geochemical analysis of archaeological soils in a field laboratory is available



Field Geochemistry, Figure 1 A triangular grid was superimposed on the Conchita Plaza group near Caracol, Belize. Each grid point was 10 m from adjacent grid points. North-south pathways through the dense vegetation were cut 8.67 m apart to allow equidistance sampling at 10 m.

in battery-powered form, including electronic balances, timers, pH meters, and colorimeters. Deionization cartridges can be linked by flexible tubing in the field lab to provide laboratory-quality water for chemical analyses.

Limitations inherent in a field laboratory setting likely preclude the use of concentrated acids for sample digestion in preparation for total elemental analysis. There are the safety issues of toxic fumes and the necessity of safety showers, eyewashes, and climate control that are cost prohibitive in a field laboratory situation. In addition, the inductively coupled plasma (ICP) spectrometer and the atomic adsorption (AA) spectrophotometer necessary for total element analysis are not available in a format that would allow field laboratory use. However, recent advances in the development of battery-operated, portable X-ray fluorescence (pXRF) instruments may allow researchers to obtain reliable total elemental analysis both in situ and in the field laboratory.

Soil sampling

The key to excellent soil geochemical data is representative and statistically sound sampling. Only a few crumbs or a couple of grams of soil end up in an extraction vessel or an analysis vial. Those tiny amounts of soil must therefore adequately represent the specific area of sampling. Samples may be taken on a gridded system for geospatial analysis of an area, or they may be taken at intervals along a transect in search of "hot spots" for later study. In many cases, the ancient occupation surface is at the contemporary soil surface. Leaf litter should be removed and approximately 500 g of soil collected. It is recommended that this sample be obtained from three or four spots within 0.5 m of a grid point or transect location. The sample contains moisture, roots, and gravel that should be removed during sample preparation. It is important to collect sufficient sample for all of the planned analyses, along with sufficient sample to allow procedures to be repeated if necessary. In some cases, excavated occupation surfaces are exposed and lend themselves well to sampling. The archaeologist's grid can help in the sampling. If there are no excavation markers, a permanent reference point with east-west and north-south lines can establish a grid. Geospatial analysis is most effectively conducted if the distance between adjacent samples is the same, and this can be facilitated with an isosceles triangular grid (Figure 1).

The type of sampling bag to be used should be carefully considered. In either the field lab or the formal laboratory setting, the analyst is going to remove either the full contents or only part of the material repeatedly. We have found heavy (0.064 mm thick) plastic bags to work best if they must be opened and closed several times. Sandwich bags or light-duty plastic bags tend to leak, they do not stand up, they do not facilitate vigorous mixing, and they generally do not survive a bank of soil preparation and analysis procedures.

Soil sample preparation

For geochemical concentration data to be accurate, soil samples need to be air-dried, crushed, and sieved to remove rocks, roots, and non-soil debris. Soil samples should be corrected for air-dry moisture content, which can be done by weighing the sample and oven-drying it at approximately 105 °C to constant weight (generally 12–24 h depending on size of the sample). The field lab is unlikely to have access to a drying oven; therefore, upon return to the formal laboratory, the air-dry and oven-dry weights should be determined so that moisture correction factors can then be applied.

In a field lab, a few mortars and pestles can facilitate crushing of dry soil aggregates, using care so as not to crush stones and non-soil debris greater than 2 mm in diameter. A 2-mm (#10-mesh) sieve is used to remove this debris. No further grinding or sieving should be required for field lab analyses. In our laboratory, samples are air-dried for a couple of days on clean sheets of office paper. Samples are either crushed and sieved at this time or returned to the original bag to await further processing.

Field laboratory measurements

In all tests for soil P, care must be taken to avoid contamination by hands, rubber stoppers, or detergents that might contain phosphate. Phosphate-free detergent is used to clean all glass and plasticware. In some cases, it may be necessary to rinse laboratory ware with 1 M HCl to eliminate P contamination.

Spot tests

The spot test for field P analysis was described by Eidt (1973). Briefly, the procedure calls for about 50 mg of fresh or prepared soil to be placed in the center of a filter-paper disk. Two drops of reagent A are added without touching the soil with the dropper tip (Eidt, 1973). After 30 s, two drops of reagent B are added. A blue color may appear after 2 min, and readings should be taken before 8 min pass. Visual ratings of the lengths and intensities of blue lines and rings are judged to give P ratings of none, weak, regular, good, or strong. The phosphorus spot test is simple and inexpensive, but the results are not quantitative. Values are affected by sample size, color perception of the analyst, and temperature, as well as other environmental conditions in the field or the laboratory. In addition, the dynamic range of P concentrations determined by the spot test is limited (Terry et al., 2000).

Mehlich III extractable phosphate procedure

Rypkema et al. (2007) adapted a Mehlich III (solution of acetic acid, ammonium nitrate, nitric acid, and ammonium fluoride) extraction method, for infield P prospection. They used a 5-min extraction time and employed syringe filtration with a glass fiber filter. They describe a two-part color development process that mixes 3 ml of extractant with 0.3 ml of a solution of ammonium molybdate and sulfuric acid and 0.3 ml of a solution of malachite green and polyvinyl acid. They reported that both reagent solutions were stable over time and temperature ranges, making them robust field materials. The extractant-reagent mixture develops color from a light yellow-green to a dark green with increasing P levels. Concentrations of P are determined by a battery-operated colorimeter at a wavelength of 620 nm.

Mehlich II extractable phosphate procedure

Terry et al. (2000) adapted a Mehlich II extraction procedure (Mehlich, 1978) for use in a field laboratory for P prospection at the ancient Maya site of Piedras Negras. Ready-mixed Hach reagents (Loveland, CO) were convenient for field laboratory extraction and molybdate-phosphate color development. Phosphorus concentrations were determined with the use of a battery-operated colorimeter. A field laboratory setup is shown in Figure 2.

The following method was used: Two grams of air-dried, sieved (<2-mm) soil sample were placed in one of six 50-ml glass vials attached to a board that facilitated shaking and processing of multiple samples. Once each soil sample was extracted with 20 ml of diluted Mehlich II solution for 5 min, the extractant was filtered and the filtrate collected in clean 50-ml vials. One milliliter of the extract was dispensed to a reaction vial and diluted to 10 ml with deionized water, and the contents of the PhosVer 3 powder pack were added to the vial. The sample was shaken by hand for exactly 1 min, and allowed to stand an additional 4 min for color development. The concentration of P in the samples was determined on a Hach DR 850 colorimeter at a wavelength of 610 nm.

Precautions should be taken with P extraction and analysis in the field lab:

1. Both the P extraction and the phosphate-molybdate and reductant reactions are temperature dependent. We found that once the temperature of the laboratory and the extractant solution exceeded 35 °C, the blue molybdate color appeared even with no phosphate in solution. To resolve this problem in a hot climate region, one should perform the analysis only in an air-conditioned space or in the cool of the morning. In the jungles of Guatemala, we finished our analysis before about 11 AM, as, afterward, the temperatures rose above 35 °C.
2. Another source of error to be avoided is the auto-reaction of the PhosVer 3 crystals. If the crystals are allowed to settle to the bottom of the reaction vial and

Field Geochemistry, Figure 2 The field laboratory set up near Tikal, Guatemala, for Olsen bicarbonate extraction and analysis of soil P.

to remain in proximity to each other, they will auto-react. The blue color will develop even if P is absent from the solution. The way to avoid this potential problem is to dissolve the reagents immediately. The contents of the PhosVer 3 packet can be added to one sample at a time and shaken for 60 s.

The colorimeter reports the percent transmittance of specific wavelengths of light. These transmittance values are then converted to ppm in the reaction solution according to a standard curve. The Mehlich II concentrate solution that is available from Hach Co. contains hazardous acids and thus is prohibited from transport within airline baggage. The reagent can be purchased in foreign countries from Hach distributers, but our experience has been that it takes about 1 year of difficult negotiations before the reagent is imported. As an alternative for use in calcareous soils and lime-stucco floors common to most ancient Maya sites, the Olsen bicarbonate (Olsen and Sommers, 1982) extraction can be successfully used in the place of the Mehlich II extraction.

Olsen bicarbonate extraction

The Olsen procedure was developed for determination of plant available P in neutral to alkaline soils that contain calcium carbonate. The P concentrations extracted by sodium bicarbonate from the soil tend to be lower than with the dilute acid Mehlich extractant, but the results in low P concentration samples compared to samples anthropogenically enriched in P are relative. The advantage of the bicarbonate extraction is that the reagent can be purchased at local markets and pharmacies. The concentration of sodium bicarbonate is 0.5 M and the extraction time with shaking is increased to 20 min. The samples are filtered and dispensed, and color is developed as indicated above. The PhosVer 3 reagents are acidic and will cause effervescence. It is a good idea to relieve pressure occasionally by cracking open the lid of the colorimeter vial and closing again for continued shaking.

Terry et al. (2000) subjected 35 soils of household middens, patios, and pathways from Piedras Negras, Guatemala, to the Eidt spot test, the Mehlich II extraction, the Olsen bicarbonate extraction, and the nitric/perchloric acid total P digestion procedures. While all four procedures identified high soil P levels in household middens and low P concentrations in patio and pathway soils, the Mehlich II dilute acid and the Olsen bicarbonate extraction procedures provided the greatest ratios of midden P concentrations to background P concentrations of 6.7 and 10.6, respectively (Table 1). The midden-background concentration ratios obtained by total digestion and the spot tests were 2.2 and 2.5, respectively.

Trace element analysis of soils

Elevated trace metal concentrations of Fe, Mn, and Cu could be indicative of mineral paints and pigments used in ancient times. Zinc is not a primary mineral pigment but may be present as a contaminant of mineral ores. A more likely source of Zn is the vegetable matter used in households. While Fe, Mn, and Cu are also trace constituents of foodstuffs, these minerals were also specifically collected and used in workshop activities.

Chelates are complex organic molecules that surround and hold in solution metallic ions that would otherwise quickly precipitate. The diethylenetriaminepentaacetic acid (DTPA) chelate extraction method (Lindsay and Norvell, 1978) can be used to solubilize surface adsorbed and slightly soluble trace metals that may be plant available. This method is often used in determining heavy

Field Geochemistry, Table 1 Summary comparison of soil P concentrations from 35 samples determined by four different extraction and total digestion procedures. The samples were obtained from groups O and N at Piedras Negras, Guatemala (Terry et al., 2000)

	Mehlich P mg/kg	Olsen P mg/kg	Total P mg/kg	Spot test Rating 1–5
Maximum	125	65	2,949	5
Minimum	17	5	1,042	2
Mean	33	19	1,854	4
STDEV	19	12	395	1
Background	19	6	1,132	2
Midden sample N6–7	125	65	2,476	5
Midden: background ratio	6.7	10.6	2.2	2.5

The "background" levels of P were determined by averaging 10 % of the samples lowest in concentration. The midden-background ratio was determined by dividing the P concentration of the soil at a known kitchen midden by the background concentration determined by each P analysis method

Spot test rating: 1 = no blue color development; 5 = a continuous ring of strong blue color development

metal contamination of environmental samples, and it is useful in characterizing the metal ions associated with human activities such as food use and mineral use in workshop activities. Unfortunately, the method does not lend itself well to the field laboratory, but if samples are returned to a formal laboratory possessing the necessary equipment, the procedure could be used. The concentrations of Cu, Fe, Mn, Pb, strontium (Sr), Zn, and other elements of interest can be determined simultaneously on the inductively coupled plasma atomic emission spectrometer (ICP-AES).

Portable X-ray fluorescence

The cutting-edge technology of portable X-ray fluorescence (pXRF) could be used to facilitate soil chemical analysis of total mineral elements in a field laboratory (Koester et al., 2003; Hou et al., 2004; Melquiades and Appoloni, 2004; Marwick, 2005; Jozic et al., 2009; Donais et al., 2010; Donais et al., 2011; Coronel et al. 2014). The pXRF instrument not only makes the work of elemental analysis possible in situ or in a field laboratory (Bernick et al., 1995; Radu and Diamond, 2009), but the analysis can be performed more economically and much faster than sending samples to an ICP laboratory facility for analysis. The pXRF is a battery-operated, handheld device that determines total elemental content for elements heavier than calcium. The instrument is about one-fifth of the cost of an ICP-AES and is fully functional in a field laboratory. The device is equipped with a probe window and an X-ray tube that irradiates the sample. The high-energy X-rays can either scatter or be absorbed by atoms in the sample and reradiated as X-rays of specific lower energy in a photoelectric effect. A rearrangement of electrons happens as a consequence of X-ray irradiation, which can cause ionization, or the ejection of an electron from an inner orbital. X-ray fluorescence is the emission of high-energy photons as an electron from a higher orbital replaces the one ejected, allowing the atom to return to normal energy levels. Using this method, concentrations of specific elements of interest can be measured by an X-ray fluorescence spectrometer contained in the device. The determined X-ray energy of the fluorescence is specific for each element (Bernick et al., 1995; Kalnicky and Singhvi, 2001; Jang, 2010), and the amount of radiation released is related to the concentration of an element in the sample (Juvonen et al., 2009).

Unfortunately, the pXRF analysis of soil P is not adequate to differentiate soils with subtle differences in anthropogenic P within activity areas. The energy emitted by P is low, and therefore, the error in P analysis by pXRF is large. In addition, the X-ray energy of P shows up on the shoulder of the energy peak for silicon (Si), so that the large Si content of soils increases the error in P concentration measurement (Coronel, 2011; Coronel et al., 2014). For this reason, it is recommended that one of the extractable P analyses be performed in the field lab. Several scientists are developing protocols for the use of pXRF in situ and in the field laboratory (e.g., Bernick et al., 1995; Kalnicky and Singhvi, 2001; Carr et al., 2008; Jang 2010; Martín Peinado et al., 2010; Coronel, 2011; Zhu et al., 2011; Davis et al., 2012; Weindorf et al., 2012a; Weindorf et al., 2012b; Coronel et al., 2014).

For pXRF analysis under ideal laboratory conditions, it is recommended that dry soil samples be ground to pass a -100-mesh (<0.149-mm) sieve and that the sample be contained behind 0.0036-mm plastic film (USEPA, 2007; Jang, 2010). In the field lab, it is more feasible to air-dry, crush, and sieve soils to 10 mesh (<2 mm) than to spend the time and labor to grind the samples to 100 mesh. Coronel and colleagues (2014) found no significant difference in the pXRF analyses of Ti, Fe, Cu, and Zn in samples crushed to pass either 10-mesh or 100-mesh sieves. Concentrations of Sr and Zr were attenuated by approximately 10 % when samples passed only a 10-mesh sieve. Prepared samples can be poured onto a 0.0036-mm film atop the pXRF window to a depth of 1–2 cm for an analysis time of 120 s. Compared to oven-dry samples, the X-ray signals from air-dry soil (about 96 % solids) were reduced by approximately 8 %, while elemental concentrations in field-moist soils (about 82 % solids) at approximately −33-kPa (−0.33-bar) moisture potential were attenuated by 11 %.

Further improvements of in situ protocols are needed, and more robust and less cumbersome pXRF instruments should be developed. Soil moisture and soil heterogeneity of in situ samples increase the error rate of pXRF measurements, but these error rates do not preclude the use of pXRF for qualitative and semiquantitative comparisons. In situ measurements could prove useful in initial screening of samples or in prospection for archaeological features. Deposition of workshop minerals, stucco floor materials, and the leveling of land surfaces by ancient people often change the elemental content of surface soils and of deposition horizons sufficiently that in situ measurements could prove useful. Sample preparation and pXRF measurement in the field laboratory produce reliable data for activity area analysis of ancient human activities.

Summary

The high surface area and chemical properties of soil particles allow the soil medium to preserve a geochemical record of human activities from ancient times to the present. The carbon and nitrogen components of perishable food and other household and workshop items decompose and are lost as gaseous and soluble substances, but P and certain trace nutrients, including Fe, Cu, Mn, and Zn, are adsorbed onto soil particles or precipitated as insoluble compounds and can remain for centuries. These geochemical residues serve as invisible artifacts. Soil geochemical methods are used in archaeology to locate ancient sites based on geochemical concentrations and help in the interpretation of ancient human activities. Spot tests, chemical extraction, and sample digestion procedures have been used to determine areas enriched in phosphate by ancient activities.

Protocols for portable X-ray fluorescence (pXRF) use in the field are being developed to facilitate soil chemical analysis of total mineral elements. In situ pXRF measurements could prove useful in initial screening of samples and in prospection for archaeological features. Unfortunately, the low-energy X-ray fluorescence from P and the interference of X-rays from soil Si render high-error and low-quality data for total soil P concentrations. However, chemical extraction procedures and battery-operated balances and colorimeters facilitate the collection of useful, high-quality P data from archaeological soils and floors in the field laboratory. The combination of appropriate sample preparation, chemical extraction of soil P, and pXRF measurement of metallic elements in the field laboratory produces reliable data for activity area analysis of ancient human behavior.

FIELD SURVEY

John Bintliff
School of Archaeology, Classics and History, Edinburgh University, Edinburgh, UK

Definition and introduction

Archaeological field survey refers to the systematic study of the surface traces of past human activity in the landscape (see also entry Landscape archaeology). The most common forms of such evidence are broken pottery and stone tools, but in protohistoric and historic societies, visible remains range from fragments of art through house foundations to standing monuments such as hillforts and temples.

Field survey

During the fifteenth to nineteenth centuries, landscape mapping of the more substantial forms of surface remains was the dominant aspect of archaeology, with excavation being much rarer and less sophisticated. Even after the development of scientific forms of excavation by the early twentieth century, wider research in the total landscape has remained of equal importance for compiling maps of past human activity in the countryside. This is due to the early recognition that the density of archaeological sites is far greater than the capacity of archaeologists to excavate them, especially in areas where human society has a long record of intensive settlement – such as Mesoamerica, the American Southwest, large parts of the Mediterranean and Near East, and Japan. Early collaboration with geographers, especially in the first half of the twentieth century, led to a lasting interest in settlement patterns, their evolution over time, and their relationship to the physical characteristics of a region. This also required a spatially wider investigation of human activity foci than targeted excavation or chance discoveries could provide (e.g., Fox, 1923).

The methodology of field survey has continuously improved in complexity over time, and practitioners are still in the process of evolving a rigorous and agreed-upon set of practices. It is typical even today for field survey projects to continue experimenting each year and for considerable diversity in approaches to occur among projects. Initially, "topographers" travelled extensively into the countryside, often with ancient texts in hand when historic sites were mentioned or with advice from local villagers as to where "remains" of all kinds were known. Recording began with ruins and earthworks in the early centuries, supplemented by coins and sculpture, but by the late nineteenth century, the importance of the everyday, and far more plentiful, human traces such as potsherds and stone tools was realized, as such finds allowed a far greater range of sites to be discovered while providing the primary means – still true today – of dating the periods of time in the past during which a given findspot was in use.

This new phase of survey history, with its focus on pottery and lithics backed up by the evidence of ruined structures where preserved, was practiced with what today would be called "grab samples": small collections of hopefully diagnostic artifacts that would provide chronological information and some idea of site function for a findspot (e.g., settlement, burial, temporary activity in the landscape such as a hunting stand, or seasonal farming base). Moreover, the coverage of a region was still "extensive," and surveyors ranged over large areas in vehicles or on foot, gaining a general impression of the kinds of site to be encountered and the overall balance of activities from phase to phase. By the 1950s, major programs of regional survey were set in motion in different parts of the world, each conceived with a conscious intention to tackle specific historical problems. What set these projects apart from most earlier endeavors was their large scale, the deliberate inclusion of a range of complementary disciplines in addition to archaeology, and the "problem orientation" planned within a regional framework. Among the most noteworthy, during which chosen sites were also excavated on occasion, were (1) the team led by Robert Braidwood (Braidwood, 1937; Braidwood et al., 1983) researching the origins of agriculture in the Fertile Crescent of the Near East, followed by (2) Robert McCormick Adams's (1965, 1981) studies of the long-term settlement development of later prehistoric to historic Southern Mesopotamia, (3) the Valley of Tehuacán project of Richard MacNeish (1967–1972) (also particularly focused on the development from hunter-gatherers through the earliest maize farmers to the rise of civilization), (4) the South Etruria Survey led by John Ward-Perkins (Potter, 1979), and (5) the Messenia Project directed by William McDonald and Richard Hope Simpson (McDonald and Rapp, 1972) (see entry Minnesota Messenia Expedition (MME)). As these pioneering major projects proceeded, experiments were conducted with more systematic site-mapping and artifact collection procedures commensurate with the quantitative emphasis of the "New Archaeology," which in the 1960s–1970s urged that survey be brought within the model of experimental science (e.g., Redman and Watson, 1970; Flannery, 1976).

During the 1980s and 1990s, a new generation of regional projects adopted a more complete, "intensive" survey procedure, where each field or artificial study block (sometimes called a transect) in the landscape was walked at close intervals (5–20 m usually between fieldwalkers) so that even small artifact concentrations would be encountered (what this writer dubbed in 1994 the "New Wave" surveys). Visibility measurements were taken in order to control for differential recognition of sites due to the variable density of surface vegetation, and geomorphologists were increasingly deployed on the team to identify areas of likely loss or burial of artifacts due to erosion or colluvial-alluvial processes (e.g., Cherry et al., 1988). In the latter part of this phase, the concept of "non-site" survey emerged in the United States and was more generally adopted; it recognized that the landscape between the activity concentrations termed "sites" often contained significant numbers of dispersed artifacts. It became common to refocus surface survey onto the mapping of individual artifacts across the landscape, with a secondary stage being the identification of the patterns in these total distributions and the variable processes that might have created them. Besides the effects of weather, cultivation, or construction activities, which could shift artifacts out of sites into their immediate surroundings, more distant scatters could be shown to reflect "taskscapes" in the countryside: temporary bases for hunting or farming, mining, etc. An additional category was given prominence by the Near Eastern regional surveys of Wilkinson, where intensive agricultural manuring in certain periods of the past, using undifferentiated domestic rubbish, had resulted in extensive carpets of artifacts across the landscape radiating from settlement sites (Bintliff and Snodgrass, 1988a; Wilkinson, 1989). Although criticized by some, subsequent exhaustive investigations leave little doubt that in some landscapes and usually for restricted periods, massive manuring did indeed occur, with major implications, as Wilkinson argued, for detecting population pressure and ecological sustainability (e.g., Bintliff et al., 2007). Finally, motivated by the pioneer survey of the New World's largest pre-Columbian agglomeration, Teotihuacan (Millon, 1964), it proved possible to survey large urban sites in a relatively short period of one or several seasons (e.g., Bintliff and Snodgrass, 1988b; Bintliff, 2014).

As the shift from a non-site approach to regional survey occurred, awareness was growing that even if conducted on a field-by-field basis, intensive surveys detected only a certain sample of past activity in the landscape. The problem lay in evaluating what was missed and whether there were ways to compensate for such omissions. One filter was already noted: the geomorphological constraints that determined whether surface artifacts and sites could be seen at the present day (van Leusen et al., 2011). Advice from project geoarchaeologists could sensitize surveys to those localities unlikely to provide "windows" into past landscapes, and these might be omitted from study or alternatively (but rarely) probed by coring if remains were expected to be buried. Vegetation cover – grassland or forest – posed seemingly equal hindrances to effective surface survey, but coping methods have included focusing on areas temporarily opened by fire as well as shovel-pit testing, in which numerous small units one or a few meters square are stripped to the subsoil to evaluate buried finds (reviewed by Shott, 1985). On a more archaeological front, the relative survival and visibility of artifacts themselves have been raised as limiting factors in site recognition, i.e., the "hidden landscape" concept (Bintliff et al., 1999), which implies that for some eras of the past, even a handful of surface finds may represent a significant former activity focus.

In the heyday of "New Archaeology" in the 1960s–1970s, it appeared attractive to limit overall landscape coverage, the area of a located site to be studied, or the amount of artifacts to be collected, through an explicit sampling strategy linked to statistical methodologies, such as stratified sampling in which homogeneous subareas (strata) would be identified and sampled independently (cf. Cherry et al., 1978; Renfrew and Wagstaff, 1982). Warnings about such procedures (already in Flannery, 1976) have not prevented their continued use, the central failing being the concept of designing a reliable sample of a larger whole whose properties are unknown. More experiments are required where samples are compared with complete spatial coverage and artifact samples with total surface collection, before such shortcuts can be recommended.

Since the late 1990s and early 2000s, a wider process of rethinking the methodology and interpretative potential of surface surveys has been in operation as a form of "source criticism." Comparative survey analysis, where practitioners review each other's methods, theories, and interpretations and attempt to amalgamate data from separate surveys, is one aspect of this reevaluation (cf. Bintliff et al., 2000; Alcock and Cherry, 2004). Two practical examples are Farinetti's integration of site data from all forms of surface research since the nineteenth century for the central Greek province of Boeotia (Farinetti, 2011) and Gkiasta's overview of the history and results of survey on the island of Crete (Gkiasta, 2008). Another aspect of rethinking survey approaches is the publication of surface survey manuals (e.g., Banning, 2002).

Finally, one can mention a number of extra dimensions to traditional survey which are being increasingly featured in published projects. Some surveys have deliberately worked in terrain not considered ideal for surface survey, such as mountain zones, tropical forests, pastoral lowlands, or dune environments, where a range of additional techniques have been necessary to deal with problems of site detection. Problem periods, or past intervals for which it has proved difficult to find significant numbers of activity foci, have led to predictive modeling based on compiled evidence that isolates landscape characteristics where survey is more likely to recover adequate data (e.g., Paleolithic-Mesolithic sites in semiarid environments, Runnels et al., 2005). Scientific aids have become more frequently used as additional means to study past settlements, such as a battery of geophysical methods to map subsurface features, geochemical soil testing to detect human activity zones, aerial photography, and satellite imaging (e.g., Philip et al., 2005) (see entries Remote Sensing in Archaeology; Geophysics; Electrical Resistivity and Electromagnetism). Geographical information systems (GIS) have brought two contrasting advantages to field survey. First, GIS using palmtops and GPS links can allow accurate and speedy plotting of landscape units under study in the field as well as recording data in real time, and second, GIS can assist the recent interest in the phenomenology of landscape through estimating human navigation potential and the sensory perception of a particular terrain. There remains, however, a considerable lack of experimental evidence on the effects of using different methodologies on the data produced through survey, and many key issues are still uncertain. These issues include (1) the desired size and composition of artifact samples to achieve reliable representativeness for an activity focus (Bintliff, 2012), (2) the best way to reconstruct demographic estimates from survey data, and (3) whether regional surface survey can move from generalized pictures of the long and medium term (thousands to hundreds of years) to detect the dynamism of human settlement at the historical scale of decades or even individual years.

FISSION TRACK DATING

Barry Kohn
School of Earth Sciences, University of Melbourne, Melbourne, VIC, Australia

Definition

Fission track dating is a radiometric method of age determination based on the accumulation within insulating solids of damage trails formed by the spontaneous nuclear fission decay of the uranium isotope ^{238}U.

Principles

The main mode of radioactive decay for the ^{238}U nucleus is α-particle emission; however, about one in every two million decays is by nuclear fission. During fission, the heavy, unstable nucleus splits into two uneven, positively charged fragments. The two fragments are propelled in opposite directions from the reaction site, dissipating their considerable excess kinetic energy in the host crystal lattice. This interaction disrupts the crystal structure creating a single linear damage trail at the atomic scale. The trails cannot be observed optically, but because they are very reactive, they can be enlarged with chemical etchants to become visible under an optical microscope. The maximum size of an etched fission track depends on the physical and chemical properties of the host mineral but is typically about 11–17 μm long and 1–2 μm wide. Although spontaneous fission occurs in other naturally occurring heavy isotopes (e.g., ^{235}U and ^{232}Th), their half-lives are too long to produce a significant number of tracks. The time span over which fission track dating can be applied is very broad and is essentially determined by the areal density of fission tracks preserved in the material of interest. Cultural objects only several decades in age to minerals and glasses, some over a billion years old, have been dated by this method.

Materials and analysis

Uranium is present as a trace element in many of the minor rock-forming minerals, e.g., apatite (calcium phosphate), zircon (zirconium silicate), and titanate (calcium titanium silicate), as well as volcanic glass. As for any radioactive decay process, spontaneous fission occurs with a specific decay rate constant, so that the measurement of the number of tracks and ^{238}U content – determined by either neutron irradiation in a nuclear reactor or by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) – can be used to calculate a fission track age for a mineral grain or glass fragment. Precision of the dating depends mainly on the number of fission tracks counted in mineral grains, as well as in standard glass monitors (where ^{238}U content is determined by neutron irradiation) or from calculated analytical uncertainties (where ^{238}U content is measured by LA-ICP-MS).

Applications

Fission track ages can be applied in two ways.

First, where mineral samples have cooled rapidly and remained thermally “undisturbed” relatively close to or at the Earth’s surface, they may be used to determine absolute ages, e.g., volcanic units, meteorite impact events, and kimberlite emplacement.

Second, at elevated temperatures, tracks may be partially or entirely erased by thermal annealing (repair of track damage), during which they are gradually restored to the ordered structure of the crystalline matrix by progressive shrinkage from each end. For apatite, a commonly studied mineral, most track annealing proceeds progressively between about 60 and 110 °C (but this varies with heating time and chemical composition), with the fission track clock being reset to zero with total track erasure. The annealing temperature range is equivalent to depths between about 2 and 6 km in the uppermost part of the Earth’s crust. By analyzing fission track age and track length information, the thermal history of samples collected at the Earth’s surface or in deep boreholes can be determined. This provides unique information for reconstructing geological histories in terms of processes such as tectonism, fluid flow, and landscape evolution. Fission track thermal history studies have been applied to a wide range of geological problems, e.g., sedimentary basin evolution, sedimentary provenance, structural development of orogenic belts, and continental denudation patterns (e.g., Gallagher et al., 1998; Dumitru, 2000; Gleadow et al., 2002).

Archaeological applications have been related mostly to dating of man-made glasses, ceramics, obsidian, and heated stones (e.g., Wagner and van den Haute, 1992). Because of the long half-life of spontaneous uranium fission and the relative youthfulness of archaeological materials, this often requires large samples with relatively high uranium concentrations. Such circumstances are rare, which limits the archaeological application of fission track dating. Probably the best application to address archaeological questions is where the age of hominin or artifact-bearing strata can be constrained by their stratigraphic relation to datable volcanic units, particularly using zircon (e.g., Gleadow, 1980; Morwood et al., 1998). Fission track dating of unheated obsidian artifacts and their uranium content may be characteristic of a particular source area which, if matched, may provide information on ancient trade routes. Alternatively, if heat has been applied to an obsidian artifact resulting in track annealing, then study of the diameter of etched tracks can be used to determine whether the fission track clock was partially or totally reset, allowing the age of the artifact's manufacture or use to be constrained (e.g., Miller and Wagner, 1981).

FLUORINE DATING

Matthew R. Goodrum
Department of Science and Technology in Society, Virginia Tech, Blacksburg, VA, USA

Synonyms

Fluoride dating; Fluorine absorption dating

Definition

Fluorine dating is a method that measures the amount of fluoride absorbed by bones in order to determine their relative age. Unlike radiometric dating methods, it cannot provide a chronometric (or calendrical) date. Fluorine dating provides only a relative date for bone, revealing whether specimens are older or younger than one another or if they are of the same age (Berger and Protsch, 1991; Lyman et al., 2012).

Fluorine dating relies on the discovery that bone mineral, calcium hydroxyapatite, will absorb fluoride ions if, during burial, it is exposed to groundwater that contains fluoride. Groundwater and soil in most parts of the world contain small amounts of fluoride, and these ions can replace the hydroxyl ions in bone mineral to form fluorapatite. In this way, the chemically unstable $Ca_{10}(PO_4)_6(OH)_2$ is gradually replaced by the more stable $Ca_5(PO_4)_3F$. Bones absorb fluoride over time, and as a result, those that were buried long ago will contain more fluoride than those buried more recently. However, since fluoride concentrations vary significantly in different geographical areas because of sediment chemistry as well as sediment hydrology, this method is reliable only when bones from the same location are compared. Furthermore, bone density and size also affect fluorine absorption, so not all types of bone in a skeleton will absorb fluorine at the same rate. Thus, caution is required when employing this method, and for these reasons, as well as the development of other dating methods, fluorine dating fell out of common use over the last half century.

History

In the 1890s, the French paleontologist Emile Rivière solicited the assistance of Adolphe Carnot, a chemist at the School of Mines in Paris, to test human bones he had excavated along with Pleistocene animal fossils in caves near the town of Menton in southern France in order to determine if the human and animal bones were of the same age. Carnot developed techniques for measuring the fluorine content of fossil bones and conducted tests to demonstrate the validity of his new fluorine dating method. Carnot's method was successfully used in the 1890s to settle questions about the relative ages of contested human fossils found with Pleistocene animals, but the method soon fell into disuse. The English geologist Kenneth Oakley reintroduced the method in 1947 and later used it to resolve the contentions problem of the Piltdown Man fossils. Charles Dawson originally collected the skull fragments and partial jaw bone of Piltdown Man in southern England between 1908 and 1912. This presumed ancient hominin was greeted with great excitement in Britain, yet from the start there were doubts about the antiquity of the fossils and whether the jaw and skull bones belonged to the same creature. Oakley collaborated with chemist Randall Hoskins to test the Piltdown finds and eventually showed that the jaw was significantly younger than the skull bones and that both were younger than the

Pleistocene animal fossils found nearby. The fluorine dating method contributed to other evidence that convincingly demonstrated that the Piltdown fossils were a forgery. More importantly, Oakley used this method to settle disputes over other contested prehistoric human fossils (Goodrum and Olson, 2009).

FORENSIC GEOARCHAEOLOGY

J. M. Adovasio
Research Programs/Services, Florida Atlantic University–Harbor Branch, Fort Pierce, FL, USA

Definition

Forensic Geoarchaeology: The application of multidisciplinary, high-resolution analytical techniques from geology, archaeology, physical science, and earth science in the examination, recovery, and interpretation of outdoor crime scenes.

Introduction

Prior to the early 1980s, forensic geoarchaeology essentially did not exist. While the geological "context" of outdoor crime scenes had been scrutinized to varying degrees for more than a century, the use of high-resolution, geoarchaeological analytical protocols in forensic applications was unknown. The genesis of forensic geoarchaeology as a subdiscipline took place as a result of an unusual turn of events. A particular series of geoarchaeological evaluations of criminal evidence, narrowly circumscribed in time, illustrated their power in revealing information useful in a court of law.

In the late spring of 1984, the author was contacted by the then state archaeologist of Utah, D. Brigham Madsen, who inquired into the excavation protocols and attendant analyses conducted during the excavations at Meadowcroft Rockshelter, Washington County, Pennsylvania, in the 1970s. The protocols had been initiated and refined by James Adovasio, Jack Donahue, and Gary Cooke as tools in the investigation of the deeply stratified, multicomponent closed site located on an unglaciated portion of the Allegheny Plateau approximately 46 km southwest of Pittsburgh (Figure 1). From its first season in 1973 to the present, this locality has been the focal point of an intensive multidisciplinary, research project that has generated hundreds of publications and technical papers. Long famous, or infamous, for the controversial dating of its early occupational components, the site is equally well known, albeit in much smaller circles, for the extreme rigor and great precision of the excavation, analytical, and documentary methodologies employed. Unlike the age of the earliest deposits, these protocols were never the subject of any debate.

Of greatest interest to the Utah state archaeologist were the techniques used to excavate and characterize the many microstrata which composed most of the 11 major depositional units at the site (Figure 2). In some cases, these microstrata were thinner than a trowel blade ($\sim$1.35 mm) and were often tediously excavated with single-edged razor blades. Moreover, they represented, in depositional terms, just moments in time. By 1984, many of these microstrata had been subjected to a battery of macro- and micro-sedimentological analyses involving both conventional (i.e., sieve based) grain size study and rigorous instrumental compositional analyses. Among the latter were Coulter counter-based quantification of silt-sized materials (which represented the first use of this technique in North American closed site archaeology), a variety of geochemical assays, and even scanning electron microscopy (SEM) of individual sand grains. The original purpose of these analyses was to provide objective verification of the subjectively perceived differences between these microstrata in order to elucidate subtle changes in the depositional history of the site. Each microstratum had a distinctive suite of physical and geochemical attributes, i.e., each had a unique microsedimentary signature.

The Utah state archaeologist was interested to know whether the rigorous and detailed analyses conducted at Meadowcroft Rockshelter could be applied to legal cases in a forensic evidentiary capacity, and the results of several first "trials" represented the "birth" of forensic geoarchaeology.

Forensic applications

The main task in 1984 was to exploit the analytical techniques used to discriminate the Meadowcroft microstrata in the cause of helping to adjudicate ARPA violations. ARPA refers to the Archaeological

Forensic Geoarchaeology, Figure 1 General view of the new protective structure/visitors platform at Meadowcroft Rockshelter. The work here has directly led to the development of the forensic geoarchaeological techniques discussed in this entry.

Forensic Geoarchaeology, Figure 2 General view of some of the microstratigraphy at Meadowcroft Rockshelter.

Resources Protection Act of 1979, enacted to protect sites and other cultural remains on public and Indian lands from vandalism and theft. The "test case" that would become the template for all future applications was USA versus Earl K. Shumway, a notorious and, to some, a near mythic figure in the history of archaeological looting in the Greater American Southwest.

Horse Rock Ruin litigation

In April of 1984, E. K. Shumway of Blanding, Utah, plundered a cache of 28–32 Pueblo III coiled and plaited baskets from Horse Rock Ruin, in the Monticello Ranger District of the Manti-La Sal National Forest, San Juan County, Utah. Horse Rock Ruin lies within an area locally known as Jack's Pasture. The USDA Forest Service recovered about one half of the collection, which was used along with other evidence in the subsequent indictment of Shumway on 14 November 1984.

Shumway maintained that the baskets in question were ethnographic materials and did not derive from a site on federal property but rather from a site or sites on private land (which would not have been an ARPA violation). This claim has become the standard alibi in virtually all similar ARPA cases. The baskets were sent to the author for evaluation, and our collective cooperation was solicited in demonstrating that these items did, in fact, derive from Horse Rock Ruin (Donahue and Adovasio, 1986). The procedures are described in the following paragraphs.

Detailed attribute analysis of the basketry clearly demonstrated that, contrary to Shumway's claim, the items were all of Pueblo III Anasazi (or, in contemporary jargon, Ancestral Pueblo) ascription and, in fact, probably represented a single aboriginal caching event from the thirteenth century (Adovasio and Andrews, 1990).

In order to establish the provenience of the baskets, a wide range of sediment samples was obtained and analyzed. These samples included sediments from the Horse Rock Ruin itself, the roof and walls of the alcove immediately contiguous to the suspected location of illicit digging, and other nearby alcoves. Small samples were extracted from the recovered baskets, and additional surface samples taken from federal and private lands were also included for comparison.

Eighty-five sediment samples were analyzed in all, including 9 from the baskets, 58 from the Horse Rock Ruin site and contiguous alcove, 8 from four other alcoves, and 2 from open locations in the Jack's Pasture area. Interestingly, though Shumway had carefully cleaned the baskets, sufficient sediment remained under the stitches or between the plaiting elements to permit removal of enough material for analytical purposes. Indeed, the great advantage to some of these analytical techniques is that they require less sediment than normally accumulates under a gardener's fingernails.

All bulk samples were sieved through a 1 mm screen to remove coarse sand and pebbles, and the sifted fraction was then passed through a riffle sample splitter to obtain a representative subsample weighing less than 10 g. These samples were then crushed via mortar and pestle and transferred to sample cups covered with Mylar for analysis by energy dispersive X-ray fluorescence (XRF).

The X-ray fluorescence analysis detects elements heavier than aluminum and was performed on a Tracor Northern Spectrace 440 spectrometer. Two scans were made: one at 20 kV and 0.1 mA and the other at 35 kV and 0.1 mA with a thin molybdenum window to block out most of the direct signal from the molybdenum X-ray tube. The spectrum at each setting was recorded for 100 s. The individual spectral lines for the elements were identified, and their intensities were recorded. United States Geological Survey standards were also analyzed to provide calibration coefficients for the calculation of element concentrations from the intensity data. Selected samples were also analyzed by X-ray diffraction (XRD), a method which identifies the mineral phases in which the elements occur. The diffraction analysis was run on a General Electric XRD-5 unit with a copper X-ray tube at 35 kV and 15 mA. Medium resolution slits were used and a scanning rate of 2.2 was employed.

The XRF analysis detected the presence of the following elements: aluminum, silicon, sulfur, chlorine, potassium, calcium, titanium, manganese, iron, copper, zinc, bromine, arsenic, rubidium, strontium, and zirconium (Table 1). Copper, bromine, and arsenic were detected in only a few (less than ten) samples and seemed to show no specific trend in their occurrence. Aluminum was detected in about one third of the samples but is probably present in all of them; the detection capability of XRF for aluminum (and light elements such as magnesium, sodium, and carbon) is extremely poor, and because of this, no attempt was made to determine the actual amount of aluminum present in the samples. Zirconium concentrations were also not determined exactly. Imprecision in the analysis of the latter element results from the interface of the molybdenum X-ray tube peaks with the zirconium peaks.

Concentrations of elemental silicon, potassium, calcium, sulfur, chlorine, manganese, titanium, iron, zinc, strontium, and rubidium were also used to calculate their oxide content. The difference between the sum of these elements and oxides and 100 % represents the missing elements: carbon, sodium, magnesium, and aluminum, which were not included due to poor detection.

The XRD analysis showed quartz (SiO_2) to be the dominant mineral in all samples together with various clay minerals (containing potassium, magnesium, silicon, aluminum, oxygen, and hydrogen), K-feldspar ($KAlSi_3O_8$), calcite ($CaCO_3$), and gypsum ($CaSO_4\ 2H_2O$) present in lesser amounts. The mineral dolomite ($CaMg(CO_3)_2$), various iron oxides, halite, and polyhalite may also be present in some of the samples in very small amounts. The XRD analysis combined with examination of bivariate cross plots of the elemental data allowed the determination of which elements were associated with the various mineral phases (Table 1). These were as follows: silicon (associated with quartz, feldspar, and clays); potassium (associated with clays, feldspar, and polyhalite); calcium (associated with calcite, gypsum, and dolomite); iron (associated with clays and iron oxides); titanium (associated with clays and iron oxides); chlorine (associated with halite); sulfur (associated with gypsum

Forensic Geoarchaeology, Table 1 XRF analysis results for sediment samples collected from Horse Rock Ruin, Monticello Ranger District, Manti-La Sal National Forest, San Juan County, Utah

		Associated with									
Element	Comment	Quartz	Feldspar	Clays	Polyhalite	Halite	Gypsum	Dolomite	Calcite	Iron oxides	Carbonates
Al (aluminum)	Poor detection

Cu (copper)	Variable										
Br (bromine)	Variable										
As (arsenic)	Variable										

and polyhalite); zinc (associated with carbonates); strontium (associated with clays, calcite, and gypsum); rubidium (associated with feldspar); and manganese (associated with quartz and feldspar).

Further examination of the bivariate plots of the elemental data showed that the sediment samples from the various sample groups tended to cluster in relatively tight configurations. This clustering is caused by the degree of similarity within each sample group. Examination of the bivariate plots for different elements demonstrated that the degree, or tightness, of clustering was best demonstrated by the elements calcium, potassium, chlorine, and sulfur. All these elements were present in mineral phases associated with the soluble portion of the sediment (calcite, gypsum, and polyhalite). These minerals precipitate within any pore space, and one would expect their abundance to be controlled primarily by the groundwater chemistry of the specific location from which they were collected. The abundance of the four elements (calcium, potassium, chlorine, and sulfur) was used in a computerized multivariate statistical analysis to determine the degree of similarity among the various sample groups.

The four variables (calcium, potassium, chlorine, and sulfur) were converted to standardized scores by subtracting the mean of a variable from each value for that variable and dividing the result by the standard deviation of that variable. These standardized scores were the basis for calculating a Euclidean distance between each pair of the 85 sediment samples analyzed. These Euclidean distances represented how like or unlike each pair of samples was in terms of the four variables measured. Because their values were first standardized, each of the four variables contributed equally to the distance measurement.

Results of the statistical analysis clearly indicated that the sediment adhering to the interstices of the coiled and plaited baskets was most similar, if not identical, to the sediment samples from the Horse Rock Ruin site and contiguous alcove. The sediment samples from the other alcoves and open sites were clearly dissimilar. On 17 January 1986, Shumway pleaded guilty to the ARPA violations in federal court in Salt Lake City, Utah.

Tin Cave litigation

In a second and, in some ways, more egregious case (USA vs. Ralph Cortiana), R. Cortiana was indicted in 1987 for attempting to sell a Native American infant mummy to an undercover federal agent for $35,000. Cortiana had looted the mummy with a wealth of accompanying grave goods from Tin Cave on the Tonto National Forest near Roosevelt Lake, northeast of Phoenix, Arizona (Donahue and Cooke, 1987).

At the request of the US Attorney's office in Phoenix, the author and the late R. L. Andrews examined the mummy and associated grave goods and determined that they were either of Hohokam or Salado ascription. Additionally, a radiocarbon assay was processed on a fragment of deerskin (*Odocoileus* sp.) associated with the mummy. This assay yielded a date of $1350 \pm 25\,^{14}C$ yr BP.

In order to obtain a definite link between the despoiled remains and the suspected site of vandalism, sediment samples adhering to the body and the mummy's grave goods were removed, and three additional sediment samples were collected by the author from the floor of Tin Cave itself. Each Tin Cave sample was collected from a different location within the cave, including the alleged burial pit, in order to ascertain if different portions of the surface evidenced distinctive geochemical signatures (Donahue and Cooke, 1987).

The samples initially were examined via optical binocular microscopy. Microscopic examination revealed that the larger size fraction of each sample consisted of highly variable amounts of organic detritus and rock fragments. In order to eliminate this highly variable coarse material, the samples were dry-sieved, and the fraction containing particulate sizes smaller than 63 μ – that is, 63 micrometers (μm) or 0.063 mm – was retained for further analysis. Two analytic methods were then employed to characterize the samples.

Mineral composition of the samples was determined by X-ray diffraction (XRD) analysis. The diffraction analysis was again run on a General Electric XRD-5 unit with a copper X-ray tube at 35 kV and 15 mA. Medium resolution slits were used, and a scanning rate of 2.2 was employed. Bulk mineralogy was determined from a 63 μ-or-smaller sample that was mixed with an aluminum metal internal standard and ground to a finer grain size with a mortar and pestle. Each sample was sifted onto a Vaseline-coated glass slide and was then X-rayed using standard analytical procedures. Clay mineralogy was determined by examining an organic-free, oriented mount of a less than 3 μ size fraction from each sample. The organics were removed from each sample by digestion in sodium hypochlorite. The less than three micron size fraction was obtained from each sample by gravity settling in an aqueous medium. A slurry of this <3 μ size fraction was then placed on a glass slide. After drying, the sample was saturated with ethylene glycol and X-rayed using standard procedures. The samples were then heated to 300 °C and 500 °C, with X-ray patterns obtained after each heating.

Chemical composition of the samples was determined by X-ray fluorescence (XRF) analysis. The fluorescence analysis, which as noted above identifies elements heavier than aluminum, was run on the same Tracor Northern Spectrace 440 unit. Splits of the <63 μ size samples were treated by ignition of the sample to 1000 °C in order to decompose organic and inorganic carbon. During ignition, weight loss of each sample was determined at 110 °C, 550 °C, and 1000 °C. These values indicate the mass of absorbed water, organic carbon, and inorganic carbon content, respectively, that had been lost through ignition. Each sample was then crushed in a mortar and pestle and transferred to sample cups covered with Mylar. For XRF analysis, two scans were run for each sample, one at 20 kV and 0.1 mA and the other at 35 kV and 0.1 mA, each with a thin molybdenum window to block out most of the direct signal from the molybdenum X-ray tube. The spectrum at each setting was recorded for 200 s. The individual spectral lines for each element were identified, and their intensities were recorded. United State Geological Survey standards were also analyzed to provide calibration coefficients for the intensity data in order to determine element concentrations. These concentrations were then normalized to 100 % of the <63 μ size ignited sample.

Analysis by XRD determined that the following minerals were present in all four samples: quartz, calcite, feldspar, apatite, whewellite, and the clay minerals, smectite, illite, and chlorite. After identification of mineral phases, the amount of each mineral was estimated from the intensity of major peaks and the internal standard method of calculation. Correction factors to convert from peak intensities to mineral percentage were determined by running pure mineral/aluminum mixtures. The resulting percentages were normalized to 100 %. Because no pure sample of the rare mineral whewellite (hydrous calcium oxalate or $CaC_2O_4 \cdot H_2O$) was available, a ratio value was determined by comparing the whewellite peak to the aluminum internal standard peak. In addition, clay mineral percentages were determined by using clay standards to derive correction factors in order to calculate the amount of each clay mineral.

Although some difference occurred in the percentage values, the mineral composition of all four samples was the same. All of the samples contained quartz, feldspar, calcite, and the clay minerals, smectite, illite, and chlorite. This is not surprising as these minerals are commonly found in sediments. Detailed analysis of the clay minerals, however, revealed several distinctive characteristics that all four samples had in common.

The dominant clay mineral assemblage was a mixture of illite and smectite. Lesser amounts of chlorite were present. No kaolinite, a relatively common clay mineral, was detected in any of the samples. During XRD analysis of the bulk sample (<63 μ fraction) from each of the four samples, the position of the smectite 001 reflection suggested that this clay predominantly contains calcium rather than sodium in the exchange positions. This indicates a calcium-rich environment for both the Tin Cave sediments and the sediment collected from the mummified infant.

In the detailed clay mineral XRD analysis (<3 μ samples) of all four sediments, the smectite also showed unusual behavior when it was heated. Smectite, a swelling clay, usually loses its water and collapses when heated to 300 °C for 1 h. In the four samples, however, the smectite only partially collapsed at 300 °C. Complete collapse of the smectite occurred only upon additional heating to 500 °C. Although the precise cause for this unusual behavior was not determined, it is very likely that it is identical in all four samples. This further suggests a common source for all four samples.

The occurrence of apatite in all of the samples is also suggestive of a common origin for all of them. Apatite is frequently found in association with organic material, especially bones and teeth, and thus it can be expected in the Tin Cave setting. Most unusual, however, is the occurrence of the mineral whewellite, which is extremely rare. We have found only two documented occurrences in the USA. These are in concretions in the Devonian Huron black shales of Ohio and in some modern peat bogs located in Florida. Whewellite appears to be associated with the alteration of woody organic detritus in a neutral to basic, calcium-rich environment.

The XRF analysis detected the presence of the following elements: silicon, calcium, aluminum, iron, potassium, manganese, titanium, zinc, strontium, copper, and rubidium. Examination of both the mineral and chemical data makes it possible to assign the elements and their oxides to the minerals in which they occur. The chemical data, coupled with their associations, provided the basis for a statistical analysis of the Tin Cave and mummified infant soil samples. In particular, the association of the trace elements (Rb, Sr, Zn, Cu, K, Ti, Fe, and Mn) with the clay minerals formed the basis for generating a series of ratios to be used in statistical analysis. Once again, Euclidean distances were calculated between the samples, and the results conclusively showed that the soil adhering to the mummified infant was essentially identical to the samples from Tin Cave.

Cortiana elected not to plead out in this case, though the defense inexplicably stipulated to the damning geoarchaeological evidence. He was eventually found guilty in the first ARPA case involving forensic sedimentology to be argued before a jury.

Site 206 litigation

Since these first forays into the use of forensic sedimentology both involved closed sites (i.e., a cave, rock-shelter, or architectural alcove), it was decided that the logical extension of this line of evidence collecting and analysis was to employ the same protocols in a case involving open site vandalism. This posed special problems that required the use of additional highly sensitive techniques not employed in earlier cases.

The suspect in the first open-site case, W. E. Sherman, was alleged to have removed artifacts from a Pueblo-style aboriginal surface structure on an archaeological site designated AR-03-06-07-206 (hereafter called Site 206) located in the Gila National Forest in New Mexico (Donahue et al., 1990). Sherman claimed the seized materials derived from private land located very close to the suspected locus of looting. This parcel of property contained two prehistoric sites (hereafter called Sites 1 and 2) which had also been looted. Later, Sherman changed his story and suggested the seized material came from a third site also located on private land a considerable distance from Site 206. This site was designated XSX.

In order to tie Sherman's artifacts to Site 206, the suspected location of the theft, evidence was sought and scrutinized from four compositional classes of samples. These included bedrock samples, soil samples, daub samples, and fired aboriginal potsherds. Bedrock and soil samples were provided by the USDA Forest Service and/or collected by the author from a series of archaeological locations within or adjacent to the Gila National Forest, New Mexico. Soil was also removed from the hand tools and clothing found in Sherman's possession and possibly used in the vandalizing of Site 206. Finally, soil was collected from the inner surfaces of ceramics also found in Sherman's possession, and the ceramics were seized as well.

The soil samples specifically include four samples manually collected by USDA Forest Service personnel from a vandal's pit, which was designated as Hole 6 and located within an aboriginal structure on Site 206. One sample derived from the subfloor of floor feature #7, while three samples were extracted from the modern ground surface and at depths of 30 cm and 61 cm below the modern ground surface of Hole 6, respectively.

Soils collected by the author from Site 206 included three samples from the same room sampled by USDA Forest Service personnel, but these were obtained from the buried undisturbed walls rather than the mechanically turbated fill of this structure. The samples were manually removed by trowel at depths of 50–60 cm, 60–70 cm, and 80–90 cm below modern ground surface, respectively.

The USDA Forest Service also provided soil samples from three other locations, including one each from Site AR-03-06-07-205 (hereafter called Site 205) on federal property and two sites designated Sites 1 and 2 on private land. The USDA Forest Service Site 205 sample was collected from an aboriginal structure fill at a depth of 20 cm below modem ground surface as were the general soil (i.e., non-structure fill) samples from Sites 1 and 2. In addition, the author collected two samples from the site designated as XSX and located on private land directly adjacent to the Gila National Forest. These samples were taken via trowel from gravel fill at depths of 10 cm and 14 cm below modern ground surface, respectively.

The samples provided by the USDA Forest Service from Sherman's hand tools and clothing include soil samples from an ice pick, a shovel, and a pick ax. The sample from the clothing was principally derived from the pockets of a pair of coveralls.

The last suite of soils included three samples provided by the USDA Forest Service representing scrapings of fill derived from the inner surfaces of aboriginal ceramic vessels found in the possession of the alleged pothunter.

A number of daub samples were collected by the USDA Forest Service personnel and the author; they include two specimens from Site 206, one from Site 1 and one found in the possession of the alleged pothunter.

Finally, the ceramic samples provided by the USDA Forest Service included two conjoining ceramic sherds from Site 206. The two sherds conjoin a third sherd recovered in the possession of the alleged pothunter.

Six different techniques were employed on the samples from New Mexico. These included:

1. Grain size analysis (using sieves for the sand-sized fraction of each sample and Coulter counter analysis for the silt- and clay-sized fractions)
2. Flame emission spectrophotometry to determine abundances of exchangeable and extractable metallic

cations of both major and trace elements including barium, cadmium, calcium, cobalt, copper, iron, lead, magnesium, manganese, nickel, potassium, sodium, strontium, and zinc
3. Flow injection and high-performance liquid chromatography to determine the type and amount of organic material present in the samples
4. Water leach atomic absorption (WLAA) via a Varian SpectrAA 300 unit to determine the type and amount of more water-soluble cations present in the samples
5. X-ray diffraction analysis via a General Electric XRD-5 unit with a copper X-ray tube at 35 kV and 15 mA to determine bulk mineralogy for five mineral phases (quartz, feldspar, orthoclase, microcline, and plagioclase)
6. Computer-controlled scanning electron microscopy (CCSEM)

CCSEM is an analytic technique used to acquire information on the size, shape, and both chemical and mineral composition of individual sediment grains in a soil sample in an automated manner. It is performed by combining three analytic tools under the control of a computer: (1) the scanning electron microscope (SEM), which is widely used in materials science because of its high resolution and depth of field; (2) energy dispersive X-ray spectroscopy (EDS), which adds to the SEM the extra dimension of X-ray microanalysis; and (3) the electron beam control via the digital scan generator, which allows rapid measurement of the size and shape of individual soil grains found in the SEM image.

Finally, thin sections were prepared from the two conjoining ceramic sherds and examined with a Leitz petrographic microscope. This examination allowed characterization and identification of coarser-grained temper (inclusions) as well as characterization of both paste and void space within each sherd.

After a somewhat lengthy jury trial in which, for the first time, the defense produced its own expert witness, Sherman was convicted on all counts.

More recent cases

Since these initial cases in forensic sedimentology, the author and his associates have been involved in a series of ARPA prosecutions, all of which have resulted in plea bargains or convictions. As in the three cases summarized above, in each instance, the accused had vandalized a site or sites on federal property. Additionally, all claimed the purloined artifacts were ethnographic in origin and derived from nearby private land, or they denied culpability completely. Space and time constraints preclude any in-depth discussion of the post W. E. Sherman cases; however, certain salient facts about several of them are worth noting. In the celebrated and highly publicized Polar Mesa case, actually a series of many separate ARPA prosecutions, a group of individuals was charged with vandalizing a number of closed and open localities in the Manti-La Sal National Forest in Utah. The author's participation in these prosecutions was fourfold. Together with the late R. - L. Andrews, we analyzed, described, and validated the prehistoric age of the archaeological materials recovered from two closed sites (42GR383 and 42ML3169) and/or seized from the indicted suspects. Subsequently, the author personally collected sediment samples from one of the vandalized closed site localities and, finally, oversaw the processing, analysis, and interpretation of sediment recovered from the seized artifacts as well as those collected from the location of the theft (Adovasio and Andrews, 1990; Donahue and Adovasio, 1986).

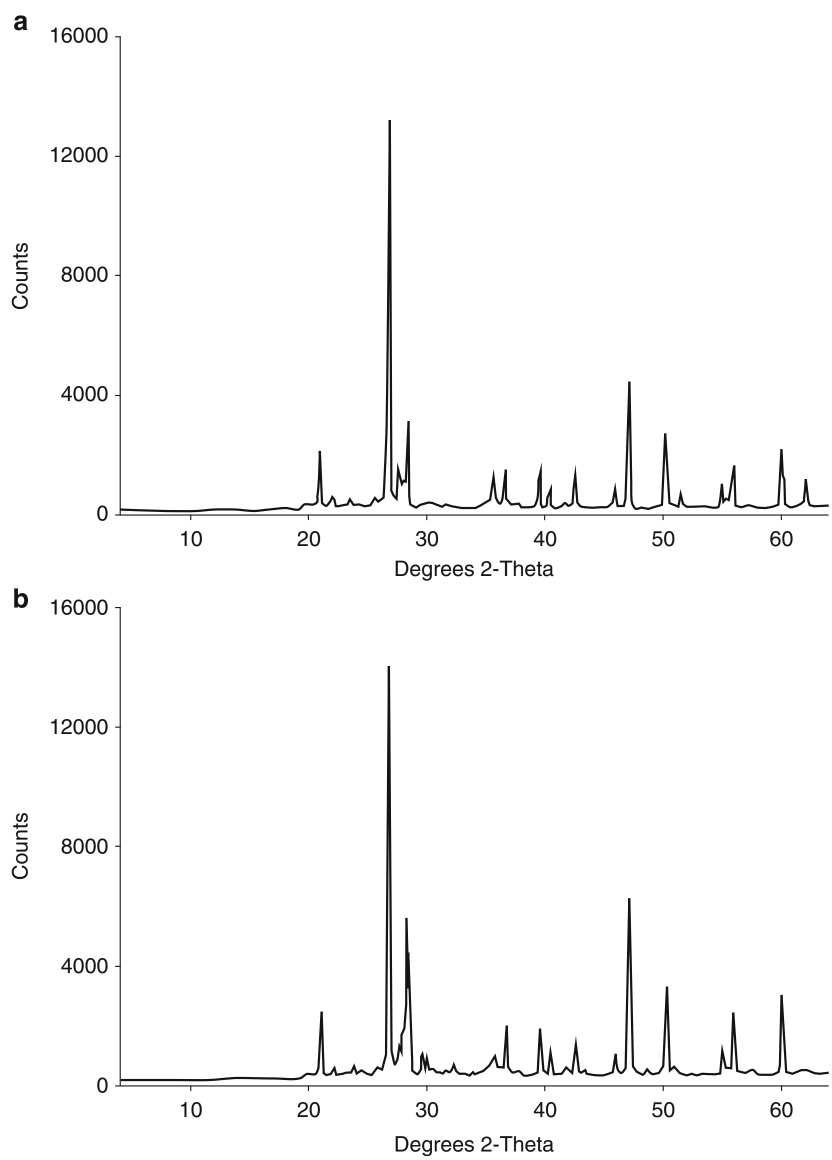
The mineralogical and chemical analysis conducted for these prosecutions involved XRD, CCSEM (with 500 or 1000 particle samples), and water leach chemical analysis employing a SpectrAA 300 Atomic Absorption unit for dissolved cations and a Dionex 2120i Ion Chromatograph for anions. These analyses were performed on two sediment samples from each site and 18 sediment samples from seized artifacts. The results of these analyses indicated that the sediments from both sampled closed sites on Polar Mesa could be readily distinguished from one another and, further, that 12 of the seized artifacts could be matched to site 42GR383. One artifact was matched with site 42ML3169 while another most closely corresponded to that locality. The sediment from four other artifacts derived from other, unsampled, looted localities. As a result of these analyses, a series of plea bargains or convictions were obtained.

In USA versus Tony Maschler and John D. Price, the accused, two Coconino County Sheriff's deputies, allegedly vandalized several locations within Kinnikinnick Pueblo (AR-03-04-05-45) on Anderson Mesa within the Coconino National Forest, ca. 30 miles southeast of Flagstaff, Arizona (Cooke and Adovasio, 2000). In this case, 24 sediment samples of three types were scrutinized: 13 of these derived from tools, gloves, or clothing seized from the suspects; 3 came from seized *Conus* sp. shell "tinklers" (small perforated and truncated cone-shaped shell ornaments); and 7 derived from vandalized rooms at the Pueblo. Analytical methodologies included manual scanning electron microscopy (MSEM) of aggregated particulate using an SEM equipped with an EDS and the capacity to examine the sediment in BEI (backscatter electron imaging) mode. Selected sediments were also subjected to bulk mineralogy analysis via XRD with a Phillips XR6 3100 XRD unit, and then the same samples were subjected to sequential chemical leaches for carbonates, sulfates, and iron oxide/hydroxide. The clay-sized samples from the sequential leaches were also examined for clay mineralogy via XRD.

The results of all these analyses were mutually supportive and conclusively linked the two suspects to the seized artifacts and the location of the vandalism. Both submitted guilty pleas.

The last case to be summarized here, USA versus Jerry Lee Young, represents one of the boldest examples of site vandalism on a grand scale (Adovasio and Illingworth, 2001; Cooke et al., 2001). Young operated a for-profit museum in Jackpot, Nevada, which contained thousands of artifacts, many of which were allegedly removed from federal property in at least three states. In August of 1998, the author and J. E. Thomas collected sediment samples from three of the vandalized properties and subsequently removed sediments from artifacts found in seven seized display cases. Also collected were sediments adhering to a bucket confiscated from Young's property. Young claimed that the bucket was used to mix cement.

In total, 20 samples were analyzed in two stages. In stage I, sediment from one of the vandalized locations was compared to sediment from the seized bucket. XRD was employed to determine crystalline phases in the samples, and CCSEM with EDS was used to determine the chemistry of individual sediment particles. A third sample, also from the seized bucket, was examined via MSEM with EDS to determine if it was cement as claimed by the suspect. In the second stage, the same analytical techniques employed in stage I were used with sediments extracted from selected seized artifacts from the Young Museum. Once again, the results of all of these analyses were conclusive. Sediments from the vandalized sites were readily distinguishable from one another. The bucket samples were not cement and directly linked Young to one of the vandalized sites; five



Forensic Geoarchaeology, Figure 3 XRD plots from the Bob's Cave case, showing: (**a**) the relative frequency of mineral components in a sediment sample from one of the looted localities and (**b**) the relative frequency of mineral components in sediment removed from a bucket found at Young's house. Peaks are unlabeled as to mineral phase represented, but the figure intends to demonstrate only the remarkable similarity between the two sample plots.

of the artifact-derived samples were congruent with an origin in one of the vandalized sites (Figure 3). Young was subsequently convicted of multiple ARPA violations.

Summary

According to local authorities, the successful prosecution of the cases summarized above had an immediate, if perhaps only temporary, dampening effect on pothunting activities in their respective areas. Unfortunately, they also probably led to increased attention by pothunters and dealers to such hitherto ignored considerations as the thorough cleaning of looted artifacts. Tying soil residues to site earth may become more challenging in the future, but the science of proving looted objects to be ancient as opposed to recent ethnographic items and documenting their origin will continue to offer avenues to conviction for illicit collectors. The basic utility of the forensic techniques discussed here remains valid and valuable in the prosecution of antiquities theft.

All of the cases discussed here clearly demonstrate the extreme resolution possible with forensic geoarchaeological analyses, generally, and forensic sedimentology, in particular. In so doing, they also provide in many cases – especially where no other probative information may be available – a very potent weapon in the armamentarium of law enforcement agents.

In retrospect, certain conclusions should be stressed. First, as with the seminal investigations at Meadowcroft Rockshelter, the collection of samples to be retrieved, analyzed, and compared in ARPA prosecutions must be rigorous and very carefully executed. Twenty-five years of experience have demonstrated that mechanically or biologically turbated sediments frequently produce misleading or erroneous results when compared to samples from carefully excavated, undisturbed contexts. Thus, as stressed previously (Adovasio et al., 1991), it is critical that "fresh" (i.e., newly cut) surfaces of walls, profiles, and "floors" be sampled by trained professionals intimately familiar with the nuances of depositional processes (Figures 4 and 5). Second, it is clear from the foregoing that these kinds of laboratory analyses are very time consuming and require sophisticated instrumentation and highly experienced personnel. Hence, they are invariably relatively expensive and should be employed judiciously. Nonetheless, it is clear that the expenditures of time and money have been justified by the success rates in these types of ARPA prosecutions. Third, though the basic field protocols and attendant laboratory analyses have

Forensic Geoarchaeology, Figure 4 A USDA Forest Service employee "facing" a looter's hole in preparation for sampling.

Forensic Geoarchaeology, Figure 5 Clear, labeled stratigraphic sequence within a looter's hole ready for geoarchaeological sampling.

remained strategically constant over the past 25 years, the tactics of recovery and analysis have evolved exponentially. Instrumentation in both field and laboratory contexts is now many technological generations removed from what was employed in 1985–1986, and, if anything, the precision and reliability has only increased. So has the portability of some very potent analytical tools. For example, now there are handheld XRF devices which function essentially like hair dryer-sized implements that permit analysis of sediments and sediment profiles *in the field* with virtually the same accuracy and reliability as tabletop instruments.

It is pertinent to reiterate (and time has corroborated) the author's final comments in Adovasio and Andrews (1990) which described the earliest applications of forensic sedimentology in ARPA prosecutions. It is now possible to detect the equivalent of "fingerprints in the sand," and this capability has become a powerful weapon in the unfortunately unending conflict with those who would destroy the archaeological legacy, not just of Native Americans, but of all people of every cultural heritage.

Despite the proven probity of forensic geoarchaeology in the cases cited above, these techniques have not become common in North America or anywhere else. The author has been the principal investigator of all such cases prosecuted to date in North America. The failure of forensic geoarchaeology to encourage a larger audience of service providers may be attributed to several causes. (1) Thus far all but one of its applications have been in the arcane arena of ARPA cases – a sphere of law enforcement known little, if at all, outside of its practitioners. (2) Even to the initiated, forensic geoarchaeology, it seems overly complex, time consuming, and therefore daunting to many potential practitioners. This is often the case in situations where carefully collected data by qualified, credentialed archaeologists is available for potential analysis. (3) The application of forensic geoarchaeological field and laboratory protocols is not inexpensive. This is compounded by the fact that few field-workers, even in archaeology, have the requisite battery of skills to assess and prepare a site for sampling, and almost none exist in traditional law enforcement agencies. Additionally, the analytical equipment needed for geoarchaeological research is not cheap to acquire and maintain, and it requires expertise to operate and interpret the results of analysis. Perhaps, as the oftentimes spectacular results of geoarchaeological analysis in forensic applications become better known, the problems of poor participation will diminish.

FOURIER TRANSFORM INFRARED SPECTROSCOPY (FTIR)

Francesco Berna
Department of Archaeology, Simon Fraser University, Burnaby, BC, Canada

Synonyms

FT-IR; Fourier transform infrared spectroscopy; Infrared spectroscopy

Definition

FTIR (Fourier transform infrared spectroscopy) is an instrumental technique used to identify the functional groups present in organic and inorganic compounds by measuring their absorption of infrared radiation over a range of wavelengths (Smith, 2011; Margaris, 2014). The FTIR method first collects an interferogram of a sample signal using an interferometer, and then it performs a Fourier transform (a mathematical algorithm) on the interferogram to obtain the infrared spectrum. An FTIR spectrometer, thus, collects and digitizes the interferogram, performs the Fourier transform, and displays the FTIR spectrum. Modern FTIR spectrometers obtain infrared spectra in absorption, total and diffuse reflectance, attenuated total reflectance (ATR), and photoacoustic modes from solid, liquid, or gaseous samples. Typically, only tens of micrograms of a sample are required, and spectrometers can be coupled to microscopes for the analysis of particles as small as 10 μm in diameter. Infrared spectrometers are also available as portable devices and can therefore be used reliably and conveniently on-site.

The Uses

Infrared spectroscopy can identify and characterize both inorganic and organic materials of geoarchaeological interest (Weiner, 2010). This analytical technique, in fact, has the major advantage of being able to identify both crystalline and amorphous minerals (e.g., quartz and opal) as well as many organic materials, including crystalline and "amorphous" inorganic compounds (such as silicates, carbonates, phosphates, sulfates, and nitrates) and organic compounds (such as fatty and humic acids, oxalates, proteins, lignin, cellulose, and graphite). FTIR is very sensitive to compositional and structural changes such as crystallinity and atomic disorder. It is thus particularly useful for the identification of authigenic minerals; the study of biomaterials such as bone, shells, and endo- and exoskeletons of cell tissues (e.g., phytoliths) and microorganisms; and the characterization of charcoal and bone collagen. FTIR is also uniquely suitable for the identification and characterization of pyrogenic calcite and high-temperature silicates; thus, it can be extremely useful for the reconstruction of ancient pyrotechnological activities. FTIR is therefore a very valuable technique for the identification and characterization of the geogenic and biogenic components of the archaeological record, stratigraphic correlations, and the reconstruction of human activities, diagenetic transformations, and site formation processes. By using FTIR microspectroscopy, which couples an FTIR spectrometer to a petrographic microscope, it is possible to perform FTIR analysis directly upon thin sections of intact archaeological materials and sediments, thus allowing the integration in real time of micromorphological, petrographic, chemical, and mineralogical analyses (Goldberg and Berna, 2010). In turn, the data produced by integrating soil micromorphology and FTIR microspectroscopy can yield high-resolution, contextualized information about technology, activities, and site formation processes.

GAS CHROMATOGRAPHY

Ruth Ann Armitage
Department of Chemistry, Eastern Michigan University, Ypsilanti, MI, USA

Synonyms

Gas-liquid chromatography (GLC); Gas-solid chromatography (GSC)

Definition

Chromatography is a method of separating mixtures based on how the molecules interact with an immobilized stationary phase and a mobile phase. It was invented in 1906 by Russian botanist Mikhail Tswett for separating various pigments in plants (thus the derivation of the name: *chroma* = color, *graph* = writing). Separation occurs because each component of the mixture undergoes different intermolecular interactions with the stationary phase through physical adsorption or interactions between the uneven distributions of charge in some molecules, called *dipoles*. Components that interact more strongly with the stationary phase are slowed in relation to those that interact less or not at all. In gas chromatography (GC), the separation occurs in the gas phase. The mixture is propelled by an inert gas, usually helium or hydrogen, as the mobile phase. In *gas-solid chromatography*, the stationary phase is a solid like alumina, where separation occurs due to differential surface adsorption. In *gas-liquid chromatography*, an immobilized liquid serves as the stationary phase; in this case, separation is effected by dipole interactions.

Background

A schematic for a basic gas chromatograph is shown in Figure 1. The instrument consists of a heated injection port, which converts a liquid sample mixture into vapor. Samples may be injected by hand using a syringe or using an autosampler. In either case, the liquid sample is contained within a syringe equipped with a sharp needle, which is used to pierce a polymer septum. When the liquid is injected into the heated port, it flashes to a vapor and is swept by the mobile phase carrier gas into the column containing the stationary phase. *Packed columns* consist of stainless steel tubing filled with finely divided silica-based material or alumina. A packed column for gas-liquid chromatography (GLC) has the liquid stationary phase chemically bonded to the packing material. *Capillary columns* are open tubes (and are sometimes called *open tubular columns*), the interior wall of which supports the stationary phase. *Porous layer open tubular* (PLOT) capillary columns are used in gas-solid chromatography, while *wall-coated open tubular columns* are used in GLC applications. One common liquid stationary phase is the highly nonpolar (meaning no uneven distribution of charge is present) polymer polydimethylsiloxane, made up of the repeating structure shown in Figure 2. In addition to the chemical bonding between the stationary phase and the column material, the stationary phase material is also usually cross-linked, wherein bonds are formed between the polymer chains for added mechanical stability. In a mixture of molecules with varying polarity, those that are most nonpolar (e.g., straight-chain hydrocarbons) will interact most strongly with this nonpolar stationary phase, while those that are less so (e.g., aromatic compounds like benzene) will interact less strongly. The result is that the aromatic compounds *elute* or are passed out of the column more rapidly than are the others.

At the outlet of the column, separated components pass into a detector, a device that produces a change in electrical signal when something other than carrier gas is present. A graph of detector response over time is called a chromatogram; components are shown as "peaks" in

A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,

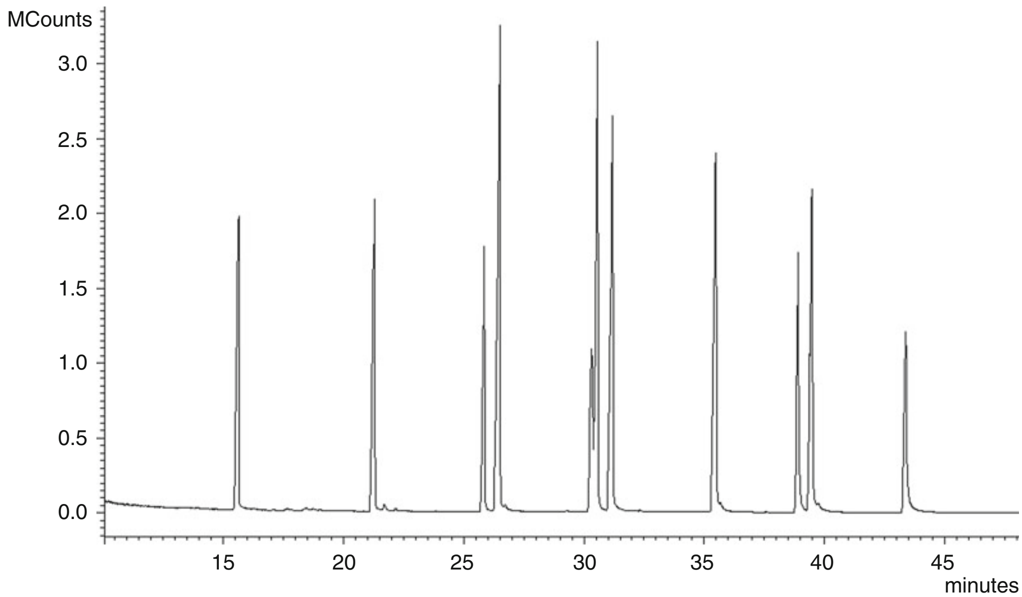
the chromatogram, representing the Gaussian distribution of interactions between the component and the stationary phase. An example chromatogram is shown in Figure 3. The area under the peak is generally proportional to the concentration of that specific component in the mixture. Thus, gas chromatography provides a qualitative picture of the nature of the mixture, and with appropriate standards, a quantitative measure of how much of each component is present.

The amount of information that can be obtained from gas chromatography is determined by the nature of the detector. Thermal conductivity detectors (TCDs) monitor the transfer of heat across a set of resistors in the column effluent. The difference between the thermal conductivity of carrier gas alone and that of the eluted compounds is measured and converted into an electrical signal that is then plotted over time. TCDs are not very sensitive (i.e., they do not yield a large change in signal with small changes in the amount of analyte present), but they are rugged and nondestructive and can be used for noncombustible substances like water and carbon dioxide. A flame ionization detector (FID) is a very sensitive detector for GC, but it provides no identifying molecular information about the components being eluted. In an FID, each component is combusted in an air-hydrogen flame, producing charged species called *ions*; these ions then produce a measurable change in voltage at a set of charged plates above the flame. TCDs and FIDs are general-use detectors for gas chromatography. Other detectors including electron capture detectors and flame photometric detectors are specific to certain elements or functional groups, providing *selectivity*, or a reduction in interferences, for GC analyses. For all of these detectors, compounds can be identified in the chromatograms based only on a comparison of the retention time (how long the compound takes to reach the detector) of each component compared to reference compounds separated under the same conditions.

A mass spectrometer can be used as a GC detector to identify the components based on more than just reference retention time. This "hyphenated method," called gas chromatography-mass spectrometry, is used for nearly all applications of gas chromatography in analyses relevant in geoarchaeology. In a mass spectrometric detector, the effluent from the column passes into a vacuum chamber where the components are ionized while they remain in the gas phase. This is typically done by a stream of energetic electrons produced at a filament. *Electron impact ionization* imparts sufficient energy to the eluted molecules to remove electrons, leaving energetically unstable *cations* (positively charged species) that typically fragment to yield a pattern called a *mass spectrum* for each component of the mixture. A mass spectrum provides a molecular fingerprint for identifying the components, often using a comparative database like the NIST/EPA/NIH Mass Spectral Library (NIST08) published by the National Institutes of Standards and Technology's Mass Spectrometry Data Center. In gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS), an additional step between separation and mass spectrometry involves a combustion chamber where individual compounds are converted to carbon dioxide



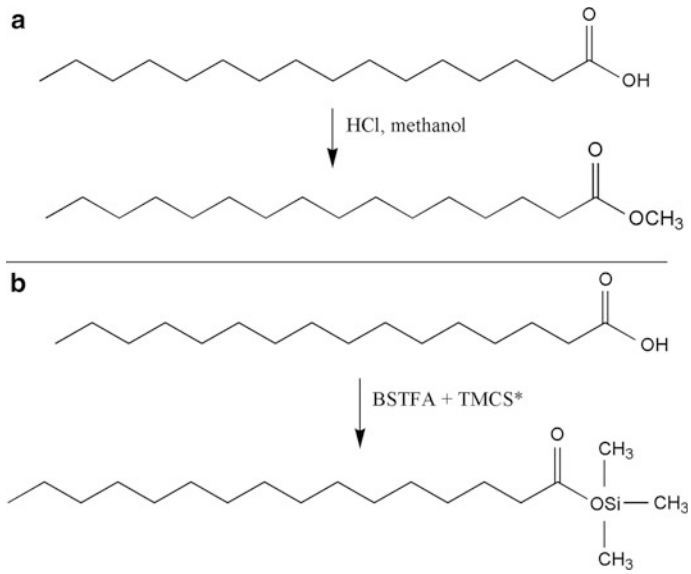
Gas Chromatography, Figure 3 Gas chromatogram of a standard mixture of fatty acid methyl esters. Each peak corresponds to a different compound. The identity of the compound is determined by retention time, which is observed on the x-axis (time in minutes), as well as the mass spectrum if a mass spectrometer is used as the detector. The first peak, around 15 min, corresponds to molecules of the compound that interacts the least with the stationary phase, exiting the column and entering the detector first. The last peak reflects the compound that is retained most strongly by the stationary phase and therefore elutes last. In this example, the fatty acid methyl esters are separated in order of chain length, where the shortest is fastest and the longest is slowest. Unsaturated compounds (those with one or more double bonds, like those in the peak at 25.5 min) elute shortly before saturated ones (like those in the peak at 26.5 min).

(and nitrogen oxides in the case of amino acids, which must then be reduced to N_2 for measurement) and water as they elute from the chromatographic column. The resulting gas is then ionized as in GC-MS and the masses of the combustion products are measured in a mass spectrometer specific to this application.

Because the components are separated in the gas phase, only compounds that can be volatilized can be separated using GC. High-temperature gas chromatography (HT-GC) may extend the range of compounds that can be separated, but it may also require conditions that are outside the capabilities of general-use gas chromatographs, while also definitely requiring a special high-temperature column. GC is generally limited in application to small molecules (less than 1,000 mass units) and those that are either readily vaporized in their native form (e.g., hydrocarbons) or that can be converted chemically into volatile forms. Fatty acids, such as those found in archaeological food residues, are not volatile due to strong hydrogen bonds between the terminal –OH groups within the carboxylic acid functional groups. A chemical conversion of the –OH to either an $-OCH_3$ (called a *methyl ester*) or $-OSi(CH_3)_3$ (called a *trimethylsilyl ester*) is necessary to render a fatty acid sufficiently volatile to be separated using gas chromatography. This conversion is called derivatization and occurs through the reactions shown in Figure 4. Nonvolatile components will not pass from the injection port to the GC column and thus will be neither separated nor detected in the analysis. For large biomolecules, a process called *pyrolysis* can be used in conjunction with GC; it is often abbreviated as Py-GC or Py-GC-MS depending on the detector used and involves the application of high temperatures in an inert environment to break large complex molecules into characteristic fragments. Derivatization and pyrolysis can be combined in a procedure sometimes termed *chemolysis*. This approach can eliminate the need for lengthy extractions, though it requires that a *pyrolysis unit* be installed at the GC injection port for work with solid samples.

Gas chromatography in archaeological applications

Gas chromatography (GC) – coupled to mass spectrometry (MS) as GC-MS – is arguably the most important analytical tool for investigating mixtures of organic molecules relevant in archaeology. Biomarkers, or molecular fossils derived from living organisms, have long been used in geology to understand the origins of petroleum. In archaeology, the biomarker idea has evolved to encompass molecules that provide evidence of past human activities as well. In geoarchaeology, gas chromatography provides a method for making connections between the organic composition of artifacts or sediments, past human activities, and the environment.



Gas Chromatography, Figure 4 Schematic of two derivatization reactions of palmitic acid ($C_{16:0}$): (**a**) methyl ester formation (methylation) and (**b**) trimethylsilyl ester formation (trimethylsilylation or silylation). *BSTFA + TMCS = N,O-Bis(trimethylsilyl) trifluoroacetamide + trimethylchlorosilane.

Peters et al. (2005) describe the analysis of a variety of different biomarkers and their use in understanding past human activity, including sourcing of Near East bitumens and the use of gums, resins, and pitch or tar derived from these resins as adhesives and their role in trade networks throughout the Old World. The most widespread application of gas chromatography in archaeology, though, is the analysis of lipids (Regert, 2011) preserved as residues in ceramic vessels and sherds. Evershed (2008) provides a critical review of organic residue analysis, as it is relevant to what he calls the Archaeological Biomarker Concept. Steele (2013) further describes some of the challenges in applying this biomarker concept in archaeological analysis, with cautionary notes on the importance of soil sampling and context for interpreting the results of such studies. Ceramic residue analyses are primarily undertaken using GC-MS. Further information can be made available from separations of the mixtures found within ceramic residues by use of stable isotope mass spectrometry, and even in some cases, direct radiocarbon dating on individual components of these mixtures.

There currently is great interest in archaeology to understand when, why, and how dairying practices first began to be implemented. Secondary animal products like dairy foods were thought to have followed the "neolithization" process, where hunting and gathering gave way to a reliance on farming of food crops after which these stable societies then proceeded to domestication of animals. GC-MS and GC-C-IRMS analyses of ceramics from across the Near East showed the first direct evidence of dairying dating back to the 7th millennium BC in parts of Anatolia, where cattle played a larger role in herding than did goats and sheep common in other areas (Evershed et al., 2008). The serial domestication of plants and then animals was not, however, universal. Dunne et al. (2012) describe residue analyses of ceramics excavated in Saharan Africa dating to the Middle Pastoral period (around 5200–3800 BC), which indicated a distribution of lipids characteristic of degraded animal fats and an isotopic signature consistent with that of dairy fats. This chemical analysis connects the excavated cattle bones with the use of secondary products from those herds at the distinct climatic period of the green Sahara without the previous domestication of plants. Recent studies have shown that this "neolithization" took place through different processes in Northern Europe, where subsistence through hunting and fishing rapidly gave way to dairy usage, as demonstrated by the isotopic and chemical characterization of ceramic residues (Cramp et al., 2014a). Even in the extreme north, above 60° latitude, where the challenges to farming would have been significant, evidence of the adoption of dairying has been observed in ceramics dating to around 2500 BC (Cramp et al., 2014b), which correlates closely with genetic studies indicating when lactase persistence became widespread in this part of the world. In order to digest milk sugar, lactose, the enzyme lactase must be continuously produced by the body into adulthood and not cease after nursing stops. Outram et al. (2009) used residue analysis in conjunction with faunal evidence to investigate the timing and process of the domestication of horses by the Botai people of Central Asia. While it was clear that horses were an important part of the Botai culture, a strong overlap between the isotopic compositions of horse milk fats and adipose fats representing meat have made it difficult to see clearly how mares' milk was utilized on its own (Outram et al., 2012).

GC and GC-MS characterization can be used to identify the geographic origin of bitumens based on the composition of *steranes*, steroid-like compounds, and terpanes. Connan (1999) reviews the use of GC-MS to determine the sources of bitumens used in building and other materials in the ancient Near East. Trade routes from sources to building sites were traced through Mesopotamia based on both sterane and terpane composition, as well as the carbon and hydrogen isotopic composition as determined by GC-C-IRMS. Analyses with GC and GC-MS were also used to show that bitumens used in embalming some Egyptian mummies likely originated from seeps located in the southern part of the Gulf of Suez (Barakat et al., 2005).

In addition to residues in or on artifacts, gas chromatography can be used to study the soils themselves, which may also contain biomarkers of human activity. Steroid compounds like coprostanol, a derivative of cholesterol formed in the gut of animals, can serve as biomarkers of fecal matter, and the spatial distribution of such compounds in soils can provide important information about the locations of ancient settlements. These compounds have low solubility in water and are stable in soils over long periods of time. While the mere presence of coprostanol in modern contexts can be used to indicate contamination from sewage, Bethell et al. (1994) found that relative abundances of several of the 5β-stanols, separated using GC and identified by MS, more reliably mark the presence of human feces in archaeological soils. GC-MS analysis of a variety of sterol compounds was used to reconstruct the history of the latrines in the Imperial Baths at Sagalassos, Turkey (Baeten et al., 2012). The change in sterol composition over time was indicative of a Byzantine-era use of the site for composting animal waste.

Analysis of lipids in archaeological soils can also provide a picture of site usage in the archaeological past. In the absence of reliable wood sources in Arctic regions, bone was one possible material that could have been used for cooking and heating. GC-MS lipid analysis of hearth soils at the Swan Point site in Alaska showed that animal bones likely served as fuel (Kedrowski et al., 2009). Unique archaeological features called "slab-lined pits" are found throughout Arctic Norway, but how these features functioned in the past was not well understood until lipid analysis of soils from the sites was undertaken (Heron et al., 2010). The fatty acid composition of the pit soils was consistent with their use in rendering marine mammal blubber for oil, though identification of specific mammals was not possible due to the variability observed in the composition of modern marine fats.

Summary

Gas chromatography is a valuable tool for the separation and characterization of organic molecules in a wide range of archaeological materials. It is commonly used in conjunction with mass spectrometry as GC-MS, which can, with the appropriate instrumentation, determine the stable isotope composition of individual components in a mixture. Analytically, gas chromatography is carried out in the gas phase, so the molecules under study must be either volatile or derivatized (as with lipids) to form volatile products.

GEOARCHAEOLOGY, HISTORY

Christopher L. Hill
Graduate College, Boise State University, Boise, ID, USA

Introduction

Since the 1970s, the term "geoarchaeology" has been applied to research that uses geoscience techniques to examine and evaluate the archaeological record. Historically, the use of the geosciences to examine archaeological questions began much earlier in the 1700s and 1800s, and by the middle of the nineteenth century, earth scientists had started systematically and empirically to study the relationships between humans and the environment by using geoscience methods to interpret the archaeological record. The history of geoarchaeology includes not only the application of earth-science methods to archaeology but also the study of long-term patterns in the interactions between people and natural systems (Hill, 2005). These methods align geoarchaeology with environmental archaeology and Quaternary geology, and they connect it to approaches used in physical geography and geomorphology, historical ecology, and landscape archaeology. Thus, geoarchaeology is fundamentally an ecological science that studies the relationships between humans and the earth.

From the time they were first applied, earth-science methods have been used to examine the archaeological record at a variety of spatial and temporal scales. They have been employed in the study of raw materials, artifacts, sediments, post-burial changes at sites, landforms, and landscape settings, as well as the dating of archaeological contexts. Besides the use of earth-science techniques, a major theme in the history of geoarchaeology has been the examination of long-term linkages between human populations and other components of the geosphere and biosphere, including questions connected with human origins, biological and behavioral evolution, and human response to (and impact on) environments.

The geosciences and archaeology prior to 1900: time and context

The application of stratigraphy to interpret archaeological sites builds on the principles formulated by Niels Stensen, also known as Nicolas Steno, in 1669 and James Hutton in 1788. Stensen's work provided the basis for the principles of superposition and original horizontality so crucial to the study of Quaternary strata, while Hutton's "Theory of the Earth" formulated a view of time that would lead to conclusions regarding the antiquity of humans by the 1850s. Early recognition of the value of understanding the context of artifacts is reflected in John Frere's 1797 report of the discovery of stone hand axes (Frere, 1800) within a stratified sedimentary sequence in England (Rapp and Hill, 2006). Describing the location of the artifacts and the sequence of sediments, he delineated the bedding and density of artifacts in the deposits and discussed the implications of his observations. The emergence of ecological perspectives connected with past human-environment interactions is visible in the pioneering works of Alexander von Humboldt and Charles Lyell. Humboldt's first formal fieldwork in geology and archaeology was in 1789 in the Rhine Valley. Then from 1799 to 1803, he conducted field studies of archaeological features in South America and Mesoamerica. His observations were often in the realm of historical ecology and landscape archaeology, characterized by an empirical approach. Humboldt provided descriptions of the raw materials used in the archaeological monuments (e.g., basalt for statues, clay, and mixed stone in the temples). In one instance, where a road cut exposed the internal structure of the pyramid of Cholula, he described its distinct layers of sundried brick and clay (Humboldt, 1814, 105). Humboldt also showed an interest in landscape evolution and human activities. In 1800, he studied the changes of lake levels in Venezuela and attributed the changes to a combination of climate change and human activities such as deforestation, cultivation, and clearing of the plains.

The publication of the three volumes of *Principles of Geology* by Charles Lyell in 1830–1833 emphasized the value of uniformitarian theory: using observations of ongoing natural processes to understand the past. The first and second volumes included descriptions of the geologic context of the archaeology of Vesuvius (Pompeii and Herculaneum), caves, and shipwrecks. Lyell provided summaries of archaeological and paleontological sites, such as those studied by William Buckland at Paviland Cave (Goat's Hole) and cave sites in France containing bones and artifacts. A concern for site formational processes and context is reflected in Lyell's evaluations: "Must we infer that man and these extinct quadrupeds were contemporaneous…? We should unquestionably have arrived at this conclusion if the bones had been found in an undisturbed *stratified* deposit…." (1831, 225).

This influential work also recognized the contribution of human activity to environmental change. Lyell used Iron Age Roman roads covered with several meters (8 ft) of peat to document changes to the landscape (Lyell, 1831, 213), and he commented on the transformation of the landscape by deforestation since it was described by Caesar.

During the 1830s, Boucher de Perthes applied the stratigraphic approach to document the context of stone artifacts and bones of extinct animals in ancient river deposits along the Somme Valley, in France. His studies, begun in 1837, were continued by Marcel Jerome Rigollot and included stratigraphic profiles showing artifacts in association with the remains of extinct animals. Their observations were not considered conclusive; it was not until the middle of the nineteenth century that a consensus was reached on the question of human antiquity.

A prominent example of the application of geologic methods in North America during this early period is Lyell's observations on human remains and their association with deposits containing the fossils of extinct animals in Mississippi. Lyell's field studies in 1846 led him to conclude that the association was probably a product of redeposition or mixing. In 1848, Ephraim Squier and Edwin Davis published *Ancient Monuments of the Mississippi Valley*, which provides a valuable example of how American archaeologists were implicitly using geologic principles by this time. Stratigraphic methods were used to determine whether human or other natural processes had created mounds found in the Mississippi Valley. Their research demonstrated that attention to the geologic context of artifacts, the same general approach applied by Boucher de Perthes and Rigollot in France, was also being used in North America.

The Antiquities of Wisconsin, written by Increase Lapham (1855), is an important early example of how the archaeological record could be used to document the connections between human land use and landscape change. Based on counting rings from trees growing on quarry rubble, he demonstrated that ancient copper mines were at least 300 years old. He also used the archaeological record to determine the antiquity of the historic forests. Lapham demonstrated that prehistoric mounds were formed by the gradual addition of materials by humans in the planting of corn, and he documented fields of up to 300 acres that were the remnants of ancient garden beds. Lapham inferred that this evidence indicated 3,000 years of landscape evolution related to the switch from hunting and gathering to agriculture, followed by the construction of mounds, then garden beds, and eventually the restoration of the forest prior to the start of European settlement. Thus, large tracts of land covered by forest in historic times had previously been cultivated landscapes, suggesting "no very great antiquity can be assigned to the dense forests of Wisconsin" (Lapham, 1855, 91).

Collaboration between archaeologists and geologists in Europe during the middle of the nineteenth century resulted in a much clearer understanding of the sequential development of societies and human antiquity. Johan Forchammer, a professor of geology at the University of Copenhagen, collaborated with archaeologist Jens Worsaae in the study of shell middens in Denmark and Sweden. In 1848, they first undertook multidisciplinary field studies with the Danish paleontologist Japetus Steenstrup, eventually demonstrating that the mounds were human habitation sites and providing some of the basis for the refinement and subdivision of the three-age system.

The history of events leading to the acceptance of prehistoric people and other animals existing together during the Ice Age is a very important example of the early use of earth-science techniques to study the human past. It was after the 1858 excavations of Brixham Cave in England, directly supervised by William Pengelly, that the evidence for the presence of humans during the Ice Age was accepted. This conclusion was based on the finds from caves in Britain and reevaluations of the alluvial deposits in France. The Brixham Cave discoveries were convincing partly because of the systematic excavation techniques devised by Pengelly to document the contextual relations between the objects recovered during the excavations and also because fossils of animals such as *Elephas* (*Mammuthus*) and *Rhinoceros* were found in the same strata as stone artifacts, which were all covered by a stalagmite-limestone floor. Besides the actual spatial relationships of artifacts and fossils within the sealed cave sediments, the confidence in the manner of the excavations and close interaction between Pengelly and Hugh Falconer, Joseph Prestwich, and Charles Lyell led to the consensus.

Falconer's initiative led to the careful excavations at Brixham Cave. In 1858, his own field observations convinced him how important it would be to travel to the Somme Valley to reevaluate the discoveries in the French alluvial gravels reported by Boucher de Perthes. The next year, Prestwich and John Evans followed; they traveled first to Abbeville and later to Saint Acheul. At Saint Acheul, they viewed stone artifacts embedded in sediments that also contained the remains of extinct animals. Lyell also visited the French discoveries at Abbeville in July 1859, concluding that the stone tools dated to the same time as the mammoth fossils. These events led to a series of public announcements at scientific meetings in Great Britain. Although Lyell was not the primary researcher, his credibility enabled him to validate the evidence from Abbeville and Brixham Cave at the 1859 meeting of the British Association for the Advancement of Science. Prestwich's observations were published the following year in the *Proceedings* of the Royal Society of London. Thus, geoscience techniques and concepts were crucial to validating the association of stone artifacts with the remains of extinct animals and the conclusion that humans had been part of the Ice Age world.

During the 1860s, a wave of influential publications evaluated the geologic contexts of archaeological discoveries or examined the impact of human activities on the environment. Lyell's *Geological Evidences of the Antiquity of Man* was first published in 1863. The book contained a detailed review of the geologic setting of Pleistocene and Holocene archaeological discoveries and glaciation, and it also included several chapters on evolution (Darwin's *Origins* had been published in 1859). John Lubbock's *Pre-Historic Times* (1865) captured the nature of investigations at the time: "Nor does there appear to be any reason why those methods of examination which have proved so successful in geology, should not also be used to throw light on the history of man.... Archaeology forms, in fact, the link between geology and history" (1865, 2–3). In 1864, the first edition of *Man and Nature* by George Perkins Marsh documented the extent of long-term changes to the environment produced by human action. Although in a discussion of ancient climates, he alludes to the Swiss lake dwellings, the Danish shell middens, and other examples from prehistoric archaeology, Marsh concentrated on ancient examples of landscape change caused by irrigation, water diversion, drainage, agriculture, and mining.

Classical archaeology also utilized geoscience methods during the second half of the nineteenth century, especially in the application of stratigraphic principles in the refinement of excavation techniques. Giuseppe Fiorelli's excavations at Pompeii, starting in 1860, emphasized stratigraphic control as did the later excavations at Samothrace by Alexander Conze in 1873 and at Olympia by Ernst Curtius in 1875. At Hissarlik (Troy), starting in 1871, Heinrich Schliemann became the first to excavate a multilayered tell, although more careful stratigraphic excavations were conducted there by Wilhelm Dörpfeld in 1882.

Along with this continued concern for improving the reliability and usefulness of field observations, broader themes were developed concerning humans and changing environments. In the 1874 edition of *The Earth as Modified by Human Action*, Marsh referred to the proposal by the Italian geologist Antonio Stoppani (1873) that a new geologic period should be designated the "anthropozoic" because the existence of humans resulted in a great impact on the earth, an idea revived with the proposal of the term "anthropocene" in the early twenty-first century (Crutzen, 2002; Zalasiewics et al., 2008). James Geikie's *The Great Ice Age and its Relation to the Antiquity of Man*, first published in 1874, provided a systematic account of what was then known regarding climate and the geologic context of deposits associated with Paleolithic artifacts, arguing for interglacials in Europe. The third edition, published in 1894, added a section on North America by T. C. Chamberlin, which summarized the evidence for multiple glaciations but, ironically, did not explicitly connect the geology to the archaeology.

The close relationship between geography, geology, anthropology, and archaeology is also reflected in the establishment of both the United States Geological Survey (USGS) and the Bureau of American Ethnology (BAE) in 1879 through the efforts of John Wesley Powell. He was director of the BAE until 1902 and served as second director of the USGS from 1881 to 1884. His *Report on the Lands of the Arid Regions of the United States* is an ecological, conservation-based approach to landscape dynamics and land use. Other geologists played a prominent role in the early development of the Smithsonian's BAE. For example, geologist William Henry Holmes succeeded Powell as director. After the studies conducted by Squier and Davis earlier in the 1840s, Cyrus Thomas used stratigraphic principles in the 1880s to study the archaeological mounds in the Mississippi Valley, as did William Henry Holmes and Frederick W. Putnam with their investigations into the possibility of an "American Paleolithic." Putnam in particular was known for careful archaeological excavations that employed arbitrary levels and documentation of stratigraphy by the early 1880s.

The key to the early man controversy in North America lay in the delineation of a relative sequence of glacial-age deposits for the continent – one of the goals of USGS geologists in the 1880s. For Powell (1890), evidence for a version of the Paleolithic in North America had to be based on geology. Likewise, Holmes, an energetic critic of the American Paleolithic, wrote that the only reliable test for human antiquity in North America rested on geologic evidence. He also did significant work in excavating ancient mines and quarries. During the last decade of the nineteenth century, a range of researchers including Henry W. Haynes, Charles Abbott, and Rollin D. Salisbury believed the reliability of the geologic context of potential Paleolithic artifacts to be very important. The application of geologic methods to buttress the argument that humans existed in North America during the Ice Age is reflected in Holmes's 1893 *Journal of Geology* and *American Geologist* articles concerning contextual problems associated with potential Paleolithic sites in Ohio and Minnesota. Newton Horace Winchell summarized many of the questions about the geologic context of early humans in North America in his presidential address to the Geological Society of America (GSA) in 1902.

1900–1950: collaboration, techniques, and a legacy provided

The first part of the twentieth century witnessed a variety of interactions between archaeology and the geosciences. Multidisciplinary cooperation characterized some of the research during the period. There were instances when geologists, geographers, and paleontologists coordinated their efforts with archaeologists working in the same area. These efforts resulted in regional studies that could be used as the basis for paleoclimatic interpretations and the development of a time framework that could also be applied to dating archaeological sites. Geomorphic, stratigraphic, and paleontologic criteria were critical to the chronological studies. After 1900, more laboratory specialists were involved in the analysis of specimens collected as part of archaeological research. Investigations of landscapes incorporated the study of both natural processes and human activities, and a growing list of examples of sedimentologic and stratigraphic applications to the evaluation and interpretation of archaeological sites emerged. The pattern of collaboration and application of techniques and approaches from geology and geography during the first half of the twentieth century developed a lasting legacy that later led to the formal establishment of the discipline of geoarchaeology.

New techniques from the geosciences were applied to questions linked to understanding the dynamics of landscapes connected with archaeological sites. The pollen-analysis methods developed by Lennart von Post were first applied in Scandinavia between 1908 and 1916, revealing climate intervals associated with postglacial environmental change. The technique of varve dating was first applied by Gerard J. De Geer in 1905 in Sweden and later by Matti Sauramo in Finland and by Ernst Antevs in North America. Tree rings were employed to provide archaeological chronologies by Andrew E. Douglass after 1914. Remote sensing techniques were applied during the early twentieth century in the form of aerial photography. In 1906, aerial photographs of Stonehenge revealed buried features not visible from the surface. Later, in the 1920s, a major effort to use aerial photography to discern archaeological features was conducted in England. O. G. S. Crawford (1923) realized the potential of using aerial photography to place archaeological sites within the context of broader landscapes. Using this remote sensing method, he was able to map the location of over 200 archaeological sites in southern Britain (Crawford and Keiller, 1928) and combine the study of archaeological settlement patterns with ancient landscapes. Charles Lindbergh applied the technique of aerial photography in the study of the archaeological ruins and their landscape context in the American Southwest in collaboration with Alfred V. Kidder.

The relationships of environmental and climatic change to human adaptation were among archaeology's principal concerns after 1900 and provided opportunities for multidisciplinary cooperation between geologists, geographers, and archaeologists. Raphael Pumpelly, who was elected President of the GSA in 1905, applied the rules of geologic reasoning to archaeology in his expeditions to Turkestan. These studies examined the origins and growth of the Anau civilization and also investigated the influence of environmental change in central Asia. During the first field season of 1903, Pumpelly conducted a reconnaissance survey documenting the distribution and environment of archaeological sites, while William Morris Davis and Ellsworth Huntington studied the geomorphic evidence for a series of glacial-interglacial episodes that documented climate and environmental change in the region during the Quaternary. During the 1904 season, Pumpelly pursued landscape studies. Huntington assisted Hubert Schmidt – who had trained under Dörpfeld in the excavation of Troy – with systematic archaeological excavations. Results of the expedition, *Explorations in Turkestan*, were published as two volumes in 1905 and 1908, and Pumpelly presented a summary of the field results entitled "Interdependent evolution of oases and civilizations" at the 1906 meeting of the GSA.

Interpretations of the archaeological record at the site-specific scale relied on a growing awareness of the value of stratigraphic control. Max Uhle (1903) used the phrase "geological stratification" to describe the context of archaeological discoveries in Peru. Later, while excavating a shell mound on the east shore of San Francisco Bay, Uhle (1907) documented a sequence containing artifacts in ten strata overlying alluvial clay. Influenced by the approaches observed in Europe, Manuel Gamio and Nels C. Nelson employed stratigraphic principles at other American sites, and A. V. Kidder, in turn, applied the techniques of stratigraphic excavation to the ruins at Pecos, New Mexico.

In 1911, Gamio initiated stratigraphic excavations at Azcapotzalco in Mexico City, Mexico. Excavations revealed three groups of pottery and their stratigraphic relationships, which were used by Gamio to demonstrate the relative order of the artifacts. In 1914, after observing the methods of stratigraphic excavation by Hugo Obermaier and Henri Breuil at Castillo Cave, Nelson employed similar methods at Pueblo San Cristobal. Kidder's excavations at Pecos Pueblo also applied a stratigraphic methodology to evaluate the relative age of archaeological materials. Beginning in 1915, Kidder's excavation techniques enabled the collection of artifacts from distinct deposits instead of the arbitrary levels used by Nelson and Gamio (Kidder, 1924). This made it possible to document the relative stratigraphic position of pottery types within the archaeological deposits and allowed him to demonstrate that specific pottery types occurred in particular strata; it also enabled him to document the presence of a sequence and relative ordering of these types. Other research in the American Southwest soon followed. Kirk Bryan began geologic studies of Chaco Canyon in 1924 (Bryan, 1954), and dendrochronology was used by A. E. Douglass (1929) to date the sequence of changing artifact types at Pecos and at other sites. The extension and elaboration of the techniques of stratigraphic excavation after World War I are exemplified by the innovations of Mortimer Wheeler, first at Iron Age sites in Britain and later in the at Harappan sites in the Indus Valley (Wheeler, 1954).

After participating in Pumpelly's 1903–1904 Turkestan explorations, Ellsworth Huntington pursued the idea that the physical environment in the form of climate change was a primary factor in determining the development of human societies. Notable examples of his research include *Civilization and Climate* (1915, first edition; 1924, third edition) and "Maya civilization and climatic changes" (1917).

The concern with validation of potential Ice Age artifacts continued to be of interest in North American research in the early twentieth century. As before, purported Pleistocene human remains or artifacts had to be verified by unquestionable stratigraphic evidence. Interactions among American archaeologists and geologists during this period are exemplified by articles published in 1917 in the *Journal of Geology*. Discussions revolved around the sedimentologic context and validity of association for artifacts and fossils found at Vero, Florida. Rollin Chamberlin and George MacCurdy concluded that the fossils were in secondary deposits, but Chamberlin also believed that there was evidence to support the association between the extinct fauna and the human remains. In contrast, Aleš Hrdlička believed the discovery could not be supported because of the depositional context of the remains.

The field studies of Elinor Wight Gardner illustrate the collaboration between geologists, paleontologists, and archaeologists in the 1920s and 1930s. In 1925–1926 and 1928–1929, Gardner collaborated with archaeologist Gertrude Caton-Thompson in the study of the northern Fayum, southwest of Cairo, Egypt. Gardner focused on mapping the region, tracing the shorelines of an ancient lake associated with Neolithic archaeological sites. This work was published in the *Geographical Journal* in 1929 and later as a two-volume monograph (Caton-Thompson and Gardner, 1934). In 1930–1931 Gardner and Caton-Thompson began a study of Kharga Oasis in the Egyptian Western Desert, which included an aerial reconnaissance. Gardner continued the fieldwork without Caton-Thompson in 1932–1933. With Dorothy Garrod, she conducted field studies during 1935 along the eastern coast of the Mediterranean in the vicinity of Haifa. They studied a kurkar-hamra (sand-red silt) sequence containing Middle Paleolithic artifacts that could be related to the nearby excavations at et-Tabun and el-Wad, Mount Carmel. Later that same year, they explored the northern Jordan Valley and found Acheulian artifacts in association with fauna at Gesher Benot Ya'akov (Jisr BanatYaqub). In 1937, Gardner collaborated with Dorothea Bate in the excavation of Pleistocene deposits at Bethlehem. Gardner also conducted geomorphic studies as part of an expedition to the Arabian Peninsula in 1937–1938, excavating and mapping parts of Hureidha, in the Hadhramaut, Yemen.

This period saw a growing emphasis on the application of geographic concepts to interpreting the landscape settings and patterns of archaeological sites. For example, Cyril Fox (1923, 1932) examined the distribution of archaeological sites within the context of vegetational patterns and environmental settings. In a review of the relationship between nature and prehistoric humans, Clark Wissler (1924, 312) stated "the anthropologist is… not only trying to show what all forms and forces of nature have done to man, but even with more emphasis what man has done to nature." His statement was a deliberate attempt to apply ecological concepts of resource use to patterns of human behavior.

Carl Sauer articulated a view of the landscape as a product of space, time, and natural and human processes. Sauer conceptualized landscape as the combination of physical geology and modification by humans or the natural landscape as transformed by humans (Sauer, 1925). He designated the study of archaeological sites in relation to their environmental setting as "archaeogeography" (Sauer and Brand, 1932, 2). This approach is illustrated by the studies Sauer and Brand conducted, partly in collaboration with Alfred Kroeber, which examined the distribution, size, and relationship of archaeological sites. Sauer's approach was to look at archaeology at the landscape scale: "I considered that archaeologists were too concerned with the taxonomy of artifacts and not enough with the analysis of habitat and habitation" (Sauer, 1939 in West, 1979).

The nature of the interaction between archaeology and geology throughout the world during the early part of the twentieth century is represented in the volume *Early Man* (MacCurdy, 1937). Studies linking the geosciences and archaeology in Eurasia included reviews by Dorothy Garrod on the Near East, Teilhard de Chardin on the stratigraphy of China, Helmut de Terra on India, and Gerard De Geer on geochronology, to name a few. Examples focused on North America included geomorphologist Morris Leighton's essay on the significance of profiles of weathering in stratigraphic archaeology, paleobotanist Paul Sears's paper on the use of pollen for dating archaeological deposits, geologist Ernst Antevs's essay on climate and "early man," and geologist Kirk Bryan's discussion of the geology of Folsom deposits (the discoveries at Folsom in 1927 had documented the primary association between undisputed artifacts and extinct fauna, demonstrating Ice Age human antiquity in the New World). The volume demonstrates that many approaches derived from the natural sciences were being applied in early twentieth-century prehistoric studies.

Evidence of multidisciplinary interaction in the Old World is reflected by Frederick Zeuner's application of archaeology for its geochronological and climatic implications. Zeuner was Professor of Environmental Archaeology at the University of London's Institute of Archaeology. *The Pleistocene Period* (Zeuner, 1945) reviewed the principles of stratigraphy, including soils and terraces, and then summarized the chronology of climate change and its impact on patterns of biogeography. *Dating the Past* (Zeuner, 1946, first edition; 1952, third edition) reviewed chronologic approaches to dating archaeological sites and constructed regional chronologies (just at the time radiocarbon dating was first being used). Thus, the third edition provided a chronologic framework for archaeological discoveries that relied on stratigraphic and geomorphic evidence, combining this data with the first sets of radiocarbon dates from the laboratories at Chicago and Lamont Geological Observatory of Columbia.

In North America, a pervasive geoscience approach is connected with archaeological research in the Great Plains and Southwest (Haynes, 1990; Holliday, 1997; Mandel, 2000b). Edgar Howard's research in the American Southwest used geologic and archaeological evidence, including excavations of caves and the study of lake sediments in New Mexico. In 1935, he proposed a reconstruction of the Late Pleistocene environments on the southern High Plains and reviewed the chronological and climatic theories associated with the end of the Pleistocene. Ernst Antevs (1935) studied the geologic and archaeological aspects of the Clovis type site at Blackwater Draw, New Mexico, as a member of Howard's expedition in 1934. His series of influential publications from the 1930s through the 1950s employed geologic techniques to develop paleoclimatic models that could be related to archaeological studies.

In the 1920s, Kirk Bryan investigated evidence for environmental change at Chaco Canyon, New Mexico. From about 1924 to 1950, Bryan dominated research at the interface between geology and archaeology in North America. Although a major facet of Bryan's research was the application of paleoclimatic chronologies to date Paleoindian sites, he also made efforts to delineate the environmental settings and interpretations of other archaeological sites. The interpretations of the settings were largely based on evaluations of the processes of landscape evolution linked to erosion and sedimentary deposition that could be affected by climatic processes and human activity (cf. Bryan, 1925).

Bryan's legacy is also reflected in his collaborative studies where he often served as teacher and mentor. Bryan initiated geologic studies on the Lindenmeier bison site in Colorado in 1935, returning with Louis Ray in 1936. Ray conducted field studies from 1936 to 1938 (Bryan and Ray, 1940). In 1937 and 1938, Bryan's former student Harold T. U. Smith studied the alluvial terrace deposits in Kansas as part of a multidisciplinary archaeological study with Loren Eiseley. In 1938, Bryan collaborated with Claude Albritton, Jr. and archaeologists J. C. Kelley and T. N. Campbell to investigate the Quaternary geology of the Davis Mountains (Albritton and Bryan, 1939). Sheldon Judson carried out a geologic study of the San Jon site and its Plainview artifacts in northeastern New Mexico under Bryan's supervision (Judson, 1953). Bryan and Roberts visited the site in 1940, and Judson and Bryan conducted a reconnaissance in 1941 with fieldwork completed in 1947 by Judson. In 1941, Emil Haury excavated the deep sequence at Ventana Cave in Arizona, with Bryan studying the stratigraphy in 1942.

In 1947, Bryan's student Herbert E. Wright, Jr. conducted a sedimentary and geomorphological study of the rock-shelter at Ksar Akil, near Beirut, Lebanon, which contained Mousterian and Upper Paleolithic archaeology. Wright then participated as the geologist with Robert Braidwood's multidisciplinary Jarmo project in Kurdistan, northern Iraq. Braidwood's interdisciplinary project ran from 1947 to 1955. In 1948, Bryan initiated the investigations of the rock-shelter at La Colombière in the Rhone Valley of southeastern France, later completed by Judson. Investigations at the Horner site, located near Cody, Wyoming, were started in 1948 with Loren Eiseley and Glenn Jepsen. In 1950, Bryan visited Fred Wendorf's field camp at the Petrified Forest in Arizona. Shortly after, while in the field at the Horner site in 1950, Bryan died. By the middle of the 1900s, Bryan and his collaborators had effectively applied a geoscience approach to archaeological questions. Some of Bryan's students continued active research into the early part of the twenty-first century, directly training and less directly influencing several generations of Quaternary scientists.

1950s to today: bridging applications, geoarchaeology defined and organized

During the 1950s and 1960s, many people who would become the founding group of the new "geoarchaeology" were beginning their careers. They actively pursued research that would later be labeled as geoarchaeology or archaeological geology starting in the 1970s and 1980s. Much of this research was conducted by specialists on multidisciplinary teams, applying standard geoscience field techniques while taking advantage of advances in analytical techniques. Innovations in dating, such as the development of radiocarbon dating in the 1940s by Willard Libby (Arnold and Libby, 1949) or the application of K-Ar dating to late Cenozoic stratigraphic sequences in the 1960s, reinforced the value of close interaction between geoscientists and archaeologists. However, the development of a recognized discipline was derived from collaborative field studies and from an expanding network of practitioners focused on applying earth-science methods and concepts to understanding ecological patterns of the human past.

Research at the interface of the geosciences and archaeology thrived during the 1950s. In the American Southwest and Great Plains, environmental studies of the Late Pleistocene prevailed. Glen Evans conducted stratigraphic studies at the Clovis type site in 1949 and 1950 while continuing studies he had started at Lubbock Lake, Texas. Judson, John Schullinger, and John Moss continued the geological studies that had been started at the Horner site. Moss later conducted detailed studies of the nearby Pleistocene terraces. In 1951, Emil Haury and Ernst Antevs began investigations in Greenbrush Draw, Arizona, where Haury excavated the Naco mammoth Clovis site in 1952. This was followed by studies of the nearby Lehner mammoth Clovis site in 1955–1956. In 1954, Harold Malde conducted geologic investigations of the Dent mammoth Clovis site and the Cody complex Claypool site in Colorado. At about the same time, Luna Leopold and John Miller were studying the postglacial alluvial valleys of Wyoming. In 1953 and 1954, Fred Wendorf, in collaboration with Alex Krieger and Claude Albritton, undertook field studies of the Late Pleistocene Midland site in west Texas. In 1956, Wendorf and Miller conducted field studies of the relationships between alluvial terraces and Pueblo sites in New Mexico. That same year, Wendorf and A. E. Dittert excavated at the Clovis type site, to which Wendorf returned in 1958 as part of the High Plains Ecology Project. C. Vance Haynes, Jr. began his geological studies of archaeological sites in the 1950s, sometimes working in collaboration with archaeologist George Agogino. For example, Haynes and Agogino investigated the Hell Gap site in Wyoming in 1959 and 1960. Charcoal collected by Haynes at the Lindenmeier bison kill led to the first reliable radiocarbon date from a Folsom site (Haynes and Agogino, 1960). Likewise, in Old World studies, Sheldon Judson conducted a study of the geological and geographical setting of Abri Pataud in the Dordogne region of France in 1957, 1958, and 1968. The study did not focus on the site stratigraphy but rather attempted to relate the sediments and geomorphic features in the Vézère River valley to the site. Concurrent fieldwork by John Stewart documented the regional glacial geology (Judson, 1975). John Miller began sedimentological studies of the stratigraphy within Abri Pataud in 1958; these were later completed by Bill Farrand in 1964. The primary purpose for field investigations in Egypt by Karl Butzer during 1956 and 1958 was to study Pleistocene stratigraphy. The 1958 studies included topographic survey and mapping of surficial deposits, in cooperation with Werner Kaiser, related to Neolithic and Predynastic sites in the Nile Valley.

The benefits of interactive collaboration between geologists and archaeologists are indicated by the publication of a series of works by the end of the 1950s. Mortimer Wheeler wrote: "Archaeology is increasingly dependent on a multitude of sciences and is itself increasingly adopting the methodology of a natural science. It draws today upon physics, chemistry, geology, [and] biology...." (Wheeler, 1954, 2). Hallam Movius, Jr. (1949, 1957) stressed the bond between prehistoric archaeology and the natural sciences. The goal of investigating human adaptation to natural environments, Movius emphasized, could be achieved through natural-science studies concerned with the sequence and correlation of Pleistocene events. He argued that environmental reconstruction was important. Troy Péwé's paper in *American Antiquity* (1954) emphasized the geologic approach to dating archaeological sites and focused on the value of understanding the geologic and biotic responses to climate changes to help evaluate archaeological contexts. In a volume published by the US National Academy of Sciences and the National Research Council, Wright emphasized that the most useful contributions geologists could make to archaeological problems were in the interpretation of the physical and climatic environment. He noted the importance of this approach to the study and evaluation of the whole archaeological site and suggested that Pleistocene geologists would be most interested in the climatic environment and chronology associated with archaeological sites. In the same volume, Judson wrote about the value of collaboration between Pleistocene geologists and archaeologists, and Braidwood wrote that some might choose to be "natural-science archaeologists" and described a "Pleistocene ecology" or "Quaternary geography" which would "include man as an element in and a factor acting upon the environmental scene" (Braidwood, 1957, 15–16).

Ian Cornwall's *Soils for the Archaeologist* (1958) demonstrated the great potential sediments and soils offered in archaeological analysis and interpretation. It has been described as the first systematic attempt at geoarchaeology (Butzer, 1982). Cornwall argued for contextual studies in archaeology that used the geosciences. Soon afterward, Edward Pyddoke published *Stratification for the Archaeologist* (1961). He advocated that, besides interpreting and understanding human activities, the job of the archaeologist was also to evaluate the stratigraphic context of artifacts. The books by Cornwall, Pyddoke, Wheeler, and Zeuner show that the basis for an earth-science approach was present in the study of Old World archaeology by the 1960s. This is reflected in the studies of environment and human ecology in Egypt conducted by Butzer and his advocacy of the use of the methods of Quaternary geology, geography, and geomorphology to study the immediate site and its wider habitat or setting (Butzer, 1959a; Butzer, 1959b; Butzer, 1960). The role of geology in Pleistocene paleoecology and archaeology was summarized by Haynes (1964a), providing his views on the importance of geologic stratigraphy, interdisciplinary cooperation, and the geologist's role in paleoecologic interpretations.

Karl Butzer's landmark text *Environment and Archaeology* (1964) used the phrase "Pleistocene geography," which was chosen because it served to "emphasize both man and environment" during the Quaternary (Butzer, 1964, 4). Butzer first published his detailed studies and reviews of the stratigraphy and climatic chronology of the late Quaternary in the Near East in the 1950s. Following those publications, Butzer's *Environment and Archaeology* provided a worldwide comparison of archaeological and environmental contexts, placing an emphasis on the value of integration. It included sections on stratigraphy and chronology; vegetation, soils, and geomorphology as environmental indices; mammal biogeography; sediments; regional reconstructions; and human-land relationships. Starting in the 1950s and throughout the 1960s, Butzer applied this approach to his fieldwork in Egypt, East Africa, and Spain. Working primarily along the Nile Valley, he focused on the late Quaternary of Upper and Middle Egypt and then expanded southward into Nubia as part of the Yale studies in 1962–1963. In 1961–1963, and 1967, he conducted research associated with the excavations of Torralba-Ambrona in Spain, and, in 1969, he participated in an expedition to Omo in southwestern Ethiopia.

Other important studies combining geology and archaeology were initiated in the Nile Valley and East Africa during this time. In the Nile Valley, Rhodes Fairbridge and Ralph Solecki conducted studies in 1961–1962 along the Nile in Sudan, followed by four seasons of fieldwork by Jean de Heinzelin (beginning in 1961, then as part of the Combined Prehistoric

Expedition, or CPE, from 1962 to 1965). Geological fieldwork by Butzer and Carl Hansen (1962–1963) and Robert Giegengack (1963–1967) in Egypt and Nubia were part of Yale University's expeditions. In Nubia, Claude Albritton conducted field studies of the Tushka area during the 1965–1966 field season as part of the CPE. In East Africa in 1962, Richard Hay initiated his geologic studies of Olduvai Gorge (Hay, 1963). This was the beginning of a long-term study that would produce *Geology of the Olduvai Gorge*: *A Study of Sedimentation in a Semiarid Basin* (Hay, 1976). Along with Hay's stratigraphic studies, K-Ar dating was applied to date the Olduvai Gorge sequence (Evernden and Curtis, 1965). In Kenya, Glynn Isaac (1967) focused on investigating sedimentologic processes to interpret Acheulian occurrences at Olorgesailie, and Bill Farrand conducted geological research in the Baringo district of Kenya as part of an interdisciplinary team in 1973.

In Europe and the Middle East, Bill Farrand conducted studies of Paleolithic cave sequences at: Yabrud, Syria, in 1963–1964; Abri Pataud, France, in 1964–1965; Tabun Cave, Israel, in 1967–1972; and Franchthi Cave, Greece, in 1974 and 1975. As part of the Tabun project, the stratigraphy and sedimentology were studied by Paul Goldberg from 1967 to 1970; in 1966, he had served as a field assistant to Farrand studying loess in the Rhine Valley, France. In Greece during the 1960s, William McDonald included earth scientists in a survey of Messenia, bringing in Wright (who had previously collaborated in archaeological projects in Lebanon and Iraq), then George Rapp, Jr. in 1966. Field studies conducted by Chris Kraft, Stan Aschenbrenner, and Rapp from 1971 to 1975 focused on the paleogeography of the coastal plain of the southwestern Peloponnese, while the geology of the Bronze Age site of Nichoria was studied by Julie Stein (Stein and Rapp, 1978). The studies initiated by Kraft and Rapp in the 1970s turned into a long-term investigation of the ways coastal change has affected major archaeological sites in Greece and Turkey, such as Troy, Ephesus, ancient Pylos, and the landscape of the famous battle at Thermopylae. The model of multidisciplinary studies of archaeological sites in the Mediterranean was also applied at Tel Michal, Israel, in the late 1970s where geologic studies were conducted by John Gifford and Rapp with field assistance in 1978 from Christopher Hill (Gifford et al., 1989).

In North America, Vance Haynes conducted detailed investigations of the Blackwater Draw as part of the interdisciplinary High Plains Paleoecology Project organized by Fred Wendorf. This included studies of the Clovis type site in 1962. The stratigraphic and geochronological investigations initiated by Haynes in the 1950s and 1960s were the beginning of a series of significant contributions to research along the interface of the geosciences and archaeology. In North America, Haynes focused on the geologic contexts of Late Pleistocene and early Holocene sites using radiocarbon dating to (1) interpret the stratigraphy and setting of archaeological sites and (2) to revise the broader-scale alluvial chronologies developed by Antevs, Bryan, Miller, and others (Antevs, 1955; Haynes, 1964b; Haynes, 1968). In 1968, 1973, and 1975–1977, Haynes was a member of the CPE, which involved geologic studies in Egypt and Ethiopia. Haynes continued his Paleoindian research focus as well as studies of the Eastern Sahara throughout his prolific career, along the way training and mentoring several generations of geoarchaeologists or archaeological geologists. During the 1970s, John Albanese served as geologist for research teams investigating Paleoindian sites of the Great Plains, such as Casper, Agate Basin, and Colby, to name a few.

The overlap between geoarchaeology and landscape ecology is illustrated by the research of Pedro Armillas (1971) on the chinampas in the Valley of Mexico. This was part of a comprehensive project to study the human role in shaping the landscape. It provided a view of the landscape as a product of interaction between the natural environment and human behavior. Following on the concepts formulated by people such as Humboldt and Sauer, Armillas's studies were not at the scale of artifact or the immediate site, but they used archaeological data at the scale of landscape to evaluate modifications of the natural environment brought about by human activity. Although the studies were aimed at the interrelationships between humans and the environment, the goal was to examine how humans could modify the natural environment. This was in contrast to the prevailing focus of environmental archaeology at the time, which explored the natural aspects of human habitats.

The terms "geoarchaeology" and "archaeological geology" have also been used since the 1970s to designate the earth-science approach to archaeological studies as well as the use of archaeological occurrences to understand natural patterns and processes of the geological record. The term "geoarchaeological" was used in a paper on the site stratigraphy and sediments of an Acheulian spring site in South Africa (Butzer, 1973, 315) and "geoarchaeology" was used in the first article in the first volume of the *Journal of Archaeological Science* (Butzer, 1974). The deliberate connection of "geoarchaeology" to an ecological approach was advocated in a paper published in *American Antiquity*. Butzer suggested that the solution to developing "a more effective ecological interpretation of man's past" was for earth scientists to directly identify with the goals of archaeology by applying the label geoarchaeology (Butzer, 1975, 106).

A symposium on the theme of sediments in archaeology held at the University of Southampton in 1973 resulted in *Geoarchaeology*: *Earth Science and the Past* edited by Donald Davidson and Myra Shackley (1976). The book provided a view into what was considered the potential scope of the term "geoarchaeology." It was divided into sections on techniques, coastal and lacustrine environments, terrestrial environments, and biological sediments. Geoarchaeological techniques included the recording of sediments and their consideration as paleo-land segments, as well as specific techniques of material analysis used to examine sediments, soils, artifacts, and rock-shelters. The chapters devoted to environments evaluated archaeological sites at the scales of stratigraphic sections and landscapes, while paleobotanical and invertebrate studies were presented in the section on biological sediments.

One of the most insightful contributions in *Geoarchaeology* was Colin Renfrew's introductory chapter titled "Archaeology and the earth sciences." After describing the origin in the 1950s of archaeometry and bio-archaeology, he observed that there also had been developing "the emergence of a new discipline" with a focus on "soils, sediments, and landforms. . .primarily concerned with context" (Renfrew, 1976, 2). The questions to be answered by geoarchaeology, according to Renfrew, concerned the position of the site in time, processes of site formation and site location, and environment as part of an ecological framework connected with changes in landform and human use of resources. For Renfrew, geoarchaeological studies "bring into closer relationship the geomorphologist and physical geographer. . .and the human geographer and anthropologist" (1976, 5).

There were other efforts to delineate the research connections between geoscience and archaeology. The role of geologist as part of an archaeological team was described by Rapp (1975). Two papers published in *American Antiquity* serve to illustrate perceptions at this time. Bruce Gladfelter (1977) advocated a geomorphic, paleoenvironmental approach to geoarchaeology. He proposed a scheme that emphasized the depositional context at site-specific locations, local landscape (habitat), and regional scales. Fekri Hassan (1979) equated geoarchaeology with archaeological geology and advocated a broader view of the field, suggesting that the ultimate aim of geoarchaeology was to "provide an understanding of those key paleoenvironmental variables that were or could have been influential" within a human ecosystem (Hassan, 1979, 269). This ecologic perspective was also expressed in the environmental and interdisciplinary perspectives of Roald Fryxell (1977). Noting that anthropology is a synthetic discipline that draws from a diverse number of fields, Fryxell argued that anthropological training required an understanding of environmental interpretation and technical interdisciplinary skills.

Since the 1970s, opinions have consolidated regarding the importance of a natural-science perspective in archaeology and the value of geoarchaeology as a discipline embedded in the ecological approach to the study of human-environment relationships. Archaeological data appear as the product of varying proportions of human behavioral activities and the processes of nature. The dynamics and connections of the long-term past can be understood more fully when the environmental context and the processes involved in creating the archaeological record are empirically documented and evaluated. Butzer (1982, 11) advocated an ecologic or broadly contextual approach to archaeology that emphasized the application of geoarchaeology: "It has been said that archaeology is anthropology or it is nothing.... I beg to differ with this view. Archaeology. . .has been equally dependent on geology, biology, and geography. . .during its development. . . [and] is heavily dependent on . . .the natural sciences."

Geoarchaeology has sometimes been applied in a restricted way to describe the study and interpretation of sediments and physical landscapes as a way to connect landscape evolution and human activities. Robert Thorson (1990) viewed archaeological sites as geological localities with remains of interest to archaeologists. Reid Ferring (1994) emphasized the changes in archaeological perspectives since the emergence of processual archaeology and perceived geoarchaeology as an empirical approach to archaeological questions. Mike Waters (1992) applied the term geoarchaeology to studies of site stratigraphy, formation processes, and landscape-human interaction, as compared to archaeometry with its goals of archaeological prospecting, provenance, and dating. Rolfe Mandel (2000a) viewed geoarchaeology as employing geoscience methods and concepts to archaeological deposits and formation processes.

The history of the discipline of geoarchaeology is about its development over time, not only as it has been practiced or defined but also how it has emerged as a community of scientists organized and connected in the pursuit of understanding the long-term relationships between humans and the environment. Geoarchaeology as a discipline has been blessed by a cadre of "true believers" who have connected the strong but loose ends of the geosciences and archaeology and woven them into a resilient, dynamic field of interdisciplinary, ecological science. Progress toward this result began even before there was a named and recognized field of geoarchaeology or archaeological geology, but a more formal set of institutional arrangements has emerged since the 1970s. These structures provide mentoring and training in the skills needed to practice geoarchaeology; opportunities to interact, to compare experiences, and to disseminate and critique research; and a sense of intellectual tradition or heritage.

Professional groups and publications dedicated to geoarchaeology were established during the last part of the twentieth century. Members of the Geological Society of America (GSA) began to see the value of a forum for archaeologically related geological studies in the 1970s. At the 1973 GSA meeting, Vance Haynes and Harold Malde chaired a session on archaeological geology. The enhanced visibility of geological applications to archaeology led to a short article coauthored by George Rapp, Reuben Bullard, and Claude Albritton titled "Geoarchaeology?" (1974). After Rapp sent in a formal proposal to the GSA, the Archaeological Geology Division of the GSA was formed in 1977 with Rapp serving as Chair, and the Division's newsletter was first printed in 1978. The first volume of *Geoarchaeology*: *An International Journal* was published in 1986. The founding editor, Jack Donahue, credited Rhodes Fairbridge for suggesting a journal at the 1983 meeting of the GSA. In 1996, the Society for American Archaeology (SAA) put out a call for the formation of interest groups. Rolfe Mandel drafted a proposal that was reviewed by Julie Stein, and they submitted it to the SAA as co-organizers. Mandel served as the first Chair of the Geoarchaeology Interest Group from 1997 to 1998, and volume 1 of the newsletter was printed in 1998. Academic programs have also been established. By the early part of the twenty-first century, there were several officially designated master's and bachelor's degree programs in geoarchaeology. In retrospect, it was during the 1970s and 1980s that the *practice* of applying the earth sciences to the study of the human past had reached a threshold and the *discipline* of geoarchaeology had been established.

Summary

The use of an earth-science approach to evaluate the archaeological record began in the eighteenth and nineteenth centuries with an appreciation of "prehistoric" time and the development of basic principles for linking past and ongoing environmental processes. By the twentieth century, collaboration between earth scientists and ecologically oriented archaeologists had intensified with the convergence of goals and techniques. Throughout the history of interaction, ideas and methods originating with the geosciences have been used to study the processes involved in the formation of the sedimentary archaeological record, to measure and classify the physical characteristics of artifacts and geofacts, to develop chronological frameworks, and to infer the paleoenvironmental settings associated with archaeological sites. A fundamental component of geoarchaeology throughout its history has been its focus on human-environment relationships.

Geoarchaeology unites the study of the record of past human activity with the natural (physical and biological) sciences. Historically, the geoscience approach in archaeology has been applied to preparing for and conducting fieldwork and collecting field data, the choice and application of laboratory techniques, and the interpretation of human-environmental relationships. The types of archaeological questions that have been addressed by using earth-science approaches include: studies of environmental settings and natural resources linked to land use; predicting the location of archaeological sites; documenting sedimentological, stratigraphic, and landscape contexts; identifying and describing raw materials, sediments, and soils; site formation; dating; and ecological integration.

The history of using a geoscience approach to examine these questions began in the late 1700s and 1800s and is illustrated by a preliminary interest in human-earth interactions, stratigraphic chronology, and human antiquity. During the early part of the 1900s, there was a refinement in the application of stratigraphic principles to archaeological sites and an expansion of the use of geoscience-derived field and laboratory techniques in areas like the study of past environments and raw material analyses. Although the application of geoscience techniques and geoecological principles became more pervasive throughout the 1900s, a real turning point in the history of geoarchaeology occurred during the 1950s–1970s. By the 1970s, it had become clear that the use of geoscience was essential to understanding the connections between humans and the environment and to applying an empirical, contextual, and interdisciplinary approach to interpreting the archaeological record. From a historical perspective, geoarchaeology is ultimately an interdisciplinary, ecological science focused on the relationships that connect humans and environmental systems.

Archaeometry Laboratory, Research Reactor Center, University of Missouri, Columbia, MO, USA

Introduction

Archaeologists who study past human societies do so by investigating the remains they left behind. One of the questions that is frequently asked about recovered finds is "Where did the artifacts come from?" Efforts to answer this question are often carried out in collaboration with colleagues from the physical and chemical sciences, and the evidence obtained is used to determine the locations (i.e., sources) of the raw materials that were used to produce the artifacts. Because instrumental measurements are usually required to address such matters, most of the work involved takes place in a laboratory environment. In some instances, measurements may be possible in situ within a field context.

Past humans preferred to live near the sources of raw materials needed for making artifacts. Those who lived far away made long journeys to obtain the raw materials, or they acquired raw materials or finished goods by indirect means (e.g., trade or exchange). Information about artifact and source material composition can help archaeologists infer past human behaviors for which no other documentation exists. Such behaviors may include the procurement of raw materials, mobility patterns, recognition of political boundaries, and competition for resources. Other applications of sourcing involve artifact authentication, development of technology, and collecting information in support of dating.

Sourcing studies make use of the chemical and physical properties of artifacts and source materials to trace artifacts from their findspot to their place of origin. In some cases, artifact sourcing involves visual methods based on characteristics such as color and texture. For example, lithic artifacts may have been made using source materials with distinctive colors or unique textures (e.g., streaks or inclusions). Inspection of petrographic thin sections of pottery or stone under a microscope sometimes permits the identification of minerals that can be traced to specific sources. Although visual methods of sourcing are less expensive than geochemical ones, they are too subjective and unreliable to use for the routine sourcing of large numbers of artifacts. Geochemical techniques offer more reliability, they can be automated, and they are quantitative, which means they can be validated by statistical procedures.

A basic understanding of geochemical sourcing should include a brief history of its use, an explanation of its principles, and a description of a systematic approach to characterizing sources and artifacts from which the obtained results will be both reliable and valid.

History of sourcing and the provenance postulate

According to a review of the early literature on archaeological chemistry by Caley (1951), the first report of a chemical analysis performed on artifacts of any type was made by the chemist Martin Heinrich Klaproth (1743–1817). Klaproth's work describing the analysis of several ancient Greek and Roman coins was read before the Académie Royale des Sciences et Belles-Lettres de Prusse in Berlin on July 9, 1795, and published in a volume of memoirs by the Royal Academy in 1798. Klaproth discovered that the coins in his study were made of pure copper or copper alloys, and he used this information to estimate their compositions. Because this type of work had never been done before, Klaproth is also recognized as a pioneer in the development of analytical methods in the study of ancient alloys.

Three years later, on October 4, 1798, Klaproth presented a second paper before the Royal Academy describing his investigation of three samples of Roman glass from a mosaic discovered in the ruins of the Villa of Tiberius at Capri. The samples were highly colored and opaque; one was red, one was green, and the third sample was blue. The main objective of his study was to determine the reasons for the different colors. By chemical analysis, he concluded that the different colors were due to the presence of copper and iron, and he also produced a nearly complete analysis of the major constituents. It is interesting to note that in both of Klaproth's works and in subsequent studies of glass by Sir Humphry Davy (1815), the main purpose was to increase understanding of ancient technology rather than to investigate the sources of the raw materials used.

A pamphlet by Göbel (1842) describes the first known attempt to examine a collection of artifacts with the goal of determining both the source and archaeological significance. Several brass artifacts excavated from the Russian Baltic provinces were analyzed, and their compositions were compared to prehistoric brass objects known to be of Greek and Roman origins. The similarity in composition to brass from the Roman Empire was used by Göbel to propose the interpretation that the objects were probably acquired by trade.

Following work by Damour (1865), chemists began to study archaeological materials other than metals and glass. Damour determined the density and composition of rocks and stones for the purpose of establishing their origin. A chemical analysis by Fouqué (1869) of pottery from the island of Santorini concluded that local clay sources had been exploited for pottery production on the island.

Throughout the remainder of the nineteenth and into the first half of the twentieth century, analytical chemists continued to be interested mainly in the compositions of ancient glass and coins. They employed methods such as optical emission spectrometry (OES) or atomic absorption spectrometry (AAS). Use of these methods was limited by the labor demands because the samples required tedious dissolutions, and constituent elements could be measured only one at a time. Other than studying technology and artifact authentication, these works did very little to advance the practice of geochemical sourcing.

The first application of neutron activation analysis (NAA) to archaeological materials occurred in the 1950s. Sayre and Dodson (1957) discovered that the Mn-to-Na ratios in potsherds from several locations in the Mediterranean region (Asia Minor, Greece, and Italy) had similar compositional profiles when they came from the same place of manufacture, but distinctly different profiles when they came from different sources. Soon afterward, Emeulus (1958) used NAA to produce a comprehensive fingerprint for Samian ware potsherds from the western Mediterranean by measuring the major, minor, and the trace elements, simultaneously.

The first geochemical study of obsidian was conducted by Cann and Renfrew (1964), who used OES to examine obsidian from sources located in Anatolia, Africa, and the Mediterranean. This work demonstrated that sources from the different regions differed chemically and that specimens from yet other regions were also different in composition. Heizer et al. (1965) employed X-ray fluorescence (XRF) to identify the sources of obsidian artifacts from sites in Mesoamerica. Soon afterward, Griffin and Gordus (1967) used NAA to determine that prehistoric obsidian tools found on Hopewell sites in Ohio came from sources located in Wyoming and Idaho.

As the instrumentation and procedures for NAA gradually improved, scientists at the Lawrence Berkeley National Laboratory (Perlman and Asaro, 1969, 1971) described a standard comparator procedure for routine sourcing work on ceramic materials based on the use of a homemade pottery standard. With the development of other reliable standard reference materials (SRMs) by the United States Geological Survey (USGS), the National Institute of Standards and Technology (NIST), and their counterparts in other countries (see below), NAA procedures similar to those of Perlman and Asaro were employed at the Brookhaven National Laboratory (BNL) by Bieber et al. (1976) and at many other NAA laboratories around the world (Speakman and Glascock, 2007).

NAA has been regarded as one of the most reliable techniques for geochemical sourcing studies because of its precision and accuracy. (Precision is a measurement of the reproducibility of an analysis, i.e., how consistent the results of analysis are over repeated trials. Accuracy is a measurement of the correctness of the analytical results; i.e., how close analysis gets to the true value.) NAA also has advantages for automation, which enables large numbers of samples to be analyzed systematically. The main drawbacks to NAA are that sample preparation is destructive and radioactive waste is produced.

Since the 1960s, several other analytical methods have been employed to characterize trace and minor elements present in a variety of archaeological materials. The earliest reported study using particle induced X-ray emission (PIXE) on archaeological materials by Ahlberg et al. (1976) was a study of gold alloys on the surface of slate. The first use of electron microprobe analysis (EMPA) on archaeological materials by Merrick and Brown (1984) involved sourcing obsidian artifacts from East Africa. In recent years, various types of inductively coupled plasma-mass spectrometry (ICP-MS) have been employed for bulk and surface analysis of archaeological samples. For example, microwave digestion (i.e., MD-ICP-MS) was used by Pingitore et al. (1997) to study prehistoric ceramic samples from the El Paso area, and laser ablation (i.e., LA-ICP-MS) was used by Gratuze (1999) to identify the sources of obsidian artifacts from Turkey. More recently, the convenience of handheld XRF spectrometers for rapid, nondestructive, on-site analysis of archaeological materials has gained widespread recognition (Williams-Thorpe et al., 1999).

The use of isotope-ratio mass spectrometry (IRMS) has grown in popularity in recent years. Sourcing applications with isotope ratios rely on the isotopic variations arising from mass-dependent fractionation of the light stable isotopes (e.g., of H, C, O, N, S) in natural systems or changes in isotopic ratios for the decay-product isotopes (e.g., of Sr and Pb) populated by the naturally radiogenic isotopes of Rb, Th, and U. Archaeological applications for IRMS include the use of gas source mass spectrometry (GSMS) of foods (Evershed et al., 2002) and human artifacts to measure oxygen isotope ratios, which can vary by latitude. Strontium isotope analysis has proven to be a successful method for studying human migration and mortuary rituals in the Andes region of South America (Knudson et al., 2004), and lead isotope ratios have been used to study lead exchange and provenance patterning in Southeast Asia (Pryce et al., 2011).

Although the prerequisites for sourcing of artifacts were clearly understood by the early analytical chemists, it was not until the mid-1970s that a precise description of the requirements was made. In a study of turquoise artifacts and sources from the American Southwest (Weigand et al., 1977), the authors state that success in linking artifacts to their true sources is dependent on the hypothesis "that there [must] exist differences in chemical composition between different natural sources that exceed, in some recognizable way, the differences observed within a given source." In other words, for a sourcing study to be successful, the between-source difference for the raw material must be greater than the within-source variation. The hypothesis is commonly referred to as the Provenance Postulate. The requirements described by the Provenance Postulate apply to any study involving chemical, mineralogical, and/or isotopic differences between sources.

What is a source?

Unfortunately, use of the term "source" can be ambiguous. When geologists use the term "source," they are usually referring to a specific geographic location for a particular material. On the other hand, geochemists describe a "source" on the basis of its chemical composition, which must be different from the composition of other sources. The former implies a geographic exactness, while the latter emphasizes the distinctiveness of a chemical type or "chemical group." Another way to imagine this distinction is that a geographic source is defined by its coordinates; but a geochemical source is defined by the composition of a group of samples which may have been dispersed spatially due to dynamic processes such as erosion and landform change.

As explained by Harbottle (1982), Hughes (1988), and Neff (1998), the two definitions correspond to different analytical units which, depending on the archaeological and geological circumstances and on the degree of resolution, may vary in their relevance to answering a specific archaeological question.

Raw material sources can be very complex. Primary deposits can range in size from a few tens of square meters to thousands of km^2. The materials from a source can have chemical fingerprints that are very homogeneous (e.g., obsidian) or highly heterogeneous (e.g., marble). As a result of natural geologic processes, primary sources are sometimes separated by tens of kilometers due to the emergence of mountain ranges or the incision of valleys, yet still reveal a single compositional signature for the entire source area. Fluvial transport processes can move raw materials hundreds of kilometers, thereby establishing displaced secondary deposits of essentially the same source (Shackley, 1995). Sources can also contain overlapping mixtures of raw materials representing several distinct chemical types (Ambroz et al., 2001).

In addition to the natural geologic processes that sometimes affect the locations and compositions of raw materials, other factors can make it very challenging to link artifacts geochemically to raw material sources. Among these factors are (1) modifications to the raw materials by technological, chemical, or biological processes at the moment of artifact production, (2) uses for artifacts that have the potential to induce changes in composition after manufacture, and (3) changes to artifact composition induced by postdepositional processes. Manufacturing practices, such as mixing, firing, or smelting, may alter the composition by enriching certain elements while diluting others; such activities can result in the production of artifacts (e.g., ceramics, glass, metals) that possess chemical signatures differing markedly from those of the original ingredients. The composition of artifacts can be altered by the incorporation of residues within the sample matrix during use or by diagenetic effects that occur after disposal and burial. Also, biological processes that create biofacts (e.g., bones, teeth, coprolites) convert food sources into plant or animal tissue; as artifactual indicators of past human behavior, these biofacts will be chemically different from their source materials.

Different approaches to source determination

As explained by Neff (2000), identifying a source based on the Provenance Postulate will generally follow either of two lines of attack. The two approaches differ according to whether compositional groups are defined through analysis of the source materials or the unknown artifacts. Sampling procedures and interpretation of the data will depend upon which approach is used.

The first approach is followed when the artifacts to be sourced were manufactured from natural materials by physical modification methods such as knapping, carving, or shaping. The raw materials may be compositionally homogeneous, such as most obsidians, or more heterogeneous, such as basalt, chert, limestone, and gemstones. Because artifact composition is not altered during manufacture, the compositional signatures remain essentially unchanged from those of the natural sources. In such cases, the sources should be analyzed first in order to establish the range of variation within, and differences between, the compositional reference groups for all available sources. Ideally, the reference groups should have some relationship to the primary geographic location of the source, but geological processes that displace raw materials may create secondary locations or mixtures of raw materials corresponding to multiple primary sources. After the source reference groups have been established, artifacts can be analyzed and compared to the reference groups to find the best matches.

The second approach is more often employed when the artifacts were made by technological, chemical, or biological modification of source materials or when the sources are so widespread that sampling all of them is impractical. Examples include artifacts such as ceramics, bricks, man-made glass, metals produced by smelting of raw ores, and biofacts. For this second approach, compositional reference groups are usually created by analyzing large numbers of artifacts. Artifact reference groups may reveal some relationship to archaeological sites, time periods, or other characteristics, but such associations do not necessarily emerge. Information regarding the frequencies of particular compositional groups present at archaeological sites is used to suggest whether the archaeological site is a production center or a use site (Bishop et al., 1982). The final step involves projecting the raw material sample compositions against the artifact reference groups and inferring the most likely locations for the raw materials used to manufacture the artifacts. Alternatively, artifact reference groups (e.g., for pottery and bricks) can be compared to other similar artifacts for which there is a known place of manufacture (such as sherd wasters from a potter's kiln or bricks from a former brickyard) in order to establish a location of production if not raw material source.

A systematic approach to characterization of sources

Reviews of the early literature on sourcing investigations indicate that many of the studies did not realize their full potential because they were poorly planned, poorly executed, or poorly communicated (Hughes, 1984; Glascock et al., 1998; Shackley, 1998). The problems ranged from: (1) incomplete source descriptions that failed to account for all possible primary and secondary deposits before assigning artifacts, (2) failure to collect and analyze a sufficient number of samples to describe the full variability within and differences between sources, and (3) analytical deficiencies that produced results that were incompatible with data from other studies or laboratories and therefore could not be broadly compared. As pointed out by Glascock et al. (1998), a well-planned, systematic approach to sourcing investigations can be more efficient, be less expensive, and realize greater potential.

The locations of raw material sources in the region of interest should be identified first. Through studies of geologic and topographic maps and on-the-ground surveys, the primary outcrops, secondary deposits, and prehistoric quarries should be investigated. Observations regarding erosion, weathering, volcanic activity, farming, and road cuts should be noted, because the landscape may have undergone significant changes since prehistoric times. The locations where prehistoric sources were formerly exploited may now be buried, or new source areas that were never used prehistorically may now be exposed. All available descriptive information should be recorded on the geologic setting, along with the geographic coordinates for samples collected at the source. Different names may be attributed to the same source, and therefore, clarification of all names used to describe the sources of raw materials is essential to avoid confusion by other archaeologists as well as the laboratory analysts, who are unlikely to have been engaged in the field collecting. Days or weeks of field reconnaissance, discussions with geologists, and consultations with the local populace may be necessary to complete an effective sample survey.

Raw material samples should be collected intensively throughout the source area so that enough specimens are available to detect and identify possible sub-sources. A handful of samples may be sufficient to assess internal variability within a homogeneous, localized obsidian source; however, one never knows until chemical analysis is completed and the results are assessed how many samples will be enough. There is no magic number of samples that should be collected and analyzed. Since it may be difficult or expensive to make multiple visits to collect additional samples, it is preferable to collect too many than too few. When sources cover large geographic areas and show substantial internal variation, and when outcrops are numerous, it may be necessary to collect hundreds of samples.

Samples collected for analysis should be representative of raw materials likely to have been used to manufacture artifacts. The size (i.e., mass) of individual samples should be large enough so that multiple analytical techniques can be conducted, and archival portions can be retained to allow for future analyses or for exchanges with colleagues from other laboratories. All details regarding the handling of samples should be recorded. Information regarding the tools used to extract raw materials, containers used to transport them, equipment used to grind them, chemicals used to digest them, and vessels used during chemical analysis should be documented so that potential sources of contamination can be recognized. All available analytical methods should be performed on the samples from each source so that the compositional data will have the highest possible precision and accuracy.

Calibration curves assign a value to a variable; they show the relationship between the analytical signal yielded by an instrumental technique and the quantity of an element present in the sample. Such curves are usually established by analyzing a series of primary standard reference materials (SRMs), including those available from the National Institute of Standards and Technology (NIST), United States Geological Survey (USGS), Geological Survey of Japan (GSJ), and other providers. The chemical uniformity of each standard means that it should always give very similar results for constituent elements, even when analyzed by different instruments, by different laboratories, by different techniques, and in different sample batches. The standards employed should be similar to the archaeological materials representing the unknowns, and when the standards are analyzed alongside the unknowns as quality control samples, they would indicate some form of bias if the results obtained for the standards varied from their predetermined values. Standards are routinely included in batches of samples to insure that no systematic errors are affecting accuracy and that consistent yields for a suite of elements confirm an acceptable level of precision.

Once analytical results have been obtained, examination of sample data for a range of sources using univariate and multivariate statistical methods (e.g., box-and-whisker plots, cluster analysis, factor analysis, principal components analysis, discriminant functions, bivariate plots, etc.) should be performed to identify compositional groups. Such groups represent clusters of samples that show similar chemical makeup; they will usually be associated with specific geographic coordinates, but they do not always turn out to be spatially constrained. Individual compositional groups should be described by approximately three times as many samples as the number of parameters (i.e., elements, minerals, isotope ratios, principal components, or factors) necessary to differentiate between the individual source groups (Harbottle, 1976). Careful examination of compositional group profiles may help to detect critical parameters (i.e., elements or combinations of elements that are distinctive and hold constant throughout one group but are absent in other groups and might thus be used as a shortcut). If critical parameters are discovered, it may be possible to design abbreviated analytical procedures that target specific measurements of those critical parameters. Use of abbreviated procedures has the potential to make analysis of certain artifacts more efficient and less expensive (Glascock et al., 1994).

Summary

Geochemical sourcing of artifacts has proven to be one of the most effective ways of identifying past human activities, including resource procurement practices, mobility patterns, trade and exchange, and recognition of political boundaries. Geochemical sourcing makes use of the compositional fingerprints of artifacts and source materials as measured by chemical, isotopic, or mineralogic methods, and the data obtained can be used to trace artifacts from their findspot to their place of origin, or source. The analytical techniques in most frequent use today are NAA, XRF, and ICP-MS, each of which are capable of measuring the abundances of elements and isotopes in a wide range of archaeological materials with high precision and accuracy.

In order for artifact sourcing studies to be successful, the most important requirement is that the source materials satisfy the Provenance Postulate, which requires that the compositional differences between sources be greater than the compositional variability within each source. Before analyzing large numbers of artifacts, it is essential that one undertake a systematic study in order to collect and analyze large numbers of source materials from all likely source areas (i.e., primary and secondary) to establish a reliable database against which the artifacts can be compared. Source and artifact data should be analyzed by a combination of univariate and multivariate statistical methods, including cluster analysis, principal components analysis, discriminant functions, and other methods to validate the robustness of any source assignment.

Evidence for the popularity of geochemical sourcing is demonstrated by the hundreds of articles that have appeared in journals such as *Archaeometry*, *Geoarchaeology*, *Journal of Archaeological Science*, and others over the past half century. A few recent examples of sourcing studies have been reported on human skeletal material, obsidian, ceramics, and chert, respectively, by Knudson et al. (2004), Glascock (2002, 2010), Anderson et al. (2011), and Huckell et al. (2011).

Definition

GIS are software programs for creating, managing, manipulating, analyzing, modeling, and presenting spatially distributed information.

Introduction

GIS are complex software systems that enable one to encode, manage, and display information that has a spatial component; they also offer tools for data editing, manipulation, spatial analysis, and modeling. Included as well are components for database management, advanced graphics and cartography, image processing, and statistical analysis. Many benefits arise from these closely linked software systems, but GIS possess unique capabilities because all information is spatially referenced. This permits diverse data sets – environmental, social, land use, political – to be compared at any location. The results of queries, analyses, or models occur in map form, facilitating visualization of relationships. The synergy that results has promoted rapid growth of GIS applications in virtually all spatially oriented disciplines. This is particularly true in archaeology with its focus on site distributions within regions and artifact distributions within sites. Mapped information is not confined to Earth features or even to human scales because applications may range from atomic surfaces to galactic distributions and mappings of other planetary bodies.

Archaeological applications

GIS have a long history in archaeology beginning with the origins of the technology in the 1980s, represented by several papers in the Computer Applications in Archaeology conference proceedings and a major review article (Kvamme, 1989). Since then, the importance of GIS to the discipline is revealed by countless overview and research articles that illustrate multiple uses of the technology (e.g., see Allen et al., 1990; Lock and Stančič, 1995; McCoy and Ladefoged, 2009) and instructional textbooks (Wheatley and Gillings, 2002; Conolly and Lake, 2006). As in any field, the principal archaeological application of GIS is for database management. In archaeology, this refers to site-specific, state-wide, or regional databases typically used for cultural resource management (CRM) purposes, but also for research. Archaeological site files may include tens of thousands of archaeological records that must be managed. In these contexts, GIS are primarily employed for searches and queries, data displays, and reporting. GIS are also commonly used for managing projects that focus on a single archaeological site and which include historic and recent maps, records of excavated finds, imagery from geophysical surveys, aerial and satellite data, and digital elevation models (DEM).

More exciting are archaeological applications of GIS analytical tools for spatial analyses and problem solving. GIS have been employed to model prehistoric routes of travel over the landscape (Madry and Rakos, 1996) and to define territories and catchments around settlements based on resource distributions, natural boundaries, and travel time models (Gaffney and Stančič, 1991). Studies of intervisibility between settlements have been conducted to explain their settings, the dominance of some sites that command large regions of view, or socially important landscapes by the regions they define (Wheatley, 1995). GIS have enhanced prehistoric computer simulations by permitting them to function in realistic landscapes containing multidimensional features of actual environments (see papers in Kohler and van der Leeuw, 2007). GIS-based "predictive" models of archaeological location indicate regions where past settlement is likely to have occurred. They are typically based on extant data from known settlements, preferably taken from surveys that utilized some sort of regional random sampling scheme to reduce past survey biases. These settlements are analyzed for location preferences, such as tendencies for good soils, proximity to water, level ground, defensive positions on hilltops, etc. A wide variety of GIS techniques, ranging from simple Boolean intersections to complex logistic regression models, are then employed to combine these preferences into region-wide maps that describe spatial patterns of past settlement. The element of "prediction" arises when such maps permit prospecting for sites not yet discovered by traditional field surveys (see Mehrer and Wescott, 2005).

Software and hardware

The organization of GIS can be characterized as having four components: (1) a data input system that permits capture of information from maps, photographs, remote sensing devices, and databases; (2) a spatially organized data storage and retrieval system that allows rapid access and display of information using spatial or attribute searches while providing basic editing and updating functions; (3) a variety of geographical, image, and statistical processing routines for data manipulation and analysis, plus routines for transforming and aggregating information to produce new data as well as statistical analyses, summaries, and models; and (4) a reporting system that displays all or parts of the database in multiple graphical forms and in tables, charts, and graphs.

GIS databases can be large, so storage space and processing speed are issues, and high-resolution color graphics monitors are essential. Because the focus is on mappable information, specialized input and output devices are required, such as digitizers, scanners, and large-format color plotters. Popular GIS used in archaeology currently include ArcMap, TerrSet, MapInfo, GeoMedia, Grass, QGIS, and gvSIG.

Key concepts

Several concepts are fundamental to all GIS. One is "database region," which defines a window describing the space of interest, whether it is continental in scale, statewide, the area of an archaeological site, or even a single square meter of excavation. Individual mapped data sets represent distinct "layers" of information, each representing a spatially distributed variable for the region in question, such as hydrological drainage, population density, vegetation cover, etc. Layers may contain discrete objects that have size and shape (e.g., rivers, roads, buildings), or they may vary continuously as surfaces composed of numeric measurements (e.g., temperatures, elevations).

All positional data are defined by a coordinate system (e.g., Cartesian x-y, longitude-latitude), and individual layers are co-registered to the same coordinate system; this insures that any locus in one layer coincides with the same place in others. Additionally, GIS databases may be associated with a particular projection, which is necessary for large regions where the curved surface of a planetary sphere must be transformed in order to be projected onto a two-dimensional display (e.g., Universal Transverse Mercator, Albers Equal Area Conic).

The data that form the layers may be derived from digitized or scanned paper maps, global positioning system coordinates, aerial or satellite imagery, or geophysical instruments, for example. The processing power of GIS permits a great diversity of new layers to be derived. Such secondary layers may include processed and classified satellite data, terrain form measures derived from basic elevation data, or complex multivariate models based on numerous inputs.

Map data and GIS types

In cartography, maps are composed of discrete elements (including point, line, or area objects symbolizing lakes, roads, houses, towns), plus surfaces (e.g., a shaded terrain surface). Point features might represent a mountain summit, a surveyor's datum, or a town on a small-scale map. Lines are employed to indicate rivers or roads on small-scale maps, or elevation contours at any scale. Area data include lakes, forests, property parcels, or counties. The boundaries of areas form polygons. Surface data represent measurements that do not relate to arbitrary area units (such as counties), but to continuous variations that can be quantified anywhere. Examples include elevations, geomagnetic data, or continent-wide temperature changes. Two approaches to GIS have developed in response to these data types: "vector GIS" are designed for handling discrete point, line, or area objects, while "raster GIS" are best suited for continuous surface data. Each has very different characteristics, but most GIS permit work in both domains, and information can frequently be transformed from one to the other.

Raster GIS

A raster data structure is defined when measurements occur systematically across a region in a matrix composed of rows and columns. Location is controlled by row and column position within the raster where each cell is linked with real-world spatial coordinates. The attribute held in a particular cell of a raster grid represents the measurement corresponding to a specific area on the ground. In image or picture data, cells in a raster are frequently referred to as "pixels" (for "picture elements"). Raster layers are well suited for representing surface phenomena that vary continuously across a region, such as temperature, magnetic fields, terrain elevations, or reflected light variations in a satellite image or photo. Virtually all data from remote sensing occur in raster formats. Displays simply color-code or grayscale each cell, which can attain a photographic quality when all pixels are assembled.

Attributes held within cells may be continuous or categorical. The former may hold individual elevation measurements distributed every 10 m across a region to form a DEM of terrain, while the latter might portray soil distributions with numeric codes that indicate soil type. This means that raster GIS may hold discrete point, line, and area data types indicated by appropriate attribute codes in each cell. Accuracy is controlled by the area represented by a cell, which defines spatial resolution. The portrayal of discrete objects is therefore less accurate than in vector systems because "points" possess the area of an entire cell, and diagonal lines and area boundaries appear to have jagged "stair-step" edges inherent to the cell structure of rasters.

Vector GIS

Vector GIS possess data structures and display formats that parallel the three discrete cartographic types. *Point* vectors are defined by single points associated with spatial coordinates. *Line* vectors and *area* vectors include inferred line segments between a series of coordinate points. In the latter, line segments circumscribe areas to form polygons. Modern GIS employ an "arc-node" data structure for spatially representing the area data type. Arcs include a sequence of coordinates and the assumed lines between them that form a border between two adjacent polygons (or a map edge). Nodes are the end-points of arcs that occur where three or more polygons meet. All vector objects are linked to records in a data table that can include many attributes. For instance, an area vector that portrays the extent of a specific soil type might be linked to a data table that gives its classification, pH, texture, fractions of sand, silt, clay, organic matter, and the like. Most GIS provide a digitizing function that permits tracing of point, line, or area features on-screen to generate corresponding vector data. Vector GIS can be spatially accurate and precise because the positions of objects are controlled by the coordinates of the points which define them, and modern surveying methods ensure both. Vector GIS are required whenever accurate locations, area, or perimeter data are necessary (e.g., in portraying property boundaries).

Continuously varying information, such as elevation data, are generally represented by isoline contours in vector GIS. Alternatively, triangulated irregular network (TIN) models permit surfaces to be described by numerous triangular facets, where each corner or node represents a measurement in the continuous field. Unlike the common cell size of rasters, TIN models are variable in resolution, which means that regions with little change may be covered by larger triangles, while many small triangles can represent the greater detail necessary in areas showing more surface complexity.

The dominant application of vector GIS lies in working with spatial databases. Municipalities manage properties, power lines, and basic infrastructure, while archaeologists manage archaeological sites in regions or artifacts within individual sites (e.g., see Conolly and Lake, 2006). Regional databases are managed by vector systems because such discrete objects as "sites" or "artifacts" are best described by points, lines, or areas. Database queries can be bidirectional – made by pointing to elements on a display screen or through *structured query language* (SQL), a standard set of rules for asking such questions of databases as "Sites = Archaic" (which will select and display only the locations of Archaic sites). Selected elements may be simultaneously displayed in map and tabular form, yielding complete information that includes spatial relationships seen graphically.

Fundamental operations and tools

The GIS toolbox offers a wide variety of operations that may be performed with functionality varying between vector and raster systems. Their real power occurs in their combination, when several are chained together to achieve complex results.

Map reclassification

Reclassification is one of the most widely employed of all GIS operations. It permits generalization of a map from many to fewer categories and might be employed to reduce several hundred soil types to three that indicate relative suitability for maize agriculture, for example.

Distances and buffering

The spatial character of GIS permits proximities and distances to be computed. With discrete vector objects, a fixed distance defines a zone known as a *buffer*, represented by an area vector. An example might be a 500 m exclusion zone around a sensitive riparian habitat. Raster GIS permit continuous distance surfaces to be generated where each cell holds a distance to the nearest target cell of interest (e.g., a water source). Distances might be linear or a "cost-distance" based on premises about difficulty of movement considering slope, elevation changes, and land cover types.

Boolean operations and models

Boolean algebra utilizes variables that assume only two values (typically 0 or 1, or false and true). The Boolean intersection compares two or more binary GIS layers: if A represents proximity to water and B good soils, then their intersection represents those locations where both conditions are true. For a true result under a Boolean union, only one of the inputs must be true, however. Boolean methods form a fundamental tool for constructing simple yet powerful models based on a potentially large number of relevant inputs.

Map algebra

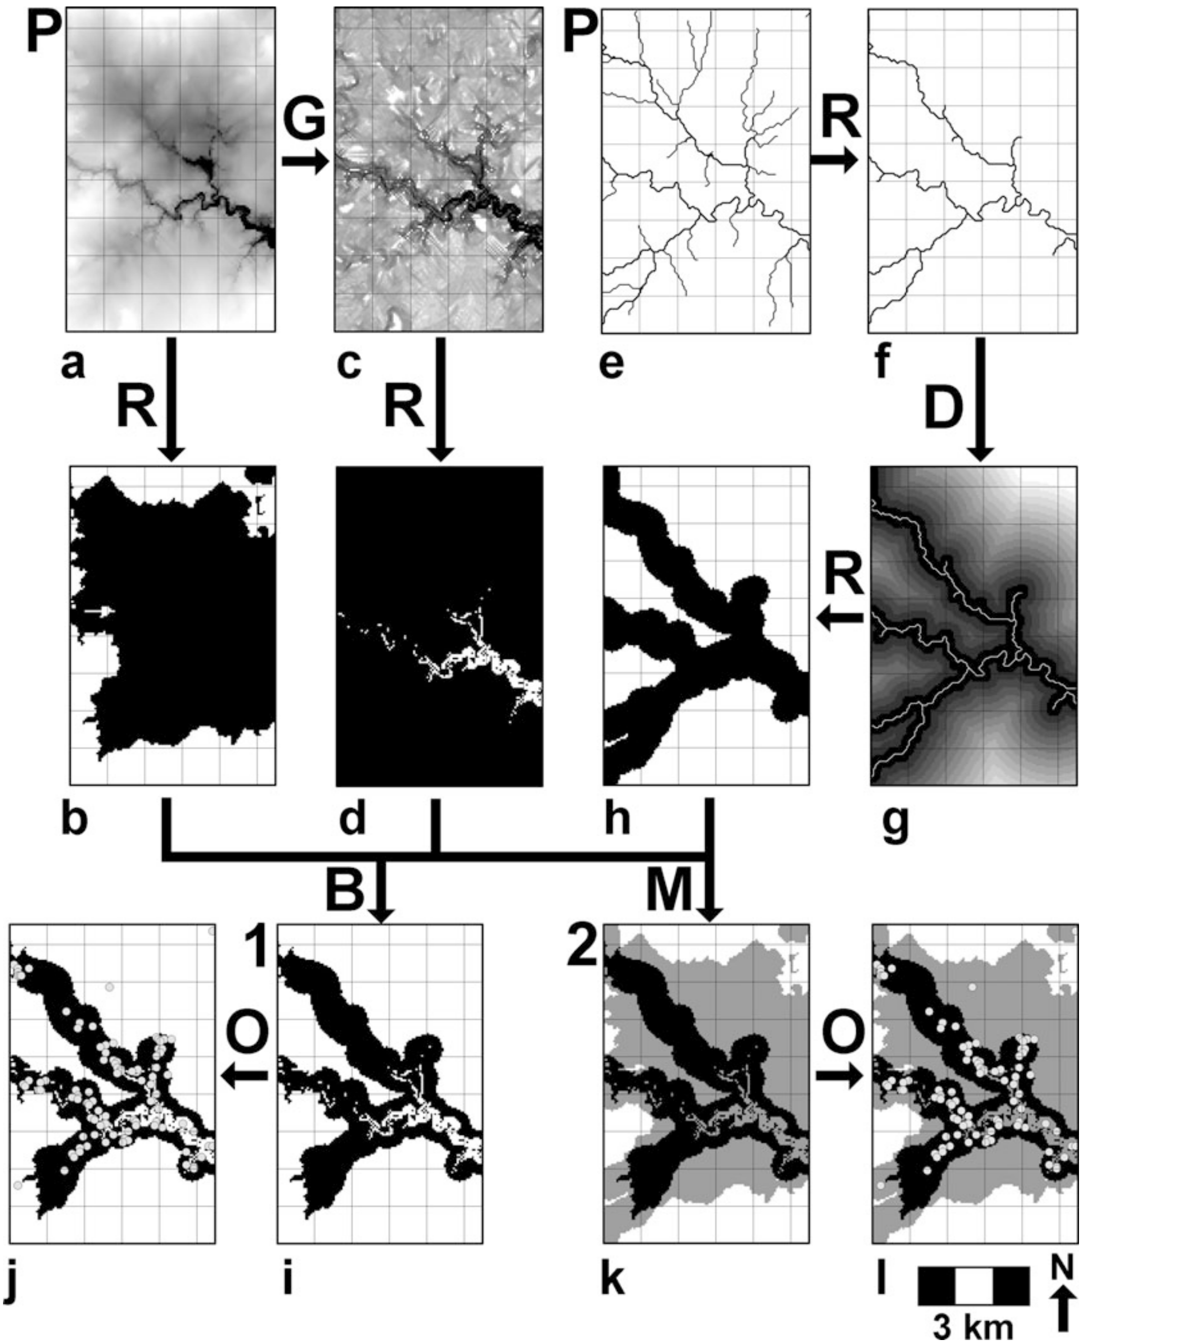
The application of mathematical operations to layers is uniquely a raster technique and one of the most powerful tools in GIS because it permits the development and application of complex mathematical and statistical models. Operations include addition, subtraction, multiplication, division, square roots, logarithms, the finding of minima and maxima, and the computation of means. Map algebra can be thought of as a mathematical function applied locally on a cell-by-cell basis where

$$\text{newlayer} = f(\text{oldlayer}_1, \text{oldlayer}_2, \ldots, \text{oldlayer}_k)$$

for a k multilayer operation (where f represents a mathematical function).

Neighborhood and zonal operations

While map algebra manipulates raster data in a single cell vertically through multiple layers, neighborhood operations function in a single layer by evaluating cells in a neighborhood of varying sizes or shapes around each cell, returning, for example, the minimum, maximum, or average of neighborhood values. Many of these operations amount to filters that are employed in terrain or image processing.



Geographical Information Systems (GIS), Figure 1 GIS operations in the context of building archaeological location models based on the premise that archaeological sites tend to occur at low elevations, on level ground, and close to secure water. In (**a**), the primary (*P*) layer, a DEM, is subjected to a reclassification (*R*) operation to yield a Boolean (true-false or 0–1) layer showing (**b**), *low elevation*, based on a threshold value. A gradient (*G*) operation is also applied to the DEM to yield (**c**), a *slope* layer, which in turn is reclassified to indicate (**d**) *level ground*, also Boolean. The primary layer (**e**), *water*, is reclassified to indicate (**f**), *permanent water*, which is used as input to a distance operation (*D*) to yield (**g**), *linear distance to permanent water*, and reclassified for (**h**), a Boolean indication of *proximity to permanent water*. *Model 1* (**i**) is formed by the Boolean intersection (*B*) of b, d, and h, and its performance is evaluated through an overlay (*O*) of (**j**) containing *known archaeological sites*, which registers as 86 % correct in a model encompassing 29 % of the region. *Model 2* (**k**) arises through the application of (*M*) map algebra to compute the sum of **b**, **d**, and **h**, where higher sums indicate locations that meet a greater number of the specified conditions. The overlay of (**l**), *known archaeological sites*, shows that all occur in the two highest categories, which encompass 75 % of the area, while results for the highest category are identical to the Boolean model.

Related are zonal operations that evaluate data in one layer within a zone defined by another, such as average income among households (layer 1) within a county (layer 2).

DEM creation and processing

With the prominence of landform variables in many archaeological applications, most GIS include interpolation tools, including geostatistical routines, for generating DEM (digital elevation models) from point or contoured elevation data. Additionally, numerous tools generate specific terrain characteristics making use of neighborhood operations. *Shaded relief* illuminates a terrain surface to mimic the effects of a light source shining on an actual surface, with bright areas and cast shadows. *Slope* is simply the first derivative or gradient which quantifies steepness, while *aspect* defines the azimuth or direction of maximum slope. *Drainage lines* may be derived analytically by modeling water flow as it runs through dropping elevations, and *ridge lines* can be obtained by reversing the algorithm. Watersheds may be generated by defining a drainage system and all points that flow into it. *Intervisibility* between two points involves computing a ray between them and determining whether intervening terrain is of sufficient elevation to block it. A *viewshed* refers to all locations visible from a point or points. Much of the terrain functionality originally developed in raster GIS can now also be performed on TIN models in the vector domain.

Image processing

Image processing modules exist within raster GIS for the manipulation and enhancement of imagery, whether from satellite, aerial, or terrestrial sources. These tools utilize neighborhood operations to perform such tasks as low-pass filtering to reduce noise, high-pass filtering to eliminate trends, and edge detection to isolate and enhance discrete boundaries. Brightness and contrast changes can improve visualization, and a variety of image classification methods permit identification of naturally similar regions.

Statistical operations

Some GIS offer a limited suite of descriptive statistics, conventional inferential and spatial statistical tests (such as tests for autocorrelation), and multivariate procedures for spatial modeling.

Network analysis

A network, such as a road lattice or a dendritic drainage system, is typically represented by line vectors. Each arc in the network can indicate impedances to flow or movement. Network analysis is useful to fire departments, emergency services, or traffic controllers because it permits optimum travel times and routes to be computed through complex networks by considering such variables as distances, typical velocities, traffic, and other relevant factors.

Several fundamental GIS operations are illustrated in Figure 1 where their utility for problem solving is demonstrated in the context of archaeological location modeling.

Summary

GIS are all-purpose software for handling and processing spatially distributed information. Because archaeological data are inherently spatial, GIS have had great impact on the discipline as general data management tools for regional and within-site databases, for analyzing past routes of travel, defining site catchments, understanding resource distributions, examining social landscapes based on mutual intervisibility, analyzing settlement choices with respect to environmental conditions, and for developing models of archaeological location.

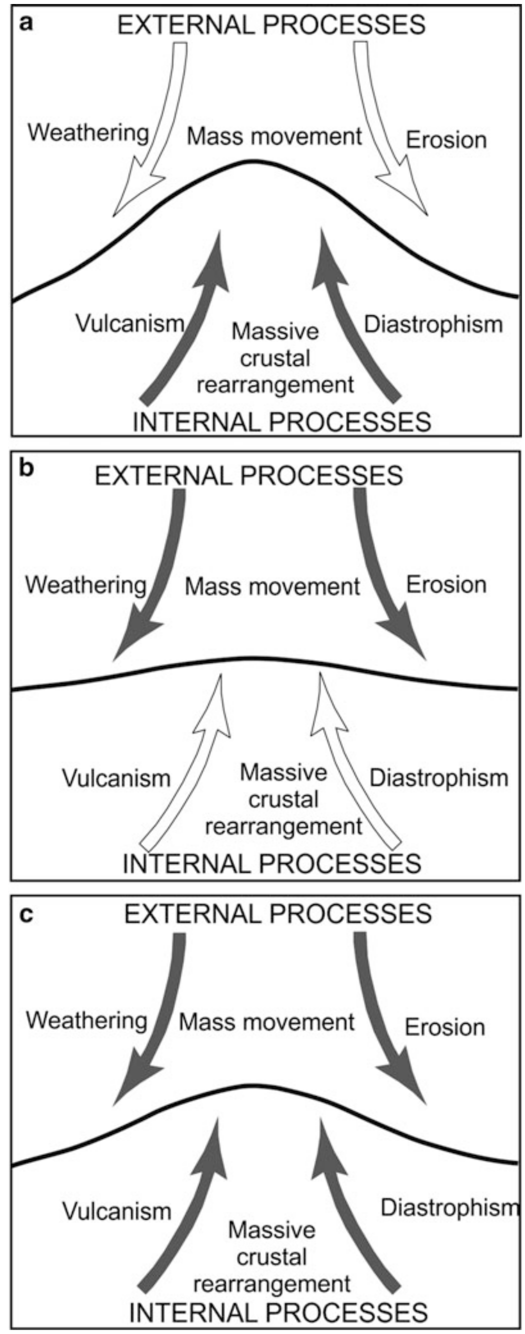
Definition

Geomorphology is the systematic study of landforms and the processes that form and change them.

Introduction

Geomorphology and its close ally, soil science, are major components of geoarchaeological practice today, and they were significant contributors to the emergence of the field of geoarchaeology. As the study of landforms, geomorphology helps to explain the evolution of the physical landscape, often referred to as "relief." Landforms are the result of physical forces referred to as geomorphic processes, and these processes are broadly divided into internal (endogenic) and external (exogenic) (Figure 1). The internal processes include movements of the earth's crust that build surface relief by means of diastrophism (folding and faulting of rocks) and volcanism. The external processes, on the other hand, are those that sculpt the landscape through weathering, mass movement, and fluvial, eolian, glacial, and coastal processes. When internal forces predominate (indicated by dark arrows in Figure 1a), the land surface is dominated by high elevations. In contrast, where there is little or no uplifting by internal forces, the land surface is eroded so as to form low relief (Figure 1b). Over long periods of time, most continental landscapes are normally the result of a balance between both forces (Figure 1c).

Explaining the relationship between generative processes and resulting landforms has been one of the main objectives of geomorphology. It is a complicated task because the landscape (i.e., the relief) is often created by a combination of processes acting at various intensities at different times and over varying durations. For this reason, geomorphologists have proposed different conceptual themes to analyze the origin of landscapes. William Thornbury enounced ten basic concepts in the early 1950s (Thornbury, 1969, 16–33). Concept 1 was borrowed from the theory of uniformitarianism: "the same physical processes and laws that operate today operated throughout geologic time, although not necessarily with the same intensity as now." Concept 2 states that "geologic structure is a dominant control factor in the evolution of landforms and is reflected in them," which alludes to the influence of geology in the shaping of landforms. Concept 6 proposes that "complexity of geomorphic evolution is more common than simplicity," as a reference to the ideas of polygenesis and inheritance, which state that (1) multiple processes acting at the same time or at certain times produce complex suites of landforms, and (2) current landforms bear shapes that are sometimes inherited from climates or environments of the past (Bauer, 2004). Emphasis on the influence of climate is expressed in



Geomorphology, Figure 1 Internal tectonic versus external climatic forces: landscape is affected by the dominance of internal forces (**a**) and external forces (**b**), and, over time, both forces tend to be in balance (**c**). Based on Hess and Tasa (2011) with modifications.

Geomorphology, Table 1 Time scales of geologic (geomorphic) events. A localized landslip or flow would be considered a mega-event if it occurred during a single day (such as a massive mudslide) but only a micro-event if it took 10 years for the material to be fully displaced (After Schumm 1991)

Relative magnitude of event	Time scale							
	1 day	1 year	10 years	10^2 years	10^3 years	10^5 years	10^6 years	10^8 years
Mega-event	Local soil slip or flow	Gully	Meander cutoff	Volcanic eruption	Terrace formation	Continental glaciation	Major folding, faulting	Mountain building
Meso-event	Rill	Local soil slip or flow	Gully	Meander cutoff	Volcanic eruption	Terrace formation	Continental glaciations	Major folding, faulting
Micro-event	Sand grain movement	Rill	Local soil slip or flow	Gully	Meander cutoff	Volcanic eruption	Terrace formation	Continental glaciation
Nonevent[a]	–	Sand grain movement	Rill	Local soil slip or flow	Gully	Meander cutoff	Volcanic eruption	Terrace formation

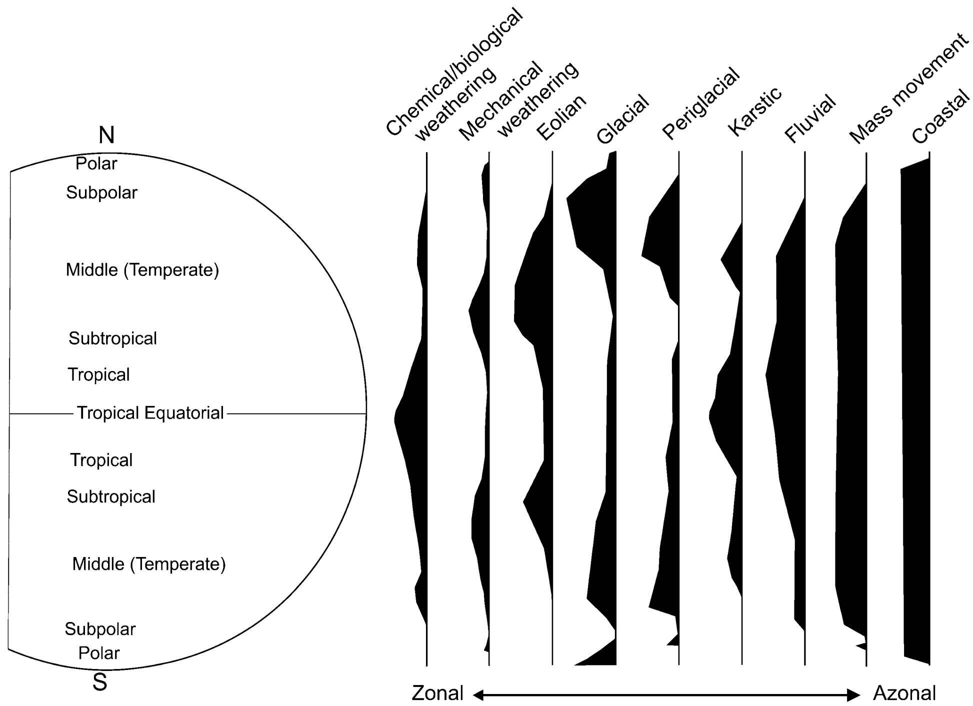
[a]A nonevent is explained in Schumm (1991, 34): "A mega-event during a short period may become a nonevent over longer time spans, as its effects are obliterated"

Concept 9 as "an appreciation of world climates is necessary for a proper understanding of the varying importance of the different geomorphic processes." The importance of Pleistocene climates in shaping modern relief is also emphasized in Concept 8 as "a proper interpretation of present-day landscapes is impossible without a full appreciation of the manifold influences and climatic changes during the Pleistocene," as well as Concept 7, which states "little of the earth's topography is older than Tertiary and most of it no older than Pleistocene." The fact that most of the landforms we see today were created during the Pleistocene – that is to say between ca. 1.8 million years and 10,000 years ago – suggests that we are looking at a relatively young landscape. Although recently superseded by new theoretical and empirical research, these concepts encapsulate the idea that process-landform is highly complex in the context of different lithologies, geological structures, tectonic movements, and climates.

The complexity of landform development derives primarily from the time scales and magnitudes at which geomorphic processes occur (Table 1). Processes of continental magnitude occur over longer periods of time than those affecting a particular landform, such as a dune or a point bar in a stream, which can change in a matter of days. The two main approaches to studying landforms, dynamic and historical geomorphologies, reflect the differences in time scales and magnitude of varied research goals. *Dynamic geomorphology* is the study of ongoing processes that requires observation and measurement of actual phenomena, while *historical geomorphology* is the study of long-term landform development that relies upon study of the evidence left behind by successive landscape changes. The two approaches benefit from each other because, for example, geomorphologists studying paleofloods based on the geologic record of fluvial deposits often draw their interpretations from studies of modern flood dynamics.

Time and magnitude are not the only subdivisions of geomorphology, as nearly every geomorphology treatise or textbook acknowledges other geomorphological approaches. Yet, opinions on how many range from unity (e.g., Butzer, 1976; Bloom, 1998) to the liberal idea that there are several geomorphologies (e.g., Thorn, 1988). Thus, in addition to the structural-climatic and dynamic-historical dualities, more elaborate subdivisions of geomorphology have been made. One of the most significant subdivisions in geomorphology is that between the structural and climatic approaches, which were emphasized during the middle decades of the twentieth century. Structural geomorphology (often referred to as tectonic geomorphology) is allied closely with the field of geology, where the interest lies in longer periods of time and a focus on internal processes. In contrast, climatic geomorphology has a stronger grounding in geography and emphasizes the effects of external processes.

The link between geomorphology and climate is based on the concept of a zonal distribution of landforms and processes, that is, the general – but not universal – distribution of geomorphic phenomena within global latitudinal belts. In geomorphology, therefore, a zonal distribution suggests that certain landforms and processes predominate at certain latitudes (Figure 2). Eolian environments, for example, tend to be predominant in the world's deserts, which are mostly found along the subtropical latitude high pressure belts. However, eolian environments, and particularly sand dune formation, exist at many latitudes and occur frequently along coasts where the supply of sand is substantial. In some cases, they may be found at middle latitudes, particularly in the cold deserts (e.g., the Gobi Desert in Eurasia and the Great Basin Desert in North America), and even in subpolar latitudes, where fluvioglacial activity also produces large amounts of sand. Likewise, glacial and periglacial phenomena are more typical of subpolar latitudes but are widely found atop mountain chains in all latitudes (and would be more common at high elevations today in the absence of global warming). Karstic environments, in which caves form by dissolution, are widely distributed over the continents, but they

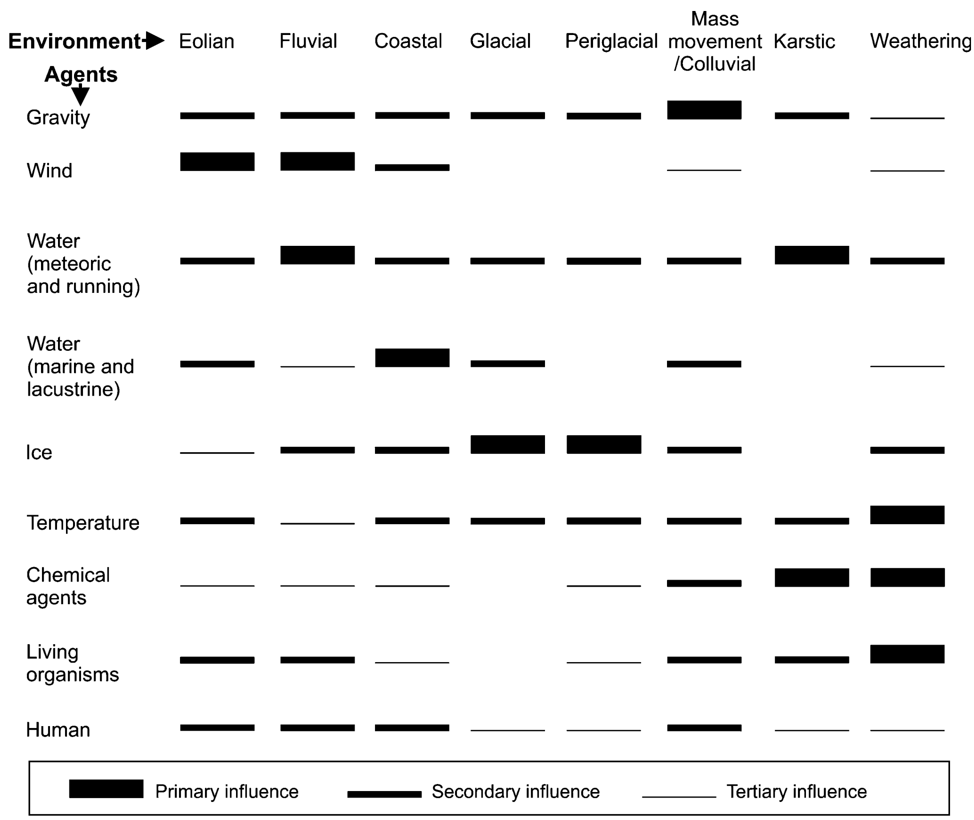


Geomorphology, Figure 2 Latitudinal distribution of main external geomorphic environments. Blackened areas on the vertical frequency scales for each environment show in which zones they are most influential.

actively occur only when water flows in abundance, particularly in tropical and middle latitudes. Finally, coastal (both marine and lacustrine) and fluvial environments are common throughout all latitudes regardless of climate types, and thus they are azonal. Their distribution and abundance vary in relation to areas where landmasses interface with bodies of water. Most processes that are not related to ice, however, are absent on and around the poles.

Sediments are the result of cumulative geomorphic processes resulting from erosion, transport, and deposition that, over time, form the sedimentary sequences that allow geomorphologists to determine the geomorphic environments of deposition at a specific location for the duration of the depositional interval. Each geomorphic environment was characterized by particular depositional systems, some of which were related to a specific process or agency or a combination thereof (Figure 3). In the case of eolian environments, the dominant processes are related to wind; with fluvial environments, it is meteoric/running water and wind; with glacial environments, it is the power of ice. In each environment, however, more than one agency is usually responsible for the development of a particular depositional system. For example, although wind is the most important agent in eolian deposition, there is also a smaller affect by gravity, water, temperature, etc. Additionally, the sand or silt being blown about has often been made available by previous fluvial or glacial processes, so that other environments may also be influential. This means that there are no sharp boundaries between environments, not spatially (as other contributor processes may be occurring nearby) and not temporally (as ancient processes that took place in the same locality can affect modern landforms). One can point to further complexities: the floodplain environment in a desert may contain facies produced by fluvial deposition, the sediments of which can be further entrained by eolian processes. Likewise, cave and rock-shelter formation is linked to the combination of two processes: dissolution and mass movement (collapse by gravity). It is important to note that humans are also geomorphic agents via their deliberate modifications of geomorphic systems through the construction of dams, canals, levees, and other features, as well as indirect destabilization of systems, such as lowering of the water table through pumping, which in turn may cause river channel entrenchment.

The properties of sediment (e.g., grain size, grain shape, bedding structure, mineral composition, etc.) are important for identifying the depositional environment. In turn, sediments contain within their characteristic features proxy data useful for other analyses. These may include charcoal for radiocarbon dating, magnetic properties for paleomagnetic dating, and microfossils for paleoenvironmental reconstruction as well as dating. Therefore, the work of geomorphology in determining the properties and origin of the sediment in a stratigraphic sequence is crucial for many different questions.

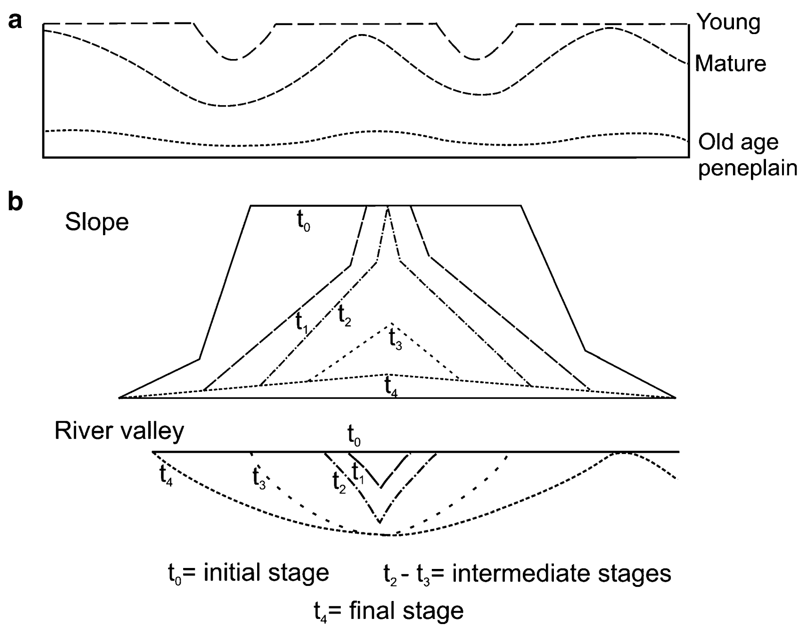


Geomorphology, Figure 3 Geomorphic agents that define each geomorphic environment. The relative influence of each agent on each environment is portrayed by line thickness as indicated in the key at the bottom of the diagram: primary means that this agent is the unique or fundamental agent in the environment; secondary means that the agent is important in the environment but not fundamental; and tertiary means that the agent occurs in the environment but is neither important nor fundamental.

History and evolution of geomorphology

Landforms and their origin have been subjects of scientific interest for several centuries. Geologists, naturalists, science enthusiasts, and even travelers have been intrigued by the formation of landscape features. The ideas of catastrophism by Georges Cuvier (1769–1832) and uniformitarianism by James Hutton (1726–1797) implied opposing modes of change, as both attempted to explain the formation of the landscape in different ways. Many lesser known geomorphologists lived and worked in Europe during the seventeenth and eighteenth centuries, and early practitioners of geomorphology numbered among the geologists of the eighteenth century (Davies, 1989). But it was not until the end of the nineteenth century when geomorphology took shape as a discipline (Goudie, 2011). In North America, the work of John Wesley Powell (1834–1902) and Grove Karl Gilbert (1843–1918), both of whom studied landforms in the western United States, provided the basis for a modern geomorphology, particularly through the introduction of new ideas. For example, in 1875, Powell introduced the concept of base level, by which he meant the level to which all rivers erode (i.e., the sea level), a concept that is still in use. Similarly, in other parts of the world, other scientists left an imprint in geomorphology that persisted through the following centuries. One is the case of the Swiss paleontologist Louis Agassiz (1807–1873), who established the basis for studying and interpreting glacial environments, including the vestiges left by past ice ages.

The American William Morris Davis (1850–1934) and the German Walther Penck (1888–1923) are often seen as the founders of modern geomorphology. Each of these geologists developed synthetic models of landscape evolution, which, despite criticism, became the basis for landform interpretation by geomorphologists in the first half of the twentieth century. The geographic cycle proposed by Davis (1899) considered the vertical downwearing of the landscape by erosion from which young, mature, and old landscapes could be identified (Figure 4a). Yet, the uplifting of an old landscape would mean rejuvenation and initiation of a new cycle. In contrast, Penck's (1924) model considered erosion acting laterally so as to create parallel slope retreat and parallel valley widening



Geomorphology, Figure 4 Abstract representation of models of erosion and landscape evolution by W. M. Davis (1899) (**a**: *top*) and W. Penck (1924) (**b**: *bottom*).

(Figure 4b). These models of landscape evolution were soon replaced by explanations based on field data.

Because certain processes occur mainly at specific latitudes or climatic zones, the term climatic geomorphology was popularized particularly by French and German schools in the early twentieth century (Goudie, 2011). The field has grown to the point that, in addition to glacial, periglacial, and desert landscapes, sometimes references are made to tropical landscapes and even more specific environments such as savanna and Mediterranean geomorphology (Butzer, 1976). An alternative to the climatic approach is a structural approach, which has been developed to emphasize not only the effect of tectonic structure but also broader aspects of continental and even planetary scale. The theory of plate tectonics energized the development of structural geomorphology from the mid-twentieth century. Although this focus was developed in many countries, it characterized most of the geomorphological studies in the former Soviet Union, a trend that made sense given the size of their territory (Walker and Grabau, 1993). Throughout the world, however, the climatic and structural views drew heavily from the disciplines of geography and geology/geophysics, respectively.

By the 1970s, geomorphology around the world was developing nationalistic styles, sometimes based on each country's territorial characteristics, economic trends, and even academic policies (Walker and Grabau, 1993). This led to the creation of different models, standards, terminology, and approaches. But over the years since then, geomorphologists have come to realize that global collaboration, understanding, and standardization are important. Unification of geomorphological thoughts and efforts materialized with the creation of the International Association of Geomorphologists (IAG), under whose auspices the first international conference in geomorphology was held in Manchester in 1985. It was not until 1989, during the second geomorphological conference meeting in Frankfurt, that the association was formally created. Subsequent meetings took place every 4 years in Hamilton, Canada (1993); Bologna, Italy (1997); Tokyo, Japan (2001); Zaragoza, Spain (2005); Melbourne, Australia (2009); and Paris, France (2013). Regional meetings, some sponsored by the IAG and/or national and regional organizations, are also taking place around the world. Additionally, small specialized sections in the European Geological Union, the International Geographical Union, the Association of American Geographers, the Geological Society of America, and the Society for American Archaeology have sponsored geomorphology-related sessions during their annual meetings.

Almost three decades before the creation of the IAG, the Binghamton Geomorphology Symposium had laid a foundation for discussion of theoretical and technical matters in geomorphology. The first symposium was conducted under the direction of Marie Morisawa and Donald Coates of the State University of New York (SUNY) at Binghamton in 1970. Symposia were organized every year afterwards. Although first attended primarily by American and Canadian geomorphologists, the event has gradually attracted participants from all continents. The published proceedings of the symposia have become important sources of information on the theoretical and technological advances of geomorphology.

Some have become keystone publications in geomorphology, for example, *The Scientific Nature of Geomorphology*, edited by B. L. Rhoads and C. E. Thorn (1996). Although individual proceedings volumes exist, in recent years, the Elsevier journal *Geomorphology* publishes the proceedings. The Binghamton Symposia are organized around a specific subject. Some examples of symposia topics include Quantitative Geomorphology (1971), Geomorphology of Arid Regions (1977), Space and Time in Geomorphology (1981), Soils and Landscape Evolution (1991), Biogeomorphology (1995), Geomorphology and Ecosystems (2005), Complexity in Geomorphology (2007), and Geospatial Technologies and Mapping in Geomorphology (2010).

Geomorphology has been subdivided into several areas of topical specialization. Currently, the most common specialization subdivisions in the United States are fluvial geomorphology, eolian and coastal geomorphology, weathering geomorphology, mass movement, periglacial and glacial geomorphology, Quaternary geomorphology, biogeomorphology, environmental geomorphology, geoarchaeology, and planetary geomorphology (Butler, 2003). Advances in information technology have also had an impact. The development of GIS (geographic information systems), DEMs (digital elevation models), and software with statistical capabilities has been crucial to the development of geomorphic models, and these have supplanted many of the old approaches, since a single model can incorporate information on climate, structure, soil, vegetation, and even different time scales, as well as quantitative and qualitative aspects of landform development.

Aided by computerized cartography and animation, modeling has had a great impact on the discipline. It has also been important for mapping the evolution of slopes under erosive forces, which in turn has provided important elements for geomorphic hazard mapping. Three- and four-dimensional models have become important in the reconstruction of ancient river systems, even in areas now below sea level (Brown, 2008). In many instances, four-dimensional models incorporating time have been useful for explaining landscape evolution in the classroom. Thus, modeling in geomorphology has essentially become the bridge between theory and practice, past and present, reality and abstraction, and pure and applied research.

A positive surge in geomorphological research resulted from advances in chronometric dating techniques. This derived not only from the increased accuracy achieved through accelerator mass spectrometry (AMS) radiocarbon dating but also from the application of several other methods, particularly luminescence dating. Although the latter is mainly applied to eolian environments, where carbon for AMS dating is often scarce or unavailable, the technique is being extended to other environments, particularly coastal and fluvial. In volcanic geomorphology, K-Ar and Ar-Ar have been of great value for dating periods deeper in time. Advances in the use of other isotopic methods such as uranium series and cosmogenic nuclides (e.g., ^{10}Be, ^{25}Al, ^{36}Cl) are making a strong impact on the geomorphology of the twenty-first century. The use of tracers in geomorphology has helped in tracking and modeling movements of water, wind, and sediments. Tracers can be passive (e.g., painting, exotic minerals or particles, fluorescent, magnetic, and radioactive materials) or active (e.g., radio transmitters) (Hassan and Ergenzinger, 2003). Beyond fluvial geomorphology, tracers can include atmospheric and hydrological tracers and those tracers used for monitoring soil erosion and hillslope processes (Foster, 2000). More recently, GPS technologies have added more accurate ways of tracing geomorphic processes (Stockdale et al., 2008). Advances in remote sensing and mapping have also been influential in the development of geomorphology earlier in the present century.

Currently, there are no geomorphology departments or academic units in universities. Normally, geomorphology is a specialization within geology, geosciences, or geography departments. It figures as a mandatory course in the curricula of geologists, geophysicists, and geographers and in some colleges among the courses required for archaeologists. Specialists in geomorphology are often employed in a variety of jobs ranging from state and national geological surveys to private consulting firms, oil companies, environmental assessment, contract archaeology, and very commonly in academic centers of higher education for teaching and research.

Theoretical aspects

Interest in concepts and models has existed among practitioners of geomorphology throughout the history of the discipline. Conceptual models that explain the origin of landforms were popularized first by the works of William M. Davis and Walther Penck (see "History and Evolution of Geomorphology" section, Figure 4). Theoretical interest is also seen in the creation of conceptual themes proposed by W. Thornbury (see "Introduction" section). But in the second half of the twentieth century, the so-called theoretical geomorphology was enriched by the new scientific paradigms that appeared during the 1960s and 1970s in the realms of quantitative research and systems theory. This trend gave birth to many geomorphological models expressed in mathematical terms, i.e., in the form of equations and graphs. Theoretical research began appearing in journals and books in the 1970s, some of it as part of the proceedings of the Binghamton Symposia, as well as other venues sponsored by the IAG.

Richard Huggett (2007) wrote that geomorphological theory borrowed concepts from other disciplines, very often from physics, and in particular from thermodynamics. As a result, concepts such as equilibrium, stability and non-stability, complexity, and chaos are still ingrained in geomorphological modeling. The concept of geomorphological threshold is tied to equilibrium of the landscape and implies that a geomorphic system, say a fluvial stream, evolves from its original state and passes through different states of equilibrium and nonequilibrium; when the system crosses a threshold, however, its parameters change, and it is unable to return to its original state (Schumm, 1973, 1979). The concepts of threshold and landscape equilibrium encapsulate the idea of landscape sensitivity, which implies that streams and their valleys have the propensity to change, sometimes triggered by minor impulses (Brunsden, 1990). This understanding has formed a basis for explaining the responses of geomorphic systems to climatic change (Bull, 1991). Thus, threshold and equilibrium have developed into a process-response model that allows one to predict the behavior of geomorphic systems, e.g., in small streams and alluvial fans. A process-response model explains phases of equilibrium and threshold events in terms of four stages: (1) a reaction time (which is the lag time between the perturbation created by a weather event and the time a change in the system is observed), (2) the relaxation time (the time needed by the system to establish a new equilibrium or threshold condition after it has reacted to the perturbation), (3) the response time (the sum of the reaction time and the relaxation time), and (4) the persistence time (the time span of the new equilibrium condition after a stream has adjusted to a perturbation) (Bull, 1991).

The processes of stream equilibrium were worked out in several models by Stanley Schumm (1973, 1979, 1991), who further suggested different types of equilibria – static, steady, and dynamic – implying that equilibria occur over different time scales and that changes in the system do not necessarily imply a crossing of thresholds. The linearity of the threshold system has been challenged by the bifurcation and catastrophe models (Huggett, 2007). The catastrophe theory, which is a branch of the bifurcation model, suggests that streams have different bifurcation points. According to the model, in passing through a bifurcation point, the system loses its structural stability and undergoes a sudden or catastrophic change to a new form.

Complexity in geomorphic systems, derived from multiple processes acting simultaneously at different scales, is a theoretical aspect conceptualized in a series of principles (Huggett, 2007). In essence, the principles describe the chaotic nature of geomorphic systems, which are inherently unstable and self-organizing. Although it is chaotic, the dynamic stability of the systems does not occur randomly; in other words, the chaotic events occur in an orderly way. Additionally, the chaotic nature of the systems and their ability to self-organize vary with scale. In some situations, a system may look chaotic at a small scale, but non-chaotic at a larger scale.

Synergetic developments with other disciplines

The historical development of geomorphology has paralleled the development of other scientific disciplines that deal with landscape evolution. Beyond geography and geology, geomorphology has had close connections with hydrology and hydraulic engineering, from which it borrowed many concepts and models of hydraulic geometry (Knighton, 1984). Many geomorphologists in the United States work in projects related to the hydrological network of the country, particularly those related to flood control and hazards (Butler, 2003).

Geomorphology also evolved parallel to, and in frequent collaboration with, Quaternary science. In Europe and most of North America, Quaternary studies were initially focused on glacial morphology, but, during the second half of the twentieth century, attention turned steadily to non-glaciated areas. First, interest was directed toward loess deposits and, subsequently, to Quaternary changes in deserts and the tropics. Another aspect of Quaternary research where geomorphology has been deeply involved is that of sea-level change related to glacial-interglacial cycles. The cyclical locking up of global water in ice sheets and its subsequent release through melting caused fluctuations in sea level that affected the base level for the world's rivers. Lower sea level brought about a drop in base level, which triggered erosional downcutting within river valleys, and the following sea-level rise flooded the valleys and floodplains. Thus, glacial and interglacial phases led to changes well beyond the glacial systems themselves, especially in other systems affected by sea level as well as atmospheric circulation because the shifts in wind patterns during glacial stages extended outside the higher latitudes. For example, shifting atmospheric cell systems brought dryness to some areas, while eolian systems moved by the spreading ice sheets created characteristic landforms, such as stabilized sand dunes or loess plateaus. Quaternary science has particularly strong ties with climatic geomorphology and with historical geomorphology. Process geomorphology (dynamic geomorphology) is still important in the sense that many modern glacial processes observable in higher latitudes provide clues to the interpretation of numerous glacially related landforms in middle latitudes where they were left behind by Pleistocene glacial advances.

Recently, geomorphology has established ties with biogeography, hence creating biogeomorphology, which explores the role of plants in landform stability. Geomorphic stability has often been discussed, but the involvement of biological systems is a new addition to such concerns (Butler, 2003). Biogeomorphology was the topic of two Binghamton Symposia (in 1995 and 2009).

Geomorphologically stable surfaces permit soil formation processes to begin, and this important aspect of landscape evolution demonstrates the close connection of soil science to the growth of geomorphology. Paleosols (or geosols) are buried soils that once formed at the ground surface but were then covered by sediments. The presence of one or many stratified paleosols indicates not only the periods of landscape stability, but it also provides evidence for dating the soil and determining characteristics of the paleoenvironment at the time soil formation was ongoing. In the same way, the absence of soil formation in a sedimentary sequence can be indicative of landscape instability, perhaps caused by erosion or a rapidly changing environment. Presently, there are many practitioners within the subdiscipline of soil geomorphology, and numerous publications exist in the form of treatises (e.g., Daniels and Hammer, 1992; Gerrard, 1992; Birkeland, 1999) as well as shorter publications in journals such as *Geoderma*, *Catena*, and *Geomorphology.*

Geomorphology and geoarchaeology

Geomorphologists who engage geoarchaeological questions view archaeological sites as part of one or more geomorphic systems. Thus, geoarchaeological settings can be nested within other depositional settings or environments, which in turn form part of a greater geomorphic system (Table 2). In geoarchaeology, the most common among these settings are eolian (sand and loess), alluvial (i.e., fluvial), colluvial, littoral, and cave and rock-shelters. Less common worldwide, but frequent in certain regions, is the volcanic setting. Very uncommon but possible are geoarchaeological settings in glacial and periglacial environments.

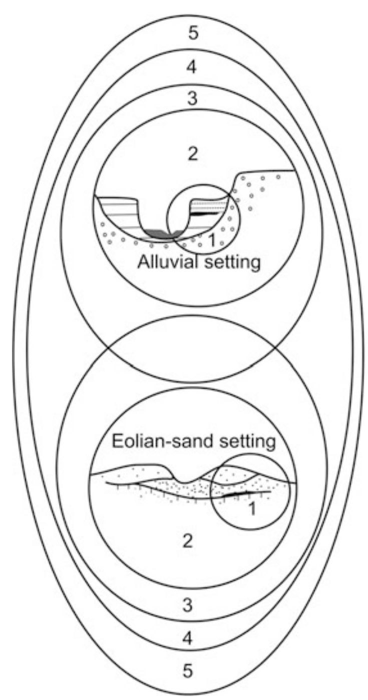
Geomorphology also provides evidence to reconstruct the paleoenvironment of an archaeological locality at different scales. Bruce Gladfelter (1977) exemplified these scalar relationships in a series of levels from as small as the depositional setting associated with a specific site to as large as the greater morphoclimatic system. But in a more modern version of this model, the geomorphological context of archaeological material can be conceptualized within at least five different levels: (1) the depositional setting associated with the archaeological material, in which the perspective of sedimentary facies becomes important; (2) the greater depositional/geomorphic environment (equivalent to the right column in Table 2); (3) the level of geomorphic system (left column in Table 2), which in turn represents a larger landscape/landform unit; (4) the greater regional system; and (5) the morphoclimatic level, which may or may not be directly associated with zonality.

Geomorphology, Table 2 Geomorphic environment and associated depositional environments

Geomorphic system	Depositional/geomorphic environments
Eolian	Sand and loess
Alluvial	Alluvial (overbank, channel, levee, deltaic facies)
Colluvial	Mass movement, overland flow, landslides, mudflows
Littoral	Beach, estuarine, deepwater, lagoonal, tidal
Volcanic	Lava and pyroclastic
Glacial[a]	Moraine, eskers, fluvioglacial, limnoglacial
Periglacial	Solifluction/gelifluction, polygons, pingos
Weathering	Deluvial, weathering crust, soils

[a]Archaeological sites are very rare, but possible, in active glacial environments

These levels of geomorphological analysis can be exemplified by two archaeological sites located in alluvial and eolian settings within the same region (Figure 5). At the first (lowest) level, evidence retrieved from sediments directly associated with the archaeological material is used in the analysis of the stratigraphy of the archaeological site itself. At the second level, evidence is retrieved from a larger area within the system, e.g., a segment of the river or a particular dune field, and the analyses conducted with this evidence are intended to understand the functioning of the fluvial or eolian system within the area immediately around the site. At the third level, evidence is retrieved in order to analyze the responses of the entire geomorphic system (the fluvial basin or sand sheet) with the goal of establishing correlations within each of the broader geomorphic alluvial and eolian systems and perhaps intersecting tectonic systems as well. At the fourth level, the analysis requires the correlation of data with those developed from a far broader region, wherein several fluvial basins and sand sheets may occur. At the fifth and highest level, correlations can be drawn to major global climatic trends, particularly using the evidence from deep-sea ocean and ice cap core records. The fact that the two settings (alluvial and eolian) in this example are located in the same region makes some of the analyses and correlations at higher levels (3, 4, and 5) inclusive, potentially demonstrating that geomorphic transformations at the two localities might have been responses to



Geomorphology, Figure 5 Geomorphological levels of analyses involving different scales around the geomorphic/depositional setting of an archaeological site.

the same climatic changes. In the case of the example in Figure 5, eolian sand destabilization may be correlative with stream incision due to a particular climatic factor of regional extent.

The above example uses an archaeological site (on-site research) as its point of reference. Although on-site geoarchaeology is the most common kind, particularly in the context of anthropological research, geoarchaeology is evolving to consider off-site research (Cordova, 2007). When it is conducted within the framework of geoarchaeological research, off-site geomorphological research avoids the potential biases created by site selection on the part of the excavator as well as the deliberate modification of the depositional system on the part of the ancient inhabitants. Sedimentological data removed only from within a site might misrepresent some process under study because the site might be in some way atypical of the regional environment surrounding it. The site might be located in a protected area, favored by peculiar conditions that were favorable for settlement. Certain evidence might be missing from the within-site record, thereby giving a false impression of the true patterning of geomorphic processes in the region beyond. Geomorphic settings might have been modified by the very act of establishing a human occupation, which might lead to misinterpretation. For example, dune invasion into an inhabited site may have been slowed or even halted by tree barriers and walls, thus hindering sand movement, an event that can mistakenly be taken as a natural process. In an alluvial setting, the accumulation of laminated sediments behind an artificial dam may give a false impression of a natural lake deposit. These two examples show how humans modify geomorphic systems by controlling geomorphic processes to some extent. One must not mistake the anthropogenically induced changes for natural ones. Doing so represents essentially sample error in that the evidence one collects is in fact unrepresentative of the area being studied.

Because geoarchaeology goes beyond the physical aspects of sediments to encompass biogeographic and cultural aspects (Butzer, 1982), geomorphological processes are often understood as being part of a more complex matrix of processes. Thus, the construction of a dam – a cultural structure – may create changes in the geomorphic system, which may then result in a change to the fluvial environment and its constituent facies. At the same time, the geomorphological analysis of the fluvial basin may provide information on the reason and purpose for the construction of the dam. On a broader spatial scale, the fluvial basin may not only be part of the climatic system but also part of a culturally produced architectural system, which may have further implications for the fluvial dynamics within the basin, as well as information bearing upon the reason for construction and failure of the dam.

Geomorphological modeling and technologies have also become part of geoarchaeological research. Remote sensing, in particular, has emerged as a prime tool in the mapping of features of large scale on the ground or features not clearly visible when in the field, such as the configuration of river meanders and scars. The evolution of the landscape is an important consideration in any archaeological research program, and it can be reconstructed or predicted using GIS and DEMs together with the typical ground-truthing inputs from empirical data obtained during geomorphological field exploration.

Summary

Geomorphology is the systematic study of surface processes that build and degrade landforms. In a broad sense, it encompasses the study of endogenic (internal) processes like volcanism and tectonism and exogenic (external) processes acting through the forces of weather and climate. Geomorphologists view these processes at different scales, from planetary through continental and down to a microscale. Processes involve different time scales as well: processes such as mountain building often take thousands to millions of years, while processes such as floods, landslides, earthquakes, and volcanic eruptions take hours or days. Climatic geomorphology has evolved into different areas, focusing on the main geomorphic/depositional environments: fluvial, eolian, colluvial, karstic, littoral, glacial, and periglacial. Geomorphology coevolved along with other developments in the fields of geology and geography. Geomorphology is finally a major component of geoarchaeological research, much of which has concerned the study of depositional and erosional settings associated with archaeological sites, as well as the major regional context of a site's surroundings/catchment or site complexes.

Definition

Geophysics. The science dealing with quantitative measurements of the physical properties, phenomena, and processes of the Earth.

Introduction

Geophysics is a branch of the remote sensing sciences that focuses on the study and measurement of the Earth's properties and processes. Applied, or exploration, geophysics (also called geophysical prospection) often involves measurements taken at the Earth's surface to infer changes in properties beneath the surface. Various techniques have been developed for carrying out such measurements, mainly to conduct medium- or high-depth investigations involving geological or resource exploration applications. Within the archaeological domain, these methods have been adapted in order to address questions related to the buried residues of past human activities (e.g., habitation, husbandry, workshop activity) and mainly for the detection of architectural remains.

Initially, geophysics as employed in archaeology was considered a subfield of archaeometry, but it gradually obtained its independence to form the field of archaeological prospection, of which the earliest examples emerged toward the middle of the twentieth century through the employment of aerial photography, soil resistance, and magnetic techniques (Clark, 1990; Scollar et al., 1990; Linford, 2006). Applications have been multiplied in the decades since then.

The success of the varied methods depends mainly on the contrast between the properties of the underground targets compared to those of the soil matrix that surrounds them. This is especially true when the subsurface contains increased levels of complicating noise due to recent anthropogenic activity or other shallow geologic processes. Target detection is thus a function of various parameters, including the dimensions and physical properties of the target, the depth of investigation, the degree of preservation of the remains, and the sampling interval.

Methodological approaches

Geophysical methods can be active (in which an energy source is required in the detection process) or passive (in which no energy is emitted from the device). Some of the major methods briefly summarized below are electrical resistivity, magnetometry, magnetic susceptibility, electromagnetic methods, ground-penetrating radar, seismic techniques, and gravimetry. Extended overviews of these methods can be found in Gaffney and Gater (2003) and Milsom and Eriksen (2011).

Electrical methods

Electrical methods can be either passive (e.g., self-potential techniques that measure equipotential surfaces) or active (direct current resistivity or induced polarization techniques). Soil resistivity techniques utilize various electrode configurations to send electrical current into the ground while measuring the variation in subsurface electrical resistivity based on Ohm's law. Electrode arrays are capable of penetrating to greater depths by increasing the electrode spacing. Electrical current is conducted within the subsurface, and resistivity meters register either high- or low-resistance anomalies, compared to the background soil resistance, due primarily to low or high water content, respectively, which is a result of either the presence of stone structures and voids or concentrations of clay and organic material within ditches and pits. Soil resistance techniques can be used in different modes: vertical electric soundings (VES), resistivity profiling or mapping, and electrical resistivity tomography (ERT). ERT has been increasingly employed in the last few years to provide a 3D resistivity reconstruction of the subsurface through the use of inversion techniques (Sarris, 2008).

Magnetometry

Magnetometry is based on the detection of weak local variations of the Earth's magnetic field caused by either the concentration of ferrous metal artifacts, the presence of building materials containing higher or lower concentrations of magnetic oxides, the thermomagnetic remanence of the past magnetic signature of the Earth's field, or the enhancement of the magnetic susceptibility of soils (Thompson and Oldfield, 1986). Measurements can be carried out with a variety of instruments, measuring either the total magnetic field–proton free precession magnetometers, optically pumped alkali/cesium vapor magnetometers, and SQUIDs (superconducting quantum interference devices) or one of its components, usually the vertical (fluxgate gradiometers). SQUID and alkali vapor magnetometers offer a much higher sensitivity.

Magnetic susceptibility

Complementary to magnetic surveys, magnetic susceptibility is employed to detect single-domain grains of soil that are related to past human activity in order to draw conclusions on the intensity or the multiple phases of occupation in a settlement. In addition, it can define areas of industrial land use and predict the potential success of a magnetometer survey within an archaeological site. Magnetic susceptibility measurements are often carried out in parallel with chemical analysis of soils because a number of chemical constituents such as phosphate, zinc, pH, calcium, magnesium, iron, copper, and potassium can be used as markers for anthropogenic activities, such as workshop activities, farming, and animal husbandry. Phosphate analysis is the most commonly used, as it is considered a proxy for animal husbandry activities. Applied either in a macro- or microscale survey, and sometimes in tandem with surface surveying (concentration of bones, scatters of ceramics, etc.), field geochemical surveys can provide suggestions about the extent of sites, land use practices, and the function and intensity of occupation.

Electromagnetic systems

Electromagnetic (EM) systems, the most popular being conductivity meters, are capable of simultaneously measuring both soil conductivity and magnetic susceptibility by generating time-varying magnetic fields (usually < 30 kHz). Penetration depth depends on the separation distance between transmitter and receiver coils and their orientation, but newer systems that can operate at different frequencies are capable of penetrating to various depths. Pits, metal artifacts, and areas of high moisture content are easily detectable through EM methods. Electromagnetic sensors include pulse induction meters (such as metal detectors) that use short step changes in the electrical field and very-low-frequency (VLF) transmitters that employ a receiver separate from the transmitter source.

Ground-penetrating radar

Ground-penetrating radar (GPR) is a specific EM technique that emits high electromagnetic frequencies ($\sim$50–1000 MHz) to map the stratigraphy of the subsurface, locate discrete objects, or even detect fracture zones in monuments. The velocity of propagation for radar waves is a function of the soil's conductivity, dielectric permittivity, and magnetic permeability. GPR waves reflected from the various strata or objects beneath the ground provide information regarding the vertical extent of the targets. Parallel radargrams formed through the registration of the amplitude of the reflected signals can be combined to yield information on the horizontal extent of remains at various depths (depth or time slices). Architectural vestiges, cavities, tombs, and voids can be easily detected through GPR techniques. Antennas using lower frequencies (longer wavelengths) are also used for mapping the ancient geomorphology (e.g., ancients ports filled with alluvial deposits), usually in correlation to ERT or seismic techniques (Shahrukh et al., 2012).

Seismic methods

Seismic techniques exploit the travel times of reflected or refracted acoustical waves via a series of geophones located on the ground surface, making them appropriate for studying the stratigraphy of the ground and revealing large underground structures. Seismic techniques estimate the variation in the velocity of propagation of acoustical waves passing through the ground, and thus they provide estimates of the location and the depth of subsurface targets.

Microgravimeters

Microgravimeters are employed for revealing weak variations in the Earth's gravitational field (1–200 μgals out of a total of about 9.8×10^8 μgals) which may be related to the presence of voids, cavities, tunnels, or other buried solid architecture that are responsible for changes in mass density with respect to the surrounding soil matrix. Microgravity techniques have also been applied in the detection of buried chambers within large monumental structures. Since localized variations in topography and the presence of other structures influence the values of gravity, high-resolution mapping of the terrain and nearby buildings is necessary in order to apply corrections to the corresponding measurements (Pánisová et al., 2013).

Discussion

Seismic, GPR, ERT, and magnetic susceptibility measurements have been taken within boreholes in order to provide information regarding the stratigraphy of archaeological sites and to delineate their characteristics at particular depths. Other measurements have been reported in the literature, varying from radiometric methods to thermal imaging. Whatever the case, the archaeological interpretation of geophysical results is often enhanced when more than one technique is applied, since the use of varied measurements can provide complementary information by focusing on different properties. Recent trends with geophysical methods have focused on the speed of the survey and the use of towed multi-sensor, multi-antenna, multi-electrode systems. Undoubtedly, coupled with real-time kinematic differential global positioning system (RTK DGPS) measurements, these systems offer fast and high-resolution coverage of sites. Other systems focus on using multifrequency signals capable of penetrating the subsurface to multiple depths.

Geophysical techniques can be coupled with other means of remote sensing, such as aerial and satellite imagery. Both have proven effective for recognizing site locations based on subtle differences in topsoil characteristics, which are mainly caused by variations of soil texture or vegetation stress that create soil and crop marks. Imaging the surface through the visible or non-visible (e.g., infrared or radar) portions of the electromagnetic spectrum provides spectral signatures that can be correlated with the presence of archaeological features. Together with LiDAR (light detection and ranging) sensors, which contribute to the construction of digital elevation models (DEM), airborne and satellite remote sensing contribute to the mapping of sites, the study of regional settlements, cultural resource management practices, etc. The synthesis of these multiple datasets is facilitated through the use of geographical information systems (GIS), the spatial tools of which provide useful information for the geomorphometric attributes of the terrain and other elements that have a direct consequence for site-catchment analysis and settlement pattern modeling and in constructing predictive habitation models (Sarris, 2008).

Summary

Geophysical techniques used for archaeological prospection make use of the measurements of almost all physical quantities where the existence of archaeological sites or past human activity has modified the background values. Efforts have been made to amalgamate, combine, and invert diverse datasets that originate from the use of different methodologies. This kind of integrated approach is capable of increasing the confidence level of data interpretation.

The current trend in archaeological geophysics has been moving toward rapid reconnaissance of sites in order to reduce the time involved while obtaining accurate information, but there remain many challenges to address. Multi-method systems may offer higher resolution and faster coverage of sites, but they are deficient in ways that need particular attention (e.g., urban surveys, rocky environments, rough terrain, medium depth to deep mapping). Yet, the use of manifold geophysical strategies will continue to provide complementary evidence of the subsurface in order to address a wide range of archaeological questions (Sarris, 2012).

Archaeological prospection inherently encounters problems from later human disturbances of sites as well as various geological processes that make it difficult to resolve a useful signal from background noise, especially when the site incorporates complex, multiple habitation phases. This may impose a limit on the use of geophysical techniques, but they currently play, and undoubtedly will continue to play, a primary role in archaeological landscape studies.

Gesher Benot Ya'aqov

Gesher Benot Ya'aqov (GBY) is an Early-Middle Pleistocene archaeological site located in the course and on the banks of the Jordan River, Israel. Seven excavation seasons (1989–1997) under the direction of Naama Goren-Inbar exposed a 34 m depositional sequence in which 15 archaeological levels were recorded. Tectonic activity on the transform fault of the Dead Sea Rift resulted in the tilting of the GBY strata. The oblique archaeological horizons are embedded within a generally fine-grained sedimentary sequence that documents rapid shifts in abundance of carbonate and organics typical of a low-energy fluctuating lake margin environment (Feibel, 2004).

The GBY sequence consists of a reversed-polarity zone overlain by a normal-polarity zone correlated with the 0.79 Ma Matuyama-Brunhes chron boundary; the entire depositional sequence is assigned to OIS (oxygen isotope stages) 18–20, and its estimated duration is ca. 100,000 years. Archaeological data indicate that hominins regularly occupied the lake margin (paleo-Lake Hula) during Lower Paleolithic times.

The lithic assemblages of GBY are attributed to the Acheulian cultural complex, during which the earliest human migrations into the Levant occurred through the Levantine Corridor as a migration route out of Africa and into Eurasia (Goren-Inbar et al., 2000). The lithics of GBY thus exhibit typological and technological similarities to their African counterparts. These include a variety of cores and core tools, bifacial tools (handaxes and cleavers), and flakes and flake tools modified on different raw materials (flint, basalt, and limestone).

The paleontological assemblages include mammals (e.g., elephants, rhinos, cervids, bovids, hippos, equids, and micromammals) as well as birds, fish, crabs, and mollusks. A skull of a straight-tusk elephant (*Palaeoloxodon antiquus*) was found with its rear part (the brain case) absent (Goren-Inbar et al., 1994). Large quantities of cranial bone splinters were obtained from sediments next to the skull, suggesting battering and processing of the skull. Assemblages of fallow deer (*Dama* sp.) illustrate systematic and repeated utilization of complete carcasses by the GBY hominins. Cut marks, percussion marks, and hack marks on the bones and their anatomical position suggest that carcass processing followed systematic practices that reflect in-depth knowledge of fallow deer anatomy (Rabinovich et al., 2012).

The unique waterlogged environment of GBY preserved rich botanical assemblages including wood and bark (27 species of trees, shrubs, and woody climbers) and over 130 species of fruits, nuts, and seeds (Goren-Inbar et al., 2002a). A man-made polished wooden plank of a willow tree (*Salix*) (25 × 13.5 × 4 cm) was also recovered (Goren-Inbar et al., 2002b).

Early use of fire is recorded throughout the long stratigraphic sequence (Alperson-Afil, 2008; Alperson-Afil and Goren-Inbar, 2010). Burned flint microartifacts occur in dense concentrations interpreted as the remnants of ancient phantom hearths. The repetitive use of fire indicates that the hominins of GBY had a profound knowledge of firemaking. Spatial analyses of the variety of archaeological finds indicate that the GBY hominins differentiated their activities across space (Alperson-Afil et al., 2009). These activities were organized in discrete locations including those associated with hearths.

GLACIAL SETTINGS

Christopher L. Hill
Graduate College, Boise State University, Boise, ID, USA

Introduction

The growth and melting of continental and mountain glaciers, as well as the related environmental changes that occur as part of these episodic fluctuations, influence the habitability of certain landscapes by humans and play a role in the formation of archaeological sites. The processes connected with glaciers have an impact on the types of settings used by humans and on the preservation and visibility of archaeological sites. At times, large regions of the northern hemisphere were covered by continental glaciers during the Quaternary, i.e., the last several million years. In addition, mountain glaciers and ice fields are found on every continent. They have played a critical role in (1) the development of glacial theory and (2) climate change and the study of human-environmental relationships.

Glaciers are moving accumulations of ice originating from snowfall. They are moving masses of ice, in contrast to nonmoving ice fields and ice patches. As glaciers move across a landscape, they erode and scour the earth, transporting and then depositing sediments. Sediments can be deposited by the direct action of glaciers, or they can be deposited indirectly as, for instance, outwash sediments carried in meltwaters. When a glacier expands over a landscape that contains archaeological sites, these sites can be preserved, transformed or altered to various degrees, or destroyed by the actions of the glacier.

There are three major forms of glaciers: mountain glaciers, valley glaciers, and continental ice sheets. Today, mountain glaciers are found on all continents and are connected with various human activities. During global cold events, glaciers expanded from the mountains into the valleys and mountain fronts. Some glaciers merged to form larger, continental glaciers, including the Cordilleran and Laurentide Ice Sheets in North America and the Scandinavian Ice Sheet in Eurasia.

Glacial settings consist of both glaciated terrains and areas subjected to proglacial and periglacial conditions. Proglacial areas are adjacent to glaciers, while periglacial conditions occur in areas of frozen ground regardless of proximity to a glacier. Each of these settings contains particular sedimentological and geomorphic contexts that can be related to human use of the landscape. Glaciers and the physical record of glaciation are *key types of evidence* for local environmental change, and global warming and cooling. Glacial settings are important for geoarchaeological studies because (1) they provide a temporal framework associated with environmental change and humans, (2) they can be used to document landscapes (habitats and resources) that were present in the past, and (3) they are useful in studies of the dynamics of landscape evolution and human land use. After a summary of research history, this review focuses on erosional and depositional processes connected with glaciation and the glacial settings associated with human activities.

History of glacial theory and its importance to geoarchaeology

The discovery that vast expanses of the earth had been covered by glaciers in ancient times played an important role in the history of geoarchaeology. Louis Agassiz is usually credited with promoting the Ice Age Theory. His proposal of a "Great Ice Age" as a time of expanded glaciers at the 1837 meeting of the Swiss Society of Natural History was based on his own field observations and the studies of Jean de Charpentier in the alpine regions of Europe. Prior to this, James Hutton (in 1795) and John Playfair (in 1802) had interpreted erratic boulders found in the Alps as evidence of expansion of mountain glaciers. Based on observations in the mountains of Norway, Jens Esmarkin (in 1824) proposed that there had been much larger glaciers in the region in the past. Ignatz Venetz (in 1829) proposed that both the Alps and northern Europe had once been glaciated, and A. Bernhardi (in 1832) argued that erratic boulders found in Germany were deposited by glaciers. Similar conclusions were made by J. de Charpentier (in 1834) and

Karl Schimper (in 1837). Schimper has been credited for first using the term *Eiszeit* or "ice age."

In 1840, Agassiz published *Études sur les Glaciers* and conducted fieldwork in Britain with Roderick Murchison and William Buckland, providing evidence of glaciation in this region. In 1846, Agassiz recognized the evidence of glaciation in North America, the same year that Edward Forbes used the term "Pleistocene" as the equivalent of the Glacial Epoch, the time of ice-age deposits. In 1847, Agassiz argued that the glaciers from northern Europe and the Alpine region of Europe were the result of independent glacial sources.

The initial concept of an ice age was as a single climate event, but in the late 1840s and early 1850s, studies in eastern France, Switzerland, Wales, and Scotland documented the existence of two glaciations separated by an interglacial period. This evidence, in areas of glaciated terrain, included a stratigraphic sequence containing two tills, or deposits of glacial sediments, separated by interglacial deposits. The first extensive overview of glacial stratigraphies was James Geikie's *The Great Ice Age* in 1874 that evaluated deposits and landforms under present conditions in Greenland, causes of the Ice Age, and stratigraphic sequences throughout Europe and North America, with a focus on Scotland. This text was revised several times, but by 1877, Geikie was arguing the stratigraphic evidence indicated at least four and perhaps five major intervals of glaciation with intervening interglacials. (A similar text, *The Ice Age in North America*, was published by G. F. Wright in 1889.)

By 1882, Albert Penk had identified three glaciations in the Alps and had mapped the general limits of glaciation in Europe and some other parts of the world. Using a sequence of terraces connected with the rivers Günz, Mindel, Riss, and Würm, Penck and Eduard Brückner developed the classic glacial series in the first decade of the 1900s. Moraines, glaciofluvial deposits, and terraces in the foothills of the Alps were used by Penck and Brückner to document a sequence of glacial episodes (labeled Günz, Mindel, Riss, and Würm) alternating with interglacials. During the first half of the nineteenth century, this framework was applied to other regions and served as the basis for global correlations, until marine stable isotope records demonstrated that the interpretation of a fourfold terrestrial sequence was an oversimplification of the global record of Quaternary glacial-interglacial cycles. The equivalent fourfold sequence of continental glaciation in North America (Nebraskan, Kansan, Illinoian, and Wisconsinan) was partly abandoned in the 1970s and 1980s, and the terms Nebraskan and Kansan are not commonly applied today. Illinoian continental ice sheet glacial advances are often correlated with Bull Lake advances in the mountains of western North America, while Wisconsinan advances are correlated with the Pinedale mountain glaciations. This glacial and non-glacial framework developed since the 1880s is critical to a geoarchaeological view focused on relations between humans and past environments.

Essential concepts: glacial processes (sediments and landforms)

Glaciers originate as the result of the deep accumulation of snowfall densely packed by gravity. Glaciated terrains exhibit various erosional and depositional features that provide evidence of past landscape processes. These same landscape processes may have an influence on the formation and preservation of the archaeological record (Ashley et al., 1985; Hambrey, 1994; Ehlers, 1996; Bennett and Glasser, 2009). Abrasion by glaciers creates striations (scratches), polish, crescentic marks or chattermarks on bedrock surfaces, and larger erosional features such as whalebacks, stoss-and-lee forms (*roches moutonées*), crag-and-tail, drumlins, and ice-thrust features. Erosion also occurs on a broader scale, contributing to the character of the landscape and forming U-shaped or parabolic valley cross sections and fjords. Eroded materials may include unconsolidated sands, silts, clays mixed with larger gravels, cobbles, and boulders, all deposited and reworked as glaciers advance and recede. Meltwaters move and redeposit these materials, as wind and ice lift new materials from the ground surface. Thus, glacial erosion processes provide evidence of the extent and dynamics of previous glaciations and can lead to the incorporation, transport, and redisposition of archaeological materials.

Rock fragments that are different in composition compared to the underlying bedrock are defined as *erratics*. These can provide an indication of the dispersal direction and origin point of the glacier. For instance, distinctive fragments of Oslo district and Dala porphyry bedrock found in Germany show the southward dispersal path of the Scandinavian glacier, while Precambrian rocks found in northern Montana are derived from glaciers moving southward from Saskatchewan, Canada. Besides being used to trace the route of glacier movement, erratics can be used by people as raw materials for tools and structures (Williams-Thorpe et al., 1999). For instance, the blocks used in the construction of Stonehenge may have been transported by glaciers from their original bedrock source (Kellaway, 1971).

Materials eroded by glaciers result in sedimentary deposits and distinctive landforms which provide clues about past landscapes. The term *drift* was applied historically to designate materials deposited directly by glacial ice as well as sediment resulting from glacial meltwater. *Till* is nonstratified sediment directly deposited by glacial action; such sediments are transported and deposited by glacier ice with no sorting by water. Historically, it was also referred to as boulder clay, and it is often texturally heterogeneous and unsorted, containing a wide range of particle sizes (the term *diamicton* is used to describe poorly sorted sediments regardless of origin).

Stratified deposits, in contrast, exhibit size sorting of constituent particles and are usually associated with direct transport and deposition by water. These include ice-contact as well as proglacial sediments. Thus, *stratified* *drift* (for instance, glaciofluvial outwash deposits) may extend beyond the area of glaciated terrain forming *sandar* (Icelandic term used to indicate proglacial outwash plains) and braided stream channels. Sediments deposited in lakes dammed by ice or formed along the margin of a glacier are also stratified drift. These deposits can be well sorted but vary in particle size, which can reflect whether they are deltaic, littoral, or deeper water deposits.

Depositional landforms produced by glacial activity include *moraines*, *kames*, *kame terraces*, *kettles*, and *eskers*. A ground moraine is deposited on land surfaces covered by the glacier and is an accumulation of sedimentary particles of various sizes. End moraines, either lateral or terminal, mark the margin of a glacier. A recessional moraine is formed during a halt in the melting of a glacier. Kames and kame terraces consist of stratified sediments and are ice-disintegration features found at the margin of a glacier; kames represent sediment deposited within depressions atop a retreating glacier that eventually become mounds on the ground surface with further glacial melting, while kame terraces are linear glaciofluvial ice-contact ridges that form along the sides of glaciers between the ice and valley slopes. Kettles are closed depressions formed by the melting of a block of glacier ice that separated from the glacier and became buried within outwash sediments; the holes created by the melting block indicate a landscape that was subjected to ice decay. Eskers are linear landforms composed of sediments deposited by streams in tunnels below glaciers or confined on their sides by ice; these are usually elongate ridges filled with sediments and are ancient subglacial meltwater streams.

Deposits and landforms associated with glacial lakes are widespread in areas that were previously at the margins of continental glaciers. In Europe, the southern margin of the Weichselian phase of the Scandinavian Ice Sheet was bounded by the Baltic Ice Lake. In North America, an extensive series of glacial lakes developed along the Wisconsinan margin of the Laurentide ice sheet. The largest of these was proglacial Lake Agassiz. Landforms associated with glacial lakes include flat plains formed by lake-bottom sediments, shorelines, and deltas. The "parallel roads" of Glen Roy in Scotland are well-known examples of abandoned shorelines created by changing water levels in an ice-dammed lake.

Glacial isostatic downwarping or deformation of the Earth's crust was caused by the weight of the Scandinavian and Laurentide ice sheets. Since melting of the continental ice sheets, the land has rebounded. In uplifted regions that contain glacial lakes, shorelines are tilted or inclined because of isostatic rebound. Isostatic adjustment also causes changes in the base levels of streams. Detailed uplift studies have been undertaken in Scandinavia and Britain (Steffen and Wu, 2011). In North America, the tilted shorelines of Lake Agassiz, glacial lakes in the Great Lakes region, and the New England coastal area have been studied for their geoarchaeological potential (Phillips and Hill, 2004; Lovis et al., 2012). In glaciated coastal areas, deglaciation and flooding caused by rising sea levels combined with isostatic rebound results in the exposure of marine sediments. This leads to different landscape histories in areas within and beyond the limits of deposition of marine sediments. These differences in landscape evolution have an effect on the visibility and preservation of archaeological sites.

Landforms and sediments that are the result of cold climate conditions beyond the limit of glaciation are important settings in geoarchaeology since they are areas that were often close to active glacial processes and also inhabited by humans. In glaciated terrain and areas that were previously adjacent to glaciers or permafrost regions (areas with frozen ground), distinct geologic features are formed. These features include either frost-wedged debris or other shatter, such as taluses, rock glaciers, and angular rubble in caves. *Downslope mass movement* refers to the transport of earth downhill, often resulting in zones of erosion and zones of accumulation. Downslope movement of water-soaked ground by *solifluction* (soil flow) results in destruction of primary sedimentary features and original stratigraphy. This happens because meltwater blocked by frozen ground saturates the soils, which flow down hills in solifluction lobes. *Cryoturbation* is the mixing of sediments and soils by the action of ice and is reflected by involutions and contorted stratigraphy. Some distinctive structures that form as the result of frost action are frost cracks or ice wedge casts, *pingos*, and patterned ground. Ice wedges are used as an indication of former permafrost and lower temperatures. Pingos are the result of ice-cored mounds; in periglacial areas, permafrost rises toward the ground surface forcing pore water upward, which in turn pushes the ground upward gradually as the ice core slowly grows in height. Patterned ground features also are formed in cold regions and are usually associated with frost heaving and cracking resulting in patterns of angular, fragmented rocks (Bertran et al., 2010). Rock debris sorted into piles of stone by frost action (patterned ground) can be reminiscent of archaeological features. For instance, areas with large rock fragments and some vegetation can form semicircular stone pits or stone-banked terraces, while areas with little vegetation can form sorted stone rings or circles and stone streams.

Extent of glaciation and glacial temporal framework

Presently, glaciers cover around 10 % of the Earth's land surface and contain almost 75 % of the fresh water supply. There are about 92 million km^2 of land on Earth, and it is estimated that about 26 million km^2 were glaciated about 20,000 years ago; thus, ice covered as much as 28 % of total land area during the most recent major glacial episode. Today, most of the ice is in the Antarctic and Greenland, with the rest in alpine regions and polar sea ice caps.

During the last major glaciation, virtually all of Canada, as well as some of the northern areas of the United States, were covered by ice sheets. The Laurentide ice sheet at times covered almost all of Canada east of the Rocky Mountains with lobes of ice advancing southward to the northern Great Plains, Great Lakes, and New England regions (Hill, 2006a, b, c). The Cordilleran ice sheet formed in western Canada and the adjacent regions of the northern United States.

Besides North America, glaciers have formed on every other continent. In South America and Africa, glaciers expanded from the mountain regions (Ehlers and Gibbard, 2004a; Ehlers and Gibbard, 2004c; Ehlers and Gibbard, 2011). For example, the Patagonian Ice Sheet covered Chile and much of Argentina. In northern Europe, the Scandinavian Ice Sheet extended southward into Germany, Poland, and Russia. Independent glaciers formed in the highland and mountain regions of Europe, the largest in the Alps. Britain had several ice centers, and Iceland was covered by glacial ice. There is little physical evidence for continental-scale ice sheets in northern Asia, although glaciers formed in highland and mountain regions. The absence of continental ice sheets may be partially related to lower amounts of available moisture. Nevertheless, many mountain areas in Asia experienced intensified glacial activity during the Quaternary, including glaciers in Turkey, the Caucasus Mountains, the Sayan (Altai) Mountains, the Vitim Plateau, the Yablonovy Mountains, the Stanovoy Mountains, the Aldan/Dzhug-Dzhur Mountain complex, the Putorana Mountains, the Verkhoyansk-Chersky region, and the Kamchatka Mountains.

The glacial and postglacial time framework has been refined by comparing evidence of glaciation on land with the more complete and continuous ocean record of global climate change and by using several dating techniques. Prior to the availability of radiocarbon dating, the postglacial time framework was estimated using a varve chronology. A varve consists of two layers of sediment that form in 1 year. It is a seasonal pair of layers deposited in still water, such as a proglacial lake or a kettle depression. The study of varve sequences in glaciated northern Europe and North America provided a constraining age for the timing of deglaciation; by counting a sequence of varves and correlating from basin to basin, it is possible to determine the beginning of sedimentation in a basin in a glaciated landscape. These chronologies were used as the basis for broad ranging geomorphic correlations prior to the advent of radiocarbon dating. The varve dating method was pioneered by Gerard De Geer in Sweden starting in 1905 and was refined by the work of Matti Sauramo in Finland in the 1920s. Varve chronology provided the first age estimates for the Allerød and Younger Dryas events, well before the use of radiocarbon dating. Ernst Antevs started using varves in the 1920s in North America as a way to estimate the amount of time since deglaciation.

The global-scale climate record, based on the stable isotope curve from the ocean floor, is used for linking glacial sequences on land; however, local and regional terms are still applied. For any particular glaciated area, there are special terms assigned to sedimentary deposits or lithostratigraphic units, landforms, glacial lobes (tongues of ice), ice margins, and phases of ice advance, as well as an array of designations for lakes, lake phases, *stadials* (a cooler interval within a time of warm climate), and *interstadials* (a warmer interval within a glacial episode).

Typically, local names have been used to designate the various episodes of mountain and continental ice sheets throughout the world. For instance, the last major expansion of the Scandinavian Ice Sheet is called the "Weichselian," a German reference to the Vistula River in Poland, where glacial deposits now estimated to date to about 20,000 years ago were first described in the early 1900s. In the North American Rocky Mountains, the youngest major Pleistocene glaciation dating to about this time is termed "Pinedale," based on a local name, while in the Pacific Northwest, the "Fraser" glaciation is usually associated with the most recent Pleistocene glaciation. Even within major intervals of glaciation, there were advances and retreats of ice lobes or ice sheet margins. An important example is the Younger Dryas which is used to designate a short, cold period at the very end of the Pleistocene. The age of the Younger Dryas has been measured using varves and radiocarbon dating. The Younger Dryas dates to about 11,000–10,000 ^{14}C BP, right before the start of the Preboreal, which was the beginning of the Holocene. The term *postglacial* refers to the time after a glacier had melted from a local area and is a relative time designation since some areas were deglaciated before others. It signifies the time after a glacier had retreated, leaving a landscape available for colonization by plants and animals, including humans.

Applications: glacial settings and geoarchaeology

Glacial settings consist of landforms and sediments produced above or below glaciers (supra- and subglacial), those formed in contact with ice margins, and those under proglacial and periglacial conditions. These can include areas of little or no erosion, as well as areas of intense erosion or deep deposition. Kames and hummocky terrains may reflect rock debris that once rested on top of glaciers. Drumlins and eskers are associated with subglacial settings. Indications of ice-marginal areas are terminal moraines and outwash fans. Glaciofluvial settings are associated with eskers, meltwater channels, kames, kame terraces, and outwash fans. Proglacial lakes are associated with shorelines, deltas, outwash fans, laminated sediments, varves, rain out from ice rafting, and meltwater channels. Ice-stagnation features associated with ice disintegration and deglaciation of a landscape have the potential to be linked to landscape habitability.

Glaciated terrain and postglacial landscapes

There have been instances when glacial ice expanded over a region that was previously inhabited by people, and, consequently, archaeological deposits were removed from their original context. Under these circumstances, artifacts were incorporated into younger glacial tills and outwash or redeposited in other younger sediments. The Paleolithic site of High Lodge located in eastern England contains blocks of sediment bearing Mousterian artifacts that were glacially transported intact and laid down over younger deposits (Ashton et al., 1992; Roe, 1993). Eroded and transported Acheulian artifacts were then incorporated into glaciofluvial and debris flow deposits that actually buried the Middle Paleolithic sediments, creating a confusing situation where presumed older Acheulian artifacts were recovered above younger Mousterian artifacts. While the Middle Paleolithic artifacts had been moved, they were still incorporated in their original block of sediment, in contrast to the Acheulian materials, which were in a secondary position, as a result of glaciofluvial processes.

Other sites are associated with reworked glacial sediments. For instance, the Norse settlement of L'Anse aux Meadows is in a region of Newfoundland with glacially modified bedrock and recognizable glacial deposits, but the site itself is situated on beach and terrace deposits composed of reworked till (Davis et al., 1988; Kristensen and Curtis, 2012). The Dundee Canal site in New Jersey is underlain by outwash deposited by melting ice of the Augusta-Mud Pond recessional moraine; reworked till and outwash were the sources for the overlying sediments containing artifacts (Thieme, 2003). There are also instances of glacial advances leading to the burial of ancient landscapes. In England, the stumps of trees and fossils dated to the Middle Pleistocene Cromerian interglacial are overlain by glacial till. The buried Cromerian Forest dates to before 478,000 years ago and is sometimes correlated with the warmer environments between the Günz and Mindel glaciations in the European Alpine region, possibly correlated with global isotope stages 21–13. Lower Paleolithic Acheulian artifacts are found in Cromerian deposits (Moir, 1924; Stout et al., 2014).

The glacial setting associated with the Cordilleran ice sheet in western North America is an important area for testing the idea that late Pleistocene human groups could have traveled along the Pacific coast from Beringia to unglaciated regions farther south (Fedje et al., 2011). The question to be tested is whether there is evidence of environments that would have been suitable for human presence along the glaciated coast. The dynamics of glaciation along the Pacific coast have been examined in terms of potential landscapes for late Pleistocene human migration, although interpretations are complicated by the effects of eustatic sea-level changes, isostatic depression and uplift, and local tectonics (Hill, 2006a; Fedje et al., 2011). During the late Wisconsinan, glaciers advanced westward from the mountains onto the coastal areas. In some regions of Alaska and British Columbia, the forebulge effect along the margins of expanding glaciers resulted in the presence of inhabitable landscapes. A forebulge is a rising land level at the margins of an area under glacial load. At On Your Knees Cave, on Prince of Wales Island, radiocarbon-dated bones of brown bears indicate that they were able to inhabit the area throughout the Frasier Glaciation, the local equivalent of the last major Pleistocene glaciation. Even though the area was surrounded by the Cordilleran ice sheet, there seems to have been an unglaciated coastal habitat that could sustain large mammals. Port Eliza Cave on Vancouver Island contains a stratigraphic sequence with till indicating the onset of glaciation around 16,000 ^{14}C BP and deglaciation by 12,500 ^{14}C BP, implying this coastal region would have been unavailable only for about 3,000 years (Al-Suwaidi et al., 2006). The islands between the Washington mainland and Vancouver Island also contain fossils of large mammals, indicating the habitability of this deglaciated landscape. At Ayer Pond, glaciomarine drift is overlain by lake deposits containing bones of an extinct form of bison dating to 11,990 ^{14}C BP (Wilson et al., 2009; Kenady et al., 2011). The Manis mastodon site on the Olympic Peninsula of Washington State documents the presence of humans in this deglaciated landscape by 11,960 ^{14}C BP (Waters et al., 2011). The locality contains mastodon, bison, and caribou fossils overlying late Wisconsinan Cordilleran till.

The evidence of interaction between the Laurentide and Cordilleran ice sheets in North America is particularly interesting because of the implications for deglaciated landscapes that could have been inhabitable and used as a route of movement by late Pleistocene human populations (Hill, 2006a). It is possible that an ice-free corridor was entirely open by 13,500 ^{14}C BP or possibly as late as 12,500 ^{14}C BP, suggesting it was available for human habitation even prior to the Clovis interval, which began about 11,000 ^{14}C BP (Dyke, 2004, 411; Dixon, 2013). Within the corridor region of the northern Great Plains, there are early sites that are associated with glaciated terrain. Deglaciated landscapes in Alberta, Saskatchewan, and Montana, for instance, supported a diverse biotic community by Clovis times (Hill, 2006a, d; Kooyman et al., 2006; Waters et al., 2015). Just south of the St. Mary River, artifacts and Pleistocene fauna dated to 11,450–11,320 ^{14}C BP have been recovered in windblown sands and silts capped with a *paleosol* (an ancient buried soil). In Montana, the Sun River mammoth was found in organic-rich bog deposits dating to 11,500 ^{14}C BP that formed after the melting of glacial ice that had advanced eastward out of the Rocky Mountains. The sediments containing the mammoth were deposited after the melting of the Sun River lobe of the Pinedale phase glacier, and they are overlain by a 6-m-thick sequence of alluvium interbedded with volcanic ash and colluvium. A date of 11,170 ^{14}C BP on bone recovered in deposits above the Laurentide till in the Marias River Valley suggests that this deglaciated region north of the Missouri River was a viable habitat for human land use by the time of Clovis (Hill, 2006d).

Proglacial lakes formed along the southern margin of the Laurentide Ice Sheet as it advanced southward. Along its southwest margin in Montana, different ice lobes expanded from Canada into northern Montana and North

Dakota, some extending as far south during the Last Glacial Maximum as the present location of the Missouri River. As the ice receded, lakes formed along the melting front of the glacial lobes. North of the Saskatchewan River, the Kyle mammoth is associated with glacial lake deposits. The colluvial and alluvial sediments of the Vermillion Lakes site in Alberta also lie above glacial lake sediments. In Manitoba, Folsom-Midland artifacts have been found within the basin of glacial Lake Lind. This suggests that a fairly rapid pattern of human land use accompanied the drainage of proglacial lake surfaces.

The largest proglacial lake in North America was glacial Lake Agassiz, which formed over the region of eastern North Dakota, western Minnesota, and southern Manitoba and Ontario. The lake initially filled as ice receded from the Big Stone Moraine and went through several phases and water levels based on oscillations of the southern margin of the Laurentide Ice Sheet. The highest major strandline, the Herman Beach, contains mammoth fossils, while the Lockhart phase dates to Clovis times (Buchner and Pettipas, 1990). The Moorhead low phase dating to about 10,500 ^{14}C BP is associated with the Folsom period (Boyd, 2007). A rise in the water levels during the Emerson phase brought the waters of Lake Agassiz to the level of the Campbell beach strandline and flooded the landscape exposed during the Moorhead phase. This rise in lake level after the Moorhead (Folsom-age) phase was caused by a blocking of the eastward drainage route by the Marquette advance in the Superior Basin. Because of isostatic rebound, the Lake Agassiz shorelines are tilted to the south; the uplift continues to the present day and has changed base levels for streams flowing in this region. The Rustad site in North Dakota contains artifacts and bison bones in alluvial sediments overlying Emerson phase lake deposits that bury a Moorhead phase alluvial terrace.

The region between Lake Agassiz and the Lake Superior Basin provides an example in which the dynamics of glaciation can be linked to human use of deglaciated landscapes, and postglacial conditions impact the preservation and visibility of archaeological sites (Phillips and Hill, 2004; Hill, 2007; Hill et al., 2011). Three glacial lobes of the Laurentide Ice Sheet were active in the region west of Lake Superior. While the Rainy River lobe melted northward into Canada, another lobe of ice expanded from the west toward the Lake Superior Basin, which also periodically contained glacial ice. Although mammoth remains suggest that viable environments may have been present earlier, the oldest direct indicator of human presence in this glaciated terrain of northeastern Minnesota is a Clovis point from the Cloquet River drainage. In the Superior Basin, a series of abandoned shorelines of different ages mark the changes in ancient water levels of glacial lakes. Because of isostatic rebound, the ancient shorelines are tilted; the same shoreline is higher in the north and lower in the south. Thus, archaeological sites on ancient shores of the same age will have different altitudes depending on their geomorphic location. Preservation and visibility of archaeological sites in this type of glacial setting is influenced by the changing positions of the ice margin, the differences in isostatic uplift, and lake level fluctuations (Phillips and Hill, 2004).

Fluctuations in the position of the Laurentide Ice Sheet also buried ancient landscapes. In eastern Wisconsin, the Two Creeks forest was preserved because of an advance of the Green Bay lobe. The buried forest overlies Woodfordian age till and lake clays deposited as the Green Bay lobe advanced into the region. Following a recession of the Green Bay lobe ice, shortly after 12,000 ^{14}C BP, the forest developed on the lake sediments. Around 11,750 ^{14}C BP, the forest was buried by muds and sands deposited in the proglacial lake of the advancing glacier. The lake deposits are overlain by the Two Rivers till deposited by the Greatlakean ice advance that buried the forest, which had been in existence for over 250 years.

As ice of the Lake Michigan lobe of the Laurentide Ice Sheet retreated from eastern Wisconsin, it formed the Tinley and Lake Border recessional moraines. A set of mammoth localities (Schaefer, Heboir, Mud Lake, Fenske) attest to the presence of habitable environments soon after this landscape was deglaciated. At Schaefer and Heboir, butchered mammoth bones and artifacts have been found in lake clays or peat overlying till in a topographic low between moraines. The sites date to about 12,000 ^{14}C BP, approximately the same age as the beginning of the Two Creek forest.

Other sites in the Great Lakes region provide insights into human connections with glacial and early postglacial settings (Hill, 2006b; Holliday and Mandel, 2006). In Michigan, the Holcombe site contains Paleoindian artifacts and caribou bones on the shoreline of a glacial lake behind a recessional moraine, and the Gainey site lies on the edge of a moraine near a kettle lake. The Parkhill site in Ontario, dating from between 11,000 and 10,000 years ago, lies on an abandoned shoreline. The Arc and Hiscock sites are Gainey-Clovis sites that are associated with abandoned shorelines in western New York. The Hiscock site contains mastodon remains and is situated between the Batavia and Barve moraines, while the Arc site is situated with a soil formed in till on the strandline of an ancient lake. The Burning Tree mastodon site in Ohio dating to about 11,500 years ago is in a kettle pond.

The glaciated region stretching from the Great Lakes to the Atlantic coast and northward into Canada contains examples of inland settings associated with ice-contact features and deglaciation, and the dynamic processes associated with glaciated coastal settings. In northeastern Massachusetts, the Bull Brook site is on a kame terrace and contains caribou bones with fluted points. The Vail site in northwestern Maine is located in a knob and kettle setting, adjacent to an abandoned stream channel. The Whipple site is on deglaciated terrain in New Hampshire and is situated on an alluvial terrace or delta deposit. In Nova Scotia, the Debert site overlies an ablation till and possible outwash and windblown deposits. Radiocarbon dates indicate that the locality may have been inhabited during the

Younger Dryas, a time when Nova Scotia was experiencing active glaciation and periglacial conditions (Byers, 1954; McDonald, 1968; Gramley, 1982; Curran, 1984).

As the last glacial period progressed leading up to the Last Glacial Maximum, worldwide sea levels dropped when water became stored in the ice sheets covering the continents. Sea levels dropped by about 123 m, or possibly more, and stayed around this level until the large ice sheets in North America and Europe began to melt after about 18,000 years ago. Lowered sea levels during glacial periods exposed parts of the now flooded continental shelf (Bailey and Flemming, 2008). Along the Pacific coast, in the Queen Charlotte Island region, artifacts have been found at 152 m below sea level. In the coastal Atlantic region, mastodon teeth have been recovered at 40–55 m below the present sea level on the continental shelf off Massachusetts Bay, and they have also been found on the coastal shelf adjacent to Nova Scotia (Hill, 2006c). The formerly glaciated continental shelf along eastern North America contains moraines and deposits of glacial-marine mud. In this setting, there are submerged archaeological sites that were inhabited during times when sea levels were lower than today (Kelley et al., 2010).

As with glaciated regions along the Atlantic and Pacific coastlines, other regions were subjected to both isostatic forces and eustatic sea-level changes. Parts of the North Sea floor were exposed by lowered sea levels and available to prehistoric humans. These areas have the potential for buried Paleolithic and early Mesolithic sites (Ward and Larcombe, 2008). After the melting of the Scandinavian Ice Sheet in Norway, the ice-free coastline and its resources became available. Although there is no definitive archaeological evidence of human presence before 11,500 ^{14}C BP, paleontological evidence suggests that the deglaciated Norwegian coastline ecosystem would have contained useful resources (Bailey and Flemming, 2008).

Where deglaciation has been followed by deposition of marine sediments and then isostatic uplift, such as coastal New England or Scandinavia, areas that were once flooded became inhabitable landscapes. The emergence of previously submerged areas in Maine provides a geomorphic explanation for the visibility and preservation of archaeological sites (Putnam, 1994). The differences between upland areas beyond the marine limit compared to lowland areas containing marine sediments are reflected in the landscape and the archaeological record. Likewise, in coastal Norway, there are differences in the postglacial geomorphic history and stratigraphy based on the marine limit (Sveian and Olsen, 1984; Sveian, 1997; Solberg et al., 2008). In the Trondheim region of central Norway, the Vuku substage marks the Younger Dryas and early Preboreal (the Pleistocene-Holocene boundary). A marine transgression following the recession of glaciers has led to differences in landscape history as reflected in the stratigraphy of valley fills and the distribution of landslides. These conditions lead to predictable patterns of preservation of landforms that have the potential of containing archaeological assemblages.

Periglacial settings, remains from glaciers and ice patches

Cryoturbation features, reflecting the mixing of sediments by ice action, are pervasive in archaeological stratigraphic sequences situated in past periglacial landscapes. They provide evidence of former environmental conditions and also information regarding site formation processes. Ice in soils goes through cycles of freezing and melting, resulting in frost cracking, heaving, sorting, creep, solifluction, and other forms of mass displacement. Cryoturbation processes lead to upward and lateral movement of artifacts, thus rearranging the original spatial pattern of objects within an archaeological site. Periglacial processes can modify site stratigraphy and damage artifacts and ecofacts. The Onion Portage site in northwestern Alaska provides an example of how cryoturbation distorts archaeological stratigraphy and changes the spatial arrangement of artifacts while it also provides information on environmental change (Schweger, 1985). The site is situated in the Kobuk River Valley which is filled with late Wisconsinan outwash that forms alluvial terraces 35 m above the present river. The terraces are the result of downcutting after 16,000 ^{14}C BP. The site consists of stratified floodplain (overbank) silts and windblown sands with paleosols that overlie coarse gravel outwash. Cryoturbation features at the site include frost cracks, involutions (interpenetrations of layers caused by frost action), hummocks, and the effects of solifluction. The age range for the development of involutions and solifluction activity ranges from before 8,400 ^{14}C BP to about 5,800 ^{14}C BP (Schweger, 1985). In the periglacial environment of northeastern Canada, the late Holocene Paleoeskimo site of Tayara has been subjected to downslope mass movement caused by solifluction (Todisco and Bhiry, 2008). Postglacial marine sediments have been reworked by solifluction at three separate intervals linked to short-term climatic fluctuations. While waterlogging related to solifluction may have led to its abandonment, burial by solifluction also promoted the preservation of the archaeological components. The stratigraphic record at Kents Cavern in southwestern England contains Acheulian artifacts as well as evidence of periglacial activity in the form of frost heave, solifluction, and frost-shattering (Lundberg and McFarlane, 2007).

Cryoturbation has also had an impact on archaeological sites, for example, in the Rocky Mountains, France, and in Russia. The stratigraphic sequence at the Fourth of July Valley site, in the Colorado Front Range, was almost continually affected by frost-sorting, which at times increased in intensity. Artifacts were moved upward in the stratigraphy by upfreezing (cumulative forcing of buried objects to higher levels due to the pressure of freezing soil), and this frost action led to the mixing of older early Holocene Paleoindian artifacts with younger Altithermal age charcoal (Benedict, 2005). Postdepositional convolutions and wedge features may be an indication of frost action at Owl Cave, a volcanic blister on the Snake River Plain in Idaho (Dort, 1977). The stratigraphic sequence contains extinct animal fossils, such as mammoth and camel, as well as fluted points.

Paleolithic sites in France also contain evidence of periglacial activity. For example, at the well-known La Ferrassie rockshelter, solifluction during the last cold maximum of marine isotope stage 2 was similar to semi-desert-like periglacial conditions of today (Bertran et al., 2008). Solifluction appears to be the best explanation for geoarchaeological patterns at other French Paleolithic sites as well (Lenoble and Bertran, 2004; Lenoble et al., 2008).

In Russia, at Kostenki, an Upper Paleolithic locality on the Don River south of Moscow, heavily contorted and convoluted beds are an indication of solifluction or creep processes in deposits dating to around 35,000 ^{14}C BP (Holliday et al., 2007). The Diring Yuriakh Paleolithic site on a terrace of the Lena River contains permafrost sand wedges. Upper Paleolithic sites situated on terraces of the Chikoi River in Siberia east of Lake Baikal, such as Studenoe and Prisskovoe, contain cryoturbation features (Buvit et al., 2003; Buvit et al., 2011). At the late Pleistocene Berelekh mammoth site in northern Siberia, the bone bed truncates an ice wedge (Pitulko, 2010), while the Yana Rhinoceros Horn Site (Yana RHS) contains ice wedges that form a polygonal grid (Pitulko et al., 2004; Basilyan et al., 2011). The numerous ice wedges and slope deposits formed by solifluction at these sites document several cycles of freezing and thawing.

Glacial settings can lead to remarkable preservation of organic remains in archaeological and paleontological sites (Dixon et al., 2005). Melting glaciers and ice patches expose and release artifacts (Hare et al., 2012; Reckin, 2013). Perhaps the best known example is the preservation of Ötzi (the “Ice Man”) discovered in 1991 near a glaciated pass in the Alps (Baroni and Orombelli, 1996). In the southern Yukon, archaeological and paleontological specimens were discovered in thawing ice patches. Remains have been discovered in British Columbia along an ice ridge on a glacier. In the Rocky Mountains of Colorado, late Holocene remains of bison, mountain sheep, and cervids have been found in ice patches. Organic remains have also been preserved in Alaska. These include archaeological remains (Dixon et al., 2005) and Pleistocene animals preserved in ice or frozen ground (Guthrie, 1990).

Summary

Glacial settings are often the locations of ancient human activities. Archaeological sites may lie above glacial-related deposits, or they may be covered by drift. In addition, artifacts can be incorporated into glacial deposits. In short, glacial processes can preserve, modify, or destroy the evidence of human presence within a landscape. Rebound of the land resulting from the loading and unloading of large masses of ice is especially important in glaciated areas associated with glacial lake and coastal island settings. This situation prevails in landforms of proglacial and postglacial lakes, such as those associated with the southern margin of the Laurentide Ice Sheet. Additionally, in coastal areas, changes in relative sea level have had a dramatic impact on sediment deposition and landscape evolution. Sea-level fall associated with glacial advance first expanded coastal zones and created land bridges resulting in landscapes inhabitable by humans, then during warm periods, these areas are flooded, leading to significant impacts on site visibility and preservation. Periglacial processes, such as mixing and sorting of sediments by frost action or movement by soil flow, have the capacity to mix stratigraphic sequences or bury and preserve them. Glacial settings are critical to developing archaeological time frameworks, examining changing environmental conditions and landscape evolution, and integrating humans with past ecosystems.

GLASS

J. Victor Owen
Department of Geology, Saint Mary's University, Halifax, NS, Canada

Definition

Glass is an amorphous solid, typically brittle, and optically transparent or translucent.

Introduction

Glass can form naturally, notably by the rapid cooling (quenching) of lava (forming obsidian), or more rarely as a mineraloid lechatelierite when lightning strikes sand (forming fulgurites) and by bolide impacts (forming tektites). Man-made glasses traditionally have been made by heating silica-rich sand with suitable fluxes (e.g., Na, K, and/or Pb) and stabilizers (e.g., Ca). These materials, once mixed together for the purpose of making glass, are referred to as a glass batch. The clarity and color of man-made glass depend on the purity of the silica sand used in its manufacture, on the concentration and type of metals in the glass batch, and on the oxygen fugacity of the furnace atmosphere. The rapid cooling of molten glass creates stresses that can cause the object to crack. These stresses are dissipated by annealing the object in a lehr kiln, usually at temperatures between about 370 °C and 500 °C.

Although specialized types of glass (e.g., borosilicate glass) and glass-ceramic materials have been manufactured in recent years, most glass presently made is similar to historical glass that has been produced for centuries (e.g., soda-lime glass and alkali-lead glass).

Character of glass

The character of glass is perhaps best understood by contrasting its properties with those of crystalline solids and liquids. The molecules in crystalline solids are arranged in an orderly pattern: a crystal lattice. If heated to a sufficiently high temperature, the lattice breaks down, and the crystalline material begins to melt. There is thus an abrupt change – a first-order phase transition – in the physical properties (e.g., density) of the material.

In contrast to crystalline solids, liquids are a viscous medium. Viscosity is a measure of a liquid's resistance to flow, and the property depends on the composition (e.g., the silica content of silicate liquids) and temperature of the liquid. The viscosity of liquids generally increases as their temperature decreases, i.e., they become thicker and more resistant to flow. Ordinarily, a liquid will crystallize when it is cooled below the melting temperature of its solid counterpart, but if it is cooled very quickly (quenched or supercooled), it can solidify before nucleation and crystallization occur. Some liquids are characterized by slow nucleation kinetics at temperatures below their melting point. These are the glass formers, and silica-rich liquids are an example. When cooled at a standard cooling rate, the molecules in such glass formers remain disordered, and the solidified material is thus amorphous. The reasons for the sluggish nucleation rates of glass formers are not fully understood, so this topic remains an area of active research in condensed-matter physics (Angell, 2008).

The supercooling of glass-forming liquids to a glass state is referred to as vitrification, but it should be noted that ceramists use the same term to describe the generation of a melt phase in ceramic bodies being fired at high temperature. The transition between a liquid and its amorphous, solid counterpart, i.e., the glass transition, is characterized by a dramatic change in viscosity and by changes in heat capacity and thermal expansivity (Ojovan and Lee, 2006). At a temperature below that of the glass transition (T_g), the material is solid; above T_g, it is rubbery. Glass is indeed solid. The observation that very old pane glass can be relatively thick at its base has been misconstrued as evidence that glass is an extremely viscous liquid (Brill, 1962; Elliott, 1983). However, viscosity curves calculated for ancient and modern glass show that the flow of pane glass at room temperature would take an inordinate amount of time – about 10^{32} years, much longer than the age of the universe itself (Zanotto, 1998). Instead, differences in pane glass thickness have recently been interpreted as an artifact of the production process, whereby glass blowers would spin a glob (gather) of molten glass, which would tend to become progressively thinner toward its edge. This means of producing flat glass is known as the crown method. Once cut, the thicker edge of the glass would usually (but not invariably) be placed at the bottom of the window to render it stable (Brill, 2011).

The discovery of glass

Pliny the Elder, the Roman naturalist and historian, claimed that glass was accidentally discovered by Phoenician merchants while preparing a meal on the shore near the Belus River in Palestine (now the Na'aman River in northwestern Israel). Unable to find rocks suitable to support their cooking pots, they used blocks of natron (a flux, principally $Na_2CO_3{\cdot}10H_2O$ with subordinate sodium bicarbonate) instead. The heat from the fire caused the beach sand and natron to melt. The melt cooled quickly, forming glass. This anecdote has long been discredited by scholars because the temperatures produced by campfires are insufficient to cause the beach sand to melt, even in the presence of a flux such as natron. Instead, it has been proposed that the discovery of glass originated with the manufacture of early glazed ceramic wares such as faience (Bowman, 1991).

Exactly where and when glass was first made nevertheless remain open questions. There are several late Bronze Age sites in the eastern Mediterranean region where early glass has been recovered. These include Tell Brak (Syria; Oates et al., 1998), Amarna (Egypt; Petrie, 1926), and Knossos (Crete; Panagiotaki, 2008). However, glass was produced only at some sites, whereas at others, it was simply worked. This, together with the discovery of glass ingots from shipwrecks (e.g., Pulak, 2008) and evidence from the mid-fourteenth century BC, Amarna letters (Moran, 1992) testify to the extensive trade in raw glass around the Mediterranean at this time (Smirniou and Rehren, 2011).

Raw materials

Glass is made from a mixture of silica (quartz)-rich sand, fluxing agents (e.g., alkalis and/or lead), stabilizers (e.g., lime), and, where required, colorants, decolorants, and/or opacifiers. Its manufacture requires copious amounts of fuel. Historically, this was either wood or coal. Glass production centers therefore tended to be located where glass-grade silica sand and/or abundant fuel were locally available.

Silica sand

From a quality perspective, silica sand is the single most important ingredient of glass. Where glass-grade sand is not available, some historical glass producers crushed orthoquartzite. Ideally, glass-grade silica sand and orthoquartzite should contain >99 wt% SiO_2, i.e., should be nearly pure quartz. Impurities in quartz-rich sand and orthoquartzite are commonly dominated by stable, heavy minerals including various iron, titanium, and iron-titanium oxides such as magnetite, rutile (and other titania polymorphs), and ilmenite, respectively, along with apatite and zircon. Minor amounts of alkali feldspar and traces of various ferromagnesian minerals may also be present. If not removed from the sand before it is added to glass batches, these minor minerals will impart distinctive geochemical signatures to the glass that can be used to trace the source of silica used in its manufacture (e.g., Owen and Greenough, 2008).

Cullet

Cullet is scrap glass added to batches to facilitate melting. Commonly, between a quarter and half of a glass batch consists of this material. It usually is the same type of glass that is being produced, so it often simply represents the recycling of waste glass by the manufacturer. Some glassworks, however, advertised for scrap glass to be used as cullet (Starbuck, 1983). This material, being imported, must not be mistaken as a bona fide product of the glassworks where it is found.

Fluxes

Natron is thought to have been used as a flux in the production of some early glassware, but shortages in its supply led to a decline in its use in the glass industry of the Near East in the seventh to ninth centuries AD (Shortland et al., 2006). As a consequence, the use of alkali-rich plant ashes as a flux became increasingly important in the glass industry. Plant ashes, however, have been used in the Near East for millennia. Indeed, recent work (Tite et al., 2006) provided evidence of halophytic (salt tolerant) plants being used to make glass in this area since the fourth millennium BC. Fluxes influenced the melting behavior of glass batches. Ancient Egyptian and Roman soda-lime glass tends to have a limited range in compositions that approximate the eutectic (lowest melting point) on the $CaO–SiO_2–Na_2O$ phase diagram. Rehren (2000) hypothesized that the near-minimum melt composition of this glass was an artifact of *partial* batch melting, wherein the degree of melting of the glass batch, and hence the composition of the glass, was buffered either by a solid phase (e.g., pseudowollastonite, $CaSiO_3$) or the reactant surface of the crucible.

The Roman tradition of using ash from sodium-rich plants from coastal areas continued to parts of Europe (notably Venice) that could access traditional trade routes (Tait, 1991), but inland, ash from potassium-rich flora was used during the Medieval period. The development of the Medieval glass industry thus involved the use of novel batch ingredients. This, in turn, required the development of new technologies to ensure the successful production of potash-lime glass for which there was no precedent (Rehren, 2000).

Theophilus (c. 1100) described the making of glass batches from a mixture of beech wood ashes and sand in the ratio 2:1 and the fashioning of firing pots from white pottery clay (Presbyter, 1976). Huge amounts of wood were consumed by this industry. Smedley et al. (1998) reported that Theophilus's recipe would require 63 kg of beech wood to produce 1 kg of glass. These glasswares, known as Waldglas (forest glass), were produced in northern Europe between c. AD 1000 and 1700. They are characterized by potash-lime compositions with variable amounts of soda. In contrast to his partial batch melting model for ancient glass, Rehren (2000) accounted for the compositional diversity of European Medieval glass by proposing that Waldglas batches melted entirely, so their compositions were not confined to thermal minima.

Stabilizers

Stabilizers are used to make glass stronger and less soluble in water. Sodium- and potassium-rich glasses are susceptible to dissolution. The addition of calcium carbonate renders such glass relatively insoluble, and alumina is sometimes used to strengthen glass. Lead is also employed as a stabilizer, and its introduction to alkali glass batches produces a low-viscosity melt from which bubbles ("seeds") can easily escape. The resultant glass has a high refractive index, thereby giving it a brilliant luster. The invention of lead crystal is usually attributed to the English glassmaker George Ravenscroft (1632–1683).

When high levels of fluxing agent (Na_2O or K_2O) or insufficient stabilizer (CaO) are added to glass batches, the finished object can develop glass disease, a condition that poses serious challenges to conservators of historical glass artifacts. The deterioration is caused by humidity in the air (or soil in the case of buried contexts) that gradually hydrates the exterior and dissolves alkalis out of the glass, creating salt encrustations on the surface and eventually producing a web of cracks in the glass body (crizzling) that spreads, dulls, and darkens the glass and ultimately breaks up the object. Some buried or weathered vitreous materials (glass, glazes) become enriched in phosphate and lime and develop Liesegang rings (e.g., Freestone et al., 1985). Another kind of glass deterioration appears as iridescence, a multicolored effect caused by surficial weathering (Doménech-Carbó et al., 2006). Horizontal cracks form due to volume changes from the hydration of near-surface material, and this generates multiple microscopic laminations that continually break off as minute shiny flakes. Each of these sequential layers reflects incoming light, thereby creating interference colors that produce the iridescent appearance. A thin hydrated layer that evenly covers the glass surface can produce a light iridescence, but a thick buildup of multiple scaly laminae usually results in an opaque gold appearance.

In order to gauge the degree of corrosion in glass of various chemical compositions buried under alkaline soil conditions, the Ballidon glass burial experiment was begun in England in 1970 (Newton, 1985; McLoughin et al., 2006). Sequential openings over many years will reveal the kinds and extent of deterioration to glass specimens designed to replicate the formulas used in Roman, Medieval, and seventeenth-century products.

Colorants

Small amounts of metallic and nonmetallic elements impart color to glass. Chief among the metals is iron which, in its ferrous (Fe^{2+}) state, renders glass a bluish-green tint. Ferric (Fe^{3+}) iron gives glass a yellowish-green color. Cobalt and copper have been used since the ancient times to produce blue glass. Amber glass is produced through the use of sulfur and iron, and red glass can be made using gold chloride. Uranium-bearing glass is a bright yellowish green.

Decolorants

In order to produce relatively colorless, transparent glass, a decolorant such as manganese dioxide (the mineral pyrolusite) can be added to the glass batch. Indeed, "pyrolusite" is derived from the Greek words for "fire" and "wash." Other decolorants include antimony (Henderson, 2000), cobalt oxide, and selenium. Decolorants produce complimentary colors to the green tints associated with iron, thereby chromatically neutralizing them.

Where they are used in excess, decolorants can cause glass to become cloudy or dark (Vose, 1996). Chemical analysis nevertheless shows that historical black glass can have comparatively low silica contents and high alumina and iron as well as manganese contents. This suggests that it was made using relatively impure (e.g., quartz-poor, feldspar-, and iron-bearing mineral-rich) sand.

Opacifiers

Opacifiers are used to render opaque the medium (e.g., glass, glazes) to which they are added. A wide variety of compounds serve as opacifiers, but all are relatively refractory, have a high refractive index, and are added to glass (and glaze) batches as finely ground grains. They include tin oxide, calcium antimonite, and calcium phosphate (Henderson, 2000).

Glass-working techniques

Ancient glass-working techniques included core forming, rod forming, slumping, casting, and blowing (free blowing and mold [mould] blowing). Core forming involves shaping the glass around a core. Traditionally, the core was thought to have exclusively been formed in sand, but recent work suggests that coal, dung, or crushed quartz was also used. Once formed, the core was attached to a metal rod, heated, and then dipped into molten glass. Irregularities in the surface of the glass were smoothed out by rolling the glass-coated core (marvering) over a smooth surface. Decoration was often applied as trails of glass, which commonly were combed into various patterns while still molten. The core was removed afterward. A variation of this process known as rod forming was used to make slender vessels and jewelry. It involved applying a separating agent to a metal rod, which was then coated by threads of glass.

Slumping involved heating a piece of flat glass until it softened and descended due to the pull of gravity over a refractory, convex, or concave form (mold). This differs from casting, whereby molten glass was poured into molds. The forms into which the molten glass was poured included both open molds and molds made by the lost-wax process, in which a wax model of the object to be cast was enclosed by clay and heated to remove the wax leaving a void which was then replaced within the mold by molten glass.

The technique of blowing glass originated in the eastern Mediterranean region, possibly along the Syro-Phoenician coast, during the first century BC (e.g., Frank, 1982) and was subsequently refined by the Romans. Free blowing, then as now, involved the use of a blowpipe to inflate a gather of molten glass, which was then shaped into its desired form. A contemporary variant known as the dip-overlay method was used by the Romans to produce cameo glass. This involved dipping a bubble of colored glass into a molten white glass and then blowing both together into the desired form. Finally, parts of the white glass were carefully carved away, leaving a pattern in relief set against the colored glass background. The Portland Vase (c. AD 5–25) is thought to have been made by this method.

In mold blowing, a gather of glass is inflated into a mold. Two- and three-piece molds are most commonly used; the edges of these molds leave a telltale thin ridge (seam lines) on glass objects, which included everything from bottles to tableware. A variant of this technique known as pressing involves the use of a plunger to compress molten glass that has been poured into a mold. This technique, developed in the United States in the 1820s, was perfected by the Boston and Sandwich Glass Co. (1826–1888) of Massachusetts.

The mass production of bottles began in the early 1900s, when M. J. Owens introduced the Owens Bottle Machine. This device used a piston pump to suck molten glass into a mold to measure the appropriate volume of glass for particular bottles. The action of the pump was then reversed to force the molten glass into a bottle mold. Up to four bottles per second could be produced by Owens's machines (Lockhart et al., 2010).

The production of sizeable sheets of flat glass for use as windowpanes presented glassmakers with a special challenge. Flat glass has been produced since the ancient times. It was produced either by rolling molten glass on a metal table or by spinning a large bubble of glass that had been transferred from a blowpipe to a rod (called a punty or pontil). The resulting glass disk, known as a rondelle, could be up to about 1 m in diameter; once formed, it was annealed to prevent cracks upon cooling too quickly, and then it was cut into smaller pieces for use as windowpanes. The "bull's eye" mark at the center of the disk is a signature of this type of flat glass. As noted earlier, flat glass produced by this method is known as crown glass. Crown glass was produced on a commercial scale at least until the middle of the nineteenth century.

Larger sheets of flat glass were produced by blowing a long cylinder of glass, which was then cut longitudinally, reheated, and opened up to form a flattened sheet up to 2 m square. This technique, called broad glass manufacture, yields glass that tends to be uneven in thickness, can contain abundant bubbles, and can be scored with tool marks from the metal rods used to flatten it (Phillips, 1981). A mechanized version of this technique was introduced in the early 1900s. It was supplanted first by the vertical draw (Fourcault) process, whereby a leader was pulled upward from a vat of molten glass, and subsequently by the float method developed in the 1950s by Pilkington Brothers Ltd. (Barker, 1977). Float glass is produced by pouring molten glass over a surface of molten tin.

A practical handbook reviewing the manufacture of glass at the beginning of the last century was published by Bastow (1920). More recently, Janssens (2013) reviewed various aspects of glass, its raw materials, its production, the composition of both ancient and more recent glass, the diverse methods of analyzing it, the composition and means of analyzing it, and the types of information these analytical data can provide to archaeologists.

Interpretation of archaeological glass from production centers

Glass is ubiquitous in the archaeological record, and much is known about its production over the centuries. As with archaeological ceramics, emphasis has been placed on excavating glass from production centers. The reason for this is twofold. First, careful excavation of glasswork sites can shed light on historical glass technologies. This can be accomplished by documenting kiln/furnace configurations and through the discovery of unprocessed raw materials, glass-working tools, and specimens of worked glass. Second, the compositional analysis of worked glass from production centers provides baseline data for reconstructing trade routes and sourcing glass artifacts found elsewhere. Caution must be exercised when interpreting such data, because at some sites, glass was worked but not actually manufactured from raw materials, and at others, use was made of imported cullet, which would skew the chemistry of glass produced from raw materials alone at the site. Glass-on-crucible (melting pot) samples provide definitive evidence for the local production of glass, and a priority should be placed on analyzing such material. Again, caution is advised when interpreting the significance of glass adhered to kiln materials, as in some instances, such glass can represent a melt phase originating from the kiln material itself (Owen and Culhane, 2005).

Workers migrating from one production center to another carried technical knowledge of the glass industry with them. Thus, the forms, types, and compositions of glass produced in one area gradually spread elsewhere. For example, the characteristic glass forms produced in southern New Jersey starting in the eighteenth century subsequently appeared in glassworks in upstate New York and elsewhere (White, 1950). These wares can be so similar that their distinction must be based on analytical data, including trace elements. Even these data can fail to provide a definitive means of distinguishing wares produced at competing glassworks where similar batches containing sand and other ingredients from a common source were employed.

Synonyms

Granulometry; Particle size analysis

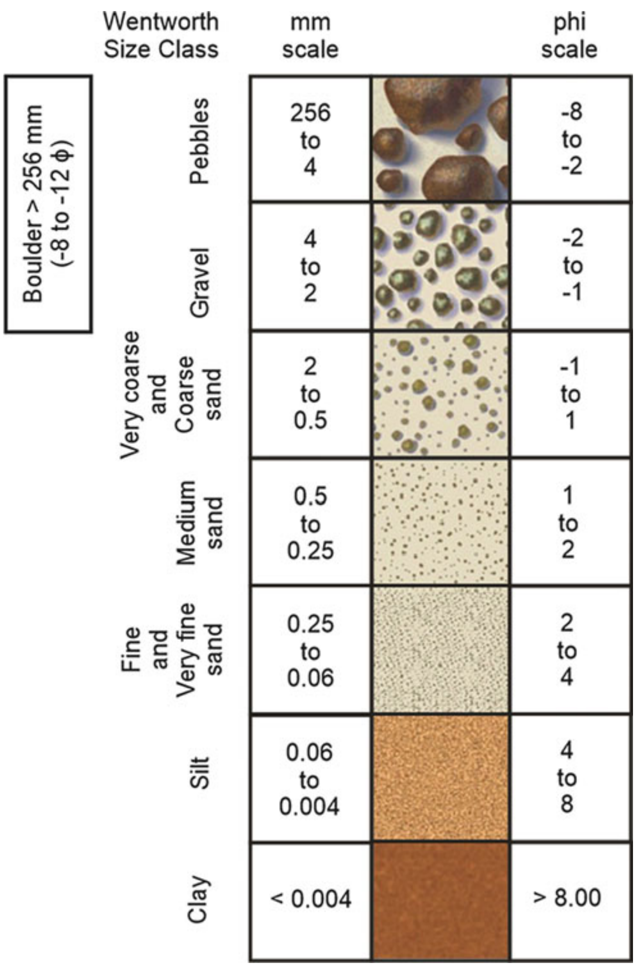
Definition

Grain size analysis is an analytical technique typically conducted within the earth sciences and implemented as a routine laboratory study. Other disciplines, such as archaeology and geoarchaeology, also use it regularly. It is a sedimentological analysis carried out in order to determine the size of the different particles that constitute a particular unconsolidated sedimentary deposit, sedimentary rock, archaeological locus, or soil unit. The main goal of this procedure is to determine the type of environment and energy associated with the transport mechanism at the time of deposition; this is done by inference from the sizes of the sediment particles analyzed and their distributions.

Introduction

Granulometry is a basic analytical technique that has wide applications within the earth and archaeological sciences. Particle or grain size is a fundamental attribute or physical property of particulate samples or sediments and sedimentary rocks (Friedman and Sanders, 1978; Folk, 1980). Much can be determined from an analysis of not only the size of clastic or detrital (inorganic), bioclastic (organic), or chemical particles but also of the overall size distribution, size fraction percentages, textural maturity of the sediment or sorting, surface texture attributes of a particle, and sphericity/angularity and shape of a particle (Krumbein and Sloss, 1963; Syvitski, 2007). Several sediment, soil, or material properties are directly influenced by the size of its particles, as well as their shape (form, roundness, and surface texture of the grains) and fabric (grain-to-grain interrelation and grain orientation), such as texture and appearance, density, porosity, and permeability.

The size of particles is directly dependent on the type of environmental setting, transporting agent, length and time during transport, and depositional conditions, and hence it possesses significant utility as an environmental proxy (McManus, 1988; Stanley-Wood and Lines, 1992). Grain size is related to a multitude of external factors acting on a local or regional scale. For example, in the coastal and marine setting, grain size is related to the bathymetry and geometry of the basin, nutrient regime, biogeochemical oceanography, coastal processes, net sedimentary



Grain Size Analysis, Figure 1 Diagram showing the different ranges of particle size, based on the Udden-Wentworth and Ø grain size scales for siliciclastic sediments (based on Wentworth, 1922; Krumbein and Sloss, 1963).

inputs from land sources, and outputs. The study of these particles can elucidate their provenance (source materials), the various processes they may have endured during their transport (by air, land, or water), their final depositional environment, their final burial setting (how much energy was present at that time; e.g., from waves or currents), and other physical and chemical factors.

Traditionally, sediments were divided into three principal categories: gravel, sand, and mud. The latter was further divided into silt and clay, mostly based on mineralogical distinction rather than (hydro-)dynamic properties. Since the early 1900s, standardization of such size ranges has been defined (Figure 1) based upon different grade scales constrained by particle size limits or range boundaries. The size of the particles is based on their nominal diameter, traditionally reported in millimeters (mm), micrometers (μm), or phi (Ø) units. The Wentworth or Udden-Wentworth scale (Udden, 1914; Wentworth, 1922) divides the size ranges into textural classes with specific terminology, from boulders (>200 mm) to clay (<0.004 mm). It is a geometric scale in which each size limit is 1/2 or twice the millimeter value of the next (Figure 1). The Krumbein Ø scale (Krumbein and Sloss, 1963) is a logarithmic scale modified from the Udden-Wentworth one and based on conveniently calculated round values, to avoid dealing with mm fractions (Figure 1). Classification of detrital sediments is based upon the quantification of, or relationship between, the proportions/percentages/ratios of different particle size fractions or textural classes within a mixed sediment (Shepard, 1954; Folk, 1980), as seen in Figure 2.

Grain size analysis is often part of the basic, initial set of analytical laboratory procedures scientists conduct upon sediment/soil samples and/or sediment cores recently collected in the field. The purpose of such analysis is to (1) obtain a deeper understanding of paleo-environmental features or modern environmental impacts, (2) reconstruct past sedimentary transport histories, depositional conditions, or sediment provenance, or (3) analyze in detail a catastrophic event, such as a tsunami or hurricane deposit, for example.

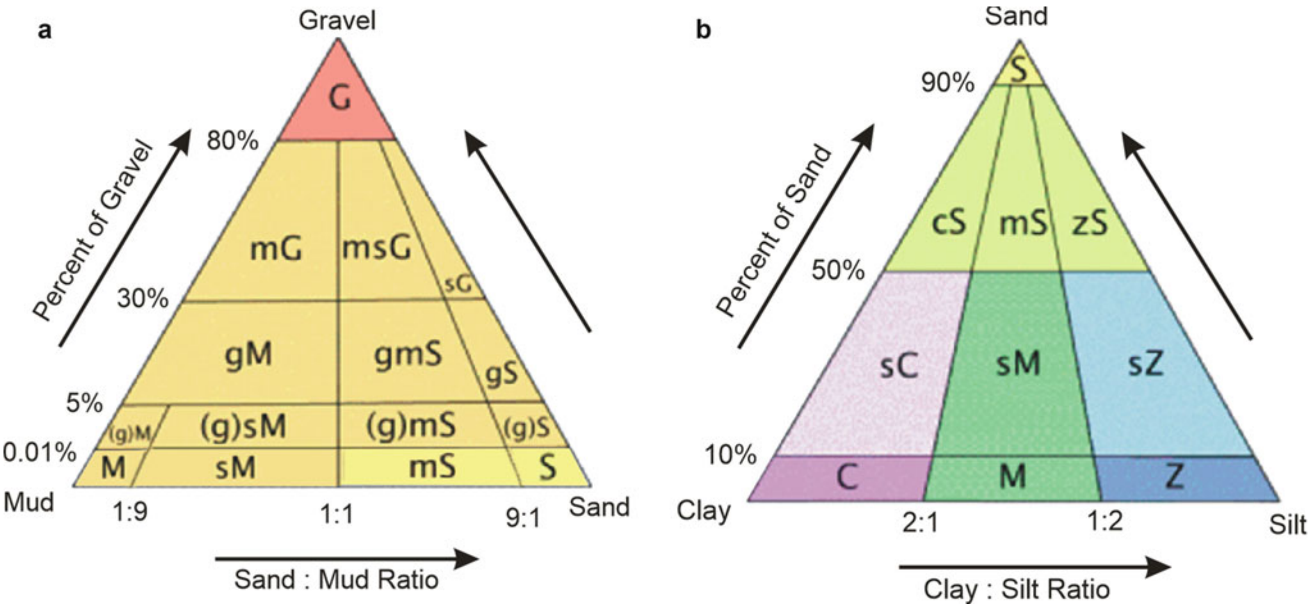
Depending on the thickness and areal extent of the sedimentary layer, unit, deposit, or archaeological locus, scientists collect one or multiple samples within that unit in order to obtain representative material and, with sufficient sampling, a more accurate statistical result. The resulting grain size analyses of samples collected from a single unit are averaged in order to obtain the overall particle size distribution.

Several analytical methodologies can be applied in the study of granulometry and the distribution of particle sizes within a sample or specific material (Table 1). These vary in terms of applicability, technique, apparatus, and cost (Table 2). Nonetheless, the method selected would depend on the range of particle sizes, the degree of consolidation of the material, and the purpose of the analysis. Traditional analyses include counting (individual clasts, manually), sieving, and settling, for gravelly, sandy, and muddy materials, respectively. Modern analyses (Table 1) have used the same analytical principles (count, sieve, and settle), however, the methodologies are much improved today due to better instrumentation and automatization (Table 2), including laser diffraction and imaging techniques (e.g., spectrometry), without discarding traditional sieving and settling (hydrometer and pipette analysis) methodologies (Syvitski, 2007).

Contextual granulometry

Granulometry in geoarchaeology

Granulometry can be considered a perfect example of geoarchaeological research in which the application of an earth sciences technique is used to understand aspects of the archaeological record. For example, in order to obtain a better understanding of the composition of a locus or stratigraphic unit, grain size analyses would be a basic parameter to estimate in order to differentiate the



Grain Size Analysis, Figure 2 Ternary diagrams (**a** and **b**) showing Folk's classification system of sediments: textural terminology conceived as a graphical representation of the relative proportions of different grain size typologies, resulting in 21 major categories (Folk, 1980). The abbreviations are: *G* gravel, *g* gravelly, *(g)* slightly gravelly, *S* sand, *s* sandy, *M* mud, *m* muddy, *Z* silt, *z* silty, *C* clay, *c* clayey.

Grain Size Analysis, Table 1 Commonly used grain size characterization techniques and the particle size ranges (from nanometers, nm, to millimeters, mm) with which they function optimally. The upper and lower range limits are only a guide, as these limits may vary from one application or instrument to another

matrix from the clasts/aggregates (*geological terms*) or inclusions (*archaeological term*), within the same locus/unit and/or across loci/units. This information enables a more precise understanding of particles that might be related to natural deposition versus those deriving from an anthropogenic origin – as some anthropogenic deposits have granulometric characteristics that cannot be compared to any natural pattern since they derive exclusively from artificial behaviors. An example is the differentiation between naturally-derived and anthropogenically-produced submerged sedimentary units found within the same archaeologically-rich coastal region of Caesarea Maritima, Israel (Reinhardt et al., 2006). Detailed analysis of *Glycymeris* spp. (saltwater clam) bio-clast distributions found at different stratigraphic intervals indicated two distinct naturally marine-derived tsunami phases; these were compared to an anthropogenically induced and/or mixed ballast and pottery layer amid naturally occurring medium sand-sized siliciclastic sedimentation related to normal marine and winter storm conditions. However, subsequent reinterpretations by some of the authors, based primarily on particle size distributions (diameters <2 mm) and several sedimentary textural and structural features, now suggest a tsunami origin for the previously identified anthropogenic layer (Morhange et al., 2014). This is an example of the complexity involved in weighting one analytical proxy more than others, or the difficulty of identifying and characterizing natural from anthropogenic units in complex environmental settings and reworked archaeological deposits.

Paleoenvironmental reconstruction

One of the goals of geoarchaeological research is to understand previous natural and anthropogenic events that took place within an archaeological context, either happening in sequence or ongoing intermittently. Based on such information, the environmental history of a site can be reconstructed from its beginnings. As a primary analytical technique, particle size analysis should always be accompanied by other basic analyses that have the potential to enhance comprehension of a targeted locus or sedimentary unit within the archaeological context. Examples of such other proxies are micropaleontology and isotope and chemical analyses. The combined use of several analytical laboratory procedures increases the likelihood of obtaining data useful in elucidating the depositional context as a whole, and with decreasing margin of error. Underwater archaeological sites, and especially those situated along coastal areas, are among the more complex settings within which to reconstruct the stratigraphic succession of ancient environments. This is due not only to the submerged conditions, but also to the highly dynamic processes occurring therein, including sea-level changes, severe storms, extreme events such as tsunamis, littoral currents, and sediment movement, etc. In conjunction with these, prolonged and heavy human occupation of the (ancient) coastline adds to the complexity of the setting. Nonetheless, well-documented reconstructions of the lateral and/or vertical progression of environments due to continuous environmental evolution, abrupt natural changes, and man-made constructions can be seen throughout ancient coastlines. Examples from the Mediterranean include the reconstruction of the now submerged ancient city and port of Alexandria on the Nile Delta, Egypt (Mostafa et al., 2000), the reconstruction of the harbor complex of Caesarea Maritima, Israel – the largest constructed artificial harbor in the Mediterranean (Reinhardt et al., 2006), and the understanding of the destruction of ancient Palaikastro in Crete following the great eruption of Santorini in the Late Bronze Age (Bruins et al., 2008).

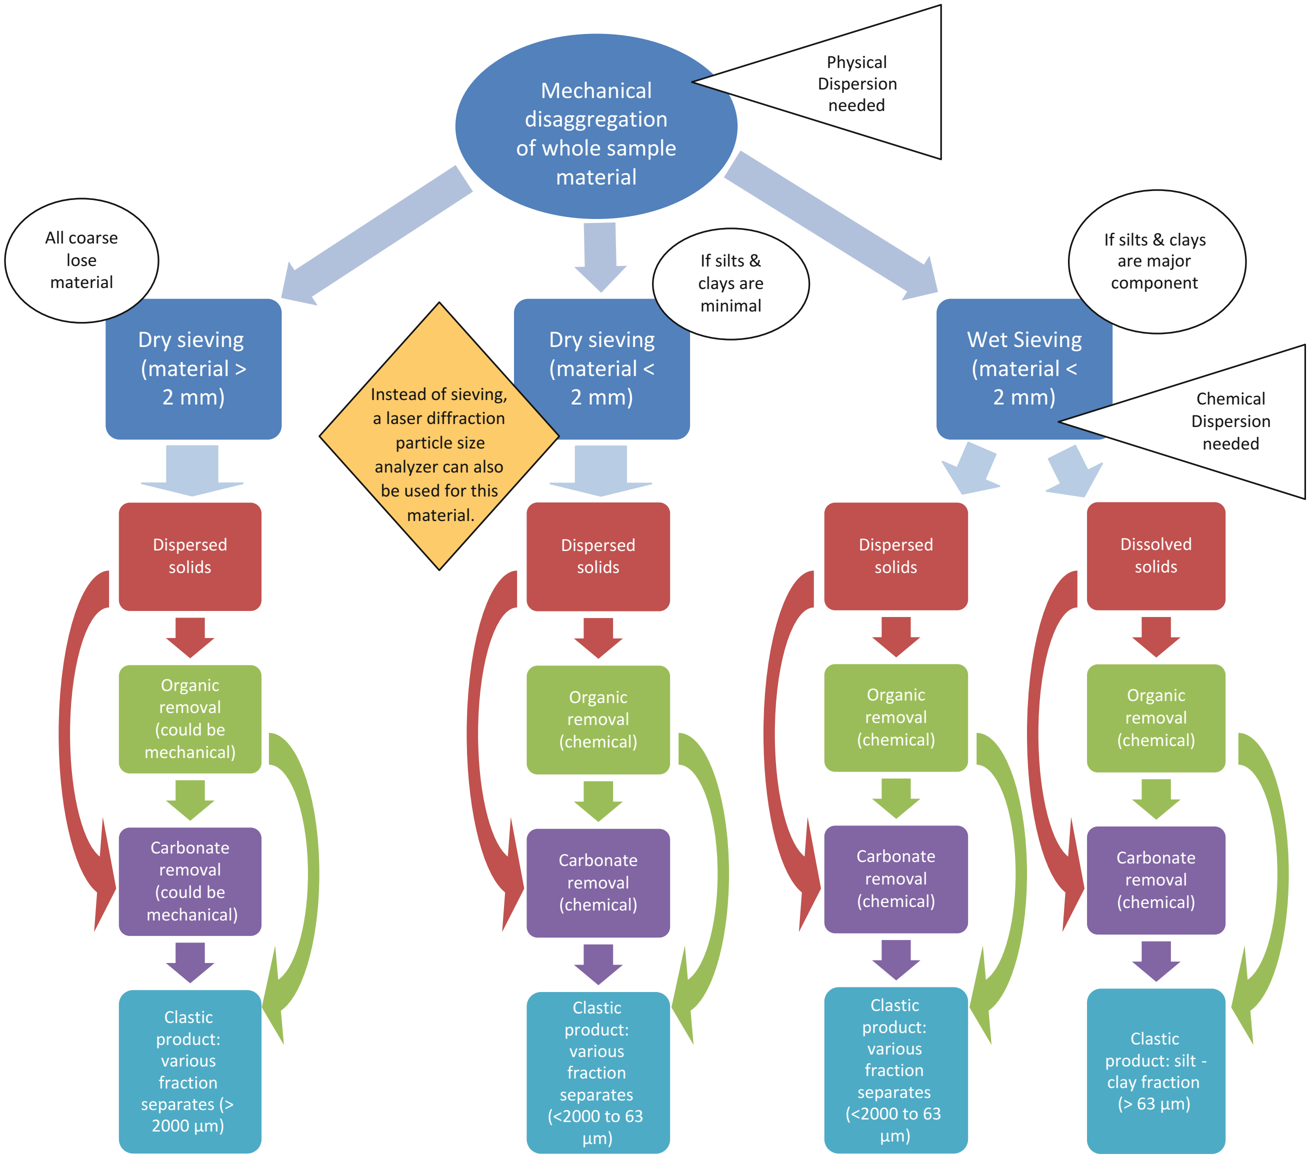
Analytical procedures and particle sizing techniques

One of the particularities of grain size analysis is the importance of estimating correctly the different size fractions that constitute the ensemble of the material being analyzed. In theory, each particle constituting the sample is to be analyzed individually, and the final result is the combination of all the individual measurements. Particles are complex three-dimensional objects with specific lengths, widths, and thicknesses, however (Folk, 1980; Stanley-Wood and Lines, 1992). Only perfect spheres can be completely described by a single number, i.e., their radius or diameter. So, in order to simplify the measurement process, particles are most commonly conceptualized as one-dimensional spheres rather than three-dimensional objects with irregular shapes. A cylinder with X length and Y diameter can be equivalent to a sphere of Z diameter that has the same volume as the cylinder. This is called the Concept of Equivalent Spheres (Jennings and Parslow, 1988). This concept can be applied to a number of different measuring properties of a particle, such as maximum and minimum diameter, surface area, volume, or weight. Based on this concept of equivalent spheres, sedimentation rates can be calculated, and simple things such as sieve aperture sizes can be specified (Folk, 1980; McManus, 1988).

If a sample is measured using different technical means, the results of each technique may not be equivalent because different apparatuses measure different parameters of the equivalent spheres. Therefore, consistency and comparability must be maintained. Grain size analyses can be performed by various means, in both dry and wet settings, depending on the type of material and its major constituent fraction. The coarse fraction of the sediment (>0.063 mm) is commonly separated through dry sieving, whereas the finer sediment can be isolated by settling or sedimentation (using a hydrometer) or using laser diffraction (see Tables 1 and 2). Preparation of the sample is also a crucial point in the determination of a credible and accurate grain size measurement, and hence the importance of the objective of the study. If the target material is clastic, removal of other allochthonous materials is compulsory (e.g., organics, carbonates, oxides, salts, etc.) to avoid erroneous measurements and vice versa (Figure 3).

Sieving analysis

Sieving is the most basic of the particle sizing techniques. It consists of having the sediment pass through (by agitation) a series of stacked sieve meshes with defined opening sizes. Each sieve catches the size fraction that is larger than its mesh size, so that the successive



Grain Size Analysis, Figure 3 Flow diagram generalizing the steps taken when dealing with particle size analyses. Steps may be bypassed or more procedures may be added depending on the amount, type, condition, and size distribution (gradation) of each sample. For example, iron oxide removal with chemical agents may be needed in some samples in lieu of organic matter or carbonate removal. The same is true for the removal of any soluble salts. Chemical dispersion with appropriate dispersing chemicals such as Na-hexametaphosphate, Na_2PO_7, or NaOH (among others) is needed after removal of cementing and flocculating agents, mostly when dealing with silt and clay materials. The number of fractions of clastic "end product" would depend on the number of sieves used during the sieving process. Most laser diffraction particle size analyzers are specialized in a particular range of size fractions in order to avoid obstruction and/or laser errors, e.g., sand fraction (maximum particle size of 2,000 µm), or fine fraction (maximum particle size of 200 µm).

sieves break up the sample into decreasing size fractions. The sediment fraction retained in each sieve is weighed in order to obtain its percentage relative to the whole sample. This technique can be used under dry or wet conditions.

The advantages of sieving are that it is cheap and user friendly, useful when dealing with very coarse samples, and the physical separation of the sample is the end result. Its limitations are its low resolution and precision, that dry particles smaller than 50 µm or cohesive materials are very difficult to separate using this technique, and that results are influenced by the operator and the duration of agitation/shaking used, i.e., the technique itself (Krumbein and Sloss, 1963; Folk, 1980).

Sedimentation or settling

Sedimentation is the oldest of the techniques used in particle size analysis. It measures the rate of sedimentation of particles suspended in a liquid. Its advantages include its relatively low cost, and its ease of applicability to soils or very fine sediments (for which it is the traditional method). Its limitations are that it is useful only for a limited range of particle sizes, that it is not useful for sediment <5 μm, and that it is extremely sensitive to particle shape (geometry) (Jennings and Parslow, 1988; Stanley-Wood and Lines, 1992).

Laser diffraction

Laser diffraction measures the angular dependence of laser light scattered by an ensemble of particles. Its advantages are that it can handle a very wide range of particle sizes (from <100 nm to ~2–3 mm), that measurements can be made rapidly and thus large numbers of samples can be processed, and that results are accurate and repeatable (Syvitski, 2007).

Laser diffraction measurements provide particle size distributions with great detail. This enhancement in technical size measurement has greatly improved the ability to differentiate and compare different environments, and sometimes even better understand their dynamics.

When using a laser diffraction particle size analyzer, sediment can be run dry or wet. If wet, however, it is advised to pour out as much water as possible from the container to minimize errors. In either case, homogenizing and dispersing the sample prior to insertion into the machine is always a must, in order to analyze a truly representative portion of the sample.

The limitations of laser diffraction include that it is not suitable for very coarse or nanomaterials. It is a medium resolution technique and is applied to the whole (ensemble) sample.

Dynamic light scattering

Dynamic light scattering measures scattered light intensity variations due to Brownian motion of particles in suspension within a liquid. Its advantages are that its dynamic range is well suited to nanomaterials (<1 nm to 1 μm), its measurement speed is rapid so that it can handle larger numbers of samples, and its results are accurate and repeatable. Its limitations include the inability to analyze dense materials, and its medium resolution (Syvitski, 2007).

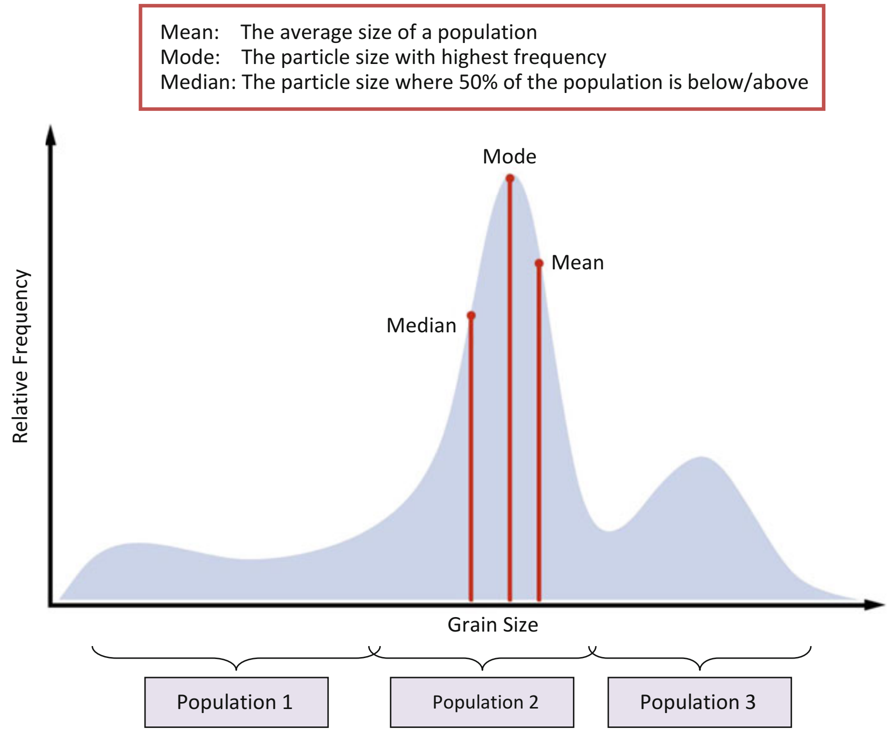
Particle size distributions

In nature, sediments do not consist of only one kind of particle, but rather an amalgamation of various particle sizes, and hence it is logical to consider grain size as a continuous variable. Only perfectly monodispersed samples possess particles of exactly the same size, for example, highly sorted sand winnowed through hydrodynamic processes. Most natural samples contain a range, or distribution, of different particle sizes and shapes.

As a result of manual or instrumental measurement of grain size, a size frequency spectrum is obtained. Such a spectrum is determined by the count of grains, weight, or volume percent of a particular particle fraction within a specific size interval. The resulting spectrum can be deployed as a distribution of grain sizes based on the relative frequency of their number per size fraction (Figure 4). The most common graphic depiction used to represent the different grain sizes within a sample consists of a statistical distribution encompassing all resulting fractions based on their relative frequency (quantity or volume). Two common representations are used routinely: relative frequency and cumulative distribution curves (e.g., Figure 4). The different shapes of the relative frequency distribution curve can be interpreted as how well sorted the sample is: a narrow size range or narrow Gaussian shaped curve implies a well-sorted sample, whereas a larger size range or ample Gaussian shaped curve implies a poorly sorted sample (i.e., a wide range of particle sizes). Moreover, the more asymmetric the curve is within a single distribution, or if the latter presents several frequency peaks (as seen in Figure 4), the greater modality of the sample: polymodality is shown by the greater frequency of distinct and different grain size range peaks. These different frequency groups are called populations and imply an ample modality of grain size fractions within the same sample, and vice versa.

Particle size distributions are based upon statistics, and description of the statistical parameters will usually depend on how the data are to be used. These calculated statistical parameters may give insight into various aspects of the environmental, depositional, and transport conditions the sediment grains endured, linking them to particular sedimentary systems. Three common parameters are the mean, the median, and the mode (Figure 4). The mean is the average size of the entire sample, as seen in Figure 4. The median is the diameter where 50 % of the particles are below or above that threshold. It is by far the easiest measure to determine but the least useful as it does not reflect the extremes of the curve (Folk, 1980). The mode is the particle size with the highest frequency, as seen in Figure 4, but it is not a good proxy of the overall sediment mixture (Folk, 1980). The only instance where all of these three parameters coincide is when the frequency distribution curve is a perfectly symmetrical Gaussian curve.

Other important statistical parameters obtained from the analysis of the distribution of particles – which can help elucidate how uniform, symmetrical, or well sorted the sediment sample is – are the standard deviation, skewness, and kurtosis (Folk, 1980). The standard deviation is a precise measure of the scatter of grain size values from the mean, corresponding then to a measure of spread or sorting of the sample. In combination with the mean, the standard deviation is the most useful and widely applied value in granulometric statistics. Three limits are useful when computing standard deviations within a single sample: 1 standard deviation ($\pm\sigma$) from the mean implies that 68 % of the grain size values fall within this limit;



Grain Size Analysis, Figure 4 Graphical representations of a grain size distribution: relative frequency distribution curve of a sediment sample, illustrating the statistical concepts of Median, Mode and Mean. Three different grain size “populations” can be depicted for this particular multimodal sample.

2 standard deviations ($\pm 2\sigma$) corresponds to 95 % of the particles; and 3 standard deviations ($\pm 3\sigma$) to 99 % (Folk, 1980).

The skewness is used to establish the normality or symmetry of the distribution, hence to quantify the degree of dispersion within a sample, rather than only visualizing it on a frequency histogram. The closer the skewness value is to zero, the more symmetrical (i.e., normal or unimodal) the distribution is. Asymmetrical and multimodal sediment mixtures exhibit high values of skewness, to maxima of +1.00 and −1.00. The positive and negative sign of the skewness value indicates whether the asymmetrical tail extends to the left or right of the curve as follows (Folk, 1980). Distribution curves highly skewed to low grain size values show a negative value and are diagnostic of environments with higher concentrations of silts and clays. The opposite are environments with higher concentrations of coarser materials which show curves skewed to higher grain sizes, hence positive values. Extremely turbid systems such as grain or turbidity flows are diagnostic of negatively skewed distributions. Tsunami, colluvial, debris flows, and torrential river deposits are diagnostic of positively skewed and multimodal distributions.

The kurtosis is also a quantitative measure to describe the degree of Gaussian normality of the grain size distribution, but in terms of how acute or flat the curve is. This is a sorting relation between the end members of the curve and its center (Folk, 1980). If the central portion of the curve is peaked, hence better sorted than its tails, the distribution curve is said to be leptokurtic with values >1.00. The opposite, a flat-peaked curve with a large spread of grain size in the center, is called platykurtic, with values <1.00. Normal probability curves have a kurtosis of 1.0 (Folk, 1980). Both kurtosis and skewness values are ratios of dispersion; thus, they are dimensionless and do not have units.

Summary

Grain size analysis is a fundamental tool for classifying unconsolidated materials and sediments, sedimentary rocks, and sedimentary environments. Quantitative analysis of the percentages of different particulate sizes yields one of the most fundamental physical properties of clastic sediments and sedimentary rocks. Grade scales, such as the geometric Udden-Wentworth or the logarithmic Krumbein Ø scales, which correspond to grain size intervals with a regular relationship to one another, were created to maintain a standardized statistical estimate of the measurement of the size of a particle, because grain size is considered a continuous variable. The almost exclusive purpose behind sizing grains is to obtain a frequency distribution of particle sizes.

A variety of principles and specific methodologies can be applied to differentiate and characterize the particle

sizes of unconsolidated materials and sediments or sedimentary rocks. The traditional analytical principles behind granulometry (counting, sieving, and settling) are still frequently used today, and in some instances, they cannot be superseded by modern techniques because certain particle ranges lie beyond the measureable limits of sensitive minuscule sensors. For this reason, when dealing with particle size analyses, it is also important to consider the particle size range of the material to be analyzed, how narrow or wide this might be, in order to select the most appropriate measurement method(s). Gravels and boulders are mostly counted manually. Pebble sizes can be determined by sieving. Sands, silts, and clays can be measured either by sieving (wet and dry conditions) or settling (hydrometer, pipette). However, automated modern techniques such as laser diffraction or dynamic light scattering can make the measurement process much faster and accurate than traditional techniques, and a greater number of samples can be analyzed at a time.

Selection of the particle size technique to use is dependent not only on the precision and accuracy required for each sample measurement, but also the skills of the operator and the time that can be spent per measurement. Another important factor to consider is the cost of the equipment and any consumables associated with that particular technique. The choice of method is basically dictated by the objective of the study and the degree of consolidation of the material. This is the reason why it is imperative to have an understanding of the complexity of the environmental system and/or archaeological site targeted for study, as well as the natural processes that may have affected the locale, both in past and present times, in order to have a better analytical appraisal of the environmental conditions and contributions of events to the resulting stratigraphical signatures.

GREAT PLAINS GEOARCHAEOLOGY

Vance T. Holliday[1] and Rolfe D. Mandel[2]
[1]Anthropology and Departments Geosciences, University of Arizona, Tucson, AZ, USA
[2]Department of Anthropology, University of Kansas, Lawrence, KS, USA

Introduction

The Great Plains area of North America has been the setting for pioneering geoarchaeological research in the Western Hemisphere. Many archaeological records in the region are in thick, stratified deposits, long recognized by archaeologists and geologists alike as important for understanding cultural chronology and Late Pleistocene and Holocene environmental change. In particular, understanding the Late Pleistocene peopling of the Americas has its origins in archaeological research on the Great Plains (Mandel, 2000). The list of geoscientists who have worked on archaeological projects in the Plains includes some of the most prominent figures to shape the discipline of geoarchaeology; among them have been Kirk Bryan, Ernst Antevs, Claude Albritton, Jr., E. H. Sellards, C. Bertrand Schultz, and C. Vance Haynes, Jr.

There are several historical reasons for the long record of geoarchaeological research in the Great Plains. Immediately following the excavations at the Folsom site in the Southern Plains, where from 1926 to 1928 the human association with extinct fauna was firmly established, archaeologists were attracted to the region because it was an area that repeatedly provided sites that contained human artifacts associated with Pleistocene fauna (Holliday, 2001). Because radiocarbon dating was not readily available until the 1950s, geologists and paleontologists were called upon to provide age estimates of those sites. Also, as outlined below, the Great Plains harbors many archaeological sites with cultural materials that are buried in thick, stratified deposits, especially in stream valleys. The Plains probably has a higher concentration of such sites than any other region of North America. On the Southern High Plains, many of the Paleoindian sites have thick, well-stratified deposits that provide evidence of depositional environments very different from those found in the region today, including meandering streams and perennial freshwater lakes, instead of dry valleys (draws) or dry lake basins (playas). During the early 1900s, these striking contrasts captured the attention of archaeologists and geoscientists alike (Holliday, 2001).

Another significant aspect of the long history of geoarchaeology on the Great Plains is the background and orientation of the archaeologists themselves. Some of the archaeologists, particularly in the early decades of Great Plains archaeology, were also trained as geologists and vertebrate paleontologists. In addition, many of the geologists and paleontologists working in the region had an interest in archaeology.

The evolution of geoarchaeology in the Great Plains was also influenced by the construction of dams during the 1920s and 1930s, especially in South Dakota. Those construction projects gave rise to campaigns of salvage archaeology, and geoscientists were sometimes called upon to place archaeological sites into geologic contexts. More consistent integration of geology with archaeology began with the development of interdisciplinary archaeological research in the 1950s and 1960s, followed by the rise of interdisciplinary cultural resource management in the 1970s.

Setting

The Great Plains region encompasses an area of approximately 2,900,000 km^2 – roughly equivalent to one-third of the land area of the United States – making it one of the largest physiographic provinces in North America (Figure 1) (Wishart, 2011). According to Fenneman (1931), the Great Plains lies between the Rocky Mountains to the west, the Central Lowlands to the east, the Gulf Coastal Plain to the south, and the Canadian boreal forest to the north. This region can be divided into a dozen or so physiographic subprovinces or sections. There are few agreed-upon generalized groupings of these sections. For this discussion (following Holliday et al., 2002), the region is divided into the Southern, Central, and Northern Great Plains. Important subdivisions include the Alberta Plains and Missouri Plateau (Northern Great Plains), the Northern High Plains and Colorado Piedmont (Central Great Plains), and the Southern High Plains and Edwards Plateau (Southern Great Plains). We also include the Rolling Plains of Texas and Oklahoma and the western Central Lowlands in our discussion.

The Great Plains is stereotypically depicted as dry, monotonously flat grassland. However, the region contains woodlands, especially along streams, as well as diverse landscapes and many prominent landforms. The Raton Section of New Mexico, the Black Hills of South Dakota, and the Bear Paw, Big Snowy, and Judith Mountains of Montana, for example, rise 450–1,200 m above the surrounding plains. Low rolling hills, such as those of the Flint Hills and Smoky Hills in Eastern Kansas and the Rolling Plains of North Central Texas and South Central Oklahoma, also are common, as are deep valleys and canyons, such as the Canadian Breaks and Palo Duro Canyon in the Texas Panhandle and Ladder Creek valley in Western Kansas.

Several factors play a role in preserving archaeological sites and in forming stratified archaeological sequences on the Great Plains. Depositional environments – alluvial, lacustrine/palustrine, and eolian – since about 14,000 years ago (all dates are in uncalibrated radiocarbon years before present) generally have been aggradational. In particular, the valleys have been the setting of many meters of infilling, largely through floodplain aggradation, and localized lacustrine deposition. There are also extensive areas where eolian sand and silt aggraded during the Holocene. Thousands of small lake basins also dot portions of the Great Plains and most have slowly filled with sediment since the Last Glacial Maximum (LGM) about 20,000 years ago. A few rock-shelters occur in the region and have stratified archaeological records, but such sites are mostly limited to the Edwards Plateau, which consists of karstic limestone, and areas of the High Plains where differential erosion has left the thick, resistant caliche "caprock" (petrocalcic horizon) of the Ogallala Formation as an overhang.

Holocene archaeological stratigraphy

The long stratified archaeological records at many sites on the Great Plains have been key components in establishing regional cultural chronologies, typically in a dated context. Those stratigraphic records have also provided paleoenvironmental data tied to numerical chronologies. The stream valleys of the Edwards Plateau in Central Texas, particularly along the southern and eastern margins (also the southern and southeastern margin of the Great Plains), have provided rich sequences of artifacts spanning

Great Plains Geoarchaeology, Table 1 Selected Paleoindian sites in valleys and alluvial settings of the Southern Great Plains

Site	Setting	Geoarchaeology	References
Edwards Plateau			
Gault (Texas)	Upper Buttermilk Creek, Brazos River tributary	Multiple Clovis and Late Paleoindian occupations in thick (>1 m) alluvium near spring head	Collins and Brown, 2000
Wilson-Leonard (Texas)	Upper Brushy Creek, Brazos River tributary	Clovis, Folsom, Golondrina, Barber, St. Mary's Hall, San Patrice, and Angostura occupations in thick (>1 m) alluvium and cumulic soils	Bousman, 1998; Collins, 1998a; Collins, 1998b; Bousman et al., 2002
Richard Beene (Texas)	Lower Medina River, on the boundary between the Edwards Plateau and inner Gulf Coastal Plain	Stratified Angostura occupations in a deeply buried cumulic soil, plus stratified Archaic and Late Prehistoric cultural deposits in buried soils above the Angostura components	Thoms and Mandel, 2007; Mandel et al., 2007
Southern High Plains			
Clovis (Blackwater Draw Loc 1) (New Mexico)	Blackwater Draw, Brazos River tributary	Clovis with mammoth in spring alluvium; Folsom with bison in lake beds; Late Paleoindian with bison in wet meadow	Haynes and Agogino, 1966; Haynes, 1975, 1995; Holliday, 1995, 1997a
Lubbock Lake (Texas)	Yellow House Draw, Brazos River tributary	Clovis age with Pleistocene fauna in stream alluvium; Folsom with bison in lake beds; Late Paleoindian with bison in marshy wetlands	Stafford, 1981, Johnson, 1987; Holliday, 1985, 1995, 1997a; Holliday and Allen, 1987

the Holocene. No one site spans the past 12,000 years, but a set of sites, including Wilson-Leonard, Richard Beene, Clovis, Lubbock Lake, Coffey, and Medicine Lodge, covers the complete archaeological sequence.

Radiocarbon dating of the archaeological record at the Wilson-Leonard site on the Edwards Plateau in Central Texas (Figure 1) resulted in a high-resolution cultural sequence and geochronology for Paleoindian and Early Archaic occupations. Of particular significance, the combined archaeological and geological research revealed Archaic-style (stemmed) artifacts and subsistence strategies (broad spectrum with increased focus on plant gathering and processing) at ca. 12,000–10,250 cal years BP, stratigraphically interfingered with more classic Paleoindian lanceolate artifact styles. This sequence provides a rare glimpse of the Paleoindian to Archaic transition in both artifact styles and subsistence practices.

The Richard Beene site (Table 1), located on the boundary between the Edwards Plateau and Inner Gulf Coastal Plain in South Central Texas (Figure 1), is a well-dated stratified locality with numerous discrete and substantial artifact and feature assemblages that span the Holocene (Thoms and Mandel, 2007). There are 20 stratigraphically distinct archaeological horizons that have yielded more than 80,000 artifacts, including flakes, tools, bones, mussel shells, and fire-cracked rocks, buried in 14 m of fine-grained, over-bank alluvium comprising a terrace fill. Nearly all of the cultural deposits are associated with buried soils that formed during relatively brief episodes of landscape stability (Mandel et al., 2007). The site's archaeological record provides a uniquely long-term perspective on regional paleoecology and riverine usage in an ecotone between North America's western grasslands and eastern woodlands. Throughout its 10,000-year history of intermittent habitation, hunter-gatherer families occupied the site, camping along the Medina River; hunting deer, rabbits, and other game in wooded areas; gathering wild roots; and fishing and collecting river mussels to supplement their diet. Climatic conditions fluctuated through the period of occupation but usually did not vary much from modern conditions (Thoms and Mandel, 2007).

The Clovis and Lubbock Lake sites (Table 1), both on the Southern High Plains (Figure 1), are best known for their stratified Paleoindian archaeological records (discussed below), but they also contain younger cultural deposits in valley fills. The Paleoindian to Archaic transition is not well recorded because of low sedimentation rates, but occurred ~8,500–8,000 years BP. This transition was roughly coincident with Early Holocene aridity that triggered widespread eolian sedimentation in valleys ~6,000–4,500 year BP (Middle Holocene/Middle Archaic). The Archaic to Late Prehistoric transition is also difficult to identify in the archaeological record because of regional landscape stability and very limited sedimentation but was probably ~2,000 year BP. Localized landscape instability and cyclic episodes of slope wash deposition and stability in the Late Holocene at Lubbock Lake provide a high-resolution archaeological record of the Late Prehistoric to Protohistoric transition, as well as the Protohistoric to Historic transition, including differentiation of Native American Historic and Euro-American Historic occupations.

At the Coffey site (Table 2) in the Flint Hills of Northeastern Kansas (Central Plains) (Figure 1), stratified Middle Paleoindian (Folsom and Midland) through Late Woodland cultural deposits occur in valley fill beneath the T-1 terrace of the Big Blue River, and Early Paleoindian (Clovis) projectile points have been recorded

Great Plains Geoarchaeology, Table 2 Selected Paleoindian sites in valley and alluvial settings on the Central Great Plains

Site	Setting	Geoarchaeology	References
Northern and Central High Plains			
Hell Gap (Wyoming)	Small valley with low-order tributary to North Platte River	Goshen, Folsom, Midland, Agate Basin, Hell Gap, Alberta, Cody, and Frederick occupations (locally redeposited) in stratified eolian and alluvial silts	Frison, 1998; Kornfeld, 2005; Larson et al., 2009
Medicine Creek sites – Lime Creek, Red Smoke, Allen (Nebraska)	Medicine Creek, tributary to Republican River	Stratified Cody, Frederick, and other Late Paleoindian occupations in thin buried soils near base of thick, silty alluvium	Davis, 1953, 1962; Roper, 2002; May, 2002
Jones-Miller (Colorado)	Terrace of Arikaree River	Hell Gap bison bone bed in and along swale on terrace	Albanese, 1977; Stanford, 1978, 1984
Olsen-Chubbuck (Colorado)	Arroyo	Firstview/Cody bison kill deeply buried under arroyo fill	Wheat, 1972; Holliday et al., 1999
Scottsbluff (Nebraska)	Terrace of Spring Creek, tributary to the North Platte River (near base of Signal Butte)	Scottsbluff-type (Cody) bison kill on terrace gravel, buried by sand and silt	Barbour and Schultz, 1932, 1936; Schultz and Eiseley, 1935; Knudson, 2013
Truman (Nebraska)	A terrace remnant at the mouth of Kilgore Creek where it joins the South Loup River	Three stratified Paleoindian cultural components, including one identified as early Cody complex (Alberta), in terrace fill	May and Holen, 2014
Stark (Nebraska)	Gully along the margin of an unnamed, flat-bottomed, first-order tributary to the lower South Loup River	Cody complex (Scottsbluff) component buried in gully fill	May and Holen, 2014
McKenzie (Nebraska)	Alluvial fan in the Middle Loup River valley	At least seven stratified components ranging from Early Paleoindian to Late Prehistoric in fan deposits	May and Holen, 2014
Clary Ranch (Nebraska)	Terrace of Ash Hollow Creek, tributary to North Platte River	Allen/Frederick bison bone bed in alluvium	Myers et al., 1981; Hill et al., 2002a; Hill et al., 2002b
Norton (Kansas)	Arroyo along Ladder Creek, a tributary to the Smoky Hill River	Allen/Frederick bison bone bed deeply buried in arroyo fill	Hofman et al., 1995
Kanorado (Kansas)	Middle Beaver Creek, a tributary to the Republican River	Stratified Clovis *Camelops* bone bed and pre-Clovis mammoth and *Camelops* in alluvium	Mandel et al., 2004
Lipscomb (Texas)	Arroyo along Sand Creek, a tributary to the North Canadian River	Folsom bison bone bed along arroyo margin	Barbour and Schultz, 1941; Hofman, 1995; Holliday, 1997a
Central High Plains – Central Lowlands Border			
Coffey (Kansas)	Terrace of the Big Blue River	Stratified Folsom, Midland and Late Paleoindian cultural deposits in an alluvial soil	Mandel et al., 2010; Ray and Mandel, 2014
Claussen (Kansas)	Terrace of Mill Creek	Stratified Dalton cultural deposits in a deeply buried alluvial soil	Mandel et al., 2006
Colorado Piedmont			
Lindenmeier (Colorado)	Small valley with arroyo tributary of Cache La Poudre River	Multiple Folsom camps and bone bed in slowly aggrading, stratified soils	Bryan and Ray, 1940; Haynes and Agogino, 1960; Wilmsen and Roberts, 1978
Dent (Colorado)	Terrace of South Platte River	Clovis mammoth bone bed in alluvium; redeposited	Haynes et al., 1998; Brunswig, 2007
Klein (Colorado)	Terrace of South Platte River	Clovis artifacts, mammoth and horse in gravely alluvium	Zier et al., 1993
Jurgens (Colorado)	Terrace of South Platte River	Cody bone bed in swale; camp on ridge	Wheat, 1979; Holliday, 1987; McFaul et al., 1994
Frazier (Colorado)	Terrace of South Platte River	Agate Basin bone bed in swale	Malde, 1984; Holliday, 1987; McFaul et al., 1994
Raton section			
Folsom (New Mexico)	Arroyo tributary to Dry Cimarron River	Folsom-type collection and bone bed in fine-grained (eolian) arroyo fill	Meltzer et al., 2002; Meltzer, 2006

on the T-2 terrace (Schmits, 1980; Mandel et al., 2010; Mandel, 2014). Hence, Coffey harbors one of the most complete records of human occupation in the Great Plains. The site is best known for yielding significant information about Middle Archaic occupation of the Central Plains from ~5,500 to 5,000 year BP, one of the least documented periods in Plains prehistory. The archaeological record at locality 1 consisted of a rich array of features,

Site	Setting	Geoarchaeology	References
Agate Basin[a] (Wyoming)	Arroyo tributary to Moss Agate Creek (Cheyenne River)	Clovis, Folsom, Agate Basin, and Hell Gap occupations in stratified arroyo fill and associated buried soils	Albanese, 1982; Frison and Stanford, 1982; Reider, 1982
Carter/Kerr-McGee (Wyoming)	Arroyo tributary to Powder River	Clovis, Folsom, Agate Basin-Hell Gap, and Alberta-Cody occupations in stratified arroyo fill and associated in poorly drained buried soils	Frison, 1984; Reider, 1980, 1990
Sister's Hill (Wyoming)	Arroyo tributary to Powder River	Hell Gap camp in poorly drained soil within stratified alluvium	Agogino and Galloway, 1965; Haynes and Grey, 1965; Reider, 1983
Casper (Wyoming)	Dune on terrace of North Platte River	Hell Gap bison kill in parabolic sand dune	Albanese, 1974; Frison, 1974
Jim Pitts (South Dakota)	Black Hills foothills	Stratified Folsom, Goshen, Agate Basin, Cody, and Alberta camp sites in aggrading soil (Leonard paleosol)	Sellet, 2001; Sellet et al., 2009
Mill Iron (Montana)	Butte above tributary to Box Elder Creek	Goshen bison kill on alluvial and colluvial surface in paleo-swale draining to creek	Albanese, 1996; Frison, 1996; Reider, 1996
Knife River Flint Quarries – Alkali Creek, Bobtail Wolf, Big Black, Benz (North Dakota)	Low terrace along Spring Creek	Goshen, Folsom, and Hell Gap artifacts in alluvium; Folsom, Cody, and Alberta occupations in eolian sand and silt	Root et al., 1985; Artz, 1995; Metcalf and Ahler, 1995; Root, 2000; Williams, 2000
Medicine Lodge (Wyoming)	Alluvial terrace and colluvial apron along the Medicine Lodge Creek	Over 60 cultural levels spanning the past 10,000 years contained in an 8-m-thick alluvial-colluvial sequence adjacent to a rock-shelter	Frison, 1976

[a]Includes Sheaman and Brewster localities

faunal remains (especially bison), and artifacts contained within 12 stratified cultural horizons in unit III, a fine-grained alluvial fill that aggraded between ~6,000 and 5,000 year BP (Schmits, 1980; Mandel et al., 2010). Recent geoarchaeological investigations at Coffey recorded stratified Middle and Late Paleoindian cultural deposits in a paleosol developed at Late Wisconsinan alluvial fill (Ray and Mandel, 2014), adding to the significance of the site.

The Medicine Lodge site (Table 3), located on the edge of the Bighorn Basin in North Central Wyoming (Figure 1), consists of over 60 cultural levels spanning the past 10,000 years, making it the most complete record of human occupation in the northern Plains. The cultural deposits are contained in an 8-m-thick alluvial-colluvial sequence adjacent to a rock-shelter (Frison, 1976). Five distinct vegetation zones occur within a radius of 19 km around the site, which provided a rich resource base for the inhabitants of the site. Analyses of faunal remains, seeds, pollen, and charcoal from Medicine Lodge, as well as the site stratigraphy, yielded information used to reconstruct Holocene paleoenvironments in the Bighorn Basin (Frison, 1976).

Paleoindian geoarchaeology

Beginning in the nineteenth century, acrimonious debate often surrounded the subject of the timing of the earliest peopling of the Americas, and the disagreements lasted for decades. The basic arguments were over a short chronology (people had been in the Americas for only a few thousand years) versus a long chronology (ancestors of Native Americans arrived in the Late Pleistocene). In the late 1920s, the debate was finally settled with the discovery of the Folsom site in eastern New Mexico, on the Southwestern Great Plains. Basic stratigraphy and paleontology at Folsom showed that artifacts (projectile points for hunting) were in association with extinct Late Pleistocene bison. This discovery launched the subdiscipline of Paleoindian archaeology and the beginning of considerable geoarchaeological research with a focus on the earliest sites in the Americas. This entry will describe in some detail that focus on Paleoindian settlement in the Great Plains.

Since the initial Folsom discoveries, combined archaeological and geological investigations of Paleoindian sites continued throughout the Great Plains. Because sedimentation was relatively continuous and because of, for the most part, low energy in stream valleys and lake basins throughout much of Plains during the Late Pleistocene and Early Holocene (as described below), the region has the highest concentration of known, in situ, stratified archaeological sites for this period anywhere in the Americas (see Mandel, 2000).

Valleys and draws

Thick, continuous stratigraphic sequences of alluvium are a striking characteristic of the drainages of the Great

Great Plains Geoarchaeology, Figure 2 Excavations in bedded diatomite and overlying homogeneous muds at the Lubbock Lake site, Northwestern Texas. These lake and marsh beds formed on the floor of Yellow House Draw, a tributary of the Brazos River. The bedded diatomite (on which most of the crew stands) contains a Late Paleoindian bone bed of extinct bison (*Bison antiquus*) dating to ~11,500 cal years BP. The smaller excavated area low in the diatomite contains a Folsom-age *B. antiquus* bone bed dating to ~12,500 cal years BP. Homogeneous palustrine mud on top of the bedded diatomite is about 50 cm thick, exposed low along the back wall of the excavations. Note the lack of deformation of the beds despite the multiple bison-butchering activities (From Holliday, 1997a: Figure 3.28).

Plains. Stratified archaeological sequences are likewise ubiquitous. This situation is largely the result of deep incision between the LGM and Younger Dryas by most stream systems, followed by aggradation and episodic stability through most of the rest of the Late Quaternary. The Paleoindian archaeological sites therefore tend to be deeply buried. For example, at the Aubrey site on the Trinity River in Northeast Texas (Figure 1), Clovis cultural deposits lie beneath ~8 m of alluvium (Ferring, 2001). At the Claussen site on lower Mill Creek, a high-order stream in the Flint Hills of Northeast Kansas (Figure 1), multiple Dalton (Late Paleoindian) occupation zones occur ~9–10 m below the surface of an alluvial terrace (Mandel et al., 2006). Along the perennial streams of the Plains, many early sites are likely below the water table. As a result, most of the recorded Paleoindian sites are in draws (dry valleys) and arroyos (dry washes) in low-order tributaries.

The most intensively investigated, stratified Paleoindian sites on the Edwards Plateau are in somewhat similar settings: low-order tributaries incised into the limestone bedrock and in proximity to springs (Table 1). Besides their setting, both Wilson-Leonard and Gault (Figure 1) exhibit remarkably similar stratigraphic sequences: (1) multiple Paleoindian occupations in thick (>1 m), well-stratified sediments (Table 1); (2) a fining-upward sequence of alluvium during the Early Paleoindian period from ~11,500 to 10,000 years BP; and (3) stability and soil formation beginning ~10,000 years BP and lasting ~500–1,000 radiocarbon years, then colluvial and alluvial deposition coincident with Late Paleoindian and Early Archaic occupations.

The draws of the Southern High Plains are now dry tributaries of the Red, Brazos, and Colorado rivers (Haynes, 1975, 1995; Stafford, 1981; Holliday, 1995, 1997a). Clovis occupations, characterized by mammoth kills and megafauna processing, are associated with active alluvial settings such as point bars and spring-fed drainageways (Table 1). Flowing water gave way to standing water in ponds and marshes during the Folsom occupation. Bone beds of extinct *Bison* with Folsom artifacts were recovered from microstratified diatomite beds and muds (Figure 2). These deposits formed in lakes that were scattered along the floors of several draws. By 10,000 year BP, the draws were characterized by deposition of muds, carbonates, and localized eolian sand. Late Paleoindian occupations characterized by Plainview, Firstview/Cody, and other unfluted lanceolate styles were found in these settings in camps or in bone beds from kills or processing of extinct *Bison*. A few Folsom and Late Paleoindian camping features are also recorded from valley-margin settings or from the uplands immediately adjacent to the draws (Holliday, 1997a).

Draws on the Northern High Plains also have yielded stratified Paleoindian cultural deposits (Mandel, 2006). Specifically, the Kanorado locality in Northwest Kansas (Figure 1) is on the valley floor of Middle Beaver Creek, a draw that today carries water only immediately after heavy rainfalls. A cluster of three sites at Kanorado has deeply buried Early Paleoindian and Folsom cultural deposits with disarticulated remains of mammoth and extinct bison, respectively (Mandel et al., 2004, 2009). During the period of Early Paleoindian occupation (11,000 years BP), the site was characterized by standing water in spring-fed ponds surrounded by a savanna with coniferous trees and C_3 grasses (Cordova et al., 2011). The ponds were beginning to dry up during the Folsom occupation (~10,350 years BP), and the number of drought-adapted C_4 Chloridoideae grasses increased at the expense of the C_3 grasses and woody plants. Other stratified Paleoindian occupations associated with draws on the Northern High Plains include the Powell site (Mandel et al., 2004) and Simshauser site (Mandel and Hofman, 2006) in Northwestern and Southwestern Kansas, respectively, and the Clary Ranch locality in Southwestern Nebraska (May et al., 2008) (Figure 1).

Several better-known Paleoindian sites on the Great Plains are associated with the upper South Platte River and its tributaries in the Colorado Piedmont, the broad topographic basin between the High Plains and Rocky Mountains created by the upper South Platte and Arkansas rivers (Figure 1; Table 2). The sites tend to be near the top of Late Pleistocene alluvium (Dent and Klein Clovis sites, Figure 1; Table 2) or on top of the associated terrace (mapped as the Broadway terrace near Denver and the Kersey terrace in the Greeley area) (Powars Folsom site; Jurgens and Frazier Late Paleoindian sites, Figure 1, Table 2). Clovis material appears to be in the upper alluvium, while Folsom and other post-Clovis occupations are on top of the terraces, buried by thin layers of mud (Frazier and Jurgens sites) or by eolian sand (Powars Folsom site). The data suggest that the upper South Platte was in the early stages of entrenchment from Clovis through Late Paleoindian times.

The famous Lindenmeier site (Figure 1; Table 2) is in an unusual valley setting: a low-order tributary of the Cache La Poudre River, which joins the South Platte (Figure 1). Scouring of the small valley preceded the Folsom occupation; hence, Clovis-age erosion far up a - low-order tributary of the South Platte was coincident with the final stages of mainstream alluviation. Downcutting was followed by slow aggradation and pedogenesis during the Folsom occupation.

Geoarchaeological data for Paleoindian sites along other mainstreams and tributaries on the Central Great Plains, particularly the High Plains, provide a sharp contrast with the record on the upper South Platte. Medicine Creek, Nebraska, a tributary of the Republican River (which flows into the South Platte), yielded three prominent Late Paleoindian sites (Allen, Lime Creek, and Red Smoke; Figure 1, Table 2), all deeply buried beneath floodplain silt that was likely derived from loess on the uplands (Figure 3). Likewise, Late Paleoindian sites along the North Platte (Scottsbluff), Loup (Truman, Stark, and McKenzie), and Smoky Hill rivers (12 Mile Creek and Norton) are deeply buried in alluvium (Figure 1, Table 2). Thus, while the mainstream upper South Platte was quasi-stable or downcutting in Paleoindian times, lower-order tributaries and adjacent mainstreams had already undergone deep entrenchment and were aggrading during the Paleoindian occupation of the region.

Geoarchaeological data are sparse for the Missouri Plateau, particularly from Paleoindian sites, given its size in comparison to the Central and Southern Great Plains. This is likely due to extensive alluvial erosion in this headwater setting of the Missouri River system. The principal exceptions are in headwater areas of the major drainages in Wyoming and Montana.

Most known and investigated Paleoindian sites in the Missouri Plateau were exposed along arroyos in low-order tributaries, particularly in the headwater areas. These exposures yielded a number of key Paleoindian sites, including Carter/Kerr-McGee, Sister's Hill, Agate Basin, and Lange-Ferguson (see Albanese, 2000) (Figure 1; Table 3). Most of these occupations are associated with buried soils exhibiting evidence of poor drainage, which suggests that local water tables were high at the time (e.g., Sister's Hill, Agate Basin, Carter/Kerr-McGee). But changes in soil morphology also indicate that the wetlands dried through Paleoindian time.

Two of the few Paleoindian sites in mainstream settings of the Missouri Plateau provide unique insights into Paleoindian activities: Beacon Island and the Knife River Flint Quarries. Beacon Island is a multicomponent archaeological site in northwestern North Dakota that includes an Agate Basin (Paleoindian) component consisting of the butchered remains of at least 29 *Bison antiquus*, along with projectile point fragments and other artifacts (Mandel et al., 2014) (Figure 1). The bison bone bed is a product of a single kill at ca. 10,300 years BP, and it is buried in a shallow kettle basin (Figure 4). Based on phytolith and stable carbon isotope data, cool-season C_3 prairie species dominated the site at the time of the bison kill. Although the Agate Basin occupation coincided with the coolest and perhaps the wettest climatic episode during the past 12,000 years, it is likely that the people associated with the Agate Basin culture at Beacon Island did not experience environmental conditions dramatically different from the modern conditions at the site (Mandel et al., 2014).

The well-known Knife River Flint Quarries are found along the Knife River and its tributary Spring Creek (Figure 1). Knife River flint is a high-quality raw material for stone tool manufacture used throughout the human occupation of the Northern Great Plains and adjacent areas (Clayton et al., 1976; Ahler, 1986; Root, 2000). The flint occurs in Pleistocene alluvium and colluvium in both fill

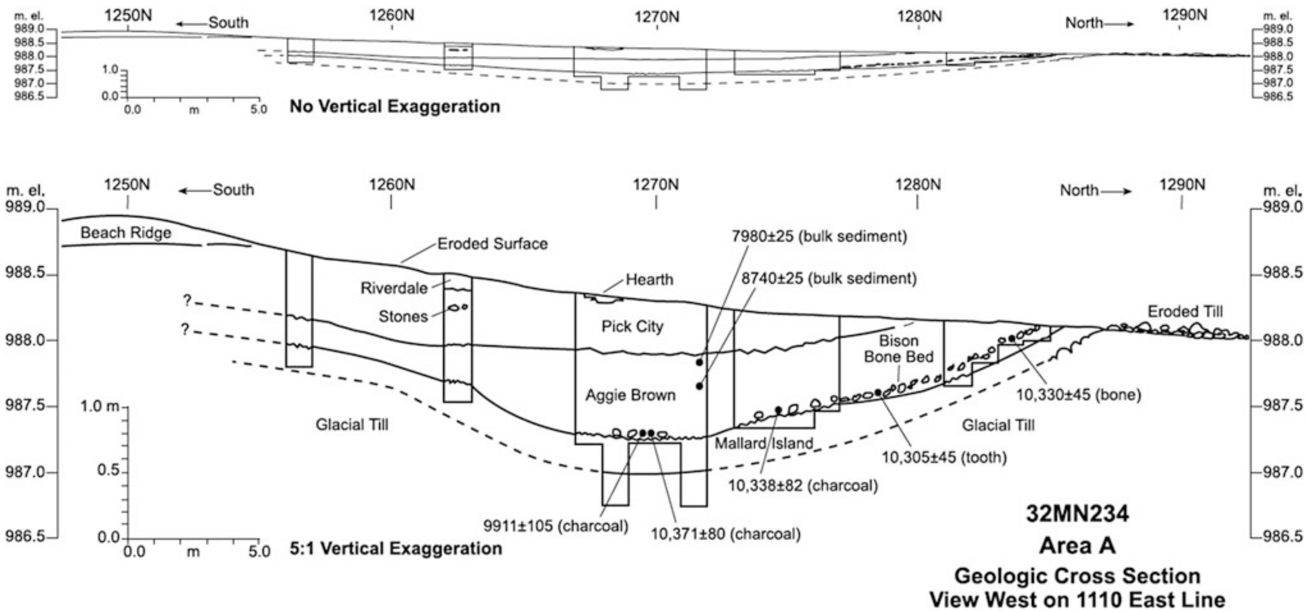
Great Plains Geoarchaeology, Figure 3 Photograph of the 1947 excavations at the Lime Creek site (25FT41) in Southwestern Nebraska. Late Paleoindian cultural deposits associated with a buried soil at the bottom of the exposure are mantled by 12 m of silty alluvium derived from Late Quaternary loess on the uplands (Photo courtesy of the University of Nebraska State Museum).

and strath terraces (Figure 5). In the reported sites (Table 3), the flint was at or just below the surface during the various Paleoindian occupations of the area (Artz, 1995; Van Nest, 1995; Root, 2000; William, 2000).

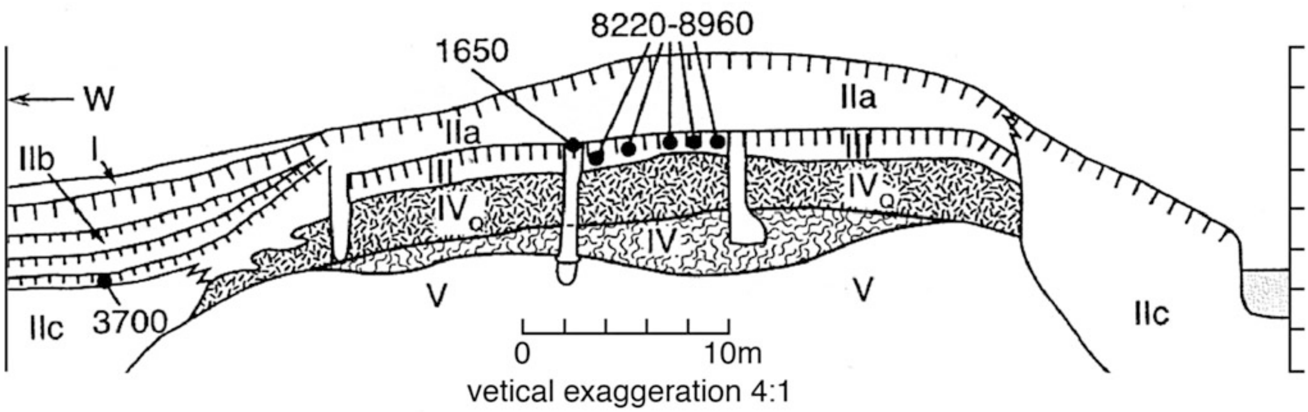
The Alberta Plains was deglaciated essentially coincident with the peopling of the New World as the Laurentide and Cordilleran ice sheets retreated at the end of the LGM and opened the gateway (the "ice-free corridor") between Beringia and the Americas. As the area was deglaciated, proglacial lakes probably covered the landscape. Drainage of the lakes likely resulted in deep incision of the meltwater channels, followed by rapid filling of these drainageways. These processes probably explain the relative absence or lack of visibility of early archaeological sites in the region. Most of the well-documented Paleoindian sites on the Alberta Plains for which geological data are available are in valleys in or near foothills of the Canadian Rockies. The early occupations at Vermilion Lakes (~10,800 year BP) and Charlie Lake Cave (~10,500 year BP) are associated with slope wash or debris-flow deposits owing to the footslope settings, but the ancient inhabitants may have been attracted by proglacial lakes once located in the valleys where the sites are situated (Figure 1; Table 4). There are indications of Clovis hunting at Wally's Beach. Butchered remains of extinct horse were found on alluvium and buried by eolian sand along the St. Mary River, just east of the foothills (Table 4) (Kooyman et al., 2006).

Lakes and playas

Lakes, dry lake basins, and playas (seasonally dry basins; "pans" in other regions) are locally common on the Great Plains, largely on the level and poorly drained High Plains and Alberta Plains. On the Southern High Plains, Paleoindian archaeology is common around basin margins (Hester, 1975; Litwinionek et al., 2003), but these relatively stable settings rarely produce buried archaeological features. The only in situ Paleoindian features known from playas are in the basin fills, but only three are known



Great Plains Geoarchaeology, Figure 4 Stratigraphic cross section of area A of the Beacon Island site. The beach ridge on the southern margin of the kettle basin is associated with modern Lake Sakakawea (From Mandel et al., 2014).



Great Plains Geoarchaeology, Figure 5 Stratigraphic cross section through the Alkali Creek site, one of the Knife River Flint Quarries, showing the relationship of the Paleoindian occupation surface to the Leonard Paleosol (unit III), the high-quality flint gravel (unit IV), and quarry spoil in the gravel (unit IV_Q). Units I–II are Holocene alluvium, and unit V is Pleistocene alluvium. Numbers are uncalibrated radiocarbon years before present (From Holliday and Mandel, 2006: Figure 3).

(Table 5), largely because exposures, natural or artificial, are rare.

Playa basins on the Northern High Plains have received significantly less attention stratigraphically, geoarchaeologically, and geomorphologically than their southern counterparts but have produced in situ Paleoindian finds (Table 6). For example, the Winger site, a Late Paleoindian bison kill located in southwestern Kansas (Figure 1), is on the edge of a playa basin (Mandel and Hofman, 2003). The bison bone bed is in a deeply buried soil developed in fine-grained basin fill overlain by Early Holocene alluvium (arroyo fill). Allen points and point fragments were recorded in the bone bed. Limited excavation revealed some fully articulated skeletons, and taphonomic observations suggest some of the bison collapsed while standing in a playa or pond margin setting. The remains of at least six bison are represented in the excavated sample, but many more animals are represented in the bone bed. A radiocarbon age of ~9,000 year BP was determined on bone collagen, which is consistent with the diagnostic artifacts found at Winger.

Great Plains Geoarchaeology, Table 4 Selected Paleoindian sites on the Alberta Plains, Northern Great Plains

Site	Setting	Geoarchaeology	References
Charlie Lake Cave (British Columbia)	Peace River	Multiple occupations 10,500 (including fluted style)– 9,500 ^{14}C years BP in slope wash below rock-shelter	Fladmark et al., 1988
Vermilion Lake (Alberta)	Mountain footslope, Bow River valley, Alberta Front Ranges	Multiple occupations 10,800–9,000 ^{14}C years BP (including stemmed lanceolates) in stratified debris-flow deposits and eolian silt and sand	Fedje, 1986; Fedje et al., 1995

Lake basins			
San Jon (New Mexico)	Eroded playa basin near northwest edge of S. High Plains	Firstview/Cody bone bed in playa mud	Roberts, 1942; Judson, 1953; Hill et al., 1995, Holliday, 1997a
Miami (Texas)	Small, filled playa basin near northeast edge of S. High Plains	Clovis with mammoth in playa mud	Sellards, 1938; Holliday et al., 1994
Ryan (Texas)	Small, filled playa basin	Cache of Plainview points (13) in playa mud	Hartwell, 1995; Holliday, 1997a
James Pass (Alberta)	Bedrock bench on the margins of a basin surrounded by mountains	Stratified Late Paleoindian and Early Archaic cultural deposits beneath the Mazama Ash	Ronaghan, 1993
Dunes			
Milnesand (New Mexico)[a]	Lea-Yoakum Dunes	Milnesand-type artifacts and bison bone bed in eolian sand	Sellards, 1955; Warnica and Williamson, 1968; Holliday, 1997a; Hill, 2002
Ted Williamson (New Mexico)[a]	Lea-Yoakum Dunes	Plainview artifacts and bison bone bed in eolian sand	Holliday, 1997a
Elida (New Mexico)	Lea-Yoakum Dunes	Folsom camp in eolian sand, adjacent to small playa basin	Warnica, 1961; J. Hester, 1962; Holliday, 1997a
Shifting Sands (Texas)	Andrews Dunes	Folsom/Midland camp and bison processing site in eolian sand	Amick and Rose, 1990; Hofman et al., 1990; Holliday, 1997a

[a]Milnesand and Ted Williamson sites are 550 m apart

Six of the seven reported Paleoindian sites in playa basins on the High Plains are essentially single component features (e.g., a bone bed from a kill or an artifact cache) located on the basin floors. The Nall site is unusual among Paleoindian sites in either playa or eolian sediments in that it lies along a playa margin, and it yielded a record of occupation throughout Paleoindian time (Table 6). This is probably because the occupation area was around or near likely springs or seeps (LaBelle et al., 2003).

Great Plains Geoarchaeology, Table 6 Selected Paleoindian sites in or around lake basins and in dune fields, Central and Northern Great Plains

Fowler-Parrish (Colorado)	Dune field (and playa)	Folsom bison kill in stratified eolian sand	Agogino and Parrish, 1971

[a]Large surface collections
[b]Also listed in alluvial table

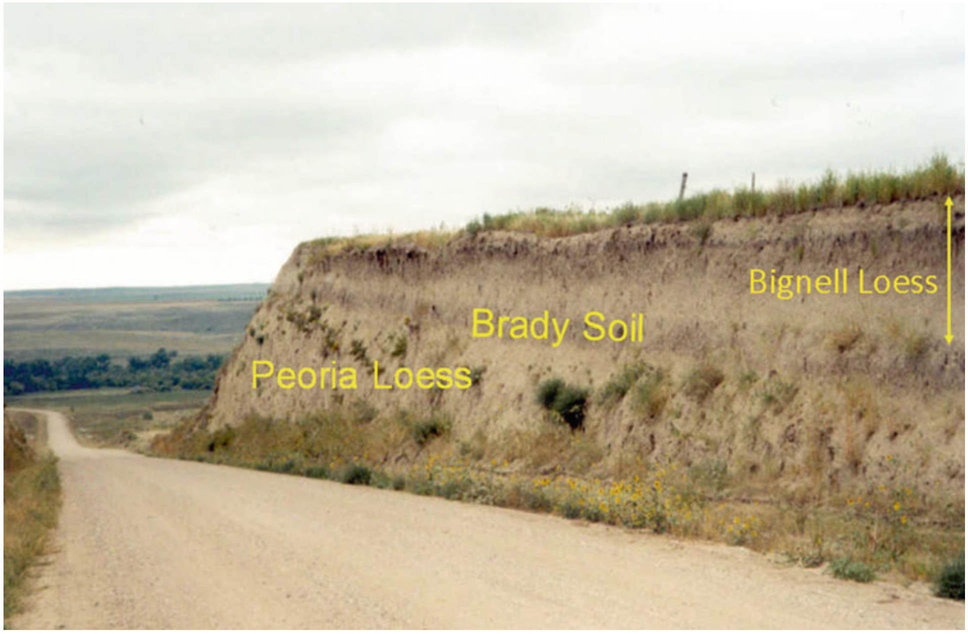
The few Paleoindian sites known and reported on the Alberta Plains away from the Rocky Mountain front tend to be associated with either lake or marsh sediments or nearby wetlands. Most fluted point sites are near extinct lakes (Gillespie, 2002, 120–123). Proglacial lakes inundated many lowland settings as ice retreated (Beaudoin et al., 1996). These lakes drained before and during the Paleoindian occupation of the region. The locations of Paleoindian sites, especially the earlier ones (i.e., Clovis), may have been dictated by the presence of these shrinking lakes. Thus, site locations shifted through time as the lake declined (Beaudoin and Lemmen, 2000, 39).

Dunes and loess

Eolian deposits and landforms are ubiquitous on the Great Plains owing to the open, windy environment, the semiarid climate, and the availability of easily erodible substrate. The deposits include sand in dune fields, lunettes, and sheets, and silt in primary and redeposited loess. Few Paleoindian sites are found within eolian deposits, but Holocene-age eolian sediments buried many sites on Pleistocene and older landscapes. Most were exposed by historic wind deflation of these eolian mantles. The sites suffer from wind erosion, exposure, and reburial (and perhaps several cycles of these processes) and, therefore, typically do not yield useful chronological or paleoecological data.

Dunes and sand sheets are common on the western side of the Southern High Plains, and lunettes border some of the larger playa basins (Holliday, 1997b, 2001; Rich et al., 1999). Paleoindian sites and collections of Paleoindian artifacts are relatively well known from the dune fields. Some of the dunes (e.g., at Shifting Sands and Winkler-1 in the Andrews Dunes; Table 5; Figure 1) rest on older (Clovis age or pre-Clovis age) lake and marsh deposits or other indicators of moist settings that could have attracted Paleoindian foragers.

Extensive deposits of loess and eolian sand cover the Central Great Plains (Muhs and Zarate, 2001; Bettis et al., 2003; Busacca et al., 2004). In some areas of Western Nebraska, the Pleistocene loess is more than 20 m thick. The Peoria Loess, which largely predates the Paleoindian occupation, is the most common Quaternary deposit on uplands of the Central Plains. Landscape stability and soil formation that occurred after aggradation of the Peoria Loess included Paleoindian time (Holliday, 1997a). In some areas of the Central Plains, especially on bluff tops adjacent to major rivers such as the Platte, Republican, and Arkansas, Bignell Loess mantles the Peoria Loess (Figure 6). Maximum limiting ages of the Bignell are based on radiocarbon ages determined on soil organic matter from the Brady Paleosol developed at the top of the Peoria Loess (Mason et al., 2006). These ages in combination with radiocarbon and luminescence ages determined on materials



Great Plains Geoarchaeology, Figure 6 Loess stratigraphy exposed at Bignell Hill overlooking the Platte River in Southwestern Nebraska. This is the type locality for the Bignell Loess and Brady Paleosol. The Brady Paleosol, which typically developed between ca. 15,500 and 9,000 years ago, represents a buried Paleoindian landscape that has yielded cultural deposits at other localities in the Central Plains. There is potential for Late Paleoindian and younger cultural deposits in the overlying Bignell Loess (Photo courtesy of Peter Jacobs).

Great Plains Geoarchaeology, Table 7 Selected rock-shelters on the Great Plains

Site	Setting	Geoarchaeology	References
Bonfire Shelter (Texas)	Mile Canyon, tributary to Rio Grande	Plainview/Folsom bison bone bed	Dibble and Lorrain, 1968; Bement, 1986; Robinson, 1997
Kincaid Shelter[a] (Texas)	Sabinal River (both shelter and terrace)	Clovis in spring and flood plain backwater fines and on stone "pavement"; Folsom (not in situ); Golondrina, Texas Angostura and San Patrice in midden deposits	Hester et al., 1985; Collins et al., 1989; Collins, 1990
Baker Cave (Texas)	Phillips Canyon, tributary to Devil's River	Golondrina occupation in fine midden debris	Word and Douglas, 1970; T. Hester, 1982
Charlie Lake Cave (British Columbia)	Peace River	Multiple occupations 10,500 (including fluted style)–9,500 year BP in slope wash below rock-shelter	Fladmark et al., 1988

[a]Kincaid also associated with floodplain

from the Bignell Loess indicate that the Bignell aggraded episodically throughout the Holocene (Mason and Kuzila, 2000; Mason et al., 2003, 2006). The Brady Paleosol, which typically developed between 15,500 and 9,000 years ago during a time of warming and drying (Feggestad et al., 2004; Mason et al., 2008), represents a buried Paleoindian landscape that has yielded cultural deposits. For example, at site 25KH67 in Western Nebraska along the South Platte River, a Paleoindian component that may represent a Hell Gap (ca. 10,000 year BP) or Agate Basin (10,500–10,000 year BP) occupation occurs in the lower Brady Paleosol (May and Holen, 2003).

Eolian sand on the Northern High Plains is largely in the form of dune fields, most notably the huge Nebraska Sand Hills, along with other dune systems from throughout the region (Figure 1) (Muhs and Zarate, 2001). Collections of Paleoindian artifacts are well known from these settings (see Holen, 1989; Holen and Hofman, 1999). The Wray Dunes in northeastern Colorado (Figure 1) produced large collections of Paleoindian artifacts during the

1920s and 1930s (Table 6), forming the basis for one of the first systematic studies of large Paleoindian collections. These assemblages were in the uppermost Peoria Loess, likely in the Brady soil, and exposed by deflation of the overlying sand dunes.

Thin deposits of eolian sand and silt are scattered across the Alberta Plains. Some eolian sedimentation was contemporaneous with Paleoindian occupation and is indicative of the unstable, recently deglaciated character of the region at the time. Most of the sites reported from the Alberta Plains are Late Paleoindian (mostly Cody), and several were exposed due to deflation of the eolian sands that encase them.

Rock-shelters

Rock-shelters on the Great Plains (Table 7) with documented Paleoindian records are almost exclusively on the Edwards Plateau, where they are ubiquitous owing to the thick, extensive, and karstified limestone (Collins, 1991, 1995). Debris of Archaic and later occupations is widespread in these settings, but reports of Paleoindian features are relatively uncommon (Dibble and Alexander, 1971; Collins, 1991). According to Collins (1991: Table 6.2), Paleoindian materials are reported from only 10 (~18 %) of 55 recorded rock-shelters.

Multiple Paleoindian occupations are known from Baker Cave, Horn Shelter, and Kincaid Shelter (Figure 1). They seem to be associated with fine-grained fill with a high percentage of midden debris (Table 2), though there are hints of coarser limestone spall dating to earlier Paleoindian or pre-Paleoindian times (e.g., Ross, 1965). Mixing, probably bioturbation, appears to be a significant problem in other shelters, e.g., Levi (see Alexander, 1963), confusing the artifact and radiocarbon associations (Bousman et al., 2004). The single component Paleoindian bone bed at Bonfire Shelter is associated with coarser fill.

GRIMALDI CAVES

Francesco G. Fedele
Formerly University of Naples ‘Federico II’, Naples, Torino, Italy

Synonyms

Balzi Rossi (Italian for “red cliffs”); Grottes de Menton (France)

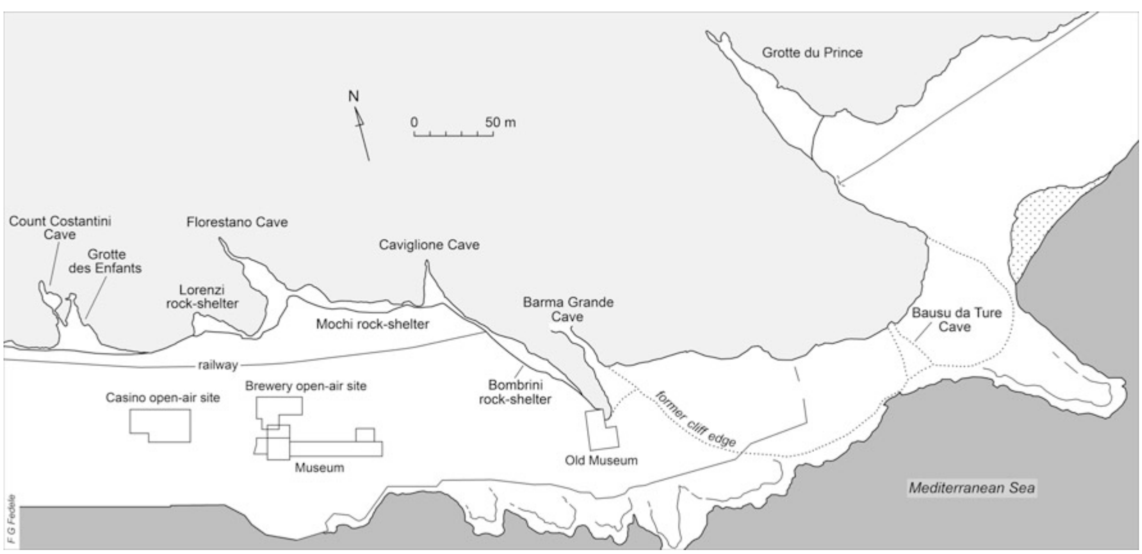
Definition

The Grimaldi caves include a group of 15 caves and rock shelters in coastal cliffs 5 km west of Ventimiglia near the French-Italian border, Liguria, Italy (Figure 1). The geographical coordinates are 43°47′ N and 7°32′ E, and the sites lie at 8–15 m asl.

Due to a combination of rocky coast, deeply stratified deposits, and cultural occupation, Grimaldi represents an important locality for both coastal geoarchaeology and Paleolithic studies in Europe. Steep seaward slopes descend from mountain ridges nearby, and the indented, plunging cliff coast is carved into Jurassic limestone. Tidal notches developed during major sea level stands, the present one associated with an intertidal shore platform in a staircase formed by Pleistocene marine terraces (Furlani et al., 2014, 96–97). Two Paleolithic open-air sites on the platform in front of the cave complex have been recognized.

Overall, the Grimaldi sedimentary sequences span an interval from 300 to 200 ka BP to the present, with the Marine Isotope Stage (MIS) 5 interglacial transgression and the subsequent glacial best represented within the deposits. An interesting cultural-ecological aspect, due to the high coastal relief, is the unusual stability of the marine habitats through time; this greatly reduces the two most common causes of noncultural variation in sea resource procurement – species biogeography and reconfiguration of shoreline habitats – allowing for human foraging agendas to be better assessed (Stiner, 2003).

Two sites deserve special mention for geoarchaeology. At Grotte du Prince, MIS 7 marine deposits are preserved, overlain by MIS 6 (“Riss”) bone-bearing cryoclastic breccias from which Acheulian tools and a *Homo* sp. iliac bone were recovered. Riparo Mochi, a rock shelter, has become a southern European reference for the so-called Middle-to-Upper Paleolithic (MP-UP) transition, thanks to recent radiocarbon determinations on marine shell beads suggesting an earlier UP start than previously thought – 43–42 ka cal BC (Douka et al., 2012). Flint and jasper come from distances of 40–200 km, greatly exceeding the MP ranges. Also steatite, used to carve female figurines during the Gravettian tradition (30–18 ka cal BP), was obtained through faraway contacts (Mussi, 1991). Together with 18 UP burials from the extensive excavations of 1860–1905, these “Venuses” gave the Grimaldi caves great fame and made these caves an important place in the history of Paleolithic research.



Grimaldi Caves, Figure 1 A plan of the Grimaldi caves and associated open-air Paleolithic sites.

GROUND-PENETRATING RADAR

Lawrence B. Conyers
Department of Anthropology, University of Denver, Denver, CO, USA

Synonyms

Georadar; Ground-probing radar

Definitions

Amplitude: The intensity or strength of a recorded electromagnetic wave.

Attenuation: The dissipation of electromagnetic energy due to the spreading of energy in the ground and the conductivity of earth materials.

Noise: Any recorded energy from a source that is not the object of study.

Point target: A spatially restricted object in the ground that usually produces a hyperbolic-shaped reflection.

Pulse: A very short duration electrical charge placed on an antenna in order to produce an electromagnetic wave that propagates outward.

Range-gain: A data processing step that increases the amplitudes of waves recorded in the ground so that they are visible in two-dimensional reflection profiles.

Reflection hyperbola: The reflection produced by a buried point source.

Stacking: The averaging of recorded waves in sequential traces to produce one composite trace as a way to even out surface disturbances, ground clutter, or noise.

Time window: The two-way travel time within which radar waves are recorded, measured in nanoseconds (ns).

Trace: A series of waves recorded at one spot on the ground surface.

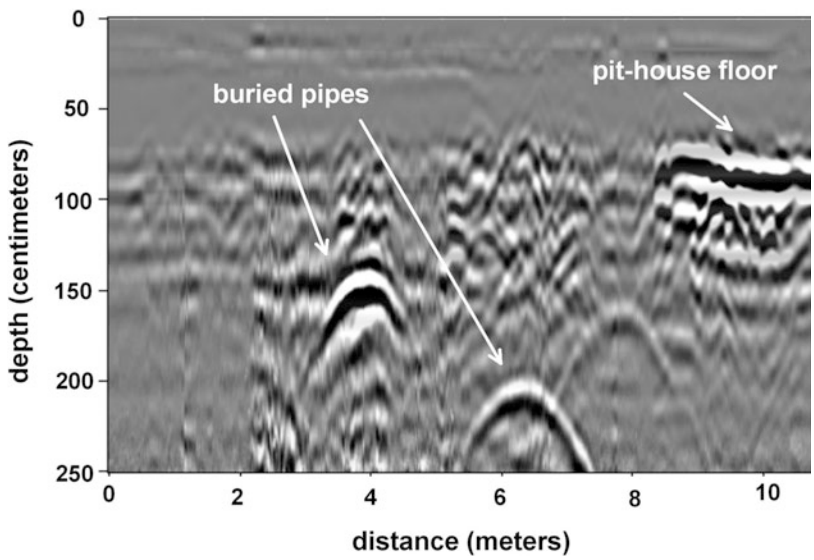
Introduction

Ground-penetrating radar is a near-surface geophysical technique that is employed in order to discover and map buried archaeological features and associated geological units in ways not possible using traditional excavation field methods. It is the best near-surface geophysical method that characterizes the three-dimensional arrangement of subsurface geological units and associated archaeological features. The method consists of measuring the elapsed time between the emission of pulses of electromagnetic (radar) energy (generated at the ground surface by an antenna), transmitted to some depth as propagating waves, reflected off buried discontinuities, and then received back at the surface by a receiving antenna. The distribution and orientation of such subsurface reflections of geological or archaeological importance are then identified and mapped. When aspects of those radar reflections are related to buried features of archaeological sites – such as the presence of architecture, living surfaces, use areas, or other associated cultural features – high-definition three-dimensional maps and images of buried sites can be produced. Ground-penetrating radar is a geophysical technique that is most effective at buried sites where artifacts and features of interest are located between 20 cm and 4 m beneath the surface, but it has occasionally been used for more deeply buried deposits.

Ground-penetrating radar data are acquired by radar waves reflecting off buried objects, features, or bedding contacts in the ground and then detected back at a receiving antenna (Figure 1). Antennas are usually moved along transects, and hundreds or even thousands of reflections are recorded every meter. Distance along transects is commonly measured by an attached survey wheel, as reflections are digitized and saved on a computer. As radar pulses are being transmitted through various materials on their way to the buried target features, their velocity will change depending on the physical and chemical properties of the material through which they are traveling (Conyers, 2013, 107). Each distinct velocity change at an interface of differing materials generates a reflected wave, which travels back to the surface. When the velocity of radar energy in the ground is calculated, travel times of the reflected waves can be converted to depth within the ground (Conyers, 2013, 28), producing a three-dimensional dataset.

Most typically in archaeological GPR, surface radar antennas are moved along the ground in linear transects, and two-dimensional profiles of a large number of reflections at various depths are created, producing profiles of subsurface stratigraphy and buried archaeological features along parallel and sometimes perpendicular lines like long cross sections through the ground (Figure 2). However, depending on surface complexity and vegetation cover, reflection profiles can be oriented in any direction and length in order to answer a variety of geological and archaeological questions. When data are acquired in a closely spaced series of

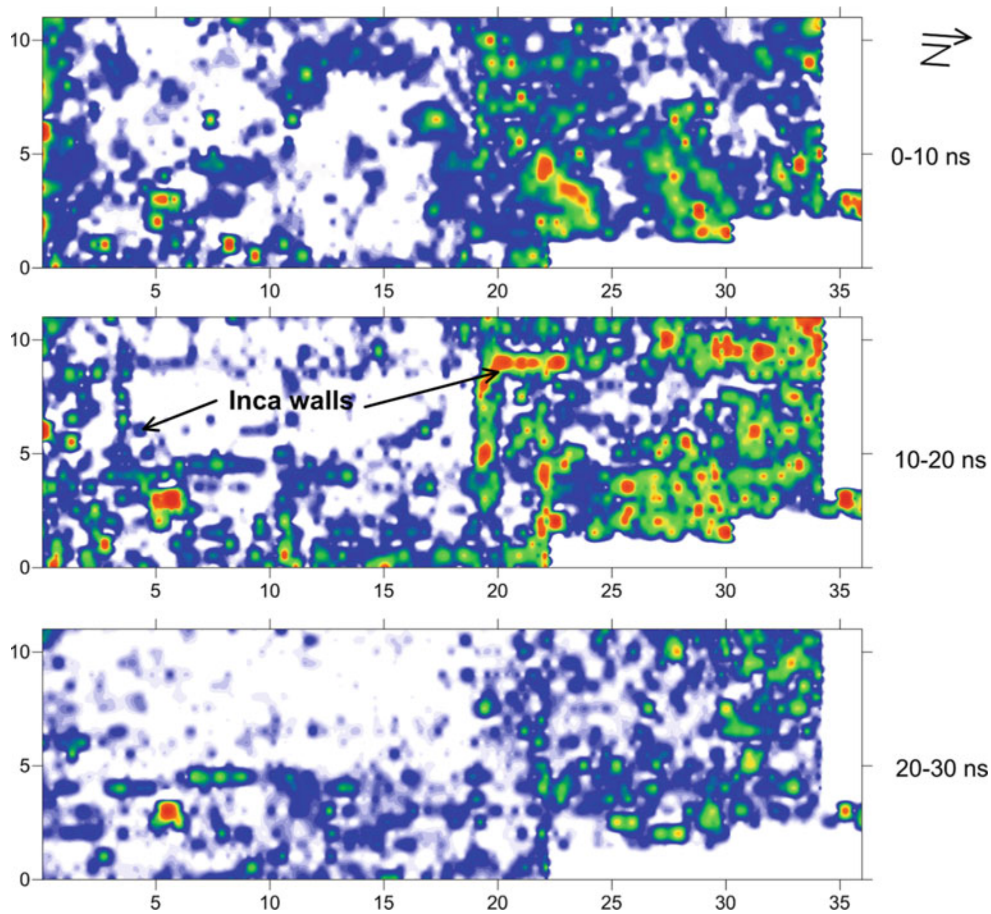
Ground-Penetrating Radar, Figure 1 GPR equipment including 400 MHz transmission and reception antennas in the fiberglass box, attached survey wheel for distance measurement, and the radar control unit and computer attached to the operator's back. This is a Geophysical Survey Systems SIR-3000 system.



Ground-Penetrating Radar, Figure 2 A reflection profile 11 m long displaying reflections to a depth of 250 cm. Two hyperbolic reflections from buried pipes are point source reflections, and a distinct planar reflection was produced from a buried house floor. This profile was collected in a water pipeline right-of-way near Alamogordo, New Mexico, USA.

transects within a grid, and reflections are correlated across transects and processed, three-dimensional maps and other images of buried features and associated stratigraphy can be constructed (Conyers, 2012, 25; Conyers, 2013, 69; see also Conyers, 2015). These images and maps are produced with the aid of computer software that can create maps using many thousands of reflection amplitudes from all profiles within a grid at various depths (Figure 3).

Ground-penetrating radar surveys allow for a relatively wide coverage of surface area in a short period of time, with grids of 50 × 50 m composed of as many as 100 profiles collected in a few hours. Often, the GPR method is used for detailed three-dimensional analysis of smaller grids within more extensively surveyed areas that are mapped using other geophysical methods, such as magnetometry and earth resistance that can be used later to produce scaled two-dimensional maps.



Ground-Penetrating Radar, Figure 3 Amplitude slice-maps displayed in two-way radar travel time measured in nanoseconds (ns). Each 10 ns interval represents approximately 40 cm of depth. The horizontal slice representing 10–20 ns shows distinct high-amplitude walls, produced from buried Inca structures in highland Ecuador.

Ground condition variables

The success of GPR surveys is to a great extent dependent on soil and sediment mineralogy, clay content, ground moisture, depth of burial, surface topography, and vegetation (Conyers, 2013, 24). Radar wave penetration, and the ability to transmit energy through the ground and reflect energy back to the surface, is often enhanced in a dry environment, but dry ground is not necessarily a prerequisite. Some GPR surveys have been quite successful even in very wet environments as long as the medium through which the radar energy passes is not electrically conductive (Conyers, 2004). The mineralogy of materials in the ground is also important, especially clay type and content. Sediments that contain electrically resistive clay minerals such as kaolinite are excellent at allowing the transmission of radar waves, while bentonite, montmorillonite, and other electrically conductive clays are generally poor. Fresh water is an excellent medium for GPR, so radar energy transmission and energy can travel to great depths in lakes and through glacial ice. But when water comes in contact with electrically conductive minerals, an attenuating environment is created that destroys radar energy rapidly, conducting away the transmitted energy. Salty or brackish water will not allow radar energy transmission, and therefore, the method cannot be used in environments of this sort.

Transmission, reflection, and recording of radar waves

The transmission of high frequency radar waves into the earth begins at the surface, with waves moving at the speed of light, then decreasing in velocity as they propagate into the ground. The elapsed time between transmission, reflection off buried discontinuities, and reception back at a surface radar antenna is then measured. Radar energy is generated at a transmitting antenna that is placed on, or near, the ground surface, and waves are generated which propagate downward into the ground where some of those waves are refracted at some interfaces and others reflected back to the surface. The discontinuities where reflections occur are usually created by changes in electrical properties of the sediment or soil, lithologic changes, differences in bulk density at stratigraphic interfaces, and, most importantly, water content variations, which are affected by all these variables (Conyers, 2012, 37; Conyers, 2013, 26). Any change in the velocity of propagating radar waves caused by changes in these ground conditions will generate a reflection. High-amplitude reflected waves are therefore often generated at the interfaces of archaeological features and the surrounding soil or sediment and at the contacts between geological units that vary in composition, density, and porosity, all of which affect the water saturation and therefore the velocity of transmitted radar energy. Void spaces, which may be encountered in burials, tombs, or tunnels, will also generate significant radar reflections due to a significant change in radar wave velocity, as propagating energy increases back to the speed of light in air.

The depth to which radar energy can penetrate and the amount of definition that can be expected from reflections generated at buried surfaces is partially controlled by the frequency of the radar energy transmitted. Radar energy frequency is dependent on the type of antenna used, as the antenna controls both the wavelength of the propagating wave and the amount of attenuation of the waves in the ground. Standard GPR antennas used in geoarchaeology propagate radar energy that varies in bandwidth between 10 and 1,200 megahertz (MHz). Antennas usually come in standard frequencies, with each antenna having one center frequency, but actually producing radar energy that ranges around that center by about one octave (one half and two times the center frequency). In general, low-frequency waves can propagate deeper into the ground, but they yield less subsurface resolution. For instance, 200 MHz antennas can potentially transmit energy to 4 or 5 m depth, but they are capable of resolving features or stratigraphy of only about a meter or so in dimension or thickness. In contrast, a 900 MHz antenna can resolve features as small as a few centimeters, but it is capable of energy transmission to only about a meter under most ground conditions. In electrically conductive ground, all radar energy is usually attenuated at very shallow depths, no matter what its frequency.

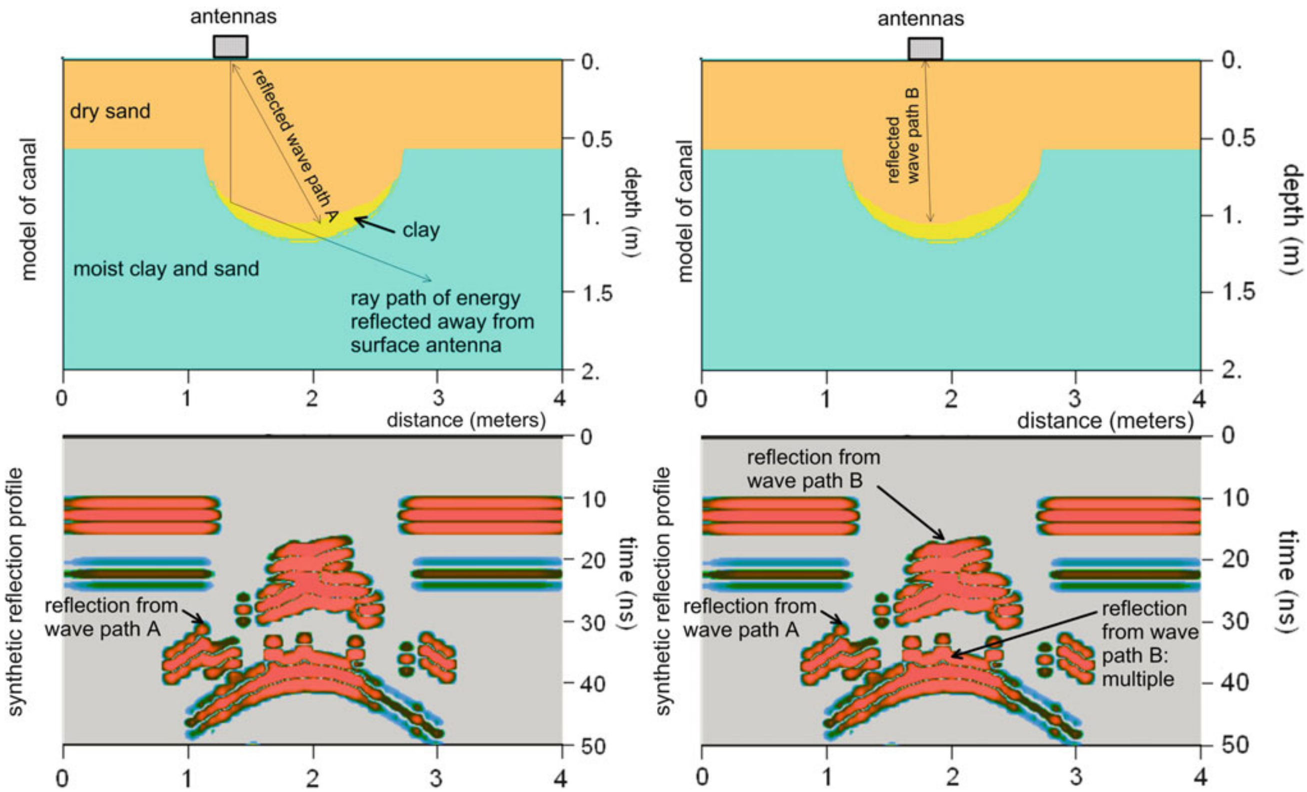
The two-way travel time, amplitude, and wavelength of the reflected radar waves produced by buried interfaces are recorded at the surface antennas, amplified, processed, and recorded for immediate viewing and later post-acquisition processing and display. Many reflections are recorded from various depths in the ground, with one series of waves at one location termed a reflection trace. Reflections are recorded within preset time windows, measured in nanoseconds of two-way travel time. During usual data acquisition procedures, two-dimensional profiles are created as the radar pulse transmission, reflection, and recording process is repeated many times a second and at programmed distances along transects as the antennas are pulled along the ground surface. Individual traces are then collected and placed in sequential order to produce profiles that represent vertical "slices" through the ground (Figure 2). Distance along each line is recorded for accurate placement of all reflection traces within a surveyed grid; this can be done using a survey wheel, GPS, or manual distance marks ticked off along tape measures.

Radar energy becomes both dispersed and attenuated as waves move into the ground after emerging from surface antennas. Energy that is reflected back toward the surface then will suffer additional attenuation by the material through which it passes, before finally being recorded at the surface. Therefore, to be detected as reflections, important subsurface interfaces must not only have sufficient electrical contrast at their boundary but also must be located at a shallow enough depth where sufficient radar energy is still available for reflection. As radar energy is propagated to increasing depths, the signal becomes weaker as it spreads out over a greater volume of the subsurface and is absorbed by the ground, making less energy available for reflection. For every site, the maximum depth of penetration will vary with the geological conditions and the equipment being used. Post-acquisition data filtering and other data amplification techniques (termed range-gaining) can sometimes be applied to reflection data after acquisition that will enhance some very low-amplitude reflections in order to make them more visible.

Other variables affecting GPR

Radar waves transmitted from standard commercial antennas radiate energy into the ground in an elliptical cone with the apex of the cone at the center of the transmitting antenna (Conyers, 2013, 67). This elliptical cone of transmission forms because the electrical field produced by the antenna is generated parallel to its long axis and therefore usually radiates into the ground perpendicular to the direction of antenna movement along the ground surface. The radiation pattern is generated from a horizontal electric dipole to which elements called shields are sometimes added that effectively reduce upward radiation. Some antennas, especially those in the low-frequency range from 10 to 200 MHz or so, are often not well shielded, or not shielded at all, and will therefore radiate radar energy in all directions. Lower frequency antennas also transmit energy that spreads out more as it leaves the antenna and moves into the ground. Unshielded antennas can generate reflections from a nearby person pulling the radar antenna, or from any other objects nearby, such as trees or buildings. Discrimination of individual buried features can then become more difficult, but anomalous reflections can sometimes be filtered out later during data processing.

Radar energy that is reflected off a buried subsurface interface that slopes away from a surface transmitting antenna will be reflected away from the receiving antenna and will not be recorded (Figure 4). A buried surface of this sort would be visible only if additional traverses were

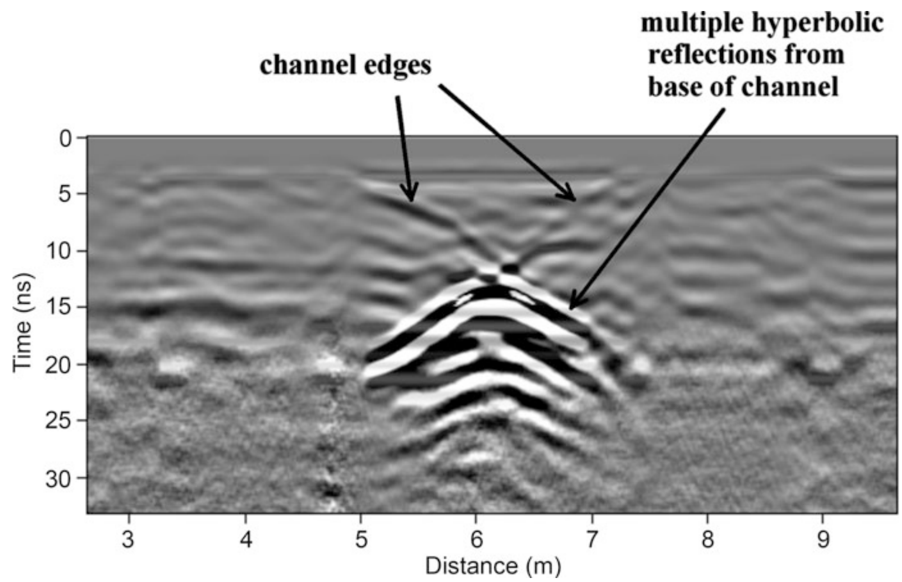


Ground-Penetrating Radar, Figure 4 Computer-generated reflection model of a buried canal filled with a thin layer of clay illustrating how complex reflections can be recorded as energy is transmitted through the ground. On either side of the trench, the reflections are accurately recorded from the interface of the dry sand and the underlying moist clay and sand layer. However, when the antennas are over the trench but not over its center (*left side*), radar waves transmitted directly down intersect the clay layer and reflect away from the surface antenna, so their direct return is not recorded. Energy also is transmitted in front (and behind) the antennas, and thus, the waves that emerge from the antenna and move along path A are recorded as if they were reflected below the canal due to their longer travel times. As the antennas are moved forward and into the center of the canal, the actual location of the bottom of the canal reflection is recorded correctly from energy moving along path B. The same cycle and recording are repeated many thousands of times, creating this complex series of reflections in the synthetic reflection profile. Only the channel's base is recorded correctly in space with the other interface indications created by reflections that travel along other, longer wave paths.

collected at an orientation that would allow reflected energy to travel back to the surface recording antenna. For this reason, it is always important to acquire lines of reflection data within a closely spaced surface grid and sometimes in transects perpendicular to each other.

Small buried objects that reflect radar energy are termed point targets (Figure 2), while broader more extensive units such as stratigraphic and soil horizons or large, flat archaeological features such as floors are termed planar targets. Point targets can be walls, tunnels, voids, artifacts, or other nonplanar objects that often possess little of their own surface area with which to reflect radar energy. If they are too small, they will be totally invisible if lower frequency energy is transmitted into the ground. However, if high frequency energy is transmitted, many reflections will be generated from many small point targets, and this potentially crowded return of reflections can be described as clutter, if they are not the targets of the survey. In all cases, buried features need to be larger than the clutter to be visible, and they are generally not visible unless they are larger than about 40 % of the wavelength of the propagating energy (Conyers, 2013, 72).

Point source reflections often occur in the shape of hyperbolas (Figures 2 and 5). This reflection shape is produced because, as described above, most GPR antennas produce a transmitted radar beam that propagates downward from the surface in a conical pattern, radiating outward as energy travels to depth. Radar waves will therefore be reflected from buried point sources that are not located directly below the transmitting antenna but are still within the "beam" of propagating waves. The travel paths of oblique radar waves to and from the ground surface to point sources in front and back of the antenna are longer (as measured in radar travel time), but the reflections generated are recorded as if they were directly below but just deeper in the ground. As the surface



Ground-Penetrating Radar, Figure 5 Reflection profile from a buried channel that demonstrates reflections similar to those modeled in Figure 4. The channel edges are very low amplitude, while a very high-amplitude series of hyperbolic reflections are recorded from the base of the channel, which are recorded as high amplitude due to the upwardly convex surface that focuses energy. This profile was collected over an early agricultural age canal near Tucson, Arizona, USA.

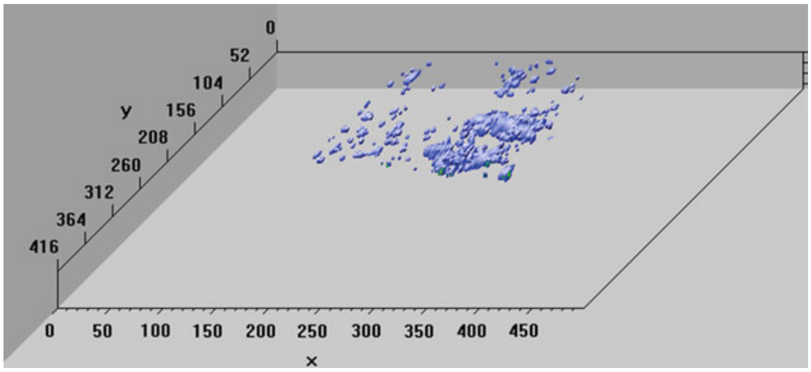
antenna moves closer to a buried point source, the receiving antenna will continue to record reflections from the buried point source prior to arriving directly on top of it and continue to record reflections from it moving away. A reflection hyperbola is then generated with only the apex of the reflection denoting the actual location of the object in the ground, with the arms of the hyperbola creating a record of reflections that traveled the increasingly oblique wave paths. In some cases, only half of a hyperbola may be recorded, if just the corner or edge of a planar feature is causing a discrete reflection, such as the edge of a buried house floor or platform. The shape of such hyperbolas can also be used to calculate radar travel velocity in the ground since their shape is a function of the velocity of radar energy as it moves in the ground (Conyers, 2013, 113). Hyperbola analysis to obtain velocities is therefore an extremely efficient and accurate way to convert radar travel times to depth in the ground.

Radar waves travel through the ground in complex ways, spreading out with depth, refracting, reflecting, and attenuating, as energy encounters differing materials in various orientations. This can sometimes lead to the recording of reflections that have not always traveled directly from the surface antenna to some buried reflection surface and back to the antenna. Radar energy can often reflect multiple times from various layers or even from the ground surface or the antenna itself, leading to reflections that are not indicative of the buried features of interest. To minimize the amount of reflection data that are recorded from the sides of a two-dimensional transect, the long axes of the transmitting antennas are usually aligned perpendicular to the profile direction. However, if there are buried elongated features parallel to the direction of antenna travel (and therefore parallel to the electromagnetic field generated by the antenna), only a small portion of the radar energy will be reflected back to the surface, so these features are likely to remain invisible.

Most GPR antennas produce radar energy in frequencies lying within the same frequency spectrum as those used in television, FM radio, and portable communication devices, and therefore, background noise will also be recorded along with reflections that come from within the ground. This noise can sometimes be removed during data collection or during post-acquisition processing where some frequencies can be enhanced and others filtered out.

When antennas move over uneven ground and clumps of vegetation, transmitted radar energy couples with the ground in various ways and can move into the ground in various orientations, producing anomalous recorded amplitude reflections. For this reason, it is preferable to move antennas in transects lying as flat as possible and at the same distance from the ground, in order to reduce coupling change anomalies.

Reflection from a buried interface that contains ridges or troughs, or any other irregular features, can focus or scatter radar energy, depending on the surface's orientation and the location of the antennas on the ground surface. If a reflective surface is convex upward, energy will tend to be reflected away from the receiving antenna, and only a low-amplitude reflection will be recorded.



Ground-Penetrating Radar, Figure 6 Isosurface image of a buried pit house floor and associated rocks in a three-dimensional block of reflections. These reflections are from a pit house buried in sand dunes near Port Orford, Oregon, USA.

The opposite is true when the buried surface is concave upward, which will focus energy, and a very high-amplitude reflection will be recorded.

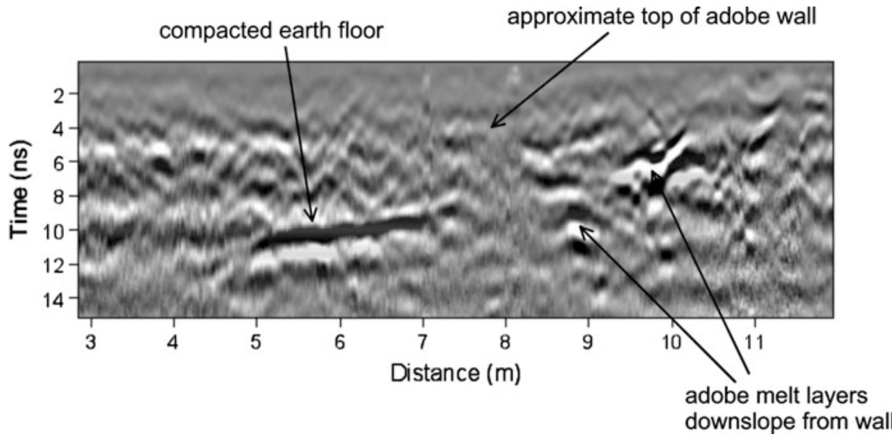
Reflection analysis and interpretation

Raw GPR reflection data comprise a collection of individual traces consisting of reflections recorded at different times within a recording time window. When two-dimensional profiles are collected, these traces are spaced at various distances along transects, which can be displayed as profiles. New systems are being developed that can send and receive multiple radar pulses within complex three-dimensional grids that can potentially produce very precise three-dimensional images, but these systems have not yet been perfected (Conyers and Leckebusch, 2010). Each reflection trace contains a series of waves that vary in amplitude depending on the amount and intensity of energy reflection that occurs at buried interfaces. When these traces are plotted sequentially in standard two-dimensional profiles, amplitudes created from buried interfaces often denote layers of importance, with the strength of the reflections indicating the differences in composition between buried materials.

Each profile can be interpreted individually, after which buried features of interest are often immediately visible. When many tens or hundreds of profiles are collected forming a grid, this method of interpretation can often be laborious, so it is efficient to use computer software to produce maps and other images of the relative amplitudes of reflections in slice-maps (Figure 2) or to produce three-dimensional isosurfaces (Figure 6). In these images, areas of low-amplitude reflected waves indicate little or no reflection and therefore uniform materials, while high-amplitude reflections denote buried interfaces between highly contrasting materials, which could be stratigraphic interfaces or buried archaeological features. Amplitude slices need not be constructed horizontally or even in equal time intervals. They can also vary in thickness and orientation, depending on the questions asked. Surface topographic variations and the subsurface orientation of features and stratigraphy of a site may necessitate the construction of slices that are neither uniform in thickness nor horizontal. To compute amplitude slices, computer software compares amplitude variations within traces that were recorded within a defined window, averages them over a defined search radius, and grids and displays the relative reflection amplitudes. Degrees of amplitude variation in each time-slice can be assigned arbitrary colors or shades of gray along a nominal scale in map view or placed in a three-dimensional block and assigned colors or patterns so that reflections are visible (Conyers et al., 2002; Leckebusch, 2003; Goodman et al., 2004; Conyers, 2013, 187). In isosurface images, computer-generated light sources that simulate rays of the sun can then be used to shade and shadow the rendered features in order to enhance them, and the features can be rotated and shaded until a desired image is produced.

Both high and low amplitudes can denote buried features of interest, and only an understanding of the nature of the geological or archaeological features in the test area will allow for accurate interpretations. Compacted floors will often retain moisture and produce distinct planar high-amplitude reflections (Figure 7), while adjacent earthen walls of homogeneous material will remain invisible because there are no buried surfaces to reflect energy. The vertical contact between the wall and the adjacent material will also not reflect waves because transmitted radar energy passes by that interface at too low an angle without producing any reflections. Other stratigraphic features adjacent to the otherwise invisible walls might be visible, but they could be difficult to interpret without knowing something of the buried architectural context or understanding the types and composition of archaeological or geological features common in the area.

Amplitude slice-maps in areas of earthen architecture must be evaluated by locating areas showing no reflections, which denote the location of important features (Figure 8). This demonstrates how important it is to define whether the features of interest are highly reflective or



Ground-Penetrating Radar, Figure 7 Reflection profile shows a distinct high-amplitude reflection from a compacted earth floor, with an associated vertical adobe wall which does not reflect radar energy. The wall is effectively invisible because it is composed of homogenous clay and sand, which contains no stratigraphic interfaces to reflect energy. The wall edges also do not reflect energy, as they are vertical and do not provide an interface that can reflect waves transmitted from the surface antenna. This profile was collected over Hohokam architecture in Tucson, Arizona, USA.

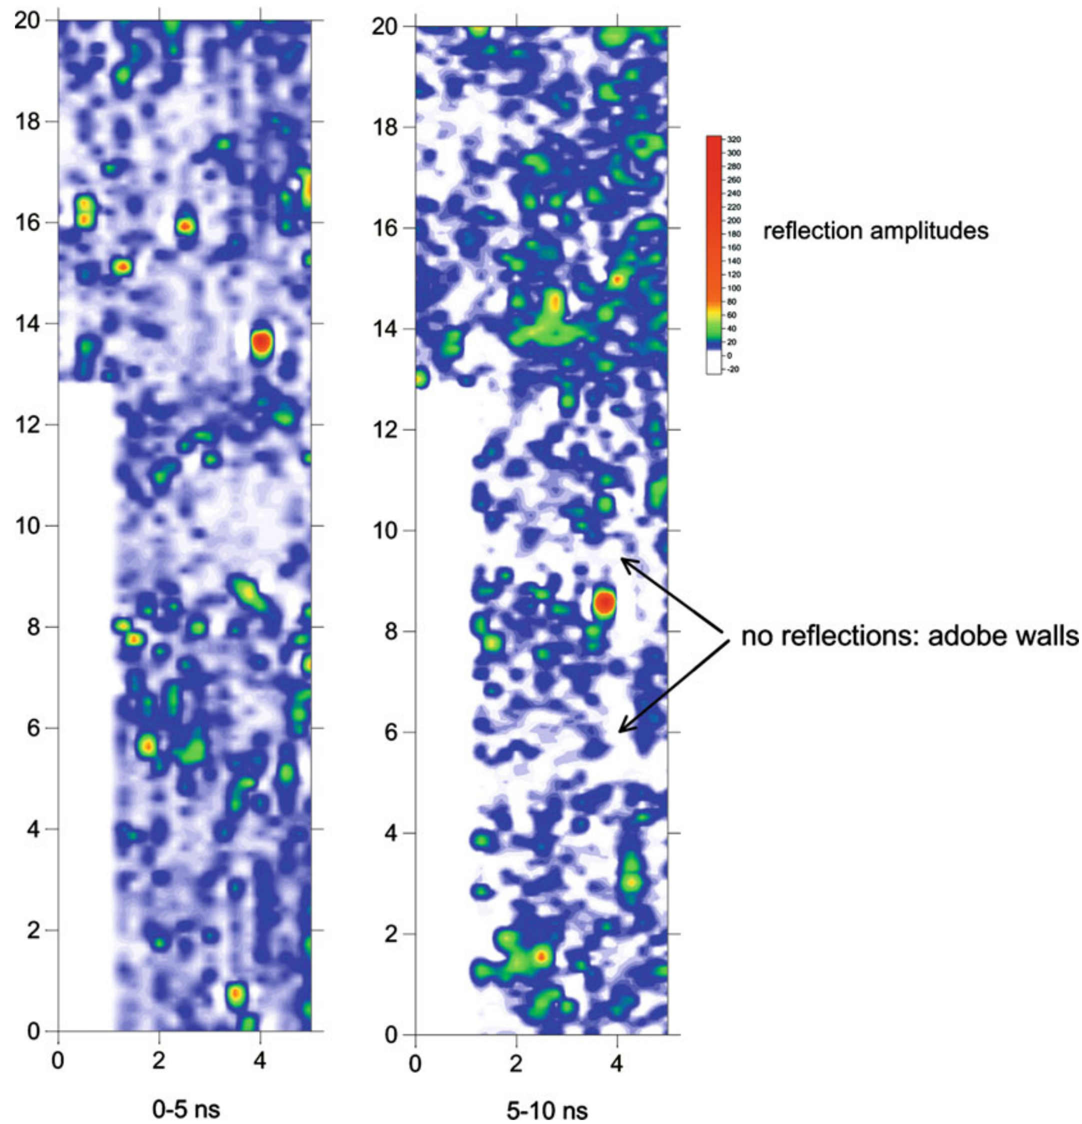
perhaps not reflective at all. There has always been a bias in GPR toward analyzing and mapping only the strongest reflections recorded; however, low- or no-amplitude areas may also be important, depending on the type of materials buried in the ground.

Various computer programs are available that use different algorithms for producing amplitude maps, all of which can be modified by the user depending on the types of questions being asked. Some programs tend to average reflections, producing more general maps, while others produce images of almost every reflection in the ground, which tend to be more exact but also highly complex. Other programs were developed for certain commercial applications, such as pipe location or other geotechnical uses, and are less useful for archaeological feature mapping and identification (Figure 9).

Using GPR for archaeological interpretation

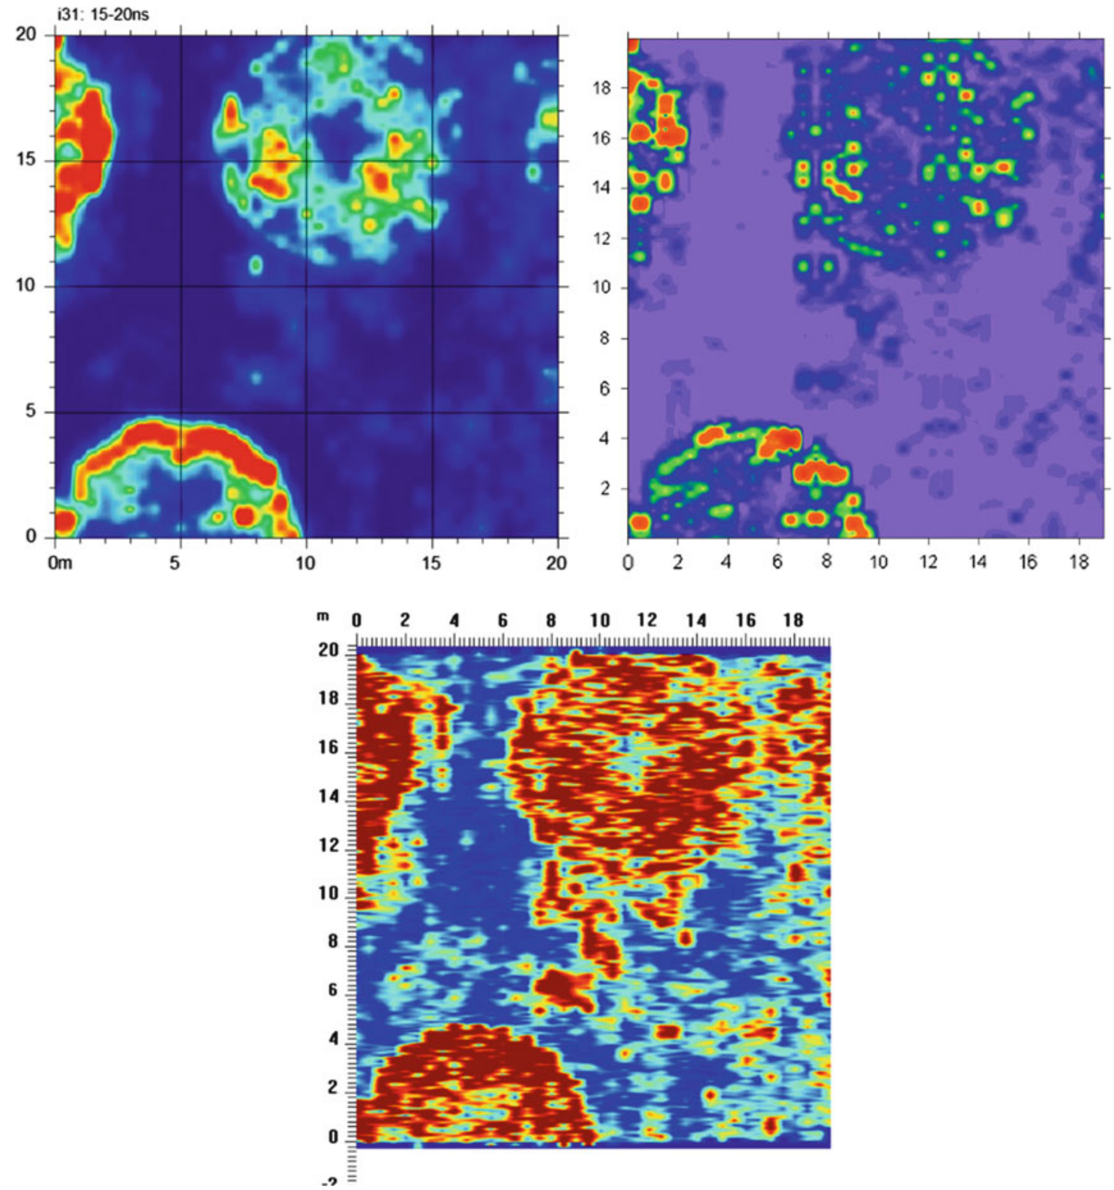
Archaeological geophysics has historically been used as a method for discovering buried archaeological remains and less often as a dataset for interpreting aspects of human history and testing anthropological hypotheses relating to culture. However, GPR, with its three-dimensional mapping ability, can, and should, be used to test ideas about humans in ways that are similar to standard archaeological methods (Conyers, 2010; Conyers and Leckebusch, 2010). If architecture, site organization, or any other aspects of human construction or modification of the buried landscape can be indicative of behavior, then GPR mapping can be of great benefit (Conyers, 2009). The GPR method can be an especially powerful tool when combined with standard archaeological excavations, especially when the geophysical images are used as a guide to the placement of subsurface tests. In this way, limited excavation and the exposure and study of important archaeological features and associated geological layers can be made, and information about those buried features can be projected in three-dimensions over a wide area.

An example of this type of GPR analysis is the testing of extensive surface features in southeastern Utah, USA, where a number of circular depressions were visible on the surface associated with scattered pottery that suggested there might be great kivas below. During the interval when the pottery recovered at the surface was made (about AD 900–1150), this general area in the southwestern USA was dominated by one political and economic entity centered about 200 km away at Chaco Canyon, New Mexico (Conyers and Osburn, 2006; Conyers, 2010; Conyers, 2012, 183). At Chaco Canyon and elsewhere in the American Southwest, great kivas of this age were architectural structures used to indicate strong political and economic ties to Chaco. In order to test the hypothesis that the area of presumed great kivas in Utah was connected in some way with Chaco Canyon, GPR data were collected on five of the large surface depressions. GPR maps at sites 1 through 3 (Figure 10) showed that there were kivas buried below the surface; they were not “great” kivas, however, but instead small, circular kiva structures consistent with a low population density farming community that was perhaps aware of Chaco Canyon, but not connected in the ways that had been hypothesized. Two of the sites tested with GPR contained no architecture whatever and are likely remnants of modern water reservoirs. In this case, GPR was the only method, barring extensive excavations, that could have discovered and mapped the presence and function of these buried architectural remains.



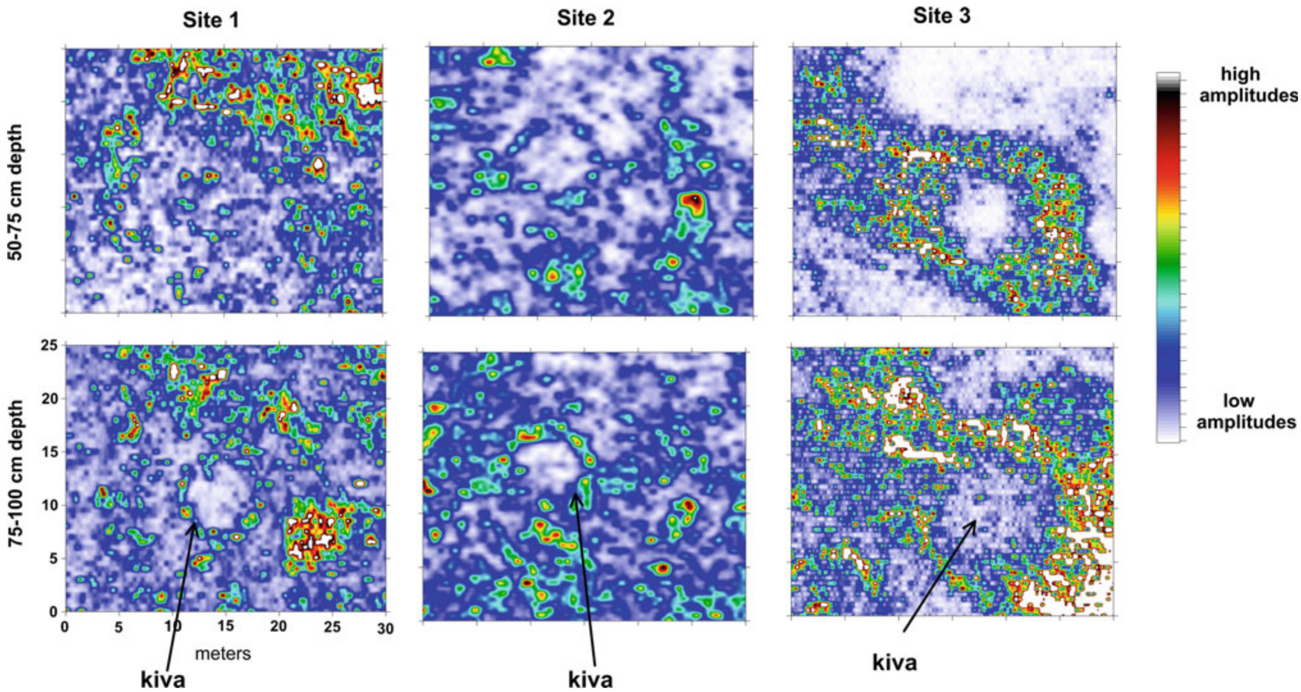
Ground-Penetrating Radar, Figure 8 Amplitude slice-map of the adobe walls shown in Figure 7. The walls are shown in white as areas of no reflection, while random stones or layers of adobe melt adjacent to the walls produce high-amplitude reflections. These are Hohokam walls in Tucson, Arizona, USA.

In the Middle East, much is known about the late Nabataeans, desert traders who constructed monumental architecture in the vicinity of Petra, Jordan, and other areas along trade routes between Arabia and the Mediterranean coast (Conyers, 2010; Conyers, 2012, 187). In an attempt to understand the habitation of the Petra area prior to the construction of monumental architecture beginning in the first few centuries BC, GPR data were collected in an area called the Lower Market (Conyers et al., 2002). While the near-surface remains were easily mapped with GPR (Figure 11a), the deeper reflections were more complex and necessitated buried topographic adjustment to sloping stratigraphy. It was apparent by studying the reflection profiles that this area had been at one time on the edge of a wadi (small valley), which had been artificially filled and leveled prior to construction of temples and other structures in late Nabataean time. All GPR profiles were then interpreted to find the reflection corresponding to the buried living surface prior to filling, and amplitudes were mapped on that surface alone (Figure 11b, c). Those mapped reflection features showed that simple structures had been built bounding pathways leading to the valley bottom along with remains of other buildings along the upper edge of the valley; these

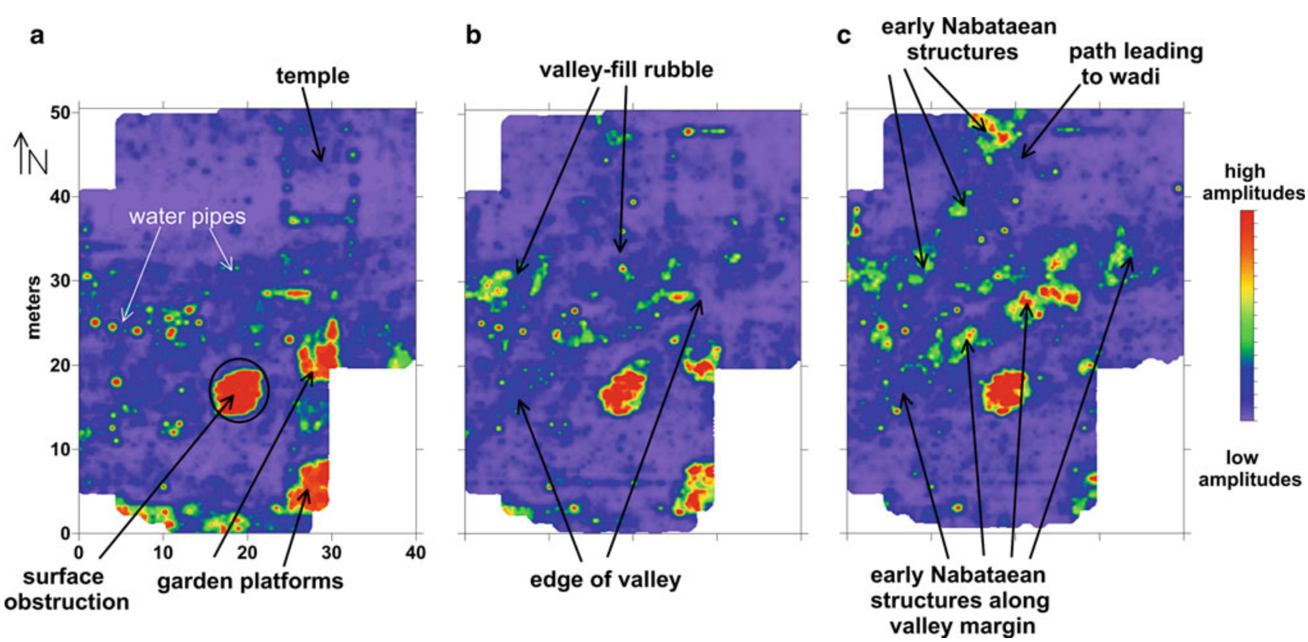


Ground-Penetrating Radar, Figure 9 Amplitude slice-maps of one layer from 15 to 20 ns constructed using three different software programs. Each uses different resampling and gridding algorithms, which create very different images of the same features. At this site, in Ohio, USA, there are three buried kiln floors. On the left is an averaged horizontal slice showing the general features, in the middle a very exact slice showing every reflection, and on the right a slice produced by a program used to map mostly buried pipes and other linear features.

structures were then covered during the filling and leveling process. Excavations along the north edge of the GPR grid confirmed that those structures were of early Nabataean age, a time when the valley was in the early stages of habitation by people who would later become the famous builders and wealthy traders of Petra. The GPR mapping showed that the ancestors of the Nabataeans of Petra lived in simple structures aligned with the natural topographic features of the valley and that these structures were later abandoned as the wealth from control of trade with Arabia increased and the site became commercially connected to the complex cultures of the Mediterranean (Conyers, 2010). Only the three-dimensional mapping capabilities of GPR that produced accurate images of this stratigraphically complex site could have yielded this interpretation of the early history of Petra without laborious and expensive excavation.



Ground-Penetrating Radar, Figure 10 Amplitude slice-maps of three sites in southeastern Utah, USA, illustrating high-amplitude circular kiva walls and other associated features. The interiors of these structures are filled with homogeneous wind-blown sand, which is non-reflective. At site 3, the kiva was constructed into bedrock, and therefore, both slices also display high-amplitude reflections from bedrock features.



Ground-Penetrating Radar, Figure 11 Amplitude slice-maps need not be horizontal but can be constructed to follow stratigraphic horizons which are not level with the ground surface. Map (**a**) shows architectural features in a horizontal slice between 50 and 100 cm of the surface. Maps (**b**) and (**c**) are subhorizontal slices and display features built on an ancient living surface, which slopes to the north. These are early Nabataean in age, from Petra, Jordan.

Conclusions

Ground-penetrating radar has the unique ability among near-surface geophysical methods to produce three-dimensional maps and images of buried architecture and other associated cultural and geological features. It can be used in any type of ground as long as the sediments and soils are not highly electrically conductive. Using high-definition two-dimensional reflection profiles produced along transects, three-dimensional maps of amplitude changes can be assembled that define physical and chemical changes in the ground that are related to archaeological and geological materials of importance. Interpretations that use individual two-dimensional reflection profiles combined into images of grids containing many tens or hundreds of profiles can be used to help understand buried archaeological sites, especially those that are geologically complex. When these data and maps are used to test ideas about human adaptation to ancient landscapes, they offer a powerful and time-effective way to study ancient human behavior, social organization, and other important archaeological and historical concepts.

In the processing of GPR reflection data for purposes of landscape analysis, maps and images must be generated and integrated with information obtained from other archaeological and geological data in order to provide age and context for the mapped sites. This can be done by inserting cultural data derived from excavations within amplitude maps that use only certain amplitudes within a three-dimensional volume of radar reflections. In all cases, the results of these amplitude images must be differentiated from the surrounding geological layers. When these multiple datasets are interpreted archaeologically, they can serve as a powerful tool that can integrate archaeological sites into the overall geological context.

HARPPA

Joseph Schuldenrein
Geoarchaeology Research Associates, Yonkers, NY, USA

Introduction

Together with Mohenjo-daro, Harappa is the signature site of the third millennium BC culture of South Asia known as the Indus Valley or Harappan Civilization (Kenoyer, 1998; Possehl, 2002). The site formed the epicenter of a state society contemporaneous with the Mesopotamian and Egyptian cultures to the west, and it featured analogous elements of complex urban organization, trade, and commerce. In contrast with these other "cradles of civilization," Harappan script, while pervasive across the area's cultural heartland (Pakistan and India), remains undeciphered. There is, however, a growing body of archaeological evidence for contact among these three state-based societies.

Geoarchaeology of Harappa and the Indus Valley

The site of Harappa is in north-central Pakistan (Figure 1). It consists of at least four major mounds, which are the product of the accumulation of cultural deposits documenting the site's evolution as a major urban center whose date range is 3300–1700 BC. As is the case with Near Eastern tells, the Harappan mound complex was built on a base of natural floodplain sediments that irregularly flooded the local trunk stream, the Ravi River. The Ravi is one of "the Five Rivers," a series of subjacent, southwest trending drainages along which smaller Harappan mound complexes emerged. These Upper Indus channel and terrace landscapes emerge from the foothills of the Himalayas. They converge in central Pakistan to form the Indus River proper.

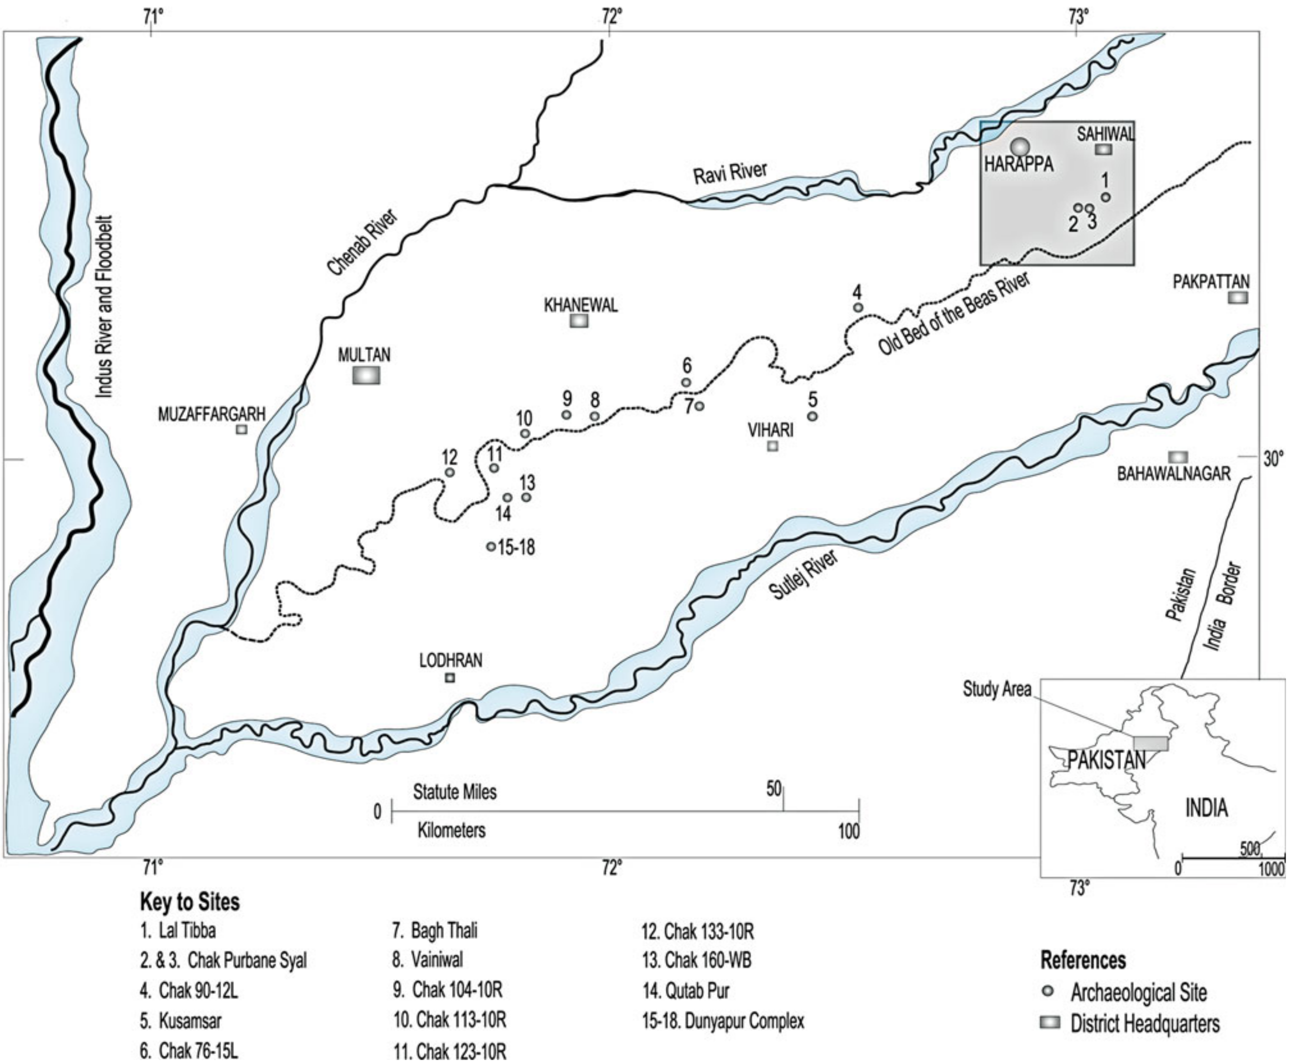
The 17 m high Harappan mound complex was recognized as early as 1834, and excavations date to the late nineteenth century, continuing into the twentieth century. Modern scientific archaeological research was initiated in the 1980s by combined US-based teams (chiefly Harvard, the University of Wisconsin, and New York University) and several European institutions. Work has been ongoing, intermittently, under the auspices of the Department of Archaeology and Museums, Government of Pakistan.

Baseline stratigraphic relations for the Harappa site were established by Wheeler (1947), who identified the base of the mound at an unconformity separating "natural" from "cultural" sediments. Two stratified units comprise the natural sediments; the uppermost is described as "alluvium" and the lower as "a dark brown earth" (Meadow et al., 1998). While over 100 radiocarbon dates have been processed to refine the 17 m high cultural stratigraphies, these pre-cultural horizons were only recently dated to the terminal Pleistocene. The unconformity marks an early Holocene interval of nondeposition (and probable cumulic soil development) at the site (Schuldenrein et al., 2004). Examination of the profile implicated longer-term stability of the upper alluvium. It represents a buried surface marking the top of a deeply weathered Pleistocene paleosol (ABk horizon) that graded into the lower "dark brown earth" (Bt1k-Bt2-Bt3y-C horizons).

More comprehensive mapping of the alluvial landscape incorporating and surrounding Harappa and its terraces centers on chronologically based, formal soil taxonomies. Within the non-cultural soils and sediments, antiquity is determined by degrees of clay translocation as well as carbonate redistributions and reprecipitation in the B horizon(s). Soil orders are entisols and alfisols, with the former representing late Holocene to historic weathering and the latter pre-dating 5000 BP (the period of cultural florescence) and extending to the terminal Pleistocene (Pendall and Amundson, 1990; Belcher and Belcher, 2000).

Smaller mounds and sites along the "Five Rivers" have been investigated geoarchaeologically over the past 30 years, and similar studies have been undertaken in southern Pakistan, along the Lower Indus (linked to the Mohenjo-daro

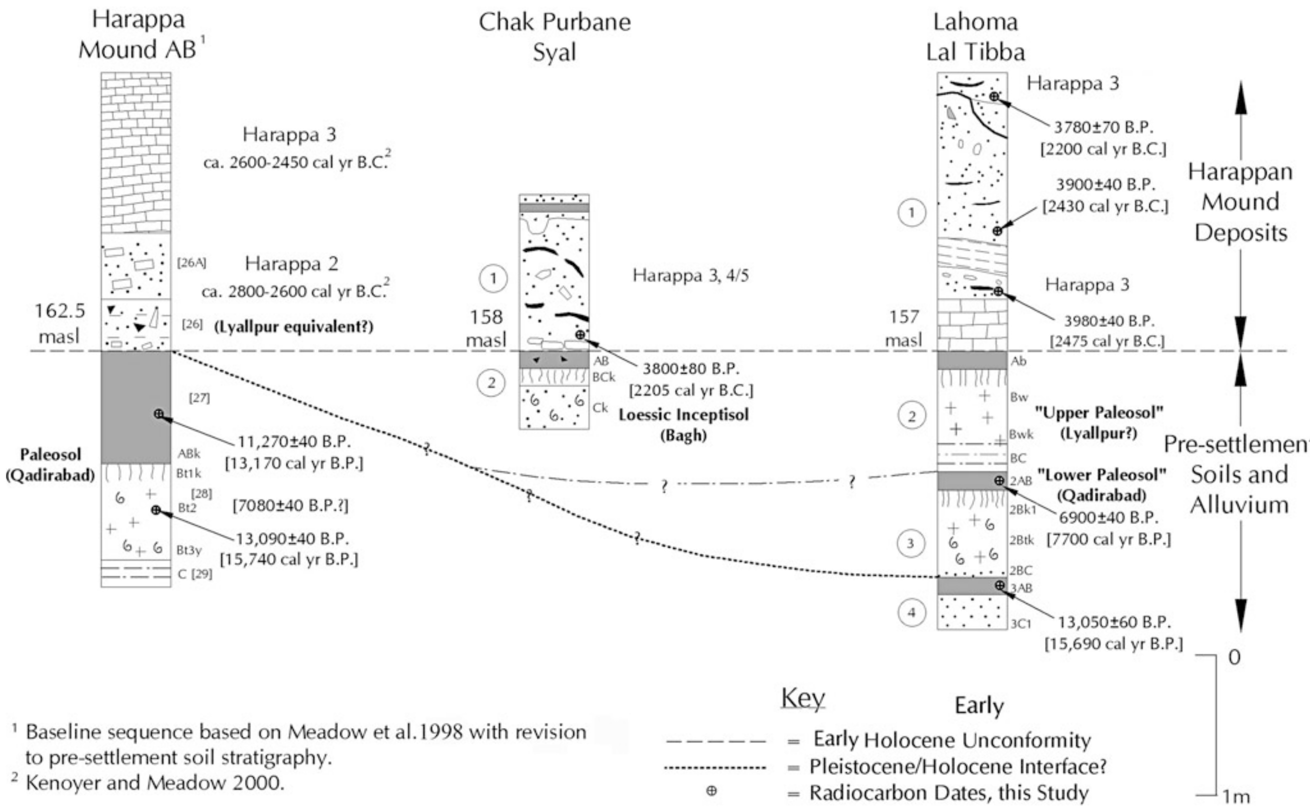
A.S. Gilbert (ed.), *Encyclopedia of Geoarchaeology*, DOI 10.1007/978-1-4020-4409-0,



Harappa, Figure 1 Location of the Harappa site in north-central Pakistan. The site is a mound complex on an abandoned channel of the Ravi River. The old bed of the Beas River and secondary Harappan sites along its reach are also shown.

urban complex). Dated sequences at stratified sites along the buried channel of the Beas River, south of the Ravi (Figure 1), facilitate regional, cyclically based reconstructions of Holocene paleoenvironmental conditions and landscape histories. In the vicinity of Harappa, the linkage of soil chronologies between secondary sites and Harappa underscores the stability of stable surfaces that gave rise to and ultimately accommodated Harappan settlements. Similarly, inter-site correlations of sediment-based alluviation regimes (indicative of surface burial and geomorphic dynamism) identified climatically triggered periods of landscape disequilibrium. The linked profiles (Figure 2) illustrate that while there is local variability in soil formation histories and intervening alluviation episodes, major phases of landscape stability – specifically those that formed extensive Harappan-era surfaces – are expressed on a regional scale. Such refined reconstructions enable researchers to sort out the complex influences of local vs. regional edaphic factors.

Advances in Harappan geoarchaeology reflect current exponential leaps in interdisciplinary research strategies as well as in the field's methodological and technological achievements. In general, the work in the Upper Indus has focused on developing baseline paleoenvironmental chronologies, structured by soil chronologies, and intervening alluvial successions that help explain settlement geography and differential site preservation. In southern Pakistan, along the Lower Indus, a geomorphology-centered approach is applied to correlate settlement variability with changing stream dynamics. That approach is conditioned by a history of fluvial geomorphic modeling in that area, which draws on the trunk stream's behavior of deep deposition coupled with periodic, often catastrophic, channel migrations. Finally the most recent methodological advances have integrated remote sensing strategies and advanced dating techniques (optically stimulated luminescence or OSL) to advance expansive extra-regional



Harappa, Figure 2 Site and regional stratigraphies of Harappa and other Upper Beas sites. A soil stratigraphic scheme indexed by radiocarbon dates was used to establish chronostratigraphic contemporaneity between Harappa and two secondary sites Kenoyer (2000).

reconstructions accounting for the emergence, florescence, and ultimate collapse of the Harappan culture across its geographic domain. A current model suggests that "climatic forcing" was the primary mechanism explaining decline of the civilization. The paradigm is structured on simulations for long-term weakening of the monsoon and thinning out of population centers, as documented by high-resolution shuttle radar topographic mapping (Giosan et al., 2012). Diminished precipitation resulted in substantially reduced stream flow and water supply. Data sets were taken to infer landward mobilization of Harappan populations, attendant shrinkage of the Harappan heartland, and profound changes in land use that were unsuccessful in the long run (Giosan et al., 2012). Such ecologically-based modeling, while beneficial, implicates the need for longer and more rigorous geoarchaeological testing on the site-specific and local levels. The development of even more sophisticated methodologies stands to extend the scope of geoarchaeological applications in the years to come.

Definition

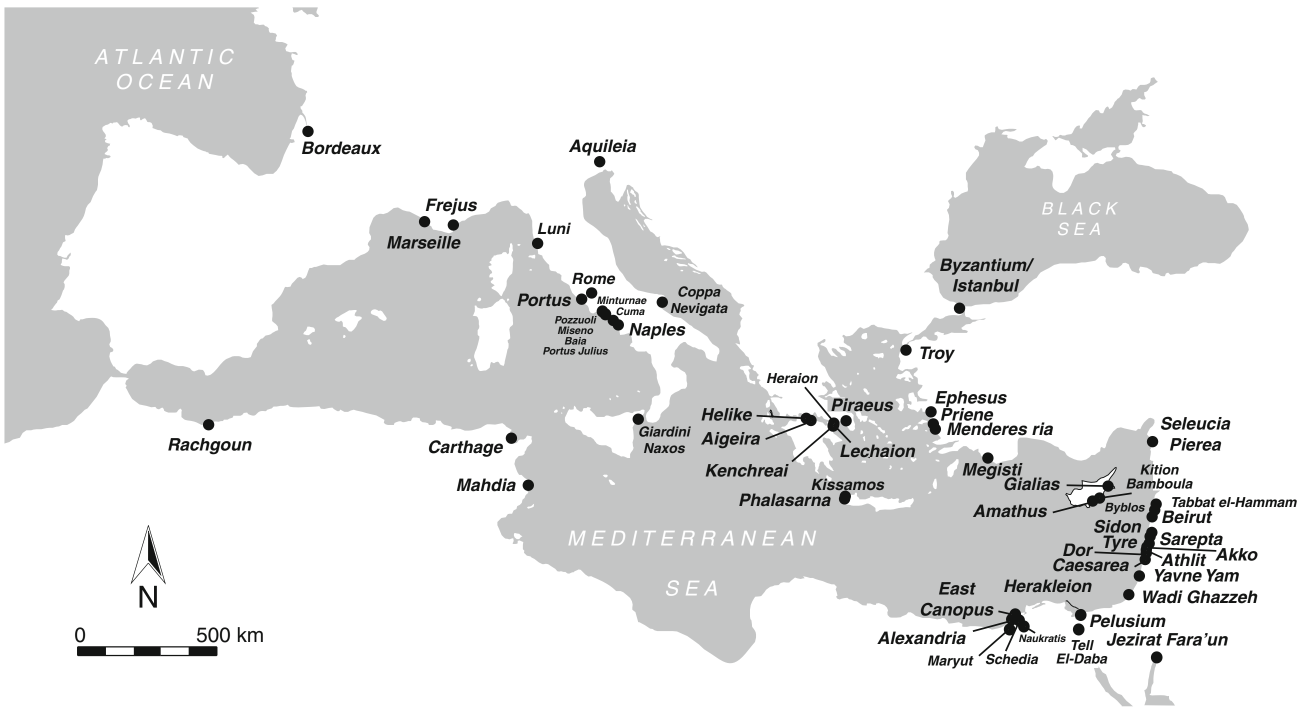
Coastal areas have been used as natural roadsteads at least since prehistoric times. In the Oxford English dictionary, a harbor is "a place on the coast where ships may moor in shelter, especially one protected from rough water by piers, jetties, and other artificial structures." This safe refuge can be either natural or artificial. As a result, the term "harbor" can often be ambiguous when it refers to a premodern context because it incorporates a plethora of landing site types, including offshore anchorages, in addition to different mooring facilities and technologies (Raban, 2009). Conceptions of ancient Mediterranean harbors have frequently been skewed by all-season harbor facilities such as Alexandria (Egypt), Piraeus (Greece), and Valletta (Malta) with their favorable geomorphological endowments. The archaeological record is, however, more complex. Port is derived from the Latin *portus* meaning "opening, passage, asylum, refuge." Drawing on multidisciplinary archaeological and geoscience tools, there has been a renewed interest in ancient harbors during the past 30 years, including the Indian Ocean (Rao, 1988), the Atlantic, Scandinavia (Ilves, 2009), the Mediterranean (Marriner and Morhange, 2007), and Africa (Chittick, 1979).

Introduction

Until recently, coastal sediments uncovered during Mediterranean excavations received very little attention from archaeologists, even though, traditionally, the received wisdom of *Mare Nostrum*'s history has placed emphasis on the influence and coevolution of physical geography in fashioning its coastal societies (Braudel, 2002; Stewart and Morhange, 2009; Martini and Chesworth, 2010; Abulafia, 2011). Before 1990, the relationships between Mediterranean populations and their coastal environments had been studied within a cultural-historical paradigm, where anthropological and naturalist standpoints were largely considered in isolation (Horden and Purcell, 2000). During the past 20 years, Mediterranean archaeology has changed significantly, underpinned by the emergence of a new culture-nature duality that has drawn on the North European examples of wetland and waterfront archaeology (Milne and Hobley, 1981; Coles and Lawson, 1987; Purdy, 1988; Coles and Coles, 1989; Mason, 1993; Van de Noort and O'Sullivan, 2006; Menotti and O'Sullivan, 2012). This built on the excavation of Alpine lake settlements in Switzerland and elsewhere from the 1850s onwards (Keller, 1866). Because of the challenges of waterfront contexts, the archaeological community is today increasingly aware of the importance of the environment in understanding the socioeconomic and wider natural frameworks in which ancient societies lived, and multidisciplinary research and dialogue have become a central pillar of most large-scale excavations (Walsh, 2004; Butzer, 2005; Butzer, 2008; Walsh, 2008).

It is against this backdrop that ancient harbor contexts have emerged as particularly novel archives, shedding new light on how humans have locally interacted with and modified coastal zones since the Neolithic (Marriner and Morhange, 2007). Their importance in understanding ancient maritime landscapes and societies (e.g., Gambin, 2004; Gambin, 2005; Tartaron, 2013) makes them one of the most discussed archaeological contexts in coastal areas (Figure 1). Around 6,000 years ago, at the end of the Holocene marine transgression, societies started to settle along "present" coastlines (Van Andel, 1989). Older sites were buried and/or eroded during this transgression (Bailey and Flemming, 2008). During the past ~4,000 years, harbor technology has evolved to exploit a wide range of environmental contexts, from natural bays and estuaries through to the completely artificial basins of the Roman and Byzantine periods. Although some of these ancient port complexes continue to be thriving transport centers, now, many millennia after their initial foundation, the vast majority have been completely abandoned, and their precise whereabouts, despite rich textual and epigraphic evidence, remain unknown. Although not the sole agent of cultural change, these environmental modifications indicate in part that long-term human subsistence has favored access to the open sea. Key to this line of thinking is the idea that societies have adopted adaptive strategies in response to the rapidly changing face of the coastal environment, and in many instances, harbor sites closely mirror modifications in the shoreline (e.g., Brückner et al., 2004). Nonetheless, it is important to emphasize that regional environmental change, although strong, must not be seen as the principal agent of cultural shifts and that site-specific explanations remain fundamental (Butzer, 1982).

During the 1960s, urban regeneration led to large-scale urban excavations in many coastal cities of the Mediterranean. It was at this time that the ancient harbor of Marseille (France) was rediscovered. Nonetheless, it was not until the early 1990s that two large-scale coastal excavations were undertaken at opposite ends of the Mediterranean in Marseille (Hesnard, 1994; Hesnard, 1995) and Caesarea Maritima in Israel (Raban and Holum, 1996). Both projects placed emphasis on the harbor archaeology and their articulation within the wider landscape. The first, at Caesarea Maritima, investigated a completely artificial Roman harbor complex on the Levantine coast, active between the first and second centuries AD (Reinhardt



Harbors and Ports, Ancient, Figure 1 Mediterranean harbor sites discussed in the text.

et al., 1994; Reinhardt and Raban, 1999; Raban, 2009). At Marseille, meanwhile, researchers set about reconstructing the archaeology and environmental history of the city's ancient harbor since the seventh century BC, founded in a naturally protected limestone embayment by Greek colonists from Ionia (Figure 2).

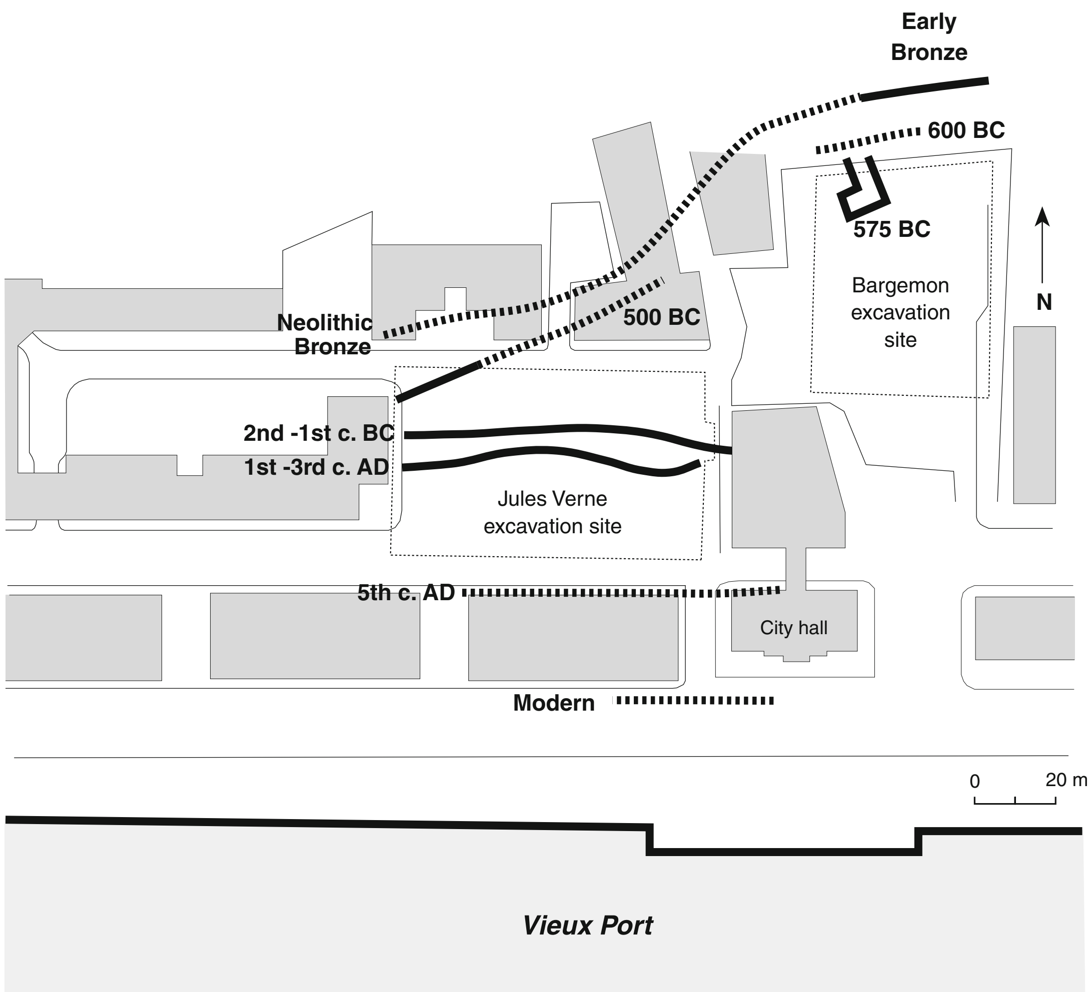
In contrast to deltaic areas, the smaller analytical scale of harbor basins meant that coastal changes could be studied not only with greater facility but also more finitely. The research at Marseille (Morhange et al., 2003) reconstructed a rapid shift in shoreline positions from the Bronze Age onwards and demonstrated the type of spatial resolution that can be obtained when large excavation areas are available for geoarchaeological study. These studies were unique in that, for the first time in a Mediterranean coastal context, both sought to embrace a multidisciplinary methodology. Investigative fields included not only archaeology but also geomorphology, geography, sedimentology, history, and biology (Raban and Holum, 1996; Hesnard, 2004). The waterlogged conditions were particularly conducive to environmentally contextualized analyses, and both studies demonstrated how coastal archaeology could benefit from being placed within a broader multidisciplinary framework.

Since these projects, there has been a great proliferation of studies looking into coastal and ancient harbor geoarchaeology (see Marriner and Morhange, 2007 for multiple references; Figure 1), building on pioneering archaeological work in the first half of the twentieth century (e.g., Negris, 1904a; Negris, 1904b; Paris, 1915; Jondet, 1916; Paris, 1916; Lehmann-Hartleben, 1923; Poidebard, 1939; Halliday Saville, 1941; Poidebard and Lauffray, 1951). Ancient harbor basins are particularly interesting because (1) they served as important economic centers and nodal points for maritime navigation (Casson, 1994; Arnaud, 2005); (2) there is generally excellent preservation of the material culture (Rickman, 1988; Boetto, 2012) due to the anoxic conditions induced by the water table; and (3) there is an abundance of source material for paleoenvironmental reconstruction (Marriner, 2009). Seaports are particularly interesting, as they allow us to understand how people "engaged with" the local environmental processes in coastal areas.

Here, we will explore the specific interest of harbor sediments in reconstructing ancient coastal landscapes and their evolution through time. In particular, we will discuss the stratigraphic evidence for these changes and set them within the wider context of coastal changes driven by various natural and anthropogenic forcing agents. We will also address present challenges and gaps in knowledge.

Harbor origins

The ease of transport via fluvial and maritime routes was important in the development of civilizations. At least three areas – the Indus, China, and Egypt – played an important role in the development of harbors and their infrastructure.



Harbors and Ports, Ancient, Figure 2 Coastal progradation in the ancient harbor of Marseille since Neolithic times. Chronostratigraphy and marine fauna fixed upon archaeological structures document a steady 1.5 m rise in relative sea level during the past 5,000 years. Sea level was broadly stable around the present datum between AD 1500 and the last century.

Egypt

It has been suggested that the Egyptians were one of the earliest Mediterranean civilizations to engage in fluvial and maritime transportation. Evidence for the use of boats in ancient Egypt derives from deepwater fish bones found at prehistoric hunter/gatherer campsites (Shaw et al., 1993). The earliest boats were probably rafts made of papyrus reeds, which enabled these societies to navigate between camps. It is speculated that wooden boats were adopted during Neolithic times, around the same time as the introduction of agriculture and animal husbandry. The rise of chiefdoms during the Egyptian Predynastic period (3700–3050 BC) was accompanied by the widespread adoption of boats as attested by art and pottery depictions (Fabre, 2004–2005). North of the First Cataract in Egypt, ships could travel almost anywhere along the Nile. On the delta, the then seven branches served as navigable waterways into the Eastern Mediterranean (Tousson, 1922; Stanley, 2007; Khalil, 2010). The Eastern Mediterranean was also a natural communications link for the major cultural centers of the Levant, Cyprus, Crete, Greece, and North Africa. In light of this, it is unsurprising that the works along the fluvial banks and coastlines of the Red Sea and Mediterranean were many and varied. During the third millennium BC, canals were excavated from the Nile to the valley temples of the Giza pyramids so that building materials could be transported (Fabre, 2004–2005; Butzer et al., 2013). Quays were also commonly established along the Nile, for instance, at fourteenth century BC Amarna, boats have been depicted parallel to shoreside quays equipped with bollards (Blackman, 1982a; Blackman, 1982b). An artificial quay dating to the second millennium BC is attested at Karnak, on the Nile (Lauffray et al., 1975; Fabre, 2004–2005). High sediment supply and rapid changes in fluvial systems mean that few conspicuous remains of these early riverine harbors are still visible, particularly on the delta (Blue and Khalil, 2010). In Mesopotamia, a similar evolution is attested (Heyvaert and Baeteman, 2008).

Navigation in the Red Sea during pharaonic times is a theme that has attracted renewed interest during the past 30 years, underpinned notably by the discovery of a number of exceptional coastal sites, shedding new light on the extent and chronology of human impacts in maritime areas. Extending for over 2,000 km from the Mediterranean Sea to the Arabian Sea, the Red Sea was a major communications link. Egyptian seafarers traveled along its shorelines during the Predynastic period and were probably the first to contact the peoples living on the Sudanese coast and around the Horn of Africa. Since the discovery of remains at Mersa/Wadi Gawasis in 1976, new findings have been made more recently at Ayn Soukhna, El-Markha, and Wadi al-Jarf (Tallet, 2009). In the absence of harbor excavations, much of the data available remain preliminary. At Mersa/Wadi Gawasis, archaeological data have documented evidence for some of the world's earliest long-distance seafaring, including bundled ropes, ships, and remnants of storage boxes used for the transport of goods. The site was used extensively during the Middle Kingdom (around 4,000–3,775 years ago), when seafaring ships departed from the harbor for trade routes along the African Red Sea coast (Bard and Fattovich, 2010; Hein et al., 2011).

The Indus Valley

On the Indian subcontinent, archaeological explorations during the past century have brought to light a large number of structures related to ancient harbor works and maritime activities (Rao, 1988). The Indus valley in particular has been a key focus of research, where high sediment supply in a context of rapidly changing deltaic environments is responsible for the landlocking of many ancient port sites (Gaur and Vora, 1999). The oldest reference to a harbor in India derives from a mid-third millennium Mesopotamian text mentioning boats from Meluhha that were anchored in Agade harbor (Kramer, 1964). Nonetheless, despite rich textual evidence, the exact location of many of these ancient harbor sites is equivocal. Most would have exploited riverbanks that served as natural harbors. Many of the best-studied examples derive from the region of Gujarat, which attests to significant paleoshoreline changes during the past 4,500 years (Gaur and Vora, 1999).

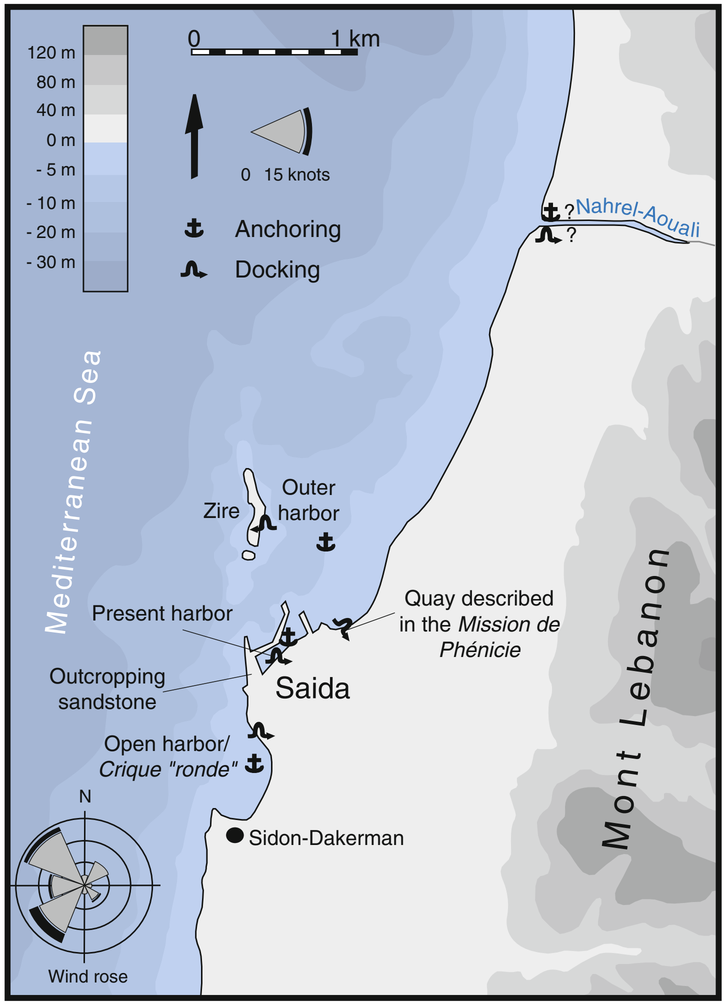
Archaeological sites of Harappan age (3000–1500 BC), including Lothal, Padri, and Bet Dwarka, have yielded particularly interesting archaeological records consistent with maritime activity (Gaur and Vora, 1999). Lothal, on the paleo-banks of the river Sabarmati, is one of the best-studied examples of a Harappan harbor city. The site presently lies 35 km from the coast at the head of the macrotidal Gulf of Cambay and is believed to have been an important trade center during the Harappan period (Rao, 1991). A number of Egyptian and Mesopotamian imports have been recovered from the site. Excavations have brought to light a brick basin of trapezoidal shape that measures 214 × 36 m and is 3.3 m deep. It has tentatively been labeled as the world's first dockyard (Rao, 1979), although these interpretations are not without contention (e.g., Gaur, 2000), and the basin presents striking similarities with water storage basins used throughout the region. Based on present knowledge, it is difficult to confirm that Lothal's basin was used as a harbor. Elsewhere in the Indus valley, Chalcolithic/Harappan landing platforms attributed to harbor works have been identified at Kuntasi and Inamgaon. Paleoenvironmental changes are seen as important causes of harbor abandonment.

China

Between 7000 and 5000 BC, agricultural villages and towns began to emerge and grow along the Yellow and Yangtze River basins and coasts. Research has focused on this transitional period because it corresponds to the onset of deltaic sedimentation and the emergence of agriculture and early complex societies (Zong et al., 2007; Chen et al., 2008). Ancient Chinese history is marked by three successive dynasties that became the roots of Chinese culture: the Xia Dynasty (2200–1766 BC), the Shang Dynasty (1766–1122 BC), and the Zhou Dynasty (1122–256 BC). Despite the importance and continuity of Chinese civilization, understanding of its harbors is relatively limited in western academic circles due to obvious language barriers. Nonetheless, the recent rediscovery of Hepu harbor of the Western Han Dynasty (206 BC to 25 AD) is particularly promising in shedding new light on this question. Now located within Beihai City in south China's Guangxi Zhuang Region, recent archaeological work suggests that Hepu harbor – probably the oldest seaport in China – served as a very important "marine silk road." This navigation link allowed western goods to be transported into the vast continental interior of Asia.

Early Mediterranean harbors

Our understanding of early harbors is poor. In the Mediterranean, the first artificial structures appear to date to the Middle/Late Bronze Age. For example, submerged boulder piles are attested at Yavne-Yam, a Middle Bronze Age site on the coast of Israel; these suggest premeditated human enterprise to improve the quality of the natural anchorage (Ezra Marcus, personal communication). Recent geoarchaeological work in Sidon (Lebanon) has tentatively dated the presence of a semi-protected cove beginning around 4410 ± 40 BP (2750–2480 cal BC; Marriner et al., 2006b; Marriner, 2009). This sedimentological unit has been interpreted as a Middle Bronze Age to Late Bronze Age proto-harbor, with possible reinforcement of the shielding sandstone ridge improving the quality of the natural anchorage. It is suggested that small boats were beached, with larger vessels being anchored in the outer harbor of Zire (Frost, 1973; Carayon, 2008; Figure 3).



Harbors and Ports, Ancient, Figure 3 Sidon's ancient harbor areas (Adapted from Carayon (2008) and Marriner (2009)).

At Kommos, in southern Crete, a large building with six galleries (Puglisi, 2001) has been interpreted as a hangar for the dry-docking of Minoan ships during the winter months. This building, dated to the fifteenth century BC, is an illustration of Minoan harbor construction even though, in this instance, it had no direct impact upon the quality of the anchorage haven.

After this period, the maritime harbors of the ancient Mediterranean evolved in four broad technological leaps.

Bronze Age to early Iron Age ashlar header technology

A double ashlar wall infilled with stones is a harbor construction method common to the Phoenicians; it is known as the pier-and-rubble technique (Raban, 1985). This system has been noted in an eleventh century BC layer at Sarepta, Lebanon (Markoe, 2000). Van Beek and Van Beek (1981) have suggested that this technique is Levantine in origin and that it spread from the Late Bronze Age Levant to the western Punic colonies, Greece, and Roman North Africa, where it can be found as late as the sixth century AD. The use of ashlar techniques is well attested in the Persian period harbor of Akko (Israel), the Hellenistic harbor at Amathus in Cyprus (Empereur and Verlinden, 1987), and the Roman quay at Sarepta, Lebanon (Pritchard, 1978), Dor, and Athlit (Israel). Iron Age Athlit is one of the best-studied Phoenician harbors (Haggi, 2006; Haggi and Artzy, 2007). The northern harbor's mole extends about 100 m into the sea. It is about 10 m wide and constitutes two parallel ashlar headers that are 2–3 m in width. A fill of rubble and stones was placed between the ashlar walls. This form of construction improved the stability of the mole against high-energy waves. The mole was placed on a foundation of ballast pebbles of various sizes. Underwater excavations have revealed that the layer of pebbles extends more than 5 m beyond the outer side of each wall, a total width of over

20 m. Radiometric dating of wood fragments constrains this Phoenician structure to the ninth century BC (Haggi, 2006), although paradoxically there is very little pottery dating from this period (Michal Artzy, personal communication). A similar example is also known from the Syrian coast at Tabbat el-Hammam, where the archaeological evidence supports a ninth/eighth century BC age (Braidwood, 1940).

Depending on the time and culture, different variations are noted in the use of headers. From the fifth century BC, metal links were used to reinforce blocks (e.g., Sidon and Beirut). At Amathus (Cyprus) during Hellenistic times, the header masonry was built upon a ballast base of disorganized blocks.

Cothons

Archaeologists refer to the sites of Carthage (Tunisia), Mahdia (Tunisia), Phalasarna (Crete), Jezirat Fara'un (Egypt), and Lechaion (Greece) as "cothon" harbors. The Greek term was applied to the harbor at Carthage by Strabo and Appian, the original meaning of "drinking cup" which is metaphorically appropriate to the protected harbor basin. Carthage is the only site that has been referred to as a "cothon" in ancient texts, although a Punic etymology has not yet been supported, meaning it is difficult to propose that the concept was Carthaginian in origin or that all harbors built into the shoreline in the same manner were felt to be variations on a "cothon" (John Oleson, personal communication). Nowadays, specialists agree that the term can be associated with an artificially dug harbor basin linked to the sea via a man-made channel (Carayon, 2005). The design solves some of the problems involved in building a harbor along a shallow, featureless coastline, or on the bank of a river, and a number of cultures appear to have adopted this solution, from the Bronze Age onwards. Some authors have suggested that Trajan's basin at Portus also qualifies as a cothon, in addition to some of the proposed Etruscan harbor basins associated with river mouths (John Oleson, personal communication). It would appear that the carving of a cothon is a simple but energy-consuming technique used to create a particularly well-sheltered basin. This type of infrastructure poses three problems: (1) rapid silting up in a confined environment; (2) the carving of a basin in rocky outcrops or clastic coastlines, which is energy consuming; and (3) maintaining a functional channel outlet to the sea in a clastic coast context. Despite these shortcomings, the cothon persisted for many centuries (Carayon, 2008). A Latin author, writing in the fifth century AD, noted that this type of harbor was common at this time: "*ut portus scilicet faciunt*" (Deutero-Servius, *Aeneidos*, I, 421).

Hydraulic concrete

Pre-Roman ashlar block methods continued to be used throughout the Roman era. Nonetheless, another technique was introduced during the second century BC (Gazda, 2001) that completely revolutionized harbor design and construction – the use of hydraulic concrete. This technological breakthrough meant that natural roadsteads were no longer a prerequisite to harbor loci, and completely artificial ports, enveloped by imposing concrete moles, could be located on open coasts (Hohlfelder, 1997). The material could be cast and set underwater. Roman architects and engineers were free to create structures in the sea or along high-energy shorelines (Brandon et al., 2005; Brandon et al., 2010). Pozzolana facilitated the construction of offshore basins such as Claudius's harbor at Portus of Rome (Testaguzza, 1970). The Roman author Vitruvius (first century BC) provided an inventory of harbor construction techniques (Vitruvius, *De Architectura*, V, 12).

Romano-Byzantine harbor dredging

Vitruvius gave a few brief accounts of dredging, although direct archaeological evidence has, until now, remained elusive. The ancient harbors of Marseille and Naples have both undergone widespread excavations (Figure 4; Hesnard, 1995; Giampaola et al., 2004), and extensive multidisciplinary datasets now exist for the two sites. At Tyre and Sidon, geoarchaeological research has led to the extraction of 40 cores that have facilitated a chronostratigraphic reconstruction of basin silting (Marriner et al., 2005; Marriner and Morhange, 2006a; Morhange and Marriner, 2010a). Why were ancient harbors dredged? On decadal timescales, continued silting induced a shortening of the water column. De-silting infrastructure (Blackman, 1982a; Blackman, 1982b), such as vaulted moles, partially attenuated the problem, but in the long term, these appear to have been relatively ineffective. In light of this, repeated dredging was the only means of maintaining a practicable draft depth and ensuring long-term harbor viability. At Marseille, although dredging phases are recorded from the third century BC onwards, the most extensive enterprises were undertaken during the first century AD, at which time huge volumes of sediment were extracted. At the excavations of Naples, absence of pre-fourth century BC layers has been linked to extensive dredging between the fourth and second centuries BC (Carsana et al., 2009). Unprecedented traces 165–180 cm wide and 30–50 cm deep attest to powerful dredging technology that scoured into the volcanic substratum, completely reshaping the harbor bottom. Notwithstanding the scouring of harbor bottoms, this newly created space was rapidly infilled and necessitated regular intervention. Repeated dredging phases are attested up until the late Roman period, after which time the basin margins were completely silted up. At Marseille, three dredging boats have been unearthed (Pomey, 1995). The vessels were abandoned at the bottom of the harbor during the first and second centuries AD. They are characterized by an open central well that is inferred to have accommodated the dredging arm.

It was not until the Industrial Revolution in England that cement and iron structures were developed on

Harbors and Ports, Ancient, Figure 4 Harbor dredging in Naples (Photograph: D. Giampaola, Archaeological Superintendence of Naples).

a large scale (Palley, 2010). In 1756, Smeaton made the first modern concrete (hydraulic cement) by adding pebbles as a coarse aggregate and mixing powdered brick into the cement. In 1824, Aspdin invented Portland cement by burning ground limestone and clay together. The Frenchman Monier invented reinforced concrete in 1849 using imbedded steel. It can withstand heavy loads because of its tensile and compressional strengths. Reinforced concrete was widely used in railway ties, pipes, floors, arches, bridges, and ports.

Geoarchaeology of harbor basins: tools and methods

Over the past two decades, ancient harbors have attracted interest from both the archaeological and earth science communities. In tandem with the development of rescue archaeology, particularly in urban contexts, the study of sedimentary archives has grown into a flourishing branch of archaeological inquiry (Milne, 1985; Leveau et al., 1999; Milne, 2003; Walsh, 2004; Leveau, 2005). The growing corpus of sites and data demonstrates that ancient harbors constitute rich archives of both the cultural and environmental pasts. Ancient harbor sediments are particularly rich in research objects (archaeological remains, bioindicators, macrorests, artifacts, etc.), and they yield insights into the history of human occupation at a given site, coastal changes, and the natural processes and hazards that have impacted these waterfront areas (Reinhardt et al., 2006; Bottari and Carveni, 2009; Morhange and Marriner, 2010b; Bony et al., 2012).

Ancient harbors are both natural and constructed landscapes and, from a geoarchaeological perspective, comprise three elements of note.

The harbor basin

In architectural terms, the harbor basin is characterized by its artificial structures, such as quays, moles, and sluice gates (Oleson, 1988; Oleson and Branton, 1992). Since the Bronze Age, there has been a great diversity in harbor infrastructure in coastal areas, reflecting changing technologies and human needs. These include, for instance, the natural pocket beaches serving as proto-harbors (Frost, 1964; Marcus, 2002a; Marcus, 2002b), through the first Phoenician mole attributed to around 900 BC (Haggi and Artzy, 2007), to the grand offshore constructions of the Roman period made possible by the discovery of hydraulic concrete (Oleson et al., 2004).

In their study of harbor landscapes, geoarchaeologists are also interested in the sedimentary contents of the basin and relative sea-level changes.

Ancient harbor sediments

Port basins constitute unique coastal archives. Shifts in the granularity of these deposits indicate the degree of harbor protection, often characterized by a rapid accumulation of heterometric sediments following a sharp fall in water competence brought about by the installation of artificial harbor works. The harbor facies is characterized by three poorly sorted fractions: (1) human waste products, especially at the base of quays and in areas of unloading (harbor depositional contexts are particularly conducive to the preservation of perishable artifacts such as leather and wood); (2) poorly sorted sand; and (3) an important fraction (>90 %) of silt that signifies the sheltered environmental conditions of the harbor. They are also particularly pertinent archives for reconstructing the history of heavy metal pollution at coastal settlements (e.g., Véron et al., 2006). Harbor basins are characterized by rapid accumulation rates. For instance, sedimentation rates of up to 20 mm/year have been recorded in undredged areas of the Graeco-Roman harbor of Alexandria (Goiran, 2001). High-resolution study of the bio- and lithostratigraphical fractions can help shed light on the nature of ancient harbor works, such as at Tyre (Marriner et al., 2008) or Portus (Goiran et al., 2010). Recent research has sought to characterize and date these chronostratigraphic phases using the unique sedimentary signature that each technology brings about (Marriner and Morhange, 2007; Marriner, 2009). In the broadest sense, these are characterized by an evolution from natural roadsteads before the Bronze Age towards completely artificial seaport complexes from the Roman period onwards.

Relative sea-level changes, the paleo-water column, and ship circulation

Nowadays, most ancient harbors are completely infilled with sediments – e.g., the Roman harbor of Luni at the mouth of the river Magra (Bini et al., 2009) or the Roman harbor of Aquileia (Arnaud-Fassetta et al., 2003). Harbor sediments are particularly conducive to the preservation of biological remains. Within this context, it is possible to identify and date former sea-level positions using biological indicators fixed to quays, that, when compared with the marine bottom, allow the height of the paleo-water column to be estimated (Laborel and Laborel-Deguen, 1994; Morhange et al., 2013). Such relative sea-level data are critical in understanding the history of sedimentary accretion in addition to estimating the draft depth for ancient ships (Pirazzoli and Thommeret, 1973; Morhange et al., 2001; Boetto, 2012). Archaeological work undertaken upon ancient wrecks suggests that the largest fully loaded ships during antiquity required a draft of less than 3 m (Casson, 1994; Pomey and Rieth, 2005). These two reference levels, the paleo-sea level and sediment bottom, are mobile as a function of crustal movements – e.g., local-scale neotectonics (Stiros et al., 1996; Stiros, 1998; Evelpidou et al., 2011), regional isostasy (Lambeck et al., 2004), sediment budgets (Vött et al., 2007; Devillers, 2008), and human impacts such as dredging (Marriner and Morhange, 2006b). All these factors can potentially impact the available accommodation space for sediment accretion.

Sediments versus settlements

As outlined above, one of the key problems posed by artificially protected harbors relates to accelerated sediment trapping. In the most acute instances, it could rapidly reduce the draft depths necessary in accommodating large ships (Pomey and Rieth, 2005). From a cultural perspective, therefore, harbors were important "economic landscapes," and many changes in harbor location can be explained functionally by the need to maintain an interface with the sea in the face of rapid sedimentation. The best example of this coastal dislocation derives from Aegean Anatolia (Brückner et al., 2005). Delta areas in particular serve as excellent geo-archives to understand and analyze the impacts of rapidly evolving settlement phases.

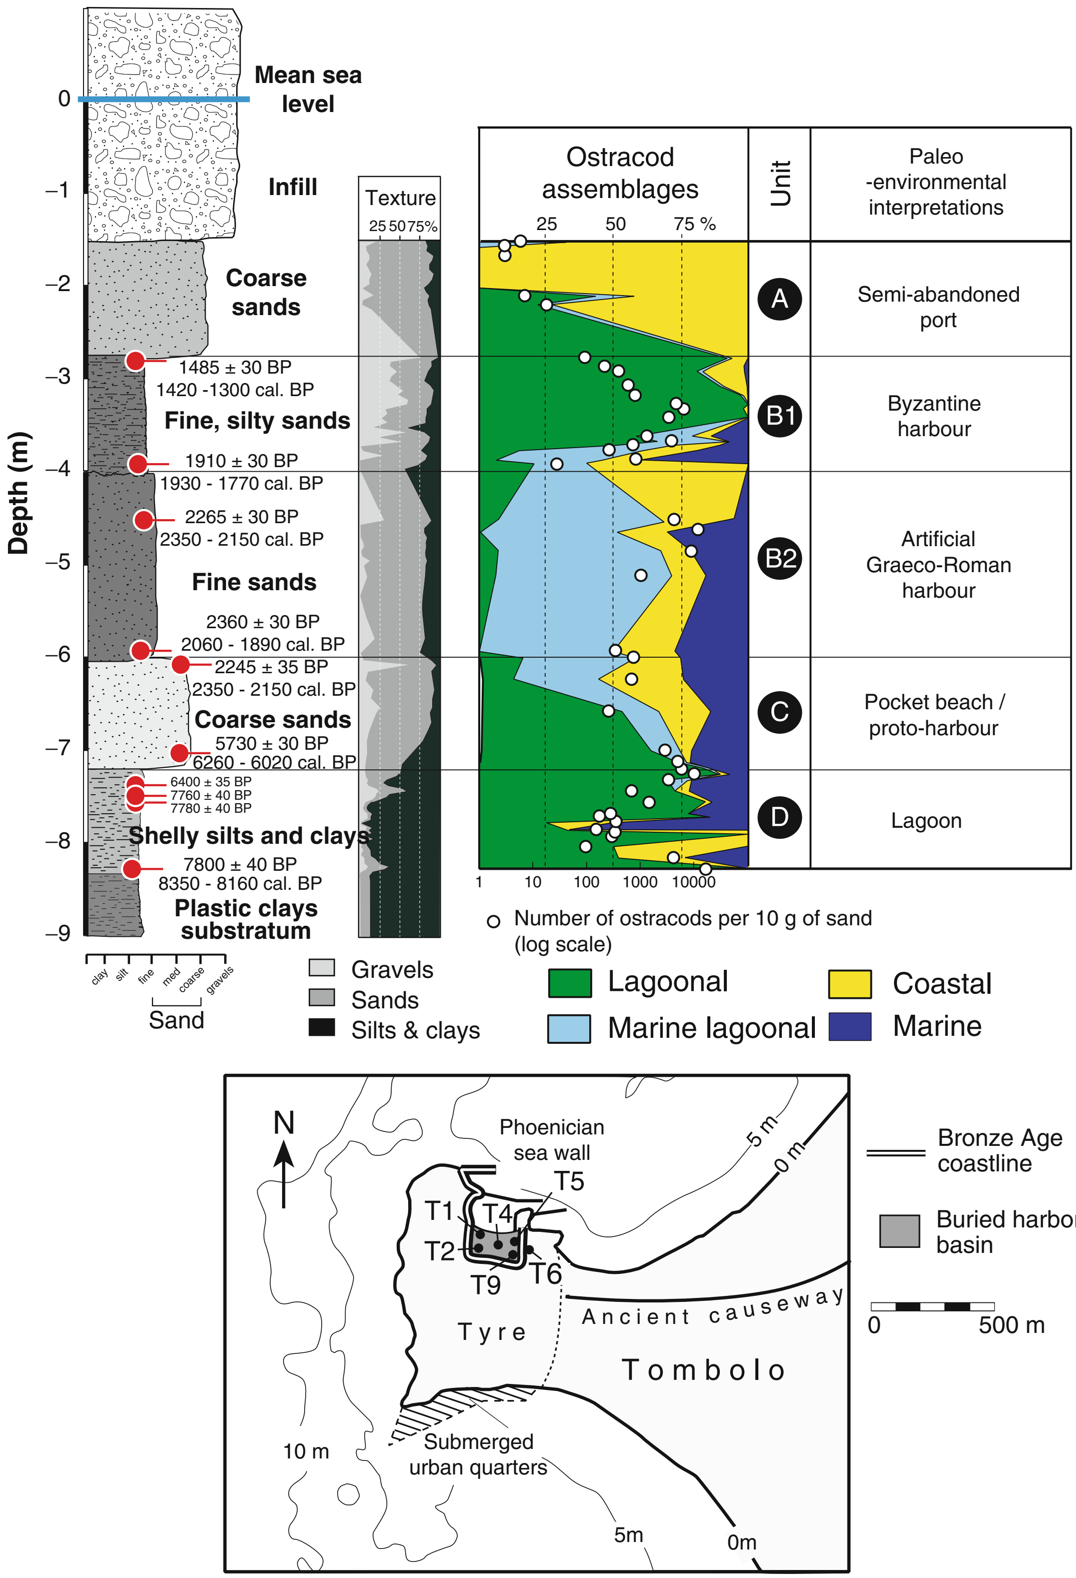
It is important to set these geoarchaeological results within a wider spatiotemporal framework using archaeological data from coastal and hinterland valley areas. Changes in sediment supply at the watershed scale are particularly important in understanding base-level changes in deltaic and coastal contexts, as is the case of the Gialias in Cyprus (Devillers, 2008) or the paleo-island of Piraeus (Goiran et al., 2011). Probing the rates of progradation is also key to understanding the timing, origin (climate or human forcings), and rhythm of local and basin-scale erosion.

Ancient harbor stratigraphy, terminology and research goals

During the past 20 years, multidisciplinary inquiry has allowed a better understanding of where, when, and how ancient Mediterranean harbors evolved. This is set within the wider context of a new "instrumental" or "quantitative revolution" towards the environment. A battery of research tools is available, tools that broadly draw on geomorphology and the sediment archives located within this landscape complex (Marriner and Morhange, 2007).

Where?

The geography of ancient harbors constitutes a dual investigation that probes both the location and the extension of the basins. Biostratigraphical studies of sediments, married with a GIS investigation of aerial photographs and satellite images, can be used to reconstruct coastal evolution and identify possible anchorage areas (Ghilardi and Desruelles, 2009). Traditionally, urban contexts have been particularly problematic for accurate archaeological studies because the urban fabric can hide many of the most important landscape features. In such instances, chronostratigraphy can be particularly useful in reconstructing coastal changes (Morhange et al., 2003). For example, litho- and biostratigraphical studies of cores drilled in the city center of Tyre attest to a well-sheltered port basin between the Hellenistic and Byzantine periods, today buried beneath the modern market by thick sediment tracts. The chronostratigraphy demonstrates that during antiquity, the harbor was approximately twice as large as present (Figure 5). This approach helps not only in reconstructing ancient shorelines and changes through time (e.g., as at Ephesus, Priene, Frejus, Alexandria, or Pelusium on the Nile Delta) but can also aid in relocating



Harbors and Ports, Ancient, Figure 5 Chronostratigraphic evolution of Tyre's ancient northern harbor since the Bronze Age (core T9).

ports for which no conspicuous archaeological evidence presently exists, as in the case of Cuma (Stefaniuk and Morhange, 2005) or Byblos (Stefaniuk et al., 2005).

Geophysical techniques can also provide a great multiplicity of mapping possibilities, notably in areas where it is difficult to draw clear parallels between the archaeology and certain landscape features (Nishimura, 2001). Because geophysical techniques are nondestructive, they have been widely employed in archaeology and are gaining importance in coastal geoarchaeology (Hesse, 2000) and ancient harbor contexts (Boyce et al., 2009). Very rapid and reliable information can be provided on the location, depth, and nature of buried archaeological features before excavation. At Alexandria, geophysical surveys have allowed Hesse (1998) to propose a new hypothesis for the location of the Heptastadium. Hesse suggests that the causeway linking Pharos to the mainland was directly tied into the city's ancient road network. In this instance, the findings have since been corroborated by sedimentological data from the tombolo area (Goiran, 2001). Stratigraphic data are therefore critical in providing chronological insights into environmental changes and coastal processes. Such a dual approach has also been successfully employed at Portus, one of the ancient harbors of Rome. Large areas of the seaport and its fringes have been investigated using coastal stratigraphy (Bellotti et al., 2009; Giraudi et al., 2009; Goiran et al., 2010; Di Bella et al., 2011; Mazzini et al., 2011; Salomon et al., 2012), geophysics, and archaeological soundings (Keay et al., 2005; Keay et al., 2009; Keay and Paroli, 2011), yielding fresh insights into the harbor's coastal infrastructure and functioning. On the Tiber delta, geophysics has also been used to accurately map the progradation of the coastal ridges. Bicket et al. (2009) have demonstrated that the Laurentine ridge, ~1 km inland from the modern coastline, constitutes the Roman shoreline of the Tiber delta.

When and how?

Chronostratigraphy is essential in understanding modifications in harbor technology and the timing of human impacts, such as lead pollution from the Bronze Age onwards (Véron et al., 2006) or ecological stresses demonstrated by changes in faunal assemblages (Leung Tack, 1971–72). The overarching aim is to write a "sedimentary" history of human coastal impacts and technologies, using quantitative geoscience tools and a standardized stratigraphic framework (e.g., sequence stratigraphy). Research in the eastern and western Mediterranean attests to considerable repetition in ancient harbor stratigraphy, both in terms of the facies observed and their temporal envelopes. There are three distinct facies of note: (1) middle-energy beach sands at the base of each unit (e.g., the proto-harbor), (2) low-energy silts and gravels (e.g., the active harbor phase), and (3) coarsening up beach sands or terrestrial sediments which cap the sequences (e.g., post-harbor facies). In the broadest terms, this stratigraphic pattern represents a shift from natural coastal environments to anthropogenically modified contexts, before a semi- or complete abandonment of the harbor basin.

There are a number of stratigraphic surfaces that are key to understanding the evolution of ancient harbor basins.

The maximum flooding surface (MFS)

Ancient harbors form integral components of the highstand parasequence (aggradational to progradational sets). For the Holocene coastal sequence, the maximum flooding surface (MFS) represents the lower boundary of the sediment archive. This surface is broadly dated to around 6000 cal BP and marks the maximum marine incursion (Stanley and Warne, 1994). It is associated with the most landward position of the shoreline. In the eastern Mediterranean, it is contemporaneous with the Chalcolithic period and the Early Bronze Age. Indeed, the MFS along the Levantine coast clearly delineates the geography of early coastal settlements from this period (Raban, 1987).

Natural beach facies

The MFS is overlain by naturally aggrading beach sands, a classic feature of clastic coastlines. Since around 6000 cal BP, relative sea-level stability has impinged on the creation of new accommodation space, leading to the aggradation of sediment strata. This is particularly pronounced in sediment-rich coastal areas such as deltas and at the margins of fluvial systems. Where this sedimentation continued unchecked, a coarsening upward of sediment facies is observed, consistent with high-energy wave dynamics in proximity to mean sea level. For example, Gaza bears witness to important coastal changes since the Bronze Age. During the mid-Holocene, the coast comprised estuaries at the outlets of major wadi systems. This indented coastal morphology spawned important maritime settlements such as Tell es-Sakan and Tell al-'Ajjul at the outlet of Wadi Ghazzeh, which probably served as a natural harbor. During the same period, the rate of sea-level rise slowed, leading to the formation of the Nile Delta and small, local deltas along the coasts of Sinai and Palestine. From the first millennium BC onwards, the coast was regularized by infilling of the estuaries, and the harbor sites became landlocked. In response, new cities, such as Anthedon, were founded on a Quaternary ridge along the present coastline (Morhange et al., 2005).

The harbor foundation surface (HFS)

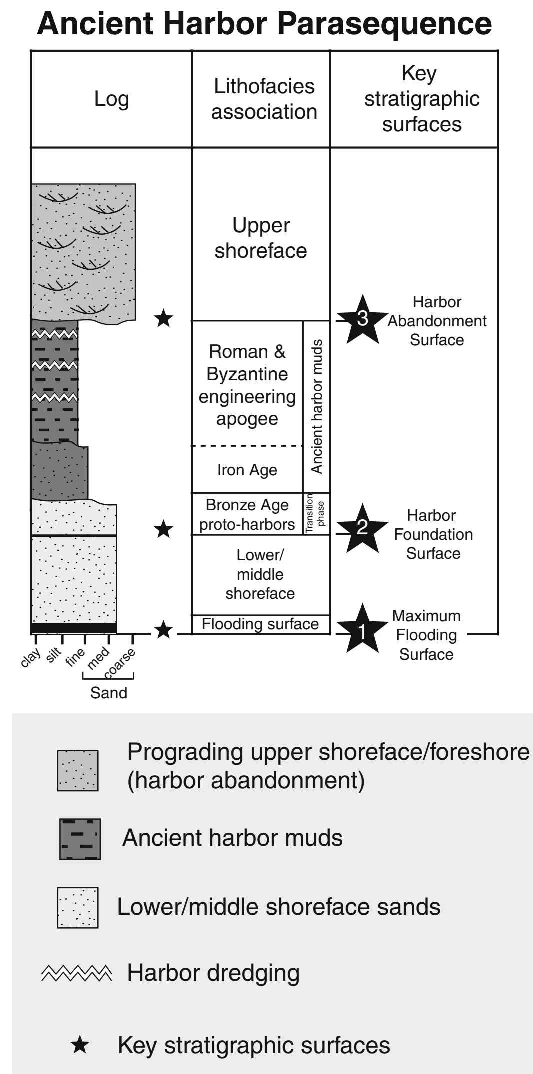
This surface marks important human modification of the sedimentary environment, characterized by the transition from coarse beach sands to finer-grained harbor sands and silts (Marriner and Morhange, 2007). This surface corresponds to the construction of artificial harbor works and, for archaeologists, is one of the most important surfaces to date the foundation of the harbor.

The ancient harbor facies (AHF)
The AHF corresponds to the active harbor unit. This artificialization is reflected in the sedimentary record by lower-energy facies consistent with a barring of the anchorage by artificial means. Harbor infrastructure (quays, moles, and jetties) accentuated the sediment sink properties by attenuating the swell and marine currents leading to a sharp fall in water competence. Research has demonstrated that this unit is by no means homogeneous, with harbor infrastructure and the nature of sediment sources playing a key role in shaping facies architecture. Of note is the granulometric paradox of this unit consisting of fine-grained silts juxtaposed with coarse gravels made up of ceramics and other urban waste.

In some rare instances, a proto-harbor phase (PHP) precedes the AHF. Before the major changes characteristic of the AHF, biosedimentological studies have elucidated moderate signatures of human presence when societies exploited natural low-energy shorelines requiring little or no human modification. For instance, coastal stratigraphy has demonstrated that the southern cove of Sidon, around Tell Dakerman, remained naturally connected and open to the sea throughout antiquity (Poidebard and Lauffray, 1951; Marriner et al., 2006a; Marriner et al., 2006b). The PHP interface is by no means transparent, particularly in early Chalcolithic and Bronze Age harbors, and the astute use of multiproxy data is required (Figure 6).

During the Late Bronze Age and Early Iron Age, improvements in harbor engineering have been recorded by increasingly fine-grained facies. Plastic clays tend to be the rule for Roman and Byzantine harbors, and sedimentation rates 10–20 times greater than naturally prograding coastlines are recorded. The very well-protected Roman harbors of Alexandria, Marseille, and Frejus (Gébara and Morhange, 2010) all comprise plastic marine muds consisting of 90 % silts and a coarse gravel fraction of human origin. Significant increases in sedimentation rates can also be attributed to human-induced increases in the supply term, for example, anthropogenic changes in the catchments of supplying rivers (deforestation, agriculture), erosion of mudbrick urban constructions (Rosen, 1986), and finally use of the basins as waste dumps. This underlines the importance of an explicit source-to-sink study integrating both the coastal area and the upland hinterland. Such high rates of harbor infilling were potentially detrimental to the medium- to long-term viability of harbor basins and impinged on the minimum 1 m draft depth.

The harbor abandonment surface (HAS)
This surface marks the "semi-abandonment" of the harbor basin. Recent studies have focused upon the role of natural hazards in explaining the decline or destruction of ancient Mediterranean harbors. While these factors may have had a role to play, it seems that the financial weight of maintaining harbor works in the face of the Mediterranean's shifting political and economic makeup was simply too burdensome (Raban, 2009). A relative decline in harbor works after the late Roman and Byzantine periods is



Harbors and Ports, Ancient, Figure 6 Chronostratigraphic evolution of ancient Mediterranean harbors in coastal areas.

characterized by a return to "natural" sedimentary conditions comprising (1) coarse-grained sands and gravels in a coastal context and (2) terrestrial facies in fluvial environments. Following hundreds to thousands of years of artificial confinement, reconversion to a natural coastal parasequence is sometimes expressed by high-energy upper shoreface sands. This shoreline progradation significantly reduced the size of the basins, often landlocking the heart of the anchorages beneath thick tracts of coastal and fluvial sediments.

Ancient harbor case studies: from natural to artificial ports

Today, it is recognized that harbors should be studied within broader regional frameworks using a multidisciplinary methodology (Carayon, 2008; Blackman and Lentini, 2010). There is great variety in harbor types, and, broadly speaking, three areas or physical processes are important in influencing harbor location and design: (1) geographical situation, (2) site and local dynamics, and (3) navigation conditions dictated by the wind and wave climate. The diversity of contexts investigated during the past 20 years has brought to light some striking patterns. Numerous processes are important in explaining how these have come to be preserved in the geological record, including the distance from the present coastline, position relative to present sea level, and geomorphology (Marriner and Morhange, 2007). Ancient harbors can be divided into six non-exhaustive types on the basis of preservation. Sediment supply, human impacts, crustal changes, and coastal energy dynamics are significant in explaining how ancient harbors have been preserved in the geological record (Bony, 2013).

Drowned harbors

Drowned cities and harbors have long captured the public imagination and inspired research (Marinatos, 1960; Frost, 1963; Flemming, 1971; Bailey and Flemming, 2008), fueled by mediatized legends such as Atlantis (Collina-Girard, 2001; Gutscher, 2005) and the "biblical flooding" of the Black Sea (Yanko-Hombach et al., 2007a; Yanko-Hombach et al., 2007b; Ravilious, 2009; Buynevich et al., 2011).

After the Last Glacial Maximum, when global sea level lay around 120 m below present, transgression of the continental platform gradually displaced coastal populations landwards until broad sea-level stability led to a sedentarization of populations along present coastlines (Van Andel 1989). The continental shelf between Haifa and Atlit (Israel) is one of the best-studied examples (Galili et al., 1988; Sivan et al., 2001). A series of submerged archaeological sites dating from the Pre-Pottery Neolithic B (8000 BP) and late Neolithic (~6500 BP) were found at depths of 12 to 8 m and 5 to 0 m, attesting to the postglacial transgression of the Levantine coastline. Since 6000 cal BP, coastal site and port submersion can be attributed to crustal mobility (e.g., historical subsidence in eastern Crete and uplift on the western coast) and/or sediment failure in deltaic contexts.

For example, on the western margin of the Nile Delta of Egypt, the coastal instability of the Alexandria area is responsible for a ~5 m drowning of archaeological remains since antiquity (Empereur and Grimal, 1997; Goddio et al., 1998; Goiran, 2001; Fabre, 2004–2005). The subsidence has been variously attributed to seismic movements (Guidoboni et al., 1994) and Nile Delta sediment loading (Stanley et al., 2001; Stanley and Bernasconi, 2006). Approximately 22 km east of Alexandria, around Abu Qir bay, an ~8 m collapse of the former Canopic lobe of the Nile is responsible for the drowning of two ancient seaport cities, Herakleion and East Canopus, during the eighth century AD (Tousson, 1922; Stanley et al., 2001; Stanley et al., 2004a; Stanley et al., 2004b).

Italy's Phlegraean Fields volcanic complex testifies to a very different crustal context that has led to a series of yo-yo land movements during the late Holocene. The ancient ports of Miseno, Baia, and Portus Julius are located inside a caldera (Gianfrotta, 1996; Scognamiglio, 1997; Figure 7). Since Roman times, tectono-volcanism inside this collapsed volcanic cone has led to significant shoreline mobility and is responsible for a 10 m submergence of the Roman harbor complexes (Dvorak and Mastrolorenzo, 1991). The pattern of movement inside the bay is spatially contrasted because around the fringes of the caldera the columns of the Roman market attest to an upper limit of marine bioerosion at 7 m above present sea level. Recent research suggests a series of post-Roman inflation-deflation cycles at both Pozzuoli (Morhange et al., 2006a) and Miseno (Cinque et al., 1991) linked to the interplay of deep magma inputs, fluid exsolution, and degassing (Todesco et al., 2004), all acting as drivers of rapid coastal change. Other studied examples of drowned cities include Helike and Kenchreai in the Gulf of Corinth, Greece (Kiskyras, 1988; Soter, 1998; Soter and Katsonopoulou, 1998; Rothaus et al., 2008) and Megisti on the island of Castellorizo, Greece (Pirazzoli, 1987).

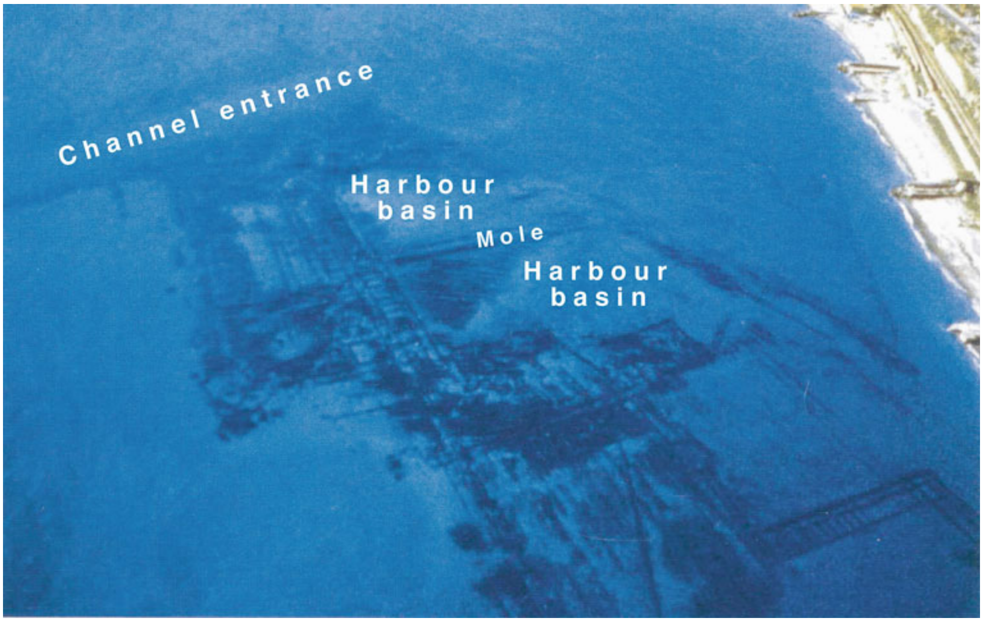
Uplifted harbors

The best geoarchaeological evidence for uplifted harbors derives from the Hellenic arc, one of the most seismically active regions in the world (Stiros, 2005).

In western Crete, Pirazzoli et al. (1992) have ascribed a 9 m uplift of Phalasarna harbor, founded in the fourth century BC, to high seismic activity in the eastern Mediterranean between the fourth to sixth centuries AD (Stiros, 2001). This episode is concurrent with a phase of Hellenic arc plate adjustment linked to uplift (1–2 m) in Turkey, e.g., the uplifted harbor of Seleucia Pieria (Pirazzoli et al., 1991), Syria (Sanlaville et al., 1997), and parts of the Lebanese coastline (Pirazzoli, 2005; Morhange et al., 2006b). Phalasarna's ancient harbor sediment record is of particular interest because its rapid uplift has possibly trapped tsunami deposits inside the basin (Dominey-Howes et al., 1998).

The Gulf of Corinth constitutes a neotectonic graben separating the Peloponnese from mainland Greece (Moretti et al., 2003; Evelpidou et al., 2011). It is one of the most tectonically active and rapidly extending regions in the world (6–15 mm/year) with a marked regional contrast between its subsiding northern coast and an uplifting southern flank borne out by its geomorphological features and archaeology (Papadopoulos et al., 2000; Koukouvelas et al., 2001). Biological and archaeological proxies attest to pronounced spatial disparities in the amplitude of uplift. The position of the gulf's ancient harbors can help to refine the recent tectonic history. The harbor of Heraion on the gulf's northern coast is, for instance, modestly uplifted by around 1 m (Pirazzoli et al., 1994).

The western harbor of Corinth at Lechaion is also uplifted. Emerged *Balanus* fossils indicating a former



Harbors and Ports, Ancient, Figure 7 Pozzuoli's drowned harbor remains presently ~10 m below mean sea level. The site lies inside a caldera, where shoreline mobility is attributed to volcanism and faulting (Photograph: Centre Jean Bérard, Naples).

biological sea level 1.2 m above the basin surface have been dated to around 2470 ± 45 BP, i.e., 375 ± 120 cal BC (Stiros et al., 1996). The location of the port basin in a well-protected depression suggests silting was already a problem during its excavation and not favorable to the basin's long-term viability as a seaport (Morhange et al., 2012). At Aigeira, an artificial Roman harbor was functional between ~100 AD and 250 AD (Papageorgiou et al., 1993). Biological and radiometric evidence from the city's harbor structures attests to ~4 m of uplift tentatively attributed to an earthquake around 250 AD (Stiros, 1998; Stiros, 2005).

In a different geodynamic context, Holocene evolution of Etna's coastline is associated with subduction of the African plate under the Eurasian plate. It presents a number of uplifted harbors, such as the neoria of the military harbor of Giardini-Naxos (Blackman and Lentini, 2010). This category of harbor is often poorly represented due to destruction by modern urbanization, e.g., the harbor of Kissamos, northwestern coast of Crete (Stefanakis, 2010).

Landlocked harbors

Around 6000 cal BP, the maximum marine ingression created an indented coastal morphology throughout the Mediterranean. During the ensuing millennia, these indented coastlines were gradually infilled by fluvial sediments reworked by longshore currents, culminating in a regularized coastal morphology. This process was particularly intense at deltaic margins.

Coastal progradation as a driver of settlement and harbor changes is best represented by Ionia's ancient ports in Turkey (Brückner, 1997), many of which are located inside infilled ria systems. Such rapid coastal change is linked to two factors: (1) broad sea-level stability since 6000 cal BP; and (2) the morphology of these paleovalleys, which correspond to narrow, transgressed grabens with limited accommodation space (Kayan, 1996; Kayan, 1999). For example, the Menderes floodplain has prograded by ~60 km during the past 7,000 years (Schröder and Bay, 1996). The best-studied examples include Troy (Kraft et al., 2003), where the harbor areas were landlocked by 2000 cal BP, and also Ephesus, Priene, and Miletos in Turkey (Brückner et al., 2005; Kraft et al., 2007).

In Cyprus, Devillers (2008) has elucidated the infilling of the Gialia's coastal embayment. The sedimentary archives attest to an easterly migration of the coastline. Human societies constantly adapted to this changing coastal environment as illustrated by the geographical shift of at least four ancient harbors: Early/Middle Bronze Age Kalopsidha, Middle/Late Bronze Age Enkomi, Graeco-Roman Salamina, and Medieval Famagusta. The latter is located on a rocky coast outside the paleo-ria.

Despite the ecological attraction of estuaries and fluvial mouths for harbor location, ancient engineers were aware of the longer-term hazards to survival. Greek settlers, for instance, founded Marseille around 600 BC at the distal margin of the Rhone delta in order to avoid the problems of rapid siltation. It is only in instances of absolute necessity that artificial ports were located inside deltaic systems. The Imperial harbors of Portus on the Tiber delta are a classic example (Goiran et al., 2010).

Eroded harbors

Eroded harbors can result from two complementary geological processes: (1) a fall in sediment supply to the coastal zone and/or (2) the destruction of harbor works in areas exposed to high-energy coastal processes. The best examples of eroded harbors date from the Roman period, when natural low-energy roadsteads were no longer a prerequisite for harbor location. At many high- to medium-energy coastal sites across the Mediterranean, the Romans constructed large enveloping moles to accommodate mooring facilities and interface installations such as fishponds and industrial saltpans. Good examples of eroded ancient harbors include Carthage and the outer Roman basin of Caesarea Maritima (Raban, 2009).

Fluvial harbors

River harbors are not subject to the same geomorphological and sedimentary processes as coastal seaports, and therefore diagnostic harbor sediment signatures can be markedly different. Unfortunately, geoarchaeological study of such contexts has been relatively limited until now. It is nonetheless an interesting avenue for future research and provides opportunities with which to compare and contrast the coastal data (Milne and Hobley, 1981; Good, 1991; de Izarra, 1993; Bravard and Magny, 2002; Arnaud-Fassetta et al., 2003). In particular, current research has focused upon the relationships between fluvial settlements, including their harbors, and flood hazards (Arnaud-Fassetta et al., 2003).

The environmental challenges of fluvial harbors are linked to: (1) seasonal and exceptional flood episodes (Stewart and Morhange, 2009); (2) river mouth access and rapidly shifting longshore bar development; and (3) the lateral instability of riverbanks (Bruneton et al., 2001; Brown, 2008).

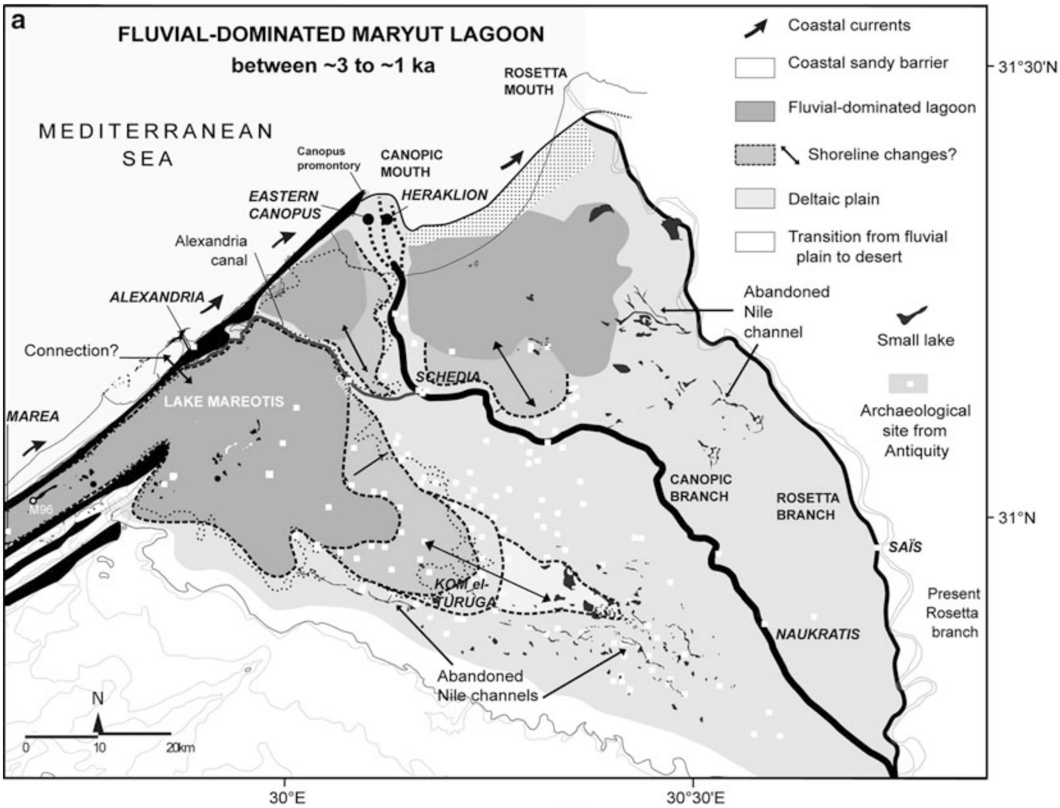
The Egyptians and Mesopotamians were among the earliest western civilizations to engage in fluvial transportation, and primeval Bronze Age harbor works are known from the banks of the Nile at Memphis and Giza (Fabre, 2004–2005). Despite excavations at a number of sites on the Nile Delta, e.g., Tell El-Daba/Avaris and Tell el-Fara'in (Bietak, 1996; Shaw, 2000), the exact location of many of the river ports is equivocal. There has been extensive research looking at the Canopic branch of the Nile Delta coast (Stanley and Jorstad, 2006; Stanley, 2007). Geoarchaeological data show that the Ptolemaic and Roman city of Schedia (Egypt) once lay directly on the Canopic channel, which was active from the third to second centuries BC until the fifth century AD. Abandonment of the site resulted from the avulsion of Nile waters to the Bolbitic and later Rosetta branches in the east. The discovery of a series of active and abandoned channels around the Greek city of Naukratis (Egypt) attests to significant fluvial mobility during antiquity. These channels served as transport pathways for the ancient settlement, although the site's fluvial port has never been precisely located (Villas, 1996). In the northeastern part of the Nile Delta, a number of sites on the now-defunct Pelusiac branch (Sneh and Weissbrod, 1973) have attracted geoarchaeological interest. Goodfriend and Stanley (1999) have shown that Pelusium, an important fortified city located at the mouth of the Pelusiac branch, was abandoned during the twelfth century AD following a large and rapid influx of Nile river sediment in the ninth century AD. This discharge in sediment led to the avulsion of a new distributory to the west, probably the Damietta branch.

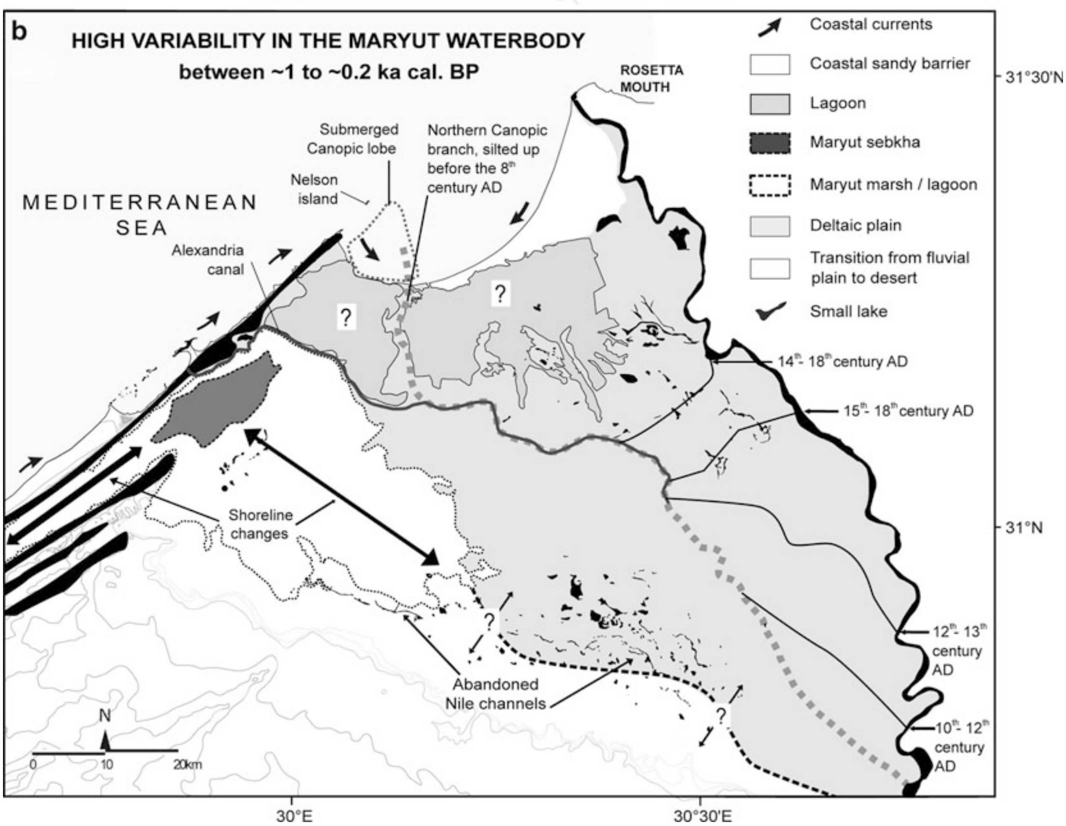
Aquileia in northeastern Italy is a well-studied example of a Roman fluvial harbor. A series of important waterways characterized the Aquileia deltaic plain during antiquity. These were channelized during the Roman period so as to ensure favorable conditions for navigation and to mitigate against the impact of floods (Arnaud-Fassetta et al., 2003). A similar evolution is attested at Minturnae (Italy), which controlled the bridge on the Appian Way over the Liris River. It occupied a prime location that allowed the Roman colony to evolve into a flourishing commercial center until its final abandonment around 590 AD. Recent geoarchaeological work undertaken at the mouth of the Tiber delta, around the ancient site of Ostia, has probed the evolution of the city's ancient harbor, which serviced ancient Rome around 32 km upriver (Goiran et al., 2012). Problems of basin silting meant that the harbor had already experienced an important phase of sediment infilling by the first century AD (Goiran et al., 2014). Continued late Holocene progradation dynamics have isolated ancient Ostia, which is now about 4 km from the present coastline. The silting of the harbor basin probably acted as a precursor to the construction of Rome's new port basin at Portus, although Ostia and the fluvial banks of the Tiber continued to accommodate smaller, shallow-draft vessels.

At a number of sites, the excavation of ancient harbor quays has facilitated the precise reconstruction of fluvial bank mobility since antiquity. This can be linked to the vertical accretion of riverbanks by flooding and the gradual funneling of fluvial waters by human activities. In London, for instance, Milne (1985) has described a 100 m shift in the port's waterfront between AD 100 and today. Under a mesotidal fluvial regime, funneling of the waterbody has led to a positive increase in tidal amplitude. A similar evolution is also attested at Bordeaux (France), where the staircasing of numerous quays and platforms has been described at two sites in the Garonne estuary (Gé et al., 2005). Three ancient and medieval platforms attest to a positive change in tidal amplitude of around 1.1 m during the twelfth to fourteenth centuries AD that can probably be linked to human impacts on the fluvial system.

Lagoonal harbors

Since 6000 BP, spit accretion on clastic coasts has disconnected a number of paleo-bays from the open sea. This process formed lagoons that have gradually infilled to yield rich geological archives. Lagoons offer natural protection,





Harbors and Ports, Ancient, Figure 8 (Continued) and their use as anchorage havens has been widespread since early antiquity. Nevertheless, lagoons pose a number of challenges that explain why these contexts were largely avoided as harbors during later periods: (1) difficult accessibility, namely, the mobility of the outlet channel that was particularly problematic for navigation, and (2) seasonal fluctuations in lagoon level, especially in the case of large waterbodies at the margins of fluvial systems.

Maryut lagoon lies at the northwestern margin of the Nile Delta, in a depression between two consolidated sandstone ridges of Pleistocene age (Flaux et al., 2011; Figure 8). The lagoon presently extends for 70 km on a - SW-NE axis with a maximum width of ~10 km. During antiquity, Nile inflow into the Maryut was supplied by the Canopic, the westernmost branch of the Nile. The Maryut's location at the intersection between the Mediterranean Sea and a major fluvial system has driven important paleoenvironmental changes during the past 8,000 years (Flaux, 2012; Flaux et al., 2012; Flaux et al., 2013). It is also responsible for significant seasonal variations in lagoon levels, driven by annual Nile flood cycles. There has been renewed interest in the Maryut because mounting archaeological evidence suggests that the lagoon was an important waterway during antiquity, with a densely occupied shoreline and numerous harbors and mooring sites (Blue and Khalil, 2010). Recent work by Flaux (2012) has demonstrated that the lagoon's Hellenistic and Roman harbors present a steplike mooring architecture to accommodate these seasonal fluctuations. Similar annual variations of around 1.4 m are also attested in the Dead Sea and the Sea of Galilee (Hadas, 2011). Reinforced landing quays at the Roman harbor of Magdala (Israel) comprise a comparable architecture to offset such variation and avoid erosional undercutting (De Luca, 2009). Recent work has unearthed a well-preserved harbor structure, extending for more than 100 m, which was functional during the Hellenistic and Roman periods (Sarti et al., 2013). Chronostratigraphic investigations have demonstrated that the harbor basin silted up and was abandoned during the Middle to Late Roman period (270–350 AD).

Lagoonal systems were particularly conducive to endo-lagoonal harbor circulation. A number of lagoon strings were exploited in the Mediterranean during Roman times, most famously the Fossa Neronis (Italy) in the direction of Rome (Cuma, Campania), Narbonne in southern France (Sanchez and Jézégou, 2011), and the upper Adriatic lagoons between Istria and the Po (Degrassi, 1955). New archaeological data from the Maryut lagoon in Egypt also suggest that the basin possessed a series of harbor complexes and mooring sites during Hellenistic and Roman times (Blue and Khalil, 2010). At present, the archetype of a harbor lagoon is medieval Venice which operated very successfully as a port up until recent modification of its marginal marine system.

Conclusions and future research directions

The impact of ancient harbor geoarchaeology on our understanding of the archaeological record in waterfront areas is clear and explicit. We have presented methods for reconstructing ancient harbor landscapes at a wide range of temporal and spatial scales, drawing on geoscience techniques, paleoecology and archaeology. With particular emphasis on the Mediterranean region, we have concentrated on the description and illustration of selected case study examples drawn from different geomorphological contexts. These lay the foundations for more geographically extensive studies, integrating the archaeological record with sediment archives for many Holocene time periods.

Some of the main advances made during the past 20 years include (1) the precise characterization of harbor facies in coastal contexts, using a variety of sedimentological, geochemical, and paleoecological proxies; (2) the characterization and intensity of human impacts in coastal areas (e.g., Véron et al., 2006); and (3) the scope to derive high-resolution RSL data (e.g., Morhange et al., 2001). Ancient harbor research is a rapidly evolving offshoot of geoarchaeology, and there is reason to be optimistic about its future prospects and applications. For the Mediterranean, as geographical gaps are gradually being filled and new research methods developed, more finite, regional-scale interpretations are becoming possible at a variety of temporal scales.

Current gaps in knowledge relate to the chronostratigraphic characterization of harbor facies in fluvial contexts that, in the absence of archaeological structures, renders the precise localization of harbor basins particularly challenging. Furthermore, our understanding of ancient harbor geoarchaeology is biased towards later periods, particularly Greek and Roman ports. Major gaps remain with regard to the Bronze Age, and future studies must look to probe these earlier periods. While our understanding of Mediterranean harbors continues to improve, it seems important to extend research to new geographical regions such as China, the Red Sea, and the Persian Gulf. One area of concern is the rise in catastrophic research in harbor contexts that mirrors the growth of neocatastrophic research during the past 20 years (Marriner et al., 2010; Marriner and Morhange, 2013). We advocate for the adoption of more nuanced approaches to the study of high-energy episodic events such as tsunamis and earthquakes.

Harbors and Ports, Ancient, Figure 8 Evolution of the Maryut lagoon during the past 3,000 years (From Flaux, 2012). The general aridification trend described during this period appears to be linked to the gradual decline of the Canopic branch of the Nile, which supplied the Maryut lagoon with freshwater.
