The Little Colorado River basin is isolated from the Colorado River system by a series of falls, especially Grand Falls, and intermittent reaches and therefore harbors several unique fishes. There are 33 species of fishes in the LCR Basin, only 9 of which are native; 5 in the upper reaches and 4 in the lower 14km reach. The native fish species in the upper 75km are represented by three families, which include two cyprinids (Little Colorado spinedace and speckled dace), two catostomids (bluehead sucker and Little Colorado River sucker), and one salmonid (Apache trout). Native species have been forced from their natural habitats by competition and predation by nonnative fish species and degradation and loss of habitat (Minckley 1991, Blinn et al. 1993). For example, roundtail chub are presently found only in the Chevelon and Clear creek basins and not in the LCR (Young and Lopez 1999). In addition, the Zuni bluehead sucker historically occurred in the LCR basin above Grand Falls but is presently restricted to the upper Zuni River drainage of west-central New Mexico. Two of the native fishes, Apache trout and roundtail chub, are sport fishes with regulated takes. The Little Colorado spinedace, which occurs in disjunct populations in north-flowing tributaries to the LCR, is federally listed as threatened and endangered (Blinn et al. 1993), and most of the other native species are listed as wildlife of special concern in Arizona.

The lower 14km of the LCR has received more attention than any other section of the river corridor due to concerns over the federally endangered humpback chub. Other native fishes in the reach include bluehead sucker, flannelmouth sucker, and speckled dace (Douglas and Marsh 1996, Gorman and Stone 1999). All four native species inhabit this lower reach, but only speckled dace are found above the Blue Springs complex and in the higher-elevation reaches.

The common nonnative fishes in the upper LCR basin include rainbow trout, brown trout, fathead minnow, green sunfish, and red shiner. Most of these fishes were introduced into the LCR basin in the early 1900s (Young and Lopez 1999). No resident fish populations reside in the intermittent sections of the river. Nonnative fishes in the lower 14km include channel catfish, common carp, fathead minnow, and red shiner. Beaver are present in the headwaters of the LCR where their preferred tree species (alders, cottonwoods, willows) occur, but are rarely encountered in the lower region. Muskrats are also found in the headwater system.

Ecosystem Processes

Although the LCR is one of the longest intermittent streams in North America, studies on ecological processes such as primary and secondary production, autochthonous versus allochthonous carbon, and autotrophy versus heterotrophy have received virtually no attention. However, based on the limited riparian vegetation along much of the river in combination with high suspended sediment loads and unstable channel substrates, one would predict an autochthonous system dominated by cyanobacteria and diatoms, with limited external energy inputs. Aquatic macrophytes are typically lacking due to high suspended sediment loads and unstable channels.

The interrupted periods of flow, standing pools, and dry riverbed, along with the general "flashy" nature of the LCR, are instrumental in structuring the aquatic communities within the channel and along the riparian zone. Conditions along the river corridor change from torrential flows to standing or no water in a matter of days, with associated rapid swings in salinity and water temperature. This harsh, flashy environment is characterized not only by temperature, moisture, and salinity extremes, but also by high levels of ultraviolet radiation during periods of low water. Hyporheic communities are poorly represented in the LCR except in the headwaters, due to the high degree of embeddedness throughout much of the river corridor.

Although the lower 21 km of the LCR are perennial, the high concentrations of dissolved CO₂ emitted from the alkaline springs along the limestone walls, along with stochastic floods, greatly reduce overall biomass and species richness. As high concentrations of dissolved CO₂ degas from the water with exposure to the atmosphere and aggressive photosynthesis, carbonate precipitates on aquatic vegetation and invertebrates and interferes with photosynthesis, respiration, and general metabolism.

The intermittent nature of the LCR along a gradient of harsh, environmental conditions provides an open opportunity to study the strategies of organisms under a variety of extreme conditions and the role of ephemeral systems as evolutionary loci in aquatic ecosystems. It also provides an opportunity to compare genetic relationships within fragmented populations. A recent study has shown that the threatened and endangered Little Colorado spinedace population in the perennial upper reaches of the LCR is genetically different from disjunct populations in north-flowing tributaries joining the LCR that are separated by intermittent flows some 200 km downstream (Greenberg 1999). The loss of connectivity in intermittent streams such as the LCR and long dispersal distances across arid landscapes in the Southwest contribute to greater genetic variation within populations.

Human Impacts and Special Features

The LCR basin was chosen as the first watershed-based fisheries management program in Arizona, in part because it contains several indigenous fishes, four of which are listed under the Endangered Species Act (Young and Lopez 1999). The upper headwaters of the LCR were recommended as an important site for the conservation of freshwater biodiversity in North America by the World Wildlife Fund (Abell et al. 2000), and the mouth of the LCR is a major spawning reach for the displaced humpback chub (Douglas and Marsh 1996).

There is concern regarding the effects that groundwater development will have on surface-water resources. For example, the LCR basin has the dubious distinction of having three of the four coal-burning power plants in Arizona. These facilities draw heavily on groundwater and greatly influence discharges from the more than 900 isolated desert springs along the river corridor (L. E. Stevens, personal communication). The recent applications to double the number of power plants within Arizona will potentially further impact these groundwater

resources. In addition, agriculture in localized regions continues to contribute to alterations in the LCR system.

The entire Colorado River freshwater ecoregion, which includes the LCR basin, has a critical conservation status (Abell et al. 2000). Between 50% and 89% of the catchment has been altered, with a very high proportion of the original habitat fragmented and a very high occurrence of nonnative species. Further degradation will occur without aggressive conservation of these varied and dynamic arid fluvial systems.

GILA RIVER

Three major tributaries (East, West, and Middle forks) arise at ~3100 m asl from the Mogollon, Black, and Pinos Altos mountains to form the main-stem Gila (HEE-luh) River at about 1750 m asl in the Gila Wilderness Area in southwestern New Mexico (Fig. 11.7). The river flows south in New Mexico for ~190 km and then enters Arizona near Duncan at an elevation of 1325 m asl. The river goes underground at Verdin, New Mexico, and reemerges 8 km downstream near Duncan. From Duncan, the river meanders westward for about 770 km through grasslands, scrublands, the northern edge of the Chihuahuan Desert, and much of the Sonoran Desert until it reaches the Colorado near Yuma, Arizona, at an elevation of ~50 m asl (Fig. 11.21).

The Salt River is a major tributary of the Gila and drains much of the higher elevations to the northeast via the White and Black rivers and parts of the Mogollon Rim by Tonto Creek. The Verde River also flows into the Salt and delivers water from the rim country in central Arizona into the Gila River (see Fig. 11.21). Much of this water is utilized by metropolitan Phoenix.

Like the Colorado River, the Gila River basin is divided into an upper and lower basin at the confluence with the Salt River. Today, nearly all tributaries in the lower basin are intermittent. Only the upper 500 km of river corridor is perennial with either unregulated or regulated flows. The remainder of the river corridor in the lower basin has been intermittent since the closure of Coolidge Dam (San Carlos Lake) in 1928 and the expansion of agriculture and rapid growth of metropolitan Phoenix. Coolidge Dam was constructed to control the periodic heavy floods from snowmelt in the higher elevations of New Mexico.

The name “Gila” originated from the Yuma Indians, who referred to the stream flowing into the

FIGURE 11.7 Upper Gila River at the Gila Preserve, Grant County, New Mexico (PHOTO BY D. M. MERRITT).

Colorado River as “Hahquahsael” (McNamee 1998). Spanish soldiers shortened the name to “Xila,” which ultimately became Gila. The upper corridor of the Gila River in New Mexico is rich in Native American culture. The area is located in the Gila National Wilderness, lands that conservationist Aldo Leopold helped establish in 1924. The Mogollon and Anasazi cultures occupied the region as early as 2200 years ago and likely abandoned the area starting in the thirteenth century due to drying southwestern climates. Evidence of the Mogollon culture can be found at the Gila Cliff Dwellings National Monument, New Mexico. Several Native American tribes, including the Mogollon, Anasazi, San Carlos, Gila, and Yuma, have utilized the Gila River drainage for centuries.

A fur trader by the name of Ewing Young trapped along the Salt and Verde rivers and was the first Anglo American to explore the Gila to its mouth in the early 1820s (Trimble 1989). In the 1850s, army personnel explored and documented the flora and fauna along the Gila River corridor. The first important gold discovery along the Gila came ~30 km east of Yuma, Arizona, in 1858.

Prior to the arrival of Anglo Americans, the Gila River normally flowed to its mouth as a wide, shallow stream, and river float trips were occasionally conducted on the river. In fact, Lieutenant William H. Emory made the first scientific survey of the Gila River in 1870 and reported its flow as about one-half the Colorado River at their confluence (Fradkin 1981).

Physiology, Climate, and Land Use

The Gila River basin lies mostly in the Basin and Range (BR) physiographic province and flows primarily in a westerly direction from its headwaters in New Mexico to its convergence with the Colorado River near Yuma (see Fig. 11.21). The Gila begins in the Arizona Mountains Forests terrestrial ecoregion and flows through sections of the Madrean Sky Island Montane Forests and Chihuahuan Desert ecoregions and finally through much of the Sonoran Desert ecoregion.

Quaking aspens and spruce/fir occur in the upper watershed (>2400 m asl) of the Gila River. The

vegetation at the intermediate elevations (2400 to ~2000m asl) include mixed conifer and alligator juniper, pinyon pine, ponderosa pine, and scrub oak between 2000 and ~1200m asl (Brown 1994). The desert vegetation (<1000m asl) throughout much of the upper and lower Gila basin is dominated by creosote bush, desert saltbush, ragweed, screwbean, and assorted Cactaceae and Fouquieriaceae. The non-native cheat grass has displaced much of the native bunch grasses of the Gila River basin.

The climate of the basin is strongly affected by convective storms that originate in the Gulf of Mexico and the Gulf of California, and cyclonic storms that originate over the Pacific Ocean deliver most of the precipitation throughout the Gila River corridor in the summer. Precipitation and temperatures are highly variable due to the variations in altitude throughout the basin. Mean monthly precipitation for the basin ranges from 0.5 cm/mo during April and May to 4.4 cm during July (see Fig. 11.22). Average rainfall in the headwaters is over 55 cm/yr, with highs of around 9 cm during the summer monsoons in July and August (Brown 1994). Total rainfall in the remaining basin is lower, averaging <15 cm/yr, with nearly 60% of the precipitation falling in the late summer. Precipitation at the mouth of the Gila River near Yuma is <2 cm/yr, one of the most arid regions in North America. Mean monthly temperatures for the basin range from 27°C in July and fall to <5°C in December and range from <-10°C to 26°C in the higher elevations and 5°C to 39°C in the lower elevations (see Fig. 11.22). Diurnal temperature variations of 17°C or more are characteristic of the arid regions and daily high temperatures near the mouth of the Gila can exceed 45°C. Annual evaporation rates range from <100 cm in the higher elevations to >170 cm in the lower elevations.

Eight of the fifteen Indian tribes in Arizona live in some part of the Gila River basin and use the land for fishing and/or agriculture. In addition, many regions in the drainage basin have been under heavy agriculture, ranching, mining, flood control, and municipal development, which have placed heavy demands on the river for well over a century (Fradkin 1981). Crops in the area include cotton, alfalfa, pecans, citrus, wheat, and winter vegetables. In the late 1590s, Spanish ranchers drove cattle and churro sheep into the Gila drainage, where the native tall-grasses were reported to stand as high as a man on horseback (McNamee 1994). As a result, a third of the Southwest's grazing land is now severely desertified: Permanent streams have been degraded, their banks collapsed by cattle, their waters contaminated

by defecation, their topsoils reduced through erosion, and their soils compacted from passing cattle, and there has been an invasion of many nonnative species (McNamee 1994). Arizona's crop farming in the late 1800s essentially drained the water from the middle and lower Gila River. By 1920, over 80,000 ha along the Salt River was planted in cotton. Mines sprouted all over the Gila basin in the 1850s, and by 1870 there were ~6500 mining operations within the basin extracting a variety of minerals, including gold, silver, lead, zinc, manganese, molybdenum, and copper (McNamee 1994). Mining still occurs today in the "Copper Basin" alongside the Gila River in the vicinity of Globe and Clifton, Arizona.

Dense urban areas are generally lacking throughout most of the basin. Major communities in the upper basin include Safford and San Carlos, each with <10,000 people, and in the lower basin Yuma has a population of over 100,000 people. However, the rapid growth of the "Valley of the Sun" in metropolitan Phoenix, with over 2 million people, and metropolitan Tucson, with well over half a million people, has played a major role in the fate of the Gila River, with additional impacts yet to come. There are ~25 people/km² in the entire basin, but over 6500 people/km² are localized in the region of metropolitan Phoenix.

River Geomorphology, Hydrology, and Chemistry

The catchment basin in the perennial corridor of the river drains approximately 47,000 km², of which 13,274 km² is below Coolidge Dam (Pope et al. 1998). The entire 960 km of river has a catchment basin of about 149,832 km², or nearly half the area of Arizona. Less than 7% of the Gila River catchment is in New Mexico. Over 80% of the Gila River corridor meanders through desert scrublands. The Gila River is considered a 5th order stream, with an average gradient along the entire 960 km river corridor of ~3.2 m/km.

The upper 250 km of the Gila main stem consists of riffle/runs and associated pools. Much of the remainder of the river channel is composed of fine sediments and patchy hard substrates, with a high degree of channel embeddedness. Channel width in the upper 150 km of the main stem ranges from 2 to 6 m during base flow, whereas the floodplain in the lower corridor may extend to over 0.5 km wide.

The principal south-flowing tributaries into the Gila River are the San Francisco, San Carlos, and Salt/Verde rivers and the ephemeral Aqua Fria and

Hassayampa rivers; the San Pedro along with the ephemeral San Simon and Santa Cruz tributaries flow north. Prior to the early 1900s these rivers combined carried up to 4.9 billion m³ of water annually (McNamee 1998). During the last 50 years these tributaries have delivered <20% of that amount of water to the Gila River due to upstream storage reservoirs and irrigation diversions for agriculture and mining. The San Pedro now stands as the last surviving desert river without dams and with yearly rejuvenating monsoonal flooding during August and September that contributes a major portion of the unregulated flow below Coolidge Dam.

Runoff throughout much of the Gila basin is very low due to high mean annual evapotranspiration (>150cm) and low mean annual precipitation (24.7cm; see Fig. 11.22). Mean monthly runoff ranges from a high of 0.2cm in January to a low of ≤0.02cm during June and July for the drainage basin above Coolidge Dam. These values are more representative of the basin before the extensive impact of human extractions and regulation below the dam. Runoff values near the mouth are much lower today.

Since closure of Coolidge Dam (San Carlos Reservoir), annual mean streamflow has averaged less than 10m³/s, or less than half that prior to the placement of the dam. There are currently many demands for water in the semiarid regions above Coolidge Dam, including diversions for irrigation (about 33,000ha irrigated land), metallurgical treatment of ore, and municipal water supplies.

In addition to Coolidge Dam, there are several downstream earthen dams, the largest of which are Gillespie and Painted Rock. Painted Rock Reservoir (nearly 3.1 billion m³) was built in 1959 for flood control. The reservoir is usually dry but fills about every six to eight years from floods in the upper catchment (Pope et al. 1998). Floods deliver intermittent flows of up to 1400m³/s above the dam, and have exceeded 170m³/s about every 5 years over the last 50 years. The river channel above and below the dam is dry for most of the year because of transbasin diversions, storage reservoirs, power developments, groundwater discharge, diversions for irrigation, and municipal and industrial uses.

The last time the Gila River flowed from headwaters to the confluence with the Colorado River was during the 1992–1993 El Niño storms in the mountains of New Mexico, when flows averaged 185m³/s near the mouth of the Gila. Annual mean streamflows have gradually declined over the past 150 years. Before settlement of the Gila River basin, maximum runoff occurred in the winter, with flows

up to 1500m³/s (Sykes 1937). Annual mean streamflow in the Gila was over 40m³/s near its mouth in the early 1900s but has averaged <6m³/s over the last 75 years, most of which is recharged water from irrigation and municipalities (USGS 2004a <http://water.usgs.gov/public/nasqan>).

The headwaters of the Gila River, as well as base flows in the perennial river corridor in the upper basin, are relatively clear (suspended sediments <5mg/L), have low levels of solutes (≤1000μS/cm), and are dominated by CaCO₃ salts (Earl and Blinn 2003). In contrast, base flows in the lower basin are frequently turbid, with flows carrying suspended sediment loads >500mg/L during storm events, have high concentrations of solutes (≥4500μS/cm), and are dominated by NaCl salts (Pope et al. 1998). Also, a large proportion of the base flow in the lower basin contains wastewater from irrigated lands and from the Chandler treatment plant (Pope et al. 1998). Total nitrogen concentrations in the lower basin may exceed 10mg/L, compared to ≤0.05mg/L in the upper basin (Pope et al. 1998). Wildfires in the upper watershed also periodically deliver fire ash to the Gila River and elevate nutrients in the region by an order of magnitude during summer monsoons (Earl and Blinn 2003).

Alkalinity is <50mg/L as CaCO₃ in the upper Gila River and increases to >260mg/L by the time the river reaches the lower basin. pH varies along the corridor but averages about 8.3. Water temperatures normally range from 28°C in the summer to <5°C in the winter in the upper basin and >28°C in the summer to about 12°C in the winter in the lower basin (Earl 1999, Pope et al. 1998).

River Biodiversity and Ecology

The Gila River lies within the Gila freshwater ecoregion, which is considered continentally outstanding in terms of its biological distinctiveness (Abell et al. 2000). It shares many species with the Colorado ecoregion with which it connects, but has several distinctive species. In spite of this distinctiveness, the Gila main stem has received the least attention, from an ecological standpoint, of any large river in southwestern United States, even though it drains nearly half of the state of Arizona.

Algae and Cyanobacteria

The algal communities in the canopied headwaters of the East and West Fork tributaries in New Mexico are quite diverse, with benthic assemblages dominated by epilithic diatoms. In a recent four-year study, Earl and Blinn (2003) reported that *Achnan-*

thidium spp., *Cocconeis placentula*, *Cymbella affinis*, *Diatoma vulgare*, *Epithemia sorex*, *Fragilaria pinnata*, *Navicula cryptocephala*, *Nitzschia frustulum*, *Staurosira construens*, and *Synedra ulna* made up over 75% of the diatom taxa in the upper watershed.

One hundred kilometers downstream (Gila Bird Area of the Gila National Forest), in a reach that traverses through an intense agricultural region, diatom taxa were dominated by *Cocconeis pediculus*, *Navicula amphibia*, *N. frustulum*, and *N. subminuscula* (Earl and Blinn 2003). Filamentous green algae, namely *Cladophora glomerata* and zygnemataleans, occurred in wider, more exposed sections of the channel.

Plants

The riparian vegetation in the headwaters (>2500 m) of the Gila River consists of Bebb willow, narrowleaf cottonwood, and thin-leaf alder; whereas the vegetation along the river channel at elevations between 1500 and 2000 m is primarily Arizona sycamore, box elder, Fremont cottonwood, Gooding willow, and velvet ash. Much of the riparian community in the Sonoran Desert (<1500 m) consists of scattered mesquite bosques, commonly supported by floodplain groundwaters. Historically, mesquite bosques were common along ephemeral and intermittent stream channels, but they have been largely replaced by salt-cedar. Salt-cedar was imported into California by farmers to control erosion, but quickly invaded the lower Gila River basin. Today salt-cedar is found all the way into the headwaters of the Gila River.

Invertebrates

Riffle habitats in the same headwater sites described for algae were typically composed of the following insect categories: 32% mayflies, 26% caddisflies, 23% true flies (Diptera), 13% stoneflies, and 5% beetles (Earl and Blinn 2003). The most abundant mayflies in riffle habitats were *Choroterpes*, *Epeorus*, *Leptohyphes*, and *Serratella*. *Cheumatopsyche* and *Hydropsyche* were common caddisfly taxa, and chironomid midges and black flies made up most of the dipteran assemblage. Insect densities were typically higher in May and June compared to late summer and fall. Riffles averaged 524 animals/m² compared to 1954 animals/m² in pool habitats.

Total insect densities were comparable at the same downstream site used for algae; however, insect diversity was reduced. Insect proportions below the agricultural reach were 44% dipterans, 34%

mayflies, and 20% caddisflies in riffles (Earl and Blinn 2003). Stoneflies were absent at the lower site.

Vertebrates

Many native fishes in the Gila drainage are well adapted to the periodic flash flooding, heavy suspended sediment loads, and harsh conditions of the desert environment as described for the Little Colorado River. When stream channels stop flowing during the summer months, fishes move into standing pools that undergo dramatic diel physicochemical changes. Some fishes have been reported to survive in tiny volumes of water beneath mats of filamentous algae (Rinne and Minckley 1991).

The 14 native fishes presently found in the Gila River basin are represented by four families, including eight cyprinids (bonytail chub, Gila chub, headwater chub, roundtail chub, loach minnow, longfin dace, speckled dace, and spike dace), two catostomids (desert sucker and Sonora sucker), two salmonids (Apache trout and Gila trout), one cyprinidontoid (desert pupfish), and one poeciliid (Gila topminnow).

The desert sucker, spike dace, and Gila and Apache trout occur only in the headwater streams of the Gila River, whereas the Sonora sucker and speckled dace are widespread throughout the perennial sections of the Gila. The loach minnow, desert sucker, headwater chub, and Sonora sucker occur in the middle elevations of the Aravaipa and San Carlos tributaries of the Gila. Typically, native fishes predominate above the confluence of the San Francisco River in the upper basin, whereas nonnatives are the dominant fishes below. Historically, the Gila chub occurred only in the headwaters but is now restricted to the middle section of the Gila River. All native fishes are currently listed as either federally endangered or threatened except for longfin dace, desert sucker, and Sonora sucker, which are under review for a listed status.

Bonytail chub, Colorado pikeminnow, flannelmouth sucker, and razorback sucker have all been extirpated from the Gila River main stem. The last confirmed report for Colorado pikeminnow in the Gila River was in 1950. Pikeminnow were once abundant in the Gila and an important source of food for Native Americans along the river until the late 1800s. A dramatic reduction in numbers occurred shortly after the construction of Hoover Dam on the Colorado main stem in the early 1930s. Gila trout formerly occurred in the headwaters of the Gila and Verde rivers of the Gila River drainage, but they are now restricted to a few remote headwater

streams in New Mexico. Reasons for the extirpation and decline in these and other native fishes include regulated flow below dams, competition and predation by nonnative salmonids, hybridization with nonnatives, loss and degradation of habitat, and changes in water quality and quantity (Minckley and Deacon 1991, Rinne and Minckley 1991, Blinn et al. 1993).

Numerous nonnative fishes have been introduced and become established in the Gila River drainage, including black bullhead, black crappie, bluegill, brown trout, channel catfish, common carp, fathead minnow, flathead catfish, golden shiner, green sunfish, goldfish, guppy, largemouth bass, mosquitofish, Mozambique mouthbrooder, redear sunfish, red shiner, rainbow trout, Rio Grande killifish, Rio Grande sucker, sailfin molly, smallmouth bass, threadfin shad, and yellow bullhead. Yellow bass and white bass occur in reservoirs in the Gila basin.

Some of these nonnative fish species were introduced into canals and reservoirs in the lower Colorado River in the early or mid-1990s as sport or aquarium fishes and have migrated into the Gila River system. The Rio Grande sucker was recently introduced into the headwaters of the Gila River from the Rio Grande River in Texas (Rinne 1995). Sailfin mollies were introduced in 1952 and now occur throughout the lower Gila basin in canals and wastewater ponds. Mozambique mouthbreeders were introduced into the lower Colorado River in the early 1960s and presently occur in water refuges in the lower Gila River. Striped mullet moved into the lower reaches of the Gila River from the Gulf of California through the lower Colorado River and became landlocked in the brackish waters above diversion dams in the Gila River. It is now considered by some to be native to the lower Colorado River.

Beaver occur along upper sections of the Gila River where their preferred tree species (alders, cottonwoods, willows) occur, as do muskrat. The Chiricahua leopard frog and northern leopard frog have been reported from the higher elevations of the Gila River. The Ramsey Canyon leopard frog is found exclusively in the San Pedro River valley and the Rio Grande leopard frog has been inadvertently introduced into the lower Gila between Phoenix and Yuma. The lowland leopard frog has been extirpated from the lower Gila River.

Ecosystem Processes

Information on ecosystem processes is conspicuously lacking for the Gila River. However, like the LCR and other Sonoran Desert rivers, it is probable that much of the Gila River corridor is an autochtho-

nous system, depending on diatoms and cyanobacteria as organic energy sources, due to the limited woody vegetation along stream channels and the xeric landscape. Aquatic macrophytes are typically absent due to the high suspended sediment loads and unstable channels.

Although the main stem has received limited attention, two small tributaries, Aravaipa and Sycamore creeks, have been well studied. Aravaipa Creek is a tributary to the San Pedro River and Sycamore Creek is a tributary to the Verde River, each located in semiarid mountainous terrain. Studies have shown that flood-related disturbances and succession between disturbance events contribute greatly to the structure of these desert streams (Fisher and Grimm 1988). Due to intermittent flooding, succession is a continual process. Floods tend to thoroughly scour stream channels, which is followed by high primary ($3.3 \text{ g C m}^{-2} \text{ d}^{-1}$) and secondary ($135 \text{ g dry mass m}^{-2} \text{ yr}^{-1}$) production (Fisher 1995). Hydrologic linkage between surface and hyporheic subsystems increases ecosystem stability following flash floods (Valett et al. 1994).

Wildfires frequently occur in the higher elevations of the Gila Wilderness Area in New Mexico during summer electrical storms and deliver large quantities of fire ash to the Gila. Earl and Blinn (2003) reported a shift in diatom composition to smaller, more adnate forms, namely *Achnantheidium* spp. and *Cocconeis* spp., as a result of fire ash delivery. They also reported that stream drift was increased by tenfold and insect densities were reduced by nearly two orders of magnitude following the entry of coarse fire ash into streams.

Human Impacts and Special Features

The early development of the American Southwest has been largely at the expense of the Gila River basin. Early American Indians and Anglo settlers used its drainages as corridors to explore regions in the Southwest and its once perennial waters as a fishery and for agriculture. It has a rich history in American Indian culture from its headwaters to its mouth. The Gila River drainage continues to serve as an oasis for numerous desert animals that rely on its waters for food and protection. Unfortunately, few studies have been conducted on the ecological processes in this desert river, even though tributaries like the San Pedro River, which originates in Mexico, have been given special status as biodiversity reserves. Even the San Pedro is now threatened by the expansion of Fort Huachuca, Arizona.

The basin of the Gila River has been greatly changed by agriculture, ranching, mining, groundwater pumping, flood control, and municipal development for well over a century. Historically, sections of the Gila River were made up of large marshy areas and oxbow lakes that would become several kilometers wide in flood (Rinne 1994). The natural waters of the Gila no longer reach their historical mouth at the Colorado River but are contaminated by agriculture, mining, and municipal activities. By the early 1900s the surface flow was used up before the halfway mark of the river corridor at Coolidge Dam; now only flash floods and return flows from irrigation fields deliver intermittent water to the Colorado River. In the last three decades groundwater levels have dropped by nearly 25 m in parts of the lower basin (McNamee 1998).

The large zooplankter *Daphnia lumholtzi* has been introduced into a number of warmwater lakes, including Saguaro, Bartlett, Roosevelt, Canyon, and Apache reservoirs. This crustacean undergoes strong seasonal cyclomorphosis to avoid fish predation and may potentially alter the zooplankton structure of the reservoir systems (Dobberfuhr and Elser 2002).

Major cities, such as Phoenix, have been highly dependent upon the Gila River drainage for over a century and the groundwater beneath agricultural lands carries toxic agricultural pesticides. Sections of the lower Gila have been placed on the Environmental Protection Agency Superfund cleanup roster (McNamee 1998). As a result, many native fishes have disappeared from the Gila River and the cottonwoods and willows that once lined the river are generally gone. In spite of these enormous human impacts, the Gila River drainage still serves as a critical habitat for nearly all desert animals. Continued depletion of water will lead to further reduction in numbers of desert dwellers and perhaps to their extinction.

ADDITIONAL RIVERS

The Gunnison River begins as small streams in the high mountains of central Colorado (>4200 m asl) and flows to the west and north (Fig. 11.23). The winters in the upper Gunnison Basin are extremely cold (record minimum -42.7°C). As headwater streams drop rapidly through spruce and pine forests, they converge to create the East and Taylor rivers, which themselves unite at Almont to form the Gunnison River. As the river flows southwesterly toward

and through Gunnison, it picks up Ohio Creek from the north, Tomichi Creek from the east, and Cebolla Creek from the south. The natural flow of the upper Gunnison is influenced by transbasin diversions to the eastern slope of the Rockies and by Taylor Reservoir on the Taylor River. The main stem below Gunnison is heavily regulated by three main-stem dams of the Aspinall Unit (Blue Mesa, Morrow Point, and Crystal). During the irrigation season, about 16% of the annual runoff is diverted via the East Portal to the southwest near Montrose in the heavily agricultural Uncompahgre River basin. Below this diversion the Gunnison flows through a spectacular chasm, the Black Canyon of Gunnison National Park. The river winds north until its confluence with the North Fork, at which time it turns west to Delta, where it is joined by the Uncompahgre River, which carries high selenium loads from irrigation return water. The Gunnison then flows to the northwest until its confluence with the upper Colorado at Grand Junction (~1600 m asl) (Fig. 11.8).

FIGURE 11.8 Gunnison River above Whitewater, Colorado (PHOTO BY TIM PALMER).

FIGURE 11.9 Virgin River above Virgin, Utah (PHOTO BY TIM PALMER).

The San Juan is the river of the Four Corners area, originating in extreme southwestern Colorado and then arcing south and west through New Mexico before flowing briefly back through Colorado to the northwest into Utah (Fig. 11.25). Almost all of its flow is contributed by snowmelt runoff from permanent streams in southwestern Colorado. Heading in the San Juan Mountains at ~4000 m asl, the river flows southerly through Pagosa Springs and then into the Navajo Reservoir on the Colorado–New Mexico state line, where it is joined by the Piedro River. Below the reservoir the San Juan flows westward to Farmington, where it receives two major tributaries, the Animas and La Plata rivers, flowing southward out of Colorado across the Southern Ute Indian reservation. The river valleys of all of these rivers in this area are arid and extensively developed via irrigation withdrawals. The San Juan enters the Navajo Indian reservation near Shiprock, New Mexico, and then flows toward the Four Corners, where it briefly crosses Southern Ute Indian reservation lands in

Colorado before reentering Navajo lands in southeastern Utah. For the last ~150 km of its length the San Juan continues westerly through desert lands, eventually entering the impounded Colorado River at Lake Powell at ~1128 m asl (Fig. 11.1).

The Virgin River begins at about ~3000 m asl and drains the edge of the Markagunt Plateau. The Virgin flows southwesterly for 300 km along the western boundary of the Colorado Plateau through southwestern Utah, northwestern Arizona, and southeastern Nevada until it enters Lake Mead, Nevada, at about 365 m asl (Fig. 11.27). Lake Mead currently floods the lower 50 km of the Virgin. The terrain along the river corridor changes from steep-walled, mountainous canyons and sheer gradients near Zion National Park, Utah, to Colorado Plateau shrublands with broad, open canyons and low stream gradients and on to the arid Mohave Desert as it approaches Lake Mead (Fig. 11.9). A series of channel springs (Pah Tempe Springs) near La Verkin, Utah, have a major influence on downstream water quality. The

springs contribute warm water (38°C to 42°C) at a rate of about 18m³/min, and a salinity of about 9650mg/L. Three native fishes (woundfin, Virgin spinedace, and Virgin River chub) are restricted to the Virgin River drainage and all have received some form of federal protection.

Three intermittent streams, the Big Sandy River, Santa Maria River, and Date Creek, join to form the Bill Williams River at ~295m asl. Alamo Dam was built at the head of the Bill Williams in 1968 (Fig. 11.29). The Bill Williams flows westerly through a series of wetlands and backwaters that are periodically flooded from Alamo Dam. Annual mean discharge (4m³/s) since the closure of the dam has been similar to before closure. A maximum flow of 1845m³/s was recorded during August 1951 following a major summer storm. The lower 16km of the river runs through the Bill Williams River National Wildlife Refuge before converging with the Colorado. The riparian corridor through the refuge is 10°C to 15°C cooler in the summer than nearby desert communities due to high evapotranspiration rates in the dense riparian vegetation. The refuge has the distinction of being one of a few reaches of southwestern rivers that still maintains a naturally regenerating riparian forest with most of its original communities intact. The periodic flood releases through the narrow channel from January through March are largely responsible for these conditions. The refuge serves as a sanctuary of plants and animals that were once present in the lower Colorado but are now found only on the refuge.

The Black River begins in the White Mountains in eastern Arizona at over 2700m asl and flows onto semiarid grasslands (Fig. 11.10, Fig. 11.31). Two major headwater streams (West and East forks) flow south and eventually form the Black River below Buffalo Crossing. The headwaters contain some of the most natural riparian communities remaining in Arizona. From this point the Black flows through sections of the Bear Wallow Wilderness Area, a wild and scenic isolated mountain wilderness. The Black continues to flow southwesterly along the borders of the Fort Apache and San Carlos Indian reservations until it meets the White River at ~1300m asl to form the Salt River. The Black has no major diversions except for three small reservoirs (Big Lake, Sierra Blanca Lake, and Crescent Lake) in the upper headwaters. The cool, clear, nearly unaltered waters in the higher elevations support one of the most diverse aquatic insect assemblages in Arizona, with over 30 species of caddisflies representing 22 genera reported at one site (Three-Forks) on the East Fork. These tribu-

FIGURE 11.10 Black River at Wildcat Bridge, Arizona (PHOTO BY D. BLINN).

taries also include some of the best sport fisheries in Arizona.

The Verde River begins at the headwaters of the intermittent Big Chino Wash, Arizona, at ~1325 m asl and flows for over 300 km through the Verde Valley (Fig. 11.33). Presently, the upper 60 km are relatively undisturbed. However, developers have proposed a recreational community near the springs that supply nearly 80% of the upper river's flow. The Verde flows easterly to Clarkdale, southeasterly to Camp Verde, and then arches sharply south through semiarid lands until it joins the Salt River near Phoenix at ~400 m asl (Fig. 11.11). Mean evaporation rates within the basin range from about 120 to 160 cm/yr. Six primary tributaries, including Sycamore Creek, Oak Creek, Wet Beaver, West Clear, Fossil Creek, and the East Verde River, deliver water to the Verde, each of which is <2.5 m³/s at its confluence. Oak Creek supports one of the most diverse aquatic insect assemblages in Arizona and Fossil Creek has active travertine spring deposits. Nonnative virile crayfish have greatly restructured the invertebrate community in the

FIGURE 11.11 Verde River below Camp Verde, Arizona (PHOTO BY TIM PALMER).

middle corridor of the Verde River. There are two main-stem dams, Horseshoe and Bartlett, ~50 km above the confluence with the Salt River that affect the hydrograph below; discharges average $<17 \text{ m}^3/\text{s}$ compared to $>23 \text{ m}^3/\text{s}$ prior to their completion. A 65 km section of the Verde between Camp Verde and Horseshoe Dam has been designated as a National Wild and Scenic River. The river contains one of few native fish communities in Arizona.

The Salt River forms at the junction of the White and Black rivers at ~1300 m asl and flows through Salt River Canyon in central Arizona (Fig. 11.35). The Verde River joins the Salt on the Fort

McDowell reservation and contributes an average discharge of about $17 \text{ m}^3/\text{s}$. Air temperatures along the Salt range from 46°C in the lower valleys in the summer to -18°C during winter nights in the mountains. Annual precipitation ranges from 25 cm in the valleys to 64 cm in the mountains. Annual evapotranspiration approaches 178 cm. The first 200 km is unimpeded by dams, but the river is then fragmented by Theodore Roosevelt Dam and its lake, Horse Mesa Dam (Apache Lake), Mormon Flat Dam (Canyon Lake), and Stewart Memorial Dam (Saguaro Lake). Water stored in these reservoirs is diverted to the Granite Reef Diversion by the Salt

FIGURE 11.12 Salt River near Phoenix, Arizona (PHOTO BY C. E. CUSHING).

River Project and used by metropolitan Phoenix. Historically, the Salt ran through the present metropolitan Phoenix area and joined the Gila River ~70 km southwest of Phoenix (Fig. 11.12). Estimates show that annual mean discharge at the site of Roosevelt Dam were ~60 m³/s between 1888 and 1913. Since then annual discharge has been <25 m³/s. When the Salt finally reaches the Gila, even with contributions from the Verde, little water is left except for that redirected from irrigation and municipal canals (USGS 2004a <http://water.usgs.gov/public/nasqan>). Water in sections of the Salt can reach >5000 μS/cm at base flow due to evaporite deposits on soils, high evapo-

ration rates on desert reservoirs, and recharged water from irrigation activities.

ACKNOWLEDGMENTS

We thank the following people for their contributions to the preparation of this chapter: Robert J. Hart and Cheryl K. Partin for climatological, hydrological, and water-quality information on the lower basin, and Kathleen Blair, Paul Boucher, Owen T. Gorman, Michael Lopez, Charles O. Minckley, John N. Rinne, Phil C. Rosen, Patti Spindler, Michael J. Sredl, David E. Ruiter, Mark J. Wetzler, Eric C. Dinger, and Michael Yard for general information on the

biota and fisheries throughout the lower basin. Mark R. Vinson provided information on rivers in the upper basin, James E. Deacon provided information on the Virgin River, and David Merritt assisted with botanical taxonomy and color photographs. Emma Benenati and David Cooper also provided color photographs, and Kirsten Rowell provided information on the Colorado River delta. Finally, we would like to give special thanks to Julian Older for providing general library research on the upper basin. Dana Franz also assisted with general library research on the upper basin. We also thank Joseph Shannon for insightful discussions of the Colorado River basin and a review of an earlier draft of the chapter, and the editors, Arthur Benke and Colbert E. Cushing, for their valuable comments on this chapter.

FIGURE 11.14 Mean monthly air temperature, precipitation, and runoff for the Colorado River basin.

COLORADO RIVER

Relief: ~4100 m

Basin area: 642,000 km²

Mean discharge: 550 m³/s (virgin) ~40 m³/s (present)

River order: 6

Mean annual precipitation: 22.1 cm (upper basin), 10.6 cm (lower basin)

Mean air temperature: 14°C (upper basin), 21.1°C (lower basin)

Mean water temperature: 11°C (upper basin), 21°C (lower basin)

Physiographic provinces: Middle Rocky Mountains (MR), Southern Rocky Mountains (SR), Wyoming Basin (WB), Colorado Plateaus (CO), Basin and Range (BR), Baja California (BC)

Biomes: Tundra, Temperate Mountain Forest, Desert

Freshwater ecoregion: Colorado

Terrestrial ecoregions: 9 ecoregions (see text)

Number of fish species: ~75 to 85 (42 native)

Number of endangered species: 16 fishes

Major fishes: bonytail chub, brook trout, brown trout, channel catfish, common carp, fathead minnow, flannelmouth sucker, humpback chub, longfin dace, rainbow trout, razorback sucker, red shiner, roundtail chub, speckled dace

Major other aquatic vertebrates: American coot, American widgeon, Arizona toad, beaver, bullfrog, Great Basin spadefoot toad, great blue heron, mallard, muskrat, northern leopard frog, snowy egret, Sonoran mud turtle, Woodhouse toad

Major benthic invertebrates: mayflies (*Baetis*, *Drunella*, *Ephemerella*, *Epeorus*, *Heptagenia*, *Paraleptophlebia*, *Traverella*, *Tricorythodes*), stoneflies (*Capnia*, *Paraleuctra*, *Suwallia*), caddisflies (*Ceratopsyche*, *Chimarra*, *Hydropsyche*, *Hydroptila*, *Ochrotrichia*, *Oecetis*), chironomid midges (*Eukiefferiella*, *Orthocladius*), snails (*Lymnaea*, *Physa*)

Nonnative species: Asiatic clam, bullfrog, >30 fishes carp, channel catfish, rainbow trout, threadfin shad, *Daphnia lumholtzi*, *Gammarus lacustris*, New Zealand mudsnail, red swamp crayfish, saltcedar, virile crayfish, water fern

Major riparian plants: Arizona sycamore, bulrush, coyote willow, Fremont cottonwood, gamble oak, narrowleaf cottonwood, saltcedar, southern cattail, velvet mesquite

Special features: large, highly regulated desert river; drains nearly 8% of United States; most native fishes are threatened; many nonnative species; runs through Grand Canyon

Fragmentation: over 40 flow-regulation structures, 4 large main-stem reservoirs and numerous diversions; one of most regulated rivers in world

Water quality: pH = 8.3, alkalinity = 105 mg/L as CaCO₃, NO₃-N = 0.12 mg/L, PO₄-P = 0.04 mg/L, specific conductance = 1000 μS/cm, suspended sediments = 28 mg/L; some sections subject to mine contamination

Land use: 67% agriculture, 25% forest, 8% urban

Population density: 7 people/km²

Major information sources: Tyus et al. 1982, Stanford and Ward 1986, Marzolf 1991, Starnes 1995, Webb et al. 1999, Patrick 2000, Patten and Stevens 2001, Patten et al. 2001

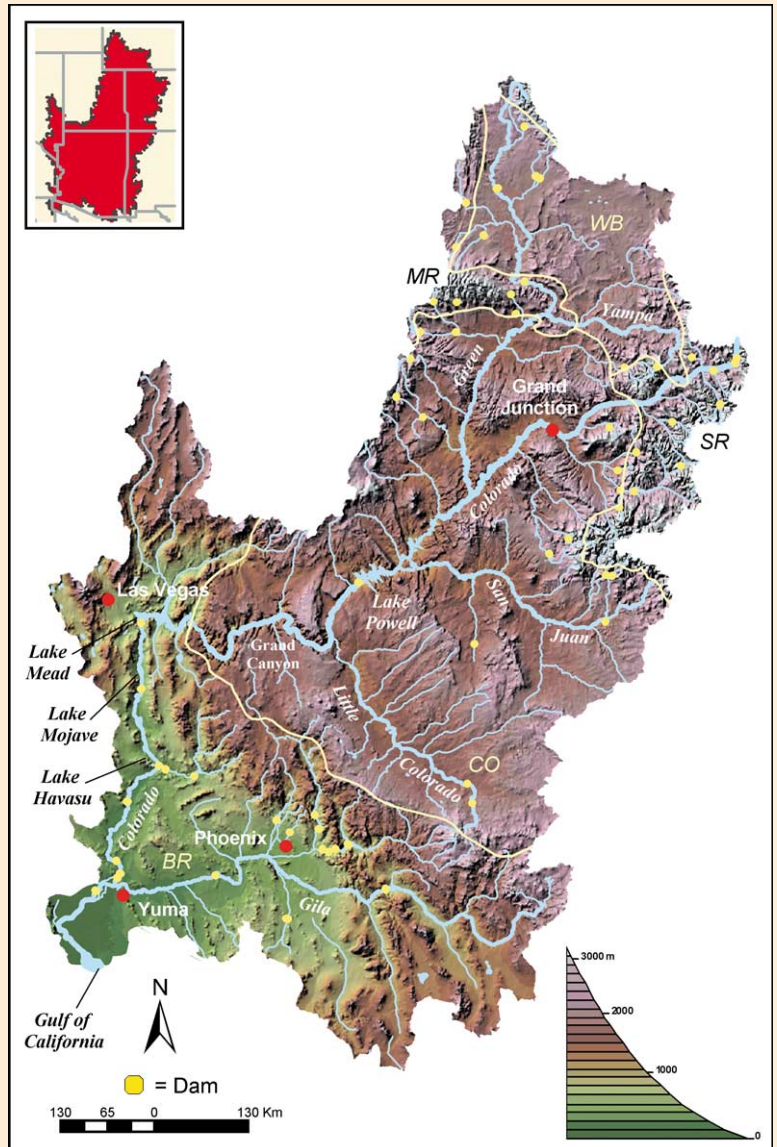

FIGURE 11.13 Map of the Colorado River basin. Physiographic provinces are separated by yellow lines.

FIGURE 11.16 Mean monthly air temperature, precipitation, and runoff for the Green River basin.

GREEN RIVER

Relief: ~2950 m

Basin area: 116,200 km²

Mean discharge: 172 m³/s

River order: 5

Mean annual precipitation: 31.9 cm

Mean air temperature: 6.3°C

Mean water temperature: 2°C to 14°C below Flaming Gorge Dam, 2°C to 25°C at Rkm 189

Physiographic provinces: Middle Rocky Mountains (MR), Wyoming Basin (WB), Southern Rocky Mountains (SR), Colorado Plateau (CO)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Colorado

Terrestrial ecoregions: Wyoming Basin Shrub Steppe, South Central Rockies Forests, Wasatch and Uinta Montane Forests, Colorado Plateau Shrublands

Number of fish species: 37 (12 native)

Number of endangered species: 3 fishes

Major fishes: bonytail chub, Colorado River cutthroat trout, Colorado pikeminnow, humpback chub, razorback sucker, roundtail chub, rainbow trout

Major other aquatic vertebrates: beaver, boreal western toad, Clark's grebe, muskrat, northern leopard frog, spadefoot toad, tiger salamander, white-faced ibis, whooping crane

Major benthic invertebrates: mayflies (*Baetis*, *Drunella*, *Ephemerella*, *Heptagenia*), stoneflies (*Arcynopteryx*, *Capnia*, *Hesperoperla*, *Taenionema*), caddisflies (*Brachycentrus*, *Helicopsyche*, *Hesperophylax*, *Hydroptila*, *Leucotrichia*, *Oecetis*, *Psychoglypha*, *Rhyacophila*), crustaceans (*Gammarus*, *Hyalella*, signal crayfish, virile crayfish)

Nonnative species: channel catfish, common carp, fathead minnow, rainbow trout, saltcedar, signal crayfish, virile crayfish

Major riparian plants: alkali sacaton, big sagebrush, black greasewood, Fremont cottonwood, saltcedar, saltgrass

Special features: large desert river; important habitat for endangered fishes indigenous to Colorado River system

Fragmentation: major reservoirs on main stem in upper basin (Flaming Gorge and Fontenelle); major tributaries extensively dammed or diverted, except Yampa River

Water quality: pH = 8.3, alkalinity = 165 mg/L as CaCO₃, NO₃-N = 0.04 mg/L, PO₄-P = <0.001 mg/L, specific conductance = 585 μS/cm, suspended sediment = 900 mg/L

Land use: 80% agriculture, 15% forest, 5% urban

Population density: <0.5 people/km²

Major information sources: Woodbury 1963, Wolz and Shiozawa 1995, Muth et al. 2000, Merritt and Cooper 2000, Vinson 2001

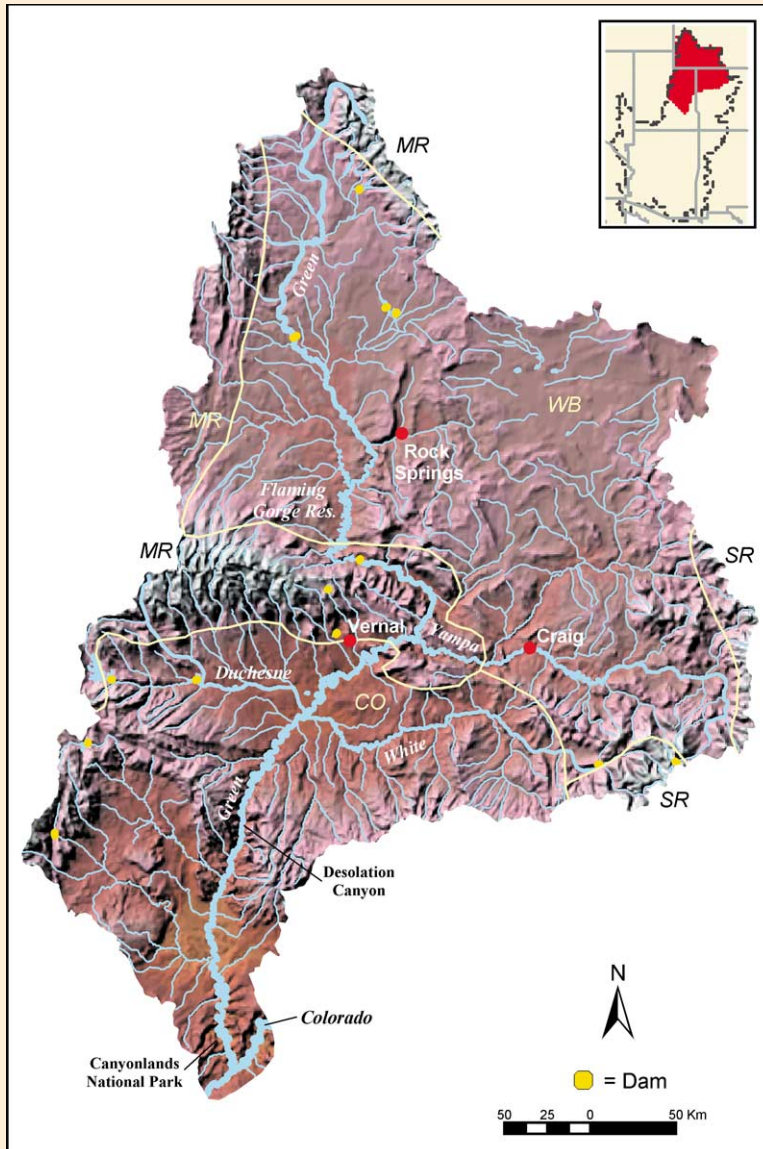

FIGURE 11.15 Map of the Green River basin. Physiographic provinces are separated by yellow lines.

FIGURE 11.17 Map of the Yampa River basin. Physiographic provinces are separated by yellow lines.

YAMPA RIVER

Relief: ~2276 m

Basin area: 24,595 km²

Mean discharge: 64 m³/s

River order: 4

Mean annual precipitation: 42.8 cm

Mean air temperature: 5.9°C

Mean water temperature: 9°C

Physiographic provinces: Southern Rocky Mountains (SR), Middle Rocky Mountains (MR), Wyoming Basin (WB)

Biomes: Tundra, Temperate Mountain Forest, Desert

Freshwater ecoregion: Colorado

Terrestrial ecoregions: Colorado Rockies Forests, Colorado Plateau Shrublands

Number of fish species: 30 (12 native)

Number of endangered species: 4 fishes

Major fishes: bluehead sucker, bonytail chub, channel catfish, Colorado pikeminnow, Colorado River cutthroat trout, flannelmouth sucker, green sunfish, humpback chub, mountain sucker, mountain whitefish, northern pike, razorback sucker, roundtail chub, speckled dace

Major other aquatic vertebrates: beaver, boreal western toad, Great Basin spadefoot toad, muskrat, northern leopard frog, river otter, wood frog

Major benthic invertebrates: mayflies (*Baetis*, *Choroterpes*, *Ephemerella*, *Heptagenia*, *Paraleptophlebia*, *Tricorythodes*, *Rhithrogena*, *Traverella*), stoneflies (*Alloperla*, *Isoperla*, *Pteronarcella*, *Pteronarcys*), caddisflies (*Cheumatopsyche*, *Helicopsyche*, *Hydropsyche*, *Lepidostoma*, *Oecetis*, *Polycentropus*), Coleoptera (*Optioservus*), crustaceans (*virile crayfish*)

Nonnative species: channel catfish, green sunfish, northern pike, saltcedar, virile crayfish

Major riparian plants: biennial sage, Canada bluegrass, coyote willow, foxtail, Fremont cottonwood, horseweed, slender wheatgrass, western wheatgrass

Special features: last remaining free-flowing river in upper Colorado Basin; montane, high plains, and canyon river with perennial flow; critical to recovery of endangered native fishes in upper basin

Fragmentation: minimal, small headwater dams and water abstraction ≤10% of annual flow

Water quality: pH = 8.4, alkalinity = 85 mg/L as CaCO₃, NO₃-N = 0.04 mg/L, PO₄-P = 0.005 mg/L, specific conductance = 500 μS/cm, suspended sediments = <500 mg/L near confluence with Green River

Land use: 65% agriculture, 30% forest, 5% urban

Population density: <0.5 people/km²

Major information sources: Woodbury 1963, Ames 1977, Tyus and Karp 1989, Muth et al. 2000, Merritt and Cooper 2000

FIGURE 11.18 Mean monthly air temperature, precipitation, and runoff for the Yampa River basin.

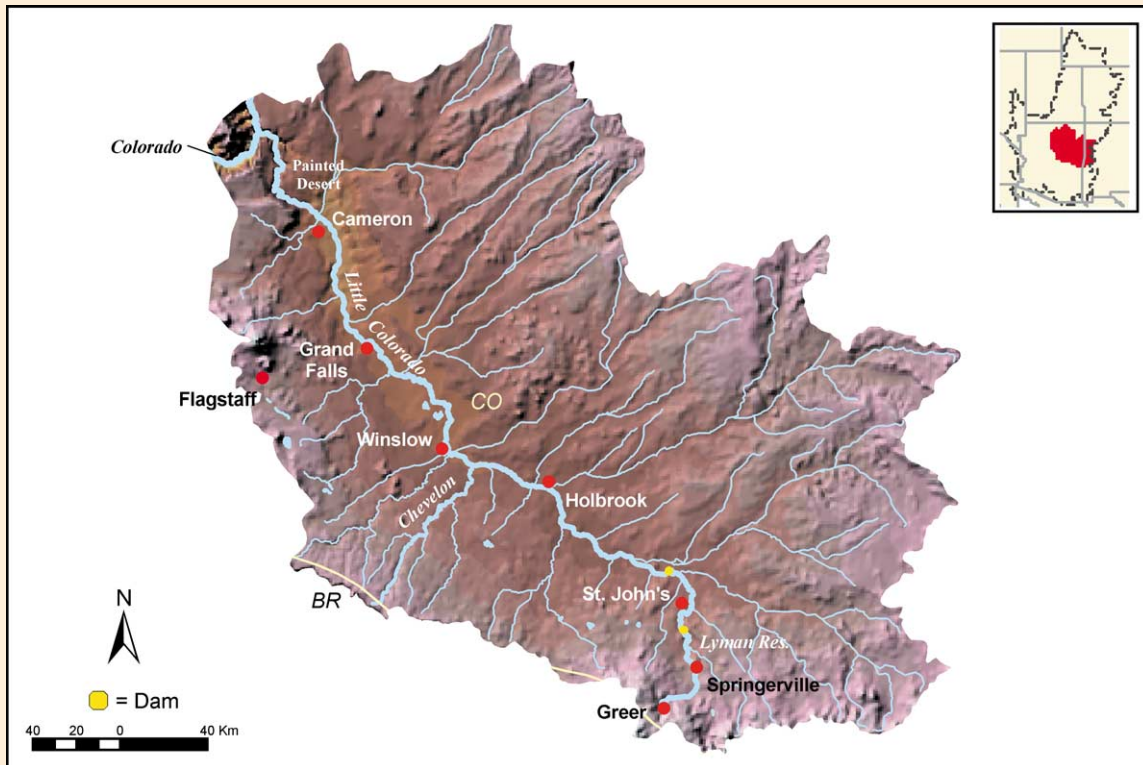

FIGURE 11.19 Map of the Little Colorado River basin. Physiographic provinces are separated by a yellow line.

LITTLE COLORADO RIVER

Relief: ~2600m
Basin area: ~69,000km²
Mean discharge: 6.5m³/s
River order: 4
Mean annual precipitation: 17.2cm
Mean air temperature: 13.5°C
Mean water temperature: 18°C
Physiographic province: Colorado Plateaus (CO)
Biomes: Temperate Mountain Forest, Desert
Freshwater ecoregion: Colorado
Terrestrial ecoregions: Arizona Mountains Forests, Colorado Plateau Shrublands
Number of fish species: 33 (9 native)
Number of endangered species: 2 fishes, 1 clam
Major fishes: Apache trout, bluehead sucker, brown trout, fathead minnow, flannelmouth sucker, green sunfish, humpback chub, Little Colorado River sucker, Little Colorado spinedace, rainbow trout, roundtail chub, speckled dace
Major other aquatic vertebrates: Arizona toad, beaver, bullfrog, Chiricahua leopard frog, great blue heron, belted kingfisher, mallard, muskrat, red-spotted toad, Sonoran mud turtle, striped chorus frog
Major benthic invertebrates: mayflies (*Baetis*, *Cinygmula*, *Drunella*, *Epeorus*, *Tricorythodes*), caddisflies (*Anabolia*, *Atopsyche*, *Cheumatopsyche*, *Glossosoma*, *Gumaga*, *Helicopsyche*, *Hesperophylax*, *Hydropsyche*, *Limnephilus*, *Oecetis*, *Oligophlebodes*, *Onocosmoecus*, *Polycentropus*, *Rhyacophila*), stoneflies (*Claassenia*, *Sweltsa*), crustaceans (virile crayfish) chironomid midges, black flies
Nonnative species: Asiatic clam, brown trout, bullfrog, rainbow trout, fathead minnow, green sunfish, saltcedar, virile crayfish
Major riparian plants: Bebb willow, bulrush, cattails, common reed, Goodding willow, thin-leaf alder, saltcedar
Special features: large, ephemeral desert river; river dry or pooled >60% of year; headwaters recommended for conservation by World Wildlife Fund
Fragmentation: no major dams but has Lyman Lake; Zion Reservoir used for flood control until 2000; numerous diversions
Water quality: pH = 8.3, alkalinity = 195 mg/L as CaCO₃, NO₃-N = 0.7 mg/L, PO₄-P = 0.03 mg/L, specific conductance = 2500 μS/cm (4500 μS/cm at confluence with Colorado River), suspended sediments = >500 mg/L
Land use: <1% agriculture, 15% forest, <5% urban, 55% Indian reservation, allotments, and trusts
Population density: 1.5 people/km²
Major information sources: Silvey et al. 1986, Young and Lopez 1999

FIGURE 11.20 Mean monthly air temperature, precipitation, and runoff for the Little Colorado River basin.

FIGURE 11.21 Map of the Gila River basin. Physiographic provinces are separated by a yellow line.

GILA RIVER

Relief: ~3050 m
 Basin area: ~149,832 km²
 Mean discharge: >40 m³/s (virgin), <6 m³/s present
 River order: 6
 Mean annual precipitation: 24.7 cm
 Mean air temperature: 15.2°C
 Mean water temperature: 21°C
 Physiographic provinces: Basin and Range (BR), Colorado Plateaus (CO)

Biomes: Temperate Mountain Forest, Desert
 Freshwater ecoregion: Gila
 Terrestrial ecoregions: Arizona Mountains Forests, Madrean Sky Islands Montane Forests, Chihuahuan Desert, Sonoran Desert

Number of fish species: 36 (19 native)
 Number of endangered species: 2 fishes

Major fishes: channel catfish, desert sucker, flathead catfish, loach minnow, longfin dace, roundtail chub, smallmouth bass, Sonora sucker, speckled dace, spike dace

Major other aquatic vertebrates: beaver, bullfrog, muskrat, Arizona toad, Chiricahua leopard frog, lowland leopard frog, Sonoran mud turtle, red-spotted toad, Sonoran Desert toad, Woodhouse toad

Major benthic invertebrates: mayflies (*Choroterpes*, *Epeorus*, *Ephemerella*, *Serratella*, *Thraulodes*, *Tricorythodes*, *Traverella*), caddisflies (*Cheumatopsyche*, *Chimarra*, *Helicopsyche*, *Hydropsyche*, *Polycentropus*, *Oecetis*, *Protoptila*, *Ochrotrichia*, *Smicridea*, *Zumatrichia*), hellgrammites (*Corydalus*), chironomid midges, black flies, crustaceans (virile crayfish)

Nonnative species: bullfrog, channel catfish, *Daphnia lumboltzi*, flathead catfish, Rio Grande leopard frog, saltcedar, smallmouth bass, virile crayfish

Major riparian plants: Arizona sycamore, Bebb willow, box elder, Fremont cottonwood, Goodding willow, green ash, mesquite, narrowleaf cottonwood, thin-leaf alder, saltcedar

Special features: several sites in upper basin recommended for conservation by the World Wildlife Fund; ≥800 bird species in Gila Cliff Valley

Fragmentation: Coolidge, Painted Rock, and Gillespie dams on main stem; numerous main-stem diversions

Water quality: pH = 8.3, alkalinity = 160 mg/L as CaCO₃, NO₃-N = 0.03 mg/L, PO₄-P = 0.1 mg/L, specific conductance = 900 μS/cm, suspended sediments = 300 mg/L

Land use: 70% agriculture, 20% forest, 10% urban; heavy agricultural, mining, and municipal use

Population density: ~25 people/km²

Major information sources: Silvey et al. 1986, Cordy et al. 1998, Earl and Blinn 2003, Abell et al. 2000

FIGURE 11.22 Mean monthly air temperature, precipitation, and runoff for the Gila River basin.

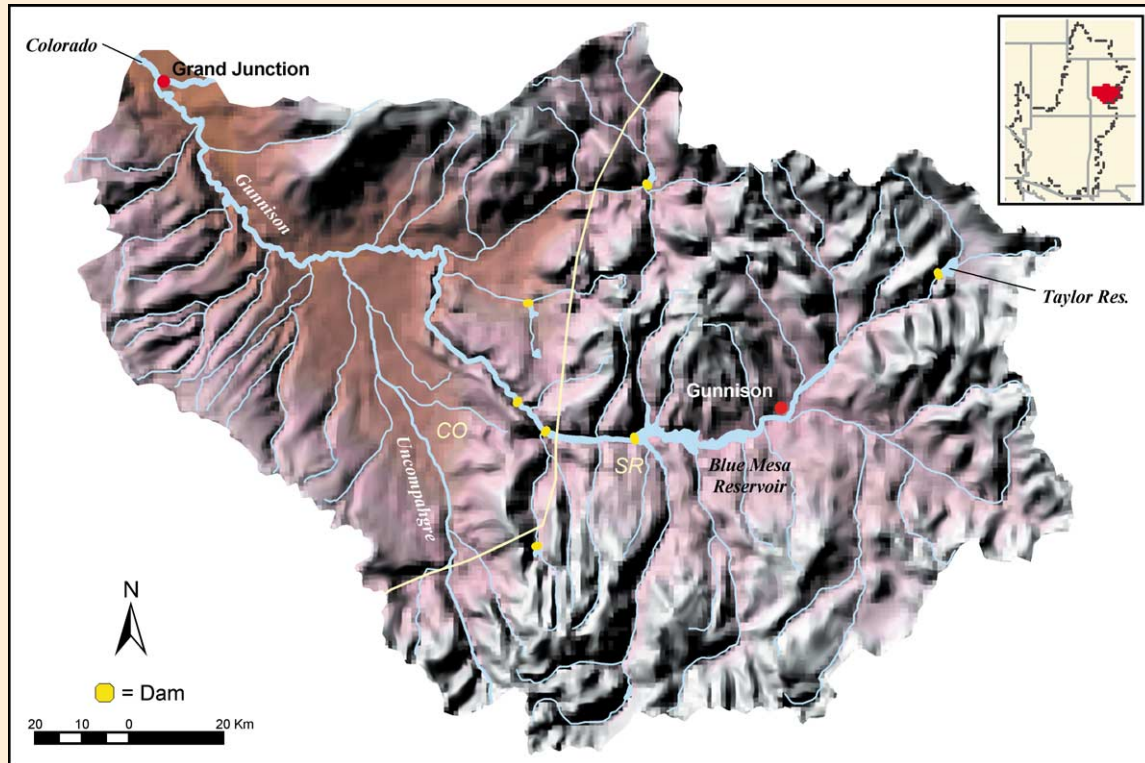

FIGURE 11.23 Map of the Gunnison River basin. Physiographic provinces are separated by a yellow line.

GUNNISON RIVER

Relief: ~2600 m

Basin area: 21,000 km²

Mean discharge: 74 m³/s

River order: 4

Mean annual precipitation: 27 cm

Mean air temperature: 9.5°C

Mean water temperature: 10°C

Physiographic provinces: Southern Rocky Mountains (SR), Colorado Plateaus (CO)

Biomes: Tundra, Temperate Mountain Forest, Desert

Freshwater ecoregion: Colorado

Terrestrial ecoregions: Colorado Rockies Forests, Colorado Plateau Shrubland

Number of fish species: 30 (11 native) and 4 hybrids

Number of endangered species: 4 fishes

Major fishes: bluehead sucker, bonytail chub, Colorado pikeminnow, Colorado River cutthroat trout, flannelmouth sucker, humpback chub, mottled sculpin, mountain whitefish, razorback sucker, roundtail chub, speckled dace

Major other aquatic vertebrates: beaver, boreal western toad, Great Basin spadefoot toad, muskrat

Major benthic invertebrates: mayflies (*Baetis*, *Heptagenia*, *Ephemera*), stoneflies (*Isoperla*), caddisflies (*Hydropsyche*), true flies (*Atherix*), chironomid midges, black flies

Nonnative species: brown trout, common carp, rainbow trout, red shiner, sand shiner, virile crayfish, white sucker

Major riparian plants: bent grass, bluegrass, box elder, Canada bluegrass, canary grass, goldenrod, muhly, scouring rush, smooth horsetail, spikerush, woolly sedge

Special features: critical habitat for four endangered Colorado River fishes; river runs through Black Canyon of Gunnison National Park

Fragmentation: highly fragmented by headwater dams and three main-stem dams of Aspinall Unit; transbasin diversion through Gunnison Tunnel in lower river

Water quality: below the Aspinall Unit dams pH = 6.6 to 8.2, alkalinity = 100 to 170 mg/L as CaCO₃, specific conductance = 1200 μS/cm; historical problems with selenium pollution from agricultural runoff in lower river

Land use: 50% agriculture, 45% forest, 5% urban

Population density: 2 people/km²

Major information sources: Hauer et al. 1989, McAda 2000

FIGURE 11.24 Mean monthly air temperature, precipitation, and runoff for the Gunnison River basin.

FIGURE 11.25 Map of the San Juan River basin. Physiographic provinces are separated by a yellow line.

SAN JUAN RIVER

Relief: ~2800m
 Basin area: 59,600 km²
 Mean discharge: 65 m³/s
 River order: 4
 Mean annual precipitation: 25 cm
 Mean air temperature: 11.3°C
 Mean water temperature: 4°C to 18°C (Navajo Dam), 2°C to 23°C (Shiprock, New Mexico)
 Physiographic provinces: Southern Rocky Mountains (SR), Colorado Plateaus (CO)
 Biomes: Temperate Mountain Forest, Desert
 Freshwater ecoregion: Colorado
 Terrestrial ecoregions: Colorado Rockies Forest, Colorado Plateau Shrublands

Number of fish species: 26 (7 native) and 3 hybrids

Number of endangered species: 2 fishes

Major fishes: bluehead sucker, channel catfish, Colorado pikeminnow, common carp, fathead minnow, flannelmouth sucker, mottled sculpin, razorback sucker, roundtail chub, speckled dace

Major other aquatic vertebrates: beaver, boreal western toad, bullfrog, muskrat, northern leopard frog, northern water shrew, plains leopard frog, tiger salamander, western chorus frog

Major benthic invertebrates: mayflies (*Acentrella*, *Baetis*, *Callibaetis*, *Drunella*, *Epeorus*, *Ephemera*, *Ephemerella*, *Heptagenia*, *Rhithrogena*, *Tricorythodes*), caddisflies (*Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Oecetis*, *Ochrotrichia*, *Smicridea*), hellgrammites (*Corydalus*), damselflies (*Argia*, *Enallagma*, *Ischnura*), dragonflies (*Erpetogomphus*), stoneflies (*Isoperla*), bugs (*Rhagovelia*)

Nonnative species: black bullhead, channel catfish, common carp, red shiner, fathead minnow, largemouth bass, Rio Grande killifish, Russian olive, saltcedar

Major riparian plants: Fremont cottonwood, Russian olive, upland herbs and shrubs, wetland herbs, willows

Special features: large desert river; important for the recovery of two native endangered fishes; mimicking of natural flow regime implemented for restoration; runs through Four Corners

Fragmentation: Navajo Reservoir in upper basin; flows into Lake Powell at mouth

Water quality: pH = 8.2, alkalinity = 105 mg/L as CaCO₃, NO₃-N = 0.05 mg/L, PO₄-P = <0.01 mg/L, specific conductance = 550 μS/cm, suspended sediments = 3500 mg/L

Land use: 75% agriculture, 20% forest, 5% urban; irrigated agriculture, dispersed livestock grazing, petroleum extraction

Population density: 0.6 people/km²

Major information sources: Gido and Propst 1999, Holden 1999

FIGURE 11.26 Mean monthly air temperature, precipitation, and runoff for the San Juan River basin.

FIGURE 11.27 Map of the Virgin River basin. Physiographic provinces are separated by a yellow line.

VIRGIN RIVER

Relief: ~2635 m

Basin area: 13,200 km²

Mean discharge: 6.8 m³/s

River order: 3

Mean annual precipitation: 27 cm

Mean air temperature: 17.1°C

Mean water temperature: 17°C

Physiographic provinces: Basin and Range (BR), Colorado Plateaus (CO)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Vegas-Virgin

Terrestrial ecoregions: Colorado Plateau Shrublands, Mohave Desert

Number of fish species: 21 (11 native)

Number of endangered species: 5 fishes, 21 reptiles and amphibians

Major fishes: black bullhead, desert sucker, flannelmouth sucker, green sunfish, mosquitofish, red shiner, speckled dace, Virgin River spinedace, woundfin

Major other aquatic vertebrates: American white pelican, beaver, belted kingfisher, Clark's grebe, great egret, lowland leopard frog, muskrat, northern leopard frog, osprey, snowy egret

Major benthic invertebrates: mayflies (*Baetis*, *Tricorythodes*), caddisflies (*Cheumatopsyche*, *Chimarra*, *Hydropsyche*, *Nectopsyche*, *Ochrotrichia*), beetles (*Microcyllopus*), dragonflies (*Ophiogomphus*), snails (*Physella*), crustaceans (virile crayfish), bugs (*Ambrysus*), chironomid midges, biting midges, black flies

Nonnative species: black bullhead, bullfrog, green sunfish, red shiner, Russian olive, saltcedar, virile crayfish

Major riparian plants: box elder, coyote willow, Emory baccharis, Fremont cottonwood, Russian olive, saltcedar

Special features: runs through Zion National Park to Lake Mead; highest water quality through Zion; recommended for conservation by World Wildlife Fund

Fragmentation: no dams but two major main-stem diversions include Quail Lake diversion near Virgin, Utah, and the Washington Fields diversion near Saint George, Utah

Water quality: pH = 7.9, alkalinity = 240 mg/L as CaCO₃, relatively high salinity (9.6 g/L) near La Verkin from Pah Tempe Springs, NO₃-N = 0.17 mg/L, PO₄-P = 0.03 mg/L, specific conductance = 2400 μS/cm, suspended sediments = 1050 mg/L

Land use: 60% agriculture, 30% forest, 10% urban

Population density: ~7 people/km²

Major information sources: Winget and Baumann 1977, Cross 1985, Gregory and Deacon 1994, McMahon et al. 2001, Abell et al. 2000

FIGURE 11.28 Mean monthly air temperature, precipitation, and runoff for the Virgin River basin.

FIGURE 11.30 Mean monthly air temperature, precipitation, and runoff for the Bill Williams River basin.

BILL WILLIAMS RIVER

Relief: ~1250 m

Basin area: 13,950 km³

Mean discharge: 4.3 m³/s

River order: 3

Mean annual precipitation: 13.2 cm

Mean air temperature: 22.4°C

Mean water temperature: 20°C

Physiographic provinces: Basin and Range (BR), Colorado Plateaus (CO)

Biome: Desert

Freshwater ecoregion: Colorado

Terrestrial ecoregion: Sonoran Desert

Number of fish species: 13 (1 native)

Number of endangered species: 1 fish

Major fishes: bluegill, common carp, fathead minnow, green sunfish, largemouth bass, mosquitofish, razorback sucker, red shiner, yellow bullhead

Major other aquatic vertebrates: Arizona toad, beaver, lowland leopard frog, muskrat, river otter, red-spotted toad, Sonoran Desert toad, spiny-spotted turtle

Major benthic invertebrates: mayflies (*Baetis*), caddisflies (*Cheumatopsyche*, *Culoptila*, *Helicopsyche*, *Hydroptila*, *Leucotrichia*, *Nectopsyche*, *Ochrotrichia*, *Protophila*, *Smicridea*), beetles (*Helichus*, *Microcylloepus*, *Tropisternus*), damselflies (*Argia*), bugs (*Ambrysus*), crustaceans (*Hyaella*, red swamp crayfish), snails (*Fossaria*, *Gyraulus*, *Physella*), bivalves (*Corbicula*, *Pisidium*)

Nonnative species: bluegill, common carp, fathead minnow, golden shiner, goldfish, green sunfish, largemouth bass, mosquitofish, redear sunfish, red shiner, red swamp crayfish, saltcedar, spiny-spotted turtle, yellow bullhead, *Daphnia lumholtzi* in Alamo Lake

Major riparian plants: broadleaf cattail, bulrush, coyote willow, Fremont willow, Goodding willow, narrowleaf cattail, saltcedar

Special features: runs through Bill Williams Wildlife Refuge; high bird density (≥335 species); dramatic lateral and vertical variations in microclimate

Fragmentation: almost entirely regulated by Alamo Dam; low to zero flows from July through October

Water quality: pH = 8.0, alkalinity = 235 mg/L as CaCO₃, NO₃-N = 0.05 mg/L, specific conductance = 1000 μS/cm, suspended sediment = <10 mg/L

Land use: 75% agriculture, 25% forest

Population density: 1.5 person/km²

Major information source: Silvey et al. 1986

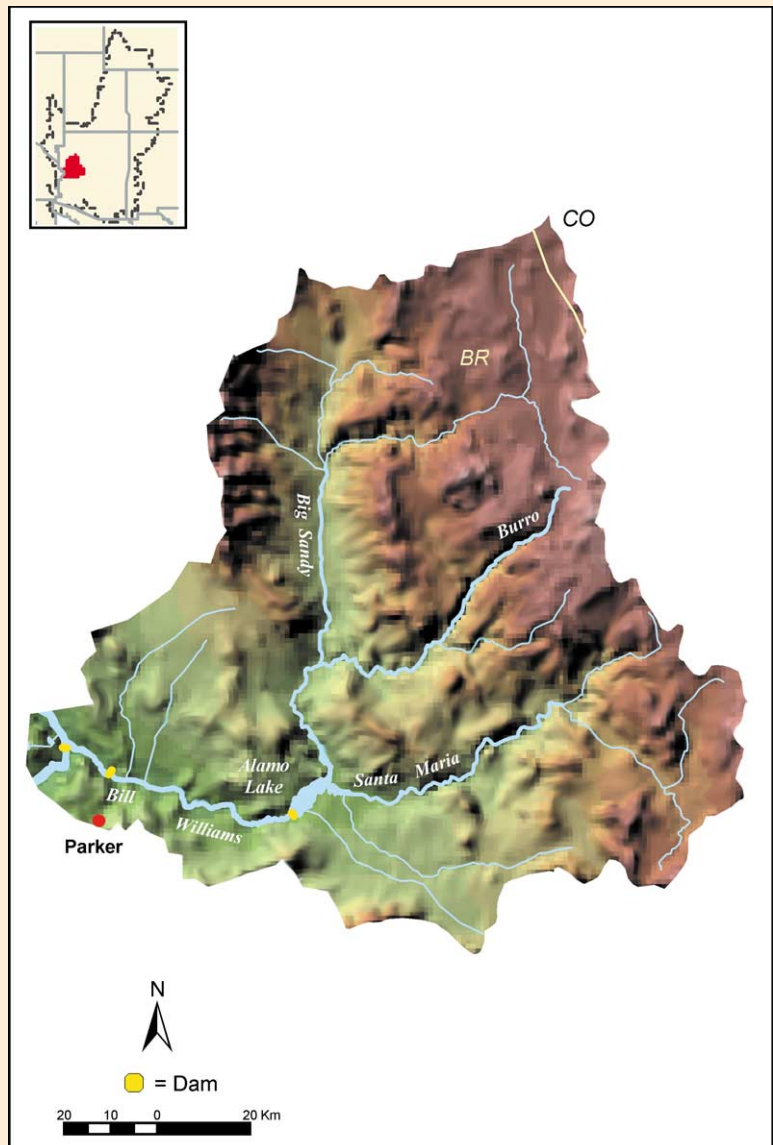

FIGURE 11.29 Map of the Bill Williams River basin. Physiographic provinces are separated by a yellow line.

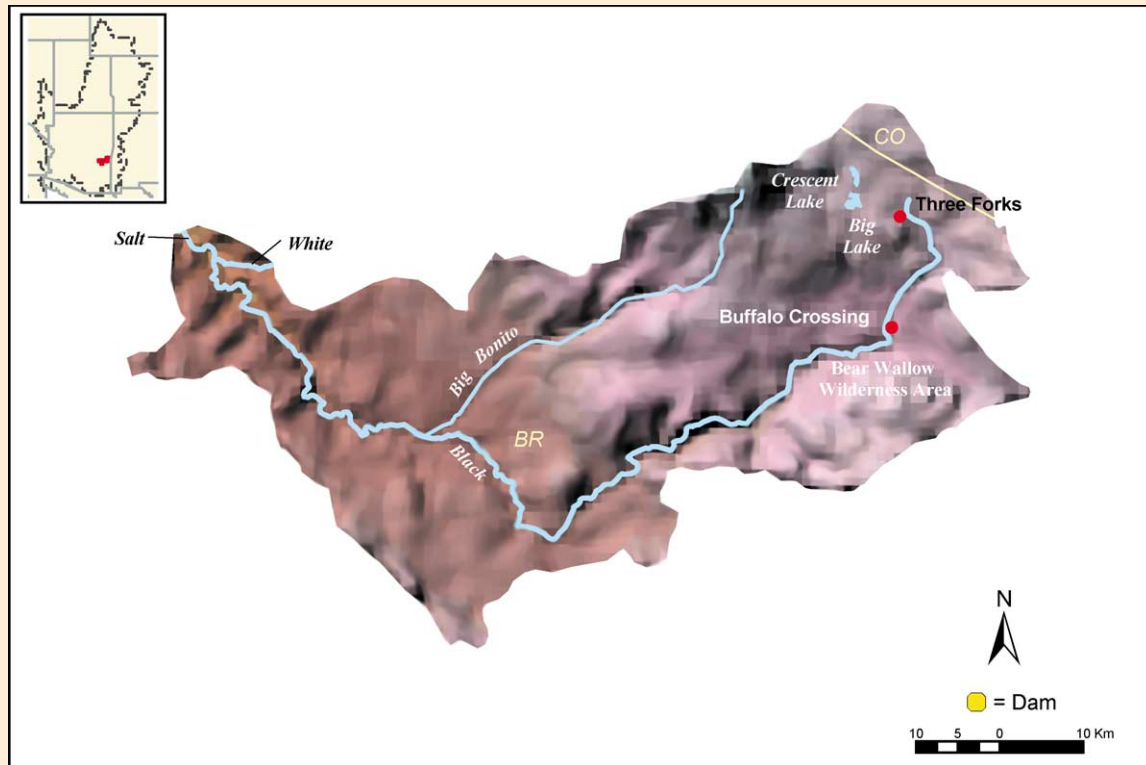

FIGURE 11.31 Map of the Black River basin. Physiographic provinces are separated by a yellow line.

BLACK RIVER

Relief: ~1400 m

Basin area: 3400 km²

Mean discharge: 12 m³/s

River order: 4

Mean annual precipitation: 53.5 cm

Mean air temperature: 14°C

Mean water temperature: 15°C

Physiographic provinces: Basin and Range (BR), Colorado Plateaus (CO)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Gila

Terrestrial ecoregion: Arizona Mountains Forests

Number of fish species: 13 (5 native)

Number of endangered species: 2 fishes, 1 frog, 1 clam, 1 snail

Major fishes: Apache trout, brown trout, channel catfish, desert sucker, fathead minnow, rainbow trout, roundtail chub, smallmouth bass, Sonora sucker, speckled dace

Major other aquatic vertebrates: beaver, belted kingfisher, great blue heron, mallard, muskrat, osprey, river otter

Major benthic invertebrates: mayflies (*Baetis*, *Epeorus Heptagenia*, *Tricorythodes*, *Thraulodes*), caddisflies (*Agapetus*, *Atopsyche*, *Brachycentrus*, *Ceratopsyche*, *Cheumatopsyche*, *Chimarra*, *Glossosoma*, *Helicopsyche*, *Hydropsyche*, *Lepidostoma*, *Limnephilus*, *Marilia*, *Micrasema*, *Phylloicus*), beetles (*Psephenus*), bugs (*Ambrysus*), chironomid midges, black flies, crustaceans (virile crayfish)

Nonnative species: bluegill, brown trout, bullfrog, channel catfish, cutthroat trout, fathead minnow, green sunfish, rainbow trout, smallmouth bass, saltcedar, virile crayfish

Major riparian plants: Bebb willow, coyote willow, Fremont cottonwood, Geyer willow, Goodding willow, narrowleaf cottonwood, thin-leaf alder, saltcedar

Special features: some of most natural riparian communities remaining in Arizona; passes through scenic Bear Wallow Wilderness Area and Fort Apache and San Carlos Indian reservations

Fragmentation: relatively unfragmented; three small reservoirs in headwaters fed by tributaries during snowmelt

Water quality: pH = 8.8, alkalinity = 150 mg/L as CaCO₃

Land use: 15% agriculture, 80% forest, 5% urban

Population density: ~1 person/km²

Major information sources: Silvey et al. 1986, Novy and Lopez 1991

FIGURE 11.32 Mean monthly air temperature, precipitation, and runoff for the Black River basin.

FIGURE 11.34 Mean monthly air temperature, precipitation, and runoff for the Verde River basin.

VERDE RIVER

Relief: ~925 m

Basin area: 16,190 km²

Mean discharge: 17 m³/s

River order: 4

Mean annual precipitation: 34.5 cm

Mean air temperature: 20°C

Mean water temperature: 16.5°C

Physiographic provinces: Basin and Range (BR),
Colorado Plateaus (CO)

Biome: Desert

Freshwater ecoregion: Gila

Terrestrial ecoregion: Arizona Mountains Forests

Number of fish species: 27 (10 native)

Number of endangered species: 8 fishes

Major fishes: common carp, desert sucker, flathead catfish, Gila chub, green sunfish, headwater chub, largemouth bass, mosquitofish, red shiner, roundtail chub, smallmouth bass, Sonora sucker, yellow bullhead

Major other aquatic vertebrates: Arizona toad, beaver, belted kingfisher, bullfrog, Chiricahua leopard frog, great blue heron, lowland leopard frog, river otter, Sonoran mud turtle, striped chorus frog, Woodhouse toad

Major benthic invertebrates: mayflies (*Baetis*, *Heptagenia*), caddisflies (*Cheumatopsyche*, *Chimarra*, *Helicopsyche*, *Heterelmis*, *Hydropsyche*, *Hydroptila*, *Ochrotrichia*, *Oecetis*, *Polycentropus*, *Protoptila*, *Smicridea*), hellgrammites (*Corydalus*), damselflies (*Enallagma*), bugs (*Ambrysus*), black flies, biting midges, chironomid midges, crustaceans (*Gammarus*, virile crayfish)

Nonnative species: Asiatic clam, bullfrog, common carp, flathead catfish, green sunfish, largemouth bass, mosquitofish, red shiner, smallmouth bass, saltcedar, virile crayfish, yellow bullhead

Major riparian plants: Arizona alder, Arizona sycamore, Arizona walnut, arroyo willow, box elder, cattails, common reed, coyote willow, Fremont willow, Goodding willow, saltcedar

Special features: one of the largest perennial rivers in Gila basin; upper section recommended for conservation by World Wildlife Fund; upper 72 km one of few remaining sections with roundtail chub; 65 km National Wild and Scenic River

Fragmentation: lower third regulated by dams (Horseshoe and Bartlett lakes); 7 water-diversion dams

Water quality: pH = 8.4, alkalinity = 250 mg/L as CaCO₃, NO₃-N = 0.03 mg/L, PO₄-P = 0.01 mg/L, specific conductance = 550 μS/cm, suspended sediment = 60 mg/L

Land use: 70% agriculture, 25% forest, 5% urban

Population density: 3 people/km²

Major information sources: Cordy et al. 1998, Rinne et al. 1998

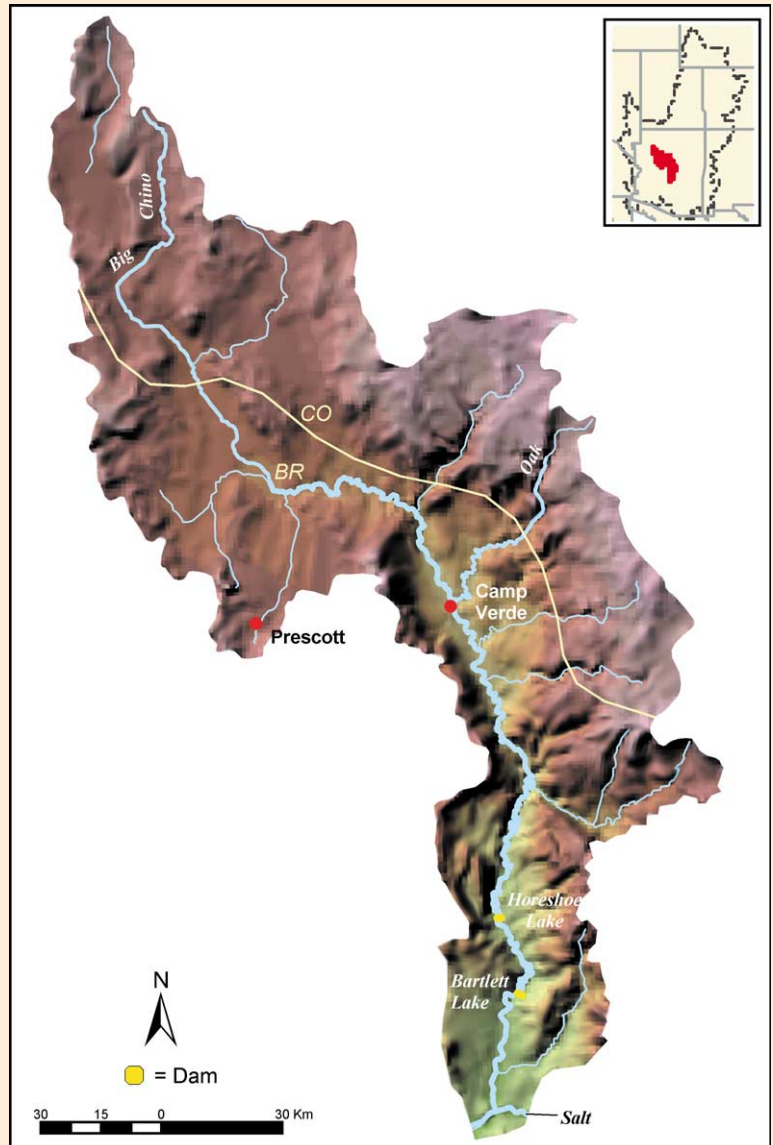

FIGURE 11.33 Map of the Verde River basin. Physiographic provinces are separated by a yellow line.

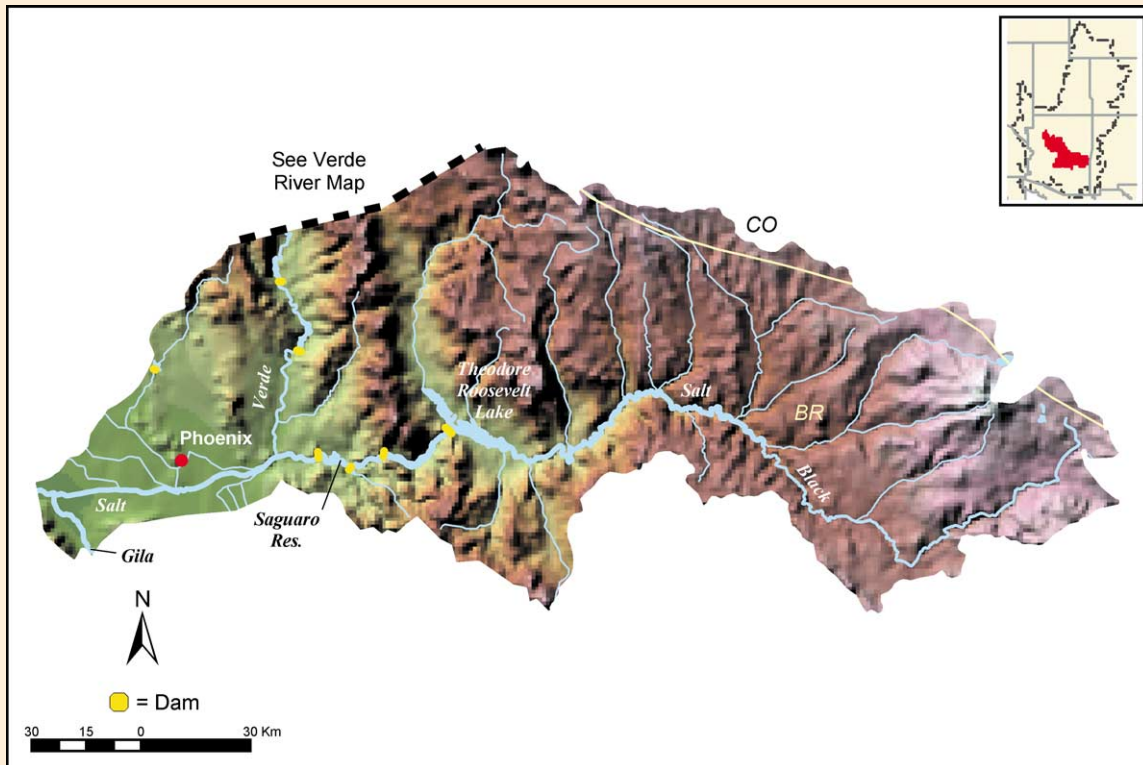

FIGURE 11.35 Map of the Salt River basin. Physiographic provinces are separated by a yellow line.

SALT RIVER

Relief: ~2540 m

Basin area: 35,480 km²

Mean discharge: < 25 m³/s

River order: 5

Mean annual precipitation: 39.6 cm

Mean air temperature: 22°C

Mean water temperature: 19°C

Physiographic provinces: Basin and Range (BR), Colorado Plateaus (CO)

Biomes: Temperate Mountain Forests, Desert

Freshwater ecoregion: Gila

Terrestrial ecoregions: Arizona Mountain Forests, Sonoran Desert

Number of fish species: 16 (9 native)

Number of endangered species: 7 fishes

Major fishes: bluegill, channel catfish, common carp, desert sucker, fathead minnow, flathead catfish, golden shiner, green sunfish, longfin dace, red shiner, Sonora sucker, speckled dace

Major other aquatic vertebrates: Arizona toad, bullfrog, Chiricahua leopard frog, northern leopard frog, lowland leopard frog, Sonoran mud turtle, virile crayfish

Major benthic invertebrates: mayflies (*Baetis*, *Callibaetis*, *Tricorythodes*), caddisflies (*Hydropsyche*, *Hydroptila*), chironomid midges

Nonnative species: bluegill, bullfrog, channel catfish, common carp, fathead minnow, flathead catfish, golden shiner, green sunfish, red shiner, Rio Grande leopard frog, saltcedar, virile crayfish

Major riparian plants: mesquite, saltcedar

Special features: lower section flows through scenic Salt River Canyon

Fragmentation: lower sections highly regulated by Roosevelt, Stuart Mountain (Saguaro Res.), Mormon Flat, and Horse Mesa dams; heavy use of diversion canals

Water quality: pH = 8.3, alkalinity = 185 mg/L as CaCO₃, NO₃-N = 0.01 mg/L, PO₄-P = 0.03 mg/L, specific conductance = 3700 μS/cm, suspended sediment = 125 mg/L

Land use: 75% agriculture, 15% forest, 5% urban

Population density: >90 people/km²

PACIFIC COAST RIVERS OF THE COTERMINOUS UNITED STATES

JAMES L. CARTER VINCENT H. RESH

INTRODUCTION

SACRAMENTO RIVER

SAN JOAQUIN RIVER

SALINAS RIVER

KLAMATH RIVER

ROGUE RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

The rivers discussed in this chapter are mainly located in the southern portion of the Pacific Mountain System (Hunt 1974) and discharge into the Pacific Ocean (Fig. 12.2). Located from south of the Columbia River to southern California, these river basins occupy an area just over 10° of latitude and 10° of longitude. The rivers and the biota of this region have been influenced more than any other rivers in North America by tectonic activity that is both geologically recent and ongoing, including (1) periods of mountain building through uplift, volcanism, and accretion; (2) periods of massive erosion; (3) changes in sea level; and (4) large-scale faulting. These factors have influenced the aspect and gradient of the rivers and created a topography that affects subregional precipitation patterns, which in turn influences the hydrology, geomorphology, and consequently the present-day biology of the region's rivers. The importance of the recency of these events is shown by the uniqueness and high endemism of the

regional flora and fauna (e.g., Ricketts et al. 1999, Abell et al. 2000, Moyle 2002).

From the time of the arrival of the first people to this central Pacific region of North America, which occurred approximately 11,000 years ago (Heizer and Elsasser 1980), rivers have provided humans with food, water, and transportation. Furthermore, in the northern part of the Pacific region the life cycle of the Native American tribes, their religions, and their wars focused on the rivers and, in particular, on the salmon occurring there. In contrast, the tribes in the southern portion of the region utilized a more diverse resource base; fishes, although part of their economy, were less important to them than to the tribes of the north. The diversity of freshwater and estuarine species as well as abundant terrestrial wildlife and plants, particularly acorns, supported some of the highest densities of Native Americans in North America (Heizer and Elsasser 1980).

Spanish exploration began in the early to mid-sixteenth century. Throughout the 1700s numerous

FIGURE 12.2 Pacific Coast rivers of the coterminous United States covered in this chapter.

settlements along the Pacific Coast were established around Spanish missions. However, their northern extent was limited, and when Russian fur traders arrived in California and settled at Fort Ross (100 km north of San Francisco Bay) in 1812, occupation by the Spanish was not much further north than the Bay. The small Russian settlement at Fort Ross was abandoned around 1840.

Even though Native American population densities were high relative to other areas of North America, they (as well as the early Spanish and Russian colonists) appeared to have had relatively little impact on the region. However, Native Americans did use fire as a game-management method and, at least within their area of influence, significantly modified the landscape (Keeley 2002). One of the

principal influences of the Spanish occupation was the introduction of European annual grasses, which displaced native bunchgrasses (Schoenherr 1992).

Clearly, the defining event in the human history of the Pacific region was John Marshall's discovery of gold at Sutter's Mill, California, in 1848. Immigration associated with this event significantly increased the population of the region (e.g., by 1850, 100,000 miners had arrived). The negative effects of excess sediment from hydraulic mining on stream channels and the contamination of water and biota from the mercury that was used to extract gold led to the first great assault on the region's rivers. However, today the most significant human influences on lotic systems in this region are associated with the alteration of natural flows and sediment

transport (the amount and timing of) caused by impoundments and withdrawals, with the water principally (~80%) used for irrigated agriculture.

Numerous major rivers are found in the southern portion of the Pacific Mountain System. We will discuss the Sacramento, San Joaquin, Salinas, Klamath, and Rogue in detail and include abbreviated descriptions for five additional rivers: the Umpqua, Eel, Russian, Santa Ana, and Santa Margarita.

Physiography and Climate

The Pacific Mountain System includes three physiographic provinces (Hunt 1974): (1) the Cascade–Sierra Nevada Mountains province, which extends from southern California north into British Columbia; (2) the Pacific Border province, which includes those lands to the west of the Cascades and Sierra Nevada; and (3) the Lower California (Peninsular Range) province, which extends between the Salton Trough and the southern California coast. These three provinces contain the greatest range in climate, geology, geomorphology, hydrology, and biology in North America. This diversity of environmental setting has produced an enormous range in basin physiography. Importantly, the Pacific Mountain System lies along the very tectonically active Pacific Rim, and the recency of its formation and its continuing tectonic activity strongly influence both the geomorphology and biology of its rivers.

The topography of the Pacific Mountain System includes mountain ranges of five types: granitic (e.g., Sierra Nevada, Klamath); volcanic (Cascades); pre-Tertiary, complexly folded and faulted formations (Northern California Coast Ranges); Tertiary, moderately folded but much faulted (Oregon Coast Ranges, Southern California Coast Ranges); and dome (e.g., Marysville Buttes in California's Central Valley). These base materials provide for a diversity of soil types and nutrient availability for the rivers that originate in them. Differences in the geology and time of formation of these ranges also influence the geomorphology, hydrology, and biology of the streams and rivers that occur in individual regions.

The mountain ranges of the entire Pacific Mountain System have been described as being arranged like a chain (Hunt 1974). The northern link consists of the Cascade Range, the Oregon Coast Range, and the Olympic Mountains. This link is joined at the south by the Klamath Mountains, with the Puget Trough forming the “hole.” The Sierra Nevada and California Coast Range form the middle link, with

the Central Valley forming the hole. The Transverse Range and the Lower California Province, with the Salton Trough as the hole, form the southernmost link.

The Cascade–Sierra Nevada Mountains province extends for 1600 km from southern California to British Columbia. The range has uplifted and, particularly in the Cascades, is topped by volcanoes and lava flows. The northern and southern extremes of the range are higher than the middle and consist of granitic rocks and metamorphosed sedimentary formations. The middle portion of the range (near the northern extent covered in this chapter) is lower and the rocks are buried by volcanic flows. The only two rivers covered in this chapter that cross the range (the Klamath and Pit) are located in this topographically depressed area. Even though geologic differences exist between the Sierra Nevada and the southern Cascade Mountains, the altitudinal zonation of flora and fauna is characteristic (although species assemblages vary) regardless of mountain range, and stream form (gradient, width, etc.) is often a function of longitudinal location, which is also highly correlated to altitude.

The Pacific Border province represents those lands west of the Cascade–Sierra Nevada ranges and north of (and including) the Transverse Range in southern California (Hunt 1974). This province includes a wide variety of landforms, such as the Great Valley of California (the Central Valley), the Coast Ranges, the Transverse Ranges, and the Klamath Mountains. This province contains some of the wettest and driest areas in the region. Land cover and land use within this province is the most varied, with the Klamath Mountains supporting vast, species-rich coniferous forests.

The Lower California (Peninsular Range) province is the smallest of the three provinces. It includes the ranges south of the Transverse Ranges, as well as the very densely populated and highly developed coastal lowland areas of southern California (Hunt 1974), and is essentially the northern extent of the Baja California peninsula.

The climate of the Pacific Mountain System is possibly the most varied of all the regions reviewed in this volume. As can be seen in the figures of this chapter, precipitation is extremely seasonal. Each figure depicts a summer dry period and a wet winter period. This annual cycle is very consistent from year to year. However, extreme interannual variation occurs and can lead to extended periods of drought and years of extremely high rainfall and runoff (e.g., El Niño events). Spatial differences in the amount

and type of precipitation also occur. In general, precipitation decreases from north to south; however, spatial variation in precipitation (amount and form) is strongly influenced by topographic factors. For example, high elevations tend to receive more precipitation as snowfall and greater precipitation in general than low elevations. Low-elevation valleys and leeward slopes can be extremely dry (e.g., Tulare basin) because of rain shadow effects and adiabatic evaporation. The differences in the amount and form of precipitation greatly influence the runoff patterns and consequently the geomorphology and biology of the region's rivers.

Temperatures across the region vary considerably. Distance from the coast, altitude, and north-to-south location greatly influence temperature regimes. Coastal summer temperatures are influenced by the upwelling of deep, cold ocean waters and are generally cool. These waters also moderate winter temperatures, and freezing rarely occurs along the coast. Further inland, summer temperatures often exceed 38°C. Temperature decreases with altitude and can drop below freezing throughout the year at the highest elevations; however, in this region winter temperatures never approach the extreme cold of midcontinent.

Basin Landscape and Land Use

Rivers of this region are rarely contained within a single ecoregion, and more often traverse several ecoregions along their courses. Geology, topography, and precipitation are the dominant controls over river form and terrestrial vegetation. The number of combinations of these three factors is evident in the variety of terrestrial ecoregions found in the region. Ricketts et al. (1999) identified 10 terrestrial ecoregions in the southern portion of the Pacific Mountain System covered here. These 10 terrestrial ecoregions are grouped into three major habitat types: the Temperate Coniferous Forest, the Mediterranean Shrub and Savannah, and the Temperate Grasslands/Savannah/Shrub.

The Temperate Coniferous Forest habitat type encompasses just less than two-thirds of the total area. It includes the Central Pacific Coastal Forests, Central and Southern Cascades Forests, Eastern Cascades Forests, Klamath-Siskiyou Forests, Northern California Coastal Forests, and Sierra Nevada Forests terrestrial ecoregions. This habitat type is found in the northern and eastern portion of the region, both along the coast and above the foothills

in montane areas. It includes most of the Sierra Nevada, Cascade, and Klamath mountains, and the Coast Ranges north of Monterey Bay, California. In general, this habitat contains forested areas that are dominated by Douglas fir, western hemlock, western red cedar, and ponderosa pine. In suitable coastal areas between Monterey Bay and the Oregon border, 10% of the pre-Columbian population of redwoods still exist. The remaining giant sequoia occur further inland in isolated areas in the central Sierra Nevada. Throughout these forests plant associations are greatly influenced by edaphic factors, precipitation, and elevation and form predictable sequences. Although this habitat is still extensively forested, it continues to be impacted by logging, road building, fire suppression, grazing, flow capture, and loss of riparian habitat. Many areas within this habitat type are considered unique because the level of plant and animal endemism is extremely high, particularly in the Klamath Mountains to the north and the Sierra Nevada in the south.

The Mediterranean Shrub and Savannah habitat type represents approximately one-quarter of the area and includes the California Interior Chaparral and Woodlands, California Montane Chaparral and Woodlands, and California Coastal Sage and Chaparral terrestrial ecoregions. The California Interior Chaparral and Woodlands ecoregion is the largest in this habitat type and forms a perimeter around the Central Valley of California, separating the valley floor from the more montane areas. The other two ecoregions are mainly located south of the Central Valley; however, the Santa Lucia Range, located just south of Monterey Bay, also is included in this habitat type.

Visually, Mediterranean Shrub and Savannah habitat is a mixture of open forests, low chaparral scrub, and grasslands. Forest types include oak woodland with scattered California buckeye, closed cone pine–yellow pine forests, sugar pine–white fir forests, lodgepole pine forests, and desert piñon–juniper woodlands. The shrub habitat includes lower chaparral and chamise, and upper chaparral dominated by manzanita, desert chaparral, and coastal sage shrub. This habitat type was severely impacted by the loss of native bunchgrasses through the introduction of annual European grasses during the Spanish settlement; much of the habitat in the southern portion of California continues to be lost to urban and agricultural development. Shrublands throughout California have been subject to physical and chemical removal to provide additional lands for grazing.

Last, the Temperate Grasslands/Savannah/Shrub habitat type only includes the California Central Valley Grassland terrestrial ecoregion. Although representing only about 10% of the area, it was probably the most productive habitat type in the region. This habitat type and the ecoregion are represented by California's Central Valley. The California Central Valley Grassland ecoregion was the location of extensive freshwater marshes, vernal pools, and the largest lake (Tulare Lake) west of the Mississippi River prior to agricultural development and modification. Extensive tule marshes, riparian woodlands, and native bunchgrasses existed before the 1850s. Riparian woodlands contained willows, western sycamore, box elder, Fremont cottonwood, and valley oak. Reportedly, riparian widths on the lower sections of the Sacramento and San Joaquin rivers exceeded 30 km (Ricketts et al. 1999). This entire habitat type has been extensively modified from its original condition through the development of agriculture.

The Rivers

The ecology of the rivers flowing into the Pacific Ocean is as diverse as the lands through which they flow, and this region contains one of the most diverse assemblages of watersheds on the continent. This diversity is a result of the range of climate zones (from deserts to Mediterranean areas to temperate rainforests) but especially the result of millions of years of activity along a tectonic plate boundary.

The mosaic of geologic form, the recent tectonic activity of the area, and the climatic characteristics that determine the frequency, intensity, and type of storms ultimately shape the characteristics of each of the watersheds in this region. In addition to the ecoregion classification for the terrestrial environments already described, many different classification systems exist for the drainage systems as well. Although every basin has unique characteristics, the lotic environments of this region have been classified into three freshwater ecoregions (Abell et al. 2000).

The Pacific Mid-Coastal freshwater ecoregion, with an area of 108,880 km², extends along the Pacific Coast of Oregon and California to the north shore of San Francisco Bay. It encompasses the western drainages of the Klamath and Siskiyou mountains and includes the Umpqua, Rogue, and Klamath as well as many other important rivers. This area has the highest yearly rainfalls of the region, sometimes exceeding 500 cm/yr. Although the Klamath Mountains and Trinity Alps have heavy snowfall, most precipitation in this ecoregion occurs

as rain. The rivers of this area also have the highest sediment yields, which are caused by high rainfall, high rates of uplift, unstable rock types and soil, and logging and grazing practices that promote erosion. The smaller, coastal watersheds in this region exhibit a rapid hydrographic response to rainfall events, whereas the larger, eastern rivers generally exhibit less flashy hydrographs and higher overall base flows because of precipitation storage as snow and snowmelt.

The Pacific Central Valley freshwater ecoregion has an area of 184,129 km². It lies entirely within California and encircles the Central Valley. The largest rivers are the Sacramento and San Joaquin, but it also includes the high-water-quality rivers located in the western drainages of the Sierra Nevada. This area has high precipitation, with approximately 50% occurring as snowfall. The rapid Pleistocene uplift and global cooling produced glaciers (e.g., throughout the Sierra Nevada) that altered the profiles of many rivers. In contrast to the Pacific Mid-Coastal ecoregion, sediment yields of watersheds here are lower, but land use (logging, grazing, and especially the historic effects of hydraulic mining) has increased sediment yields locally. Because of accumulations of precipitation as snowpack, lag times are long, peak runoffs are dampened, and extensive spring runoffs from snowmelt occur.

The San Francisco Bay and portions of the central coast are also part of this ecoregion but are probably best considered as a distinct hydrological area (and are separate in most water classification schemes). The northern portions of this region have higher rainfall totals over mountain ranges than in the interior valleys. The precipitation in southern regions is generally about 50% of that in northern ones, and snowmelt influences are insignificant. The tectonics associated with the San Andreas Fault system have influenced the orientation and location of the major river valleys. Sediment yields are high because of high-intensity rainfall, high rates of uplift, and unstable rocks. These small, steep watersheds have short lag times and high peak runoffs, and rivers often flood during winter storms.

The South Pacific Coastal freshwater ecoregion has an area of 170,320 km² and encompasses the coastal area that begins just south of Monterey, California, and extends to the southern tip of the Baja California peninsula in Mexico. The high frequency of low-rainfall years, interspersed with occasional high-rainfall years, results in most runoff being the consequence of intense subtropical storms. Like the Central Coast, many watershed characteristics

are a product of past and present activity along the San Andreas Fault system. Although sedimentary rocks in this region are prone to landslides and produce locally high erosion rates, the high level of relief, limited vegetation cover, and wildfires are other causes of erosion. Most rivers in this region are ephemeral, with limited base flow and snowmelt, and are prone to highly variable flows and floods.

Of these different ecoregions, the coastal rivers of the San Francisco Bay area and the central and southern coastal areas are unique hydrologically when compared to most of the rivers covered in this book. The rivers in these areas are physically, chemically, and biologically shaped by sequential, predictable, seasonal periods of flooding and drying over an annual cycle. Intermittency is common in many tributaries. Correspondingly, the aquatic communities that occur in the tributaries of these rivers (and consequently in the main stems) undergo a yearly cycle whereby the communities are dominated by abiotic (i.e., environmental) factors during floods and biotic factors (e.g., predation, competition) as discharges approach base-flow conditions. However, as the dry season progresses, habitat conditions become harsher, and environmental pressures again become important regulators of stream populations and community structure (Gasith and Resh 1999).

Rivers in these areas, besides experiencing high seasonal variation (more than 80% of the rain falls in the three months of winter, often with precipitation from a few major storms responsible for most of the flooding), also experience high variation in inter-annual precipitation. Deviations in discharge of more than 30% from a multiannual average are common and lead to low constancy within a highly predictable seasonal discharge pattern. Besides the temporal differences in flow, this area is also characterized by extreme spatial differences in rainfall. From north to south, coastal to inland areas, and mountaintops to valleys, precipitation in this region varies not only in its form (rain or snow) but also its amount (e.g., from <10 cm to >500 cm).

Given the high seasonal predictability of floods and drying in streams and rivers of this region, we might expect differences in the life cycles of organisms inhabiting lotic habitats in this region compared to other areas of North America. For example, many fishes and aquatic invertebrates that occur here reproduce in spring during the declining stage of the hydrograph when temperatures are increasing. In contrast, in streams and rivers in other areas, where flooding may occur at almost any time of the year, the spawning seasons of most species are protracted

or staggered. Consequently, the composition, at least of the fish assemblage, may vary far less from year to year in streams of coastal parts of the Pacific Central Valley and South Pacific Coastal ecoregions than in many of the other North American systems (Moyle and Vondracek 1985).

Humans have significantly influenced the rivers addressed in this chapter since the mid 1800s, when the principal settlement of the region occurred. Within this relatively short period of time the natural functioning of many of the rivers has been severely impacted. Although there have been and continue to be a variety of human-induced factors contributing to these impacts, two stand out.

Hydraulic mining, which entailed directing a high-pressure jet of water onto an exposed placer deposit of gravel, sand, and/or silt and then running the sediment through sieves to remove the gold, severely impacted the region's rivers during the mid-1800s. Outlawed in California in 1884, this mining technique washed large portions of mountains into local streams, which then transported this debris into the lower reaches of the rivers. This excess sediment input exceeded the rivers' transport capacity, led to severe flooding, and permanently altered river channels in California and Oregon. Gold mining also left a legacy of mercury contamination of lotic, lentic, and estuarine systems throughout the region. Recreational mining for gold still contributes to local sediment impacts.

Flow capture and diversion have severely altered the rivers of this region. The rivers described in this southern portion of the Pacific Mountain System are extremely seasonal, with high winter-spring flows and low to intermittent summer-autumn flows. The geomorphological and biological form and function of the rivers have evolved in concert within this natural discharge regime. The extreme variability in the amount of water, spatially and temporally, has conflicted with human needs since the region was first settled. Dams have been constructed for flood control and energy production, and to support one of the most intensively agricultural and densely settled areas in North America, and the rivers of this region have been captured and diverted more than anywhere else in North America. This has led to a complex set of interrelated impacts to the channels and the biology of the rivers located in this ecologically diverse region.

On the positive side, there are thousands of water-resource professionals, scores of volunteer and citizen action groups, and many federal, state, and local programs dedicated to the maintenance and restoration

of the region's rivers, particularly the restoration of threatened and endangered salmonids and other native fishes. However, many challenges exist given the limited total supply of water and an ever-increasing demand for high-quality water to meet both societal and environmental needs.

SACRAMENTO RIVER

The Sacramento River is the largest river in California (Fig. 12.12). It is 644 km long and has a basin of 72,132 km² that ranges in altitude from 4000 m asl in the Sierra Nevada to sea level at its mouth, which is located in the Sacramento–San Joaquin Delta. The Sacramento begins just west of Mt. Shasta, and although most of the basin is located in the northern half of California, the basin of a northern tributary, the Pit River, extends into southern Oregon. Below Shasta Dam numerous tributaries flow into the lower Sacramento from the western slopes of the northern Sierra Nevada and the eastern slopes of the Coast Range. The largest tributaries that flow from the Sierra Nevada are the Feather and American. The Feather itself has two large tributaries, the Yuba and Bear. Although the Sacramento proper does not have any reaches designated as Wild and Scenic, portions of the Feather and American Rivers have been given Wild and Scenic status.

The Sacramento basin contained a rich diversity of Native Americans (Heizer and Elsasser 1980). To the north were the Pit River tribes (Achomawi and Atsugewi), the Modoc, and the Yana and Yahi (of which the famous Ishi was a member). On the west side of the Sacramento in the northern portion of the valley lived the Wintu, in the central portion of the valley the Central Wintun, and in the southern portion of the valley the Southern Wintun (Patwin). To the east of the Sacramento River in the Feather and American river basins lived the Maidu. The Miwok inhabited the central portion of the Sacramento–San Joaquin Valley and were divided into numerous geographic groups. The Plains and Coast Miwok, the northern portion of the Yokuts and the Costanoans (Olhone) lived in and around the Sacramento–San Joaquin Delta and San Francisco Bay.

Differences in local habitat greatly influenced the lifestyles of the Native Americans inhabiting the Sacramento basin. The salmon that once seasonally filled the Sacramento and its tributaries were used whenever available. The vast wetlands of the valley and shallow northern lakes provided native fishes and mussels, seasonally available waterfowl, and

abundant starchy cattail roots and tule seeds. The valley and foothills contained abundant deer, elk, pronghorn, and rabbit. Acorns from the many species of oak were a staple and were harvested during the autumn and stored throughout the winter.

Other than a few explorers and trappers, the principal settlement of the Sacramento valley by Europeans occurred in relationship to the Gold Rush during the mid-1800s. Agriculture to support the miners rapidly developed.

Physiography, Climate, and Land Use

The Sacramento River basin is part of the Basin and Range (BR), Cascade–Sierra Nevada Mountains (CS), and Pacific Border (PB) physiographic provinces (see Fig. 12.12) (Hunt 1974). Only a small portion of the Sacramento basin (the Pit River basin) is located in the Basin and Range province. The Cascade–Sierra Nevada Mountains province includes most of the high-elevation montane areas within the basin. The Southern Cascade Mountain section is principally volcanic in origin and remains volcanically active. Mount Shasta and Mount Lassen are the most prominent topographic features of this section.

The Sierra Nevada Mountains section begins just south of Lassen Peak and continues for 640 km. Plutonic rocks in the Sierra Nevada are late Jurassic to late Cretaceous, with some in the northern portion dating to the Paleozoic. The principal impression of the range is one of a massive granitic block; however, there are considerable sedimentary and volcanic rocks in the northern portion. Climatic, topographic, and precipitation patterns create a situation where several major tributaries originate in this section.

Much of the Sacramento River proper lies in the Pacific Border province. The Sacramento Valley represents the northern portion of the California Trough section. Most of the valley contains alluvial sediments from both continental and marine origins, which range in age from the Jurassic to the Holocene. In some locations the estimated depth of sediments exceeds 16 km (Domagalski et al. 1998).

The California Coast Ranges section forms the western border of the Sacramento Valley. These are northwest–southeast aligned, low-elevation mountains formed in the north by faulting and active subduction of the Pacific plate beneath the continental plate. The largest extant natural lake entirely within California, Clear Lake, is located in this section.

The Sacramento basin is a part of at least five terrestrial ecoregions (Ricketts et al. 1999). Differences in vegetation are strongly influenced by altitude,

moisture, and soil type. The upper portion of the basin is part of the Eastern Cascades Forests ecoregion and includes much of the Pit River drainage. The dominant forest type is ponderosa pine, but there also are large areas of shrublands and grasslands. To the southeast lies the Klamath–Siskiyou Forests ecoregion, which is considered a global center of biodiversity (the area will be covered more thoroughly in the section on the Klamath River). The eastern part of the Sacramento drainage is in the northern portion of the Sierra Nevada Forests ecoregion, which contains one of the most diverse temperate conifer forests in the world. The coniferous forests are arranged in altitudinal belts, with lowest elevations (~1500 m asl) dominated by ponderosa pine, grading into mixed forests consisting of ponderosa and sugar pines, Douglas fir, and white fir. From 2100 to 2700 m asl forests are a mix of lodgepole, Jeffrey, and western white pines and juniper. Above 2700 m asl mountain hemlock and whitebark, foxtail, and limber pines are found. To the west, across the Sacramento Valley, is the California Interior Chaparral and Woodlands ecoregion, which is a mix of chaparral, grasslands, oak savannahs and woodlands, closed-cone pine forests, montane conifer forests, wetlands, and riparian forests. Tree species are dominated by blue oak, but many other oaks are found, including coast, canyon, valley, and interior live oaks. In many areas chaparral plants dominate the landscape and include California buckeye, manzanita, and scrub oak.

The final terrestrial ecoregion in the Sacramento River drainage is the California Central Valley Grasslands, the region in which the higher-stream-order section of the Sacramento River lies. This region once contained extensive native grasslands, oak woodlands, and dense riparian and floodplain vegetation, including expansive tule marshes. Much of these lands are now used for agriculture.

The climate in the Sacramento basin is as varied as the landforms it contains. Variability in precipitation is extremely high both intra- and interannually. Average annual precipitation for the basin is 90 cm/yr, most of which occurs from November through March (Fig. 12.13). However, the annual mean precipitation in different parts of the basin varies from <10 to >200 cm/yr. The amount and form of precipitation often is orographically determined. Precipitation increases with altitude, and the form of precipitation changes from rain at lower altitudes, to rain and occasional snow in the coastal range, to extremely high snow levels in the Sierra Nevada and southern Cascade Range. These spatial and temporal

precipitation patterns significantly affect the amount and timing of river flows. Temperature also varies with altitude. Average temperature for the basin is 12.9°C, and monthly averages range from 4.5°C to 22.4°C, with subzero temperatures frequent in winter (see Fig. 12.13). Summer daytime temperatures often exceed 40°C, both in the central valley and in the foothills and mountains. Summer temperatures in the Sierra Nevada can drop to below freezing at any time of the year.

Land cover in the basin can be divided into urban, agricultural, and nonagricultural uses. Urban land cover comprises only 1.7% of the basin, with the state capital, Sacramento, the largest city upstream of the San Francisco Bay area. Nonurban land use can be partitioned into four categories: forest (49.3%), shrub (13.7%), grasslands (16.2%), and wetlands (0.8%). Agricultural land use makes up 15.1% of the basin. Approximately 2% of the basin is classified as open water (Vogelmann et al. 2001).

River Geomorphology, Hydrology, and Chemistry

The Sacramento River contains two distinct geomorphological sections: the upper Sacramento, which is upstream of Shasta Reservoir, and the lower Sacramento. The upper Sacramento is a high-gradient (10.4 m/km) montane stream that contains cobble and coarse gravels in areas that are not underlain by bedrock. The lower Sacramento, below Shasta and Keswick dams, has a moderate to high gradient (0.8 m/km) and contains a mixed substratum, including spawning gravels. Further downstream in the valley proper the Sacramento becomes low gradient (0.26 m/km), with well-established levees and much finer sediments (Fig. 12.3). The river meanders to the delta through a highly developed agricultural setting.

In general, rivers in California are characterized by extreme inter- and intraannual variations in flow. However, the Sacramento River, as most rivers in California, is highly regulated and has numerous impoundments, water withdrawals, and irrigation return flows that alter its natural discharge pattern. These controls are obvious when mean precipitation and runoff are compared through the annual cycle (see Fig. 12.13). Although much of the winter precipitation is in the form of snow, total runoff within the channel is far less than would be expected in the absence of flow capture. Peak flows in spring have all but been eliminated. In addition, summer flows are higher than would occur under a natural hydrograph.

FIGURE 12.3 Sacramento River below Chico, California (PHOTO BY TIM PALMER).

However, this winter water storage is necessary because of the uneven seasonal and interannual distribution of precipitation, flood-control, and agricultural needs during the summer growing season. All major tributaries (McCloud, Pit, Feather, Yuba, and American rivers) of the Sacramento are also impounded. Total reservoir storage within the basin far exceeds one-half of the total annual runoff of 27.6 km^3 of water; consequently, over half of the annual flow out of the basin can be captured for human use. In the lower section of the river, near Sacramento, flood-diversion structures and ship channels also influence main-channel flow characteristics. In the Sacramento–San Joaquin Delta, channels are leveed and a significant portion of the flow of the Sacramento is diverted to the southern portion of the state via the California Aqueduct and Delta–Mendota Canal.

The highest recorded extreme flow in the Sacramento River, $3313 \text{ m}^3/\text{s}$, occurred on February

19, 1986; however, an observed (but not measured) extreme flow event through the Sacramento–San Joaquin Delta occurred in 1862 and was estimated to be $120,000 \text{ m}^3/\text{s}$ (Peterson et al. 1985). That suggests a maximum discharge of $>60,000 \text{ m}^3/\text{s}$ or 20 times the maximum recorded flow (assuming one-half of the estimated flow originated in the Sacramento basin).

In general, the Sacramento River has high-chemical-quality water because much of the flow is derived from snowmelt-dominated tributaries draining the Sierra Nevada. In the main stem, dissolved oxygen is often near saturation and conductivity is low, $\sim 100 \mu\text{S}/\text{cm}^2$ (Domagalski and Dileanis 2000), as is alkalinity, $\sim 50 \text{ mg/L}$ as CaCO_3 . pH is just under 8. Although nutrients can be locally high, particularly in feeder streams and agricultural drains, in general $\text{NO}_2\text{-N} + \text{NO}_3\text{-N}$ is $<0.2 \text{ mg/L}$.

River Biodiversity and Ecology

The Sacramento River basin lies within the Pacific Central Valley freshwater ecoregion, which is considered one of the richest aquatic ecoregions west of the Rocky Mountains. However, the ecology of the system has been altered greatly by humans.

Algae

Algae found in the Sacramento basin are dominated by chrysophytes and chlorophytes. Common diatoms include *Nitzschia dissipata*, *N. inconspicua*, *Cymbella muelleri*, *Cymbella minuta*, *Fragilaria pinnata*, *F. construens*, *Cocconeis pediculus*, *Cocconeis placentula*, and *Achnanthes minutissima*. Common green algae include *Cladophora glomerata*, *Oedogonium* sp., *Hyalotheca* sp., and *Scenedesmus* sp.

Plants

Riparian vegetation throughout the basin varies according to latitude and altitude. Trees and shrubs commonly found are arroyo, black, narrowleaf, Pacific, and red willows; black and Fremont cottonwoods; California sycamore; mulefat; mountain and white alders; buttonbush; and water birch. Prior to the rivers of the Sacramento basin being dammed, floodwaters supported extensive floodplain vegetation (e.g., cattails and sedges), particularly in the delta.

Invertebrates

As with most biological aspects of the rivers of the Sacramento basin, the distributions of aquatic

invertebrates are influenced by the diversity of habitats found in the basin. Upland stream invertebrate assemblages are dominated by cold stenothermic taxa that are often located in high-gradient streams containing high levels of dissolved oxygen. Aquatic insects common to these areas include the stonefly families Perlidae (e.g., *Hesperoperla pacifica*), Chloroperlidae (*Suwallia autumnna*), and Capniidae (*Eucapnopsis brevicauda*); the mayfly families Baetidae (*Baetis tricaudatus*, *B. bicaudatus*), Heptageniidae (*Epeorus longimanus*), and Ephemerellidae (*Drunella grandis*, *D. doddsi*); and the caddisfly families Rhyacophilidae (*Rhyacophila*) and Hydroptychidae (*Arctopsyche grandis*, *A. californica*, *Hydroptycha*) (Carter and Fend 2001).

As one enters the foothills and lower-elevation streams the composition of the invertebrate fauna changes. Taxa more frequently found in lower-elevation streams include stoneflies in the families Perlodidae (*Isoperla*) and Nemouridae (*Malenka*), mayflies in the families Siphonuridae (*Siphonurus*) and Baetidae (*Baetis tricaudatus*, *Callibaetis*), and caddisflies in the families Hydroptychidae (*Hydroptycha californica*, *Cheumatopsyche mickeli*) and Hydroptilidae (*Hydroptila*).

Relatively little is known of the native molluscan fauna; however, species probably common to the basin included the California floater, western ridge mussel, and western pearl shell. Nonnative bivalves such as the Asiatic clam now dominate some freshwater streams and rivers. *Potamocorbula amurensis*, a recently introduced bivalve, now dominates the benthos in the downstream portion of the delta and in portions of San Francisco Bay and may have altered the area's food web by influencing nutrient availability to the crustacean *Neomysis mercedis*, which once was an important component in the diet of the introduced striped bass (Orsi and Mecum 1996).

Vertebrates

Moyle (2002) provides a fascinating account of the distribution and ecology of both native and introduced fishes of California. The long period of isolation of the California fauna from most of the rest of the continent (~17 to 10 million years ago), and both the long- and short-term tectonic history of the state, has greatly influenced the existence and distribution of fish species. In addition, the temporal and spatial environmental variability within the state led to a native fauna of freshwater fishes well adapted to seasonal extremes in flow and temperature.

Nonanadromous native fishes once common to the Central Valley included Sacramento perch, the only native of the Centrarchidae west of the Rocky Mountains; tule perch; numerous cyprinids, including Sacramento blackfish, hardhead, hitch, California roach, Sacramento splittail, Sacramento pikeminnow, thicktail chub (now extinct), and speckled dace; Sacramento sucker; and riffle sculpin. There also are seasonal runs of chinook salmon and steelhead trout that spawn in the cold, upland streams; however, many of these spawning areas are now inaccessible. In addition, both white and green sturgeon spawn in the Sacramento River.

The Pit River drainage contains the Goose Lake redband trout and the Goose Lake lamprey, Pit-Klamath brook lamprey, marbled and rough sculpin, tui chub, and redband trout. The McCloud River, a former tributary of the Pit, contained bull trout.

The evolution of the Clear Lake fauna occurred after the uplift of the Coast Range restricted the upstream migration of Sacramento Valley species. Consequently, numerous species or subspecies distinct from but related to Sacramento Valley fishes are only found in Clear Lake, including Clear Lake splittail, Clear Lake hitch, and Clear Lake tule perch.

There are approximately 40 nonnative fish species throughout the Sacramento basin, including the delta and San Francisco Bay. These species include numerous species of bass, sunfishes, catfishes, and trout.

Ecosystem Processes

There are no adequate accounts of the ecological functioning of the Sacramento basin prior to the massive changes caused by human modifications. We would speculate that the seasonally predictable discharge overlain by extreme variability in interannual precipitation and runoff greatly influenced the river's form and, consequently, its biota. Upland reaches were, and still are, principally in a high-elevation forested landscape dominated by conifers, with broadleaf species along its riparian corridor. The unaltered hydrograph and sediment regime in upland reaches were substantially influenced by winter precipitation and snowmelt runoff in the spring, creating very favorable conditions for salmonid spawning and rearing.

Lowland reaches most likely contained extensive riparian forests of willows, cottonwoods, and sycamores interspersed with seasonally flooded tule marshes. Floodplain vegetation must have dominated a great deal of the valley's floor, providing habitat for native lowland fishes and extremely high dissolved and particulate organic matter to the river. Given the

naturally low nutrient conditions, this must have created a system very much driven by allochthonous inputs.

Currently, however, every major stream is impounded at least once along its course for the retention of water for flood control, irrigation, and/or hydroelectric power production. These impoundments have drastically changed the intra- and interannual hydrograph, often eliminating flood flows and the seasonal floodplain wetlands that once dominated the valley floor. Dams creating the impoundments have eliminated both upstream and downstream migrations of anadromous fishes and greatly altered natural sediment regimes necessary for maintaining spawning habitat and natural channel functioning.

When taken as a whole, and particularly in comparison to its historic state, the Sacramento River basin is basically a water storage and delivery system used to support agriculture in the Sacramento and San Joaquin valleys and urban centers in the Central Valley, the San Francisco Bay area, and the Los Angeles basin.

Human Impacts and Special Features

Although the Sacramento proper has been substantially modified in its lower reaches, several of its tributaries retain much of their natural features. Two of these tributaries, the Feather and American rivers, are designated as National Wild and Scenic rivers in portions of their basins. The Middle Fork of the Feather River has a 125 km portion that includes Feather Falls, the third-highest waterfall (195 m) in the United States, designated as Wild and Scenic. The North Fork of the American River has 62 km designated as Wild and the American main stem has 37 km flowing through the state capital of Sacramento designated as Recreational.

In contrast to these remaining scenic tributaries, much of the Sacramento system has been dramatically altered by dams, flow diversions, agriculture, mining, logging, and the introduction of nonnative species. California has one of the most extensive systems of water storage and conveyance in the world. Approximately 1400 dams, >8000 km of levees, and >140 aqueducts and canals exist in the state (Mount 1995). The three major purposes for dams are (1) municipal and agricultural water supply, (2) flood and debris control, and (3) hydropower production (Kondolf and Matthews 1993). Ditches and flumes built during the Gold Rush period in the mid-to late-1800s were the first major flow diversions.

However, the large-scale State Water Project (SWP) and federally supported Central Valley Project (CVP) systems were built in the twentieth century.

The CVP includes 16 reservoirs (including Lake Shasta) and 39 pumping plants and delivers approximately 8.6 km³/yr (California State Water Project Atlas 1999). The SWP is designed to deliver 5.2 km³/yr, with 70% going to urban users and 30% to agriculture. The extensive network of dams and water diversions are necessary to maintain the current irrigated agriculture and geographic population distribution in California because 75% of the runoff occurs from the northern portion of the state, whereas 80% of the demand for water is in the southern portion of the state (Mount 1995). However, this extensive system has numerous detrimental effects on the hydrology and ecology of rivers in the Sacramento basin. Water retention behind dams modifies normal hydrologic patterns by trapping sediment, reducing peak flood flows, and altering seasonal flows by limiting winter high flows and often increasing summer low flows. Most large dams also eliminate the transport of coarser gravels that would be suitable as salmonid spawning habitat (Kondolf and Matthews 1993). Reduction of peak flood flows in combination with levees and canalization practically eliminates any connection between the river and its floodplain. Elimination of flood flows also allows riparian encroachment to occur. Dam releases also can alter the seasonal temperature regime, whether releases are from the surface or hypolimnion. Seasonal changes in total discharge can also alter normal temperature regimes. However, the primary effect of dams on migratory salmonids is to exclude them from much of their historic spawning habitat; for example, chinook spawning habitat loss has been estimated to be >90%. In addition, many fishes are killed by unscreened water diversions throughout the state and at the massive screened diversions associated with the large-scale water diversions in the delta.

Mount (1995) suggests that agriculture has altered the rivers of California more than any other industry. Impacts include increased erosion, degradation of riparian corridors, and increased concentrations of pesticides and salts. Agriculture accounts for 80% (~38.1 km³) of the total nonenvironmental water use in California. Alfalfa, irrigated pasture, cotton, and rice represent approximately one-third to one-half of this agricultural water use. When viewed on a county basis, the total number of cattle in the Sacramento basin is ~656,000 (California Agricultural Statistics Service 2001

<http://www.nass.usda.gov/ca/coest/104lvstp.htm>). During California's dry summers cattle often enter riparian corridors, degrading streamside habitat quality; the American Fisheries Society has listed grazing as the most important cause of riparian corridor degradation in western streams (Mount 1995).

Three types of mining—gold, hardrock, and gravel—have influenced and in some cases continue to influence rivers in the Sacramento basin. Hydraulic mining (outlawed in 1884) associated with gold extraction washed entire hillsides into streams and severely degraded channels and riparian corridors. In total, 42,500,000 m³ of mining debris was washed into the Central Valley. Along with gold mining came the contamination of the tributaries of the Sacramento, and in particular the contamination of the delta and San Francisco Bay with mercury. Mercury was used to amalgamate gold in the Sierra Nevada and over time entered streams and was transported to the delta and San Francisco Bay, where it was readily transformed to the more biologically available and toxic methylmercury. Health advisories have been issued on the consumption of many non-migratory fishes found in the bay and delta, in part because of the methylmercury toxicity.

Of the 1500 abandoned mines in California, approximately 150 are discharging metal-rich waters (Mount 1995). Within the Sacramento basin, Iron Mountain Mine, an Environmental Protection Agency Super Fund Site, is the most thoroughly studied. The mining area releases approximately 544 kg of Cu and 363 kg of Zn to Keswick Reservoir located just below Shasta Dam on the Sacramento River. Elevated levels of Cd, Cu, Pb, and Zn have been detected in the caddisfly *Hydropsyche californica* up to 120 km below the reservoir (Cain et al. 2000).

Over 1 billion tons (>900 billion kg) of sand and gravel were mined in California between 1985 and 1995, and although not all was extracted from streams, this represents ~10 times the bedload of the state's rivers (Mount 1995). The effect of gravel mining is often long lasting, particularly downstream of dams. When Shasta Dam was built in 1944, 5,400,000 m³ of gravel was removed from the Sacramento for its construction; the bed was excavated to a depth of 15 m. Because of the initial excavation and the elimination of the supply of new gravel from upstream by Shasta Dam, to date the bed of the reach downstream of the dam contains only coarse cobble and bedrock (Kondolf and Matthews 1993). Gravel mining often leads to incision of stream channels. Cache Creek, a tributary to the

Sacramento, has incised >3.7 m over a 50-year period of gravel mining (Mount 1995).

Logging also degrades rivers in the basin. California produces approximately 11,800,000 m³ of lumber annually. Although the majority of the state's lumber is derived from the north coast forests, logging is an important industry in the Sierra Nevada and some Coastal Range areas. Some logging practices have led to the degradation of stream habitat by causing soil compaction, increased fine sediment runoff, and reduction in riparian quality.

Many nonnative invertebrates and fishes have been both intentionally and unintentionally introduced into the lakes, rivers, and bays of the Sacramento basin. One of the first (1869) recorded introductions to San Francisco Bay was the eastern oyster, which became the bay's most valuable product by the late 1890s. Two early fish introductions included the American shad (1872) and the striped bass (1879). A commercial fishery for striped bass existed between 1889 and 1935. Many fishes have been introduced to the Sacramento basin. In a recent study, of the 35 species collected throughout the lower portion of the basin only 12 were native species (May and Brown 2002, Domagalski et al. 2000).

Introductions continue to occur. For example, an introduced estuarine bivalve, *Potamocorbula amurensis*, which was first collected in 1987 (Carlton et al. 1990), has the potential to greatly alter food webs (Alpine and Cloern 1992) and possibly affect contaminant transport in the delta and San Francisco Bay. A very recent introduction to the bay/delta/river system is the Chinese mitten crab. This crab is catadromous, spawning in the bay and then migrating upstream to mature. It has the potential to cause substantial damage to natural streambanks and levees (particularly in the delta) because of its extensive burrowing habits (Rudnick et al. 2003).

SAN JOAQUIN RIVER

The San Joaquin River originates high (>4000 m asl) in the Sierra Nevada near the middle of California (Fig. 12.14). The river is 560 km long and has a drainage area of 83,409 km². The San Joaquin lies entirely within California and drains the southern portion of the Central (or Great) Valley. The basin can be divided into two regions, with a low topographic divide formed by the alluvial fan of the Kings River separating the southern Tulare basin from the San Joaquin River. Only during exceptionally wet periods does water flow from the Tulare basin into

FIGURE 12.4 San Joaquin River, within the Central Valley, California (PHOTO COURTESY OF GREAT VALLEY MUSEUM, MODESTO, CALIFORNIA).

the San Joaquin (Gronberg et al. 1998). Today, almost all of the water of the San Joaquin is diverted for agricultural and municipal use (Fig. 12.4).

All large tributaries draining into the San Joaquin basin originate in the Sierra Nevada. Tributaries draining directly into the San Joaquin include the Stanislaus, Tuolumne, and Merced rivers. Tributaries draining into the Tulare basin include the Kings, Kaweah, Tule, and Kern rivers. Portions of four tributaries (Tuolumne, Merced, Kings, and Kern) have been designated as Wild and Scenic Rivers.

The total number of Native Americans (~70,000) and number of tribes (~50) attests to the diversity of habitat and productivity of the pre-Columbian San Joaquin Valley. The tribes inhabiting the basin included the Plains and Sierra Miwok in the north, the Yokuts in the south, and the Tübatulabal in the Kern River canyon (Heizer and Elsasser 1980). In the lakes area (Tulare, Kern, and Buena Vista lakes), the Southern Valley Yokuts fished and hunted waterfowl using rafts made of tule. They gathered the starchy roots of cattail and seeds from tules and

grasses and hunted pronghorn, elk, and rabbits in the foothills. Many of the villages in the valley were constructed on higher ground because of the annual spring flooding of the valley during snowmelt. The main European settlement began in the mid-1850s during the Gold Rush.

Physiography, Climate, and Land Use

The San Joaquin River basin is part of the Cascade–Sierra Mountains (CS) and Pacific Border (PB) physiographic provinces (see Fig. 12.14) (Hunt 1974). To the east and south is the Sierra Nevada Mountains section. These mountains begin in the north, just south of Lassen Peak, and continue for 640 km in a southeasterly direction. They are considered the structural backbone of California (Hunt 1974). They are composed of pre-Tertiary granitic rocks that are separated from the valley floor by Mesozoic and Paleozoic marine rocks and Mesozoic metavolcanic rocks. The southern Sierra Nevada are higher in altitude and have less volcanic overburden

than the northern Sierra Nevada. The highest point in the basin, Mt. Whitney, is the highest point (4418 m asl) in the contiguous United States. The basin is bordered on the south by the Tehachapi Mountains.

The remainder of the basin is contained within the Pacific Border province. To the west of the Central Valley lies the California Coast Ranges section. These are northwest–southeast aligned, low-elevation mountains formed in the south by tectonic movement along the San Andreas Fault zone. These mountains are composed of a core of Franciscan assemblage dating from the late Jurassic to Cretaceous or Paleocene age and Mesozoic ultramafic rocks. Marine and continental sediments of Cretaceous to Quaternary age overlie these rocks, with some Tertiary volcanic rocks included (Gronberg et al. 1998).

The Central Valley lies in the California Trough section of the Pacific Border province. This portion of the Central Valley can be divided into two parts: a northern portion, extending from the Sacramento–San Joaquin Delta to just south of the San Joaquin River, and a southern portion, the Tulare basin, extending from south of the San Joaquin River to the Tehachapi Mountains. The Tulare basin is a hydrologically closed system. Historically, the Kings River drained into Tulare Lake, which overflowed into Buena Vista Lake to the south and, during extremely wet periods, the San Joaquin to the north (Schoenherr 1992).

The San Joaquin basin is part of three terrestrial ecoregions (Ricketts et al. 1999). The California Central Valley Grasslands ecoregion represents the southern portion of the Central Valley of California (in contrast to the northern portion, drained by the Sacramento River) and is the most anthropogenically modified from its pre-Columbian condition.

Surrounding the floor of the Central Valley at a slightly higher altitude is the California Interior Chaparral and Woodlands ecoregion. It represents foothill communities, which are dominated by grasslands, chaparral, oak savannahs, and oak woodlands. Numerous plants and animals are endemic to this ecoregion.

To the east and at higher altitude is the Sierra Nevada Forests ecoregion. This southern portion of the ecoregion has one of the highest concentrations of terrestrial endemic species. As in the north, plant assemblages are arranged in altitudinal zones forming a gradient from ponderosa pine forest, to mixed conifers (including the giant sequoia), to the subalpine zone of lodgepole and Jeffrey pines, moun-

tain juniper, and aspen, to mountain hemlock and whitebark pine at >2700 m asl.

As throughout all of California, the basin experiences extremes in climate that are often orographically driven. In general, this southern portion of the Central Valley, including the surrounding lower ranges, is much drier than the Sacramento River drainage. There is both an east–west and a north–south gradient in precipitation. Precipitation in the coastal mountains ranges from 25 to >50 cm/yr. Precipitation in the valley, which lies in the rain shadow of the coast range, averages from 38 cm/yr in the north to only 12 cm/yr in the south. Precipitation increases as moisture-laden air rises over the Sierra Nevada and ranges from 50 cm/yr at lower altitudes to >200 cm/yr at the summit. As throughout this region, precipitation mainly occurs from October through April, with only occasional thunderstorms occurring during summer (Fig. 12.15). Average temperature for the basin is 15.7°C, but monthly averages range from 6.8°C in January and December to 25.2°C in July. Maximum daily average summer temperature in the basin, 30.8°C, occurs in July. Temperature in the basin generally decreases with increasing altitude.

Land cover in the basin can be divided into urban, agricultural, and nonurban/nonagricultural uses. Urban land cover comprises only 1.9% of the basin. The four most populous cities, Fresno, Bakersfield, Stockton, and Modesto, represent almost 50% of the total population of the basin. Nonurban/nonagricultural land cover includes forest (26.8%), shrub (13.4%), grasslands (23.0%), and wetlands (0.4%). Agricultural land use is the dominant single classification and represents 30% of land use in the basin (Vogelmann et al. 2001).

River Geomorphology, Hydrology, and Chemistry

Although the natural course of the San Joaquin River is interrupted at many locations, it originates in the high Sierra as an extremely high-gradient (22.7 m/km) stream flowing over granitic bedrock. As it transitions between the high Sierra and the foothills, it has a riparian corridor of willows and cottonwoods and flows over cobble and gravel substrates at a gradient of 4.8 m/km. Once in the lower valley the San Joaquin changes to a low-gradient (0.16 m/km) sand-bed river and takes a meandering course through the Central Valley to the delta (see Fig. 12.4). It once supported extensive tule marshes.

Tributary stream types in the basin include high-altitude, high-gradient streams, large tributary streams draining the Sierra Nevada, and lower-elevation and foothill intermittent streams.

It is difficult to imagine a river that is more hydrologically modified by humans than the San Joaquin. As with many other rivers in the Central Valley of California, it is primarily used to store and deliver water and remove municipal, industrial, and agricultural wastes. The basin has experienced a long history of flow capture and diversion; almost all the surface-water flow of the basin had been diverted by as early as 1910 (Williamson et al. 1989). Nevertheless, a substantial portion of the water used in the basin for irrigation is derived from local groundwater and surface water delivered by canals from the more northern, wetter Sacramento River basin.

Numerous small reservoirs located in the headwaters of the San Joaquin retain a portion of its flow; however, just before the river enters the valley Friant Dam captures the remaining flow at Millerton Lake (0.641 km^3). Most of the captured water is used for irrigation in the Central Valley. Water pumped from the Sacramento–San Joaquin Delta that flows through the Delta–Mendota canal functionally reverses the normal south to north flow of the San Joaquin River (see Fig. 12.14). Downstream of Mendota Pool, discharge is augmented from tributaries (Stanislaus, Tuolumne, and Merced rivers) entering from the Sierra Nevada.

All major tributaries to the San Joaquin are now impounded at least once along their course. Major reservoir storage is $\sim 9.498 \text{ km}^3$ in the San Joaquin drainage (excluding the Tulare basin) and is only about one-half the storage capacity of the Sacramento basin. Prior to impoundments, all of the rivers flowing from the Sierra Nevada would have had spring–early summer peak flood flows fed by snowmelt runoff. These waters would inundate a great deal of the valley floor and supported lush tule marsh habitats with their associated biota. The lakes and marshes of the Tulare basin were drained in the mid 1800s, and now the four major rivers in the basin (Kings, Kaweah, Tule, and Kern rivers) have all been impounded.

The mean annual discharge to the basin from the Sierra Nevada is approximately $10.855 \text{ km}^3/\text{yr}$ ($344 \text{ m}^3/\text{s}$). Discharge from the Coast Ranges is only $0.114 \text{ km}^3/\text{yr}$ ($3.6 \text{ m}^3/\text{s}$) (Nady and Larragueta 1983), just over 1% of the total flowing from the Sierra. The potential annual discharge from the San Joaquin basin for the period from 1979 to 1992 has been estimated to be $7.524 \text{ km}^3/\text{yr}$ ($238.6 \text{ m}^3/\text{s}$); however,

actual discharge downstream on the San Joaquin near the town of Vernalis is only $4.564 \text{ km}^3/\text{yr}$ ($144.7 \text{ m}^3/\text{s}$), which is $\sim 60\%$ of the potential discharge from the basin (Gronberg et al. 1998). The small difference between $144.7 \text{ m}^3/\text{s}$ and the value shown in the San Joaquin summary ($132 \text{ m}^3/\text{s}$) is due to differences in coverage periods.

Water management to provide for irrigation during the summer growing season severely alters the natural hydrologic cycle. Normal spring peak flows are dampened by reservoir retention of winter–spring floodwaters, and normally low summer–autumn flows are augmented by reservoir releases and seasonal irrigation return flows (see Fig. 12.15). Runoff now only reaches $0.7 \text{ cm}/\text{mo}$ in spring, which is only about 15% of the spring runoff in the Sacramento River.

The natural water chemistry of the drainage is influenced directly by precipitation patterns, bedrock geology, and soil types. Because most of the water in the basin drains from the Sierra Nevada over granitic bedrock and flows through poorly developed, low-solubility quartz and feldspar soils, the waters contain very low levels of dissolved solids. However, waters draining from the Coast Ranges, where soils are derived from marine sediments that are rich in soluble calcium, sodium, and magnesium sulfates, are much higher in dissolved solids. Extensive irrigation of these soils located on the west side of the San Joaquin Valley has led to the contamination of some areas by selenium (Ohlendorf et al. 1986).

The water chemistry of the San Joaquin is strongly influenced by agricultural tailwaters and inflows from the Sierra Nevada tributaries. From the upper portion of the basin to just below Friant Dam the San Joaquin has very low conductivity ($<100 \mu\text{S}/\text{cm}$) and hardness ($<20 \text{ mg}/\text{L}$ as CaCO_3) (Kratzer and Shelton 1998). However, downstream of the city of Mendota conductivity increases to $>1000 \mu\text{S}/\text{cm}$ and hardness is $>250 \text{ mg}/\text{L}$ as CaCO_3 . Dissolved oxygen is in excess of $8.0 \text{ mg}/\text{L}$ and pH is slightly alkaline, ranging from 7.1 to 8.0. Nutrients are extremely low in Sierran waters and moderate in the downstream main stem. Median $\text{NO}_3\text{-N}$ levels just exceed $2 \text{ mg}/\text{L}$ and total phosphorus is $<0.5 \text{ mg P}/\text{L}$. Dissolved ortho-P is normally $<0.2 \text{ mg P}/\text{L}$ (Kratzer and Shelton 1998). However, many of the agriculturally and municipally influenced drains, canals, and sloughs in the valley often have extremely high concentrations of measured constituents (conductivity $<3000 \mu\text{S}/\text{cm}$; hardness $>800 \text{ mg}/\text{L}$ as CaCO_3 , $\text{NO}_3\text{-N} >20 \text{ mg}/\text{L}$).

River Biodiversity and Ecology

The San Joaquin River lies entirely within the Pacific Central Valley freshwater ecoregion (Abell et al. 2000). This ecoregion has been isolated from the rest of North America for approximately 10 to 17 million years. This isolation and the diversity of habitats in the basin led to the evolution of a unique fish fauna with a high level of endemism.

Algae and Cyanobacteria

Leland et al. (2001) found that the diatoms *Navicula recens* and *Nitzschia inconspicua* dominated the benthos of the San Joaquin. The principal cyanobacteria was *Oscillatoria*. Diatoms common in phytoplankton included *Cyclotella meneghiniana*, *Skeletonema* cf. *potamos*, *Cyclostephanos invisitatus*, *Thalassiosira weissflogii*, *Nitzschia acicularis*, *N. palea*, and *N. reversa*. Salinity appeared to be an important factor in the distribution of algae within the river system.

Plants

Historically, the southern portion of the San Joaquin Valley supported some of the largest freshwater marshes in the west. Tulare Lake was the largest (1800 km²) lake west of the Mississippi River in the mid 1800s (Schoenherr 1992). Marsh plants were distributed in predictable zonation patterns. Open-water plants included watercress, Pacific marsh purslane (marsh seedbox), water fern, and duckweeds. Within the water proper were rushes, bulrushes, sedges, and cattails. Higher in the marsh were black, red, and Pacific willows. Plants at the highest level included mulefat and buttonbush.

Invertebrates

Invertebrate species are generally distributed along an altitudinal gradient. In the upper reaches of the San Joaquin invertebrate faunas include upland taxa such as the mayflies *Baetis bicaudatus*, *Epeorus*, and *Drunella*; the stoneflies *Hesperoperla pacifica*, *Suwallia autumnna*, and *Eucapnopsis brevicauda*; and the caddisflies *Rhyacophila*, *Arctopsyche grandis*, and *A. californica*.

Little is known of the original distribution of invertebrates in lower reaches, but they currently appear to be influenced by available habitat and water chemistry, particularly agriculturally derived salinity (Leland and Fend 1998). Abundant taxa in lower reaches include the caddisfly *Hydropsyche californica* and the Asiatic clam, along with chironomid midges and oligochaete worms. Downstream reaches

of the large tributary streams often contain the mayflies *Caenis*, *Heptagenia*, *Fallceon*, and, less frequently, *Ephemerella*. Also abundant is the caddisfly *Nectopsyche* (Leland and Fend 1998). The sooty crayfish (possibly extinct) may also have been present in the basin. The most common crayfish now is the nonnative swamp crayfish (Schoenherr 1992).

Vertebrates

The Central Valley of California has been a “center of fish speciation” in California (Moyle 2002). Its freshwater dispersant fauna became isolated from the rest of the fish fauna of western North America 10 to 17 million years ago (Minckley et al. 1986). It contains 17 endemic species (40 if subspecies and distinct salmon runs and species shared with adjacent drainages are included) and 5 euryhaline marine species in the delta.

As a result of this long-term isolation, the fishes of the Central Valley appear to have limited ancestry. The Sacramento perch is the only native member of the Centrarchidae (sunfishes) west of the Rocky Mountains. The closest relatives of hardhead and Sacramento perch are only known from late Pliocene fossils found in Idaho. Tule perch and delta smelt have a marine origin. The Sacramento sucker and Sacramento pikeminnow have ancestry outside of the system. Numerous minnows (splittail, hitch, Sacramento blackfish, California roach, and thicketail chub) are also present. In addition to the strictly freshwater fauna, numerous anadromous species are present from the families Petromyzontidae, Acipenseridae, Salmonidae, and Gasterosteidae.

Altitude, stream gradient, and stream order strongly influenced the historical composition of the native fish fauna (Brown 1996). Prior to the introduction of trout in the high Sierra the only fishes found at the highest elevations were the Little Kern River golden trout, the Kern River rainbow trout, and the California golden trout. At elevations between 450 and 1000 m asl the fauna was dominated by rainbow trout and included riffle sculpin, California roach, and Sacramento pikeminnow and Sacramento suckers. Between 30 and 450 m asl the fauna was dominated by Sacramento pikeminnow and Sacramento suckers and included California roach, riffle or prickly sculpin, rainbow trout, and hardhead. At the lowest elevations were deep-bodied fishes, including thicketail chub (now extinct), Sacramento perch, hitch, Sacramento tule perch, Sacramento blackfish, Sacramento splittail, and large Sacramento suckers and pikeminnows. The principal

migratory salmonids in the San Joaquin River include chinook salmon, steelhead rainbow trout, and Pacific lamprey.

Numerous fishes found in the San Joaquin basin have been listed as threatened or endangered. These include the delta smelt, Sacramento splittail, Little Kern golden trout, and Lahontan and Paiute cutthroat trout. Also listed as threatened is the Central Valley spring-run chinook salmon population.

Today, approximately 40 nonnative fishes are found in the San Joaquin basin. These nonnative species include bass, sunfishes, catfishes, perch, and trout. The severely reduced freshwater marshes associated with the San Joaquin provide important habitat for migratory waterfowl, muskrat, and beaver in the northern portions of the valley (Schoenherr 1992).

Ecosystem Processes

As with the Sacramento basin, there are no adequate accounts of ecosystem processes prior to the massive changes caused by human modifications. We would speculate, however, that the productivity of the San Joaquin basin was probably very high. For example, the seasonally predictable discharge in the San Joaquin, and particularly the streams flowing from the Sierra Nevada, provided excellent spawning and rearing habitat for salmonids.

Lowland reaches and the upland areas around Tule Lake contained extensive marshes and extensive riparian forests of willows, cottonwoods, and sycamores. Floodplain vegetation must have dominated a great deal of the valley floor, providing habitat for native lowland deep-bodied fishes, and contributing large amounts of dissolved and particulate organic matter to the river. Given the naturally low-nutrient waters flowing from the Sierra Nevada, this must have created a system very much driven by floodplain allochthonous inputs.

The productivity of the Tulare basin must have been extremely high to support the waterfowl and fishes reported there in the early to mid 1800s (Schoenherr 1992). Under natural hydrologic conditions the Tulare basin portion of the San Joaquin basin most likely overflowed into the San Joaquin via Fresno Slough whenever wet years increased lake levels; this also provided extremely high loads of suspended and dissolved organic matter. A more frequent connection between the two basins most likely influenced the hydrology, chemistry, and biology of both the northern and southern basins within the San Joaquin Valley.

Human Impacts and Special Features

Although the San Joaquin River has been greatly altered in the Central Valley, several of its scenic Sierra Nevada tributaries retain many of their natural features. The Tuolumne, Merced, Kings, and Kern rivers all have long sections listed as National Wild and Scenic Rivers. The Tuolumne, starting at its source and continuing to Don Pedro Reservoir, has approximately 134 km (76 km Wild, 37 km Scenic, and 21 km Recreational) designated. The Merced, originating in spectacular Yosemite National Park, has two main sections totaling 197 km (114 km Wild, 26 km Scenic, and 57 km Recreational). The Middle and South Forks of the Kings have a combined total of 130 km (105 km Wild, 25 km Recreational). The North Fork and South Fork of the Kern are designated for a total of 243 km (198 km Wild, 34 km Scenic, 11 km Recreational). The South Fork begins in Inyo National Forest and is golden trout habitat; the California golden trout is the state fish of California. The North Fork begins in Sequoia National Park and flows through the Golden Trout Wilderness.

The major alterations to the San Joaquin River and its tributaries are primarily associated with dams, flow diversion, agriculture, and nonnative species introductions. As in the Sacramento River basin, dams and flow diversions significantly influence the hydrology and biology of the San Joaquin basin. The San Joaquin itself and each of its major tributaries are dammed at least once, and most tributaries have multiple dams and/or diversions along their courses. For example, the Stanislaus River has over 40 dams upstream of the main dam (Kondolf and Matthews 1993).

The effects of dams are similar to those described for the Sacramento basin. These include alteration of the natural hydrograph, temperature regimes, and coarse sediment transport, all of which negatively influence native biota. For example, prior to building Friant Dam on the San Joaquin chinook salmon runs were estimated at 300,000 to 500,000 fish. After construction, salmon were separated from historic spawning habitat and the spring run was eliminated (Brown 1996). Dams on the Merced, Tuolumne, and Stanislaus rivers also significantly affected fall-run chinook and in 1990 fewer than 1000 adult salmon were observed in the drainage.

The California Aqueduct and Delta–Mendota canals serve principally to convey water from the delta into the San Joaquin and Los Angeles basins. Associated with agricultural withdrawals is the loss

of fishes (larvae and adults) via unscreened diversions and large screened diversions within the delta. Under low-water conditions and during periods of high water pumping from the delta normal downstream flow can actually be reversed in some channels (Mount 1995).

Agriculture is the major user of water and the major source of pollution in the San Joaquin basin. Of the 14.9 km³ of water used in 1990, 94.9% was used for irrigated agriculture and 1.5% was used for livestock (Kratzer and Shelton 1998). Fresno, Kern, Kings, and Tulare counties ranked in the top five nationally in nitrogen fertilizer applications, and Fresno and Kern ranked first and second for phosphorus application in 1985 (Kratzer and Shelton 1998). In the area around the lower San Joaquin, the use of nitrogen fertilizer increased by 500% and phosphorus by 285% from 1950 to 1990 (Kratzer and Shelton 1998). Even though nitrogen levels in some tributaries exceed drinking-water standards, only slight increases have been detected in the main stem (Dubrovsky et al. 1998). Livestock, also a source of nitrogen and phosphorus to the basin, have increased in recent years; for example, dairies in Tulare, Stanislaus, and Merced counties increased in number of dairy cows by 39%, 25%, and 42%, respectively, between 1991 and 2001 (California Agricultural Statistics Service 2001 <http://www.nass.usda.gov/ca/coest/104lvstp.htm>).

Pesticide use in the basin also is high. Pesticides are frequently detected in the San Joaquin River and at times have been found in concentrations that are toxic to aquatic life. Although many different pesticides are used in the basin, high concentrations of diazinon have been responsible for 40% of the water-quality exceedences (Dubrovsky et al. 1998).

In addition to the large quantities of irrigation water needed to farm in arid conditions, periodic flushing of excess salts is necessary in portions of the basin that have naturally saline soils. Unfortunately, these practices led to the contamination of surface waters with selenium. During the 1980s deformities found in some wildlife species in portions of the San Joaquin valley were attributed to selenium toxicity (Ohlendorf et al. 1986), which led to changes in the management of irrigation waters.

Nonnative species have considerably altered the natural environment of the San Joaquin River. One of the most visually obvious nonnative plants in the San Joaquin is water hyacinth; however, little is known about the effect it has on resident aquatic communities. Also present as nonnative species are the yellow pond lily and Brazilian waterweed.

Of 31 fish taxa collected by Brown (1998) in the lower San Joaquin River and lower portions of the large east-side tributaries draining the Sierra Nevada, only 10 were native to the basin. However, an assemblage of native species characteristic of predevelopment conditions existed in the portions of the large tributaries just below major impoundments. The more downstream reaches of the tributaries, and particularly the San Joaquin main stem, were dominated by nonnative species. Nonnative species characteristic of the main stem were fathead minnow, inland silverside, red shiner, and threadfin shad. Brown (1998) attributed the current distribution of taxa to species introductions and hydrological, chemical, and habitat modifications associated with agricultural development of the valley.

SALINAS RIVER

The Salinas River begins at 671 m asl in the portion of the Los Padres National Forest located in the La Panza Range of central California (Fig. 12.16). It flows in a northwesterly direction for 288 km and discharges into Monterey Bay on the Pacific Ocean about 18 km north of Monterey, California. The Salinas River is considered the third-longest river that flows entirely within California; it drains a basin of 10,983 km². The Salinas is known as the “upside-down river” (Fisher 1945, Anderson 2000) because it flows south to north and naturally flowed underground for approximately 129 km of its length within the lower Salinas Valley during the summer–autumn dry season. The Salinas Valley is often referred to as “America’s Salad Bowl” (Anderson 2000) because of the high production of vegetables. The principal tributaries to the Salinas River are the Estrella, Nacimiento, San Antonio, and Arroyo Seco rivers. The Salinas River has been known by various names, including the Santa Delfina, San Antonio, and Rio de Monterey (McDonnell 1962). During the 1820s it was also believed to be the mythical river San Buenaventura that flowed from the Sierra Nevada to the Pacific Ocean.

Prior to European settlement several Native American groups inhabited the Salinas Valley area. The Salinan inhabited an area that extended from the middle of the valley to the southern portion of the basin. The Esselen lived in the Santa Lucia Mountains and along the Arroyo Seco River. The Costanoans (or Ohlone) lived from King City north to and including the San Francisco Bay area. Those Native Americans living near the coast harvested vast

quantities of shellfish, as shown by many large middens containing marine invertebrate remains. As throughout most of California, acorns were a staple. Fire was regularly used to convert shrublands to more productive grasslands that better supported pronghorn, deer, and elk. Spanish settlement began in the mid to late eighteenth century and Spanish ranchos were formed at the very end of the eighteenth century (Anderson 2000).

Physiography, Climate, and Land Use

The Salinas River lies entirely within the California Coast Ranges section of the Pacific Border (PB) physiographic province (see Fig. 12.16) (Hunt 1974). The Salinas basin has a complex and rather recent geologic history, with ongoing tectonic activity. The Salinas River is a structurally controlled stream lying in a northwest–southeast synclinal trough with a long history of sediment deposition. The southern portion of the drainage, as well as the San Antonio and Nacimiento rivers, lie in a system of folds and faults, which are common throughout the coastal ranges (Norris and Webb 1990).

The Salinas Valley, which is west of the San Andreas Fault, was once located south of the Sierra Nevada (Schoenherr 1992). Movement along the fault over the last 80 million years has transported this region 600 km northward. Movement has been slow (2 cm/yr) but can also be very rapid (8 to 12 m during a single event). There are widely distributed Miocene rocks in the Coast Ranges that consist of marine sediments deposited as diatomites and silicic ash beds. Pliocene and Pleistocene alluvial deposits and lakebed deposits are also widespread in the region (Norris and Webb 1990). Serpentine, which is associated with distinctive plant assemblages because of its unique mineral content, is part of the Franciscan rocks also common to the basin.

The Salinas River basin is predominately in the California Interior Chaparral and Woodlands terrestrial ecoregion (Ricketts et al. 1999), although a small but important part of the basin in terms of water resources is in the California Montane Chaparral and Woodlands ecoregion located in the Santa Lucia Range. Both ecoregions represent Mediterranean Scrub and Savannah habitat types (Ricketts et al. 1999).

The California Interior Chaparral and Woodlands ecoregion ranges from about 90 to 910 m asl in elevation. Grasslands were originally dominated by perennial bunchgrasses but now are dominated by nonnative annual grasses. Chaparral is composed of

a mixture of herbaceous plants and shrubs and is often dominated by manzanita. At lower montane elevations foothill pine and blue oak are frequent. Although tree species are dominated by blue oak, oak diversity is high and includes coast, canyon, valley, and interior live oaks. In many areas, chaparral plants dominate the landscape and include California buckeye, manzanita, and scrub oak. In the southern Coast Ranges, north-facing slopes at higher elevations are dominated by mixed evergreen forest consisting of tanoak and Pacific madrone, with Coulter pine in the south and foothill pine in the north; both are drought-resistant yellow pines (Schoenherr 1992). The Santa Lucia fir is endemic. Serpentine soils that are formed from serpentinite (the state rock of California) are common in the area and contain unique plant assemblages with many endemics. These communities often contain leather oak, muskbrush (Jepson ceanothus), interior silktassel, milkwort, and streptanthus (Miles and Goudey 1997).

The only portion of the Salinas River basin included in the California Montane Chaparral and Woodlands terrestrial ecoregion is the portion of the Santa Lucia Mountains bordering the Salinas Valley on the southwest. This range runs parallel to the coast and is the origin of the basin's major tributaries because it receives higher levels of precipitation than the rest of the basin. Redwoods grow just west of the basin in the Big Sur area along the coast, and evergreen communities include coast live oaks, madrone, coastal sage, and chamise chaparral at low elevations. At higher elevations, tanoak and canyon live oak are frequently found. At even higher elevations the community transitions to an assemblage consisting of ponderosa, sugar, Jeffrey, and Coulter pines. Knobcone pines are often found on serpentine soils and the Santa Lucia fir is endemic to this ecoregion.

The climate of the area is mild, with relatively low precipitation. Average annual temperature is 14.4°C, with average winter temperature about 10°C and summer temperature about 18.9°C (Fig. 12.17). Most rainfall occurs from November through April. Average annual precipitation in the valley is only 36.3 cm. However, in the portion of the Ventana Wilderness on the western side of the Santa Lucia Range in the area of Big Sur, average annual precipitation is ~102 cm/yr and increases to ~127 cm/yr at higher elevations. A weighted mean annual precipitation for the Salinas basin based on precipitation isopleths is 44.5 cm/yr (<http://endeavor.des.ucdavis.edu/newcara/>).

FIGURE 12.5 Salinas River, California, looking upstream (south-southeast) from approximately Rkm 102. City in upper left is King City and highway on right is U.S. 101. Highest peaks are part of Santa Lucia Range (PHOTO BY K. EKELUND, MONTEREY COUNTY WATER RESOURCES AGENCY).

Land use in the Salinas basin is dominated by agriculture. Land cover in the basin is 17.4% forest, 15.9% shrub, 49% grasslands, and <1% wetlands. Agriculture represents only 12.8% of the basin but has profound effects on the water quality of the northern portion of the basin. Urban areas represent 0.7% of the basin (Vogelmann et al. 2001).

River Geomorphology, Hydrology, and Chemistry

The Salinas River begins as a relatively high-gradient (8.8 m/km), pool-riffle stream flowing over bedrock and cobble to gravel substrates. However, once the river enters the lower portion of the Salinas Valley it becomes a low-gradient (0.78 m/km), meandering, sand-bed river flowing through an intensive agricultural setting (Fig. 12.5).

The first major tributary is the Estrella River, which enters from the southeast and flows out of the Gabilan Range. Further downstream major tribu-

aries entering from the southwest include the Nacimiento and San Antonio rivers that flow from the Santa Lucia Range. About 70% of the runoff to the Salinas River comes from the Santa Lucia Range (Irwin 1976). Both of these southern tributaries originate about 6 km from the Pacific Coast at about 915 to 1220 m asl. Further downstream the Arroyo Seco River, also originating about 6 km from the coast at approximately 1400 m asl, flows out of the Ventana Wilderness.

As throughout much of the west the influence of dams on river discharge is extreme. The two largest reservoirs, Nacimiento and San Antonio, are located on the southwest side of the basin in the Santa Lucia Range. The Santa Margarita Reservoir is located on the main stem in the southern portion of the drainage. Flow along the Salinas River is very much a function of the soil permeability, season, reservoir releases, the extent of groundwater pumping, and the river's longitudinal position in the valley. Runoff is very much lower than precipitation during winter

because of flow capture and infiltration (see Fig. 12.17).

Flows in the upstream portion of the Salinas historically were at a minimum by September, and often $<0.0142\text{ m}^3/\text{s}$. Discharge began to increase at Pozo in October as the autumn rains began. However, at Paso Robles, downstream of Santa Margarita Reservoir, discharge was most often zero from October through December (U.S. Geological Survey 2001 <http://water.usgs.gov/nwis>). Prior to building Nacimiento Reservoir in 1957, the Salinas River discharge at Bradley, approximately 6 km downstream of the confluence of the Nacimiento and Salinas rivers, was $>2.8\text{ m}^3/\text{s}$ between January and May and decreased to just a few tenths of m^3/s during summer and early autumn. However, by 1958 the reservoir began releasing water for irrigation and aquifer recharge during the summer and discharge at the same location increased to 11 to $14\text{ m}^3/\text{s}$, at least an order of magnitude higher than prereservoir operation. Downstream of Bradley there is a general decrease in discharge from July through November as the Salinas River water recharges the underlying aquifers that are pumped for irrigation water. During this period discharge decreases in a downstream direction from 2.8 to $5.6\text{ m}^3/\text{s}$ at Soledad, to 1.4 to $2.8\text{ m}^3/\text{s}$ at Chualar, to $<1.4\text{ m}^3/\text{s}$ near Salinas. During drought periods, such as those in the late 1980s and early 1990s, the Salinas River went dry at these downstream locations.

Water chemistry of the Salinas River is strongly influenced by the intensive agricultural land use occurring in the Salinas Valley. Although the chemistry changes along the course of the river, the following estimates are for the Salinas River just upstream from Salinas. The waters are moderately hard (321 mg/L as CaCO_3) and somewhat alkaline (mean pH 7.8). Conductivity is very high, averaging $1003\text{ }\mu\text{S}/\text{cm}$, as are nutrients ($\text{NO}_3\text{-N} + \text{NO}_2\text{-N}$ averages 2.9 mg/L and $\text{PO}_4\text{-P}$ averages 4.4 mg/L) (U.S. Geological Survey 2001 <http://water.usgs.gov/nwis>).

River Biodiversity and Ecology

The Salinas River is in the Pacific Central Valley freshwater ecoregion and has the major habitat type of Temperate Coastal Rivers, Lakes, and Springs (Abell et al. 2000). Research on its fishes and benthic biota has begun only recently.

Plants

Much of the native riparian habitat of the Salinas River has been compromised by channel alterations

and agriculture. Large riparian plants that are native to the stream include willows (arroyo, narrowleaf, red, and Sitka), buttonbush, California sycamore, Fremont cottonwood, mulefat, and white alder.

An extremely invasive plant, the giant reed, is widely dispersed within the basin. Early Spanish settlers introduced this grass to North America in the 1820s (Douce 1993) and used it for building, animal feed, and erosion control. In the past, its cultivation, particularly for erosion control, has been encouraged. Giant reed frequently becomes established after disturbances such as floods and fires. When it displaces native riparian plants such as willows and cottonwoods, important habitat is lost for native riparian species, particularly streamside nesting birds.

Invertebrates

Macroinvertebrates in the Salinas basin tend to be low-elevation, fine-substratum, large-river taxa. Common mayflies include *Tricorythodes*, *Diphetera*, *Fallceon*, *Acentrella*, *Centroptilum*, *Choroterpes*, and *Baetis*. There are relatively few stoneflies other than fairly low abundances of *Suwallia*, *Sweltsa*, *Triznaka*, and *Malenka*. In the spring, the most abundant stonefly taxon is *Isoperla*.

Numerically dominant and widespread caddisflies are *Hydropsyche* and *Cheumatopsyche*. Two additional caddisflies found in the Salinas system are *Nectopsyche* and *Gumaga*. These two genera are often associated with finer substratum, which is common to the Salinas River. Naidid worms, chironomid midges, and the amphipod *Hyaella azteca* also make up a substantial portion of the invertebrate assemblage.

Vertebrates

Prior to modern human disturbances, the Salinas River system contained a freshwater fish fauna that was similar to the Central Valley fauna (Moyle 2002). The similarity between the Salinas and the Central Valley faunas is attributed to colonization via the Pajaro River system (located just to the north). Even though there is no present-day hydrologic connection between the Pajaro and Salinas system and the Central Valley of California, migration to the Salinas systems presumably occurred during the Pleistocene. Two routes have been hypothesized: (1) head capture of streams in the San Francisco Bay area by the Pajaro River and its tributaries and (2) historical drainage of Coyote Creek to the Monterey area (Coyote Creek presently discharges to San Francisco Bay).

Fishes present include Sacramento sucker, California roach, hitch, Sacramento blackfish, Sacramento pikeminnow, speckled dace, Sacramento perch, tule perch, and riffle sculpin. Sucker, roach, and hitch may be sufficiently different from Central Valley forms to be considered subspecies (Moyle 2002). Steelhead (rainbow) trout and coho salmon also are part of the basin's fauna. Moyle (2002) lists this drainage as the southern limit of coho salmon. Steelhead were historically found in the headwater areas of the Salinas River, in the Arroyo Seco River, and possibly in other tributaries. As in many other basins in this region, the Salinas basin contains many nonnative species. These include bass, sunfishes, catfishes, and trout, particularly in the reservoirs.

The basin is rich in other vertebrates as well, including both red- and yellow-legged frogs, Pacific giant salamander, and the Santa Cruz garter snake. As found in most waterways of the region, beaver, muskrat, and raccoons also are present in the basin.

Ecosystem Processes

There are no accounts of the ecological functioning of the Salinas River prior to human habitation. Early accounts of Spanish exploration indicate that the river appeared like a green ribbon running through the Salinas Valley, presumably because its banks were lined with willows and cottonwoods (Fisher 1945). This riparian corridor probably added needed allochthonous inputs to the river given that the autochthonous production was low because of the instability of its sandy bed. Historical accounts also noted the extreme differences in climate, and consequently, flow. Differences in wetted channel width at the same location ranged from a channel that could be stepped across to one that was >3km wide. High frequency cycles of flooding and drought were common. Reports indicate that the valley was transformed into a great muddy lake in 1914 because of flooding. In contrast, during the period 1828 to 1830, 22 months passed without any rain (Fisher 1945). These extremes in flow and precipitation must have severely stressed in-stream and riparian communities.

Human Impacts and Special Features

Although no portions of the Salinas River proper are under consideration for Wild and Scenic status, a section of the Arroyo Seco is under consideration. This segment is considered some of the best habitat remaining in the basin for a portion of the threatened Central Coast steelhead population, which is desig-

nated as one of several ecologically significant units (ESU) that have been identified along the Pacific Coast.

Irrigation dominates the Salinas Valley. The lack of rainfall in coastal California during the summer growing season necessitates crop irrigation. Frequent dry periods made agriculture difficult for the inhabitants of the early Spanish missions and the first irrigation projects were small diversions from local creeks and springs to support the agricultural needs of these missions.

Prior to the 1860s, the dominant land use in the basin was grazing. There were an estimated 70,000 head of cattle in the basin in the mid-1800s, which is similar to the 75,000 present now (California Agricultural Statistics Service 2001 <http://www.nass.usda.gov/ca/coest/104lvstp.htm>). However, during the early 1860s two consecutive years of drought severely impacted the grasses in the valley and led to a decline in the valley's beef production and a breakup of the traditional ranchos. These factors led the way for the development of other forms of agriculture.

Irrigation in the valley has progressed through a series of stages. Initially, water was acquired from artesian wells, but canals were built as more and more land was developed for agriculture. In 1874, a small dam was placed on the Salinas River near the present city of Gonzales to provide irrigation water to the local rancho. The first major irrigation canal (diverting about 28 m³/s of Salinas River water) was built between San Ardo and Bradley in 1884. There were several early attempts to pump irrigation water directly from the Salinas River. However, the river periodically went dry and floods often destroyed irrigation pumps (Anderson 2000).

Currently, the principal source of water used for both municipal purposes and irrigation is groundwater. As in the San Joaquin Valley, groundwater overdraft is an ongoing concern, particularly during periods of drought when there is decreased recharge and increased evapotranspiration. This overdraft has led to the intrusion of saline ocean waters into the aquifer.

The principal human impact on water quality and quantity of the Salinas River is agriculture. Discharge, particularly flows from the San Antonio and Nacimiento reservoirs, is managed to maximize groundwater recharge. The timing and amount of discharge deviates substantially from the precontrol period and functionally reverses normal hydrologic patterns. Increases in nutrients, particularly NO₃, are also related to agricultural practices.

There has only been minor gold and mercury mining in the Salinas basin. However, some mercury contamination exists in the basin. Petroleum fields have been developed in the southern portion of the valley near San Ardo.

It is difficult to imagine today, but prior to the mid 1800s the Salinas Valley contained pronghorn, tule elk, grizzly bears, and a Central Valley–type assemblage of native freshwater fishes. Currently, native blacktail deer, San Joaquin kit fox, coyote, mountain lion, and bobcat as well as large numbers of raptors, including bald and golden eagles, remain. However, numerous species have also been introduced to the area. For example, introduced boar, which are extremely fecund, have devastating effects on the native vegetation. In addition, as throughout most of California, there are many nonnative fishes, particularly in the reservoirs of the basin. These include largemouth bass, smallmouth bass, white bass, striped bass, black crappie, bluegill, inland silverside, threadfin shad, goldfish, green sunfish, redear sunfish, common carp, channel catfish, and white catfish. Many of these nonnative taxa are also present in the Salinas River. Bullfrogs were introduced for food around the turn of the century and have been implicated in the reduction of native frogs in the basin as well as in other areas of California and the west.

KLAMATH RIVER

The Klamath River begins in southern Oregon and flows through northwestern California to the Pacific Ocean (Fig. 12.18). Beginning at an altitude of 1265 m asl, the river travels 462 km to its mouth at Requa, California, just south of Crescent City. Its basin is approximately 40,700 km². The Klamath River accounts for about 18% of the discharge from California (Norris and Webb 1990). The Klamath River drainage is divided into the upper Klamath basin, located in southeastern Oregon and north-central California, and the lower Klamath basin, located almost entirely in California. Because the Klamath River proper begins just downstream of Upper Klamath Lake in Oregon, there are no large tributaries confluent with the Klamath in the upper basin. However, waters flowing into the Klamath River from Upper Klamath Lake originate in the Sprague, Sycan, Williamson, and Wood rivers in Oregon. Large tributaries of the Klamath in California include the Shasta, Scott, Salmon, and Trinity rivers. The Klamath basin has more river kilometers designated as National Wild and Scenic Rivers than

any other basin covered in this chapter, and much of the river flows through deep gorges. Crater Lake, which is located in the caldera of ancient Mount Mazama, is also within the upper basin. Crater Lake is the deepest (590 m) lake in the United States.

The Klamath basin has a rich and complex Native American cultural history. Environmental differences between the upper and lower basins strongly influenced the native peoples living in both regions. In the upper basin the Klamaths lived around Upper Klamath Lake and Klamath Marsh, the Modoc lived in the area bordering Oregon and California in the vicinity of the Lost River, Clear Lake Reservoir, and Goose Lake, and the Yahooskin Band lived in the area around Yamsay Mountain in the far northeastern portion of the basin. The Klamaths hunted deer and waterfowl, collected mussels, and gathered nuts, berries, and seeds. Particularly important was fishing the spring runs of Lost River and shortnose suckers in the rivers discharging into Upper Klamath and Agency Lakes (Klamath Tribes 2003 <http://www.klamathtribes.org/suckers.htm>). In autumn, the seeds of the “wocas” or water lily were gathered (Oregon Water Resources Department [OWRD] 1999). The abundant tules were used for constructing houses and rafts. Many Native American tribes inhabited the lower basin. These included the Tolowa, Yurok, Hupa, Karok, Shasta, Wiyot, Wailaki, Chimariko, and Wintun. These tribes were generally associated with riverine habitats and were dependent on the seasonal runs of anadromous fishes, including chinook and coho salmon, steelhead trout, and Pacific lamprey. Acorns also were a staple (Heizer and Elsasser 1980).

Similar to the Rogue basin, the first European trappers entered the Klamath basin in 1826 (Clark and Miller 1999). It was not until the 1850s that fur trappers and a few cattle ranchers began to spend extended periods of time in the basin. The permanent settlement began after Fort Klamath was established in 1863. Very rapid development in the basin followed the building of the railroad in 1909.

Physiography, Climate, and Land Use

The Klamath basin spans three physiographic provinces (Hunt 1974). The upper Klamath lies mostly within the Great Basin section of the Basin and Range (BR) province (see Fig. 12.18). The Klamath then passes through the Southern Cascade Mountains section of the Cascade–Sierra Nevada (CS) province. The lower portion of the Klamath flows through the Klamath Mountains section of the Pacific Border (PB)

province. The Klamath Mountains section contains numerous spectacular ranges, including the Siskiyou, South Fork, Salmon Mountains, and Trinity Alps. These three provinces contrast sharply in geology and climate, which in turn greatly influences the river's hydrology and biology.

The upper basin lies in a fault-formed graben in the rain shadow of the Cascade Mountains, which border it on the west. Much of the upper basin was part of ancient Lake Modoc, a pluvial lake formed during the Pleistocene that covered an area of 2850 km². The remnant of Lake Modoc is now Upper Klamath Lake, which is the largest lake in Oregon. The surrounding lands greatly reflect the former presence of the ancient lake, and wetlands and marshes are characteristic of the area. Other lakes in the upper basin include Lower Klamath Lake, Agency Lake, and the formerly hydrologically closed basin containing Clear Lake Reservoir, the Lost River, and Tule Lake. Crater Lake is also located in the upper basin.

The geology of the lower portion of the Klamath drainage is very complex and at first appears similar to the northern Sierra Nevada. Much of the range was formed by a series of accretions that occurred during the Mesozoic Era (Harden 1998). Fossilized materials suggest that the origin of some of the accreted oceanic terranes were from very distant oceanic locations. The area was intruded by granitic plutons about 150 million years ago (Norris and Webb 1990). Approximately 130 million years ago the Klamath Mountains were located just north of the Sierra Nevada. Through a process known as extension, they separated from the Sierra Nevada and moved westward to their present location.

The Klamath basin is part of the Eastern Cascades Forests, the Klamath–Siskiyou Forests, and the Northern California Coastal Forests terrestrial ecoregions (Ricketts et al. 1999). The Central and Southern Cascades Forests border the upper portion of the basin on the west. All four terrestrial ecoregions are within the Temperate Coniferous Forests habitat type.

The upper Klamath basin is predominantly in the Eastern Cascades Forests terrestrial ecoregion. Natural vegetation is a mosaic of shrublands, grasslands, and coniferous forests, with ponderosa pine the predominate conifer. Numerous plant zones have been characterized based on temperature, elevation, and moisture. Western juniper and ponderosa pine occur in drier areas, with Douglas fir and grand fir found in more mesic, midslope areas.

Most of the Wild and Scenic portion of the Klamath River flows through the Klamath–Siskiyou Forests terrestrial ecoregion. This ecoregion contains

one of the four richest temperate coniferous forests in the world; its 33 species of conifers represent a global diversity maximum (Ricketts et al. 1999). There are about 3500 different plant species known from the ecoregion and the area is considered one of the global centers of biodiversity.

Near the mouth of the Klamath a short portion of the river flows through the Northern California Coastal Forests terrestrial ecoregion. This region is most prominently characterized by the presence of redwoods in areas of fog and high moisture, and Douglas fir, tan oaks, and closed-cone pine forests in drier areas.

Precipitation in the upper and lower basins differs substantially; however, both basins have a very strong seasonal cycle (Fig. 12.19). The upper basin is in the rain shadow of the Cascade Range; therefore, the average annual precipitation for the basin is only about 41.9 cm. In contrast, the lower basin includes some of the wettest areas in the drainage and in California in general (in excess of 198.1 cm/yr). Average annual precipitation is 156.5 cm. Average annual temperature in the upper basin is 7.6°C, and frost can occur any day of the year. Temperatures near the coast are generally more moderate than temperatures inland, and average annual temperature in the lower basin is 12.9°C, slightly higher than in the upper drainage.

The upper portion of the basin is dominated by agriculture and grazing; however, land use in the lower portion includes forestry, mining, and grazing. When land cover for the entire basin is considered, 66.3% is classified as forest, 14.0% as shrub, 8% as grasslands, and 2.3% as wetlands. Agriculture represents only 5.9% of the basin but has a profound effect on the water quality in the basin. Urban areas represent only 0.2% of the basin (Vogelmann et al. 2001).

River Geomorphology, Hydrology, and Chemistry

The extreme differences in physiographic setting between the upper and lower portions of the Klamath basin has led to significant differences in the geomorphology, hydrology, chemistry, and biology of the two areas (Clark 1999). The headwaters of the Klamath River include the streams, marshes, and lakes of the upper Klamath basin; however, the Klamath River itself begins just downstream of Upper Klamath Lake, Oregon (see Fig. 12.18). Although some of the streams in the upper basin that flow from the eastern side of the Cascades and other areas of high relief are high gradient, much of the

area contains low-gradient streams, marshes, and lakes, the most prominent of which are Upper Klamath, Agency, Tule, and Clear lakes and the Klamath and Sycan marshes. The four principal rivers are the Sprague, Sycan, Williamson, and Wood. The Lost River is in the southeastern portion of the basin, and through natural channels and canals it connects a number of reservoirs, as well as Tule Lake, to the Klamath River. This area originally formed a hydrologically closed basin, with the Lost River flowing from Clear Lake Reservoir to Tule Lake. The water level of Upper Klamath Lake determines, in part, the water available to the Klamath River. Downstream of Iron Gate Reservoir the lower Klamath is high gradient (2.5 m/km) and flows freely to the coast for >300 km (Fig. 12.6).

There are 67 dams in the Oregon portion of the Klamath basin. Three of these dams (Link, Keno, and J. C. Boyle) are on the Klamath River proper. There are only two significant dams directly on the Klamath in California: Copco No. 1 and Iron Gate. Although there are no other dams on the lower Klamath, the Shasta River has 14 dams, the Scott has 3, the South Fork of the Trinity has 1, and the Trinity has 3 (only the largest shown on Fig. 12.18). These impoundments, along with private water withdrawals, affect discharge and temperature in the main stem and alter the quality and total amount of salmonid spawning and rearing habitat in the Klamath basin.

The Klamath has the second-highest mean discharge (501 m³/s) of any Pacific river south of the Columbia River. The highly seasonal precipitation creates a strongly seasonal discharge pattern, with peak runoff (>7 cm/mo) from January through March (see Fig. 12.19). Runoff slowly decreases to <1 cm/mo in August and September before increasing again in response to the beginning of the wet season in midautumn.

The upper Klamath basin is the most intensely managed basin in Oregon and water quality is greatly influenced by human as well as natural factors (<http://www.deq.state.or.us/lab/WQM/WQI/klamath/klamath3.htm>). A portion of the upper basin (Williamson subbasin) has good-to-excellent water quality; however, the other portions of the upper basin have poor water quality, with high levels of PO₄, pH, BOC, total solids, and nitrogen compounds (<http://www.deq.state.or.us/lab/WQM/WQI/klamath/klamath3.htm>). Water quality differs dramatically between the upper and lower Klamath basins. Near the town of Klamath, on the coast, total hardness is 70 mg/L as CaCO₃ and conductivity is about 170 μS/cm. The waters are alkaline, averaging

approximately a pH of 8, and are well oxygenated (dissolved oxygen 10 mg/L). Nutrients are generally low, with dissolved NO₃-N + NO₂-N about 0.155 mg/L and PO₄-P averaging 0.037 mg/L.

River Biodiversity and Ecology

The Klamath basin is part of the Pacific Mid-Coastal freshwater ecoregion, which has a habitat type of Temperate Coastal Rivers, Lakes, and Springs.

Algae

Within Upper Klamath Lake, several companies commercially harvest the alga *Aphaizomenon flos-aquae*, which is sold as a nutritional supplement. Unfortunately, more algae is produced by the lake than can be used, and the lake often suffers from low dissolved oxygen in the latter part of the summer at a time when water temperatures also are high, thereby exacerbating possible biological effects.

Plants

The upper Klamath basin once contained extensive tule marshes that were intensively used by the Native Americans of the area. However, approximately 75% of the marshes have been converted to agriculture and grazing lands. In many reaches, the lower Klamath flows through deeply incised canyons; however, where lower banks are present it has a well-developed riparian corridor that consists of willows (arroyo, black, narrowleaf, Pacific, red, sandbar, and Sitka), black and Fremont cottonwoods, mulefat, white alder, and water birch.

Invertebrates

Mayflies most often encountered include *Baetis tricaudatus*, *Drunella doddsi*, *Rhithrogena*, *Cinygmula*, *Epeorus*, *Ironodes*, *Paraleptophlebia*, and *Tricorythodes*. Commonly found stoneflies include *Yoraperla nigrisoma*, *Calineuria*, *Hesperoperla pacifica*, *Zapada columbiana*, *Malenka*, and *Sweltsa*. The most commonly collected caddisflies in the basin are in the genus *Hydropsyche*. Two lepto-cerids, *Nectopsyche gracilis* and *Oecetis disjuncta*, have been reported from the main stem. *Helicopsyche*, *Glossosoma*, *Agapetus*, *Lepidostoma*, *Micrasema*, and *Rhyacophila* caddisflies are also abundant in the basin. As in most systems, the most abundant aquatic invertebrates found in the lower Klamath basin are chironomid midges and oligochaete worms.

The three most commonly encountered beetles are the elmids *Optioservus*, *Cleptelmis*, and *Zaitzevia*; water pennies also are present, with

FIGURE 12.6 Klamath River between the towns of Seiad Valley and Happy Camp, California (PHOTO BY STEVE FEND, USGS).

Eubrianax as the most commonly encountered genus. The corixid *Sigara* is found in slower reaches and backwaters. Snails include *Juga* and the Klamath pebble snail. Mussels found in the basin include the western pearlshell and western ridge.

Vertebrates

Moyle (2002) classifies the Klamath system into three parts: (1) the upper Klamath River that lies above Klamath Falls; (2) the lower Klamath River, including the Trinity River; and (3) the Rogue River. There are 30 native fishes with 8 endemics. Faunas of the upper and lower basin are very distinct because they evolved in regions that experienced different geologic histories and because the upper and lower basins contain extremely different habitat types.

The distinctive fish fauna of the upper Klamath (15 natives) indicates that a long period of isolation existed between it and the adjacent systems. Some of the closest relatives to these fishes are found in the Great Basin. This region was connected to the Columbia drainage via the ancestral Snake River during the Eocene (~55 to 34 million years ago) and again during the Pliocene (~5 to 2 million years ago). It also was historically connected to the Pit River drainage (currently a tributary of the Sacramento River).

Just five families (Catostomidae [suckers], Cyprinidae [minnows], Cottidae [sculpins], Salmonidae [trout, salmon], and Petromyzontidae [lampreys]) are found in the upper Klamath. Suckers include shortnose sucker, Lost River sucker, and Klamath largescale sucker. Minnows include blue chub, Klamath tui chub, and speckled dace (both upper and lower Klamath). Sculpins include slender sculpin and Klamath Lake sculpin (both found only in Oregon) and marbled sculpin (both upper and lower). Salmonidae include two forms of rainbow trout (redband and coastal rainbow trout). Bull trout also are present. Four lamprey species are recognized: Miller Lake lamprey, Pit-Klamath brook lamprey (also found in the Pit River), Klamath River lamprey (confined to the Upper Klamath), and dwarf Pacific lamprey. All of these were derived from the anadromous Pacific lamprey.

The presence of Pit-Klamath brook lamprey and marbled sculpin in both the upper Klamath and the Pit River drainage indicates that these systems were connected at one time. There also is evidence that the upper Klamath was once hydrologically con-

nected to the Great Basin (see Chapter 14) because the tui chub, speckled dace, and shortnose sucker found in the upper Klamath are related to taxa found in the Great Basin (Moyle 2002).

The lower Klamath contains 21 native species, of which 17 are saltwater dispersants. These include two anadromous lamprey species, two sturgeon species, six salmonids, two smelt, one stickleback, and two amphidromous sculpins. Freshwater dispersants include Klamath speckled dace, lower Klamath marbled sculpin, Klamath smallscale sucker, and Pacific brook lamprey.

The upper and lower basins share only two species, the Klamath speckled dace and the marbled sculpin. These two species probably dispersed during the Pleistocene when the water level in Upper Klamath Lake overflowed and eroded the divide, thereby creating a permanent connection between the upper and lower basins.

Other vertebrates found in the Klamath include the Pacific giant salamander, southern torrent salamander, and rough skinned newt. Mammals intimately associated with the lotic environment include beaver, raccoon, river otter, and mink. The wetlands and lakes of the upper Klamath basin support some of the largest populations of ducks in North America and provide habitat for other sensitive species, including yellow rails and sandhill cranes. The area also contains the densest concentration of wintering bald eagles in the world.

Ecosystem Processes

Little is known of the ecosystem processes that made up the Klamath basin. The contrasting environmental settings of the upper and lower portions of the basin surely influenced the processes within each location. The principal linkage between the two areas is the Klamath itself, but because of in-stream barriers and extreme differences in the habitats available to aquatic organisms, faunal differences between the two areas increased over time (e.g., suckers in the upper basin and anadromous salmonids in the lower basin). The upper basin still contains extremely high numbers of migratory waterfowl, and one can imagine that the numbers were even greater before 75% of the marshes were converted to agriculture (OWRD 1999).

Downstream of Upper Klamath Lake the Klamath River and its tributaries were free flowing, which allowed salmonids to populate all of the sub-basins that contained sufficient water and suitable

spawning and rearing habitat. It is probable that seasonally Upper Klamath Lake provided high nutrient loads in the form of dissolved and particulate organic matter that originated from its marshes to the Lower Klamath on a seasonal basis. These nutrients likely formed the basal level of the river's trophic structure, which aided the development of a rich invertebrate fauna that ultimately supported salmonid development. Although there is still a contribution of organic matter and nutrients to the lower Klamath from the upper basin, its value is tempered by the poor water quality delivered to the lower Klamath from agricultural tailwaters originating above Upper Klamath Lake and from the Lost River subbasin.

Clearly, the upper Klamath basin contributed nutrients to the lower Klamath basin and thereby influenced salmonid populations, but prior to the relatively recent decrease in salmonid populations the lower basin had an internal source of nutrients as well. This internal source resulted from the breakdown of spent salmonid carcasses after spawning in the main stem and tributaries of the system. The decline in salmonid populations in the lower basin has had an unknown effect on the nutrient budget of the lower basin, and consequently its ability to support historic salmonid production.

Human Impacts and Special Features

The Klamath basin has >900 km of reaches designated as Wild and Scenic. The upper basin has a portion of the Sycan River and a short portion of the Klamath River (J. C. Boyce Powerhouse to the California border) designated. In the lower basin, 460 km of the main stem, as well as portions of the Salmon, New, and Trinity rivers, North and South forks, and Scott and Wooley creeks also have Wild and Scenic status.

As in most of the rest of the west, the distribution of available water between agriculture and in-stream use is problematic. Agriculture is extremely well developed in the upper basin; approximately 75% of the marshes and shallow lakes have been drained and converted for agricultural use. The largest irrigation project in the region, the Klamath Project, provides water to irrigate over 930 km². Crops grown include alfalfa, potatoes, onions, and sugar beets. Cattle ranching is the largest agricultural endeavor and accounts for more than one-third of the farm income in the region.

Agricultural practices in the upper basin affect the quantity and quality of water available to the lower

Klamath basin as well as affecting some resident fauna, such as the federally and state listed endangered Lost River sucker and shortnose sucker and the federally listed threatened bull trout. High nutrients and the addition of organic matter in agricultural return flows negatively affect water chemistry, which leads to the area having some of the poorest water-quality ratings in Oregon. The degree to which these factors (extensive reductions of freshwater marshes, reduced flows, degraded water chemistry) alone or in combination affect the fauna of the upper Klamath basin is poorly known. However, coincident with increased human development of the basin, reductions in native fauna, particularly the Lost River sucker and shortnose sucker, have occurred.

Extensive use of water in the upper basin and water captured by tributary dams within the lower basin (some of which is transported out of the basin; e.g., portions of the Trinity River) reduces the total amount of water available to the lower basin. This reduction in total discharge, along with changes in the amount and timing of peak and low flows, leads to changes in sediment supply and stream temperature (Kondolf and Matthews 1993). Both of these factors influence the quality of salmonid habitat. These human modifications most likely reduce available critical rearing habitat for chinook and coho salmon and steelhead. The sensitivity of salmonids to high water temperatures is well known, as is their need for high-quality spawning gravels.

Even though the Klamath basin is strongly influenced by human modifications, the lower Klamath supports one of the better anadromous fisheries in California. Unfortunately, the current runs in the Klamath are much lower than they were historically. The allocation of water in space and time is contentious at best (Levy 2003). Determining the amount of water to allocate for agriculture and for the restoration and maintenance of healthy aquatic habitats, particularly fishery resources, is dependent on extensive, high-quality data and is an ongoing challenge for resource managers here as it is throughout the west.

ROGUE RIVER

The Rogue River, located in southwestern Oregon, begins at 1600 m asl in Crater Lake National Park near the northern slope of ancient Mount Mazama (now Crater Lake), and flows westerly for approximately 340 km to the Pacific Ocean (Fig. 12.20). The

Rogue River drainage basin is about 13,400 km². The Rogue has many tributaries that flow from the high Cascades, but some of the more significant tributaries flow from the south. Bear Creek enters the Rogue after flowing past the rapidly developing towns of Ashland and Medford. The Applegate River enters the Rogue just downstream of Grants Pass. The Illinois River is the most downstream tributary and enters the Rogue near the town of Agness. The Rogue River was one of the first rivers to have reaches receive National Wild and Scenic designation in 1968, and portions of the Illinois River were designated as Wild and Scenic in 1984.

Prior to the settlement of the basin by Europeans the area was inhabited by numerous groups of Native Americans as early as 8560 years ago, although most researched archaeological sites are much younger (Douthit 1999). Within the Athabascan group, the Tal-tush-tun-tude lived on Galice Creek, a tributary to the Rogue; the Chas-ta-costa lived on the north side of the Rogue; and the Tu-tut-ni lived near the mouth. Further upstream, near Medford, lived the Shastan group, and the Ta-kel-man lived in the very upper reaches of the Rogue. All of the inhabitants of the basin were very dependent, as were most tribes of the northwest, on anadromous fishes. They also hunted deer and elk and gathered acorns and other foods (Purdom 1977).

The first Europeans in the basin were trappers and fur traders who arrived as early as 1826 (Douthit 1999). Almost immediately, hostile encounters occurred between the Europeans and the Native Americans. As a result, no settlements were established for many years. These early negative encounters led to the territory and its inhabitants being labeled “Rogue,” which is the basis for the river’s name. There were continuing conflicts between Europeans and Native Americans, and in the mid 1850s, during the Rogue River Indian War, several terrible massacres of whites and Native Americans occurred. When gold was discovered on Jackson Creek (a tributary to the Rogue) in 1852, settlement of the area increased substantially. From 1850 to 1890 the economy was based on gold and coal mining, agriculture, logging, shipbuilding, and commercial salmon fishing (Douthit 1999).

Physiography, Climate, and Land Use

Although originating in the Middle Cascades section of the Cascades–Sierra Nevada (CS) Mountains physiographic province, the Rogue River lies principally in the Klamath Mountain section of the Pacific

Border (PB) province (see Fig. 12.20) (Hunt 1974). It flows south and southwest across the western slope of the Cascades and then sinuously through the Klamath Mountains before reaching the Pacific Ocean at Gold Beach, Oregon.

Ancient Mount Mazama was one of a series of volcanic peaks that compose the high Cascades (Hunt 1974). These peaks are geologically younger (Mio-Plio-Pleistocene) than the western Cascades and separate drier eastern Oregon from wetter western Oregon. Bear Creek, flowing from the southeast, separates the western portion of the Cascades from the Klamath Mountains. The Klamath Mountains are composed of folded and faulted pre-Tertiary strata with intruded granitic plutons (Baldwin 1981). The Rogue maintained its westward passage during the Cenozoic uplift of the region by down-cutting; consequently, some sections of the Rogue have steep, narrow gorges that contain many rapids.

Serpentinite occurs widely in the Klamath Mountains. These soils influence plant distributions, and vegetation is often sparse on serpentine soils. Granitic intrusions, occurring during the late Jurassic, brought solutions of metals containing gold, copper, and other base metals, which have been mined in the basin. Terraces of Plio-Pleistocene alluvial deposits were also the source of placer gold mined in the mid to late 1800s.

The Rogue basin contains three terrestrial ecoregions (Ricketts et al. 1999). The major habitat type in all three ecoregions is Temperate Coniferous Forests. The Central and Southern Cascades Forests ecoregion extends from mid-Washington to the Oregon–California border and includes both the western and high Cascades. The influence of historic and recent volcanism is evident throughout the region. The area is highly dissected by many perennial streams and rivers. Potential vegetation for the region includes western hemlock, Pacific silver fir, and western red cedar. Fire suppression and logging have significantly influenced natural disturbance regimes. Although the region, in general, contains moderate biological diversity, the southern portion of the region (including areas within the Rogue drainage) is identified as containing extremely high species richness within many groups of plants and animals (Ricketts et al. 1999).

The Klamath–Siskiyou Forests ecoregion contains one of the four richest temperate coniferous forests in the world (33 species). There are about 3500 different plant species known from the ecoregion, and the area is considered one of the global centers of biodiversity (Ricketts et al. 1999). This high

species diversity results from the area's complex geologic and climatologic history, present-day diversity in soils and climates, and topographically complex gradients of moisture and temperature from the coast to inland areas.

The Central Pacific Coastal Forests ecoregion extends from Vancouver Island in the north to southern Oregon. The forests of this region are some of the most productive in the world. Dominant species include Douglas fir, western hemlock, and western red cedar, along with grand fir, and western white pine. Associated with these conifers are numerous ferns, lichens, mosses, and herbs. Sitka spruce and lodgepole pine also are present in the region. Even though most of the region is still forested, only about 4% remains intact. Impacts on the region have and continue to be logging, grazing, burning (or lack thereof), mining, and species introductions.

Precipitation in the basin varies greatly and depends on distance from the coast and local orographic influences. Precipitation at Gold Beach averages 198.6 cm/yr, but precipitation inland at Ashland is only 48.8 cm/yr. Most precipitation occurs during winter and spring, with less than 1 cm/mo in summer and >16 cm/mo in winter (Fig. 12.21). Average precipitation for the drainage is approximately 96.5 cm/yr. Temperatures are generally mild, with average monthly temperatures highest in July (19.7°C) and August (19.6°C) and lowest in December (4.4°C). Temperature varies with altitude; therefore, temperature estimates based on lower-elevation urban centers most likely overestimate temperature in the basin.

When land cover for the entire basin is considered, 82.7% is classified as forest, 2.9% as shrub, 6.4% as grasslands, and 0.2% as wetlands. Agriculture represents only 5.9% of the basin and urban areas represent only 0.8% (Vogelmann et al. 2001). Some of the more inland valleys are within what is termed the "Banana Belt" in Oregon and support a substantial amount of agriculture. Approximately 20% of the basin is National Forests.

River Geomorphology, Hydrology, and Chemistry

The Rogue River and its upstream tributaries begin in the high Cascades (Hunt 1974). Originating in Boundary Springs in Crater Lake National Park, the Rogue flows in a very sinuous but predominately western direction through the rugged Klamath

FIGURE 12.7 Rogue River, Oregon (PHOTO BY TIM PALMER).

Mountains (Fig. 12.7). Numerous tributaries draining the volcanic peaks of the west slope of the Cascades, including the South Fork of the Rogue, enter as the Rogue flows predominately southwest in the direction of Medford through older volcanic rocks. From its headwaters to Prospect the Rogue has a very high gradient (11.8 m/km), flowing over bedrock with many reaches containing substrates of cobble, boulders, and mixed gravels. Near Medford the Rogue enters a lower-gradient (1.9 m/km) section containing smaller substrates as it flows through the Rogue River Valley and Sam's Valley area, which are just north of Medford. Bear Creek enters the Rogue near this location, which is a location of intensive gravel mining. Just downstream of Grants Pass the Applegate River enters from the south and the Rogue turns northwest, beginning the portion of the lower river designated as Wild and Scenic. About 33 km downstream of Grants Pass, Grave Creek enters and

the Rogue turns west. Between Galice and Agness the river twists and turns for approximately 64 km and its gradient increases to 3.4 m/km; from Agness to the coast the gradient decreases (0.7 m/km). Just below Agness the Illinois River, also designated as a Wild and Scenic River, enters from the south.

Discharge of the Rogue River near Agness (Rkm 47.8) averages approximately 170 m³/s, but the Illinois River draining a portion of the Klamath–Siskiyou ecoregion discharges into the Rogue at river km 46.6 and the average flow increases to approximately 285 m³/s. Minimum discharge in the Rogue occurs in September and in the Illinois in August (see Fig. 12.21). Maximum average monthly discharge downstream of the confluence of the Rogue and Illinois rivers occurs in December and is estimated at 650 m³/s. During the flood flows of 1996–1997 the discharge of the Rogue near Agness during December and January exceeded 1000 m³/s.

There are approximately 80 nonhydroelectric dams in the Rogue basin. Most of them are quite small and used for local irrigation projects. Four of the larger reservoirs are Lost Creek Lake, Applegate Lake, Emigrant Lake, and Fish Lake.

The waters of the Rogue are quite soft and somewhat alkaline, with an average hardness of 41 mg/L as CaCO₃ and a pH of 7.5. Conductivity is also low, with average conductance of approximately 100 µS/cm. Dissolved oxygen is very near saturation and averages 10.5 mg/L. Nutrients in the Rogue are also low. Nitrogen as dissolved NO₃-N + NO₂-N is approximately 0.135 mg/L and PO₄-P is 0.051 mg/L.

River Biodiversity and Ecology

The Rogue River is entirely within the Pacific Mid-Coastal freshwater ecoregion (Abell et al. 2000). The region extends along the coast of Oregon and south to San Francisco Bay. Although it runs principally along the coast, in the area of the Umpqua, Rogue, and Klamath rivers it extends inland. In general, this eastward extension is associated with increased precipitation and similarity of aquatic habitat in the western Cascades, Siskiyou, and Klamath mountains. This region is part of the southern range of coho salmon and cutthroat trout.

Plants

Riparian trees and shrubs along the Rogue include sandbar, Geyer, Pacific, yellow, and Scouler willow, white and red alder, black cottonwood, and

Oregon ash. Two nonnative aquatic plants found in the basin are Brazilian elodea and curly-leaved pondweed (Michael Parker, personal communication). Once established, these plants inhibit flow and thereby lead to increased temperatures. High water temperature is considered a water-quality impairment throughout much of the basin.

Invertebrates

Little is known about the invertebrates inhabiting the Rogue River proper, although invertebrates have been collected in many tributary streams throughout the basin. The basin has a rich fauna of mayflies, stoneflies, caddisflies, and chironomid midges. Dominant taxa within the mayflies include baetids (*Baetis tricaudatus*, *Dipheter hageni*, *Acentrella turbida*), ephemereids (*Ephemerella inermis/infrequens*, *Drunella*, *Caudatella hystrix*), heptageniids (*Rhithrogena*, *Epeorus*, *Ironodes*, *Cinygmula*), and the leptohebiid *Paraleptophlebia*.

There also is a diverse assemblage of stoneflies. By far the numerically dominant stoneflies are the nemourid *Zapada cinctipes* and the perlid *Calineuria californica*. Other nemourids, *Z. oregonensis* group, *Z. columbiana*, and *Malenka* are also very numerous, as is the chloroperlid *Sweltsa*.

As in most of this region, the caddisfly fauna is dominated numerically by Hydropsychidae, including *Hydropsyche*, *Cheumatopsyche*, and, in lower abundance, *Arctopsyche grandis* and *Parapsyche elsis*. Several species of *Lepidostoma* are also common. Rhyacophilids are particularly diverse, with *Rhyacophila betteni* group, *R. narvae*, and *R. brunnea* group dominating. Second only to *Hydropsyche* in abundance is the brachycentrid *Micrasema*. *Glossosoma* and the limnephilids *Ecclisomyia* and *Hydatophylax hesperus* are common.

Some taxa more often found in lower latitudes also are found in the basin but in lower abundance, including the stoneflies *Sierraperla* and *Salmoperla* and the caddisflies *Tinodes* and *Gumaga*. The basin also has a rich fauna of psephenids (water pennies) that includes *Acneus*, *Eubrianax*, and *Psephenus*. Also abundant are numerous species of elmids (riffle beetles), including *Cleptelmis*, *Optioservus*, and *Zaitzevia* (Robert Wisseman, personal communication).

The molluscan fauna of the Rogue basin is extremely diverse, particularly with regard to Gastropoda. In a recent survey of the Klamath–Siskiyou region, Terrance Frest (personal communication) estimated that 46% of the malacofauna was unde-

scribed. In the upper Rogue basin, numerous new species of *Fluminicola* were identified as well as a new species of *Juga*. Widespread genera of freshwater snails in the basin include *Juga*, *Fossaria*, *Lymnaea*, *Physella*, and *Gyraulus*. *Ferrissia rivularis* has only been found in the main-stem Rogue. Freshwater bivalves are less diverse and include the Oregon floater (uncommon), western ridge mussel, and western pearlshell.

Vertebrates

The Rogue River contains extremely high-quality salmonid habitat and has one of the finest salmonid fisheries in the west. However, most stocks are less abundant than they were historically and indications of their decline began appearing early in the last century. Dominating this fishery are chinook and coho salmon and steelhead and cutthroat trout. Within these species there are several spawning runs. For example, there are fall and spring runs of chinook and winter and summer runs of steelhead.

Most taxa present in the Klamath River are also found in the Rogue. However, the smallscale sucker found in the Rogue may be distinct from the Klamath smallscale sucker. Moyle (2002) also notes that the Rogue is the most southern basin containing the reticulate sculpin, which is abundant in streams further to the north. Fishes other than salmon commonly encountered include rainbow trout, speckled dace, redbreast shiner, coastrange sculpin, torrent sculpin, riffle sculpin, and Pacific lamprey. Other vertebrates include Pacific giant salamander, rough skinned newt, and foothill yellow-legged frog.

As throughout the west, numerous species introductions have occurred in the Rogue River. Although precisely documenting when an introduction occurs is difficult, Rivers (1963) lists approximate dates when nonnative species were first discovered. The first was in 1883, when American shad were collected near the mouth of the Rogue. Carp were thought to have entered the Rogue from a flooded farm pond in 1890. Many other warmwater fishes were intentionally introduced into the basin in the late 1920s, including white and black crappie, bluegill, largemouth bass, and catfish. Smallmouth bass also are found in the main-stem Rogue but in relatively low abundance. More recently (~1987) an illegal introduction of Umpqua pikeminnow from the more northern Umpqua basin was made into the Rogue River. When grown, these cyprinids prey on smaller fishes, such as juvenile salmonids. Their effects on salmonid stocks are now being evaluated. Also common to the basin is the nonnative bullfrog.

Ecosystem Processes

Very little is known of the original functioning of the Rogue River. Like most West Coast rivers the seasonally predictable high and low flows probably contributed to the diversity of anadromous fishes present in the system. However, unlike most of the other rivers in this chapter the Rogue's channel is rather well constrained except in the vicinity of the Rogue River Valley and Sam's Valley. Therefore, allochthonous floodplain contributions were probably less important to the functioning of the Rogue than they were to the lower Klamath from the upper Klamath basin or to the Sacramento and San Joaquin from their extensive floodplains.

Nevertheless, several factors contribute to the quality of the salmonid habitat found in the Rogue. The river has a relatively high gradient and is well constrained in many reaches. The available sediments of the area are more easily eroded, particularly in the upper reaches, than the granites of the Sierra Nevada. Near-unimpeded high winter and spring flows aid the transport of these coarse sediments within the river. The presence of these coarse sediments within a complex channel contributes to the formation of many main-stem and tributary reaches containing high-quality spawning gravels.

Extensive forests and well-developed riparian corridors provided ample shade that maintained cool water temperatures and contributed high-quality organic matter. Within these old growth forests were extremely large streamside trees that contributed to greater channel stability and complexity (unfortunately, many of the large old-growth trees have been removed). These conditions aided the development of a diverse and productive aquatic invertebrate community, which was conducive to the development of large and healthy salmonid populations.

Human Impacts and Special Features

Parts of the Rogue River basin are relatively pristine, particularly in comparison to some of the basins located in the southern portion of the Pacific Mountain System covered in this chapter. The Rogue River was one of the first rivers to have reaches receive National Wild and Scenic designation. The first such reach, designated in 1968, begins at the mouth of the Applegate River and runs downstream for 136 km. This section is considered one of the best white-water runs in North America. In 1988, a 65 km section of the river extending from near its headwaters to the town of Prospect was added. In 1984, a section of

the Illinois River was designated as Wild and Scenic. The Rogue is well known for its white-water recreational use and salmon and steelhead sport fishery.

As detailed previously, European settlement of the basin was principally by gold miners in the 1850s. At that time gold was sufficiently important that in 1854 the name of the river was changed to Gold River; however, a year later it was renamed Rogue by the territorial legislature. As in California, miners first worked placer deposits, then lode deposits, which were located by following the placer deposits upstream. By 1911 most of the placer deposits had been depleted (Bredensteiner et al. 2001). Hydraulic mining began as early as 1856 and reached a maximum in 1885 (Purdum 1977). Early mining had devastating effects on the channels and the riparian habitats. Since 1960 suction dredge mining has been the preferred method of mining.

The Klamath–Siskiyou region (i.e., the Illinois River subbasin) also is rich in other mineral deposits, including platinum, nickel, zinc, copper, and cobalt (Bredensteiner et al. 2001). This portion of the basin has recently been the subject of a heated debate regarding increased mining because of the international recognition of the region's floral and faunal richness and its enormous ecological uniqueness (Ricketts et al. 1999). Gravel mining also has impacted the Rogue River. Although gravel mining occurs on the middle and lower portion of the Rogue and Applegate rivers, there is substantial mining on Bear Creek, particularly near its confluence with the Rogue.

Additional factors influencing water quality include water capture and diversion for agricultural development (pears, grapes, alfalfa, and corn), logging, and urban development. Urban development has been particularly important in the Medford and Ashland area of the Bear Creek drainage.

The Oregon Department of Environmental Quality (2004) summarized water quality in the Rogue basin from 1986 to 1995 (<http://www.deq.state.or.us/lab/wqm/wqi/rogue/rogue4.htm>). They found that water quality in the upper Rogue basin generally is excellent. However, water quality in the middle Rogue basin generally is of poor quality. This portion of the basin is influenced by the quality of water in the Bear Creek basin, which is affected by point and nonpoint sources, particularly the input of excessive organic matter. Water quality in the Applegate basin is considered good but impacted by irrigated agriculture and mining. Water quality of the Illinois basin is excellent and rivals the quality of the upper Rogue. The lower Rogue also is reported to have good water quality. The cause of impairment most often listed

for reaches in the Rogue basin is the exceedance of temperature criteria principally established for salmonids.

ADDITIONAL RIVERS

The Umpqua River is formed by the confluence of the North Umpqua and South Umpqua rivers (Fig. 12.22). The basin is located in the Pacific Mid-Coastal freshwater ecoregion and is part of three terrestrial ecoregions (Central Pacific Coastal Forests, Klamath–Siskiyou Forests, Central and Southern Cascades Forests). The basin has the fewest dams per area of any other large river basin in Oregon. The basin is approximate 13,000 km², of which half is under federal management. The almost contiguous Umpqua National Forest alone represents about 4000 km². The Umpqua basin, particularly the North Umpqua, is world renowned for its summer-run steelhead fishery and also its cutthroat trout, chinook, and coho salmon runs. National Wild and Scenic status was afforded to approximately 55 km of the North Umpqua in 1988. Within the basin are Douglas fir and western hemlock forests, meadows, near-vertical cliffs and spires, and many other spectacular geologic features (Fig. 12.8).

The Eel River is located in the Pacific Mid-Coastal freshwater ecoregion and is part of two terrestrial ecoregions (Klamath–Siskiyou Forests, Northern California Coastal Forests). The Eel begins in the high pine forests of Mendocino National Forest and flows in a northwesterly direction for 322 km past some of the most spectacular redwood groves in California (Fig. 12.1, Fig. 12.24). The Eel basin was once one of California's top three salmon and steelhead fisheries; water capture and diversion are suspected of contributing to its decline. The Eel is noted for producing the highest discharge (21,294 m³/s) ever recorded in California. This remarkable event, given the small basin area, occurred during the December 1964 flood, at which time the Eel transported more sediment in one day than it had in the previous 23 years. In 1981, approximately 156 km of reaches on the main stem and tributaries were designated as National Wild and Scenic River.

The Russian River is located in the Pacific Mid-Coastal freshwater ecoregion and is part of two terrestrial ecoregions (Northern California Coastal Forests, California Interior Chaparral and Woodlands). The river begins just northwest of Clear Lake, flows southeast through a long valley for 111 km, and then turns abruptly west for 66 km, flowing

FIGURE 12.8 Umpqua River at Elkton, Oregon (PHOTO BY TIM PALMER).

partly through rugged canyons within the Coast Range before reaching the coast at the town of Jenner (Fig. 12.26). In the downstream, west-flowing section, the Russian is lined with cottages and homes (Fig. 12.9). The interbasin transfer of water from the Trinity River drainage augments flow in the Russian River. The Russian basin is an excellent example of a basin influenced by a Mediterranean-type climate regime.

The Santa Ana River, one of the largest basins in southern California, is located in the South Pacific Coastal freshwater ecoregion and is part of two terrestrial ecoregions (California Montane Chaparral

and Woodlands, California Coastal Chaparral and Woodlands). The Santa Ana begins high in the San Bernardino Mountains in San Bernardino National Forest, where it is surrounded by a riparian corridor and forest of pine, fir, and oak (Fig. 12.28). However, downstream of the first 30 km the river is leveed, channelized, and functionally dewatered (Fig. 12.10). Most of its water is diverted to infiltration ponds that are used to recharge local aquifers to support the 2,000,000 to 4,500,000 people living in the basin.

The Santa Margarita River is located in the South Pacific Coastal freshwater ecoregion and the California Coastal Sage and Chaparral terrestrial

ecoregion. The Santa Margarita, one of the last free-flowing rivers in coastal southern California, begins at the confluence of Temecula and Murrieta creeks at the Temecula gorge (Fig. 12.30). It flows for 43 km to the ocean and has one of the most continuous riparian corridors in the region (Fig. 12.11). Water use upstream has decreased base flow, particularly during extended dry periods. Although many non-native species have been introduced to the system, the Santa Margarita has one of the largest remaining populations of arroyo chub. A short segment of the river is being considered for National Wild and Scenic River status.

ACKNOWLEDGMENTS

We would like to thank the many researchers who provided information for this chapter: Mary Adams (Regional Water

Quality Control Board), Aaron Borisenko (Oregon Department of Environmental Quality), Kim Bredensteiner (Conservation Biology Institute), Larry Brown (USGS), Carmen Burton (USGS), Terrence Frest (Deixis Consultants), Joseph Furnish (USDA Forest Service), David Gibson (Regional Water Quality Control Board, San Diego), Rich Hafele (Oregon Department of Environmental Quality), James Harrington (California Department of Fish and Game), Jeanette Howard (U.C. Berkeley), Jon Keeley (USGS), Jonathan Lee (Jon Lee Consulting), Douglas F. Markle (Oregon State University), Raphael D. Mazor (U.C. Berkeley), Peter Moyle (U.C. Davis), Peter Ode (California Department of Fish and Game), Kelly Palacios (Conservation Biology Institute), Ron Rogers (California Department of Fish and Game), Deborah Rudnick (U.C. Berkeley), Eric Scheuering (U.C. Berkeley), Sue Vrilakas (Oregon Natural Heritage Information Center), and Robert Wisseman (Aquatic Biology Associates, Inc.). Leila Gass and JoAnn Gronberg from the USGS helped us with many of the GIS-derived data. We are particularly grateful to

Larry Brown and Steve Fend for their thorough and helpful reviews.

FIGURE 12.13 Mean monthly air temperature, precipitation, and runoff for the Sacramento River basin.

SACRAMENTO RIVER

Relief: 4317 m

Basin area: 72,132 km²

Mean discharge: 657 m³/s

River order: 8 (estimated)

Mean annual precipitation: 89.7 cm

Mean air temperature: 12.9°C

Mean water temperature: NA

Physiographic provinces: Pacific Border (PB), Cascades–Sierra Nevada Mountains (CS), Basin and Range (BR)

Biomes: Chaparral, Temperate Mountain Forest

Freshwater ecoregions: Pacific Mid-Coastal, Pacific Central Valley, Oregon Lakes

Terrestrial ecoregions: Eastern Cascades Forests, Klamath–Siskiyou Forests, Sierra Nevada Forests, California Central Valley Grasslands, California Interior Chaparral and Woodlands

Number of fish species: 69 (29 native)

Number of endangered species: >50 threatened and endangered

Major fishes: Pacific lamprey, river lamprey, white sturgeon, green sturgeon, Sacramento blackfish, hardhead, hitch, Sacramento pikeminnow, tui chub, Sacramento splittail, California roach, speckled dace, Sacramento sucker, delta smelt, longfin smelt, Modoc sucker, chinook salmon, rainbow trout, coho salmon, threespine stickleback, Sacramento perch, tule perch, staghorn sculpin, riffle sculpin

Major other aquatic vertebrates: California newt, Sierra newt, California red-legged frog, foothill yellow-legged frog, mountain yellow-legged frog, western leopard frog, western toad, Yosemite toad, western pond turtle, western aquatic garter snake, water shrew, mountain beaver, beaver, muskrat, raccoon, river otter, ermine (short-tailed weasel), long-tailed weasel, mink

Major benthic invertebrates: mayflies (*Siphonurus*, *Baetis*, *Drunella*, *Ephemerella*, *Serratella*, *Epeorus*, *Rhithrogena*, *Cinygmula*), stoneflies (*Pteronarcys*, *Malenka*, *Zapada*, *Hesperoperla*, *Calineuria*, *Isoperla*, *Suwallia*, *Sweltsa*, *Eucapnopsis*), caddisflies (*Arctopsyche*, *Hydropsyche*, *Cheumatopsyche*, *Rhyacophila*, *Hydroptila*), bivalves (*Corbicula fluminea*, *Potamocorbula amurensis*), crustaceans (*Neomysis mercedis*)

Nonnative species: eastern oyster, bullfrog, >40 species of fishes (e.g., American shad, striped bass, and many warmwater fishes)

Major riparian plants: arroyo willow, black willow, narrowleaf willow, Pacific willow, red willow, black cottonwood, Fremont cottonwood, California sycamore, mulefat, mountain alder, white alder, buttonbush, water birch

Special features: largest river in California; several National Wild and Scenic reaches; one of largest salmonid runs in California; discharges through the highly productive Sacramento–San Joaquin Delta into San Francisco Bay

Fragmentation: hundreds of dams and water withdrawals within basin

Water quality: pH near 8, alkalinity = 52 mg/L as CaCO₃, NO₃-N = 0.25 mg/L, PO₄-P = 0.02 mg/L

Land use: 49.3% forest, 13.7% shrub, 16.2% grassland/herbaceous, 0.8% wetlands, 15.1% agriculture, 1.7% urban

Population density: 23.6 people/km²

Major information sources: Moyle 2002, Schoenherr 1992

FIGURE 12.12 Map of the Sacramento River basin. Physiographic provinces are separated by yellow lines.

FIGURE 12.15 Mean monthly air temperature, precipitation, and runoff for the San Joaquin River basin.

SAN JOAQUIN RIVER

Relief: 4418 m

Basin area: 83,409 km²

Mean discharge: 132 m³/s

River order: 8 (estimated)

Mean annual precipitation: 48.8 cm

Mean air temperature: 15.7°C

Mean water temperature: NA

Physiographic provinces: Pacific Border (PB),
Cascade–Sierra Nevada Mountains (CS)

Biomes: Chaparral, Temperate Mountain Forest

Freshwater ecoregion: Pacific Central Valley

Terrestrial ecoregions: California Central Valley
Grasslands, California Interior Chaparral and
Woodlands, Sierra Nevada Forests

Number of fish species: 63 (native and nonnative)

Number of endangered species: >50 threatened and
endangered

Major fishes: Pacific lamprey, white sturgeon,
Sacramento blackfish, hardhead, hitch, Sacramento
pikeminnow, California roach, speckled dace,
Sacramento sucker, delta smelt, longfin smelt,
chinook salmon, rainbow trout, threespine stickleback, Sacramento perch, tule perch, staghorn sculpin, riffle sculpin

Major other aquatic vertebrates: California newt, Sierra newt, tailed frog, California red-legged frog, foothill yellow-legged frog, mountain yellow-legged frog, bullfrog, western leopard frog, western toad, Yosemite toad, western pond turtle, western aquatic garter snake, water shrew, mountain beaver, beaver, muskrat, nutria, raccoon, river otter, ermine (short-tailed weasel), long-tailed weasel, mink

Major benthic invertebrates: mayflies (*Baetis*, *Epeorus*, *Caenis*, *Heptagenia*, *Fallceon*, *Ephemerella*, *Drunella*), stoneflies (*Hesperoperla*, *Suwallia*, *Eucapnopsis*), caddisflies (*Hydropsyche*, *Arctopsyche*, *Rhyacophila*, *Nectopsyche*), bivalves (*Corbicula*)

Nonnative species: bullfrog, >40 species of fishes (e.g., most warmwater species, such as largemouth bass, smallmouth bass, crappie, bluegill, catfishes)

Major riparian plants: arroyo willow, black willow, narrowleaf willow, Pacific willow, red willow, black cottonwood, Fremont cottonwood, buttonbush, California sycamore, mulefat, white alder

Special features: begins in high Sierra Nevada; several tributaries designated National Wild and Scenic Rivers; flows through intensive agricultural region before discharging through highly productive Sacramento–San Joaquin Delta into San Francisco Bay

Fragmentation: hundreds of dams and water withdrawals within basin

Water quality: pH = 7.6, alkalinity = 93 mg/L as CaCO₃, dissolved NO₃-N + NO₂-N = 1.36 mg/L, dissolved PO₄-P = 0.15 mg/L

Land use: 26.8% forest, 13.4% shrub, 23.0% grassland/herbaceous, 0.4% wetlands, 30.0% agriculture, 1.9% urban

Population density: 29.3 people/km²

Major information sources: Moyle 2002, Schoenherr 1992

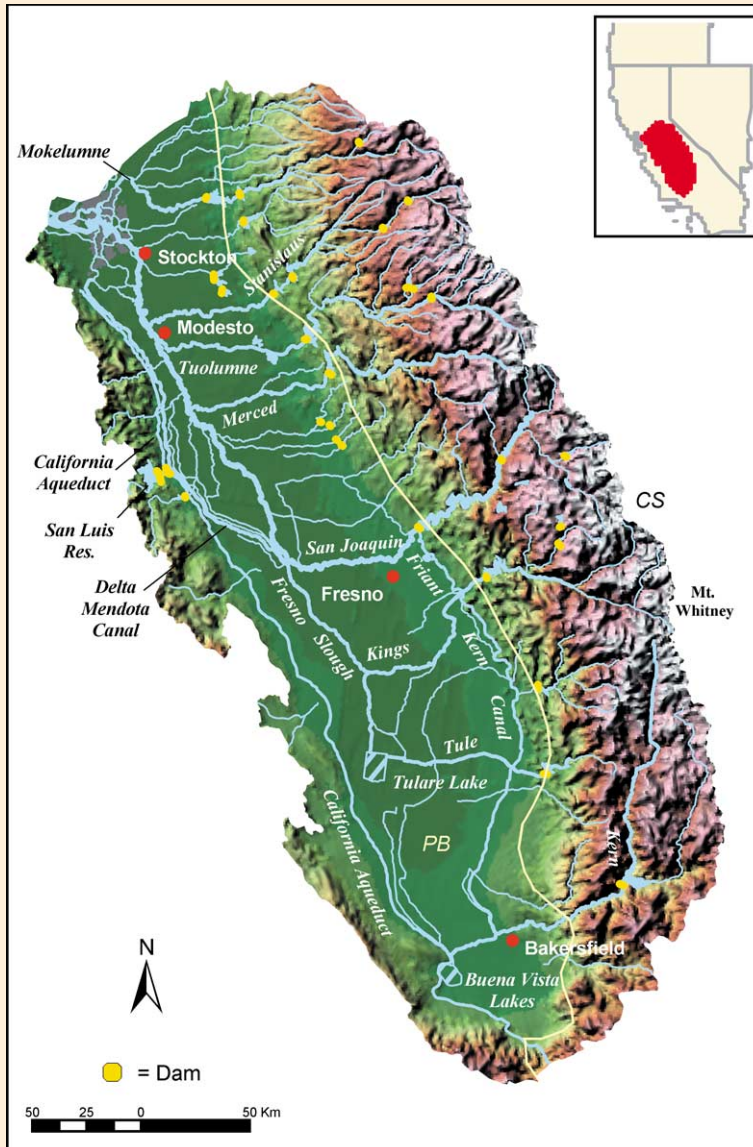

FIGURE 12.14 Map of the San Joaquin River basin. Physiographic provinces are separated by a yellow line.

FIGURE 12.17 Mean monthly air temperature, precipitation, and runoff for the Salinas River basin.

SALINAS RIVER

Relief: 1787 m

Basin area: 10,983 km²

Mean discharge: 12.7 m³/s

River order: 6 (estimated)

Mean annual precipitation: 36.4 cm

Mean air temperature: 14.6°C

Mean water temperature: NA

Physiographic province: Pacific Border (PB)

Biomes: Chaparral, Temperate Mountain Forest

Freshwater ecoregion: Pacific Central Valley

Terrestrial ecoregions: California Interior Chaparral and Woodlands, California Montane Chaparral and Woodlands

Number of fish species: 36 (16 native)

Number of endangered species: 42 threatened and endangered

Major fishes: Pacific lamprey, Pacific brook lamprey, Sacramento blackfish, hitch, Sacramento pikeminnow, California roach, speckled dace, Sacramento sucker, coho salmon, steelhead, rainbow trout, threespine stickleback, tidewater goby, staghorn sculpin, coastrange sculpin, prickly sculpin, riffle sculpin

Major other aquatic vertebrates: California giant salamander, California newt, Pacific chorus frog, California chorus frog, California red-legged frog, foothill yellow-legged frog, western toad, arroyo toad, western pond turtle, aquatic/Santa Cruz garter snake, beaver, muskrat, raccoon, long-tailed weasel

Major benthic invertebrates: mayflies (*Acentrella*, *Baetis*, *Dipheter*, *Fallceon*, *Centroptilum*, *Procloeon*, *Serratella*, *Tricorythodes*), caddisflies (*Hydropsyche*, *Cheumatopsyche*), beetles (*Optioservus*), crustaceans (*Hyaella azteca*)

Nonnative species: bullfrog, threadfin shad, common carp, golden shiner, fathead minnow, channel catfish, white catfish, brown bullhead, black bullhead, brown trout, mosquitofish, inland silverside, white bass, black crappie, white crappie, green sunfish, bluegill, redear sunfish, largemouth bass, smallmouth bass

Major riparian plants: arroyo willow, narrowleaf willow, red willow, Sitka willow, buttonbush, California sycamore, Fremont cottonwood, mulefat, white alder

Special features: flows through the Salinas Valley, which is often referred to as “America’s Salad Bowl”; under natural flow conditions it is one of longest underground rivers in North America

Fragmentation: 17 dams

Water quality: pH = 7.8, alkalinity = 258 mg/L as CaCO₃, dissolved NO₃-N + NO₂-N = 2.94 mg/L, dissolved PO₄-P = 1.73 mg/L

Land use: 17.4% forest, 15.9% shrub, 49.0% grasslands/herbaceous, 12.8% agriculture, 0.7% urban

Population density: 10.1 people/km²

Major information sources: Moyle 2002, Schoenherr 1992

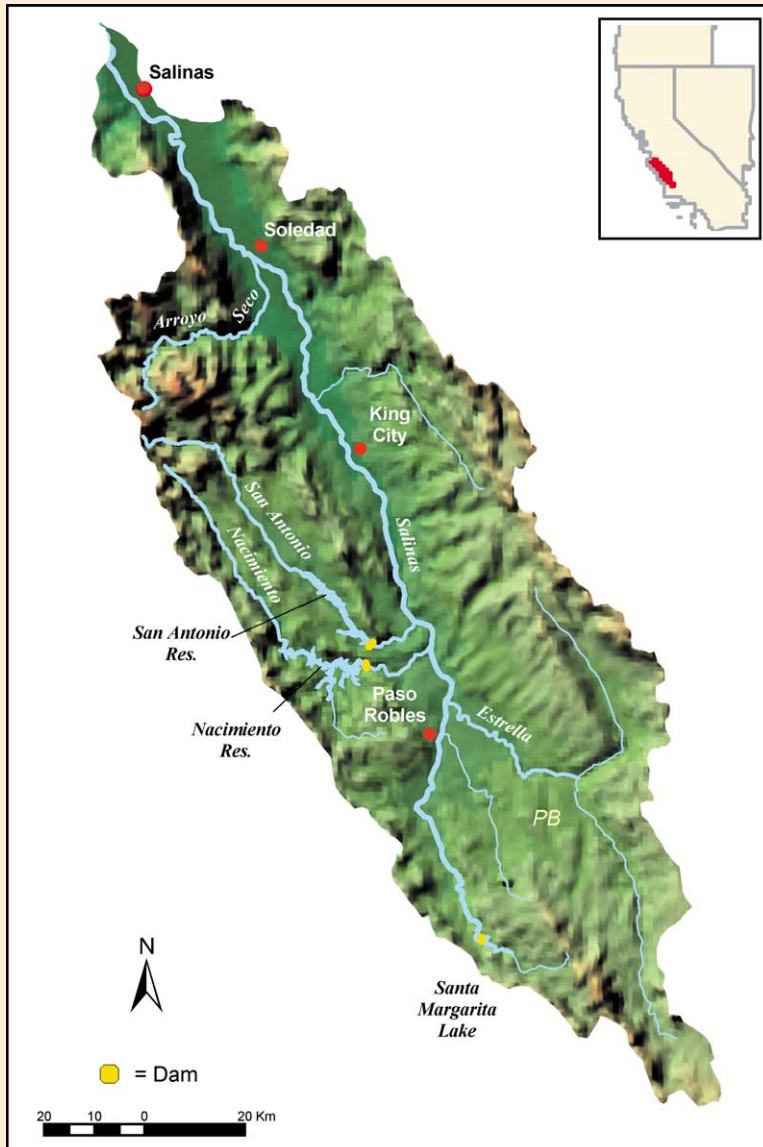

FIGURE 12.16 Map of the Salinas River basin.

FIGURE 12.18 Map of the Klamath River basin. Physiographic provinces are separated by yellow lines.

KLAMATH RIVER

Relief: 2894 m

Basin area: 40,608 km²

Mean discharge: 501 m³/s

River order: 7 (estimated)

Mean annual precipitation: 85 cm

Mean air temperature: 10.5°C

Mean water temperature: NA

Physiographic provinces: Pacific Border (PB), Basin and Range (BR), Cascade-Sierra Nevada Mountains (CS)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Pacific Mid-Coastal

Terrestrial ecoregions: Eastern Cascades Forests, Klamath-Siskiyou Forests, Northern California Coastal Forests

Number of fish species: 48 (30 native)

Number of endangered species: 41

Major fishes: Pacific lamprey, Klamath River lamprey, white sturgeon, green sturgeon, blue chub, tui chub, speckled dace, Lost River sucker, shortnose sucker, Klamath smallscale sucker, Klamath largescale sucker, longfin smelt, chum salmon, coho salmon, chinook salmon, rainbow trout, cutthroat trout, steelhead, staghorn sculpin, slender sculpin, coastrange sculpin

Major other aquatic vertebrates: northwestern salamander, southern torrent salamander, rough skinned newt, red-legged frog, California red-legged frog, foothill yellow-legged frog, Cascades frog, spotted frog, western leopard frog, western toad, western pond turtle, western aquatic garter snake, mountain beaver, beaver, muskrat, nutria, raccoon, river otter, mink

Major benthic invertebrates: mayflies (*Baetis*, *Drunella*, *Rhithrogena*, *Cinygmula*, *Epeorus*, *Ironodes*, *Paraleptophlebia*), stoneflies (*Yoraperla*, *Calineuria*, *Hesperoperla*, *Zapada*, *Malenka*), caddisflies (*Hydropsyche*, *Nectopsyche*, *Oecetis*, *Helicopsyche*, *Glossosoma*, *Lepidostoma*, *Agapetus*), beetles (*Optioservus*, *Cleptelmis*, *Zaitzevia*), bugs (*Sigara*), snails (*Juga*)

Nonnative species: bullfrog, American shad, goldfish, golden shiner, fathead minnow, brown bullhead, black bullhead, wakasagi, kokanee, brown trout, brook trout, brook stickleback, Sacramento perch, black crappie, white crappie, green sunfish, bluegill, pumpkinseed, largemouth bass, spotted bass, yellow perch

Major riparian plants: arroyo willow, Hooker willow, black willow, narrowleaf willow, Pacific willow, red willow, sandbar willow, Sitka willow, black cottonwood, Fremont cottonwood, mulefat, white alder, water birch

Special features: flows through rugged, species-rich Klamath Mountains; below most downstream dam flows unimpounded for >450 km to Pacific; one of best salmonid fisheries in California; >900 km designated as National Wild and Scenic River

Fragmentation: 24 dams

Water quality: pH = 8.0, alkalinity = 70 mg/L as CaCO₃, NO₃-N + NO₂-N = 0.155 mg/L, PO₄-P = 0.037 mg/L

Land use: 66.3% forest, 14.0% shrub, 8% grasslands, 2.3% wetlands, 5.9% agriculture, 0.2% urban

Population density: 1.9 people/km²

Major information sources: Moyle 2002, Schoenherr 1992

FIGURE 12.19 Mean monthly air temperature, precipitation, and runoff for the Klamath River basin.

FIGURE 12.20 Map of the Rogue River basin. Physiographic provinces are separated by a yellow line.

ROGUE RIVER

Relief: 2894 m

Basin area: 13,348 km²

Mean discharge: 285 m³/s

River order: 7 (estimated)

Mean annual precipitation: 97 cm

Mean air temperature: 11.6°C

Mean water temperature: NA

Physiographic provinces: Cascade–Sierra Nevada Mountains (CS), Pacific Border (PB)

Biome: Temperate Mountain Forest

Freshwater ecoregion: Pacific Mid-Coastal

Terrestrial ecoregions: Central Pacific Coastal Forests, Klamath–Siskiyou Forests, Central and Southern Cascades Forests

Number of fish species: 23 (14 native)

Number of endangered species: 11

Major fishes: Pacific lamprey, green sturgeon, white sturgeon, coastal cutthroat, pink salmon, coho salmon, rainbow trout, Chinook salmon, speckled dace, tui chub, Klamath smallscale sucker, steelhead

Major other aquatic vertebrates: northwestern salamander, Pacific giant salamander, southern torrent salamander, rough skinned newt, red-legged frog, foothill yellow-legged frog, Cascades frog, spotted frog, western toad, western pond turtle, western aquatic garter snake, water shrew, mountain beaver, beaver, muskrat, raccoon, river otter, ermine, long-tailed weasel, mink

Major benthic invertebrates: mayflies (*Baetis*, *Diphetera*, *Acentrella*, *Ephemerella*, *Drunella*, *Rhithrogena*, *Epeorus*, *Paraleptophlebia*), stoneflies (*Zapada*, *Calineuria*, *Malenka*, *Sweltsa*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Arctopsyche*, *Parapsyche*, *Lepidostoma*, *Rhyacophila*, *Micrasema*, *Glossosoma*), snails (*Fluminicola*, *Juga*, *Fossaria*, *Lymnaea*, *Physella*, *Gyraulus*, *Ferrissia*), bivalves (*Gonidea*, western pearlshell mussel)

Nonnative species: brook trout, common carp, golden shiner, Umpqua pikeminnow, redbreast shiner, brown bullhead, smallmouth bass, largemouth bass, black crappie, bullfrog

Major riparian plants: sandbar willow, Geyer willow, Pacific willow, yellow willow, Scouler willow, white alder, red alder, black cottonwood, Oregon ash

Special features: begins in high Cascade Mountains on slopes of Crater Lake National Park; one of first National Wild and Scenic Rivers; one of best salmonid fisheries in west; renowned for white-water boating

Fragmentation: ~80 dams

Water quality: pH = 7.6, alkalinity = 44 mg/L as CaCO₃, NO₃-N + NO₂-N = 0.135 mg/L, PO₄-P = 0.051 mg/L

Land use: 82.7% forest, 2.9% shrub, 6.4% grasslands, 0.2% as wetlands, 5.9% agriculture, 0.8% urban

Population density: 12.4 people/km²

Major information sources: D. F. Markle, personal communication, Oregon Natural Heritage Information Center 2002

FIGURE 12.21 Mean monthly air temperature, precipitation, and runoff for the Rogue River basin.

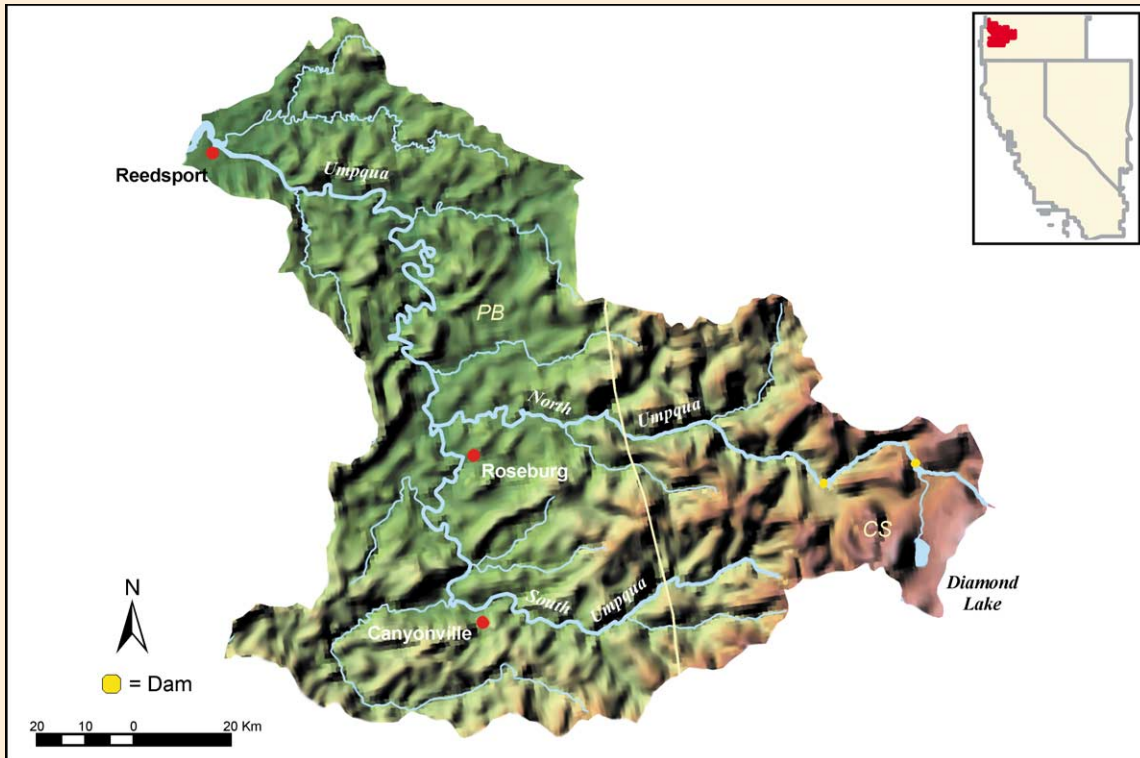

FIGURE 12.22 Map of the Umpqua River basin. Physiographic provinces are separated by a yellow line.

UMPQUA RIVER

Relief: 2799 m
 Basin area: 12,133 km²
 Mean discharge: 211 m³/s
 River order: 6 (estimated)
 Mean annual precipitation: 115 cm
 Mean air temperature: 11.7°C
 Mean water temperature: NA
 Physiographic provinces: Cascade–Sierra Nevada Mountains (CS), Pacific Border (PB)

Biome: Temperate Mountain Forest
 Freshwater ecoregion: Pacific Mid-Coastal
 Terrestrial ecoregions: Central Pacific Coastal Forests, Klamath–Siskiyou Forests, Central and Southern Cascades Forests

Number of fish species: 27 (19 native)
 Number of endangered species: 9

Major fishes: river lamprey, western brook lamprey, Pacific lamprey, coastal cutthroat, chum salmon, coho salmon, rainbow trout, chinook salmon, Umpqua chub, Umpqua pikeminnow, Umpqua dace, speckled dace, tui chub, largescale sucker, threespine stickleback, coastrange sculpin, prickly sculpin, riffle sculpin, reticulate sculpin

Major other aquatic vertebrates: northwestern salamander, Pacific giant salamander, southern torrent salamander, rough skinned newt, Pacific chorus frog, red-legged frog, foothill yellow-legged frog, Cascades frog, spotted frog, western toad, western aquatic garter snake, water shrew, mountain beaver, beaver, muskrat, nutria, raccoon, river otter, mink

Major benthic invertebrates: mayflies (*Baetis tricaudatus*, *Dipheter*, *Paraleptophlebia*, *Rhithrogena*), stoneflies (*Calineuria*, *Hesperoperla*, *Sweltsa*, *Malenka*, *Zapada*), caddisflies (*Hydropsyche*, *Glossosoma*, *Neophylax*), snails (*Juga*)

Nonnative species: American shad, reddsider shiner, yellow bullhead, western mosquitofish, bluegill, smallmouth bass, largemouth bass, black crappie, brook trout, bullfrog

Major riparian plants: sandbar willow, Geyer willow, Pacific willow, yellow willow, Scouler willow, white alder, red alder, black cottonwood, Oregon ash

Special features: begins in Cascades; world renowned steelhead and salmon fishery; portions have National Wild and Scenic River status

Fragmentation: 64 dams in Douglas County, Oregon; fewest dams of any large basin in Oregon

Water quality: North Umpqua very good water quality; South Umpqua lesser quality; temperatures higher than desired; pH = 7.4, alkalinity = 31 mg/L as CaCO₃, NO₃-N + NO₂-N = 0.109 mg/L, PO₄-P = 0.028 mg/L

Land use: 85.9% forest, 2% shrub, 4.9% grasslands, 0.1% wetlands, 4.6% agriculture, 0.5% urban

Population density: 5.2 people/km²

Major information sources: D. F. Markle, personal communication, Oregon Natural Heritage Information Center 2002

EEL RIVER

Relief: 2270 m

Basin area: 9456 km²

Mean discharge: 210 m³/s

River order: 6 (estimated)

Mean annual precipitation: 133 cm

Mean air temperature: 12.7°C

Mean water temperature: NA

Physiographic province: Pacific Border (PB)

Biomes: Temperate Mountain Forest, Chaparral

Freshwater ecoregion: Pacific Mid-Coastal

Terrestrial ecoregions: Klamath–Siskiyou Forests, Northern California Coastal Forests

Number of fish species: 25 (15 native)

Number of endangered species: 12

Major fishes: Pacific lamprey, river lamprey, Pacific brook lamprey, Sacramento sucker, coho salmon, chinook salmon, rainbow trout, cutthroat trout, threespine stickleback, staghorn sculpin, coastrange sculpin, prickly sculpin

Major other aquatic vertebrates: northwestern

salamander, Pacific giant salamander, southern torrent salamander, rough skinned newt, California newt, red-bellied newt, red-legged frog, foothill yellow-legged frog, western toad, western pond turtle, western aquatic garter snake, aquatic/Santa Cruz garter snake, beaver, muskrat, raccoon, river otter, mink

Major benthic invertebrates: mayflies (*Baetis*, *Ephemerella*, *Epeorus*, *Cinygmula*, *Rhithrogena*, *Paraleptophlebia*), stoneflies (*Malenka*, *Calineuria*, *Sweltsa*), caddisflies (*Hydropsyche*, *Rhyacophila*, *Helicopsyche*), beetles (*Psephenus*, *Optioservus*)

Nonnative species: bullfrog, American shad, threadfin shad, golden shiner, Sacramento pikeminnow, California roach, speckled dace, fathead minnow, brown bullhead, green sunfish, bluegill

Major riparian plants: arroyo willow, Hooker willow, black willow, narrowleaf willow, Pacific willow, red willow, sandbar willow, Sitka willow, black cottonwood, Fremont cottonwood, mulefat, white alder

Special features: begins in Six Rivers and Mendocino National Forests; flows past some of the most spectacular ancient redwood groves in California; more kilometers designated as National Wild and Scenic Rivers than any basin in California

Fragmentation: 14 dams

Water quality: pH = 8.0, alkalinity = 96 mg/L as CaCO₃, NO₃-N + NO₂-N = 0.082 mg/L, PO₄-P = 0.020 mg/L

Land use: 65.1% forest, 12.2% shrub, 19.2% grassland, 1.9% agriculture, 0.2% urban

Population density: 3.3 people/km²

Major information sources: Moyle 2002, Schoenherr 1992

FIGURE 12.27 Mean monthly air temperature, precipitation, and runoff for the Russian River basin.

RUSSIAN RIVER

Relief: 1324 m

Basin area: 3728 km²

Mean discharge: 66 m³/s

River order: 6 (estimated)

Mean annual precipitation: 105 cm

Mean air temperature: 14.9°C

Mean water temperature: NA

Physiographic province: Pacific Border (PB)

Biomes: Chaparral, Temperate Mountain Forest

Freshwater ecoregion: Pacific Mid-Coastal

Terrestrial ecoregions: Northern California Coastal Forests, California Interior Chaparral and Woodlands

Number of fish species: 41 (20 native)

Number of endangered species: 43

Major fishes: Pacific lamprey, river lamprey, Pacific brook lamprey, hardhead, hitch, Sacramento pikeminnow, California roach, Sacramento sucker, Klamath largescale sucker, longfin smelt, coho salmon, chinook salmon, rainbow trout, threespine stickleback, tule perch, staghorn sculpin, coastrange sculpin, prickly sculpin, riffle sculpin

Major other aquatic vertebrates: northwestern salamander, Pacific giant salamander, California giant salamander, southern torrent salamander, rough skinned newt, California newt, sierra newt, red-bellied newt, California red-legged frog, foothill yellow-legged frog, mountain yellow-legged frog, western toad, western aquatic garter snake, aquatic/Santa Cruz garter snake, mountain beaver, beaver, muskrat, mink

Major benthic invertebrates: mayflies (*Baetis*, *Diphetera*, *Tricorythodes*, *Drunella*, *Ephemerella*, *Paraleptophlebia*, *Rhithrogena*, *Epeorus*), stoneflies (*Calineuria*, *Malenka*, *Sweltsa*), caddisflies (*Hydropsyche*, *Rhyacophila*, *Lepidostoma*), beetles (*Optioservus*)

Nonnative species: bullfrog, American shad, threadfin shad, common carp, goldfish, golden shiner, Sacramento blackfish, fathead minnow, brown bullhead, green sunfish, bluegill, blue catfish, channel catfish, white catfish, brown bullhead, black bullhead, brown trout, mosquitofish, inland silverside, black crappie, white crappie, redear sunfish, largemouth bass, smallmouth bass

Major riparian plants: arroyo willow, Hooker willow, narrowleaf willow, Pacific willow, red willow, sandbar willow, Sitka willow

Special features: begins in Coast Range of California; flows through a valley of mixed land use; classic Mediterranean-type river in California

Fragmentation: 62 dams

Water quality: pH = 7.8, alkalinity = 111 mg/L as CaCO₃, NO₃-N + NO₂-N = 0.266 mg/L, PO₄-P = 0.082 mg/L

Land use: 50.2% forest, 8.0% shrub, 23.3% grasslands/herbaceous, 0.1% wetlands, 14.3% agriculture, 2.8% urban

Population density: 62.5 people/km²

Major information sources: Moyle 2002, Schoenherr 1992

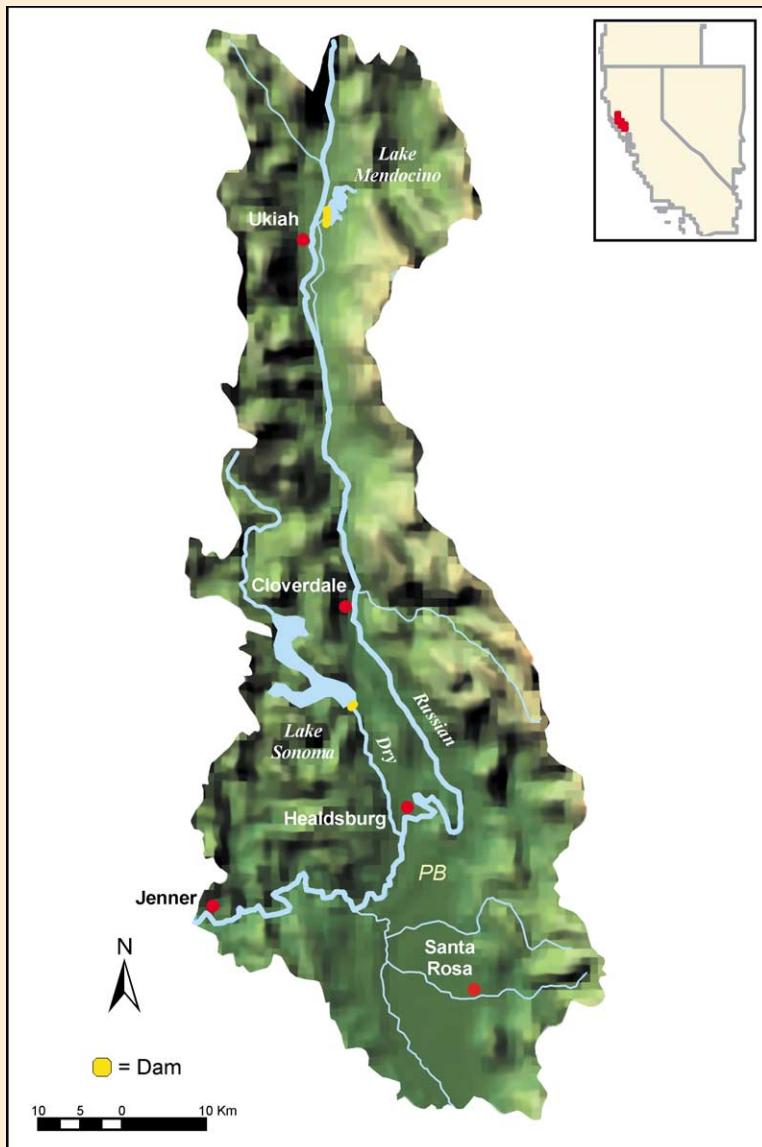

FIGURE 12.26 Map of the Russian River basin.

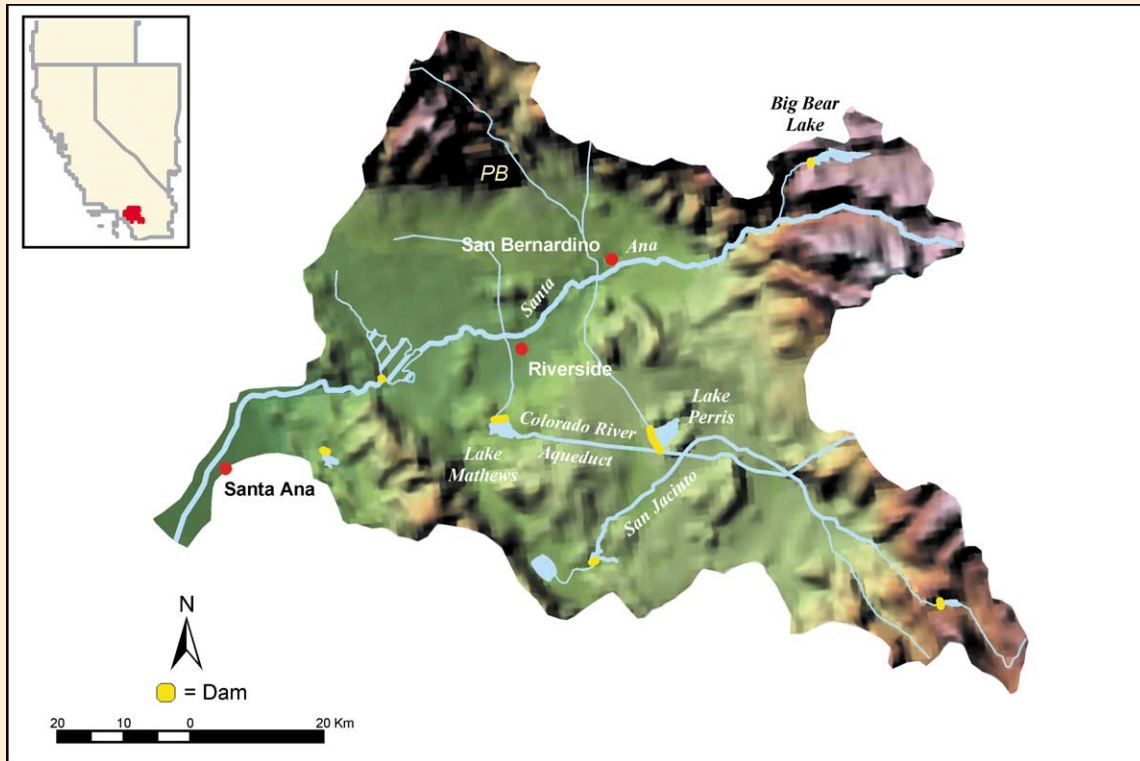

FIGURE 12.28 Map of the Santa Ana River basin.

SANTA ANA RIVER

Relief: 3506 m

Basin area: 6314 km²

Mean discharge: 1.7 m³/s

River order: 6 (estimated)

Mean annual precipitation: 34.1 cm

Mean air temperature: 17.2°C

Mean water temperature: NA

Physiographic province: Pacific Border (PB)

Biome: Chaparral

Freshwater ecoregion: South Pacific Coastal

Terrestrial ecoregions: California Montane Chaparral and Woodlands, California Coastal Sage and Chaparral

Number of fish species: 45 (9 native)

Number of endangered species: 54

Major fishes: arroyo chub, speckled dace, rainbow trout, California killifish, threespine stickleback, striped mullet, tidewater goby, staghorn sculpin, prickly sculpin

Major other aquatic vertebrates: California newt, Sierra newt, California red-legged frog, mountain yellow-legged frog, western leopard frog, African clawed frog, western toad, arroyo toad, western pond turtle, western aquatic garter snake, beaver, muskrat, raccoon, river otter, long-tailed weasel

Major benthic invertebrates: mayflies (*Baetis tricaudatus*, *Fallceon quilleri*, *Caudatella*, *Drunella*, *Tricorythodes*), damselflies (*Argia vivida*), caddisflies (*Hydropsyche californica*, *H. occidentalis*, *Helicopsyche*), moths (*Petrophila*), snails (*Physella*)

Nonnative species: bullfrog, threadfin shad, common carp, goldfish, hitch, Sacramento pikeminnow, Colorado pikeminnow, red shiner, fathead minnow, catfish, brown trout, rainwater killifish, mosquitofish, sailfin molly, inland silverside, crappie, green sunfish, bluegill, pumpkinseed, redear sunfish, largemouth bass, spotted bass, smallmouth bass, bigscale logperch, redbelly tilapia, tule perch, yellowfin goby, Shimofuri goby; list includes Los Angeles basin

Major riparian plants: arroyo willow, black willow, narrowleaf willow, Pacific willow, red willow, California sycamore, Fremont cottonwood, mulefat, white alder

Special features: one of the largest river systems in southern California, but intermittent, channelized, and highly urbanized; upper portion still retains natural characteristics

Fragmentation: 52 dams

Water quality: pH = 7.8, alkalinity = 214 mg/L as CaCO₃, NO₃-N + NO₂-N = 5.0 mg/L, PO₄-P = 1.56 mg/L

Land use: 57% vacant land and forest, 11% agriculture, 32% urban

Population density: 334.1 people/km²

Major information sources: Moyle 2002, Schoenherr 1992

FIGURE 12.29 Mean monthly air temperature, precipitation, and runoff for the Santa Ana River basin.

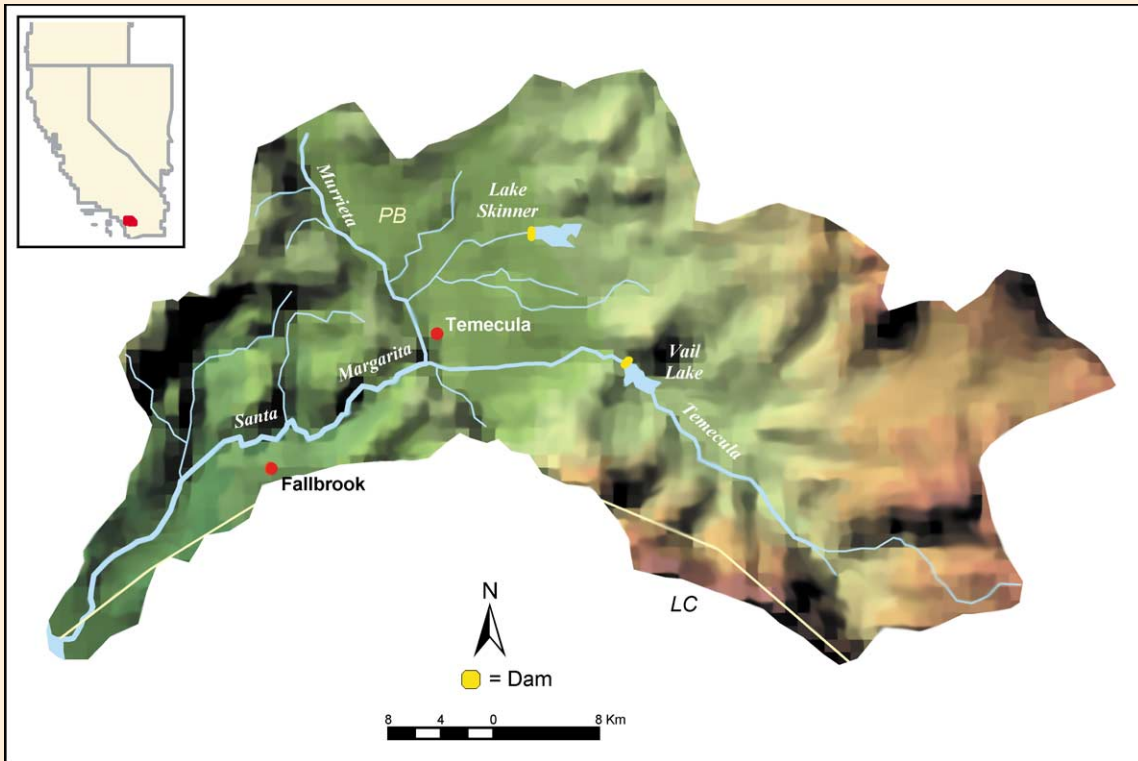

FIGURE 12.30 Map of the Santa Margarita River basin. Physiographic provinces are separated by a yellow line.

SANTA MARGARITA RIVER

Relief: 2076 m
Basin area: 1896 km²
Mean discharge: 1.2 m³/s
River order: 5 (estimated)
Mean annual precipitation: 49.5 cm
Mean air temperature: 14.6°C
Mean water temperature: N.A.
Physiographic provinces: Lower California (LC), Pacific Border (PB)
Biome: Chaparral
Freshwater ecoregion: South Pacific Coastal
Terrestrial ecoregion: California Coastal Sage and Chaparral
Number of fish species: 17 (6 native)
Number of endangered species: 52
Major fishes: arroyo chub, rainbow trout, California killifish, striped mullet, longjaw mudsucker, staghorn sculpin
Major other aquatic vertebrates: California newt, Pacific chorus frog, California chorus frog, California red-legged frog, mountain yellow-legged frog, western leopard frog, African clawed frog, western toad, arroyo toad, western pond turtle, western aquatic garter snake, beaver, muskrat, raccoon, long-tailed weasel
Major benthic invertebrates: mayflies (*Baetis*, *Tricorythodes*, *Fallceon quilleri*, *Centroptilum/Proclaeon*), stoneflies (*Isoperla*, *Malenka*, *Zapada*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Amiocentrus*, *Micrasema*), black flies (*Simulium*), crustaceans (*Hyalella azteca*, *Pacifasticus lenisculus*), bivalves (*Corbicula*, *Pisidium*), snails (*Physa/Physella*, *Gyraulus*)
Nonnative species: bullfrog, common carp, channel catfish, black bullhead, yellow bullhead, mosquitofish, black crappie, white crappie, green sunfish, bluegill, largemouth bass, redeye bass, yellowfin goby
Major riparian plants: arroyo, black, narrowleaf, Pacific, and red willow; California sycamore; Fremont cottonwood; mulefat; white alder
Special features: one of the last free-flowing rivers in southern California; one of the most intact and continuous riparian corridors in region
Fragmentation: 9 dams
Water quality: pH = 8.5, alkalinity = 184 mg/L as CaCO₃, NO₃-N + NO₂-N = 0.54 mg/L, PO₄-P = 0.152 mg/L
Land use: 11.2% forest, 58.5% shrub, 13.2% grasslands/herbaceous, 0.1% wetlands, 11.6% agriculture, 3.2% urban
Population density: 51.5 people/km²

LITERATURE CITED

INTRODUCTION

The Columbia River drains 724,025 km² of the American Pacific Northwest, including parts of Washington, Oregon, Nevada, Utah, Idaho, Wyoming, Montana, and British Columbia (Fig. 13.2). It is a 9th order river based upon analysis of the stream network at 1:100,000 scale. Landscape diversity is high, with parts of 13 terrestrial (Ricketts et al. 1999) and three freshwater (Abell et al. 2000) ecoregions included in the basin. The Columbia obtains much of its runoff from distant Rocky Mountain headwaters, flows through a huge and mostly dry interior basin, gains significant runoff from the eastern slopes of the Cascade Mountains, squeezes through a narrow gap in the Cascade cordillera, picks up the Willamette River, and softly passes through cool rainforests of the low Pacific Coast mountains. The river is a great water road for salmon and people, a purveyor of energy and irrigation water that has figured decisively in the development of the nation (White 1995).

The significance of the river was not clear to Boston fur trader and whaler Robert Gray when he first viewed and recorded the mouth of the Columbia in 1792, perhaps because of the rapid dissolve of the wood-jammed river into the mists of the coastal

rain forests. Nonetheless, the captain named the river after his ship, the *Columbia Rediviva*. Caucasian sailor-explorers had some contact and perhaps traded for furs with native people of the Columbia, but they had no idea that the river system was populated by over 100,000 Native Americans, including Nez Perce, Salish, Kootenai, Umatilla, and Yakama people with strong Pacific coastal affinity, along with several tribes such as Blackfeet and Shoshone of Great Plains origin using the headwaters.

Indeed, hunter-gatherer people have an ancient tenure in the Columbia River basin, and recent discoveries have renewed and helped reform theories regarding the peopling of the New World (Chatters 2000). The earliest evidence of human occupation corresponds to the last catastrophic floods from glacial outwash approximately 12,000 years ago (Attwater 1986). Salmon apparently were present in fairly large numbers at the Dalles on the lower main stem of the Columbia River by this time (Cressman et al. 1960, Butler 1993). Around 9000 years ago salmon were being caught at Kettle Falls on the upper Columbia (Chance and Chance 1977) and in Hells Canyon on the Snake River. Human populations during this period are characterized as “broad spectrum foraging,” indicating small group size, high seasonal mobility, and low population densities (Schalk

FIGURE 13.2 Rivers of the Columbia River basin covered in this chapter.

and Cleveland 1983). Archaeological data and tribal oral traditions from this early time period indicate the resources of the Columbia River and its tributary streams were important to early cultural systems. Human skeletal material from the middle Columbia indicates marine-derived resources were important dietary components (Chatters 2000). Hunter-gatherers shifted their life ways, adapting to changes in resource patterns associated with climatic shifts marking the early and middle Holocene period. From about 4000 years ago through the early historic period, salmon in association with gathered roots and hunting formed the basis of the human economy in the Columbia basin. Associated with floodplains of the major rivers and particularly at river junctures, large “winter villages complexes” emerged (Nelson

1973). These river-oriented villages formed the winter homes of peoples who gathered plants and hunted across a much larger territory (Uebelacker 1986). Variations in abundance and timing of fish and game migrations and broad spatial distribution of a large number of native plants with edible roots explain, in part, the cultural diversity that has so characterized the history of the Basin (see Walker 1998 for an exhaustive review of prehistoric and historic occupancy of the Columbia River basin).

The great expedition of Lewis and Clark (1804 to 1806) clearly revealed the physiographic breadth and ecological scope of the Columbia. The river and its expansive landscape and diverse native people were daunting, solicitous, and preeminent. Indeed, within 150 years the rapids were tamed and the cultural and

ecological landscape dramatically altered. Today, the river is aptly described as the great organic machine, owing to the rich legacy of fishing, mining, ranching, farming, commerce, and industry driven by the river's copious hydropower (White 1995).

In this chapter, we describe in some detail four of the Columbia tributaries, the Flathead, Snake, Yakima, and Willamette, and the Columbia main stem, along with brief summaries for seven others: Cowlitz, Grande Ronde, John Day, Methow, Spokane, Owyhee, and Clearwater. The Flathead River characterizes the distant upper segments of the Columbia. Due to its large size, the Snake and its major tributaries, the Clearwater and the Salmon, are key to understanding the Columbia. The Yakima represents the mid-Columbia rivers. The Yakima is especially noteworthy because it offers great potential for salmon restoration owing to expansive floodplains that remain largely intact, coupled with the opportunity to return irrigation diversions to the river through augmentation from the main-stem Columbia. Finally, the Willamette stands out as a culturally important large alluvial river that remains in a normative condition in spite of increasing urbanization, intense farming, and a long legacy of interaction between the timber industry and river ecology.

Physiography and Climate

The source of the Columbia River generally is conceded to be Columbia Lake in British Columbia almost exactly 2000 km from the Pacific. However, the most distant origin is via its largest tributary, the Snake, which begins on the Yellowstone Plateau in Wyoming, 2290 km from the ocean (Patrick 1995). The river and its tributaries traverse eight physiographic provinces (Hunt 1974). The Rocky Mountain headwaters include a long stretch of the Continental Divide cordillera, from the Tetons in Wyoming to the Columbia Ice Fields in Canada, and include the following physiographic provinces: the Middle Rocky Mountains, Northern Rocky Mountains, Rocky Mountains in Canada, and Coast Mountains of British Columbia and Southeast Alaska. Sequential mountain ranges extend across the Canadian portion of the catchment from the Rockies to the Cascades and other Pacific coastal ranges. The uplifted granite batholith that forms the extensive mountain ranges of Idaho west of the Rockies, including the Bitterroot, Selway, and Sawtooth mountains, also is a very prominent headwater feature of the basin. The comparatively arid Interior Columbia basin is represented by the

Columbia–Snake River Plateaus province, which includes the expansive Snake River Plain, the Blue Mountains, and the high desert steppe of eastern Oregon. Lower elevation and relatively dry ranges (e.g., Steens, Owyhee, Albion, Portneuf mountains) of northern Nevada and Utah separate the interior from the Great Basin to the south. However, some small tributaries of the Snake River drain from the northern edge of the Basin and Range province. The broad, fertile Willamette Valley is contained between the mountains of the Cascade–Sierra Nevada province and the coastal ranges of the Pacific Border province. Prominent Cascade volcanoes, Rainier, Hood, St. Helens, and Adams, are the sentinels of the Columbia basin.

The climate of the basin is predominately Pacific maritime, although cold, dry weather associated with northern continental weather intrudes into the headwaters frequently. Thus, the temperature range in the basin is extreme. Temperatures in the Rocky Mountain areas often are well below zero for many days in midwinter. Indeed, the coldest non-Alaska temperature recorded in the United States was a bitter -57°C at Rogers Pass on the Continental Divide at the headwaters of the Clark Fork of the Columbia on January 20, 1954. Summer temperatures in the mountain valleys seldom reach above 35°C , but areas in the arid interior often exceed 38°C degrees for many days in midsummer. Temperatures moderate toward the coast and the Cascade Range produces a profound rain shadow over the interior. Precipitation in the Cascades can exceed 350 cm/yr, whereas in the interior precipitation in places is 15 cm or less. Precipitation rises back to over 200 cm annually in the Rockies, although spatial variability is high owing to the complexity of the mountain and valley landscape and increasing influence of continental climate.

Basin Landscape and Land Use

Triple Divide Peak in Glacier National Park, Montana, is the common source of three of North America's great rivers: the Columbia (via the Flathead River), the Missouri (via the Milk River), and the Saskatchewan (via the Saint Mary's River). Early naturalist and glaciologist James Bird Grinnell called this mountainous area the Crown of the Continent. The glaciated landscape epitomizes the headwaters of the Columbia in the Rocky Mountains and in much of the Cascades as well. Sharp peaks tower over U-shaped valleys with large alluvial floodplains, the legacy of glacial scour and subsequent deposition of fluvial outwash deposits later reworked by the rivers.

Lobes of the Quaternary continental glaciers extended south through the Canadian ranges into Montana via the Rocky Mountain Trench, forming Flathead Lake, and into Idaho via the Purcell Trench, forming Lake Pend Oreille. Mountain glaciers draped all of the basin's ranges. Advances of the Purcell lobe, 12,000 to 15,000 years ago, dammed the Clark Fork multiple times, creating a proglacial Lake Missoula that covered over 20,000 km² to depths of several hundred meters. Cataclysmic floods burst over eastern Washington as the ice dams broke and Lake Missoula drained. Deep channels were scoured through the lava formations of eastern Washington, creating the Scablands. Water and sediments flooded into the tributary valleys of the middle and lower Columbia, modifying the river landscape (Allen et al. 1986). Glacial Lake Bonneville (now the Great Salt Lake) of the Great Basin in Utah and Nevada also spilled into the Snake in at least one cataclysmic flood, leaving many islands in the river channel as the outwash was retarded by Hells Canyon. Subsequent floods have never overtopped these distinctive features of the Snake River that now compose the Deer Flats National Wildlife Refuge (Connor 1993). Hence, the entire Columbia basin reflects the legacy of glaciation, either by ice scour or proglacial flooding or both. Glacial modification of the landscape is superimposed on the much older legacy of volcanic ash and lava deposition, and mountain uplift mediated by collision of continental plates.

Great landscape and climatic complexity is reflected by 13 terrestrial ecoregion designations in the basin (Ricketts et al. 1999). The headwaters of the North Central Rockies Forests and South Central Rockies Forests ecoregions have diverse alpine plant assemblages and conifers dominated by subalpine fir, spruce, larch, Douglas fir, and lodgepole pine. The conifers extend onto the valley floors on the wetter sites or grade into dry savannah-steppe communities dominated by bunchgrasses, bitter- and sagebrush, and ponderosa pine. The rivers cut through the mountain ranges, with precipitous canyons and expansive alluvial floodplains arrayed like beads on a string. The floodplains have distinctive cottonwood, spruce, and willow riparia. The interior Columbia basin includes the sagebrush, juniper, and ponderosa steppe of eastern Oregon and the historically expansive intermountain grasslands, the Palouse Prairie of Idaho and eastern Washington (Daubenmire 1978). These correspond to the Snake/Columbia Shrub Steppe and the Palouse Grasslands ecoregions. The Palouse Prairie today is almost completely converted to dry-land grain farms.

The Snake River plain in Idaho also is classified as grass and sagebrush steppe, but much of it has been converted to row-crop agriculture (e.g., potatoes, sugar beets, onions) by virtue of massive irrigation diversions that substantially dewater the middle reaches of the river. A robust apple, cherry, grape (wine), and other fruit industry developed from irrigation projects in the mid-Columbia region. Huge Douglas fir and Sitka spruce of the temperate rain forest zone inhabit the Eastern Cascades Forests, Central and Southern Cascades Forests, Willamette Valley Forests, and Central Pacific Coastal Forests ecoregions. Timbering, agriculture, and urban and exurban expansion has substantially cleared and otherwise altered much of this landscape, particularly in the Willamette Valley.

Placer and tunnel mining for gold, silver, copper, and other metals, especially in the hard bedrocks of the Idaho batholith, produced the first wave of immigrants as the fur trade waned. Ranches, farms, the salmon fishing/canning industry, and associated infrastructure followed. Open-pit mining and aluminum production from imported ore, along with other heavy industries, came with hydropower development. Currently, land use in the Columbia is 50% forest/alpine, 34% scrub/grassland, 15% agriculture, and 2% urban.

The Rivers

The rivers of the basin may be grouped in relation to basin physiography. The Rocky Mountain tributaries include (1) the Flathead-Clark Fork and Kootenay rivers that flow from the Continental Divide ranges of Montana and British Columbia into the upper Columbia above Grand Coulee Dam (Lake Roosevelt), (2) the Spokane-St. Joe-Coeur d'Alene that flows from the Bitterroot Range into the mid-Columbia, and (3) the upper Snake, originating on the Continental Divide in Wyoming, plus the Payette, Boise, Weiser, Salmon, and Clearwater rivers that drain the Idaho batholith and feed the Snake. A suite of mid-Columbia tributaries, the Okanagan, Methow, Wenatchee, and Yakima, drain the east or leeward side of the Cascades, adding significant flow upstream of the Snake confluence. All of these rivers have some reaches of wooded floodplains between or upstream of steep and often quite long canyon sections. The Salmon River is notably constrained in canyons, including the "River-of-No-Return" stretch that stymied Lewis and Clark. The high desert steppe of the interior has a suite of similar rivers. The Owyhee River originates in northern ranges of the

Great Basin and flows north to the Snake through long canyons. The lowermost big tributary of the Snake, the Grande Ronde, drains the Blue Mountains, the largest interior range. Other high-desert tributaries flowing into the Columbia below the Snake confluence are the Umatilla, John Day, and Deschutes. The first two have long floodplain segments, whereas the Deschutes is more constrained by incision into ancient lava (basalt) flows. The Willamette is by far the largest of the lower Columbia tributaries in the temperate rain forest zone and has expansive floodplains throughout. The Cowlitz is one of several important lower-river tributaries and is noteworthy because it is recovering from severe sedimentation after the eruption of Mount St. Helens. Like the lower Snake, the main-stem Columbia River largely is incised throughout its course owing to the immense scouring of Lake Missoula and Bonneville flooding. Nonetheless, the river was predominately alluvial, with long segments of gravel-cobble floodplains, as in the Hanford Reach. But these ecologically important features are entirely inundated today. The John Day and Methow rivers are the only free-flowing rivers of any size on the mid- and lower Columbia and the Salmon is the only completely free-flowing tributary of any size in the Snake system.

A rich literature describes the ecology of the Columbia River, mainly as a result of intensive efforts in the last two decades to research and manage declining salmon runs. The Federal Northwest Power Planning Act of 1986 mandated funds for fisheries and wildlife management and restoration from hydropower revenue as mitigation for lost habitat associated with the construction and operation of the many dams and reservoirs in the basin. The Web site of the Northwest Power Planning Council (<http://www.nwppc.org>) and an associated database system called STREAMNET (<http://205.230.28.30/>) provide subbasin management plans, river and fisheries statistics, literature citations, and links to other agency and commerce information. A recent review of river ecology (Williams 2005) done in context of the council's recovery goals is a detailed and indispensable reference.

The waters of the Columbia are generally rich in ions owing to the wide array of rock and soil types in the basin and copious irrigation return. Headwaters of the granite batholith (Bitterroot Range) and the argillites (Rocky Mountains in Glacier National Park) are the most dilute. Organic matter is rapidly transported through the canyon reaches (Minshall et al. 1992), underscoring the importance of produc-

tion and retention of organic matter in the floodplain segments. Many streams and river reaches of the basin are impaired from mining (cf. Beckwith 2002) and agriculture pollution, based on listings per the Federal Clean Water Act by the basin states and ongoing superfund restorations (e.g., Clark Fork and Coeur d'Alene rivers, Hanford site). Lower reaches of some mid-Columbia tributaries (e.g., Yakima) and the lower Snake River in late summer approach temperatures that are lethal to salmonid fishes, owing to irrigation diversions that reduce flow and limit flux of water through floodplain aquifers and impoundment by hydroelectric dams.

Food webs in the free-flowing rivers are species rich and productive, most often dominated by hypsychid caddisflies and midges, as will be described later for the Flathead and Yakima rivers. Of course, the trophic ecology of the impounded reaches is dramatically changed, as will be described later for the main-stem Columbia. Historically, the river system contained abundant beds of freshwater clams (*Margaritifera* spp.) that were intensely harvested by native people, especially during times of reduced salmon runs related to climate variation (Chatters et al. 1995). The floodplain backwaters also were filled with beds of arrowroot or wapato, with tuberous roots that were a preferred food of the Indians and also sustained the Lewis and Clark party at times.

The Columbia River system historically was a natural salmon factory. Over 200 different runs or stocks of four species of Pacific salmon spawned abundantly in the river system: chinook, sockeye, chum, and coho. Multiple runs of steelhead (anadromous rainbow or redband trout) also routinely made their way deep into the basin. Stock diversity apparently was driven by local adaptation to the widely varying riverine habitat conditions of the basin. Each stock had fidelity to particular rivers and in some cases even particular segments of rivers. The floodplains likely were especially important as rearing habitat. The total numbers are unknown but may have approached 20 million fishes per year. Fertility of the river therefore may have been substantially driven by the marine subsidy provided by the biomass of decomposing salmon that died every year after spawning (Cederholm et al. 1999; Schindler et al. 2003).

Other anadromous species of cultural importance were sturgeon that reached 3 m or more in length (500 kg) and dense runs of eulachon so rich in oil they burned like candles. Coastal cutthroat trout likely were locally abundant. In all there were 65 native species in the ichthyofauna of the river system,

including three lamprey species (Ward and Ward 2004, Wydoski and Whitney 2003). Sculpin were notably diverse, with at least 13 species. The anadromous species ascended the entire main-stem Columbia but were stopped by falls on the Clark Fork below Pend Oreille Lake and by the Shoshone Falls on the Snake. Above the natural barriers the fish fauna was more limited but notably included three subspecies of cutthroat trout and bull charr. The zoogeography of Columbia River ichthyofauna clearly is related to Quaternary population radiation and subsequent isolation by the barrier falls (McPhail and Lindsey 1986), but the details are clouded by the unfortunate legacy of overfishing of many stocks and fish introductions dating to the 1880s.

At least 53 nonnative fishes have become well established in the Columbia system (Ward and Ward 2004, Wydoski and Whitney 2003). Notably robust throughout the basin are brook and lake trout, smallmouth bass, and walleye. One of the most abundant anadromous runs of the lower river is American shad. Atlantic salmon, escapees from farming operations in coastal net pens, are now routinely recorded migrating upstream, perhaps to spar with native salmon for the limited spawning habitat. Further complicating matters, the dams are migration barriers for some species but not for others. For example, formally anadromous sturgeon populations are trapped between dams on the Snake and Kootenay rivers and remaining anadromous runs cannot ascend salmon ladders at Bonneville Dam. The reservoirs promote nonnative dominance of food webs and function as predator gauntlets for outmigrating juvenile wild salmon.

The first dams of the Columbia basin were small irrigation or mining diversions; then came the big hydropower projects that eventually harnessed the river system completely. Today more than 400 dams exist in the basin, ranging from behemoth structures that store massive amounts of water to run-of-the-river structures on the main stem and small diversion dams for abstraction of irrigation water. Every major tributary of the Columbia except the Salmon is totally or partially regulated by dams and diversions to support hydropower and irrigation. The total water storage in the Columbia River system is 67.8 billion m³, of which 51.8 billion m³ are available for coordinated operation (FCRPS 2001). These dams have an installed electrical generation capacity of about 37,000 megawatts. The river system irrigates nearly 2 million ha of fruit, vegetables, hops, and hay and transports 1.2 million metric tons of grain and other commerce annually.

The development of the Columbia as an organic machine was coherent with the demise of the salmon runs, caused by overfishing and habitat loss associated with impoundment and water diversion for irrigation. Ladders for salmon passage were installed on the lower river dams, but migration was permanently blocked first at Grand Coulee and later at Chief Joseph dams on the Columbia and at Hells Canyon Dam on the Snake. The most productive floodplains of the river system are either flooded by hydropower dams or dewatered by irrigation diversions. Today, the only stable run of wild salmon left is the fall chinook stock that returns to the Hanford Reach. Some wild spring chinook and steelhead still return to some of the tributaries but are listed as threatened or endangered. Restoration of the fisheries so far has not been very successful, even with 98 salmon and steelhead hatcheries operating in the basin, expensive fish screens on almost all irrigation diversions, and sophisticated adult and juvenile bypass systems on the dams. Too little quality habitat remains to sustain wild runs, even though egg to adult survival of individual wild fishes is much higher than for hatchery fishes. Returns of hatchery fishes have increased in years of favorable ocean conditions, but by any measure the return on investment in fisheries restoration has been dismal indeed. Recovery, even of a few stocks of the once huge and diverse Columbia salmon fisheries, requires a new management paradigm. Specifically, management must focus on harvest control and habitat restoration, mainly through major changes in dam operations or dam removal, as opposed to hatchery operations (Williams 2005).

Abell et al. (2000) divide the Columbia River basin into three freshwater ecoregions, based primarily on fish distributions, for conservation purposes. The Columbia Glaciated ecoregion was glaciated during the Pleistocene and includes the northern part of the basin that is mountainous and heavily forested. The Columbia Unglaciated ecoregion was never glaciated and includes the lower Columbia main stem and most of the tributaries to the south (except the upper Snake) and is considered continentally outstanding in its biological distinctiveness. The Upper Snake ecoregion, in the southeastern corner of the basin upstream of Shoshone Falls, contains native fish species found nowhere else in the Columbia basin. All three ecoregions are considered endangered by Abell et al. (2000), primarily as a result of dams, diversions, introduction of nonnative fish species, and damage to riparian zones and floodplains.

FIGURE 13.3 Flathead River near Bad Rock Canyon, Montana (PHOTO BY C. E. CUSHING).

FLATHEAD RIVER

The Flathead River originates in the Waterton-Glacier International Peace Park of southern British Columbia and northern Montana and the massive mountain ranges of the Great Bear–Scapegoat–Bob Marshall Wilderness complex that straddle the Continental Divide of the Rocky Mountains (Fig. 13.15). The basin is 22,241 km², with 2300 km² in British Columbia, based on data from the Flathead Lake Biological Station derived from recent remote imagery. Headwater streams fed largely by snowmelt emerge from the talus slopes in the alpine and cascade off the flanks of the mountains, coalescing in the glaciated mountain valleys to form three forks of the Flathead River and the Swan River. These tributaries are characterized by expansive alluvial floodplains that are variously constrained within glacially sculptured mountain valleys. The floodplains occur longitudinally like beads on a string separated by startlingly steep and deep canyons (Fig. 13.3). Periodically, very deep glacial lakes, rather than floodplains, retard the river flow, sparkling like deep blue

jewels in photos from spacecraft. The biggest jewel is 480 km² Flathead Lake, where all the waters of the Flathead commingle. From the big lake, the Flathead River courses through the intermountain prairie of the Mission Valley, picking up a bit more flow from the Little Bitterroot and Jocko rivers. Confluence with the Clark Fork of the Columbia is near Paradise, Montana, 285 km downstream from the source at Triple Divide Peak.

The Flathead basin is part of the original homeland of the Kootenai (Kootenay in Canada) and Salish Indians (Fahey 1974). These Native Americans hunted elk and deer in river floodplains and uplands, caught huge bull trout and abundant cutthroat trout and other fishes from the streams and lakes, and harvested edible plants, such as bitterroot and balsam root, that grew profusely on the intermountain prairies. They regularly crossed the Continental Divide via the Middle Fork of the Flathead on well-worn trails to hunt the abundant bison of the Great Plains and raid the Piegan Blackfeet Indians. The Blackfeet, just as regularly and reputedly more viciously, returned the favor.

In early March 1812, the Canadian geographer and explorer David Thompson stood on a ridge between the lower Flathead and the Clark Fork. He was the first nonnative to view and record the expansive landscape of Flathead Lake and its valley (Nisbet 1994). Canadian fur trappers and merchants working with Thompson established trading posts, first on the Clark Fork and later in the Flathead. By the 1880s the vast forests and valleys of the Flathead were penetrated by the Great Northern and other railroads and the Salish and Kootenai were confined to the Flathead Indian reservation that today encompasses the south half of Flathead Lake and lands extending south to the Clark Fork. The rails brought many white settlers into the Flathead. Soon steamboats plied Flathead Lake and the upper river, linking southern rail routes to the main High Line that followed the old Indian trail on the Middle Fork through the Rockies to Kalispell and onward west to Seattle. The Flathead reservation was opened to non-Indian settlement and the federal government built an irrigation system that insured long-term commingling of native and nonnative people.

Physiography, Climate, and Land Use

The mountain ranges of the basin all are part of the Northern Rocky Mountains (NR) and Rocky Mountains in Canada (RM) physiographic provinces (see Fig. 13.15) (Hunt 1974). In this area these mountains notably feature Precambrian Belt Series argillites (metamorphosed mud and silt stones) and dolomites uplifted 3500 m asl on the highest peaks in Glacier National Park. These ancient argillites contain stromatolites, fossil algae, among the oldest on Earth. The Lewis Overthrust is the predominant geologic feature and reflects the gradual movement of the Precambrian formations on the west side of the Continental Divide overtopping Mesozoic shales and limestones on the east (Ross and Rezak 1959).

Basin physiography is dominated by the effects of Quaternary glaciation, as mountain glaciers flowed down all of the major tributaries to confluence with the massive lobe of the continental glacier that flowed south from Canada in the Rocky Mountain Trench. The terminal moraines of this huge valley glacier lay south of Flathead Lake. It was a primary source of ice and water that contributed to the ice-dammed Lake Missoula, whose cataclysmic floods created the Scablands of Washington and flooded the Willamette, Yakima, and other tributary valleys of the lower Columbia. The mountain glaciers originating in high-

elevation cirques scoured expansive U-shaped valleys, some with deep lakes.

Flathead Lake is of tectonic origin but modified by glacial scour. The outlet cuts through the terminal moraine to a bedrock sill at the town of Polson. The Mission Valley south of the lake is dotted with kettle lakes in the intermountain prairie landscape that formed as various glacial advances melted away. Today, few active glaciers are left in the basin and those have rapidly melted in the last decade (Hall and Fagre 2003).

The climate most of the time is of Pacific maritime origin, with weather fronts primarily from the southwest. However, sometimes the continental air masses from the northeast spill over the Continental Divide, creating extended very cold and dry periods. Precipitation varies with elevation: <50 cm/yr in the dry valleys to as much as 250 cm/yr in the mountains (Finklin 1986). Because of this great variation, mean monthly precipitation collected at a low elevation (Fig. 13.16) underestimates the basin average. Although precipitation is not highly seasonal, much of it accumulates in the snowpack during the winter months. Winter temperatures in the valleys average near freezing, with rare periods of -20°C and much colder in the mountains, especially toward the Continental Divide, where high winds also may occur. Summers are generally cool but with periods reaching 35°C , even in the mountains.

Valley bottom and lowland mountain forests are predominately ponderosa pine steppe or expansive lodgepole pine stands. Stands of quaking aspen exist in wetter areas or, if the site is very wet, white or water birch may be mixed into the conifer forest. Large expanses of the Mission and Kalispell valleys, located south and north of the big lake (see Fig. 13.15), historically were intermountain prairies dominated by bunchgrass (Montana Valley and Foothills Grasslands terrestrial ecoregion). The upland forests are Douglas fir and larch on the mountain flanks, with occasional stands of lodgepole pine on dry sites and white pine and western red cedar in mesic microclimates of narrow mountain valleys. Spruce are present in wet sites at all elevations. Subalpine fir and subalpine larch and stands of whitebark pine occur on the ridge tops to the timber line. This complex forest landscape, classified as the North Central Rockies Forests ecoregion, historically was maintained by succession in a mosaic of ages mediated by frequent late-summer fires. Forbe diversity is high in the extensive alpine areas.

About 80% of the basin is forested or alpine. Glacier National Park and the wilderness complex

encompass 42% of the basin. The forested areas of the basin not included in the park or wilderness are intensively managed for timber products. Most of the ponderosa steppe and grasslands of the Kalispell and Mission valleys north and south of Flathead Lake were converted to agriculture by 1950. Dry-land cereal grains are very productive on thick loam soils of the upland benches. Crops irrigated from the alluvial aquifer of the Kalispell Valley and via the Flathead Irrigation Project in the Mission Valley include potatoes, mint, and alfalfa. Cattle production is important as well, from rangeland and irrigated pastures and some feedlot and dairy operations. The massive volume of Flathead Lake moderates winter and summer temperatures, especially along the east shore, allowing the production of cherries and some apples. Agriculture and rangeland is about 18% of the basin area. From the mid 1980s through the early part of the twenty-first century, farm and ranch land was gradually subsumed by exurban development associated with increasing economic emphasis on tourism and footloose business. Basin population currently is estimated at ~100,000, but almost all of these people live in the Kalispell and Mission valleys.

River Geomorphology, Hydrology, and Chemistry

The expansive floodplains of the alluvial valleys dominate the river landscapes. Notice the wide valley form of the North and South forks and the Swan River on the Flathead map (see Fig. 13.15). These valley bottoms were initially formed by glaciation and then modified by the recent legacy of flooding and plant succession. The Middle Fork is more constrained in canyon segments. An 80 km floodplain segment on the South Fork is inundated by Hungry Horse Reservoir.

The floodplains of the Flathead rivers are composed of deep deposits of fluvially sorted sand, gravel, and rock. These coarse bed sediments transmit large volumes of river water through alluvial aquifers. Groundwater and surface water exchange is a dominant process that interacts with flood-mediated scour and deposition, plant succession, and channel avulsion to produce the shifting habitat mosaic of these floodplains.

Spring snowmelt hydrographs characterize the rivers (see Fig. 13.16). Flow may change two orders of magnitude as it rises from winter minimum to the peak of spring freshet. Rainfall on snow can vastly accelerate the meltwater flow. The flood of record

occurred in early June 1964 when a very wet maritime front collided with continental cold air, causing intense, sustained rainfall on the remaining snowpack at the higher elevations across the basin. The three forks of the Flathead each were carrying more than 2700 m³/s (compared to usual base flow of 30 to 50 m³/s and the mean annual flow of 340 m³/s). In spite of large retention of South Fork water in Hungry Horse Reservoir, floodwaters extended 3 km beyond the active floodplain in the Kalispell Valley. Erosion and deposition radically altered the stream and river corridors. Course sediment layers in cores taken from the Flathead Lake bed suggest such floods occur on less than 50 year return intervals.

Hydrology of the basin, especially late-summer base flow, may have been significantly influenced by melting glaciers until recent decades, but this has not been quantified. Hungry Horse Dam on the South Fork and Kerr Dam at the outlet of Flathead Lake alter the natural hydrographs of the main-stem river, the lake, and the lower river, tending to smooth out the monthly hydrograph compared to free-flowing rivers (see Fig. 13.16). Wave erosion associated with Kerr Dam holding the lake some 3 m above its natural base level has reconfigured much of the shoreline, especially the Flathead River delta area at the north end of the lake.

Because much of the Flathead basin bedrocks are geologically very old and therefore well leached, the streams and lakes of Glacier National Park are characterized by very low ion concentrations (conductivity <10 μS/cm) and aquatic productivity is ultralimited by a paucity of plant-available phosphorus (usually below detection of 0.5 μg/L). Some high-elevation lakes have nearly the same chemical characteristics as precipitation and therefore are slightly acidic, with very little calcium carbonate buffer capacity (Ellis et al. 2003). Acid rain, which is not occurring, would be very harmful to these waters. The headwaters of the Middle and South forks are beyond the Lewis Overthrust and cut through massive headwall-type outcrops of Mesozoic limestone, some extending for over 50 km. Glaciers carried tills from these limestone areas downstream. Hence, lowland waters of the basin are well buffered, although nutrient concentrations remain naturally low and Flathead Lake is oligotrophic (Ellis and Stanford 2001).

River Biodiversity and Ecology

The Flathead River is part of the Columbia Glaciated freshwater ecoregion (Abell et al. 2000). River and

lake ecological studies are very diverse and detailed, encompassing faunal and floral studies and ecosystem processes. A literature archive is available at the Flathead Lake Biological Station (<http://www.umt.edu/flbs>).

Algae, Cyanobacteria, and Protists

Owing to the shifting cobble bottoms and generally very low nutrient loads, periphyton of the rivers is mainly diatoms, dominated by *Achnanthes minutissima*, *Gomphonema olivaceoides*, and *Cymbella minuta*, indicators of well-oxygenated, clean water. *Ulothrix zonata* and *Hydrurus foetidus* are the common attached filamentous algae. In floodplain spring brooks, large patches of *Enteromorpha* sp. and *Nitzschia* spp., indicators of naturally high nitrogen concentrations, often occur at the spring heads. Ellis et al. (1998) described a rich assemblage of bacteria and protists in the alluvial aquifers. Stanford and Prescott (1988) described a rare, perhaps endemic alga (*Cladophora gyrfaconium*) that formed a furry covering in the littoral zone of a remote, high-altitude lake in Glacier National Park. The macroalgae *Chara* spp. commonly occurs in floodplain ponds and shallow lakes if alkalinity is fairly high. Heavy growths of *Cladophora glomerata* and *Vaucheria* sp. characterize artificially enriched areas of the river.

Over 300 species and varieties of diatoms and other algae have been identified in the phytoplankton of Flathead Lake. *Rhizosolenia eriensis*, *Cyclotella* spp., *Stephanodiscus* spp., *Coscinodiscus* spp., *Tabellaria fenestrata*, *Dinobryon divergens*, *D. bavaricum*, *D. cylindricum*, *Cryptomonas erosa*, *C. ovata*, *Asterionella formosa*, and *Gymnodinium* spp., in that order, dominate biomass. However, over 90% of the productivity in the water column is from phytoplankton less than 10 µm in size. The pollution alga *Anabaena flos aqua* has produced weak blooms in the lake along with the green alga *Botryococcus* sp. in some years, suggesting gradual eutrophication. This trend is corroborated by gradually increasing phytoplankton productivity measured by carbon uptake over 30 years since the mid 1970s (Stanford and Ellis 2002).

Plants

Aquatic vascular plants are not usually present in the benthos of the rivers, but many species of pondweed, hornwort, watermilfoil, waterweed, cattail, pondlily, and duckweed and a wide variety of rushes and sedges grow in the floodplain wetlands and shallow lakes. The endangered water howellia occurs in a few oxbows of the Swan River.

Gallery forests of black cottonwood and spruce intermixed with willow and alder dominate the floodplains of the river corridors. These floodplains are hot spots of plant richness and Mouw and Alaback (2003) showed 64% of the basin's vascular flora occurred on the Nyack Flood Plain of the Middle Fork.

Invertebrates

The benthic invertebrates of the Flathead rivers have been intensively studied throughout the river corridor. Over 500 species have been recorded and species are arrayed in relation to annual patterns of water temperature from the valley bottoms upstream to the alpine (e.g., Hauer et al. 2000). The fauna is dominated by insects and is notably species rich among caddisfly, stonefly, and mayfly species. Indeed, 82% of the stonefly species reported for the entire Rocky Mountains from the Yukon to New Mexico are documented in the Flathead basin. Forty-two species coexist in the Flathead River in the Kalispell Valley and emerge sequentially from January to October. Seven species are amphibitic, that is, the larvae inhabit the alluvial aquifers, coming to the surface only to emerge as flying adults that mate and lay eggs in the river. Some of the more abundant stonefly species are *Utacapnia* (four species), *Capnia confusa*, *Isocapnia missouri*, *Pteronarcella badia*, *Isoperla fulva*, *Suwallia pallidula*, and *Claassenia sabulosa*.

A rich Crustacean stygofauna also is present in the alluvial aquifers, including the amphipod *Stygobromus* spp., various Bathynellidae, and Copepoda (Stanford et al. 1994). Net-spinning caddisflies (e.g., *Arctopsyche grandis*, *Parapsyche elsis*, *Hydropsyche* [3 species], *Cheumatopsyche campyla*) often dominate benthic biomass in the rivers, but *Brachycentrus americanus*, *Dicosmoecus gilvipes*, and *Glossosoma alesence*, among over 40 other species of caddisflies, often are notably abundant. Side channels and gravel-bar ponds often have an abundance of larvae of the limnephilid *Psychoglypha subborealis* and nymphs of the mayfly *Siphonurus* spp. Mayflies, although not often dominant in biomass, are numerically abundant and species rich in western Montana streams and lakes. Mayflies can be found in all but the most severely polluted environments. The mayfly fauna of western Montana has not been completely cataloged, but records indicate that over 110 species have been collected in Montana. Some of the most commonly occurring lotic taxa are *Ameletus* spp., *Baetis* (>4 species), *Caudatella* (2 spp.), *Cinygmula*, *Diphetera*, *Drunella* (5 spp.), *Epeorus* (4 spp.),

Ephemerella (2 spp.), *Paraleptophlebia* (2 spp.), *Rhithrogena* (3 spp.), and *Serratella*. Some common lentic genera are *Caenis*, *Callibaetis*, *Ephemera*, and *Hexagenia*. Several mayfly taxa are occasionally found in great numbers as occasional hyporheos near the river banks (up to 100 m from the river channel), including *Ameletus* (2 spp.), *Paraleptophlebia* (2 spp.), and *Siphonurus* (2 spp.). A wide variety of chironomid midges, black flies, and other true flies, such as *Hexatoma* and *Atherix variegata*, are usually present in river benthos samples.

Mollusks are not usually present in benthos samples today. However, large freshwater clams, western pearlshell (Newell 2003, Smith 2001), were routinely collected by Salish people until after 1900, but only a few beds are known today, and all are in the lower river tributaries below Flathead Lake. The signal crayfish is native below Flathead Lake, and the virile crayfish was introduced sometime around the 1960s and is now abundant in Flathead Lake and likely moving upstream.

Vertebrates

Fishes are perhaps the least species-rich group of aquatic animals in the Flathead, with only 12 native species: bull and westslope cutthroat trout, largescale and longnose sucker, Rocky Mountain and pigmy whitefishes, peamouth minnow, longnose dace, northern pikeminnow, redbreast shiner, and slimy and shorthead sculpin. At least 17 nonnative species are naturally reproducing in the basin and some of these, notably lake, brook, and rainbow trout, are rapidly expanding their range upstream and attendant hybridization, competition, predation, and food web cascades are problematic for native species. Bull trout are listed as threatened and considerable concern exists for cutthroats. Native assemblages of fishes are largely intact only in one subbasin in Glacier National Park owing to no stocking and presence of a natural barrier falls that prevents immigration of nonnative fishes and other biota. Natives also are intact in the entire South Fork drainage above Hungry Horse Dam, except for some introgression of the cutthroats by a very few introduced rainbows.

The northern leopard frog historically was widely reported from the valley bottom wetlands of the Flathead, but for unknown reasons today is rarely observed in many of the previously reported habitats. The floodplains harbor western toads in large numbers; tadpoles sometimes number in the thousands within small scour pools. Mass migration of juvenile toads from the floodplains toward the uplands occurs annually. The spring brooks are pop-

ulated by the Columbia spotted frog and the tailed frog is commonly found in fishless, high-gradient headwater streams. The long-toed salamander is common in fishless lakes and streams (Maxell et al. 2003). One specimen was pumped from the Kalispell alluvial aquifer. All of these species are declining throughout their ranges, probably due to loss of floodplain and wetland habitat. In contrast, the common garter snake is abundant in all aquatic habitats. A notable nonnative species is the snapping turtle, although only a few confirmed reports exist.

Semiaquatic vertebrates living in the river floodplains or along stream corridors are river otter, mink, muskrat, beaver, bald eagle, osprey, water ouzel (American dipper), harlequin and other ducks and mergansers, and Canada geese. Elk, moose, and white-tail and mule deer require the thermal cover and browse of riparian vegetation in the floodplains during winter, and cottonwood gallery forests are primary birthing and nursery sites for elk and white-tail deer.

Ecosystem Processes

In addition to climate, including temperature as the master variable (Hall et al. 1992, Ward and Stanford 1982) and the zoogeographic setting of the basin, four primary natural processes interact to control biodiversity and bioproduction of the Flathead rivers. The first is fire from lightning strikes in late summer. Fires periodically reset successional trajectories of basin vegetation, thereby naturally altering water and nutrient flux and storage in the uplands and sometimes even within riparian forests. In 1988, 2002, and 2003, wildfires burned over 200,000 ha of the landscape in Glacier National Park and adjacent wilderness areas. These fires were predominately allowed to burn uncontrolled and reset most of the senescent stands of lodgepole pine. In places they even burned across floodplains. The result was a renewed landscape mosaic, a key natural process of Rocky Mountain ecosystems. Second, cut-and-fill alluviation mediated by flooding constantly is resetting the habitat mosaic of the floodplains. Third, flux and transformation of carbon, nitrogen, and phosphorus ultimately determines productivity. Finally, herbivory, predation, burrowing, and other disturbances by animals modulate the other three processes.

These linked processes play out on a river-lake ecosystem stage. Water and nutrient inputs control productivity of the valley bottom lakes and adfluvial (grow to maturity in the lake, reproduce in the tributaries) fishes, and other vertebrates carry lake

nutrients back upstream. The lakebed sediments and the floodplains function as materials and energy sinks, or storehouses. Hyporheic exchange of river water with the alluvial aquifers of the floodplains is a primary process controlling productivity and diversity of the riverine landscape. The wide riparian corridor is a dynamic ecotone that strongly influences distribution and abundance of nearly all native biota of the basin (Stanford and Ellis 2002).

Primary production in Flathead Lake is low (average $95 \text{ g C m}^{-2} \text{ yr}^{-1}$ over 30 years), owing to the natural oligotrophic condition, but has increased 30% since 1977 (Stanford and Ellis 2002). Bioavailable phosphorus concentrations in the lake and rivers usually are not detectable ($<1 \text{ } \mu\text{g/L}$) and primary production usually is colimited by paucity of labile nitrogen and phosphorus. Dissolved organic matter concentrations usually are below 1 mg/L in surface and ground waters. Benthic production measured by diel measures of community metabolism in the rivers varies but also is low ($133 \text{ to } 1063 \text{ mg C m}^{-2} \text{ d}^{-1}$; Stanford and Ward 1983). More recent measures of chlorophyll in river biofilms over a wide range of habitat types was 50.6 mg/m^2 (M. Anderson, unpublished data).

Natural river food webs in the Flathead generally are based on primary production from diatom-dominated biofilms, often enhanced locally by nutrient subsidy from upwelling groundwater from the alluvial aquifers, and on inputs of leaves from the floodplain forests. The species-rich invertebrate assemblage has representatives of all the trophic guilds (e.g., scrapers, collectors, shredders, predators), which, along with inputs of terrestrial invertebrates, support juvenile fishes of all species and adults of mountain whitefish and cutthroat trout. Flathead sculpins, in spite of their small size, and the much larger pikeminnows and bull charrs are voracious predators of the other fishes. Ospreys, bald eagles, mink, and river otters are the natural top carnivores, although grizzly bears occasionally feed on spawning cutthroat trout.

Human Impacts and Special Features

The most significant aquatic features of the Flathead rivers are the big valley bottom lakes and expansive floodplains. Ecology of the rivers, and perhaps also the big lakes, is controlled or vastly influenced by floodplain processes, including natural water storage and flow regulation, nutrient transformation and storage, and species packing associated with the shifting habitat mosaic produced by interactive flooding,

cut-and-fill alluviation, and riparian plant succession. The floodplains and glacial lakes are the jewels in the Crown of the Continent landscape of Glacier National Park and the adjacent wilderness areas. Water quality throughout the basin remains near likely historic levels and Flathead Lake remains one of the cleanest big lakes in the temperate areas of the world (Stanford and Ellis 2002).

Therefore, the main environmental concern is maintaining high water quality by minimizing increasing nitrogen and phosphorus loads from human sources, including atmospheric fallout and steadily increasing urban and exurban land conversion upstream of Flathead Lake. Some years 30% or more of the bioavailable nutrients reaching Flathead Lake come as dry and wet deposition on the lake surface. Smoke and fugitive road dust are the main sources. Historically, forest fires occurred only in late summer, but slash burning in harvest zones of the basin in winter and spring and home heating coupled with increasing vehicle use fills the valleys with smoke during inversions year-round. Unit area fallout is three times higher at Flathead Lake than in the mountains. The human population of the main valleys more than doubled in the last two decades and land conversion from forest or grassland occurred commensurately. Sewage treatment plants are state-of-the-art for the urban areas owing to documentation of water-quality decline associated with urban and exurban expansion. Of course, the largest input to the lake is natural catchment runoff in the nondeveloped areas of the basin. Seventy-five percent of the total N and P load reaching Flathead Lake occurs during the May to June spring freshet, and it settles rapidly to the lake bottom in association with fine sediments. By summer labile N and P are not detectable in the photic zone of the lake because uptake by the algae has exceeded supply. Nonetheless, primary production in the lake has steadily increased over the last three decades in relation to increasing inputs from human sources, based upon the continuous measures made at the Flathead Lake Biological Station. The problem likely would be much greater if most of the basin were not congressionally designated park or wilderness areas. Indeed, 85% of the water entering Flathead Lake annually comes from the high-mountain portions of the catchment, which is mostly protected and essentially pristine (Stanford and Ellis 2002).

Some other aspects of water pollution detract from the generality of high-quality water in the Flathead. Mercury is biomagnified in the Flathead Lake food web, resulting in levels of concern in lake trout

tissues (Stafford et al. 2002). Sources are undocumented but could also involve aerosols from forest fires and slash burning. Nonpoint runoff produces cyanobacteria blooms in some lakes and reservoirs in the basin (e.g., Echo and Mary Ronan lakes, Crow Reservoir) and herbicides and pesticides are of localized concern (Beckwith 2002).

Hydroelectric production at the two big dams is done in ways that produce erratic and nonseasonal flows and lake levels that substantially compromise near-shore food-web structure and productivity and wash juvenile fishes out of nursery areas in the rivers (Stanford and Hauer 1992). Hungry Horse Dam on the South Fork was retrofitted in 1998 for multiple-level releases, allowing a normative temperature pattern downstream. Kerr Dam at the lake outlet always has been surface release and the historic temperature pattern of the lower Flathead River has changed little. Hence, temperature problems often associated with large storage dams in the western United States do not exist in the Flathead today.

Without question the introduction of nonnative biota is the most pervasive and persistent human impact. The historically very abundant cutthroat trout in the valley bottom lakes were compromised by introduction of kokanee salmon, which is a more efficient feeder on zooplankton, and by genetic introgression from planted rainbows that have persistently immigrated upstream. In a misguided effort to increase kokanee production in the valley bottom lakes, managers introduced *Mysis relicta*, a small shrimp that feeds on zooplankton at night and rests on the lake bottom during the day. The *Mysis* introduction backfired because kokanee and cutthroat feed only in daylight. Rapidly expanding *Mysis* populations destroyed robust kokanee fisheries in Flathead and other big lakes in a few years as the population of shrimp exploded to more than 130/m². Lake trout and lake whitefish stay in deep water and therefore immediately benefited from the mysids (the three species are native in Canadian Shield lakes). Native bull trout have declined concurrently with lake trout expansion (Stanford and Ellis 2002).

The floodplains of the Flathead are designated by conservation groups as “critical lands” because they are the primary protectorates of the native biota and clearly function as natural water-cleansing systems. However, protection is uncertain owing to management of flood threat in ways that are charitable to urban and exurban expansion and gravel mining. Protection of the river corridor in the valleys needs to be aggressively pursued along with control of

nutrient pollution if the Flathead is to remain one of the most pristine river-lake ecosystems in the world.

SNAKE/SALMON RIVER

The Snake River basin (~281,000 km²) represents almost 40% of the entire Columbia River basin area. It extends from the small subalpine lakes, meadows, and streams of the Yellowstone Plateau in north-west Wyoming to the arid lands of south-central Washington (Fig. 13.17). The river flows westward and then northward for over 1400 km before its confluence with the main-stem Columbia River. Along its path to the Columbia the Snake changes from a mountain stream as it departs Yellowstone National Park to a large impounded river with ocean shipping passing through locks on its way to and from Lewiston, Idaho.

The upper Snake contains the picturesque scenery of the Jackson Hole Valley and southern Yellowstone National Park and produces blue-ribbon fishing for native cutthroat trout in a few places. Likewise, the Salmon River, its largest tributary (by area), is famous for its wilderness beauty and wild salmon and steelhead fisheries (Fig. 13.4). Unfortunately, the once abundant wild chinook and sockeye salmon runs have declined to endangered status in the Snake basin and the contemporary steelhead runs are predominately hatchery stocks. The loss of wild stocks is due to a combination of habitat loss, river corridor discontinuities and blockages to migration by large dams, chronic overharvest, and supplementation by hatcheries.

The Snake and its tributary rivers possess a rich natural and cultural history. In 1805, the Lewis and Clark expedition crossed the Continental Divide at Lemhi Pass and descended to the Salmon River, where they were able to confirm their presence in the Columbia basin by the salmon spawning in the river. Along the Salmon, Clearwater, and lower Snake rivers, the “Corps of Discovery” encountered several Native American peoples with predominantly salmon-based economies, notably the Nez Perce and Walla Walla tribes.

Physiography, Climate, and Land Use

The upper Snake River begins in the Middle Rocky Mountain (MR) physiographic province of western Wyoming (see Fig. 13.17). This area has some of the most spectacular scenery in North America with many mountain ranges, broad intermontane valleys,

FIGURE 13.4 Salmon River below Redfish Creek, Idaho (PHOTO BY TIM PALMER).

and scenic lakes and rivers. Gannet Peak (4207 m), located on the Continental Divide in the northern Wind River Mountain Range in the Fitzpatrick and Bridger Wilderness Areas of west-central Wyoming, is the highest peak in the Snake River basin. The Snake River enters the Columbia–Snake River Plateaus (CU) province along the easternmost segment of the Snake River Plain, which extends in a crescent across southern Idaho (see Fig. 13.17). After winding through Hells Canyon on the Idaho–Oregon border the Snake River is joined first by the Salmon River draining the rugged Northern Rocky Mountains (NR) province of central Idaho from the southeast, then by the Grande Ronde River draining the Blue Mountain region of

the Columbia–Snake River Plateau from the west, and finally by the Clearwater River flowing from the Northern Rocky Mountains just north of the Salmon subbasin (Fig. 13.5). The remaining section of the lower Snake River flows through a portion of the Columbia–Snake River Plateau in southeastern Washington before joining the Columbia River.

The headwaters of the Snake River and much of the Salmon River drain the South Central Rockies terrestrial ecoregion (Ricketts et al. 1999). In this ecoregion the dominant vegetation type is coniferous forest, and the most common trees are Douglas fir, Englemann spruce, subalpine fir, and lodgepole pine. The Clearwater River drains the southern portion of

FIGURE 13.5 Snake River below confluence with Grande Ronde River, Washington (PHOTO BY C. E. CUSHING).

the adjoining North Central Rockies Forests ecoregion. Coniferous forest also characterizes this ecoregion, which also includes hemlocks, white spruce, alpine fir, and larch. The middle Snake River primarily flows through the Snake–Columbia Shrub Steppe ecoregion of the Columbia–Snake River Plateaus. The dominant vegetation here is sagebrush, with various wheatgrasses and bunchgrasses. As the Snake flows north into northeastern Oregon it enters the Blue Mountains Forests ecoregion, a relatively arid mountainous area characterized by sagebrush and various conifers, such as pinyon–juniper, and mountain grasslands. As the river leaves the Blue Moun-

tains it enters the Palouse Grasslands ecoregion, which has become an intensive agricultural region with only patches of natural grassland vegetation.

The climate of the Snake basin is variable owing to the rain shadow of the Cascades, which keeps the interior plain quite dry but increases precipitation in the mountains. Weather is mainly Pacific maritime, but cold, dry continental air masses occasionally predominate. Overall, annual precipitation is about 36 cm, with highest amounts occurring in the winter as snow (Fig. 13.18). Temperatures in Jackson Hole, Wyoming, near the headwaters, average between -9°C to 16°C over the year, with annual precipita-

tion averaging 41 cm. Downstream, the Snake River plain is cool and dry; temperatures average -2°C to 21°C over the year in Twin Falls, Idaho, and annual precipitation averages 25 cm. The Salmon River sub-basin of mountainous central Idaho is colder and wetter. The climate of the Salmon subbasin is typified at Galena, Idaho (elevation 2228 m asl), which has an annual mean temperature of 1.6°C , with average winter lows of -17°C and highs of 24°C in summer. Annual precipitation is 62.8 cm, with nearly 70% as snowfall from November through April. Further downstream at Lewiston, Idaho, temperature averages 11.1°C , typically ranging from 1°C to 21°C over the year, with annual precipitation of 32.5 cm.

Much of the mountain country of the Snake basin is designated wilderness: Sawtooth, Selway-Bitterroot, Frank Church, Gospel Hump, Hells Canyon, Teton, and Gros Ventre. Yet many of the valleys and hill slopes of the upper Snake/Salmon basin have a history of resource extraction, particularly timber harvest and mining on both private and public lands. The Snake River plain of southern Idaho is dominated by irrigated crop farming of potatoes, sugar beets, onions, cereal grains, and alfalfa. Approximately 10% to 15% of the Snake basin is forest/alpine, 50% scrub/rangeland, 30% agriculture, 4% barren, and 1% urban.

River Geomorphology, Hydrology, and Chemistry

The main-stem Snake River may be separated into three sections defined by geomorphic, hydrologic, and chemical characteristics: the headwaters (including the Palisades), the Snake River plain segment, and the lower river segment that extends upriver through Hells Canyon.

The headwaters section runs from Yellowstone National Park to the Snake River plain and includes the Henrys Fork draining the west slope of the Teton Range in Idaho. These rivers have a spring snowmelt hydrograph and bed sediments dominated by boulders, cobble, and well-sorted gravel. Confined reaches with gradients up to 10 to 50 m/km alternate with unconfined floodplain segments where the gradient is 1 to 5 m/km. River geomorphology is influenced by large wood eroded from hillslope and floodplain forests. Water chemistry of this section is characterized by high water clarity, particularly outside of the spring snowmelt discharge pulse. Mean conductivity ($268\ \mu\text{S}/\text{cm}$), pH (7.9), alkalinity ($75\ \text{mg}/\text{L}$ as CaCO_3), and hardness ($91\ \text{mg}/\text{L}$ as CaCO_3) are typical of waters draining the Yellow-

stone Plateau. There are two dams with storage reservoirs in the headwaters of the Snake River in Wyoming, the relatively small Grassy Reservoir and the larger Jackson Lake Dam at the outlet to Jackson Lake. Approximately 100 km downriver of Jackson Lake the Snake River enters eastern Idaho, where Palisades Dam impounds the river. This is the first of a series of storage reservoirs feeding an elaborate diversion and canal system that irrigates much of the Snake River plain.

The Snake River plain segment begins at the confluence of the Snake and Henrys Fork in eastern Idaho. Approximately 60 km downriver of this confluence the Snake is impounded by American Falls and then Minidoka dams, the two largest impoundments in this segment. Irrigation diversions along the Snake River plain nearly dewater the river in late summer of dry years. Flow stabilizes in the Deer Flats area (Swan Falls Dam to Hells Canyon) owing to inputs from the Thousand Springs, various small tributaries, and irrigation returns. Throughout Deer Flats the river is constrained and riparian vegetation is limited to a fringe of willows along the shoreline of the river and numerous islands formed by the proglacial Lake Bonneville flood. The snowmelt hydrograph characteristic of the headwaters apparently was substantially moderated in this segment by natural storage of runoff within the huge areas of basalt of the Snake River plain and its fringe areas. In spite of substantial irrigation influences, average conductivity ($336\ \mu\text{S}/\text{cm}$), pH (8.7), and alkalinity ($75\ \text{mg}/\text{L}$ as CaCO_3) values are lower than values at the upstream end of the segment, apparently due to ion retention in the reservoirs and limited dissolution from the basalt bedrock.

The lower section begins at the entrance to Hells Canyon. Hells Canyon is among the deepest river gorges on earth, as the river is 1600 to 2400 m below the canyon rim. Today, this magnificent canyon is impounded (Brownlee, Oxbow, and Hells Canyon dams) except for 60 km below Hells Canyon Dam. These dams, built between 1959 and 1967, are operated by Idaho Power Company and have a power generation nameplate capacity of 585 mW, 220 mW, and 450 mW, respectively. A short, constrained section below Hells Canyon Dam to the Salmon River is unimpounded, but the rest of the river is continually impounded to its confluence with the Columbia River by four dams: Lower Granite (1984), Little Goose (1970), Lower Monumental (1969), and Ice Harbor (1961). These are “run-of-the-river” hydroelectric and navigation dams and are equipped for fish passage.

Mean discharge of the Snake River below Ice Harbor Dam just before it enters the Columbia River is 1565 m³/s. The Clearwater (433 m³/s) and the Salmon (315 m³/s) rivers together contribute almost half of the total flow of the Snake. In spite of extensive regulation and diversions all along its path, the Snake still has a seasonal pattern in mean monthly discharge and runoff (see Fig. 13.18). Runoff is usually highest from April to June, largely the result of melting of the snowpack. Runoff declines in late summer as precipitation falls and continues low into the winter as precipitation is stored in the mountains as snow. The dams undoubtedly have played a major role in reducing the variation in high and low discharge since the 1960s. Runoff is a higher fraction of precipitation than one might expect in a relatively arid region, but much of the flow is due to the accumulation of snow collected in mountainous areas with greater precipitation than in the Columbia–Snake River Plateaus.

River Biodiversity and Ecology

The Snake River flows through two freshwater ecoregions (Abell et al. 2000). The Upper Snake ecoregion is primarily that portion of the Snake River upstream of 65 m high Shoshone Falls, near Twin Falls, Idaho (see Fig. 13.17). Shoshone Falls once represented the upstream range of anadromous salmon before construction of Hells Canyon Dam. The remainder of the Snake River basin, including the Salmon River, is located in the Columbia Unglaciaded ecoregion. Hauer et al. (2002) provide a comprehensive review of river ecology of the headwaters segment of the Snake, particularly as it relates to the legacy of flow regulation. The ecological characteristics of the Salmon River have been summarized by Minshall et al. (1992). A great deal of river and fisheries information and data collected by state, federal, and tribal agencies are available through STREAMNET (<http://205.230.28.30/>) and the Columbia Basin Fish and Wildlife Authority (www.cbfwa.org).

Algae, Cyanobacteria, and Protists

Minshall et al. (1992) reported attached algae, measured as chlorophyll, ranged from 21 to 179 mg/m² longitudinally on the Salmon River. The dominant species in the colder upper reaches were *Hydrurus*, *Gomphonema*, and *Ulothrix*. The filamentous green algae *Cladophora glomerata* occurred abundantly in association with warmer, shallow water and higher

nutrient concentrations. Data are lacking, but this description probably characterizes the river system in general.

Plants

In broad valleys with low gradients, fine sediments dominate streams and rivers of the Snake basin. Where the water table tends to remain relatively close to the surface throughout the summer these low-gradient floodplain reaches possess riparian vegetation composed largely of willows and sedge grasses. A good example of this can be seen along the Lemhi River in the Salmon drainage, where the stream often meanders between the stabilizing structure of mature willows. In contrast, on higher-gradient floodplains in reaches with high discharge and expansive gravel–cobble bed sediments, the water table is seasonally dynamic and the scoured broad river channel is inundated annually with the snowmelt. Here, the riparian vegetation is dominated by black cottonwood or narrow leaf cottonwood (Hauer et al. 2002). Excellent examples of this can be seen along the upper reaches of the Snake River, above and below Jackson Lake in Wyoming, along the upper Snake River in Idaho, and on the Salmon River in the floodplain reaches between Challis and Salmon, Idaho. In the many canyon reaches of the Snake and Salmon rivers only a narrow ribbon of willow and alder fringe the shoreline as a boundary between the river and Douglas fir forests in montane landscapes or Ponderosa pine along the steppe of the foothills.

Dams, diversions, and levee systems have had a profound effect on the natural vegetation along significant portions of the Snake River. For example, below Palisades Dam on the upper Snake, reduction in peak flows since the mid 1950s has reduced scour required for cottonwood regeneration. Although the historical gallery forest remains intact, a demographic shift toward old (>150 years) senescent trees has occurred (Merigliano 1996). Ute lady tresses, a white-flowered orchid, occurs in wetlands of abandoned channels in association with willows, spike-rushes, sedges, and horsetails (Moseley 1998). Even in the canyon-bound reaches, the effect of regulation is profound. For example, the island-based waterfowl nesting habitat of the Deer Flats National Wildlife Refuge are progressively connecting to the mainland by establishment of native and nonnative hydrophytes, particularly purple loosestrife, due to lack of flood scour and inundation (Johnson et al. 1995).

Invertebrates

The cold gravel and cobble-bed habitat of the unaltered reaches of the Snake system are ideal habitat for stoneflies (e.g., predatory *Claassenia sabulosa*, *Hesperoperla pacificum*, and detritivorous *Pteronarcys californica*), caddisflies (e.g., *Arctopsyche grandis*, *Hydropsyche cockerelli*, *Hydropsyche occidentalis*), and ephemereid, heptageniid, and drunellid mayflies that occur in species-rich assemblages (e.g., Clearwater River; Munn and Brusven 1991). Minshall et al. (1992) found macroinvertebrate density along the Salmon River from headwater reaches to the large main-stem river decreased in density from 2550 to 7525/m² at headwater sites in the Stanley subbasin and 400 to 3700/m² not far from the mouth. Shredders were prevalent in the headwater reaches where riparian vegetation is abundant relative to stream size, but were rare in the large canyon-bound segments downstream. The collector-gatherers were increasingly abundant, coherent with increasing size of the river.

On the upper Snake River, particularly the Henrys Fork and the South Fork of the Snake, abundant resident fisheries apparently are maintained by relatively high but unmeasured secondary production of benthic invertebrates. These reaches are particularly well known by fly fishers for their emergence of salmon flies (*Pteronarcys californica*), ephemereid mayflies (*Ephemerella inermis*), and several species of caddisflies (*Hydropsyche* spp.). However, production is compromised by flow regulation below the big dams (Munn and Brusven 1987, 1991). On the lower Snake River, where slackwater conditions predominate, the benthic invertebrates are dominated by chironomid midges.

Four snails (Bruneau Hot Springsnail, Utah valvata snail, Snake River physa, Bliss Rapids snail), listed as either rare or endangered, are found in near-shore habitat of the bedrock rapids of the Thousand Springs–Shoshone Falls area of the river, where flow regulation and water abstraction are problematic for their survival. Gravel bars in the Deer Flats segment are littered with native freshwater clam shells; however, status of the population is not documented (U.S. Fish and Wildlife Service, unpublished data).

Vertebrates

The Snake system once was a wild salmon factory, with robust runs of chinook, coho, chum, sockeye, and steelhead. Sockeye were able to travel over 1500 km up the Snake/Salmon to spawn and rear in small lakes of the Stanley subbasin. Today, only a few wild chinook

and steelhead stocks remain and those are limited by dams to the Grande Ronde, Salmon, and Clearwater rivers. The last runs, near extinction, are propped up by hatchery operations. Recovery plans suggest the lower Snake impoundments are particularly problematic for outmigrating salmon and steelhead because the reservoirs are too warm and full of predatory fishes, such as pikeminnow and nonnative smallmouth bass. Removal of these dams may be the only salvation for Snake River anadromous fisheries (Williams 2005).

Several important resident salmonids exist in the upper subbasins above the natural barriers to anadromous runs. Yellowstone cutthroat and Snake River finespotted cutthroat trout are sympatric (Behnke 2002) and remain in relatively high populations in portions of the Snake River above Shoshone Falls in Idaho and Wyoming. Cutthroats are locally migratory and probably require large reaches of floodplain rivers to be sustained. The future of cutthroats may depend upon on naturalization of flows in the upper subbasin, especially below Jackson Lake and Palisades Reservoir (Hauer et al. 2002).

Bull trout are an integral part of the fish communities of the Snake River and its tributaries below Shoshone Falls. Many populations are isolated by the discontinuities and barriers to movement associated with dams. For example, adfluvial bull trout achieve maturity in CJ Strike Reservoir, where the Bruneau River joins the Snake, and migrate into the smaller tributaries, such as the Jarbidge River, to spawn.

Native redband trout, closely related to steelhead and possibly a subspecies, historically existed throughout the Snake basin below Shoshone Falls, but pure populations are rare owing to extensive introduction of rainbow trout stocked from various hatcheries (Behnke 2002). Brown, brook, and lake trout, smallmouth bass, and many other nonnative fishes also have been introduced throughout the basin. The reported composition of fishery uses in the upper Snake River, based on creel census, was 68% naturally spawning cutthroat, 4% hatchery cutthroat, 9% brown trout, 2% spawning rainbow, 2% hatchery rainbow, 0.5% lake trout, and 14% whitefish (Moore 1980).

Huge-bodied sturgeon historically were found in the deep channels of the Snake downstream from Shoshone Falls. Populations continue to survive below Swan Falls Dam upstream of Deer Flats, in the deep channels of the Snake below Hells Canyon Dam, and in the lower Salmon and Clearwater rivers. However, these populations are no longer migratory due to dams and their inability to ascend the fish

ladders. Natural reproduction has been essentially eliminated by regulated flows; thus, they persist in the wild mainly owing to their longevity. Many individuals are well over 50 years old. The species now is commercially produced in springs and ponds in the area of Hagerman, Idaho (Williams 2005).

Montane riparian areas of the Snake and Salmon occupy a relatively small portion of the total landscape, yet they are naturally heterogeneous and function as centers of high diversity and abundance of birds. The Snake River corridor and riparian areas are well-known sites for raptor nesting. Nineteen raptorial species were documented within a study area along the Snake River in Idaho, and seven more were suspected as periodic residents (Whitfield et al. 1995). A study by Saab (1999) on the Snake River illustrated that the best predictors of high bird species richness were natural and heterogeneous landscapes, large cottonwood patches, close proximity to other cottonwood patches, and microhabitats with open canopies. The most frequent significant predictor of bird species occurrence was landscape coverage. Habitat use increased with natural upland landscapes and decreased with agriculture (Saab 1998). Both interior and edge specialists were found in linear cottonwood forests with large amounts of edge. Nest predators, brood parasites, and nonnative species correlated with human-altered landscapes.

Ecosystem Processes

Comprehensive studies of organic matter production and flux were conducted on the Salmon River (Minshall et al. 1983, Minshall et al. 1992). The riverine food web is complex and allocation of organic matter from riparian and instream sources varied longitudinally with river size and slope. Instream primary production, as opposed to inputs of riparian organic matter, was the source of the majority of organic matter production. However, the conduitlike nature of the canyon-bound river resulted in very little organic matter retention. The food web of the system was predominately driven by benthic feeding on attached algae or on ultrafine particles of organic matter transported by river flow. Inputs of leaves from riparian trees was greatest (340 to 420 g/m²) in headwater streams and generally decreased downstream (24 to 90 g/m²) and correlated with the increasing width of the river. However, Hauer et al. (2002) noted the likelihood of considerable variability associated with streamside vegetation, floodplain width, and other geomorphic characteristics.

Human Impacts and Special Features

The Snake River headwaters in Wyoming is the only section of this long river that is in relatively pristine condition, but it is far removed and isolated from the lower river by dams and natural barriers (e.g., Shoshone Falls). The free-flowing Salmon and Clearwater rivers (except the Clearwater's north fork), on the other hand, are premier white-water rivers, remain in relatively pristine condition, and have the highest potential for salvation of Snake River salmonid fisheries. The Salmon River is one of the longest free-flowing rivers in the lower 48 states, with a large section of the main stem and its Middle Fork designated as National Wild and Scenic Rivers. The Middle Fork of the Clearwater River, as well as two major tributaries (Lochsa and Selway rivers), are also Wild and Scenic Rivers. The Salmon drains the extremely rugged Frank Church River-of-No-Return Wilderness Area, and much of the Clearwater drainage is in the Selway-Bitterroot Wilderness Area.

No large municipalities exist in the upper Snake or Salmon river drainages, nor are there major industries with point sources of pollution. Nonetheless, isolated sites of pollution from mining and broad-scale impacts from cattle grazing and irrigation withdrawal and return flows are documented. Although the relatively pristine character of the Snake and Salmon headwaters are similar in origin and character, these rivers are dramatically different with respect to the dominant human impact of river regulation by large dams. The Snake River proper is regulated by dams and diversions almost immediately after its exit from Yellowstone National Park and sequentially all the way to the Columbia River. Hydrologic modification has reduced the ecological integrity of the river in various ways, most significantly by substantial reduction in riparian and river productivity across all trophic levels. Historically the Owyhee, Boise, and Payette rivers had major runs of salmon, as did the main-stem Snake all the way to Shoshone Falls. However, this highly productive salmon fishery has been completely lost due to dam construction in Hells Canyon.

The lower Snake, Lower Granite, Little Goose, Lower Monumental, and Ice Harbor dams and their associated reservoirs cause very high mortality of outmigrating anadromous salmon smolts from the Salmon and Clearwater rivers. In an effort to reduce mortality, for two decades the U.S. Army Corps of Engineers has captured many of the fish at Lower Granite dam, put them in special barges, and transported them downstream to Bonneville Dam, where

FIGURE 13.6 Yakima River in Yakima Canyon below Ellensburg, Washington (PHOTO BY TIM PALMER).

they are released to continue on to the ocean. Unfortunately, this massively expensive operation is of little or no avail to Snake River fisheries (Williams 2005).

YAKIMA RIVER

The Yakima is a 5th order river located in south-central Washington and has a drainage basin of 15,900 km². It flows 344 km from the very wet Cascade Range southeast into the very dry interior basin of the Columbia River and is located between latitude 46.1°N to 47.4°N and longitude 119.2°W to 121.3°W (Fig. 13.19). The river has steep headwater tributaries that feed three large glacial lakes. Downstream the river flows through broad valleys separated by canyons cut through lateral basalt (lava) formations (Fig. 13.6). The valleys have expansive alluvial floodplains with cottonwood gallery forests transitioning into prairie steppe on the uplands. The lower river flows through a long canyon segment to its confluence with the Columbia at Richland, Washington.

Native Americans in tribes and bands that later composed the Yakama Nation and others lived in these valleys in large villages owing to the natural goods and services provided by the river and its floodplains. Ross (1855) described herds of horses totaling several thousand along with several hundred tepees in the Kittatas Valley (Ellensburg area). The largest Indian village, estimated at around 3000 individuals, was located near the current city of Yakima, where a large river floodplain exists. The ethnographic and archaeological evidence indicates salmon, particularly chinook because of their ability to be cached, provided a large portion of the food and trade (Uebelacker 1986).

Missionaries arrived in 1848 and the Yakama Indian reservation was created in 1855 to make farmers out of the Indians. White and Hispanic immigrants settled throughout the valleys and increasingly abstracted flow for irrigation of crops. By 1902, 121,000 acres of reservation and other lands were irrigated and diversions dewatered the river on dry years. Thus, in 1905, a huge federal water storage and irrigation canal project was initiated that today drives a robust agricultural economy. As throughout

the Columbia basin, these cultural changes have resulted in water pollution and vastly reduced salmon production.

Physiography, Climate, and Land Use

The western part of the Yakima basin in the Cascade–Sierra Mountain (CS) physiographic province drains the eastern Cascade Mountains, which are uplifted Eocene sandstone, shale, and some coal layers, with pre-Miocene volcanic, intrusive, and metamorphic formations (see Fig. 13.19). This part of the basin intersects with the Walla Walla Plateau section of the Columbia–Snake River Plateaus (CU) physiographic province and is characterized by numerous Tertiary lava flows over continental formations. In the Yakima basin, the Plateau deformed into a series of southeast-trending anticlinal ridges and synclinal valleys through which the Yakima River down-cut, creating the upper Yakima Canyon, Selah and Union gaps, and lower Yakima Canyon, with the broad floodplain valleys in between (see Fig. 13.6) (Kinnison and Sceva 1963).

The climate is extremely variable, ranging from maritime in the heavy snow belt of the Cascades to arid in the interior Columbia basin. Annual precipitation ranges from 350 cm to approximately 18 cm (Rinella et al. 1992). Precipitation in the lower river basin occurs primarily in late fall and early winter (>2 cm/mo) but declines to less than 1 cm/mo during summer (Fig. 13.20). Clearly, the monthly precipitation shown in the figure underestimates precipitation for the entire basin, as 85% of the annual discharge comes from the Cascade headwaters. Mean monthly temperatures in the lower basin range from 1°C in midwinter to 24°C in July.

Elevation varies from around 2500 m asl in the Cascades to 98 m asl at the Columbia River confluence. The higher areas located in the Eastern Cascades Forests terrestrial ecoregion receive the most precipitation and are thickly covered with Douglas fir, larch, lodgepole, and ponderosa pine. The conifer zone grades into the Snake/Columbia Shrub Steppe ecoregion, which is dominated by Idaho fescue and other grasses plus sage, bitter brush, and occasional stands of ponderosa in the foothills and valley flanks with floodplain cottonwood forests along the river (Franklin and Dyrness 1973). The boundary between these two ecoregions is visible along Bristol Canyon, northwest from Ellensburg along Highway 10, where the vegetation changes from grand and Douglas fir to shrub steppe. On the east side of the Cascades the northernmost distribution of Oregon white oak is

found at the confluence of the Swuak and Yakima rivers north of Ellensburg.

Within the Yakima basin about 36% is forested, 47% is shrub, and 16% has been converted to agriculture, primarily in the Walla Walla Plateau. Irrigation serves over 200,000 ha, ranking the Yakima basin among the more productive agricultural areas in the United States. Apples, cherries, peaches, grapes, and other fruits are grown along with hops, mint, asparagus, alfalfa, and timothy. Yakima County recently ranked 5th in the country for annual agricultural revenue. Viniculture is a growing industry. The foothills of the basin are range cattle country and enough timber is harvested annually from extensive federal and private holdings in the mountains to sustain several processing mills. The two main cities are Yakima and Ellensburg, but considerable exurban fragmentation of farm and ranch land is occurring in the upper basin due to proximity to the Seattle metroplex. About 500,000 people live in the basin, but only about 1% of the land is considered urban.

River Geomorphology, Hydrology, and Chemistry

The river may be divided into five geomorphic provinces: step-pool headwaters, glacial lake district, braided alluvial valleys (Cle Elum–Teaaway, Kittatas, Selah, Naches, Yakima–Union Gap, and Wapato), meandering alluvial valley (Lower Wapato), and main-stem canyons (upper and lower Yakima canyons). Riverbed sediments of the expansive floodplains are coarse sand, gravel, and cobble, except in the meander segment above the lower canyon, where sands and silts are more prevalent. Glacial ice scour advanced only as far as the upper Yakima Canyon, but outwash from Cascade glaciers and Lake Missoula flood deposits are extensive throughout the basin; for example, in the meander reach. Storage for irrigation comes from two reservoirs on the main tributary, the Naches River, and from elevation and regulation of the three glacial lakes on the upper Yakima. Together they capture approximately one-third of the annual basinwide runoff (1.23 billion m³). A key point is that storage is insufficient to prevent scouring floods from occurring on about a five-year return interval, which in part explains the presence of existing complex floodplain habitat, especially at the lower ends of the major floodplains (Snyder and Stanford 2001).

Mean discharge is quite high (102 m³/s) for the Yakima River, given its relatively small basin area (<16,000 km²). Peak flow in the lower basin his-

torically occurred from April through June from mountain snowmelt, adding substantially to a relatively high annual runoff of about 20 cm/yr (see Fig. 13.20). In contrast, the lower basin, located in the Snake/Columbia Shrub Steppe ecoregion, receives relatively little precipitation (see Fig. 13.20) and is obviously insufficient to account for the observed runoff. Fall floods of short duration and high peak discharge generated by rain events also distinguish the discharge records (see Fig. 13.20). Flooding recharges the alluvial aquifers of the floodplains and promotes ground- and surface-water exchange and associated habitat mosaics. Much of the historic base flow during late summer and winter likely was sustained by discharge from the alluvial aquifers, which also would have cooled the river and prevented anchor ice in winter. On several of the floodplains large drainage ditches were constructed to drain aquifers to prevent “souring” of soils for irrigated crops. This, of course, destroyed the natural flow and temperature buffering of the aquifer system.

Stream water in the basin is neutral to slightly alkaline and specific conductance increases longitudinally from ca 75 $\mu\text{S}/\text{cm}$ in the headwaters to greater than 300 $\mu\text{S}/\text{cm}$ in the lowlands (Carter et al. 1996). Similarly, the quantity of nutrients (nitrogen and phosphorus) increases longitudinally as a response to increasing anthropogenic alteration of the watershed (urban runoff, agricultural return flows, etc.; Cuffney et al. 1997). For example, total phosphorus increases from 0.04 mg/L to >0.1 mg/L and $\text{NO}_3\text{-N} + \text{NO}_2\text{-N}$ increases from 0.13 mg/L to >1.0 mg/L in the mountains and agricultural drains, respectively (Rinella et al. 1992). Groundwater pollution by fertilizers and pesticides contributes substantially to the river pollution load. Nutrient enrichment and biomagnification of toxic chemicals are primary problems and warnings against human consumption of fishes have been issued in recent years. However, fish kills and other extreme pollution problems are not reported and biotic productivity in the river is high (Snyder and Stanford 2001).

River Biodiversity and Ecology

The Yakima River is located in the southwestern corner of the Columbia Glaciated freshwater ecoregion (Abell et al. 2000). The Yakima River ecological literature is relatively rich, although mostly unpublished (see review by Snyder and Stanford 2001). A literature archive is available at the Flathead Lake Biological Station (<http://www.umt.edu/flbs>).

Algae and Cyanobacteria

Throughout its length the Yakima has a rich periphyton assemblage of diatoms, with areas of attached algae, mainly *Cladophora* spp. and *Stigeoclonium* spp. In synoptic sampling along the river continuum during the fall of 1989, Leland (1995) found a total of 132 algal taxa, 119 of which were diatoms. Dominant diatom taxa included *Achnanthes lanceolata*, *A. minutissima*, *Cocconeis placentula*, *Cymbella minuta*, *Diatoma vulgare*, *Navicula radiosa* var. *tenella*, *N. dissipata*, *N. frustulum*, *N. frustulum* var. *perpusilla*, *N. palea*, and *Synedra ulna*. The Cyanobacteria *Oscillatoria* sp. and *Schizothrix calcicola* were also quite abundant. Taxa were grouped according to physiographic changes from headwaters to mouth, including the density and composition of riparian vegetation, land use, and surficial geology.

Plants

The floodplains of the Yakima River are a dominant ecological feature of the basin that is structured in large part by the dominant woody taxa, mainly black cottonwood and narrowleaf cottonwood, along with several species of willow and alder (Franklin and Dyrness 1973, Guard 1995). Dunlap and Stettler (1996) described an abrupt change in black cottonwood phenotype in which populations in the xeric lower river had less stem volume, later spring flush, and earlier autumn budset and leaf fall relative to the more mesic upper river (upstream of the Teanaway River). They concluded that moisture availability was a key selective agent. This conclusion was supported by genetic analyses conducted by Reed (1995), who documented genetic differences between mesic and xeric stands. The abundant fringing wetlands and marshes are also loaded with aquatic plants, particularly arrowroot or wapato.

Nonnative grass species included the perennial reed canary grass, which is broadly distributed and more abundant throughout the river corridor than native annual grasses. In addition, purple loosestrife, silver maple, Russian olive, and European willows are commonly found, particularly along the lower reaches of the river. Braatne and Jamieson (2001) observed that younger age classes of native willow and cottonwood were largely absent and attribute this to alteration of the natural flow regime.

The physiography of the basin is such that extensive riparian galleries have developed on the broader floodplains, whereas the more constricted zones in the canyons are dominated by mixed stands of cottonwoods and ponderosa pine. The processes of

cut-and-fill alluviation have greatly enhanced structural complexity of the broad floodplains, leading to a high abundance of off-channel habitat with stagnant water where hydrophytes are common.

Invertebrates

Over 300 species of macroinvertebrates occur basinwide, with site-specific richness ranging from 20 to 69 species and mean densities ranging from <1000 to >2100 individuals/m² from headwaters to lower river reaches. Taxa richness in general was negatively related to the intensity of agricultural activity and positively related to canopy closure. Species found exclusively in the headwaters included the stoneflies *Zapada columbiana* and *Z. fridida* and the caddisflies *Parapsyche elsis*, *Rhyacophila* nr *blarina* Ross, *R. vocala*, and *R. valuma*. Headwater (1009 m asl) dominants included the flatworm *Polycelis coronata* and the ice worm *Mesenchytraeus* sp., as well as the mayflies *Baetis tricaudatus*, *Rhithrogena* nr *robusta*, *Drunella doddsi*, *Cinygmula* sp., and nr *Doddsia occidentalis*. Downstream (781 m asl) the community was dominated by some of the same taxa (*Mesenchytraeus* sp., *Cinygmula* sp., and *B. tricaudatus*) in addition to the mayfly *Dipheter hageni* and the stoneflies *Zapada cinctipes* and *Sweltsa* sp. At lower elevations (mean altitude 669 m) some of the same taxa again dominated the community (*Mesenchytraeus* sp., *B. tricaudatus*, *Cinygmula* sp., *Z. cinctipes*, and *Sweltsa* sp.) in addition to an increase in abundance of *Nais behningi*, an aquatic earthworm, the mayfly *Ephemerella* nr *infrequens*, and the dipteran *Antocha* sp. At 656 m the caddisfly *Cheumatopsyche* sp., *Aulodrilus plurisetus* (a tubificid), and the chironomid *Eukiefferiella claripennis* were most abundant, whereas most of the upstream species were no longer present. Finally, within the Wapato floodplain segment, where seasonal temperature variation and pollution concentrations were maximized, the mayflies *Baetis tricaudatus* and *Ephemerella* nr *infrequens*, the caddisfly *Hydropsyche* nr *californica*, as well as the chironomids *Cricotopus trifascia* gr. sp., *Polypedilum* nr *convictum*, *Eukiefferiella claripennis* gr., and *Thienemanniella* sp. and the planarian *Dugesia* sp. were most abundant (Carter et al. 1996, Cuffney et al. 1997).

Snyder et al. (2003) found the amphibitic stoneflies *Kathroperla perdita* and *Paraperla* spp. in the alluvial aquifers of the upper Yakima. As in the Flathead River, these genera are indicators of hydrologic connectivity between the floodplain and the river, but they were not present in the aquifers most influenced by pollution and draining. They also described the

longitudinal distribution of *Paraperla* spp. and surficial groundwater crustaceans. The distribution and abundance of these hyporheic invertebrates decreased from upstream to downstream; 88% of the variation was explained by ambient concentrations of NO₃-N + NO₂-N.

The silver-bordered bog fritillary is a rare colonial butterfly that pollinates the equally rare northern bog violet (Pyle 1974, 1992). Within the Yakima basin this interesting association is found in only one place within a fringing floodplain bog.

Of the six species of freshwater mussels reported in Washington and Oregon, four have been recommended for listing under various categories of ESA (Frest and Johannes 1995). These include western pearlshell, western ridge mussel, Willamette floater, and California floater. The other two are Oregon floater and western floater. Extensive mussel beds, probably western pearlshell, were observed in a spring brook side-channel complex in the upper Yakima, apparently owing to the stable flow of the spring brook (E. Snyder, personal observation). No other beds have been reported in the basin, although they apparently were widely distributed historically.

Vertebrates

At least 50 species of fishes exist in the Yakima basin, of which 12 are nonnative and most abundant in the warmer reaches of the lower river. The more abundant resident species are (E, nonnative; N, native) rainbow (E), brook (E), and cutthroat (N) trout, mountain whitefish (N), sculpins (N), largescale (N) and bridgelip (N) suckers, northern pikeminnow (N), speckled (N) and longnose (N) dace, smallmouth bass (E), black crappie (E), channel catfish (E), and yellow perch (E). Historically, the Yakima basin sustained four anadromous (chinook, coho, steelhead, and sockeye) and five resident salmonid species (bull charr, rainbow, kokanee and cutthroat trout, and mountain whitefish), with numerous stocks or runs associated with the great habitat heterogeneity of the basin. For example, the headwater glacial lakes supported robust runs of sockeye salmon that coexisted with all of the other salmonids, except possibly coho, along with burbot and several other native fishes. Today, all of the native salmonids and some of the other native fishes have declined to a few stocks in critical condition or have been extirpated.

Chinook salmon are grouped as spring, summer, and fall stocks, corresponding to the time when the adults return from the ocean. Spring and fall chinook can be divided into three and two stocks, respectively.

Of the latter, the more abundant stock, representing approximately 70% of the total run, is derived from the Hanford Reach of the Columbia River (Busack et al. 1991). The second stock spawns in a large drainage ditch (Marion Drain) in the Wapato floodplain and is genetically similar to stocks found in the Snake and Deschutes rivers. It is believed that this population at least partially represents the original Yakima River stock, although some genetic mixing has likely occurred with hatchery fish from the Hanford Reach (Busack et al. 1991).

Coho, locally extirpated many years ago, have been reestablished in the Yakima from hatchery releases. Sockeye runs of 200,000 or more existed in the glacial lakes of the upper basin, but they also were extirpated by the dams constructed on the outlets of the glacial lakes to allow storage of irrigation water.

Steelhead were once ubiquitous throughout the basin, occurring in all reaches that supported spring chinook as well as numerous tributaries. Because of declining runs, steelhead were listed as endangered in 1997. Genetic analysis indicated that three reproductively isolated populations still exist in two tributaries on the Yakima Indian reservation and the Naches–upper Yakima (Busack et al. 1991). Resident rainbow trout from a long legacy of hatchery stocking are common and self-reproducing in the river and a popular sport fishery exists in the Kittitas Valley and Yakima Canyons.

Native bull trout likely were distributed throughout the basin, but today they exist only in isolated headwaters (Craig 1997). A few have occasionally been observed in the upper reaches of the Yakima and Naches rivers.

Amphibians found along the river include the northern leopard frog, Columbia spotted frog, tailed frog, and the western toad, all of which have experienced declines due to numerous factors, including habitat destruction, sedimentation, altered temperature and flow (Nordstrom and Milner 1997), and predation by nonnative bullfrogs. The rare Larch Mountain salamander also has been reported. Reptiles found along the river corridor include garter snakes and the Western pond turtle, which is listed by the state of Washington as endangered.

The Yakima floodplains historically contained most of the Columbia basin's wintering ducks and geese (from 250,000 to 300,000; Oliver 1983). Species include the mallard, pintail, green-winged teal, cinnamon teal, blue-winged teal, wood duck (largest population in eastern Washington), shoveler, redhead, ruddy duck, ring-necked duck, Canada

goose, white-fronted goose, tundra swan, and trumpeter swan (Parker 1989). Since the 1970s numbers have declined (to between 30,000 and 40,000) as the population has shifted from the lower Yakima basin to the lower Columbia River (Lloyd et al. 1983). The change is attributed to increased surface water due to hydroelectric development on the lower Columbia River, changes in cropland patterns, and improved refuge conditions (Thompson et al. 1988). Bald eagle, osprey, and sandhill crane nest and feed in the floodplains. The floodplains and prairie also supported large herds of elk and deer.

Ecosystem Processes

Recent monitoring of shallow alluvial wells indicated that in the lateral dimension, key nutrients (various forms of nitrogen and phosphorus) and dissolved organic carbon tend to increase from the main stem to spring brooks to floodplain (Stanford et al. 2002). In addition, nutrients increased longitudinally and were quite variable through time, as predicted based on the fluctuating hydrologic regime. This pattern was mirrored by a general increase in chlorophyll-*a* concentrations from upstream to downstream. Pigment concentrations ranged from 0.5 to 27 $\mu\text{g}/\text{cm}^2$, and organic content ranged from 0.4 to 6 mg AFDM/ cm^2 . Although primary productivity and organic matter spiraling were not measured, the pattern and concentrations of chlorophyll suggest that allochthonous sources of energy would likely dominate in the upper reaches, with a gradual shift to autochthonous energy supply in the lower reaches. This pattern is likely enhanced by anthropogenic eutrophication of the lower reaches. Additional patterns in chlorophyll *a* and AFDM suggested off-channel habitats, such as spring brook and side-channel complexes, maintained higher pigment concentrations and biomass, particularly in the upper reaches. These patterns were correlated with heavy use of spring brooks and side channels by juvenile salmonids (coho and chinook).

These fringing floodplain features likely represent areas of refuge from native and nonnative fish predators. For example, McMichael et al. (1998) found that predation rates during downstream smolt migration were particularly substantial for fall chinook. The three main predators included the indigenous northern pikeminnow and two nonnative piscivorous species, the smallmouth bass and channel catfish. The abundance of nonnative species increases downstream as a function of accumulating anthropogenic impacts, as well as proximity to a source pool (namely the Columbia River main stem).

Salmonids likely are not food limited, because estimates of macroinvertebrate biomass ranged from 6.4 to 12.6 g/m² in samples from the main channel in the floodplain reaches (Nightengale 1998). However, juvenile salmonids favor shallow edge habitat where benthic biomass is reduced or missing entirely due to flow fluctuations associated with irrigation transfers and diversions. Moreover, sudden changes in velocity caused by irrigation transfers may wash juvenile fishes downstream or laterally into unproductive zones (Snyder and Stanford 2001).

Human Impacts and Special Features

The expansive floodplains and headwater glacial lakes are unique features of the Yakima. The floodplains are more extensive and habitat rich than generally exists elsewhere in the Columbia basin and few large lakes exist within the natural range of anadromous fishes. In spite of considerable modification by human activities, much of the system retains habitat complexity and connectivity. This is mainly because water storage in the basin is not sufficient to prevent big floods (~25-year return events). Thus, critical habitat-forming processes, namely cut-and-fill alluviation, still occur sufficiently to create and maintain floodplain habitat. The shifting habitat mosaic crucial to salmon production is intact to some extent throughout the river corridor.

Human impacts include water abstraction, flow regulation, pollution, nonnative species, and habitat alteration, especially in the floodplain segments, all of which have compromised the ecological integrity of the Yakima River. For example, 66% of the total historical area of the five floodplains has been functionally disconnected from the river by revetments and human structural encroachment (Eitemiller et al. 2002, Snyder et al. 2003). Water abstraction for summer irrigation has left the river dry some years and substantially below preregulation norm most years in the Wapato segment downstream of the Sunnyside diversion. In reference to the Federal Clean Water Act (sec. 303d), 72 stream and river segments are listed as impaired by the Washington Department of Ecology and 83% exceed temperature standards. For example, Lilga (1998) found temperatures in the lower river from June through November (1996) that were lethal (>15.6°C) for salmon egg and fry incubation between 60% and 85% of the time. Temperatures are stressful for juveniles (>18.3°C) between 25% and 65% of the time and stressful for adults (>15.6°C) between 60% and 85% of the time. Standards set for DDT, PCB, and other toxic chemicals

were exceeded in 15% of the listed (303d) reaches. In addition, high concentrations of DDT (and its breakdown products DDE and DDD) were found in fish tissue from the lower river; these concentrations are among the highest recorded in the United States (Rinella et al. 1993).

The main problem in the Yakima River, however, is artificial manipulation of base flows to facilitate irrigation. Conservation and restoration of the floodplain segments through implementation of a basin-wide naturalized flow regime is a crucial next step in the recovery of anadromous salmon and steelhead. However, the only effective ways to do this are to substantially reduce water abstraction, which will compromise agriculture production, or import water from outside the basin (Stanford et al. 2002). Whited et al. (2003) demonstrated that the ecological condition of the lower river could be improved by diversion of irrigation water from the Columbia via a process called pump-exchange, allowing Yakima water to stay in channel. Similar measures could be implemented for most of the rest of the Yakima, albeit at great expense, because of the proximity and similar channel elevation of the Columbia (U.S. Bureau of Reclamation, unpublished data).

Returning the Yakima to a free-flowing condition would be a hallmark of river restoration experiments. The idea is substantially enhanced by the fact that the Yakima flows into the only free-flowing part of the Columbia main stem (Hanford reach), which also happens to sustain the most robust salmon population left in the entire interior Columbia basin. Uncertainties beyond affordability include whether such a large-scale restoration effort can forestall inexorable floodplain encroachment and at the same time overcome documented negative influences of hatchery operations, outmigration mortality in the main-stem Columbia, variation in subscribed harvest, and human-mediated variation in oceanic productivity, among other internal and external impediments (cf. Williams 2005).

WILLAMETTE RIVER

The Willamette River is a 7th order river (1:100,000 scale) in the western edge of the Columbia River basin in western Oregon (Fig. 13.21). The Willamette River runs north for more than 230 km through the heart of the Willamette Valley and enters the Columbia River just downstream of Portland, Oregon. The Willamette River basin is the 13th largest river in the contiguous 48 states and produces more water per

land area than any of the larger rivers of the United States (Kammerer 1990). Its total annual discharge makes up 12% to 15% of the total flow of the Columbia River (Hulse et al. 2002). The Willamette River basin is 290 km long, 161 km wide, and 29,728 km² in area, bounded on the west by the Coast Range and on the east by the Cascade Mountain Range. This basin, centered at 45°N latitude and 123°W longitude, makes up 12% of the land area of Oregon and contains 68% of the state's population. The three largest cities in Oregon—Portland, Salem, and Eugene—are located on the banks of the Willamette River. The water quality is good in the headwater streams and moderately good in the main-stem river. Fishing is a major recreational use in the river and its tributaries, especially for Pacific salmon, steelhead, nonnative trout, and sturgeon. Wildlife is abundant along the rivers of the basin, with frequent evidence of the state's icon, the beaver.

Native Americans have occupied the Willamette Valley for more than 10,000 years. Lewis and Clark actually missed the mouth of the Willamette River on their expedition down the Columbia River and also on the return trip upriver. After a tribe on the Sandy River gave him directions, William Clark went back downstream and entered the mouth of the Willamette River in April 1806. Euro-American settlement began with fur trading in the early 1800s and continued, with the first settlement in Oregon on the floodplain of the Willamette in 1829. Agriculture, forestry, and commercial fishing became established after 1840. The Willamette Valley was a mosaic of wet and dry prairie, oak savannas maintained by Native American burning, and floodplain forests, creating many obstacles for transportation. Riverboats on the Willamette River served as the first major method for transporting people and materials along the valley floor.

Physiography, Climate, and Land Use

The Willamette River basin includes three major types of geological parent material. Within the Pacific Border (PB) physiographic province on the western side of the basin (see Fig. 13.21) are marine volcanic and sedimentary rocks in the Oregon Coast Range section, alluvial deposits in the Willamette Valley, and volcanic basalts and andesite that occupy the southern end of the Puget Trough section. Volcanic basalts and andesite also occupy the Middle Cascade Mountains section of the Cascade–Sierra Mountains (CS) physiographic province on the eastern side of the basin. These geological surfaces were formed by

the combined effects of tectonics and volcanism over the last 30 million years and by recent deposits of glacial floods between 15,000 to 13,000 years ago. Roughly 35 million years ago (mya), an ocean slab formed the floor of Willamette basin. The valley rose and became dry 20 mya. Two periods of volcanic activity formed the old Cascade Mountains approximately 20 to 30 mya and the new Cascade Mountains at higher elevation 10 to 15 mya. On the west side of the basin tectonic and volcanic activity formed the Coast Range around 15 mya.

The middle of the basin is a large flat valley whose present land surfaces were created by a series of glacial outburst floods from the Lake Missoula system between 15,500 and 13,000 years ago. The surface of the valley floor was modified by the deposits of the glacial Lake Missoula floods from Montana at the end of the last glacial period. As ice dams forming Lake Missoula were breached, walls of water poured down the Columbia River with discharges that exceeded the annual discharge of all present-day rivers of the world combined. The Willamette basin became a backwater of the Columbia River and filled to depths of more than 120 m. Alluvial deposits carried by these floods formed the modern surfaces of the Willamette Valley.

The climate of the Willamette River basin is relatively mild, influenced by the moderating effect of the Pacific Ocean to the west (Uhrich and Wentz 1999). Across the basin, average annual air temperature ranges from 4°C to 18°C depending on elevation. In the valley, mean minimum air temperature in January averages 3°C to 5°C, whereas in the summer monthly means range from 17°C to 20°C (Fig. 13.22). Precipitation averages approximately 100 cm/yr at low elevation and approaches 500 cm/yr near crests of the Cascade Mountains and Coast Range (Hulse et al. 2002). Across the Willamette basin, estimates of average precipitation and recharge (surface-water runoff plus groundwater recharge) are 130 cm/yr and 50 cm/yr, respectively (Lee and Risley 2002, Uhrich and Wentz 1999). Most of this precipitation (70% to 80%) occurs between October and March during the wet season and <5% of the precipitation occurs in July and August during the dry season (see Fig. 13.22).

The climate, geology, soils, and hydrology create three major terrestrial ecoregions within the Willamette basin: Central Pacific Coastal Forests, Willamette Valley Forests, and Central and Southern Cascade Forests (Ricketts et al. 1999). The Central Pacific Coastal Forests ecoregion on the western edge of the basin is characterized by Douglas fir, western

hemlock, and western red cedar. The central Willamette Valley Forests ecoregion once was a prairie with native perennial grasses and oak savannas, groves of Douglas fir, ponderosa pine, and other tree species, and was strongly influenced by anthropogenic fire. Very little of the prairie remains, however, having been replaced by agriculture. The Central and Southern Cascade Forests ecoregion on the eastern side of the basin includes western hemlock, western red cedar, and Pacific silver fir.

The Willamette River basin currently contains a population of 1,970,000, of which 86% live in urban portions of the landscape (Hulse et al. 2002). The majority (64%) of the land base is held in private ownership. Of the 36% public lands in the Willamette River basin, the U.S. Forest Service manages 30%, the U.S. Bureau of Land Management 5%, and the state of Oregon 1%. Forestlands account for most of the land use across the basin (68%) because it is so steep and heavily forested. Agriculture makes up 19% of the total land use and almost entirely occurs in the Willamette Valley. Urban areas occupy 5% of the basin. Transportation systems place a strong imprint on the land and rivers, with more than 130,000 km of roads, resulting in overall road densities of 2 to 3 km/km². The human population of the Willamette basin is projected to double to 3,900,000 people by 2050, with an increase to 93% living in urban settings.

River Geomorphology, Hydrology, and Chemistry

The highest point in the Willamette Basin is Mount Jefferson at 3199 m asl in the Cascade Mountains. The Willamette River has an elevation of 137 m asl where it enters the valley floor and descends to an elevation of 3 m asl at its confluence with the Columbia River. The river is approximately 100 to 200 m wide along the main stem, with an average gradient of 50 cm/km. Substrates in the upper Willamette River are dominated by cobble and gravel, with sand and clays becoming more abundant in the lower Willamette River. There are three major reaches in the river. The lower reach is extremely low gradient and is tidally influenced by the Columbia River. Willamette Falls creates a drop of 12 m in the lower reach at Oregon City, 72 km above the mouth (Fig. 13.7). The river flows between volcanic intrusions in the valley floor between Newberg and Albany, creating a highly variable floodplain. Above Albany the gradient increases and the floodplain widens, repre-

senting a large depositional area upstream of foothill landforms extending across the valley floor. Large wood contributed from the adjacent floodplain forests or transported from upstream reaches is a common feature of the shallow habitats and islands in the upper section of the Willamette River.

Mean discharge for the Willamette River at its mouth averages 917 m³/s, but varies seasonally from 233 m³/s in August to over 2230 m³/s in December, reflecting the seasonal pattern of precipitation (see Fig. 13.22). Much of the summer runoff depends on the high-elevation snowpack because more than 35% of the precipitation occurs as snow above 1200 m in elevation. As a result of the rain-dominated hydrograph at low elevations and snowmelt-dominated hydrograph at high elevations, stream flows overall are highest in winter and lowest in late summer. Twelve major subbasins deliver flow into the main-stem Willamette River from upstream to downstream: Middle Fork Willamette, Coast Fork Willamette, McKenzie, Long Tom, Mary's, Calapooia, Luckiamute, Santiam, Yamhill, Molalla/Pudding, Tualatin, and Clackamas rivers (see Fig. 13.21). The main stem of the Willamette River is not dammed, but there are 13 major flood-control reservoirs in the larger tributaries in the Coast Range and Cascade Mountains and many small dams for irrigation or power generation. Reservoirs control approximately 27% of the flow of the Willamette River (USACE 1999).

Historically, most major floods were rain-on-snow events and caused floodplain inundation for weeks or months. The largest flood on record was the 1861 flood, which inundated 130,000 ha with a discharge of 9700 m³/s. In contrast, the public was alarmed by a recent flood in 1996 that had a peak flow of only 3300 m³/s. Floodplains defined by the Federal Emergency Management Agency (FEMA) closely match the historical extent of floodplain inundation in the lower Willamette River, but FEMA floodplains only represent 49% of the historically inundated floodplain in the broader depositional areas of the upper Willamette River (Hulse et al. 2002). Studies of gaging stations in the main-stem Willamette River indicate the channel down-cut at a rate of 0.3 m per decade from 1930 to 1960. Possible causes for this channel degradation include dredging, gravel mining, channelization, reservoir control, and climatic decreases in peak flows (USACE 1999, Hulse et al. 2002). Limited evidence indicates this down-cutting (in conjunction with flood-control dams) has led to less frequent overbank flooding; a flood that historically (prior to 1964) had a 1-in-10-

FIGURE 13.7 Willamette River at Oregon City, Oregon. Willamette Falls is seen in background. During summer, most of the water goes through historic locks built in the 1870s rather than over the falls (PHOTO BY TIM PALMER).

year chance of occurrence now has a 1-in-100-year chance of occurrence. This trend indicates a decrease in floodplain function and a need to restore both the geomorphology and the hydrology of the Willamette River system.

The main stem of the Willamette River is a low-gradient river, which served as a major transportation corridor for early settlers in the valley. The channels of the Willamette River have been greatly simplified over the last 150 years (Hulse et al. 2002). From 1850 to 1995 total area of river channel and islands in the main-stem Willamette River decreased from 16,600 ha to 9200 ha, and the total length decreased from 571 km to 424 km, primarily through loss of side channels. Much of this loss has been caused by channelization and bank hardening. Only 27% of the length of the main-stem Willamette has revetments or rip rap on one or both banks, but more than two-thirds of the meanders in the river are hardened by revetments.

Water quality has been a major environmental concern since the late 1920s. Dissolved oxygen concentrations were less than 1 mg O₂/L at sites along the entire main stem in the 1920s and 1930s. Elimination of most point-source discharges and extensive sewage treatment along the river improved conditions but were not sufficient to improve water quality. Summer low flows in the Willamette River are now double their historical levels, increasing to roughly 140 m³/s from historical August flows of 70 m³/s. Although this “dilution of pollution” has reduced the risks of high temperatures and low dissolved oxygen, it has altered the natural flows of the river and raised numerous questions about cottonwood forest regeneration and fish passage. Water quality in the middle and upper Willamette River is generally ranked as good, but the lower Willamette River is classified by the Oregon Department of Environmental Quality as “poor to marginal.” The Willamette River was one of the 50 sites studied as part of the National Water

Quality Assessment. Overall, nutrients and contaminants in the Willamette River were ranked as typical of concentrations found in other NAWQA sites. Nitrate-nitrogen concentrations ranged from 0.054 to 22 mg/L in 98% of the samples, and increased as area of agricultural land increased (Wentz et al. 1998). Soluble reactive phosphorus concentrations in streams ranged from 0.01 to 0.93 mg/L in 89% of the samples.

In contrast to results for nutrients, the occurrence of abnormalities in fishes and the proportions of non-native fishes were far worse than most NAWQA sites. Thirty-six toxic compounds were detected in water sampling throughout the Willamette River basin. Six pesticides, including atrazine, diuron, and metolachlor, exhibited higher concentrations in agricultural lands than in urban areas. Other pesticides, such as carbaryl, diazinon, and dichlobenil, exhibited higher concentrations in urban areas than in agricultural lands.

River Biodiversity and Ecology

The Willamette River is in the westernmost portion of the Columbia Unglaciaded freshwater ecoregion, which includes most of the southern tributaries of the Columbia basin, such as the lower Snake, Salmon, and John Day rivers (Abell et al. 2000). The ecology of streams and rivers in the Willamette River basin has been reviewed and summarized in a number of recent publications (Altman et al. 1997, Uhrich and Wentz 1999, Hulse et al. 2002). The following section highlights a few of the major studies of the aquatic ecosystems in the Willamette River basin.

Algae and Cyanobacteria

Algal assemblages of the main-stem Willamette River and the thousands of miles of smaller streams in the basin have not been studied extensively. Common algae in the main-stem Willamette River include diatoms such as *Melosira*, *Stephanodiscus*, *Cymbella*, *Achnanthes*, *Nitzschia*, and *Fragilaria*, which have been noted as the dominant types of benthic and planktonic algae (Wille 1976, Rickert et al. 1977). A study of the main stem and a major tributary, the Santiam River, also observed a dominance of diatoms in the 86 species observed in the phytoplankton and benthic algae and noted no major differences in algal community structure between the main stem and the tributary (Rinella et al. 1981). A subsequent study of benthic algae in 23 sites along the main-stem Willamette River and eight major tributaries found 35 genera of algae (Gregory 1993).

More than 80% of the cell numbers were comprised of cyanobacteria, predominantly in the genera *Anabaena*, *Aphanocapsa*, and *Chroococcus*, with diatoms making up most of the remaining 20%. Benthic algal abundance, as indicated by standing stock of chlorophyll *a*, increased downstream along the main-stem Willamette River in this study.

Algal communities in smaller streams also include many genera of diatoms (e.g., *Achnanthes*, *Diatoma*, *Fragilaria*, *Gomphoneis*, *Gomphonema*, *Cymbella*, *Cocconeis*), green algae (e.g., *Zygnema*, *Spirogyra*, *Ulothrix*, *Cladophora*, *Chlamydomonas*), and cyanobacteria (e.g., *Nostoc*, *Phormidium*, *Oscillatoria*, *Schizothrix*, *Calothrix*) (Clifton 1985, Lyford and Gregory 1975). In general, heavily shaded streams in forested reaches are dominated by diatoms and cyanobacteria, but open stream reaches include greater abundance of filamentous green algae, diatoms, and yellow-green algae.

Plants

The floodplain forests of the Willamette River are dominated by extensive stands of black cottonwood, Oregon ash, bigleaf maple, white alder, and willow. In 1850, the floodplain forest averaged 1.5 km to 3 km in width and was up to 11 km wide at the confluence of the Santiam River (Hulse et al. 2002). Even from a more narrow perspective, riparian vegetation has been greatly diminished by land conversion. In a 120 m band along both banks in 1850, 89% of the area would have been covered by forests of deciduous trees, conifers, or mixed stands. By 1990 only 37% of the riparian area within 120 m was forested, 30% was agricultural fields, and 16% was urban or suburban lands. Loss of floodplain forest has been one of the most dramatic changes in the Willamette River since Euro-American settlement.

Invertebrates

The macroinvertebrate fauna of the main-stem Willamette River has received little study, with much greater attention given to headwater streams in the Coast Range and Cascade Mountains. In a small stream in the Willamette Valley, more than 325 species of macroinvertebrates were observed over a 25-year period (Anderson and Hansen 1987). The River Continuum studies in the McKenzie River basin of the Willamette observed shifts in feeding functional groups from a dominance of shredders in small headwater streams, to scrapers in midorder streams, to collectors in larger rivers (Hawkins and Sedell 1981). Abundances of caddisflies (e.g., *Hydropsyche*, *Lepidostoma*, *Heteroplectron*, *Gloss-*

soma, *Dicosmoecus*), stoneflies (e.g., *Taeniopteryx*, *Nemoura*, *Yoraperla*), and mayflies (e.g., *Rhithrogena*, *Baetis*, *Paraleptophlebia*, *Ephemerella*) have been used as indicators of stream habitat quality in small streams of the Willamette basin (Van Sickle et al. 2004). In addition to aquatic insects, small streams in lower elevations also support crayfish (*Pacifastacus*) and gastropods (*Juga plicifera*, *Juga silicula*). Abundance of these taxa that require higher-quality habitat was inversely related to the extent of development and agricultural conversion within the riparian areas along the streams (Van Sickle et al. 2004). The proportion of the good- to high-quality habitat for invertebrates was projected to be approximately 75% of the total stream habitat in 1850 and had decreased to approximately 40% in 1990. Many macroinvertebrates are associated with wood in streams. A study in the Willamette basin documented 37 invertebrate taxa that are closely associated with wood and 67 taxa that are facultatively associated (Dudley and Anderson 1982). In particular, a unique elmid beetle, *Lara avara*, lives primarily in wood, consuming wood along grooves in the wood surface (Steedman and Anderson 1985).

Human and natural disturbances potentially alter the abundance and composition of macroinvertebrate communities in streams. Studies of headwater streams revealed that abundance of invertebrates increased in open reaches, such as clear-cuts (Hawkins et al. 1982). Catastrophic disturbances also have been observed to cause abrupt changes in aquatic macroinvertebrates. A 5000 m³ landslide dramatically reduced the abundance of invertebrates in the 3rd order stream in the Cascade Mountains, but numbers of invertebrates had recovered to levels comparable to predisturbance conditions by the end of summer seven months later (Lamberti et al. 1991, Anderson 1992).

Aquatic macroinvertebrates in the main-stem Willamette River include many mayflies, stoneflies, and caddisflies (Richard Miller, personal communication), which are commonly used as indicators of better water quality. Study of a middle section of the Willamette River near a pulp mill found a midge, *Rheotanytarsus*, and a caddisfly, *Hydropsyche*, to be the most abundant invertebrate taxa (Richard Miller, personal communication). A survey of macroinvertebrates in the main-stem Willamette River found that the composition reflected degraded water quality increasingly downstream (Tetra Tech, Inc. 1994). Noninsect macroinvertebrates also are major components of the invertebrate fauna of the main-stem Willamette River. A study of rip rap or revetments in

the upper Willamette River found that polychaete worms (*Manayunkia*) and amphipods (*Anisogammarus*) were the most numerous macroinvertebrates (Hjort et al. 1984).

Vertebrates

The fish assemblage of the Willamette River basin exhibits low diversity, with 31 native fish species (Hulse et al. 2002). However, 29 species of fishes have been introduced, mostly in the main-stem river and lower tributaries. Native fish species include salmonids (cutthroat trout, bull trout, rainbow trout, mountain whitefish, Chinook salmon, steelhead, coho salmon, chum salmon, sockeye salmon), suckers (largescale sucker, mountain sucker, bridgelip sucker), minnows (northern pikeminnow, Oregon chub, chiselmouth, peamouth, leopard dace, longnose dace, speckled dace, redbelt shiner), sculpins (mottled sculpin, prickly sculpin, Paiute sculpin, reticulate sculpin, riffle sculpin, shorthead sculpin, torrent sculpin), lampreys (Pacific lamprey, western brook lamprey, river lamprey), and other species (white sturgeon, sandroller, eulachon, threespine stickleback). Some of the major nonnative species include largemouth bass, smallmouth bass, bluegill, walleye, crappie, common carp, grass carp, brown bullhead, western mosquitofish, brook trout, brown trout, kokanee, and lake trout. The lower rivers contain the largest number of fish species, with more than 20 species occurring within a 1 km reach of the main-stem Willamette River (Hulse et al. 2002). Headwater streams contain far fewer numbers of species, with cutthroat trout commonly the only fish species present in very small headwater streams. Several native fish species are currently listed as threatened or endangered under the Endangered Species Act (1973) or as sensitive species under the Oregon Endangered Species Act. Federally listed fish species in the Willamette River include spring Chinook salmon, winter steelhead, chum salmon (found only at mouth of the Willamette River), and Oregon chub. Coho salmon (found in tributary rivers below Willamette Falls) is considered to be critically sensitive by the state of Oregon.

One of the first extensive surveys of fishes in the main-stem Willamette River found increasing numbers of pollution-tolerant species near the mouth in Portland (Dimick and Merryfield 1945). Two later studies concluded that numbers of pollution-intolerant species had increased since the mid-twentieth century, reflecting improved water quality in the Willamette River as a result of pollution control measures (Hughes and Gammon 1987, Tetra Tech,

Inc. 1994). A recent study found similar patterns, but noted that nonnative species increased in abundance downstream and comprised more than 70% of the number of fish species in the lower river near the mouth (Hulse et al. 2002).

Other vertebrates in the Willamette basin include 18 species of amphibians, 15 species of reptiles, 154 species of birds, and 69 species of mammals. Not all of these species are aquatic. Pacific giant salamanders are a common vertebrate in streams of the Willamette basin and may be more abundant than fishes in headwater streams (Murphy and Hall 1981). Three species of garter snakes are very common in the Willamette River and its riparian forests. Native turtles include the western pond turtle, placed on the state sensitive species list because of its low population size. One riparian-dependent bird, the yellow-billed cuckoo, has been extirpated in the Willamette basin since Euro-American settlement. This species required closed-canopy riparian forests along the Willamette River and its extirpation may be directly related to loss of floodplain forests. One of the common aquatic birds in mountain streams of the Willamette River basin is the American dipper, a small, robin-sized bird that swims underwater and feeds on aquatic insects (Parsons 1975). Harlequin ducks migrate from the Pacific Ocean to mountain streams in the spring and early summer for nesting and rearing, also feeding on aquatic insects in high-gradient streams. Osprey, bald eagle, great blue heron, and green heron are common along the main-stem Willamette River. Osprey numbers have increased over the last two decades, and researchers have hypothesized that their increase is due to the ban on DDT and learning to use power poles for nesting (Henny and Kaiser 1996). Beaver populations are generally increasing throughout the basin, but the numbers are presumed to be far lower than historical populations and their distribution has been greatly restricted. River otter and mink also are common native mammals along the rivers and streams, and nutria and muskrat have been introduced into the region.

Ecosystem Processes

One of the four major basins for research in the River Continuum Concept was the McKenzie River at the southern end of the Willamette basin (Vannote et al. 1980, Minshall et al. 1983). This pioneering research revealed that the energy base for the smallest headwater stream, Devil's Club Creek, was dominated by allochthonous inputs from the surrounding forests, and algal production increased in

the larger streams (Mack Creek, Lookout Creek, and McKenzie River) as the increasing stream width created larger openings over the stream for solar radiation. Shredders dominated the smaller sites and scrapers and collectors became more dominant in larger streams. The riparian forests along these streams in the Willamette basin have been shown to contribute many ecosystem functions, including litter input, shading, large wood inputs, nutrient uptake, and bank stabilization (Gregory et al. 1991). Streams in the H. J. Andrews Experimental Forest in the McKenzie River basin were one of the first locations where the ecological role of large wood in stream ecosystems was documented (Swanson and Lienkaemper 1978, Harmon et al. 1986). These studies have led to the recognition of the ecological role of wood in river networks from the smallest headwaters to large floodplain rivers throughout the world (Gregory et al. 2003). The floodplains of the Willamette River and their forests are critical for aquatic ecosystems and their fish assemblages. Tributary junctions and multiple channel reaches of the Willamette River support more diverse riparian forest communities and richer fish assemblages (Hulse et al. 2002). Floods and other natural disturbances are important processes for creating complex habitat structure, diverse and abundant macroinvertebrate and fish communities, and mosaics of riparian plant communities (Lamberti et al. 1991, Anderson 1992, Johnson et al. 2000).

Human Impacts and Special Features

The Willamette River is a unique component of the Columbia River system, providing 12% to 15% of its total flow from only 4% of its area. The basin drains two major mountain ranges, the Coast Mountains to the west and the Cascade Mountains to the east, before flowing north through a low-gradient valley. It is an important basin for the state of Oregon, containing more than two-thirds of the state's population. It is home to several species of regional importance: spring Chinook salmon, coho salmon, winter steelhead, coastal cutthroat trout, beaver, river otter, bald eagle, and spotted owl. The headwater streams exhibit good water quality and the main-stem Willamette River continues to have water quality problems. The Willamette River lies in the heart of the valley and is a central feature in the lives of the communities within this basin.

Concerns over water quality in the Willamette River and declines in fish populations led to a public referendum and establishment of the state's Pollution

Control Authority in the late 1930s. These concerns surfaced again in the late 1960s; Governor Tom McCall gained national attention through the state's well-publicized efforts to clean up the Willamette River. Those actions decreased the impacts of raw sewage and industrial wastes and led to the formation of the Willamette Greenway. New concerns over continued loss of floodplain habitat and associated natural resources caused Governor John Kitzhaber to form a Willamette River Basin Task Force in 1998, which led to the development of the Willamette Restoration Strategy in 2001.

The first large dam was constructed in the city of Portland in 1894 to provide domestic water. Communities and agencies in the Willamette River basin have constructed 371 licensed dams with a storage capacity of 3 billion m³ (Hulse et al. 2002). This amount of water is equivalent to filling the entire Willamette Valley floor to a depth of more than 0.3m (1ft). These dams have blocked passage of anadromous salmonids and altered habitats downstream. Dams are one of the major causes of the declines of salmon in the Pacific Northwest (Nehlsen et al. 1991). Reductions in peak flows and deliberate channelization of the river have greatly reduced riverine habitats. Since the mid-1800s more than \$2.7 billion has been spent in direct channel alteration and operation of flood-control reservoirs in the Willamette River basin.

In addition to the creation of dams to store or divert water, water is withdrawn directly from the Willamette River and its tributaries. Most water rights (75%) for water withdrawal are recent, dating after 1960. Most streams in the Willamette basin have been fully allocated and have no remaining water to be distributed during normal years. On average, 77% of the surface waters in the Willamette River basin are withdrawn and 40% of this withdrawal is consumptive removal (the water does not return to the stream) (Hulse et al. 2002). Irrigation accounts for 49% of total withdrawal, domestic use 15%, industrial use 13%, and commercial use 20%. Most water withdrawal in the basin comes from surface waters; 88% of all withdrawals from public water-supply sources comes from surface waters. Projections of present and future water use in the Willamette basin indicate more than 130km of streams that ran perennially in 1850 are now dry during summer low flows. That distance is projected to double to approximately 275km by 2050 under current environmental policies (Hulse et al. 2002).

Introduction of nonnative species into the basin raises major concerns. In the upper main-stem

Willamette River, only 4% of the fish species are nonnative. In the lower Willamette River near Portland, more than 70% of the fish species are nonnative. In addition, rates of abnormalities increase markedly. These nonnative species and the abnormalities in native and nonnative fishes are indications of potential stresses on the aquatic ecosystems of the Willamette River.

Loss of floodplain forest and channel complexity in the Willamette River limits the current function and structure of the ecosystem and demonstrates a trend of continued decline and impairment. As society moves closer and closer to the Willamette River and calls for greater control of flows and simplification of its channel, the condition of the Willamette River ecosystem will decline. Society demands clean water, aesthetic parks and scenic resources, and opportunities for recreation, bird watching, fishing, and hunting. At the same time, the pressures of land conversion, rural residential development, population growth, and urbanization place those values in jeopardy. The state of Oregon developed a Willamette River Conservation Strategy in 2001. The future of the Willamette River and its aquatic ecosystem will depend on the effectiveness of that strategy and its implementation.

COLUMBIA RIVER MAIN STEM

The Columbia is the fourth-largest river that flows to the sea in North America. Its main stem flows from Columbia Lake in British Columbia 2000km to the ocean at Astoria, Oregon (Fig. 13.23). Along the way it receives water from 12 tributaries that are 6th order or larger, draining vast mountain ranges from the Rockies to the Cascades. The main stem is a canyon river, constrained by mountain flanks in the ranges (Fig. 13.8) and deeply entrenched in the basalt of the Columbia–Snake River Plateaus by Pleistocene floods of the Lake Missoula cataclysms (Allen et al., 1986). Only in the tidewater zone downstream from the confluence of the Willamette does it slow, historically allowing massive sediment deposition that created a shifting mosaic of large midchannel islands and fringing floodplain wetlands.

The Columbia, like all the great rivers of the world, is a conveyance for water, materials, and people. Although the tributaries organize the river as a complex stream network, natural (floods, sediment transport, salmon runs) and human cultural (commerce transport, hydropower, social interactions) attributes converge consequently along the main

FIGURE 13.8 Columbia River Gorge, looking upstream from Crown Point State Park. This tidewater section of river is just downstream of Bonneville Dam, the lowermost dam on the river (PHOTO BY A. C. BENKE).

stem. The noted historian Richard White, in his wonderfully insightful book (White 1995), characterized the river as an organic machine, a metaphor that uniquely captures the essence of the Columbia: a complex, natural-cultural system, constantly changing in time and space. The main-stem Columbia is a high-volume, high-gradient, and therefore powerful river, fed by snowmelt from vast headwater mountain ranges. Historically, it was the conveyance and habitat for enormous and diverse salmon and steelhead runs, equally diverse native peoples, and a wide variety of immigrants from all

over the world. The native peoples lived at specific sites along the river corridor for at least 10,000 years, loosely united by their salmon culture (Cressman et al. 1960, Butler 1993). In less than 200 years the immigrants used labor and ingenuity to parlay water, salmon, and water power into capital, ultimately creating a legacy that fished, dammed, diverted, farmed, and urbanized the river into an organic machine (White 1995). Indeed, the Columbia River today is among the most developed of the world's great rivers and its salmon and native people have suffered in consequence.

Physiography, Climate, and Land Use

The main stem of the Columbia may be divided into three physiographic domains. The coastal rain-forest segment from Columbia Gorge (see Fig. 13.8) through the Cascade Range to the estuary at Astoria cuts through the Cascade–Sierra Nevada (CS) and Pacific Border (PB) physiographic provinces (see Fig. 13.23). The dry interior segment of the river in the Cascade rain shadow cuts through the Columbia–Snake River Plateaus (CU) province from Kettle Falls at the United States–Canada border to the Columbia Gorge. The headwaters segment from its source at Columbia Lake in British Columbia to Kettle Falls cuts through the Rocky Mountains in Canada (RM), the Coast Mountains of British Columbia and Southeast Alaska (PM), and the Northern Rocky Mountains (NR) provinces. Additional major headwater tributaries are the Kootenay and Pend Orielle (combined Flathead and Clark Fork flows) that originate in the Precambrian Belt Series formations of the Rocky Mountains and adjacent western ranges. The Okanagan, Methow, Wenatchee, Yakima, and Spokane are the major mid-Columbia tributaries that drain the volcanic Cascade Range. The main stem becomes a 9th order river at its confluence with the Snake in the middle of the Columbia–Snake River Plateau province.

The highest point in the basin is Mount Rainier at 4392 m, one of several Cascades volcanoes that dominate the scenery when viewed westerly from the river in the interior. Many mountains in the headwaters rise above 3500 m, however, and frame the river valleys of the subbasins. The elevation of Columbia Lake is 810 m asl; thus, the average gradient of the main stem is about 0.41 m/km.

Out of the 13 terrestrial ecoregions found in the entire Columbia basin, the main-stem river actually passes through 10 of them. Its upper reaches in Canada and northern Washington drain from a wide diversity of coniferous forests, including those in the North Central Rockies Forests, the Okanagan Dry Forests, and the Cascade Mountains Leeward Forests ecoregions. After passing through the coniferous forests of northeastern Washington, the main stem enters the arid and much flatter Palouse Grasslands and Snake/Columbia Shrub Steppe ecoregions, much of which has been converted to agriculture. After flowing many kilometers through the shrub steppe, the river eventually crosses through the following forested ecoregions on its path to the Pacific: Eastern Cascades Forests, Central and Southern Cascades Forests, Willamette Valley Forests, Puget

Lowlands Forests, and Central Pacific Coastal Forests. Most of these ecoregions are dominated by conifer forests, except in the developed lowlands and valleys.

The climate is extremely variable along the main stem. The continental air masses often dominate the Columbia Valley in British Columbia resulting in winter temperatures commonly -40°C or colder; summers are correspondingly cool. In extreme contrast, the interior is dry and hot, often exceeding 38°C . Precipitation can exceed 350 cm/yr in the Purcell Mountains fringing the river in British Columbia and in the Cascades, mostly deposited as winter snow, but snowpack along the river rarely exceeds 1 m. Along the river near Richland, Washington, in the very dry interior, precipitation is less than 20 cm/yr and snow is rare. Using monthly averages collected throughout the basin, it appears that basinwide precipitation is generally highest from November through January and lowest in July and August (Fig. 13.24). However, it should be kept in mind that this is a crude approximation of monthly averages and that they vary greatly throughout the basin.

Land use in the Columbia Valley below Columbia Lake is largely pasture-based ranching and recreational development. Downstream there are a few localized wood-products and mining operations, but the economy of the Canadian portion of the Columbia is based on hydropower and recreational fishing in the reservoirs and urban and exurban development associated with the full array of recreation opportunities in the adjacent mountains. In contrast, agriculture is a key economic driver on the U.S. portion of the river, driven by irrigation from the river. Water diversion facilitated by the Grand Coulee Dam provides irrigation water to 730,000 ha of former scrubland now converted to orchards and row crops in the area from Moses Lake to Pasco, Washington. From the Okanagan River confluence (north-central Washington) to Bonneville Dam (just east of Portland) irrigation water is pumped from the river via many different intakes to the adjacent terraces and uplands along the river. All of the pump intakes and other diversion structures have been screened at enormous expense to prevent entrainment of salmon and steelhead juveniles. The dominant crops are apples, cherries, and other fruits, but hops and poplar (pulp wood) plantations are common, all substantially subsidized by federal hydropower development that provides cheap electricity and the complex irrigation infrastructure that delivers water to the farms (White 1995).

River Geomorphology, Hydrology, and Chemistry

Throughout its 2000 km length the main-stem river is predominately constrained within canyons. In the headwaters, the river cuts through the mountain ranges of British Columbia. In the middle reaches, the river geomorphology was determined largely by glacial floods, particularly the Lake Missoula floods of 13,000 to 15,000 years ago. These floods entrenched the main-stem channel deep within the ancient lava (basalt) formations of the Columbia Plateau, laid down some 30 million years ago. The lower river cuts through the Cascades and the coastal ranges in deep gorges, finally spilling into the ocean through a small estuary. In 1811, Canadian surveyor David Thompson noted that the river was 800 to 1000 m wide at base flow but narrowed to ~50 m at the great cataracts of the Dalles des Morts (death rapids) in the lower river and Kettle Falls (Nisbet 1994). The channel was a uniform, undivided ribbon with only a few islands and rapids throughout its 2000 km length. Unpublished predam surveys of the area that was inundated by John Day Reservoir show large gravel bars very similar to the huge Vernita Bar, famous as a fall chinook spawning site historically and today, downstream of Priest Rapids Dam in the unimpounded Hanford Reach (Fig. 13.9). This 75 km river segment is the last major spawning and rearing area for salmon left on the main stem. Sand deposited high on the shoreline during floods and reworked into dunes by wind and sandstorms plagued early travelers on the interior portions of the river. Mid-channel sand bars, shoals, and a shifting array of fringing floodplain wetlands were common in the tide zone of the river from the Willamette confluence downstream. Today the river is almost totally impounded by dams (see Fig. 13.23) and the tidewater reach is routinely dredged to accommodate ship traffic to Portland, Oregon.

The main-stem Columbia has a spring snowmelt hydrograph that is considerably moderated (flattened) by winter rains in the Cascade and coastal ranges, and by the dams (see Fig. 13.24). Sixty percent of the variation in annual runoff is coherent with the El Niño circulation pattern of the Pacific Ocean. Strong El Niño years tend to be dry (Redmond and Cayan 1994). Mean discharge at the mouth is 7730 m³/s. Major floods, five times the average flow, occurred in 1894 (the largest), 1876, 1894, and 1948, with the latter completely destroying Vanport, built on the floodplain near Portland and then the 2nd largest city in Oregon with 20,000

residents. Prior to the dams, flooding occurred annually and with great power owing to gradient and canyon constraint. Thompson noted trees 1 m in diameter suspended on rock ledges 14 m above the base flow level of the river at the Dalles rapids (White 1995). Of course, today flooding has been mostly eliminated by impoundments throughout the basin.

Main-stem water-quality problems are generally related to urban and agricultural runoff, latent heat storage in the reservoirs, and the legacy of plutonium manufacture and atomic energy research at the Hanford Nuclear Reservation (originally called the Hanford Engineer Works) upstream from Richland, Washington. Concern exists for radioactive isotope and heavy metal (particularly arsenic and aluminum) pollution of groundwater discharging into the river from the reservation and contaminated sediments retained in McNary Reservoir downstream. Toxic chlordane and PCBs from urban runoff and air pollution are a concern in the Columbia Slough, a remnant of a complex of shifting floodplain wetlands encompassing the confluence with the Willamette River. Hot-water pollution from Hanford, a chronic problem during the years of reservation nuclear reactor operations, has ceased, but the impoundments increase heat retention and much of the main stem from McNary Reservoir to the estuary periodically experiences summer water temperatures above 21°C that can induce severe stress if not cause death of native salmon and steelhead adults and juveniles. Dissolved nitrogen and carbon dioxide entrainment causes gas bubble disease in fishes when very turbulent water is spilled over the dams at high flows. Changes in spillway architecture to reduce turbulence have eliminated much of this chronic problem, and intentional spill, coupled with fish guidance structures to bypass salmon juveniles migrating downstream (as an alternative to turbine entrainment), has resulted in nearly 100% dam passage survival at some of the dams. Survival associated with reservoir passage is much lower due to predation (Williams 2005). Water-quality records of the U.S. Geological Survey from 1993 to 2003 provide the following average measures at the Beaver Army Terminal downstream of Portland: turbidity 8.2 NTU, specific conductance 135.4 µS/cm, alkalinity 51.9 mg/L as CaCO₃, NO₃-N 0.26 mg/L, phosphorus (total) 0.06 mg/L, calcium 13.9 mg/L, magnesium 4.0 mg/L, sulfate (water, filtered) 8.9 mg/L, cadmium (water, filtered) 0.05 µg/L, lead (water, filtered) 0.55 µg/L, aluminum (water, filtered) 12.09 µg/L, arsenic 1.05 µg/L, DDE 0.005 µg/L, dieldrin 0.002 µg/L, and PCB 0.15 µg/L. Values were similar at a monitoring site

River Biodiversity and Ecology

The main-stem Columbia River flows through two of the three freshwater ecoregions of the basin: the Columbia Glaciated ecoregion from its headwaters to just above the Washington–Oregon border and the Colorado Unglaciated ecoregion from there to the Pacific (Abell et al. 2000). The ecology of the main stem is a reservoir story with periodic retrospectives about the historic river that is now predominately

inundated and progressively invaded by nonnative biota more in tune with lacustrine than dynamic riverine conditions, such as bass and walleye. Many reservoirs fisheries studies exist, particularly focused on assessments of salmon survival during in and out migration. These were reviewed in detail by Independent Scientific Group (2000). Here we summarize the limited biotic data for the free-flowing segments, mainly the Hanford Reach.

Algae and Cyanobacteria

Algal assemblages in the Hanford Reach of the Columbia River include biofilms (periphyton) that

grow profusely on the permanently wetted portion of the channel, where the substratum is rocky, and phytoplankton. Benthic algal assemblages include the filamentous green algae *Ulothrix* and *Cladophora* and a rich benthic diatom flora, including the genera *Gomphonema*, *Nitzschia*, *Cocconeis*, *Melosira*, *Synedra*, *Achnanthes*, and *Cyclotella* (Neitzel et al. 1982). Phytoplankton populations are abundant in the reach, but are mostly derived from rich populations in the upstream impoundments. Spring population peaks are dominated by *Asterionella formosa* and *Fragilaria crotonensis*; the latter species often dominates the fall population peak. Other significant genera include *Tabellaria*, *Synedra*, and *Melosira* (Cushing and Rancitelli 1972, Cushing 1967).

Plants

The riparian zone of the main stem was limited historically, simply because much of the area through which the river flows is arid and the river was so constrained by its canyons that little floodplain existed. Hence, the riparian zone was mainly black cottonwood and various willow species growing on limited expanses of exposed gravel bars and floodplain benches near the river channel. Except for limited areas of wetlands created by impoundment, the perimeters of the reservoirs are either riprapped to prevent erosion and thus have no vegetation or are marked by a thin fringe of willows on sandy shorelines. Two notable exceptions exist. The floodplain wetlands of the unregulated river segment from Columbia Lake to Kenbasket Reservoir near Golden, British Columbia, remain intact and ecologically functional, with large, black cottonwood gallery forests and apparently rich but undocumented understory and aquatic plant communities. A fringing wetlands and island system associated with the tide zone also exists from the Willamette confluence downstream. Here cottonwood, ash, and willow stands are dispersed around sloughs and floodplain lakes that abound with aquatic and semiaquatic plants, such as scouring rushes (*Equisetum arvense*, *E. telmateia*, *E. hyemale*), wapato, cow parsnip, cattail, camas, and bracken fern. Roots (or meristem shoots of scouring rushes) of all of these plants, especially wapato and camas, were important food of Native Americans. A wide variety of native pondweeds also are present in these wetlands.

Invertebrates

Newell (2003) listed 145 macroinvertebrate taxa that have been identified from the free-flowing Hanford Reach since 1951, although far fewer are

present today. Net-spinning caddisflies (*Hydropsyche*, *Cheumatopsyche*), ephemereid (*Ephemerella*) mayflies, three genera of stoneflies (*Isogenus*, *Perlodes*, *Pteronarcys*), and chironomid midges were notably abundant. Additional caddisflies collected since 1951 include *Brachycentrus*, *Glossosoma*, *Hydroptila*, *Lepidostoma*, *Leptocella*, and *Rhyacophila*, and additional mayflies include *Ephemerella*, *Ephoron*, *Hexagenia*, *Heptagenia*, *Stenonema*, and *Tricorythodes*. Other taxa found since 1951 include stoneflies (*Arcynopteryxa*), mollusks (*Pisidium*, *Fluminicola*, Asiatic clam, western pearlshell), and crustaceans (*Corophium*, *Pacifastacus*, *Gammarus*). Considering that the Hanford Reach remains similar to the historic condition of the rest of the main stem, it seems likely that the main-stem river historically throughout its length contained a rich food web that supported substantial salmon production.

Today, a rich phytoplankton community and abundant fine particulate organic matter support a dominant macroinvertebrate population of net-spinning caddisflies (*Hydropsyche* and *Cheumatopsyche*), chironomids, and other filter-feeding organisms (mollusks), although many invertebrate genera found prior to dam closures upstream and downstream from the Hanford Reach are no longer found. The lower river reservoirs also have been colonized by estuarine amphipods.

Vertebrates

Among the 65 native fishes of the Columbia basin, at least 12 anadromous species existed (Ward and Ward 2004). Most notably, chinook salmon and white sturgeon spawned on the formerly abundant gravel and cobble bars throughout the main stem. Moreover, the main stem likely was an important rearing and presmolt conditioning area for main-stem and tributary fishes, but this was not firmly documented before overfishing and dam operations began to substantially constrain natural production. Indeed, the great salmon fisheries crash of the Columbia occurred because management focused mostly on adults and hatchery operations with blind regard to habitat constraints as attempts were made to compensate for extreme reductions in population size and structure associated with overfishing of the stocks from 1880 to 1930 (Lichatowich 1999). Perhaps the largest run of anadromous fishes today is American shad, a nonnative species.

Like the anadromous species, the native resident fishes of the Columbia River have been extensively impacted by the numerous dams along its main stem and the attendant change of the environment from

lotic to lentic conditions. Ward and Ward (2004) point out that although the total number of fish species prior to dam building is unknown, there are currently at least 53 native resident species in the Columbia basin. The most species-rich families are the Cyprinidae (12), Catostomidae (6), Cottidae (13), and resident Salmonidae (14 species or subspecies). Stober and Nakatani (1992) have estimated that there are 61 fish species (native and nonnative) in the main stem between Lake Bonneville and Lake Roosevelt (Grand Coulee Dam). Native coldwater species such as kokanee, mountain whitefish, and white sturgeon still provide important sport fisheries in different reaches of the river. Native nonsport species important in ecosystem food webs in the main stem include the northern pikeminnow, Pacific lamprey, peamouth, chiselmouth, largescale sucker, bridgelip sucker, and redbelly shiner (Stober and Nakatani 1992).

At least 53 nonnative fish species have been introduced to the Columbia basin, bringing the total number of fish species to approximately 118. Many nonnative fishes reside in the reservoirs, including popular sport fishes, such as walleye, smallmouth bass, and yellow perch (Stober and Nakatani 1992). Prominent among the nonnative species are several additional Centrarchidae (nine species) and Ictaluridae (eight species) (Stober and Nakatani 1992, Ward and Ward 2004). The combination of dams and predatory nonnative species is suspected to have caused substantial declines in native resident species, as well as the more publicized anadromous species. Li et al. (1987) noted that the proportion of nonnatives was far less in the free-flowing Hanford Reach than in the reservoirs.

The Columbia Wetlands in the headwaters is a major waterfowl production area, used by most of the western North American ducks, geese, swans, and cranes. Bald eagle and other raptors nest in the area and muskrat, raccoon, river otter, painted and pond turtle, and a wide variety of other wildlife are present. The lower river wetlands also are important waterfowl production and resting areas, as are portions of some of the reservoirs, such as the head of McNary Reservoir at the confluence with the Yakima. The riparian areas and wetlands of Columbia Slough provide cover and food for over 120 species of birds.

Ecosystem Processes

The size and complexity of the Columbia River make detailed studies of ecosystem processes difficult, particularly in the postdam era. Nevertheless,

studies of periphyton and phytoplankton productivity have been undertaken in the Hanford Reach. Cushing (1967) found net production rates of periphyton biomass ranging from 0.005 mg DM cm⁻² d⁻¹ in winter to 0.070 mg DM cm⁻² d⁻¹ in August; mean value for the 10-month experiment was 0.029 mg DM cm⁻² d⁻¹. Neitzel et al. (1982) report ¹⁴C uptake values ranging from zero (in winter) to 0.033 mg C L⁻¹ hr⁻¹ in June and September.

Although ecosystem processes of the Columbia River prior to dams can only be guessed, it is clear that the natural and cultural history of this large-river ecosystem revolved around salmon. The Columbia as a whole historically produced more chinook and coho salmon and steelhead than any other river in the world (Netboy 1980). It is unknown how many fishes were conveyed annually to spawning grounds in the main stem and the many tributaries. The Northwest Power Planning Council, in developing its salmon recovery goals for the river during the 1990s, concluded that 10 to 16 million chinook, chum, coho, sockeye, pink salmon, and steelhead annually entered the river prior to commercial fishing (National Research Council 1996). Some scientists view this as an absurdly conservative number given the size and complexity of the Columbia system. In any case, there were enough salmon to populate every major tributary from the river mouth to the Rocky Mountains some 2000 km inland. Only the upper Pend Oreille (including the Clark Fork and Flathead) and upper Snake were blocked by falls that the salmon could not ascend. Chinook dominated the run, with 8 to 10 million fish, including "June hogs" of the main-stem summer run to areas above Grand Coulee that commonly exceeded 25 kg each.

This dynamic salmon ecosystem obviously was driven by the connectivity of the main stem to the tributary network and the estuary. Water, sediment, nutrients, and organic matter transported by the river created habitat for the various life stages of the fishes. By dying in great numbers after spawning, the fishes undoubtedly enriched system productivity (Schindler et al. 2003), although the pathways for this transformation of marine-derived energy and nutrients are not clearly understood in the Columbia or any other salmon river ecosystem. In any case, many millions of juvenile salmon made their way back to the ocean from the spawning grounds annually. Chums, pinks, and sockeye migrated out with urgency in huge numbers, coherent with the speed of the main-stem flow, while the more individualistic chinook, coho, and steelhead dallied in the river and estuary of the Columbia or adjacent coastal areas, feeding and

growing into robust smolts, energetically fit for ocean survival and return to the river. Hence, the salmon ecosystem includes (1) the tributary network, where complex processes that entrain and transform nutrients and organic matter from the uplands into productive salmon habitat; (2) the main-stem conduit to the estuary that likewise was characterized by complex materials flux and transformation processes; (3) the estuary and coastal zone, where the fishes acclimated to salt water on the way out and freshwater on the way in; and (4) the variable environments of the north Pacific Ocean.

Connectivity of the river channel to its riparian floodplain zone was extremely important. Bank storage of water during floods drained back into the river during lower flows, naturally cooling the river in the hot summers of the interior when the flow in the river was lowest. The riparian forest of cottonwood and willow, although limited on the main stem, nonetheless provided leaves and tree boles to the channel that were food sources and attachment sites for invertebrates and other fish forage. Backwaters created by flood scour were rich in aquatic plants and other invertebrates and provided resting and feeding areas for very young salmon.

Owing to abundant salmon, white sturgeon, freshwater clams, and aquatic plants with nutritious roots in the backwaters, many native cultures existed along the river but were focused on several rapids where the fishes could be caught with dip nets as they jumped upstream. First in sequence from the ocean was the Cascades, where Bonneville Dam exists today (hence the name of the mountain range through which the river passes in the narrow Columbia Gorge that included the rapids), then the Dalles with its Celilo Falls upstream, Priest Rapids upstream from the Yakima confluence, and finally at Kettle Falls far upstream at the United States–Canada border. Location was important because the fishes entering the river had high caloric content from fat stored for the long, tough journey inland. Caloric content declined with distance upstream. Only 50% was left by the time the fishes got to the Nez Perce people at the confluence of the Snake, and they were 75% depleted at the Kutenai tribal fishing site on the Kootenay River near Nelson, British Columbia.

The Dalles was an especially important native fishing site because the fish were still in very good shape at that point in the migration, and they could be caught in large numbers by dip netting the fish as they jumped up the cataracts. Indeed, 500 fishes per day could be taken by a single fisherman. The dry air of the site (owing to the rain shadow of the Cascade

Mountains) allowed efficient drying of the fishes for long-term storage. The 600 or so native residents at Celilo Village at the Dalles swelled to over 3000 during the salmon season (Ross 1969).

For the native people of the Columbia, salmon belonged to everyone and thus were not currency. Trade involved things other than salmon, such as dentalium shells, and early explorers had difficulty “buying” salmon initially. The natural tendency of the native people was to allow most of the fishes to pass to the spawning grounds and elaborate ceremonies expressed anxiety about future returns rather than concern for maximum possible harvest. Hence, salmon and people coexisted on the Columbia for thousands of years. The immigrants of course did not see it that way and their legacy is one of total exploitation of the salmon runs and maximum development of the river for transportation, hydropower, and farming, which they accomplished in less than 200 years (White 1995).

Human Impacts and Special Features

Today, 15 huge dams impound most of the main stem and, along with the big storage reservoirs in the headwaters, totally regulate the flow of the river. The main-stem dams back water from one to the next throughout the river corridor from Bonneville, the most downstream dam, to Mica, far upstream in British Columbia. Indeed, only three flowing reaches remain: the headwaters from Columbia Lake to the first main-stem reservoir (Kenbasket), the Hanford Reach from Priest Rapids Dam to McNary Reservoir, and the tidewater segment from Bonneville Dam at the Cascades to the estuary. Rock Island Dam, a public utility project in the mid-Columbia, was the first main-stem dam, completed in 1932, and was built with fish ladders to pass migrating salmon around the dam. Then came the concrete behemoths—Bonneville and Grand Coulee—that the federal government completed in 1938 and 1941, respectively, the latter with no fish passage and thus blocking salmon from over 1500km of prime river habitat. The 1964 Columbia River Treaty between the United States and Canada funded Mica, Keeleyside, and Duncan dams with U.S. money. The United States gained flood control and both countries gained enormous power benefits, but Canada lost its Columbia River salmon runs entirely. Revelstoke Dam completed the impoundment of the main-stem Columbia in 1984.

The main-stem dams were justified not just for production of hydropower for the cities but also to

provide power to massive pumps that irrigate thousands of hectares along the river. Apple and cherry orchards, vineyards, hops plantations, and, believe it or not, water-loving poplar plantations for paper pulp line both sides of the river, abruptly changing the brown desert landscape of the uplands to verdant green. Thus, hydropower subsidizes agriculture throughout the lower main stem to Columbia Gorge. All of the pumps are screened at great expense to prevent entrainment of fishes.

The dams also vastly simplified barging commerce on the river by impounding the rapids. Most of the grain grown throughout the basin is transported from railheads at Lewiston, Idaho, to the oceanic shipping docks in Portland via barges that slide along the river like massive snails.

The reservoirs of the river provide recreation in many forms. The winds that howl through the Columbia Gorge provide some of the best board sailing in the world and sport fishing is a huge economic boon as anglers focus on abundant walleye, smallmouth bass, sturgeon, and salmon. But these fisheries are almost entirely a consequence of invasion of nonnatives up the reservoir-dominated environment of the main stem and sport fishing and commercial fishing in the Columbia is decidedly at odds with conservation of native wild stocks.

Over 200 distinct stocks (populations) of all five species of Pacific salmon plus an array of steelhead life-history types historically passed through all or part of the main stem (Nehlsen et al. 1991). Almost all of them are extirpated or extinct today. Most of the remaining stocks are listed as threatened or endangered (www.nwr.noaa.gov/1salmon/salmesa 2004). All of the listings in some way pertain to the main stem because it is the migratory pathway to the ocean from the tributaries. That some survive in this intensively regulated system is a testament to the resiliency of the beasts. For example, a few chum salmon return annually to spawn in a single spring system that emerges through the dredge spoils on the north bank of the river adjacent to the urbanized area of Vancouver, Washington, across from Portland.

Impoundment of the main stem is a major impediment to salmon recovery because of negative influences on food web structure and feeding habits of juvenile salmon. Juvenile salmon in the Hanford Reach feed on newly emerged adult midges, hydropsychid caddisflies, and shallow-water zooplankton. These insects, plus zooplankton discharged from the reservoir, are important food for salmon in

the unimpounded reach below Bonneville Dam. In contrast, the river downstream from Grand Coulee is impounded by 10 run-of-the-river dams and therefore turnover of water is rapid, from days to a few weeks depending on river discharge. Thus, the reservoirs function rather like the estuary; they are shallow at the head and deeper near the dam, with shifting sandy bottoms and rapid water exchange. From McNary downstream they have been colonized by estuarine invertebrates *Corophium salmonis* and *Neomysis mercedes*. Apparently these brackish-water amphipods hitched a ride upstream in barges, perhaps those used by the U.S. Army Corps of Engineers to transport salmon as a dam mitigation effort. These two species apparently are the most abundant macroinvertebrates in the reservoirs today, although midges also are abundant. Juvenile salmon migrating through the reservoirs are able to feed on *Corophium* in the shallow-water areas, especially below Bonneville. However, *Neomysis* likely is largely unavailable as a food source because it lives on the bottom of the deeper portions of the reservoirs, rising at night to feed voraciously on zooplankton near the surface. Salmon stay near the surface and are daytime sight feeders. Thus, *Neomysis* avoid fish predation and likely reduce the zooplankton forage base for the salmon. The conclusion is that the reservoirs compromise salmon by increasing temperatures and maintaining nonriverine food webs with voracious predators including native (northern pikeminnow) and nonnative (walleye, smallmouth bass) species. Impoundment has severed the interactive pathways that link the main stem to its tributaries. Ecological connectivity to riparian and backwater environments also has been severed throughout most of the river corridor by the prevention of seasonal flooding and by electrical load variations at the dams that rapidly fluctuate base flow discharge, which periodically dries out and thus sterilizes shallow shoreline environments that are crucial rearing areas. Indeed, even in the Hanford Reach, "raisin fish" or the dried bodies of juvenile fall chinook recently emerged from the redds can be observed annually in backwater areas dried out suddenly by hydropower operations at Priest Rapids Dam. The very young fish cannot endure the power of the main-stem flow without being washed downstream prematurely and thus naturally entrain in the backwaters where they are vulnerable to flow fluctuations.

The main-stem Columbia River is a ribbon of water from the Rockies to the Pacific, slowed and harnessed by dam after dam. The cataracts at the

Cascades, the Dalles with Celilo Falls, and Kettle Falls were the historic gathering places for fishes and people, the social foci of the main river. They lie buried under slack waters that now carry trade, irrigate the interior dry lands, and drive the turbines. The sloughs of the lower river and the wetlands in the headwaters remain as special natural features and the Hanford Reach with its Vernita Bar certainly is important as a salmon refugium. The dams, especially Bonneville and Grand Coulee, are special features to many people. Certainly, the electric light show nightly during the summer produced on the face of Grand Coulee Dam is special as it chronicles the Emersonian triumph of human labor and American capitalism on the Columbia.

But the pervasive persistence of the salmon culture on the Columbia somewhat belies the dam light show. Some \$500 million per year has been spent during the last two decades to enhance Columbia River salmon by federal and state management agencies and the power distributor, Bonneville Power Administration, on a wide array of mitigation actions, such as changes in dam operations and evaluation studies, habitat improvement activities, hatcheries, and a variety of oddly justified actions, such as barging of smolts and payment of bounties to fishermen to harvest native pikeminnow because they prey on salmon smolts as they pass stunned over the dams or through the turbines (<http://www.efw.bpa.gov/cgi-bin/efw/E/Welcome.cgi>). Throughout the basin, 98 hatcheries produce some 2 million smolts annually that spill downstream to the main stem, where they feed pikeminnow, walleye, smallmouth bass, and other predators that flourish in the reservoirs. Less than 1%, usually far less, of the hatchery fishes survive to return as adults, whereas naturally produced fishes, such as those from the Hanford Reach, fare much better, with a 10% or greater return rate. Canadian managers currently are spreading commercial fertilizer in Arrow Reservoir behind Duncan Dam to increase resident fish production, apparently gauged to replace the salmon that can no longer get to Canada. The salmon culture of the Columbia seems substantially confounded for the lack of a unifying management paradigm for recovery (Williams 2005).

Perhaps the dilemma for conservation of the main stem and the large-river portions of the major tributaries in general is best illustrated by the plight of white sturgeon, a giant fish commonly over 3 m long and weighing upward of 500 kg. They were historically numerous in the estuary and deep portions of

the river and migrated into shallow riparian areas to spawn during the spate of spring snowmelt. The ponderous sturgeon cannot ascend the fish ladders at the dams and populations are land locked. White sturgeon remain somewhat numerous only below Bonneville. The remnant upriver populations hang on because water quality in the main-stem rivers is generally good, they are bottom-feeders and therefore have reasonably good food from invertebrate-laced organic matter accumulating in the reservoirs and on river bottoms owing to regulated flow, and they live a long time, 80 years or more (Wydoski and Whitney 2003). They spawn on gravel and cobble scoured clean by high flows and some recruitment does occur because the main-stem rivers do flood some in very wet years. But juvenile sturgeon require shallow, productive habitat for rearing, underscoring the natural ecosystem linkage of the river channel to the riparian floodplains. Most floodplain and riparian habitat, of course, is either totally destroyed or nonfunctional because it rarely floods. But operation of the dams could be done in ways that seasonally flood the remaining nodes of riparian area, specifically as a conservation measure to increase spawning and rearing success (Coutant 2004). Otherwise they will gradually die out like an old-growth forest, no matter how much protection they are accorded.

The future of the Columbia as a salmon river ecosystem is bleak. Columbia salmon and white sturgeon, among other native fishes, are almost gone because it is not really a river any more. Critical ecological connectivity—main stem to tributaries and main stem to riparian floodplains—has been severed by dams and associated activities such as revetments, floodplain deforestation and urban encroachment, and proliferation of hatcheries and nonnative fishes. The dams serve their purpose very successfully and the Columbia is indeed an organic machine driving a huge hydropower, agricultural, and increasingly urban culture. The natural salmon culture of the river remains persistently valued, however. Enhancement of this traditional attribute of the Columbia requires reconnection of the severed ecological pathways (Stanford et al. 1996). In the main stem and the tributaries, additional nodes of functional riverine habitat, like the Hanford Reach, must be identified, naturalized, and reconnected laterally and longitudinally in an ecosystem context by substantially changing dam operations (e.g., permanent reservoir drawdown allowing river habitat to reemerge; implementation of seasonality of flow) and by allowing

natural reproduction without harvest of returning fishes so that the Columbia can regain at least some of its former status as one of the world's great salmon rivers.

ADDITIONAL RIVERS

The Owyhee River drains a region located in the arid reaches of southwestern Idaho, southeastern Oregon, and northern Nevada (Fig. 13.25). A 5th order stream, it flows in a northward direction before joining the Snake River on the Oregon–Idaho border. The Owyhee occupies the driest subbasin in the Columbia River drainage and only 16% of the drainage system flows year-round. Wild and Scenic River designation has been accorded to segments of the main stem and some tributaries. The region is sparsely populated, with only 5% of the basin devoted to agriculture; the majority (82%) of the region consists of shrub-steppe desert. A single dam, impounding Lake Owyhee, is located near the mouth. Only 25 of the 49 fish species present are native, but none are endangered.

The Grande Ronde River flows in a northeasterly direction, draining a little over 10,000 km² of extreme northeastern Oregon and a small portion of southeastern Washington (Fig. 13.27). It is a 5th order stream draining the Blue Mountains and a small area of Palouse Grassland before entering the Snake River just north of the Oregon–Washington–Idaho juncture (Fig. 13.1). Wild and Scenic designation has been given to portions of several tributaries and the lower Grande Ronde itself. Of the 38 species of fishes found in the Grande Ronde, 23 are native and 4 are endangered or threatened (fall Chinook salmon, spring/summer Chinook salmon, steelhead trout, and bull trout). Two hydropower dams are present in the system. The higher elevations of the drainage basin are forested and the lower regions are devoted to rangeland and limited agriculture.

The 7th order Clearwater River and its major tributaries (North, Middle, and South forks) drain a large area of the lower Idaho panhandle, extending from the Montana border westward to its confluence with the Snake River at the eastern border of Washington state (Fig. 13.29). The basin is 80% forested and the river contains 30 species of fishes, 19 of which are native (2 endangered; steelhead trout and fall Chinook). The Middle Fork of the Clearwater and its two major tributaries, the Lochsa and Selway rivers, are free flowing and designated as National Wild and Scenic Rivers. The North Fork (Fig. 13.10)

is blocked near its mouth by Dworshak Dam, a major hydroelectric and storage facility in the Columbia basin. Located as it is, essentially at the mouth, and with no fish passage facilities, the dam has eliminated historic runs of salmon and steelhead trout.

The 6th order Spokane River drains portions of the northern Idaho panhandle and eastern Washington (Fig. 13.31). It flows in a northwesterly direction before joining the Columbia River approximately 80 km west of Spokane. The basin is largely forested, with portions occurring in the Palouse Grassland ecoregion. One major lake, Lake Coeur d'Alene, is present and the largest tributary is the St. Joe River, one of the longest free-flowing rivers in the Columbia River basin. Twenty-four species of fishes are found in the basin, none of which are endangered. Six low-head dams for diversion and hydropower are present. Most of the basin is lightly populated, with the highest concentration living in Spokane, Washington, the largest city in the interior Columbia basin (Fig. 13.11).

The Methow River is a free-flowing 5th order stream in northern Washington, just south of the Canadian border (Fig. 13.12). It flows in a southerly direction before joining the Columbia River at Pateros (Fig. 13.33). The Methow has a relatively small basin (4831 km²) lying just east of the crest of the Cascade Mountains; small parts of the eastern basin are in the Palouse Grasslands. Of the 32 species of fishes present, 25 are native and 3 (steelhead trout, Chinook salmon, and bull trout) are endangered or threatened. The headwaters are in wilderness and the North Cascades National Park, and the Chewak River is a major tributary. Seven small irrigation-diversion dams are in the basin, which is lightly populated.

The 6th order John Day River drains a large area of north-central Oregon, flowing northwest and north before joining the Columbia River on the Oregon–Washington border (Fig. 13.35). The northern region of the drainage, prior to entering the Columbia River (Fig. 13.13), is arid, whereas the headwater regions are forested, mainly draining the Blue Mountains. The North, Middle, and South forks are the main tributaries. The region is extremely sparsely populated; 85% of the basin is scrub and rangeland. Of the 27 species of fishes present, 17 are native. The system is largely unregulated except for irrigation diversions. Three segments are designated as Wild and Scenic, and the river contains two of the last remaining intact wild populations of anadromous fishes in the Columbia River basin (spring Chinook salmon and summer steelhead trout).

FIGURE 13.14 Cowlitz River at Randle, Washington (PHOTO BY TIM PALMER).

The Cowlitz River, a 5th order stream, originates in the Cascade Mountains, flowing west and then south before draining into the Columbia River in the Puget Sound Lowlands near Longview, Washington (Fig. 13.37, Fig. 13.14). The drainage basin is largely forested. The system was heavily impacted by the 1980 Mount St. Helens eruption; it was choked by sediments but is gradually recovering. Thirty-two species of fishes are present and two are endangered or threatened (steelhead trout and chum salmon). The Toutle River is a major tributary and was even more heavily impacted by the St. Helens eruption. Three hydroelectric dams are on the main stem, impounding Mayfield and Riffle lakes.

ACKNOWLEDGMENTS

Preparation of this chapter was supported by the Jessie M. Bierman Professorship at the Flathead Lake Biological

Station. The authors thank Phil Matson, Marie Kohler, and Morris Uebelacker for research and editorial help.

FIGURE 13.16 Mean monthly air temperature, precipitation, and runoff for the Flathead River basin.

FLATHEAD RIVER

Relief: 1676 m

Basin area: 22,241 km²

Mean discharge: 340 m³/s

River order: 6

Mean annual precipitation: 56 cm

Mean air temperature: 8.6°C

Mean water temperature: 11.1°C

Physiographic provinces: Northern Rocky Mountains (NR), Rocky Mountains in Canada (RM)

Biome: Temperate Mountain Forest

Freshwater ecoregion: Columbia Glaciated

Terrestrial ecoregions: North Central Rockies Forests, Montana Valley and Foothills Grasslands

Number of fish species: 29 (12 native)

Endangered species: 1 fish (threatened), 1 plant (threatened)

Major fishes: bull trout, westslope cutthroat trout, lake trout, mountain whitefish, lake whitefish, pigmy whitefish, sculpin, peamouth chub, longnose sucker, largescale sucker, northern pikeminnow

Major other aquatic vertebrates: spotted frog, boreal toad, painted turtle, tailed frog, three-toed salamander, beaver, river otter, mink, osprey, bald eagle, American merganser, harlequin duck, water ouzel

Major benthic invertebrates: caddisflies (*Parapsyche*, *Arctopsyche*, *Hydropsyche*, *Cheumatopsyche*, *Glossosoma*, *Brachycentrus*, *Rhyacophila*), stoneflies (*Taeniopteryx*, *Pteronarcys*, *Pteronarcella*, *Hesperoperla*, *Claassenia*, *Isocapnia*, *Paraperla*), mayflies (*Rhithrogena*, *Baetis*, *Ephemerella*, *Drunella*), true flies (*Chironomidae*, *Simuliidae*, *Hexatoma*, *Atherix*), crayfish (signal), mollusks (*Margaritinopsis*)

Nonnative species: lake trout, lake whitefish, kokanee, yellow perch, northern pike, rainbow trout, brook trout, largemouth bass, smallmouth bass, pumpkinseed, black bullhead, virile crayfish

Major riparian plants: black cottonwood, green alder, coyote willow, sandbar willow, Drummond's willow, red-osier dogwood, Englemann spruce, beaked sedge, other sedges, floodplain Drayas, spotted knapweed

Special features: National Wild and Scenic River segments; 42% of upper basin designated national park or wilderness; Flathead Indian reservation; three National Wildlife Refuges; Flathead Lake largest (surface area) lake in western United States

Fragmentation: two major dams (Hungry Horse, Kerr); Flathead Irrigation Project has 17 reservoirs

Water quality: relatively free of major pollutants; pH = 8.1, alkalinity = 86 mg/L as CaCO₃, NO₃-N = 0.050 mg/L, PO₄-P = <0.001 mg/L

Land use: 80% forest/alpine, 10% range, 8% agriculture, 2% urban

Population density: 2.7 people/km²

Major information sources: Stanford and Hauer 1992, Stanford and Ellis 2002, <http://water.usgs.gov/nwis> 2003, <http://www.wcc.nrcs.usda.gov/climate/wetlands.html> 2003

FIGURE 13.15 Map of the Flathead River basin. Physiographic provinces are separated by a yellow line.

FIGURE 13.18 Mean monthly air temperature, precipitation, and runoff for the Snake River basin.

Snake/Salmon River

Relief: 3048 m

Basin area: 281,000 km²

Mean discharge: 1565 m³/s

River order: 8

Mean annual precipitation: 36 cm

Mean air temperature: 9.1°C

Mean water temperature: 11.5°C

Physiographic provinces: Columbia–Snake River Plateaus (CU), Northern Rocky Mountains (NR), Middle Rocky Mountains (MR), Basin and Range (BR)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregions: Columbia Glaciated, Columbia Unglaciated, Upper Snake

Terrestrial ecoregions: Snake/Columbia Shrub Steppe, Palouse Grasslands, Blue Mountain Forests, South Central Rockies Forests, North Central Rockies Forests

Number of fish species: 39 (19 native)

Endangered species: 5 fishes (4 threatened, 1 endangered), 6 snails (1 threatened, 5 endangered), 1 plant (threatened)

Major fishes: Yellowstone cutthroat trout, chinook salmon, steelhead, rainbow trout, bull trout, mountain whitefish, chiselmouth, carp, northern pikeminnow, longnose dace, speckled dace, Utah chub, yellow perch, black crappie, redbreasted shiner, largescale sucker, pumpkinseed, smallmouth bass, largemouth bass, sculpin

Major other aquatic vertebrates: northern leopard frog, Columbia spotted frog, tailed frog, western painted turtle, wood duck, mallard duck, Canada goose, trumpeter swan, sandhill crane, great blue heron, white pelican, bald eagle, osprey, beaver, river otter, muskrat

Major benthic invertebrates: caddisflies (*Brachycentrus*, *Glossosoma*, *Arctopsyche*, *Cheumatopsyche*, *Hydropsyche*), mayflies (*Baetis*, *Drunella*, *Ephemerella*, *Rhithrogena*, *Tricorythodes*), stoneflies (*Sweltsa*, *Zapada*, *Claassenia*, *Hesperoperla*, *Skwala*), true flies (*Chironomidae*, *Simulium*, *Tipula*), mollusks (*Pyrgulopsis*, *Valvata*, *Physa*, *Taylorconcha*)

Nonnative species: smallmouth bass, walleye, largemouth bass, carp, brown bullhead, black crappie, mosquitofish, pumpkinseed, yellow perch, brown trout, brook trout, channel catfish, black bullhead, bluegill, New Zealand mudsnail

Major riparian plants: black cottonwood, red-osier dogwood, willow, alder, purple loosestrife

Special features: headwaters of Snake in Yellowstone and Grand Teton National Parks; several tributaries are National Wild and Scenic Rivers; midchannel islands of central Snake created by late Pleistocene flooding from glacial Lake Bonneville (Deer Flats National Wildlife Refuge); Salmon River's "River-of-No-Return"

Fragmentation: several major dams on main stem, including three dams in Hells Canyon

Water quality: agricultural runoff in middle reaches; pH = 7.9, alkalinity = 69 mg/L as CaCO₃, NO₃-N = 0.37 mg/L, PO₄-P = 0.02 to 0.06 mg/L

Land use: 10% to 15% forest/alpine, 50% scrub/rangeland, 30% agriculture, 4% barren, 1% urban

Population density: 15 people/km²

Major information sources: Hauer et al. 2002, Hauer et al. 2003, Hauer and Lorang 2004, <http://water.usgs.gov/nwis> 2003, www.wcc.nrcs.usda.gov/climate/wetlands.html 2003

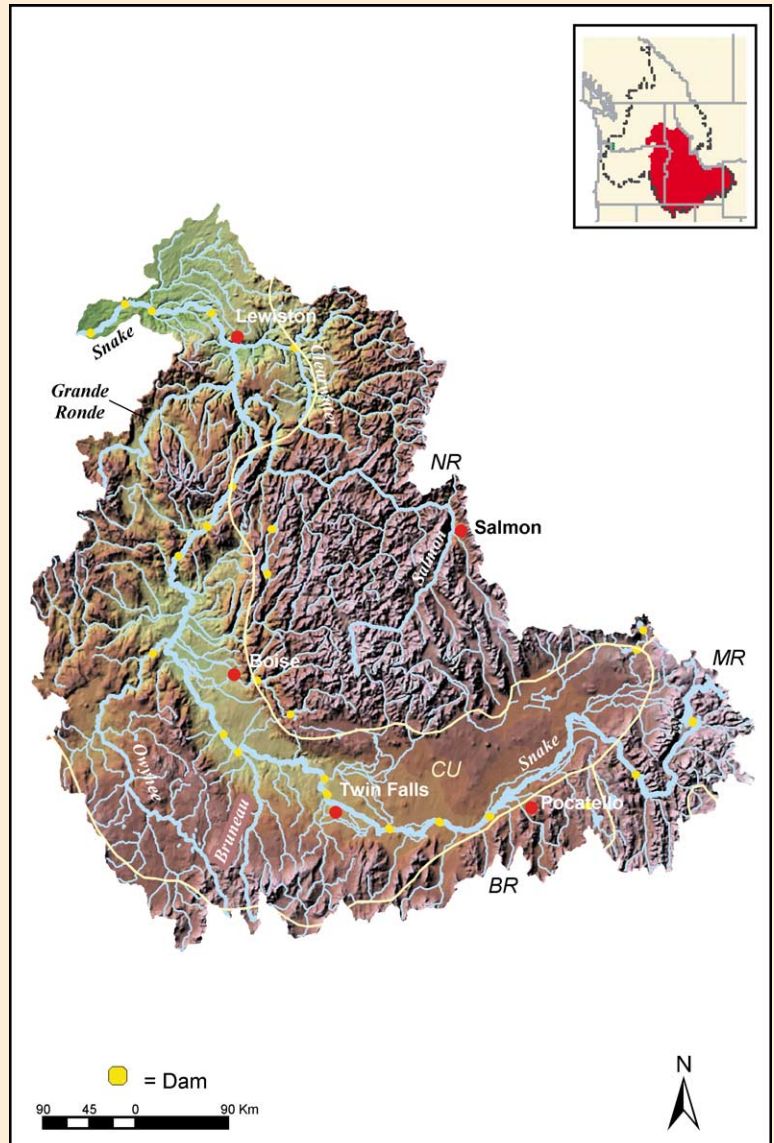

FIGURE 13.17 Map of the Snake River basin. Physiographic provinces are separated by yellow lines.

FIGURE 13.20 Mean monthly air temperature, precipitation, and runoff for the Yakima River basin.

YAKIMA RIVER

Relief: 2334 m

Basin area: 15,900 km²

Mean discharge: 102 m³/s

River order: 5

Mean annual precipitation: 19 cm

Mean air temperature: 12.3°C

Mean water temperature: 13.3°C

Physiographic provinces: Cascade–Sierra Mountains (CS), Columbia–Snake River Plateaus (CU)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregions: Columbia Glaciated, Columbia Unglaciated

Terrestrial ecoregions: Eastern Cascades Forests, Snake/Columbia Shrub Steppe, Cascade Mountains Leeward Forests

Number of fish species: 50

Endangered species: 2 fishes (threatened)

Major fishes: chinook salmon, steelhead, rainbow trout, mountain whitefish, chiselmouth, carp, northern pikeminnow, longnose dace, speckled dace, reddsider shiner, bridgelip sucker, largescale sucker, pumpkinseed, smallmouth bass, largemouth bass, sculpin

Major other aquatic vertebrates: northern leopard frog, Columbia spotted frog, northwest salamander, Pacific giant salamander, western pond turtle, wood duck, mallard duck, Canada goose, tundra swan, trumpeter swan, sandhill crane, bald eagle, osprey, beaver, river otter, muskrat

Major benthic invertebrates: caddisflies (*Brachycentrus*, *Glossosoma*, *Arctopsyche*, *Cheumatopsyche*, *Hydropsyche*), mayflies (*Baetis*, *Drumella*, *Ephemerella*, *Rhithrogena*, *Tricorythodes*), stoneflies (*Sweltsa*, *Zapada*, *Claassenia*, *Hesperoperla*, *Skwala*), true flies (*Simuliidae*, *Chironomidae*, *Tipula*)

Nonnative species: smallmouth bass, walleye, largemouth bass, carp, brown bullhead, black crappie, mosquitofish, pumpkinseed, yellow perch, brown trout, brook trout, channel catfish, black bullhead, bluegill

Major riparian plants: black cottonwood, willow, alder

Special features: five expansive floodplain segments; headwaters in Alpine Lakes Wilderness; rich agriculture area, much within Yakama Indian reservation; extremely arid in lower river

Fragmentation: six headwater storage reservoirs; seven irrigation diversion dams on main stem

Water quality: 72 segments with temperatures lethal to salmonid fishes due to irrigation withdrawal; agricultural runoff in lower river; pH = 7.9, alkalinity = 103 mg/L as CaCO₃, NO₃-N = 0.79 mg/L, PO₄-P = 0.33 mg/L

Land use: 36% forested, 16% agriculture, 47% shrub, 1% urban

Population density: 31 people/km²

Major information sources: Snyder and Stanford 2001, Stanford et al. 2002, <http://water.usgs.gov/nwis> 2003, www.wcc.nrcs.usda.gov/climate/wetlands.html 2003

FIGURE 13.19 Map of the Yakima River basin. Physiographic provinces are separated by a yellow line.

FIGURE 13.22 Mean monthly air temperature, precipitation, and runoff for the Willamette River basin.

WILLAMETTE RIVER

Relief: 3048 m

Basin area: 29,728 km²

Mean discharge: 917 m³/s

River order: 7

Mean annual precipitation: 153 cm

Mean air temperature: 11.9°C

Mean water temperature: 13.3°C

Physiographic provinces: Cascade–Sierra Mountains (CS), Pacific Border (PB)

Biome: Temperate Mountain Forest

Freshwater ecoregion: Columbia Unglaciaded

Terrestrial ecoregions: Central Pacific Coastal Forests, Willamette Valley Forests, Central and Southern Cascade Forests

Number of fish species: 61 (~31 native)

Endangered species: 5 fishes (4 threatened, 1 endangered)

Major fishes: mountain whitefish, northern pikeminnow, largescale sucker, mountain sucker, white sturgeon, pacific lamprey, western brook lamprey, river lamprey, Oregon chub, coho salmon, sockeye salmon, rainbow trout, chiselmouth, peamouth chub, speckled dace, redbreast shiner, bridgelip sucker, threespine stickleback, mottled sculpin, torrent sculpin

Major other aquatic vertebrates: bullfrog, western pond turtle, spotted frog, painted turtle, clouded salamander, western toad, red-legged frog, bald eagle, great blue heron, beaver, yellow warbler

Major benthic invertebrates: crayfish (*Pacifastacus*), caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Lepidostoma*, *Heteroplectron*, *Glossosoma*, *Dicosmoecus*), stoneflies (*Taeniopteryx*, *Nemoura*, *Yoraperla*), mayflies (*Rhithrogena*, *Baetis*, *Paraleptophlebia*, *Ephemerella*), true flies (*Lipsothrix*, *Rheotanytarsus*), mollusks (*Juga plicifera*, *Juga silicula*), polychaete worms (*Manayunkia*), amphipods (*Anisogammarus*)

Nonnative species: largemouth bass, smallmouth bass, bluegill, walleye, crappie, common carp, grass carp, brown bullhead, western mosquitofish, brook trout, brown trout, kokanee, lake trout

Major riparian plants: black cottonwood, bigleaf maple, Oregon ash, Douglas fir

Special features: Willamette Valley one of major agriculture areas of western U.S.; richest fish assemblage in Columbia basin

Fragmentation: 13 tributary dams regulate flow; 24 hydropower facilities

Water quality: relatively free of major pollutants; pH = 7.2, alkalinity = 24 mg/L as CaCO₃, NO₃-N = 0.7 mg/L, PO₄-P = 0.21 mg/L

Land use: 68% forest, 19% agriculture (one-third irrigated), 5% urban

Population density: 66 people/km²

Major information sources: Bastasch et al. 2002, Hulse et al. 2002, <http://water.usgs.gov/nwis> 2003, www.wcc.nres.usda.gov/climate/wetlands.html 2003

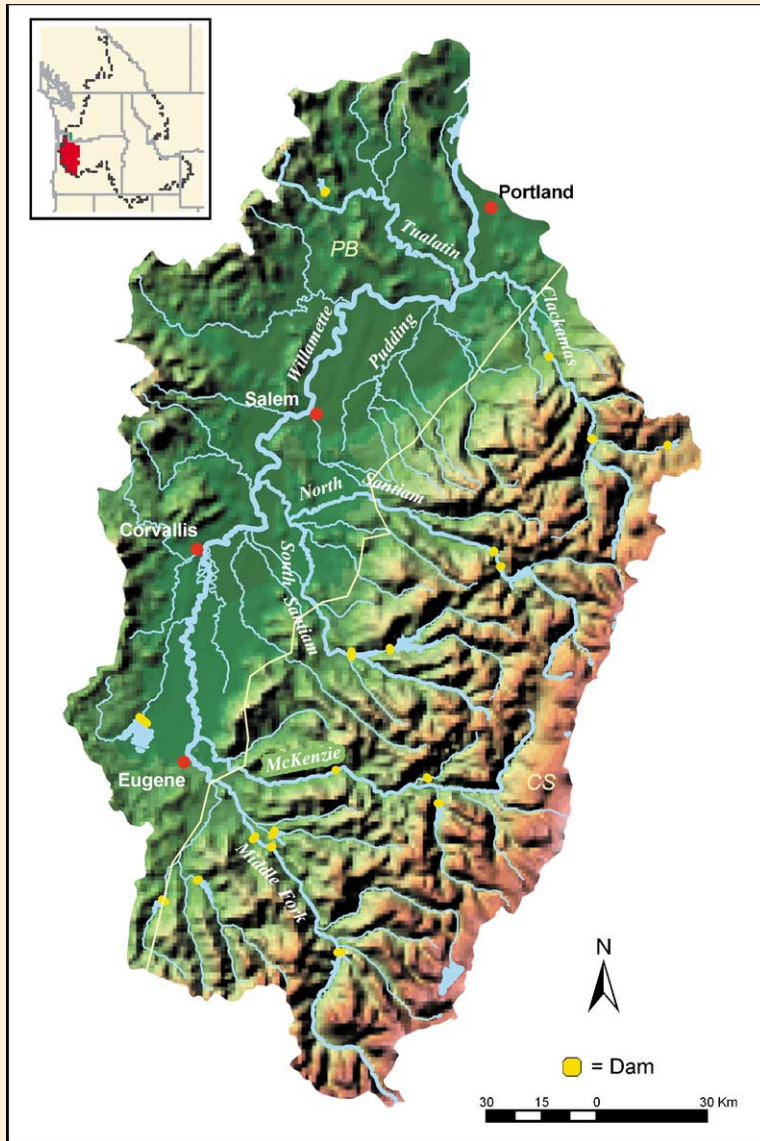

FIGURE 13.21 Map of the Willamette River basin. Physiographic provinces are separated by a yellow line.

FIGURE 13.24 Mean monthly air temperature, precipitation, and runoff for the Columbia River basin.

COLUMBIA RIVER

Relief: 4392 m

Basin area: 724,025 km²

Mean discharge: 7730 m³/s

River order: 9

Mean annual precipitation: 70 cm

Mean air temperature: 9.7°C

Mean water temperature: 13.3°C

Physiographic provinces: Northern Rocky Mountains (NR), Middle Rocky Mountains (MR), Rocky Mountains in Canada (RM), Columbia–Snake River Plateaus (CU), Cascade–Sierra Mountains (CS), Pacific Border (PB), Basin and Range (BR)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregions: Columbia Unglaciaded, Columbia Glaciaded, Upper Snake

Terrestrial ecoregions: 13 ecoregions (see text)

Number of fish species (basin): 103 (53 native resident, 15 (12 native) anadromous, 4 marine)

Endangered species (basin): 7 fishes (12 listings), 6 snails, 2 aquatic plants (threatened)

Major fishes (main stem): chinook salmon, steelhead, northern pikeminnow, largescale sucker, mountain whitefish, eulachon (candle fish), sculpins, speckled dace, chiselmouth, American shad, carp, smallmouth bass, walleye, channel catfish, yellow perch

Major other aquatic vertebrates (main stem): beaver, painted turtle, bullfrog, muskrat, nutria, American merganser, northwest pond turtle, northern leopard frog, chorus frog, bald eagle, Canada goose, osprey, mink, river otter

Major benthic invertebrates (main stem): caddisflies (*Glossosoma*, *Cheumatopsyche*, *Hydropsyche*, *Hydroptila*), stoneflies (*Arcynopteryx*), mayflies (*Baetis*, *Ephemerella*, *Ephemera*, *Ephoron*, *Heptagenia*, *Stenonema*, *Tricorythodes*), crustaceans (*Corophium*, *Pacifastacus*, *Gammarus*), mollusks (*Pisidium*, *Fluminicola*, *Corbicula*, western pearlshell)

Nonnative species (main stem): American shad, brown trout, lake trout, lake whitefish, carp, grass carp, goldfish, tench, channel catfish, black bullhead, brown bullhead, yellow bullhead, mosquitofish, largemouth bass, smallmouth bass, black crappie, white crappie, warmouth, bluegill, pumpkinseed, walleye, yellow perch, carp, northern pike

Major riparian plants (main stem): black cottonwood, Russian olive, western hemlock, water hemlock, box elder, alder, willow, red-osier dogwood, reed canary grass, cattail, bulrush, sedges, purple loosestrife

Special features: fourth-largest river flowing to ocean in North America; 62 subbasins in seven states and British Columbia; Mount Rainier is highest point in basin; Hanford Reach is major unimpounded section

Fragmentation: main-stem river almost completely impounded by large dams

Water quality: pollution includes high summer temperatures, pesticides, heavy metals, and nutrients; turbidity = 8.2 NTU, specific conductance = 135.4 μ S/cm, alkalinity = 51.9 mg/L as CaCO₃, NO₃-N = 0.26 mg/L, phosphorus (total) = 0.06 mg/L, aluminum = 12.09 μ g/L, arsenic = 1.05 μ g/L, PCB = 0.15 μ g/L

Land use: 50% forest/alpine, 34% scrub/grassland, 15% agriculture, 2% urban

Population density: 13.8 people/km²

Major information sources: <http://water.usgs.gov/nwis> 2003, www.wcc.nrcs.usda.gov/climate/wetlands.html 2003, Newell 2003, www.cbfwa.org 2003, BPA 2004, Cooper and Meiring 1989, Ward and Ward 2004, Wydoski and Whitney 2003

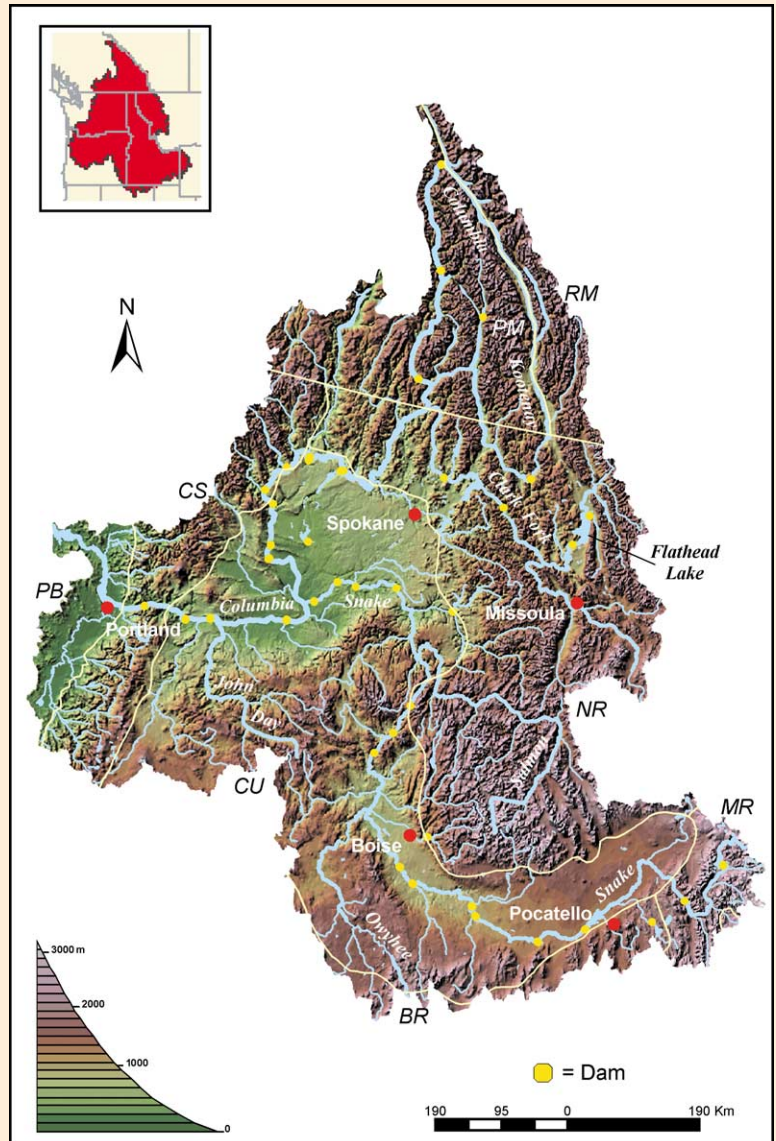

FIGURE 13.23 Map of the Columbia River basin. Physiographic provinces are separated by yellow lines.

FIGURE 13.26 Mean monthly air temperature, precipitation, and runoff for the Owyhee River basin.

OWYHEE RIVER

Relief: 2484 m

Basin area: 28,617 km²

Mean discharge: 12 m³/s

River order: 5

Mean annual precipitation: 31 cm

Mean air temperature: 10.6°C

Mean water temperature: 12.3°C

Physiographic provinces: Columbia–Snake River Plateaus (CU), Basin and Range (BR)

Biome: Desert

Freshwater ecoregion: Columbia Unglaciaded

Terrestrial ecoregions: Snake/Columbia Shrub Steppe, Great Basin Shrub Steppe

Number of fish species: 49 (25 native)

Endangered species: 0, but 6 extinct since settlement

Major fishes: yellow perch, white crappie, speckled dace, redband shiner, redband trout, sculpin, largemouth bass, Lahontan tui chub, largemouth bass, flathead minnow, carp, channel catfish, brown bullhead, black bullhead, brown trout, brook trout, bluegill

Major other aquatic vertebrates: Columbia spotted frog, Woodhouse's toad, bald eagle, white face ibis, leopard frog, bullfrog

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*), stoneflies (*Taeniopteryx*, *Pteronarcys*), mayflies (*Rhithrogena*, *Baetis*, *Ephemerella*), mollusks (*Physella*)

Nonnative species: black crappie, bluegill, brook trout, brown trout, black bullhead, brown bullhead, channel catfish, carp, flathead minnow, largemouth bass, Lahontan tui chub, oriental weatherfish, pumpkinseed, rainbow trout, smallmouth bass, tadpole madtom, Utah chub, warmouth, westslope cutthroat trout, white crappie, yellow perch

Major riparian plants: black cottonwood, juniper, red-osier dogwood, alder, willow

Special features: driest subbasin in Columbia basin; only 16% of stream network flows year-round; some segments of main stem and tributaries are National Wild and Scenic Rivers

Fragmentation: Owyhee Dam near mouth; many irrigation diversions

Water quality: Relatively free of major pollutants; pH = 8.07, alkalinity = 189 mg/L as CaCO₃, NO₃-N = 3.06 mg/L, PO₄-P = 0.74 mg/L

Land use: 82% shrubland, 4% forest, 9% grasslands/herbaceous; 5% agriculture

Population density: 1.3 people/km²

Major information sources: Perugini et al. 2002, <http://water.usgs.gov/nwis> 2003, www.wcc.nrcs.usda.gov/climate/wetlands.html 2003

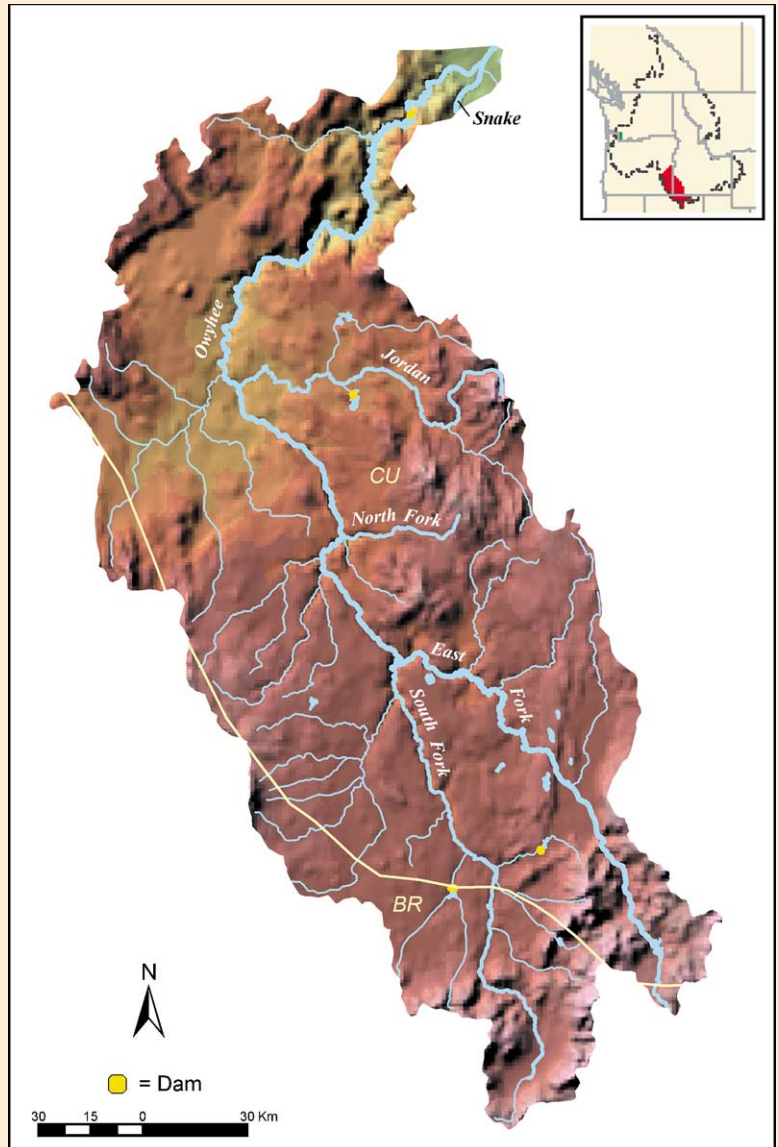

FIGURE 13.25 Map of the Owyhee River basin. Physiographic provinces are separated by a yellow line.

FIGURE 13.27 Map of the Grande Ronde River basin.

GRANDE RONDE RIVER

Relief: 2042 m

Basin area: 10,360 km²

Mean discharge: 88 m³/s

River order: 5

Mean annual precipitation: 46 cm

Mean air temperature: 7.6°C

Mean water temperature: 11.8°C

Physiographic province: Columbia–Snake River Plateaus

Biome: Temperate Mountain Forest

Freshwater ecoregion: Columbia Unglaciaded

Terrestrial ecoregions: Blue Mountains Forests, Palouse Grasslands

Number of fish species: 38 (23 native)

Endangered species: 4 fishes (threatened)

Major fishes: chinook salmon, steelhead, bull trout, mountain whitefish, brook trout, sculpin, northern pikeminnow, peamouth chub, longnose dace, speckled dace, reidside shiner, largescale sucker, bridgelip sucker, mountain sucker, redband trout

Major other aquatic vertebrates: boreal toad, painted turtle, tailed frog, chorus frog, beaver, muskrat, mink, river otter, great blue heron, wood duck

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Glossosoma*, *Rhyacophila*), stoneflies (*Taeniopteryx*, *Hesperoperla*), mayflies (*Baetis*, *Ephemerella*)

Nonnative species: brook trout, carp, lake trout, bluegill, pumpkinseed, warmouth, yellow perch, black crappie, white crappie, largemouth bass, smallmouth bass, channel catfish, flathead catfish, brown bullhead

Major riparian plants: black cottonwood, Englemann spruce, red-osier dogwood, alder, willow, yellow star thistle, diffuse knapweed, spotted knapweed

Special features: National Wild and Scenic designation for portions of four tributaries and the lower Grande Ronde

Fragmentation: two hydropower dams

Water quality: relatively free of major pollutants; pH = 7.8, alkalinity = 86 mg/L as CaCO₃, NO₃-N = 0.133 mg/L, PO₄-P = 0.050 mg/L

Land use: no data, but higher elevations forested, lower elevations rangelands with limited agriculture

Population density: 6.4 people/km²

Major information sources: Eddy and Nowak 2001, <http://water.usgs.gov/nwis> 2003, www.wcc.nrcs.usda.gov/climate/wetlands.html 2003

FIGURE 13.28 Mean monthly air temperature, precipitation, and runoff for the Grande Ronde River basin.

FIGURE 13.29 Map of the Clearwater River basin. Physiographic provinces are separated by a yellow line.

CLEARWATER RIVER

Relief: 2353 m

Basin area: 31,080 km²

Mean discharge: 433 m³/s

River order: 7

Mean annual precipitation: 74 cm

Mean air temperature: 11.5°C

Mean water temperature: 9.5°C

Physiographic provinces: Northern Rocky Mountains (NR),
Columbia–Snake River Plateaus (CU)

Biome: Temperate Mountain Forest

Freshwater ecoregion: Columbia Unglaciaded

Terrestrial ecoregions: North Central Rockies Forests, South Central
Rockies Forests, Palouse Grasslands (near mouth)

Number of fish species: 30 (19 native)

Endangered species: 2 fishes (threatened)

Major fishes: steelhead, chinook salmon, westslope cutthroat trout,
brook trout, mountain whitefish, northern pikeminnow,
chiselmouth, peamouth chub, longnose dace, speckled dace, redbelt shiner, largescale sucker, sculpin

Major other aquatic vertebrates: bullfrog, northern leopard frog, painted turtle, muskrat, beaver, river otter

Major benthic invertebrates: caddisflies (*Arctopsyche*, *Hydropsyche*, *Cheumatopsyche*, *Glossosoma*, *Brachycentrus*), stoneflies
(*Taeniopteryx*, *Pteronarcys*, *Hesperoperla*, *Claassenia*), mayflies (*Rhithrogena*, *Baetis*, *Ephemera*), true flies
(*Chironomidae*, *Simuliidae*, *Hexatoma*, *Atherix*)

Nonnative species: kokanee, brook trout, golden trout, arctic grayling, tiger muskie, carp, channel catfish, brown bullhead,
black bullhead, smallmouth bass, largemouth bass, bluegill, pumpkinseed, black crappie

Major riparian plants: black cottonwood, red-osier dogwood, alder, willows, sedges

Special features: major tributaries, Lochsa and Selway, are free flowing; Clearwater and tributaries mostly constrained in deep
canyons; headwaters mostly designated wilderness

Fragmentation: Dworshak Dam on North Fork a major hydroelectric and storage facility

Water quality: relatively free of major pollutants; pH = 7.3, alkalinity = 69 mg/L as CaCO₃, NO₃-N = 0.034 mg/L, PO₄-P =
0.006 mg/L

Land use: 20% agriculture, 80% forest

Population density: 1.9 people/km²

Major information sources: Cichosz et al. 2001, <http://water.usgs.gov/nwis> 2003, www.wcc.nrcs.usda.gov/climate/wetlands.html

FIGURE 13.30 Mean monthly air temperature, precipitation, and runoff for the Clearwater River basin.

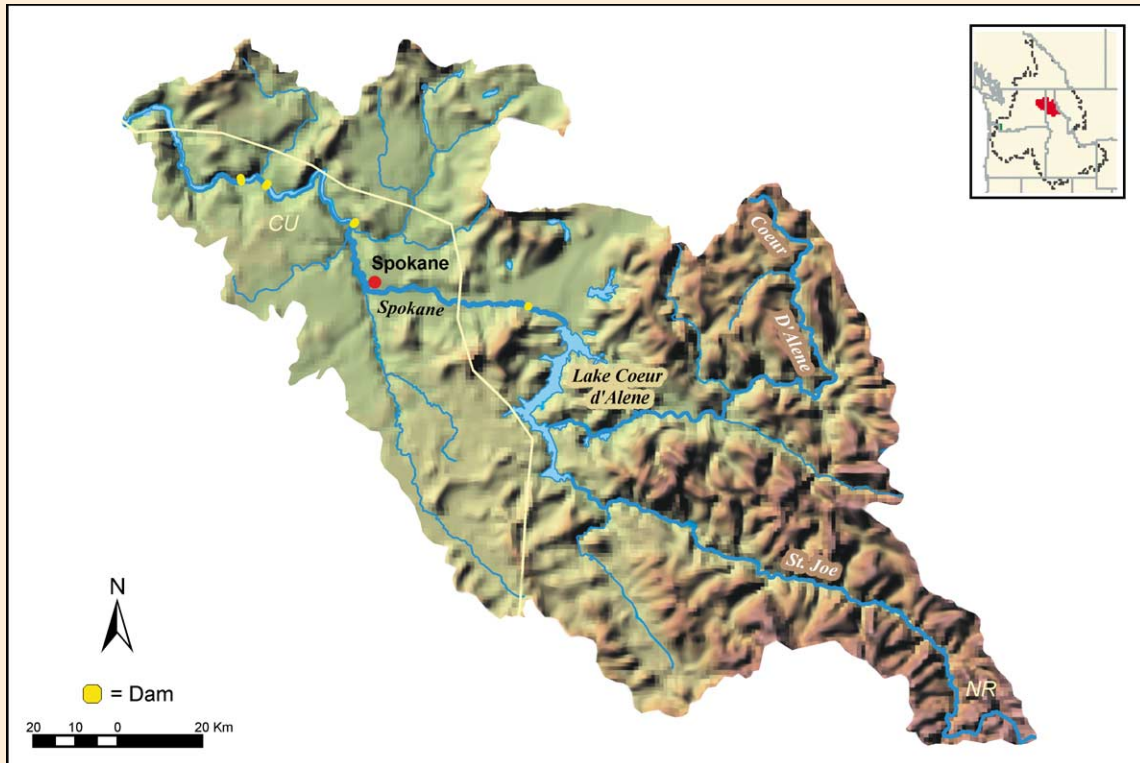

FIGURE 13.31 Map of the Spokane River basin. Physiographic provinces are separated by a yellow line.

SPOKANE RIVER

Relief: 1681 m

Basin area: 15,590 km²

Mean discharge: 225 m³/s

River order: 6

Mean annual precipitation: 63 cm

Mean air temperature: 7.5°C

Mean water temperature: 12.2°C

Physiographic provinces: Northern Rocky Mountains (NR),
Columbia–Snake River Plateaus (CU)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Columbia Glaciated

Terrestrial ecoregions: North Central Rockies Forests, Palouse
Grasslands, Okanogan Dry Forests

Number of fish species: 24

Endangered species: 0, but 2 fishes extinct since settlement

Major fishes: largemouth bass, yellow perch, tench, brown trout,
largescale sucker, reidside shiner, northern pikeminnow,
chiselmouth, kokanee, westslope cutthroat trout, bull trout

Major other aquatic vertebrates: Columbia spotted frog, beaver, muskrat, white pelican, common loon, bald eagle

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Glossosoma*), stoneflies (*Taeniopteryx*), mayflies
(*Rhithrogena*, *Baetis*, *Ephemerella*)

Nonnative species: rainbow trout, largemouth bass, yellow perch, tench, brown trout

Major riparian plants: black cottonwood, red-osier dogwood, willow

Special features: St. Joe River, one of longest free-flowing rivers in Columbia basin; Lake Coeur d'Alene, a large glacial lake on
main stem; Palouse Prairie, an expansive intermountain grassland, mostly cultivated

Fragmentation: Six low-head diversion and hydropower dams

Water quality: Upper Coeur d'Alene River polluted by mining and undergoing reclamation; eutrophication from Spokane sewage
outfall; pH = 7.5, alkalinity = 47 mg/L as CaCO₃, NO₃-N = 0.34 mg /L, PO₄-P = 0.16 mg /L

Land use: 50% forest, 15% range, 15% cropland, 8% urban

Population density: 80 people/km²

Major information sources: Whalen 2000, <http://water.usgs.gov/nwis> 2003, www.wcc.nrcs.usda.gov/climate/wetlands.html 2003

FIGURE 13.32 Mean monthly air temperature, precipitation, and runoff for the Spokane River basin.

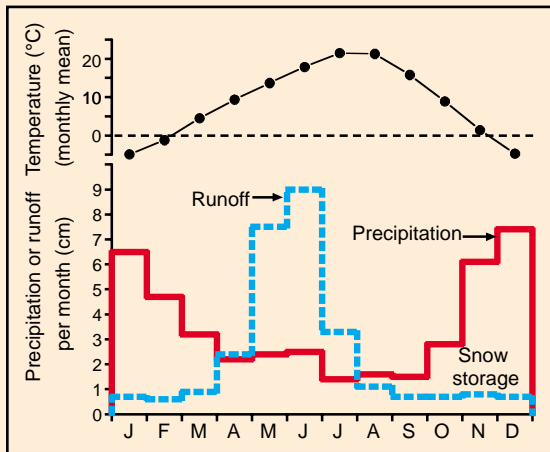

FIGURE 13.34 Mean monthly air temperature, precipitation, and runoff for the Methow River basin.

METHOW RIVER

Relief: 2347 m

Basin area: 4831 km²

Mean discharge: 45 m³/s

River order: 5

Mean annual precipitation: 34 cm

Mean air temperature: 8.6°C

Mean water temperature: 9.5°C

Physiographic province: Cascade–Sierra Mountains (CS)

Biome: Temperate Mountain Forest

Freshwater ecoregion: Columbia Glaciated

Terrestrial ecoregions: Cascade Mountains Leeward Forests, Palouse Grasslands

Number of fish species: 32 (25 native)

Endangered species: 3 fishes (1 threatened, 2 endangered)

Major fishes: chinook salmon, steelhead, bull trout, westslope cutthroat trout, bluegill, carp, bass, chiselmouth, brook trout, sculpin, largescale sucker, reddsider shiner, Pacific lamprey

Major other aquatic vertebrates: Columbia spotted frog, bald eagle, great blue heron, wood duck, mink

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Glossosoma*), stoneflies (*Claassenia*, *Hesperoperla*, *Isocapnia*, *Taeniopteryx*), mayflies (*Rhithrogena*, *Baetis*, *Ephemerella*)

Nonnative species: smallmouth bass, largemouth bass, bluegill, carp, brook trout, brown bullhead, black crappie

Major riparian plants: black cottonwood, Englemann spruce, red-osier dogwood, alder, willow

Special features: free flowing; headwaters in wilderness and North Cascades National Park; upper river with expansive floodplain but dry reach at low flow; lower river constrained in canyon; two of last (endangered) wild spring chinook salmon and steelhead runs in Columbia basin

Fragmentation: seven small irrigation-diversion dams

Water quality: relatively free of major pollutants; pH = 7.8, alkalinity = 96 mg/L as CaCO₃, NO₃-N = 0.230 mg/L, PO₄-P = 0.020 mg/L

Land use: 86.5% forest, 9.6% range, 1.6% cropland, 2.3% other

Population density: 6.2 people/km²

Major information sources: Foster et al. 2002, <http://water.usgs.gov/nwis> 2003, www.wcc.nrcs.usda.gov/climate/wetlands.html 2003

JOHN DAY RIVER

Relief: 2682 m

Basin area: 20,980 km²

Mean discharge: 60 m³/s

River order: 6

Mean annual precipitation: 37 cm

Mean air temperature: 9.2°C

Mean water temperature: 12.5°C

Physiographic province: Columbia–Snake River Plateaus (CU)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Columbia Unglaciaded

Terrestrial ecoregions: Palouse Grasslands, Blue Mountains Forests, Snake/Columbia Shrub Steppe

Number of fish species: 27 (17 native)

Endangered species: 2 fishes (threatened)

Major fishes: chinook salmon, bull trout, westslope cutthroat, mountain whitefish, brook trout, speckled dace, longnose dace, reddsider shiner, chiselmouth, largescale sucker, northern pikeminnow, black bullhead, brown bullhead, lamprey, sculpin

Major other aquatic vertebrates: northern leopard frog, spotted frog, western pond turtle, bullfrog, tailed frog, painted turtle, beaver, muskrat, great blue heron, wood duck

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Glossosoma*, *Brachycentrus*, *Cryptochia neosa*), stoneflies (*Taeniopteryx*, *Pteronarcys*, *Hesperoperla*, *Claassenia*), mayflies (*Rhithrogena*, *Baetis*, *Ephemerella*), mollusks (*Anodonta*, *Fluminicola*, *Monadenia*)

Nonnative species: brook trout, carp, black bullhead, brown bullhead, channel catfish, largemouth bass, smallmouth bass, black crappie, bluegill

Major riparian plants: black cottonwood, red-osier dogwood, alder, willow

Special features: unregulated river; three segments designated National Wild and Scenic Rivers; spring chinook salmon and summer steelhead populations are two of last remaining intact wild populations of anadromous fishes in Columbia River basin; lower river very arid landscape

Fragmentation: irrigation diversions only

Water quality: relatively free of major pollutants; pH = 8.3, alkalinity = 109 mg/L as CaCO₃, NO₃-N = 0.110 mg/L, PO₄-P = 0.022 mg/L

Land use: 10% forested, 85% scrub and rangeland, 5% agriculture

Population density: 0.9 people/km²

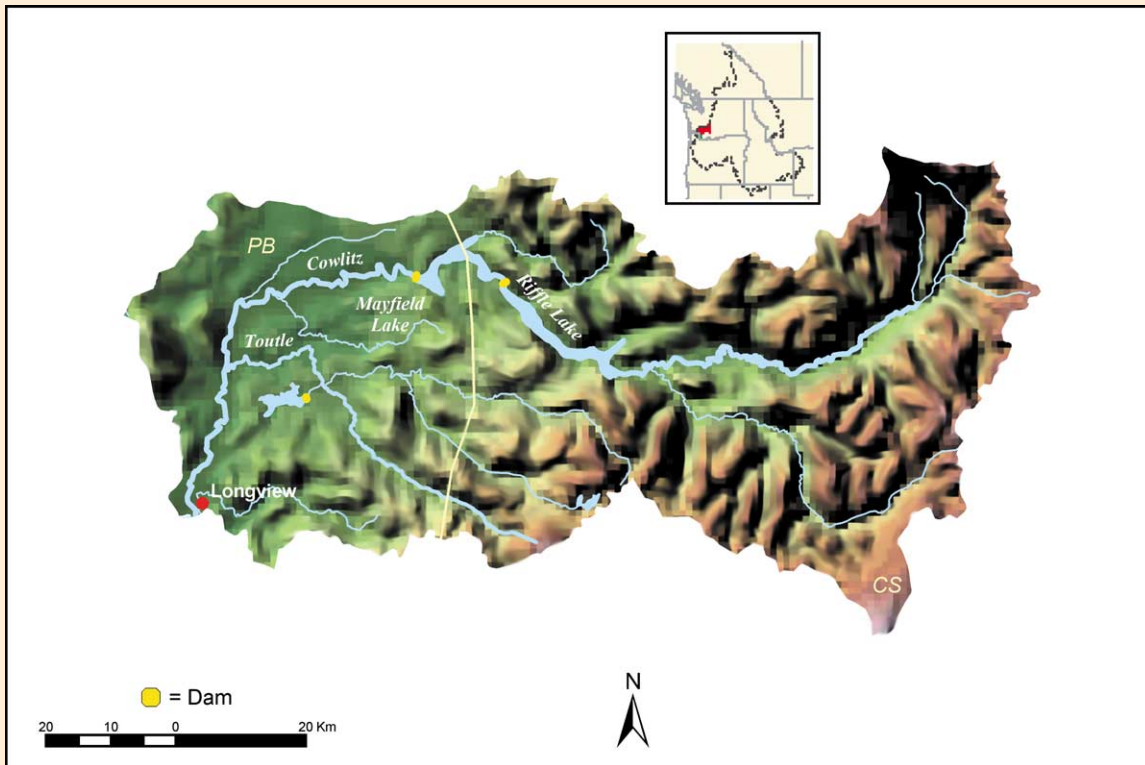

FIGURE 13.37 Map of the Cowlitz River basin. Physiographic provinces are separated by a yellow line.

COWLITZ RIVER

Relief: 4346 m
 Basin area: 8870 km²
 Mean discharge: 261 m³/s
 River order: 5
 Mean annual precipitation: 164 cm
 Mean air temperature: 10.9°C
 Mean water temperature: 10.4°C
 Physiographic provinces: Cascade–Sierra Mountain (CS), Pacific Border (PB)

Biome: Temperate Mountain Forest
 Freshwater ecoregion: Columbia Unglaciaded
 Terrestrial ecoregions: Central and Southern Cascades Forests, Puget Lowland Forests

Number of fish species: 32

Endangered species: 2 fishes (threatened)

Major fishes: chinook salmon, white sturgeon, green sturgeon, pacific lamprey, rainbow trout, largescale sucker, bridgelip sucker, mountain sucker, mountain whitefish, sculpin, longnose dace, speckled dace, western brook lamprey, northern pikeminnow, brook trout

Major other aquatic vertebrates: northwestern pond turtle, mink, blue heron, bald eagle

Major benthic invertebrates: caddisflies (*Hydropsyche*, *Cheumatopsyche*, *Glossosoma*), stoneflies (*Taeniopteryx*, *Pteronarcys*, *Hesperoperla*, *Claassenia*), mayflies (*Rhithrogena*, *Baetis*, *Ephemerella*)

Nonnative species: largemouth bass, smallmouth bass, brook trout, crappie, brown bullhead, tiger muskie

Major riparian plants: black cottonwood, red-osier dogwood, alder, willow

Special features: drains highest point in Columbia basin (Mount Rainier); river choked with sediments after 1980 Mount St. Helens volcanic eruption but gradually recovering

Fragmentation: three hydroelectric dams on main stem

Water quality: relatively free of major pollutants; pH = 7.2, alkalinity = 69 mg/L as CaCO₃, NO₃-N = 0.021 mg/L, PO₄-P = 0.011 mg/L

Land use: 16% agriculture, 84% forest

Population density: 8.5 people/km²

LITERATURE CITED

INTRODUCTION

In October 1843, John Charles Fremont, an explorer with the U.S. Army Topographical Corps, crossed the Malheur basin of Oregon and saw the Cascade Range to the Southwest. He assumed these connected with the Sierra Nevada, which was south of his position. In his journal he named the land between these western ranges and the Rocky Mountains the Great Basin (Egan 1977). The Great Basin boundaries have been redefined many times since then but generally refer to the series of contiguous desert basins and mountain ranges that lie between the Sierra Nevada and southern Cascade Range to the west (121°W longitude), the Wasatch Range to the east (111°W longitude), the Snake River Plain of Idaho (42°N latitude), the Blue Mountains and High Lava Plains of Oregon (44°N latitude) to the north, and the Sonoran and Mohave deserts (32°N latitude) and the plateaus of southern Utah (37°N latitude) to the south (Fig. 14.2).

Great Basin rivers are small with low discharge. The Great Basin is a cold desert, below freezing in the winter and hot in the summer. Nevada and Utah, which encompass the bulk of the Great Basin, are the two driest states in the United States. Thus, rivers of the Great Basin would be considered streams else-

where, but the basin's dryness has enhanced their significance and they are as regionally important as are larger rivers in other parts of North America. Rivers and streams in the Great Basin often flow into valley playas, but the two largest subbasins within the Great Basin, the Bonneville and the Lahontan, have permanent terminal lakes.

Evidence of human habitation in the Great Basin dates to over 11,000 years ago. The earliest culture lived in caves around lakes and used a fluted point, similar to the Clovis point. This culture may have been contemporaneous with or replaced by a culture using another technology, stemmed points. The stemmed point culture utilized lake margins, but by the middle Holocene, 7500 years ago, the climate dried and many of the sites were abandoned.

Wetlands rebounded 4500 years ago. Wetlands in the Carson and Owens valleys supported high human population densities and became the center of the Numic culture (Grayson 1993, Kelly 2001). Numic tribes migrated seasonally, often wintering at sites with good pinyon nut crops and foraging opportunistically, utilizing insects, shellfish, small fishes, small mammals, cattail, and bulrush seeds (Egan 1977, Grayson 1993, Durham 1997, Kelly 2001). About 1000 years ago the Numic people are thought

FIGURE 14.2 Rivers of the Great Basin covered in this chapter.

to have begun to expand into the northern and eastern Great Basin (Kelly 2001).

The Fremont occupied the Bonneville basin from 400 to 1350 A.D. They lived in adobe houses and constructed irrigation ditches, raising domesticated crops (Grayson 1993). They vanished about the time the Numic tribes are thought to have reached the eastern Great Basin. Numic tribes may have displaced the Fremont, but a 150-year drought beginning about 1350 (Cook et al. 2004) could be related to their disappearance (Grayson 1993).

By the 1700s the Great Basin was predominantly inhabited by Numic tribes: the Northern Paiute in the Lava and Lakes area and Lahontan basin; the Mono, the Panamint, and the Kawaiisu in the southwestern Great Basin; the Shoshone in the central Great

Basin and upper Bonneville basin; and the Utes in the southern Bonneville basin. The Washoe, in the Truckee and Carson region of the Lahontan basin, are linguistically related to tribes in western California.

In the 1770s the Spanish explored the Great Basin as they established overland routes from Mexico to California (Durham 1997). Fur trappers entered the northern Great Basin in the early 1800s, but by the 1840s the fur trade was in decline and pioneers began crossing the Great Basin on their way to Oregon and California. The Oregon and California trails split in the eastern Great Basin, and the Oregon Trail continued west to Oregon, whereas the California Trail dropped south, following the Humboldt River to the Sierra Nevada.

In 1847 the Mormons settled the Bonneville basin and then established small communities throughout much of the Great Basin. Oregon became a state in 1859. The discovery of the Comstock Lode that same year, near today's Virginia City, Nevada, initiated a mining boom that led to statehood for Nevada in 1864. On May 10, 1869, the transcontinental railroad was completed at Promontory Point, Utah. It crossed the Great Basin along the Truckee, Humboldt, and Weber rivers. Utah, after multiple attempts, joined the union in 1896.

In this chapter, we will consider the Bear, Sevier, Provo, and Weber rivers from the Bonneville basin and the Humboldt, Truckee, and Walker rivers from the Lahontan basin (see Fig. 14.2). We will focus on the Bear and Sevier rivers from the Bonneville basin and the Humboldt and Truckee rivers from the Lahontan basin. Abbreviated physical and biological information is provided for the Provo, Weber, and Walker rivers. Several other Great Basin rivers not treated here have similar regional significance. For example, the Carson River of the Lahontan basin, the center of Nevada's early mining industry, is now a superfund site because of mercury contamination. The Owens River, which fed Owens Lake, California, in the Death Valley basin, now supplies water for Los Angeles, California. The lake dried and became a controversial source of wind-borne dust.

Physiography and Climate

The Great Basin is the largest section within the Basin and Range physiographic province of North America and comprises approximately 4% of the United States (Hunt 1974). The hydrographic Great Basin, which includes all contiguous drainages with no active connections to either the Pacific or Atlantic oceans, is approximately 25% larger. The Great Basin includes Death Valley in California and the Malheur basin in Oregon, almost all of Nevada, and the western half of Utah. Over 90 mountain ranges with peaks commonly reaching 2100 to 3500 m asl occur in the Great Basin. Most have a north-to-south orientation.

The Great Basin has five subdivisions: (1) the Lava and Lakes area, in the northwest corner, (2) Lahontan Basin, encompassing the west central Great Basin, (3) the central basin, consisting of numerous separate elevated basins, (4) Bonneville Basin, encompassing the eastern side, and (5) the southern area, in southern Nevada and adjacent California (Hunt 1974).

Some drainages that flow into the Great Basin originate outside of Hunt's (1974) physiographic Great Basin. Streams and rivers entering the Great Basin from the west originate in the Cascade-Sierra Mountain physiographic province. Those entering the eastern edge of the basin originate in the Middle Rocky Mountain physiographic province, and streams entering the southeastern margins originate in the High Plateau section of Hunt's (1974) Colorado Plateau physiographic province.

We consider the hydrographic Great Basin to be the relevant border in this chapter. The hydrographic eastern border, from north to south, is made up of the Tump Range of western Wyoming, the western Uinta Mountains (3000 to 3800 m asl), and the Wasatch Plateau, Escalante Mountains, Awapa Plateau, and Paunsaugunt Plateau (2500 to 3500 m asl). The Sierra Nevada (2000 to 3800 m asl) and southern Cascade Mountains (1900 to 2900 m asl) form the western border of the Great Basin, whereas the northern border consists of a series of low-lying mountain ranges (2100 to 2700 m asl) and lava plains (1400 to 1800 m asl). Southern boundaries of the Great Basin include parts of the Sonoran and Mohave deserts (600 m asl or less) and high plateaus in Utah (2700 to 3000 m asl) and mountain ranges in Nevada and California (1300 to 2100 m asl). Although Death Valley, on the southwestern edge of the Great Basin, drops to -89 m asl, the floor of the Great Basin averages 1500 to 1700 m asl, about one km higher than the physiographic regions to the north or south (Eaton 1982).

During Pleistocene glacial intervals, approximately 80 pluvial lakes covered an estimated 112,500 km² of the Great Basin (Grayson 1993). Lake Lahontan, on the western edge, covered some 22,442 km² of the Lahontan basin in Nevada to a maximum depth of 274 m. It was fed by the Humboldt, Walker, Carson, Susan, Truckee, and Quinn rivers. Most drain the eastern slope of the Sierra Nevada Mountains. Lake Bonneville, on the eastern edge, covered 51,722 km² of the Bonneville basin of Utah, with depths up to 372 m (Grayson 1993). It was fed by the Bear, Sevier, and other rivers originating on the western slopes of the Wasatch and Uinta mountains. Today, Lake Lahontan remains as the Carson Sink, Humboldt Sink, Honey Lake, Walker Lake, and Pyramid Lake. The remnants of Lake Bonneville are Utah Lake, the Great Salt Lake, and an ephemeral saline playa, Lake Sevier. Lakes Lahontan and Bonneville dried about 10,000 and 11,000 years ago, respectively.

Great Basin climate changed significantly during the Holocene. In the early Holocene, 9000 years ago,

lakes and wetlands were numerous in the northern Great Basin (Bradley 1999), but by the mid-Holocene (7500 to 4500 years ago) many of the wetlands and lakes had dried (Grayson 1993, Kelly 2001). From 4000 to 2000 years ago precipitation became winter dominated (Kelly 2001), producing a resurgence of lakes and wetlands. But 2000 years ago the climate again dried, culminating in severe droughts from 1130 to 1300 and 1350 to 1500 (Cook et al. 2004). After 1500 precipitation in the western Great Basin again became winter dominated, generating the climate of today.

Although changes in Holocene climate suggest a role of orbital forcing (precession of the equinox, obliquity, and eccentricity of the earth's orbit; Lunine 1999), a number of geographical factors also influence the Great Basin climate. The Great Basin is slightly north of the Northern Hemisphere arid zone (30°N latitude), which should generate grasslands rather than a cold desert. But the Sierra Nevada, rising 1200m above the basin floor, is in the direct path of the westerly winds from the Pacific Ocean, resulting in a strong rain shadow. The rain shadow is strongest in the western Great Basin. Mean annual precipitation in Reno, Nevada (1344m asl), at the base of the Sierra Nevada, is 19.1cm, and Fallon, Nevada (elevation 1208m asl), approximately 88 km east, receives 13.5 cm. Eureka, Nevada (elevation 1993 m), at the same general latitude but further east in the central basin, has a mean annual precipitation of 33.5 cm, and Ely, Nevada (elevation 1908 m asl), at the eastern edge of the central basin, receives 25.7 cm/yr. Nephi, Utah (elevation 1562 m), at the edge of the Wasatch Mountains, receives 39.5 cm/yr precipitation.

Another factor is the Arizonal monsoon. From July through September inland heating draws moisture-laden air from the Gulf of Mexico and the Gulf of California/Pacific Ocean into the southwest. This moisture is most important in the southeastern Great Basin. For example, Panguitch, Utah (37°49'N latitude), on the southeast, Beaver (38°17'N latitude) and Delta (39°21'N latitude) in central Utah, and Corinne (41°33'N latitude) in the northern Bonneville basin receive 42%, 31%, 23%, and 18% of their precipitation, respectively, as monsoon storms between July and September. Monsoonal moisture seldom reaches the far northwestern Great Basin.

Mountains influence the amount and timing of moisture availability in the river basins. Some mountain ranges are too low to capture enough water to maintain perennial streams; however, the eastern and western borders and a few large ranges in the center

of the Great Basin can capture significant quantities of water. Snow is the primary source of moisture in these higher mountain ranges and is released to the rivers in the spring and early summer. The importance of winter precipitation is greatest in the western Great Basin and spring precipitation becomes progressively more important east across the basin. Forty percent of Reno, Nevada's annual precipitation falls from December to February and 24% of its moisture falls in the spring (March to May). Elko, Nevada, obtains 29% of its precipitation in the winter and 28% of its moisture in the spring. Ogden, Utah, receives 26% of its moisture in the winter and almost 33% of its annual precipitation in the spring. This difference may be related to the intensification of the Sierra Nevada rain shadow as the jet stream makes its seasonal shift to the north.

In the western and central Great Basin, daily July temperatures range between 10°C at night and 33°C during the day. In the eastern Great Basin, summer temperatures are 10°C to 13°C at night and 33°C to 35°C during the day. Mountain locations are cooler because of their higher elevation. The southern Great Basin has mean summer high and low temperatures of 39°C and 25°C, respectively. January temperatures in the western and central Great Basin valleys range from average highs of about 9°C to lows of -4°C. In the southern Bonneville basin, high-elevation valley temperatures have a daily January range from -8°C to 7°C, and northern Bonneville basin temperatures range from -3°C to 6°C, as they are moderated by the Great Salt Lake.

Basin Landscape and Land Use

Great Basin vegetation can be separated by terrestrial ecoregions (Ricketts et al. 1999). The Lava and Lakes area includes the Snake/Columbia Shrub Steppe ecoregion, which is dominated by sagebrush and perennial bunch grasses but also has juniper woodlands and higher-elevation patches of Douglas fir and quaking aspen. The central Great Basin includes both Great Basin Montane Forests and Great Basin Shrub Steppe ecoregions. The relatively stable Mohave Desert ecoregion occupies the southern Great Basin. In contrast to the majority of the Great Basin, it is a warm desert, dominated by creosote bush, Joshua tree, desert holly, and all-scale. The rivers and streams in this system are not perennial, although the Owens and Mohave rivers do flow in their headwaters. The Armagosa River is predominantly underground, and only occasionally exposed at the surface as pools and springs in the river bed.

The Lahontan basin includes the endangered Sierra Nevada Forests ecoregion along its western edge, the Great Basin Shrub Steppe ecoregion in the valleys, and the Great Basin Montane Forests ecoregion of the internal mountain ranges. The Sierra Nevada Forests include montane forests with ponderosa pine, Jeffrey pine, and lodgepole pine, subalpine forests, and pinyon–juniper woodlands. The relatively stable Great Basin Shrub Steppe ecoregion is predominantly sagebrush and shadscale (Ricketts et al. 1999). The Great Basin Montane Forests include juniper, singleleaf pinyon pine, white fir, limber pine, and bristlecone pine. White fir and, more sporadically, lodgepole pine occur on north-facing slopes and in ravines on higher south-facing slopes, limber pine at the heads of east-facing canyons, and mountain hemlock and whitebark pine at the heads of west-facing canyons.

The Bonneville basin includes three ecoregions. The northeastern corner is in the South Central Rockies Forests ecoregion, characterized by Douglas fir, subalpine fir, Engelmann spruce, lodgepole pine, and, at high elevations, whitebark pine. The Great Basin Shrub Steppe ecoregion dominates the northernmost eastern edge of the basin and the western Bonneville basin. The Wasatch and Uinta Montane Forests, an endangered ecoregion, forms the eastern border of the basin with Douglas fir, subalpine fir, ponderosa pine, and Engelmann spruce. Quaking aspen, white fir, blue spruce, and Gambel oak are also present.

The complex structure of many of the overlapping ecoregions in the Great Basin can be categorized in eight altitudinally based vegetation zones, influenced by both aspect and latitude (Thompson 1990). The first zone includes valley-floor playas and saline springs with areas of no vegetation or of saltgrass and black greasewood. The second zone is classified as a shadscale desert (Great Basin Shrub Steppe). Above that is the third zone, a lower sagebrush and grass zone (Snake/Columbia Shrub Steppe, Great Basin Shrub Steppe) that completes the basin floor and extends up the foot of the ranges. Sagebrush extends through the next three zones, but other plants define them. The fourth zone, the woodland zone (Snake/Columbia Shrub Steppe, Great Basin Montane Forests, Sierra Nevada Forests), is often called the pinyon–juniper zone because of the presence of singleleaf pinyon pine and both Utah and Western juniper. This zone starts between 1500 to 2100 m asl, varies in width from 300 to 600 m, and may also contain serviceberry and curl-leaf mountain mahogany. Singleleaf pinyon pine may be absent in

northern and northeastern parts of the Great Basin. The zone's elevation is thought to be strongly influenced by winter inversions in the valleys, which make lower elevations inhospitable to trees (Grayson 1993).

In the central and northern Great Basin the upper sagebrush-grass zone, a fifth zone, occurs above the woodland zone but not in the eastern and southeastern part of the Great Basin, where it is directly replaced by the sixth zone, the montane zone (Great Basin Montane Forests, Sierra Nevada Forests, Wasatch and Uinta Montane Forests). The montane zone, from 2100 to 2600 m asl, has white fir, Douglas fir, ponderosa pine, and quaking aspen. The seventh zone is the subalpine zone (Great Basin Montane Forests, Sierra Nevada Forests, Wasatch and Uinta Montane Forests). This zone extends to the treeline and is characterized by bristlecone pine, limber pine, Engelmann spruce, subalpine fir, and whitebark pine. The final zone, the alpine tundra, begins at about 3000 m asl in the Wasatch Range (Hayward 1945) and about 3200 m asl in the central basin.

Water was the key to the location of early settlements in the Great Basin and population centers still reflect that fact. Today the Great Basin has about 4.16 million residents. About 33% live in the southern Great Basin area, mainly metropolitan Las Vegas, where they are heavily supplemented by water from the Colorado River. The Lahontan basin contains 13.6% of the total Great Basin population and five of six people live in the Reno–Sparks metropolitan area, where water from the Sierra Nevada is available. The Bonneville basin, with 49.3% of the total population, has eight of ten of its residents living along the Wasatch Front in the greater Salt Lake metropolitan area. The Lava and Lakes area has less than 3% and the central basin just 1.4% of the Great Basin's population. These have densities of 1.0 and 5.2 people/km², respectively, compared to Salt Lake County's 3175/km² (www.census.gov 2004).

Desert covers approximately 41% of the Great Basin, and sagebrush-grass accounts for about 39% of the area. Pinyon–juniper, montane, and alpine forests make up the remaining 20% of the basin (Brussard et al. 1998). Private land ownership is focused in the valleys, especially along perennial rivers and streams, where the prime agriculture lands are found. Crops in high-elevation valleys consist mainly of hay. A wide variety of grains, onions, tomatoes, and other crops are grown in the lower-elevation valleys. Urbanization has increased in the eastern Great Basin and to a lesser extent in the

western Great Basin, shifting land usage to residential dwellings, business, and industrial.

After Alaska, Nevada and Utah have the greatest total of federally owned land; 87% of Nevada and 67% of Utah. Federal ownership generally consisted of lands that had no immediate value for farming or settlement. Such lands are especially abundant in the Great Basin. Low-elevation lands are largely managed by the Bureau of Land Management (BLM), whereas the U.S. Forest Service manages the mountainous regions. Both forest and BLM lands are widely used for grazing, and timber is also harvested on forestlands. Part of the federal land is under military control: Hill Air Force Range, Desert Test Center, Wendover Range, and Dugway Proving Grounds in the Great Salt Lake Desert; Nellis Air Force Bombing and Gunnery Range and Nevada Test Site in Nevada; and China Lake Naval Weapons Center and Fort Irwin National Training Center in California. These military reserves remove large blocks of land from public access. Two national parks, Death Valley National Park, California, and Great Basin National Park, Nevada, are fully within the Great Basin. Bryce Canyon National Park of Utah straddles the divide between the Bonneville and Colorado River basins.

Great Basin native grasses were quickly eliminated by intense grazing in the mid to late 1800s. The impact was recognized in as little as 30 years (Grayson 1993). Heavy grazing fostered the spread of woody plants, which cattle did not utilize, and also favored nonnative species, one of which was cheat grass. Cheat grass was in the eastern Great Basin by the late 1800s, and by 1930 it had spread throughout the basin (Grayson 1993). Cheat grass is a fire species, drying in the early summer, after which it is easily ignited. Its seeds are somewhat resistant to burning, but sagebrush, native grasses, and other plants, if not killed, are severely stunted. The frequency of fires in the Great Basin has increased with cheat grass expansion.

The Rivers

The rivers covered in this chapter are from the two largest freshwater ecoregions within the Great Basin, which correspond to the two major physiographic subdivisions: the Lahontan and Bonneville. Thus, the Bonneville freshwater ecoregion includes the Bear River, Sevier River, Weber River, and Provo River. These rivers originate in the middle Rocky Mountain and Colorado Plateau physiographic provinces and flow west to terminal lakes in the Great Salt Lake

Desert. The Lahontan Basin freshwater ecoregion includes the Truckee River, Humboldt River, and Walker River. The Walker and Truckee rivers originate in the Cascade–Sierra Mountains Province to the west of the Great Basin and terminate in separate desert lakes of the Lahontan Basin freshwater ecoregion (Hunt 1974). The upper Humboldt River is part of the Central Basin physiographic subdivision of the Great Basin. It terminates in marshlands in Hunt's Lahontan Basin subdivision.

A number of parallels exist among these rivers, although each also has unique characters that separate it from the other systems. The Bear and Truckee rivers both head in high mountains, have lakes in the upper drainages, flow about half their length in Great Basin Desert Shrub Steppe, and terminate in large natural lakes. The Humboldt and Sevier rivers begin in drier montane habitats and flow for most of their lengths through the Great Basin desert. The Weber and Provo rivers start in high-elevation alpine habitat and flow most of their length in mesic montane or high-elevation valleys. Only a relatively short portion of these rivers flow in Desert Shrub Steppe before they terminate in the Great Salt Lake. Both the Truckee and Walker rivers start in relatively soft-water environments in the Sierra batholith, whereas the Sevier and Humboldt rivers head in limestone regions and thus begin as hard-water streams. The Bear, Weber, and Provo rivers head less than 10 km apart in Precambrian sandstones of the Uinta Mountains. They begin as soft-water streams but by their middle reaches enter limestone regions and become hard-water streams.

The freshwater ecoregions (Abell et al. 2000) categorize the aquatic fauna more accurately than do the physiographic subdivisions. Relationships with adjacent freshwater ecoregions give some insight into dispersal paths into and/or out of the Lahontan and Bonneville basins. Parts of the central Great Basin, isolated from the Lahontan drainage, contain unique endemics (e.g., the relict dace); however, the general faunal associations are closest to those in the Lahontan basin. The Death Valley freshwater ecoregion shares three of its ten native fish species with the Lahontan basin (i.e., Owens sucker, tui chub, and speckled dace). The Oregon lakes and upper Klamath have exchanged fishes with the Lahontan system (Minckley et al. 1986), sharing tui chub and Paiute sculpin. The Lahontan redband of the Lahontan basin reflects an ancient connection to either the Bonneville or Snake River basin, as do mountain whitefish. The Bonneville basin shares many of its fishes with the upper Snake River (Hubbs and Miller 1948, Martin

et al. 1985, Smith et al. 2002). Spinedace, of the lower Colorado River basin, comprise the sister taxa to the leatherside chub of the Bonneville basin (Dowling et al. 2002), reflecting a previous connection with the Bonneville basin, whereas both speckled dace and roundtail chub in the upper Colorado River basin genetically show a linkage with the Bonneville basin (Shiozawa et al. 2002, McKell 2003). Corollaries are known from the distribution of mollusks (Taylor 1985).

The aquatic communities in the Lahontan and Bonneville basins and the Great Basin in general are the result of multiple invasions, speciations, and extinctions over at least the last 15 million and possibly the last 30 million years (Smith 1981, Minckley et al. 1986). The north-south orientation of the Great Basin ranges has focused the exchange of organisms along the northern and southern borders of the basin. Once aquatic organisms enter the Great Basin the harsh environment determines the final composition of the fauna and flora. The hot, dry southern Great Basin and the isolated basins of the central Great Basin provide effective barriers to even the more vagrant aquatic organisms.

BEAR RIVER

The Bear River originates on the north slope of the Uinta Mountains of Utah and flows approximately 560 km through three states (Utah, Wyoming, and Idaho; Fig. 14.9). It is a 6th order river in a drainage basin of 19,631 km². From its headwaters the river flows north to Wyoming, follows the Utah-Wyoming state line, and then enters the Bear Lake Valley of Idaho, passing the north end of Bear Lake (1805 m asl). It continues north to the lava fields near Soda Springs (Fig. 14.3), Idaho, where it turns abruptly south and ultimately reaches Bear River Bay (1280 m asl) near Brigham City, Utah, as one of three major inflows to the Great Salt Lake.

Artifacts indicative of the fluted point culture have been found at the edge of the Bear River basin north of the Great Salt Lake (Greer et al. 1981). Although no dates have been associated with them, they probably date to 11,000 years ago. The stemmed point culture (11,000 to 7500 years ago) has been well documented from caves near the wetlands around the Great Salt Lake (Grayson 1993). The lower Bear River basin wetlands were occupied through the mid-Holocene (7200 to 4500 years ago). Fremont sites (1600 to 600 years ago) are also known from the basin (Janetski 1990). By the late prehistoric

period (beginning 550 years ago) the Bear River basin was occupied by Numic tribes. One of these, the Northern Shoshone, occupied the basin when European explorers arrived, although other tribes (Bannock and Blackfeet) also used it.

In the early 1800s, beaver in the Bear River basin attracted American fur trappers operating out of St. Louis, Missouri. This concerned the British-chartered Hudson's Bay Company, which in 1825 sent Peter Skene Ogden to the Bear River with orders to exterminate the beaver so that the American trappers would leave (Durham 1997). Ogden trapped the Bear River in Cache Valley as well as the Weber River basin's Ogden (Huntsville, Utah) and Morgan valleys. His expedition withdrew after confronting American trappers. The American trappers held their rendezvous in Cache Valley (1826 and 1831) and Bear Lake (1827 and 1828; Greer et al. 1981). The beaver were gone by the early 1840s, but emigration to the Pacific had begun.

Both the Oregon and California trails followed the Bear River from near Evanston, Wyoming, to Beer Springs (Soda Springs, Idaho). There, the Oregon Trail went northwest along the Portneuf River and followed the Snake River to Oregon. The California Trail turned southwest, crossing the Malad River of the Bear River Drainage before entering western Utah. Tens of thousands of emigrants walked the upper Bear River. In 1845 alone, 3000 immigrants took the Oregon Trail to Oregon. Settlements began to appear in the Bear River basin in the 1860s, but the Northern Shoshone resisted. In January 1863 government troops stationed at Fort Douglas in Salt Lake City, Utah, and guided by Mormon scout Orrin Porter Rockwell, attacked a winter camp of Shoshone at Battle Creek on the Bear River, near Preston, Idaho. The ensuing battle and massacre opened the area to settlement (Durham 1997, Greer et al. 1981), and by 1870 towns were established throughout the basin (Haws and Hughes 1973).

Physiography, Climate, and Land Use

The Bear River basin has a total relief of 2593 m, from the 3873 m asl Yard Peak in the Uinta Mountains to the Great Salt Lake (1280 m asl). The upper basin primarily drains from the Middle Rocky Mountain (MR) physiographic province (see Fig. 14.9). After passing Soda Springs the river enters the lower basin as it turns south, mostly draining from the Basin and Range (BR) province. The basin

FIGURE 14.3 Bear River, cutting through lava flows near Grace, Idaho (PHOTO BY D. K. SHIOZAWA).

borders form a square, with a panhandle at the southeast corner (see Fig. 14.9). The eastern border is set by the Tump Range (2300 to 2500 m asl, 110°35'W longitude) and high plains (2280 to 2400 m asl, 110°50'W longitude) of Wyoming. The northern border (42°30'N to 42°45'N latitude) is set by the low-elevation (2100 to 2500 m asl) Aspen, Chesterfield, and Portneuf ranges of southeastern Idaho. The western border of the basin (112°20'W to 112°30'W longitude) is formed by low-lying hills (2000 to 2300 m asl) north of the Great Salt Lake. The southern border (41°20'N latitude) abuts the Ogden River drainage of the Weber River basin. The

Bear River Range (2500 m to 2800 m; 111°32'W longitude) separates the upper and middle Bear River basin (averaging about 1820 m asl) from the lower, western basin (averaging 1370 m asl). The Bear River headwaters, in the panhandle, begin in the Uinta Mountains (3000 to 3873 m asl, 40°45'N latitude).

The northern edge of the Bear River basin is dominated by late Cenozoic basalts of the Snake River Plain. The eastern basin is dominated by folded Mesozoic strata, and overthrust Paleozoic limestones dominate the western basin. Block faulting has exposed the thick limestone strata in the Bear River Range (Stokes 1986). The Uinta Mountains are com-

prised of Proterozoic sandstones uplifted 40 to 60 million years ago.

The late Eocene upper Bear River flowed into the Green River of Wyoming (Stokes 1979). The middle Bear River developed in the Miocene along the eastern edge of the Bear River Range. The stream flowed north, merging with the Portneuf River of the Snake River system northwest of Soda Springs, Idaho. Back cutting by the middle Bear River near present-day Evanston, Wyoming, captured the upper Bear River from the Green River in the Pliocene. The upper and middle Bear River remained tributary to the Snake River until the late Pleistocene.

Late Pleistocene volcanism blocked the Bear and Portneuf rivers, forming a lake and eventually dividing it. The southern lake, fed by the Bear River, reached 1660 m asl and spilled over its lowest divide into the Bonneville basin, cutting the Oneida Narrows (Bright 1963). The Bear River capture helped Lake Bonneville reach its pluvial maximum, where it established the Bonneville bench (1552 m asl; 51,700 km²).

About 14,500 years ago Lake Bonneville's threshold at Red Rock Pass collapsed catastrophically, resulting in the Bonneville flood (Malde 1968, Grayson 1993). The lake then stabilized, establishing the Provo bench (1444 m asl). Increasing Holocene aridity caused the lake to recede further, and the lower Bear River cut its channel through the deposits of the drying lake.

The climate is highly variable for such a relatively small basin, with high precipitation in the mountains and much lower precipitation in the valleys. The Bear River Range, the first significant mountains the west-erlies encounter in the northern Bonneville basin, receives over 100 cm/yr precipitation and, around the peaks, 125 cm/yr. The upper Bear River drainage in the Uinta Mountains receives over 75 cm/yr, as do the headwaters of Smith's Fork in the Tunp Range. The Bear River Range rain shadow influences the eastern basin. Evanston, Wyoming, Woodruff, Utah, and Montpelier, Idaho, have lower average annual precipitation (28.6, 23.4, 36.0 cm/yr, respectively) than western basin cities (Preston, Idaho, 49.0 cm/yr; Logan, Utah, 42.1 cm/yr; Corinne, Utah, 43.9 cm/yr). Over the entire basin the average annual precipitation is 55.9 cm, with the peak in January and the low in July (Fig. 14.10).

The mean annual temperature of the basin is 6.5°C, but in the Uinta Mountains mean annual temperatures range from -7°C to 0°C and in the Bear River Range from 1°C to 2°C (Haws and Hughes 1973). A series of high-elevation sinks in the Bear River Range collect cold air in the winter and some-

times register the lowest temperatures in the United States. One of these was -56°C, on February 1, 1985, the lowest temperature recorded in Utah. The western valley average annual low temperatures are 3°C to 13°C warmer and the average annual high temperatures 1°C to 5°C warmer than the eastern valleys. The record high at Bear River Bay, Utah, in the western basin is 40°C, whereas in the eastern basin, Evanston, Wyoming, has a record high of 36.7°C. Record lows for these two locations are -32.2°C and -38.9°C, respectively. The average basin air temperatures are lowest in January and peak in July (see Fig. 14.10).

The Bear River basin encompasses parts of four terrestrial ecoregions (Ricketts et al. 1999). The headwaters begin in alpine tundra of the Wasatch and Uinta Montane Forests ecoregion and progressively flow through subalpine fir and Engelmann spruce, followed by montane forests of lodgepole pine, white fir, blue spruce, and quaking aspen. From Wyoming to Idaho the basin valley is in the Great Basin Shrub Steppe ecoregion. Forests bordering the northeastern edge of the basin are an extension of the South Central Rockies Forests ecoregion, with lodgepole pine, blue spruce, subalpine fir, and quaking aspen. The lower basin is in the Great Basin Shrub Steppe ecoregion, but with shadscale more common. The Wasatch and Uinta Montane Forests ecoregion occurs in the mountains surrounding the lower Bear River basin, with Gambel oak, sagebrush, and bigtooth maple dominating the hillsides and box elder and narrowleaf cottonwood streamside in the canyons. Fremont cottonwood replaces narrowleaf cottonwood in the valleys.

Agricultural lands are concentrated between 1310 to 1480 m asl in the Great Basin Shrub Steppe ecoregion, yet the mean elevation of the entire basin is 1981 m asl. Only 12% to 13% of the basin is less than 1480 m asl (Haws and Hughes 1973). Approximately 2234 km² (11.4%) of the Bear River basin are irrigated (Utah Board of Water Resources 1992). The growing season in Corinne, Utah (1286 m asl), in the western basin is 174 days. Woodruff, Utah (1926 m asl), within the eastern basin, has a 94-day growing season. The agricultural lands in the eastern basin are mainly used for grazing and hay production. In contrast to most Great Basin drainages, the majority of the land in the Bear River basin, approximately 55%, is privately held. National forests comprise 18% of the basin and the BLM manages another 18%. State lands make up 7% and national parks and wildlife refuges 2%. Approximately 9.7% of the Bear River basin is irrigated agricultural land.

River Geomorphology, Hydrology, and Chemistry

The overall fall in the river from its headwaters to the Great Salt Lake is 2133 m (3.8 m/km). The river falls rapidly at its headwaters and in regions where interbasin captures have occurred but has relatively shallow gradients in the intervening basins. From its origin at 3413 m asl to the southernmost Utah–Wyoming border, the river falls 25.9 m/km. The next 40 km to Evanston, Wyoming, averages 7.4 m/km, and from Evanston to Woodruff Narrows Reservoir at the Wyoming–Utah border the fall averages 5.4 m/km. The next 100 km of river meanders in a relatively level 16 km wide valley (0.5 m/km) within both Utah and Wyoming. The river then enters the middle of the Bear Lake Valley (1883 m asl) just north of Bear Lake, where it remains for about 60 km before entering a region of hills and narrow canyons before emerging in Gem Valley at Soda Point Reservoir (2.0 m/km) near Soda Springs, Idaho. At Soda Springs the river turns south and enters the Oneida Narrows, flowing 19 km with an average gradient of 5.8 m/km. Once through the narrows the river enters the north end of Cache Valley, falling 1.4 m/km over a distance of 177 km to the Great Salt Lake.

The streambed substrates reflect the gradient. The headwater region has riffles with boulder, cobble, and rubble substrates, although pools have gravel and sand. The low-gradient stretches of river, such as the Bear Lake Valley, consist of sand and fine gravel bottoms. As the gradient increases in the Soda Point region, boulder and cobble again become abundant. The Oneida Narrows would have always contained large substrate sizes because of its high gradient. However, the use of the river for power generation in this region has increased the armoring of these reaches, and these substrates are now highly embedded. The lower Bear River is mainly sand with some gravel.

Of the average annual precipitation over the entire Bear River Basin (55.9 cm/yr), 11.4 cm/yr enters the runoff (Haws and Hughes 1973) and the remainder is lost to evapotranspiration or otherwise used on site (see Fig. 14.10). If the runoff were to enter the Great Salt Lake without diversion, the mean discharge of the river would be 71.2 m³/s. However, today the average discharge at the Bear River Bird Refuge, the basin terminus, is 52.0 m³/s, indicating an average annual consumptive use of 19.2 m³/s. The maximum recorded annual mean discharge was 143.4 m³/s in 1984, and the minimum was 17.3 m³/s in 1961 (Utah Board of Water Resources 1992).

The annual hydrograph, despite water storage and irrigation diversions, peaks in May at 82 m³/s (see Fig. 14.10), reflecting snowmelt in the headwaters. The low-discharge period is July through September (15 m³/s), when irrigation is at its maximum. The average discharge during the remainder of the year is about 40 to 48 m³/s (Utah Board of Water Resources 1992).

Ion concentrations are lowest during high water and highest in the fall and winter. The headwaters reflect the lower solubility of the Uinta core. Calcium, magnesium, alkalinity, and sulfate levels begin low (26 mg/L, 6.2 mg/L, 83 mg/L, and 6.9 mg/L, respectively) but increase rapidly and concentrations plateau as the river flows through the eastern basin (averaging 54.7 mg/L, 32.3 mg/L, 213.7 mg/L, and 49.7 mg/L, respectively). These four ions reach 65 mg/L, 39 mg/L, 289 mg/L, and 73 mg/L, respectively, at Corrine, Utah, near the river terminus.

Sodium and chloride ions, initially at 1.7 mg/L and 1.9 mg/L in the headwaters, reach 34.1 mg/L and 40.0 mg/L in the eastern basin, paralleling the other ions. When the river reaches Logan, Utah, sodium and chloride ions show a considerable increase (64 mg/L and 78 mg/L), and at Corinne, Utah, the concentrations have increased thirtyfold (254 mg/L and 415 mg/L) above the levels in the headwaters, reflecting leaching of the Lake Bonneville bed by irrigation. During low water the river at Corinne can have 1100 mg/L sodium and 1700 mg/L chloride.

River Biodiversity and Ecology

The Bear River is part of the Bonneville freshwater ecoregion of the Great Basin complex (Abell et al. 2000). Much of the work on the Bear River system has focused on inventories and those are usually conducted in headwater reaches.

Plants

The riparian community changes from the headwaters to the lower basin. In the upper reaches willow tends to predominate, with narrowleaf cottonwood lining the river in areas with wide floodplains. River birch and red-osier dogwood are also present, but these are more abundant in the canyons at lower elevations. The lower Bear River riparian zone includes box elder and Fremont cottonwood, willow, and wild rose.

Invertebrates

The highest diversity of invertebrates occurs in the headwaters and tributaries of the Bear River. The

intense regulation of the middle reaches of the river and the soft substrate in the lower river act to reduce the number of taxa in those parts of the main stem. The dominant mayflies in the Bear River drainage are *Ameletus*, *Baetis*, *Caenis*, *Drunella*, *Ephemerella*, *Epeorus*, *Rhithrogena*, *Stenonema*, and *Tricorythodes*. *Hexagenia limbata* occurs in the Malad River and lower Bear River. Stoneflies include the genera *Capnia*, *Utacapnia*, *Sweltsa*, *Paraleuctra*, *Podmosta*, *Prostoia*, *Claassenia*, *Isoperla*, *Kogotus*, *Skwala*, *Pteronarcys*, and *Taenionema*. At least 11 families of caddisflies have been recorded, including the genera *Amiocentrus*, *Brachycentrus*, *Micrasema*, *Culoptila*, *Protoptila*, *Arctopsyche*, *Cheumatopsyche*, *Hydropsyche*, *Lepidostoma*, *Ceraclea*, *Nectopsyche*, *Limnephilus*, and *Oecetis*. The caddisfly *Helicopsyche* is abundant in the Oneida Narrows. Aquatic moths (*Petrophila*) and alderflies (*Sialis*) are also present. Odonates typical of the region include the dragonfly families Gomphidae (*Gomphus* and *Ophiogomphus*), Aeshnidae (*Aeshna*), and Libellulidae (*Cordulia*, *Somatochlora*, *Leucorrhinia*, *Sympetrum*) and the damselfly families Coenagrionidae (*Amphiagrion*, *Argia*, *Enallagma*, *Ischnura*) and Lestidae (*Lestes*). Two large bivalves, the Oregon floater and Nuttall's high wing floater, and the crayfish *Pacifastacus gambelii* are native to the Bear River (Chamberlin and Jones 1929, Johnson 1986).

Vertebrates

The Bear River system has 17 native fishes. Four species (Bear Lake sculpin, Bonneville cisco, Bonneville whitefish, and Bear Lake whitefish) are endemic to Bear Lake, a graben lake, which, prior to water diversion and damming for downstream power generation, was isolated from the Bear River by wetlands. The other species include two salmonids (Bonneville cutthroat trout and mountain whitefish), six cyprinids (Utah chub, redbreast shiner, least chub, leatherside chub, speckled dace, and longnose dace), three suckers (bluehead sucker, Utah sucker, and mountain sucker), and two sculpins (mottled sculpin and Paiute sculpin). The native Bonneville cutthroat trout, least chub, and leatherside chub are species of concern but have not yet reached threatened or endangered status.

The Bear River capture by the Bonneville basin and the subsequent connection of Lake Bonneville to the upper Snake River system allowed fishes to invade both basins (Hubbs and Miller 1948). The nature of the exchange is still not fully understood. For example, Bonneville cutthroat trout in the

Bonneville basin were thought to have entered with the Bear River (Behnke 1992), but molecular data indicate that cutthroat trout in the modern Bear River system have diverged only slightly from Yellowstone cutthroat trout in the Snake River (Loudenslager and Gall 1980, Martin et al. 1985), whereas Bonneville cutthroat trout in the main basin have a distinctly older phylogenetic position (Smith et al. 2002). The Bear River also acted as a path for dispersal of Bear Lake fishes into Lake Bonneville. Broughton et al. (2000) report Bonneville cisco, Bear Lake whitefish, and Bear Lake sculpin were in Lake Bonneville 11,200 years ago. It is unlikely that these fishes evolved in Lake Bonneville because of its ephemeral history.

Fishes have been introduced since the mid 1800s. The prominent nonnative species in the lower basin and warmwater reservoirs include common carp, fathead minnow, western mosquitofish, channel catfish, black bullhead, bluegill, green sunfish, walleye, and largemouth bass. Cooler streams and lakes have brown trout, rainbow trout, brook trout, lake trout, and Yellowstone cutthroat trout. Brook trout displace native Bonneville cutthroat trout in headwater streams, and brown trout, being more piscivorous than the native Bonneville cutthroat trout, can reduce the numbers of most native fish species in a stream. When coupled with channelization, this can lead to the extirpation of native minnows. Furthermore, rainbow trout and Yellowstone cutthroat trout will introgress with Bonneville cutthroat trout, leading to the loss of unique evolutionary lineages.

Other aquatic vertebrates include amphibians (tiger salamander, northern leopard frog, Pacific chorus frog, Columbia spotted frog, boreal toad), the common garter snake, water vole, muskrat, beaver, river otter, raccoon, and mink. Kingfisher, dipper, osprey, bald eagle, double-crested cormorant, great blue heron, green heron, snowy egret, cattle egret, and many shore birds and waterfowl occur in the basin. Several hundred species of birds utilize the Bear River Migratory Bird refuge, either for breeding grounds or during migration.

The Columbia spotted frog and boreal toad are species of concern because of declining numbers. Land-use practices have played a major role in their decline and nonnative species have had an impact as well. Cattle egret, a relatively new addition to the North American bird fauna, does not seem to be a significant problem, but raccoons have also invaded the basin. They are aggressive omnivores, impacting both terrestrial and aquatic systems.

Ecosystem Processes

Only a few studies have investigated questions of ecosystem function in Bear Lake and its tributaries (e.g., Logan River, Blacksmith Fork, Little Bear River). These included physical–chemical descriptions and energy flows through algae and microbes and the response of invertebrates to chlorophyll concentrations in leaf packs and the resultant effects on leaf processing rates in tributary systems (Giddings and Stephens 1999). McConnell and Sigler (1959) found that chlorophyll *a* standing crop and gross primary production of epilithic algae were 4 to 5 times greater in lower, regulated sections of the Logan River (1.42 g m^{-2} and $5.0\text{ kg m}^{-2}\text{ yr}^{-1}$) than unregulated, upper sections (0.14 g m^{-2} and $1.2\text{ kg m}^{-2}\text{ yr}^{-1}$). This difference was attributed to a reduction in scouring (spring bed load and winter anchor ice) and an increase in water clarity downstream from the reservoir. Midge and mayfly (*Baetis* spp., *Drunella coloradensis*, and *Cinygmula* sp.) biomass and production were on average 5.2 times and 2.0 times greater, respectively, in an open section compared to a shaded section of a Bear River tributary (Behmer and Hawkins 1986). However, black fly production was 1.7 times greater in the shaded section. The authors attributed this pattern to higher food quality (algae and detritus) in the open section, or a phototactic attraction to sunlit areas. Osborn (1981) found that macroinvertebrate production was significantly higher in four streams with high alkalinities ($>150\text{ mg/L}$) in the Bear River drainage ($34.5\text{ g AFDM m}^{-2}\text{ yr}^{-1}$) compared to four streams with low alkalinities ($<50\text{ mg/L}$) in the Yellowstone River drainage of Wyoming ($4.7\text{ g AFDM m}^{-2}\text{ yr}^{-1}$). Higher rates of macroinvertebrate production correlated with higher rates of primary production and detrital processing in the alkaline streams.

Human Impacts and Special Features

Following his 1843 expedition Fremont wrote of the potential of the eastern shore of the Great Salt Lake for settlement. This report and encouragement from entrepreneur Lansford Hastings influenced Brigham Young, the leader of the Mormon Church, then located in Nauvoo, Illinois (Durham 1997). In 1847 the Mormons began their emigration to the Great Salt Lake valley, arriving in late July. In the next decade, 36,600 more came to Utah (Greer et al. 1981) and they began to settle the Bear River valley as well as other regions of the Great Basin. The Mormon pioneers were the first people in North

America to utilize irrigation on a wide scale (Durham 1997). In the process they established independent water companies that tightly control water distribution, even to the point of diverting the entire flow of rivers.

Today the Bear River is managed by legal agreements among water users in three states as well as with the federal government. The Bear River has the highest discharge of any Great Basin river and over 200 water companies take water from the Bear River basin (Utah Board of Water Resources 1992). The Bear River basin has 22 reservoirs with a storage capacity of over 4.9 km^3 . Six of these are on the main stem (see Fig. 14.9). In spite of this, water resource studies have determined that Bear River water is underutilized and additional reservoir storage development is projected (Utah Board of Water Resources 1992). Local opposition to further damming and export of water has developed. Further diversions could significantly impact the wildlife refuges at the terminus of the river and would also amplify the existing impacts of stream-flow regulation. Those species that rely on high spring discharge to generate or maintain microhabitats will undoubtedly be negatively affected.

Reaches of the river above Bear Lake have irrigation return flow as their main water source during the summer. Throughout the basin, leaching of irrigated lands has increased total dissolved solids in the river. The greatest problems in water quality in the lower Bear River are high levels of orthophosphate, high turbidity, high fecal coliform, and increased salinity. Upstream impacts include high turbidity, high BOD, phosphorus, and sediment input (Utah Board of Water Resources 1992). Many of the problems are associated with nonpoint sources such as dairies, feedlots, fertilizer application on croplands, septic tanks in areas of high water tables, and land-use practices in the riparian zone.

The top 6.6 m of Bear Lake is used to augment and regulate downstream flows for hydroelectric power generation. To facilitate this the Bear River is diverted into the northern end of Bear Lake with locks and lift stations. Conflicts between the power company and recreational users of Bear Lake develop when, during low water years, the company lowers the lake below the 6.6 m level in order to maintain power generation. Conflicts also occur between the power company and irrigators over irrigation diversions of water claimed by the power company (Utah Board of Water Resources 1992). Daily fluctuation in water levels has enhanced bank erosion in some parts of the river and direct impacts on the Bear River

below hydropower reservoirs is evident in the armor-ing of the channel and the development of pondweed beds.

The headwaters of the Bear River are part of a major recreation area in the Uinta Mountains. Seasonal road access to forest campgrounds and private holdings has facilitated summer use of the region. Camping opportunities range from well-developed campgrounds along highway 150, the major highway in the upper Bear River basin, to primitive camping along unimproved roads in forestlands. A number of spur roads provide trail access for backpackers hiking into the High Uinta Wilderness Area.

Bear Lake is also a major recreation destination. The clear waters and cool air temperatures at the 1805 m asl lake make it ideal for summer recreation. Boating and fishing are both popular. Although fishing in Bear Lake occurs year-round, it is best in the fall and winter months and appears to be associated mainly with spawning of resident fishes. Lake trout are most accessible during their spawning period from late October to mid November. The same is true of Bonneville whitefish, which begin spawning in November. In early to mid-January the Bonneville cisco spawn and are readily captured with dip nets along the east shore of the lake. Bear Lake whitefish spawn from late January to February. The Bear Lake cutthroat trout and the native whitefish, feeding on eggs, concentrate in these spawning grounds and are thus more easily caught by anglers. Snowmobile recreation has also become a major wintertime use of the Bear Lake area. Recreational housing development on the western side of the lake at the base of the Bear River range has helped foster that use.

The lower Bear River, because of its high discharge, played a significant role in late Pleistocene Bonneville basin and lower Snake River drainage dynamics. That has made the region geologically important. Evidence of the Bear River capture into the Bonneville basin, the scars left by an expanded Lake Bonneville, and the results of the subsequent catastrophic flood as Lake Bonneville drained to the north are classical geology textbook topics.

At the terminus of the river is the 26,300 ha Bear River Bay Migratory Bird Refuge, the first waterfowl refuge formed in the United States. This, with adjacent state (10,900 ha) and private (20,300 ha) holdings, is one of the largest freshwater wetlands in the United States (Utah Board of Water Resources 1992). State and federal agencies currently hold established water rights for the marshes. Bear River Bay is a major stopover point for migrating waterfowl in the

Pacific flyway. Because of its extensive wetlands, it has become a major area for bird watching, and it is also managed for waterfowl hunting.

SEVIER RIVER

The Sevier River is a 5th order desert river in south central Utah (Fig. 14.11). Its basin is approximately 290 km long by 190 km wide (42,025 km²). The river flows north for the first two-thirds of its length through a broad valley of high-elevation sagebrush scrub desert. It then turns abruptly southwest to its terminus in Lake Sevier, 50 km southwest of Delta, Utah. Its southerly path is in the bed of Pleistocene Lake Bonneville. Two major tributaries, the East Fork, heading near Bryce Canyon National Park, and the San Pitch River, heading near Fairview, Utah, enter the Sevier River. The Beaver River, which arises in the central basin, provides no input into the Sevier River, although prior to the early 1900s it was connected.

Prehistoric occupation of the Sevier River basin may extend back to 11,000 years ago as evidenced by fluted and stemmed points that have been found in the Beaver Bottoms and the Sevier Desert near Delta, Utah. Archaic sites (8500 to 2500 years ago) have been documented on the Wasatch Plateau, and Fremont occupation is known throughout the Sevier River basin. The Fremont (1600 to 650 years ago) in this region vanished abruptly and may have been replaced by Numic-speaking tribes (Southern Paiutes, Utes). Southern Paiutes and Utes were the inhabitants of the basin at the time of first European contact.

The first Europeans known to enter the basin were led by Franciscan padres Fray Silvestre Velez de Escalante and Fray Francisco Atanasio Dominguez. Their party left Santa Fe, New Mexico, in 1776 to find an inland route to Monterey, California. They followed the Duchesne River in eastern Utah and entered the Great Basin through Diamond Fork of the Spanish Fork River, east of Utah Lake. After resting at Utah Lake the expedition traveled south and found the Sevier River (Greer et al. 1981). They initially thought it was El Rio de San Buenaventura (the Green River), which they had crossed earlier in their expedition, but the river was too small, and they named it El Rio de Santa Isabel (Warner 1995). In 1813, traders Moricio Arce and Lagos Garcia named the Sevier River the Rio Sebero or Rio Seviro, which is thought to be the source of its present name (Utah Board of Water Resources 1999).

In 1826, Jedediah Smith, an American trapper on his way to California, opened a trail through Salina Canyon, near Salina, Utah, and followed the Sevier River upstream (south) to Clear Creek (Durham 1997), establishing what was to become part of the old Spanish Trail, a major overland route from Santa Fe, New Mexico, to Spanish southern California. In 1849, the first Mormon settlers came into the Sevier River basin, and the following year began to divert water for irrigation (Utah Board of Water Resources 1999).

Physiography, Climate, and Land Use

The Sevier River basin can be divided into four sections: the upper, middle, and lower sections of the Sevier River itself and the Beaver River subbasin. The eastern border of the upper Sevier River basin consists of the Wasatch, Fish Lake, Awapa, and Aquarius plateaus, of the high-plateau section of Hunt's (1974) Colorado Plateau (CO) physiographic province (see Fig. 14.11). The Wasatch plateau, dominated by Jurassic, Cretaceous, and early Tertiary sedimentary rocks (Hintze 1988), is over 3300 m asl and its highest peak is the 3440 m asl South Tent Mountain. The underlying strata of the Fish Lake (3000 m asl) and Awapa (2500 to 2800 m asl) plateaus are similar to the Wasatch Plateau to the north (Hintze 1988). The Fish Lake Plateau's highest peak is Mount Terrill (3520 m asl), and the plateau is capped with 100 to 300 m of mid-Tertiary lava. The Aquarius Plateau peaks at 3453 m asl and is primarily composed of basaltic flows (Stokes 1986) from the southern Great Basin hot spot (Fillmore 2000). The plateaus are in the Wasatch and Uinta Montane Forests terrestrial ecoregion, with subalpine fir, Engelmann spruce, and limber pine at high elevations, quaking aspen, blue spruce, white fir, and Douglas fir at intermediate elevations, and Gambel oak, bigtooth maple, and Utah juniper at lower elevations.

The Sevier River heads at the southernmost reaches of the Bonneville basin, adjacent to the Colorado Plateau. The western border of the Upper Sevier is produced by the Markagunt Plateau (3000 to 3446 m asl; Colorado Plateau physiographic province; southwest of Kingston, Utah) and the Tushar Mountains (Basin and Range [BR] physiographic province; west of Kingston). The Markagunt plateau, which slopes to the east, consists of basaltic dikes and lava flows with exposed Paleocene and Eocene limestones (Fillmore 2000). The Tushar Mountains, of mid-Tertiary igneous intrusives,

(Stokes 1986) include Delano Peak, the highest peak in the Sevier River basin (3710 m asl). These mountainous regions, like the eastern border, are in the Wasatch and Uinta Montane Forests ecoregion and the vegetation is similar to the eastern border, although Utah juniper tends to be more abundant. Soils are predominantly mollisols (Utah Board of Water Resources 1999).

The southern border of the upper Sevier River basin is formed by the Paunsaugunt and Markagunt plateaus. Here, late-Tertiary volcanic dikes associated with the southern Great Basin hot spot (Nelson and Tingey 1997, Fillmore 2000) intrude through uplifted plateaus of Paleocene and Oligocene lake sediments. The southern edge of the Paunsaugunt Plateau consists of these eroding limestones (Clarion Formation of Paleocene Lake Flagstaff; Hintze 1988), which form the spires of Bryce Canyon National Park. Dominant plants are ponderosa pine, Douglas fir, singleleaf pinyon pine, Utah juniper, and sagebrush, which are part of the Wasatch and Uinta Montane Forests ecoregion, plus several intervening tongues of Colorado Plateau Shrublands.

The middle Sevier River basin begins as the river leaves the Colorado Plateau physiographic province and enters the Basin and Range province, south of Kingston, Utah. The middle section ends just past the northern bend of the river at Leamington, Utah, which is northeast of Delta, Utah. Its northern border includes the San Pitch Mountains (2667 m asl) of the Wasatch Front Range, the East Tintic Mountains (2290 m asl), the Sheeprock Mountains (2500 m asl), the Simpson Mountains (2562 m asl), and the intervening alluvial and lake deposits (1600 to 2000 m asl; Great Basin Shrub Steppe ecoregion). The East Tintic, Sheeprock, and Simpson mountains are Wasatch and Uinta Montane Forests, with Utah juniper, singleleaf pinyon pine, and sagebrush at lower elevations and quaking aspen, Douglas fir, and white fir at higher elevations. The San Pitch Mountains, east of Sevier Bridge Reservoir, have similar high-elevation vegetation (also subalpine fir, Engelmann spruce, and blue spruce), and midelevation vegetation of Gambel oak, bigtooth maple, singleleaf pinyon pine, and Utah juniper. The soils are mollisols. The southern border of the middle Sevier River basin is generated by the Canyon Mountains. Valley floors are Great Basin Shrub Steppe with aridisols, and the vegetation is predominantly sagebrush and grasses.

The lower Sevier River basin, including Lake Sevier, has a western border formed by the House Range (2947 m asl) and Wah Wah Mountains (2568 m asl), both with Wasatch and Uinta Montane

Forests (sagebrush, Utah juniper, singleleaf pinyon pine, quaking aspen, ponderosa pine, Douglas fir, and western bristlecone pine). It is entirely within the Basin and Range physiographic province. The lowlands to the east of these mountains are typical Great Basin Shrub Steppe, with sagebrush, black greasewood, and shadscale dominating the community. The Cricket (2280 m asl) and San Francisco (2944 m asl) ranges form the western interior border with the Beaver River subbasin. An ancient riverbed (72 km in length, 30 m deep, and 1200 to 6000 m wide) southwest of the Simpson Mountains is the Sevier River basin's remnant connection with the receding Lake Bonneville. The channel was active until Lake Sevier fell below 1411 m approximately 10,000 years ago (Grayson 1993).

The Beaver River subbasin is usually treated as a separate watershed because the Beaver River only flows into the Sevier River under exceptionally wet conditions. Prior to European settlement, however, it maintained a perennial connection to the Sevier River (Utah Board of Water Resources 1995). The eastern, northern, and most of the western borders of the Beaver River subbasin (see Fig. 14.11) are adjacent to the Sevier River subbasin. The southwestern border extends slightly into Nevada (Great Basin Shrub Steppe) and the southern border is formed by the Bull Valley (2230 m asl), Pine Valley (2780 m asl), and Harmony (2202 m asl) mountains west of Cedar City, Utah. These are the southerly and westerly extents of the Wasatch and Uinta Montane Forests ecoregion, with ponderosa pine, limber pine, Douglas fir, and white fir. Gambel oak and Utah juniper occur in the foothills. The entire Beaver River subbasin is within the Basin and Range physiographic province.

Climate in the Sevier River basin is influenced by mountain ranges, latitude (from 37°26'N to 39°47'N latitude), and the increasing strength of the Arizonal monsoon in the southeastern basin. The annual temperature extremes within the basin are -27°C to 39°C. The record high temperature is 43.3°C (at Delta, Utah) and the record low is -40°C (at Scipio, Utah; Utah Board of Water Resources 1999). Overall, the mean annual temperature of the basin is 9.3°C, but both elevation and latitude influence local mean annual temperatures. Bryce Canyon, Utah, in the upper Sevier River basin is 4.7°C and Delta, Utah, is 9.8°C. Precipitation is >40 cm/yr in mountain areas and one-third of that in the western basin. The basin receives about half as much precipitation as the northern Wasatch Range, and the northern Sevier River basin averages 15 cm more precipitation than the southern part (Utah Board of

Water Resources 1999). Maximum precipitation (>4 cm/mo) occurs in August in concert with the summer monsoon season (see Fig. 14.12).

The majority of the Sevier River basin is managed by the federal government. The U.S. Forest Service and Bureau of Land Management administer 23.1% and 47.9% of the land, respectively. In the early 1900s mountainous lands were added to the U.S. forest system because of severe overgrazing and resultant flooding of valley communities. National Parks and other federal landholders make up about 0.2%, and state lands 7.9%, of the total area, leaving 21.1% of the basin privately owned. Irrigated lands cover 4.5% of the basin. Dry crops are raised in just over 0.4% of the land in midelevation reaches. In contrast, 80% of the entire Sevier River basin (90% of the Beaver River and 75% of the Sevier River basins) is grazed. Cattle production is the primary agricultural activity (Utah Board of Water Resources 1995, 1999) although timber harvest occurs. Bryce Canyon National Park and Cedar Breaks National Monument are major tourist destinations. Camping, fishing, hunting, and snowmobiling are important recreational uses of forest and BLM lands. Eight state parks are located in the basin. The Beaver River subbasin supports some mining. Iron County has the only extensive source of iron ore in the Bonneville basin. The Mormons began mining it in 1852. Lead and silver were mined near Minersville, Utah, beginning in the 1870s (Greer et al. 1981). The Sevier River basin also includes the majority of the potential geothermal energy sites in the Bonneville basin.

River Geomorphology, Hydrology, and Chemistry

The Sevier River heads at 2370 m asl on the southern edge of the Markagunt Plateau in Southern Utah. The overall descent of the Sevier River from its headwaters to Lake Sevier (1369 m asl) 535 river km away is about 1.9 m/km. Asay Creek, heading at 2652 m asl, and Mammoth Creek, heading at 3200 m asl, drain the Markagunt Plateau from the west and join the headwaters of the Sevier River south of Hatch, Utah, increasing the Sevier River streamflow about threefold. Mammoth Creek falls 28.9 m/km before it meets the Sevier River. The Beaver River heads in the Tushar Mountains and falls 2243 m over 196 km (11.4 m/km) to its terminus in the Sevier Desert. The upper tributaries in the Sevier River basin are rocky, cold mountain streams with clear water and mixed riffle-pool habitat. Meadows have sand and pebble bottoms.

FIGURE 14.4 Sevier River at Big Rock Candy Mountain, Utah (downstream of Paiute Reservoir) (PHOTO BY D. K. SHIOZAWA).

Below the confluence with Mammoth Creek the Sevier River flows through Panguitch Valley and is joined by the East Fork of the Sevier River at Kingston, Utah. The East Fork originates at 2500 m asl on the Paunsaugunt Plateau and parallels the Sevier River in the next valley to the east. The Sevier River continues northward, falling 3.0 m/km (Fig. 14.4). In Circleville Canyon the gradient increases to 4.2 m/km. Below Circleville Canyon the river descends at about 2.3 m/km, but when it enters Sevier Canyon above Richfield, Utah, it falls 5.8 m/km.

From the mouth of Sevier Canyon the river descends at 1.3 m/km to the middle section of the Sevier River near Sevier Bridge Reservoir. There the river turns northwest and then southwest as it skirts the Canyon Mountains. The river falls at 2.5 m/km through this section. At Leamington, Utah, the river enters the Sevier Desert, the lower section of the Sevier River. It terminates 190 river km away in Lake Sevier, falling just 0.6 m/km in this section, a reflection of its path in the bed of ancient Lake Bonneville.

The highest tributary to the Beaver River heads at 3633 m asl near Delano Peak, 32 km upstream from the mouth of Beaver Canyon (1828 m asl), for a fall of about 56 m/km. From Beaver, Utah, to Minersville, Utah, on the edge of the Escalante Desert, the river falls 258 m for an average descent of 7.6 m/km. Once in the Escalante Desert the Beaver River flows north 130 km through the Beaver Bottoms, falling an additional 180 m (1.4 m/km) to its terminus at 1390 m asl in the Sevier Desert. The tributaries to the south and west of the Beaver River are not connected with the Beaver River, being dewatered for irrigation, evaporating, or simply entering the groundwater in the Escalante Desert.

By the time the Sevier River begins to track its main channel near Hatch, Utah, in the upper Sevier River basin it is turbid and has a sand, silt, and imbedded rubble bottom with deeply undercut banks. Even near the head of the East Fork of the Sevier River, in a region utilized for open-range grazing, the water is turbid from precipitating carbonates. Near Kingston, Utah, the Sevier River is

largely sand and silt with relatively steep, raw banks from down-cutting and erosion. Where the river cuts through rock outcrops, such as Circleville Canyon and Sevier Canyon, the riverbed is partially embedded boulder and rubble. The middle and lower Sevier River bed is sand and silt with some gravel.

Desert valley streams are often influent streams feeding groundwater aquifers in their alluvial plains, and their hydrology is strongly affected by evaporative losses, irrigation diversions, and other consumptive uses. Total runoff in the Sevier River, excluding input from the Beaver River, should be capable of generating an average annual discharge of 32.2 m³/s (Utah Board of Water Resources 1999; data not available for the Beaver River), but the average annual discharge into Lake Sevier today is approximately 1.3 m³/s. At Hatch, Utah, in the upper Sevier River basin, the average discharge is 3.1 m³/s and at Piute dam, after the East Fork of the Sevier joins the river, it is 5.3 m³/s. Near Salina it falls to 3.9 m³/s, but below the San Pitch River inflow the average annual discharge increases to 7.8 m³/s (Utah Board of Water Resources 1999). Peak runoff occurs in May (see Fig. 14.12) as high-elevation snowmelt feeds the river. Summer monsoon storms moderate the post-snowmelt decline in runoff.

The concentration of dissolved ions reflects both land use and the geology of the region. The headwaters of both the Sevier and the East Fork of the Sevier originate in soluble Paleocene and Eocene limestones. At Hatch, Utah, alkalinity is 175 mg/L as CaCO₃ and calcium is 40 mg/L. These climb steadily downstream (Salina, Utah, 278 mg/L and 91 mg/L). Other ions show a similar increase, but at Sigurd, Utah, sodium, chloride, and sulfate, which were 2 mg/L, 3 mg/L, and 4 mg/L, respectively, at Hatch, Utah, significantly increase (74 mg/L, 81 mg/L, and 170 mg/L) as the river enters a region of exposed Jurassic marine shales (Arapien formation; Utah Board of Water Resources 1999). Irrigation return flows also increase salt concentrations. Below Delta, Utah, the total dissolved solids reach 2730 mg/L (1000 mg/L chloride and 880 mg/L sulfate). High NO₃-N concentrations (up to 45 mg/L) have been detected in shallow groundwater in the San Pitch valley, resulting from nonpoint sources, especially feedlots, and septic systems. Large poultry farms occur throughout the valley, which is the center of Utah's turkey industry.

River Biodiversity and Ecology

The Sevier and Beaver rivers are part of the Bonneville freshwater ecoregion of the Great Basin

complex (Abell et al. 2000). Some descriptive biological information of aquatic plants and animals in the Sevier basin is available, but ecological studies are sparse.

Plants

The riparian vegetation of the upper Sevier River includes willow, red-osier dogwood, scattered Fremont cottonwood, willow, and river birch. Both Circleville and Sevier canyons have narrowleaf cottonwood, willow, wild rose, and river birch in the riparian zone. At higher elevations box elder, narrowleaf cottonwood, red-osier dogwood, willow, and wild rose may also line the banks, but the exact community make-up depends on the deepness of the canyon. The nonnative Russian olive and tamarisk have become invasive pests along parts of the floodplain.

Invertebrates

Mayflies occur throughout the Sevier River system. *Baetis* and *Tricorythodes* are found in the turbid upper and middle Sevier. Headwater and high-gradient streams have a greater diversity of mayflies (e.g., *Rhithrogena*, *Ephemerella*, *Drunella*) and stoneflies (*Hesperoperla*, *Isoperla*, *Nemoura*, *Pteronarcys*, and *Pteronarcella*). Caddisflies include *Brachycentrus* and *Hydropsyche*, which are found in the main rivers, as well as limnephilids and leptocerids in tributary streams. Aquatic moths and the amphipod *Hyalella* are also present. Dragonflies occur in slower waters, ponds, and wetlands throughout the entire system. These include *Gomphus*, *Ophiogomphus*, *Aeshna*, *Anax*, *Libellula*, *Erythemis*, *Plathemis*, and *Sympetrum*. Damselflies include Coenagrionidae (*Amphiagrion*, *Argia*, *Enallagma*, *Ischnura*). True bugs such as *Ambrysus* and *Lethocerus* are common and even occur in highly turbid, warm waters. Two mussels, the Oregon floater and Nuttall's high wing floater, are native to the system (Chamberlin and Jones 1929). The Asiatic clam has become established.

Vertebrates

Eight species of native fishes (Utah chub, leather-side chub, redbreasted shiner, speckled dace, mottled sculpin, mountain sucker, Utah sucker, and Bonneville cutthroat trout) were reasonably widespread in the Sevier River basin prior to water development. Longnose dace and Paiute sculpin may also have been present, and least chub, a species of concern, occurs in the upper edge of the middle Sevier River basin. Today, Bonneville cutthroat trout are confined to

headwater reaches of small streams and the leather-side chub has been greatly reduced in abundance. All other species are still in the upper Sevier River. Mountain whitefish and bluehead sucker of the northern Bonneville basin are not known to be native to the Sevier River basin, but mountain whitefish have been introduced. Other nonnative fishes include Yellowstone cutthroat trout, brook trout, brown trout, rainbow trout, fathead minnow, western mosquitofish, channel catfish, largemouth bass, yellow perch, walleye, common carp, and bluegill. Most were introduced for recreational fisheries. Trout are in the upper Sevier and Beaver rivers and tributaries, and the spiny rayed fishes (yellow perch, walleye, etc.) are more common in low-elevation reservoirs. Nonnative fishes compete with, hybridize with, eat, or otherwise displace native fishes.

Among the nonfish vertebrates in the Sevier River basin, amphibians include tiger salamander, Woodhouse's toad, boreal toad, northern leopard, Pacific chorus frog, and Columbia spotted frog. Both the Boreal toad and the Columbia spotted frog are species of concern in Utah and are potential candidates for federal listing. Habitat destruction and introduction of nonnative fishes into previously fishless areas have impacted these species. The common garter snake is found throughout the basin. Aquatic mammals of the Sevier River basin include the water vole, found in the Wasatch Plateau, and muskrat, beaver, and mink throughout the valleys (Durrant 1952). Dippers can be found in the mountain streams and osprey and bald eagles use reservoirs and lakes in the basin. Numerous waterfowl and wading birds utilize the reservoirs along the river as well as state-owned wetlands.

Ecosystem Processes

No studies of ecological processes have been conducted in the Sevier River or any of its tributaries. Fish investigations conducted by the Utah Division of Wildlife Resources consist primarily of inventories. The U.S. Forest Service has also sampled invertebrates and conducted stream assessments, but those studies are establishing baseline data, not life histories or energetics information. This river, like other Great Basin rivers, has alpine headwaters where riparian communities are likely to function much as is seen in other high-mountain regions, with deciduous and coniferous litter input as a major food source. However, once the river enters the valley reaches, siltation, turbidity, and bank erosion become dominant factors. The riparian cover becomes dominated by grasses and low shrubs and this reduces

allochthonous input. Silt and sand reduce or eliminate interstitial habitat in the riffles. Runs and pools with sandy bottoms comprise the majority of the river bed. In these areas chironomid midge larvae, odonates, and true bugs tend to dominate. Black flies and the net-spinning caddis *Hydropsyche*, the case builder *Brachycentrus*, and the mayflies *Baetis* and *Tricorythodes* are found in the riffles and attached to any hard structures, such as sticks and branches that happen to be imbedded in the streambed. Many of these are filter feeders, but it is not known if their primary food source is derived from autochthonous sources (instream production) or allochthonous detritus, input from the herbaceous riparian and irrigation return flows. In any case, the impact of man is so great that the communities existing today are unlikely to resemble or function like those that existed 150 years ago.

Human Impacts and Special Features

The Sevier River is the major south–north flowing river in the Bonneville basin, tracking the linear mountain ranges formed with the extension of the Great Basin. Other rivers in the Bonneville basin flow through mesic mountain valleys before entering the Great Basin Shrub Steppe, usually for just short distances to their base-level lakes. But the Sevier River is in dry Great Basin Shrub Steppe for most of its length. It is also the only major river in the Great Basin with significant monsoonal influence.

About 57,000 people live in the Sevier River basin and an additional 38,000 live in the Beaver River subbasin. Water resources are fully allocated. The first reservoir in this basin, Scipio Reservoir, was built in 1860. By 1886 the first litigation over water use was filed (Utah Board of Water Resources 1999), indicative of dewatering of the river in the downstream reaches. The Sevier River basin has 65 reservoirs and lakes that are used for surface-water management, with four reservoirs on the main river. Additional sites for new reservoirs have been investigated, two on the main river. The basin is short on water relative to demand by about 15.2 million m³ annually. On average, 1015 million m³ of water per year are available for irrigation, yet 1114 million m³ of water are actually diverted for agriculture use. Just over 11.5 million m³ are diverted into the Sevier River basin from the Price and San Rafael rivers of the Green River and 166 million m³ of groundwater are pumped from wells. About 40% of the water diversions utilize return flows from upstream irrigation (Utah Board of Water Resources 1999). No

instream flow requirements exist on the main Sevier River. Entire sections of the river can be dewatered if demands are high and if downstream uses are not required. Irrigation return flows and side streams usually prevent complete drying of the Sevier River. That is not the case in the Beaver River subbasin. In the 1800s, wetlands existed in the Beaver Bottoms, and the river discharged into the Sevier River. With the construction of Minersville Reservoir in 1913 the wetlands dried, and the river no longer reaches the Sevier River.

The reduced flows associated with irrigation diversions, irrigation return flows, and increased turbidity combine with siltation to increase water temperatures in the lower basin. This restricts coldwater taxa to upstream locations and in tributaries. Many of the native fishes are tolerant of a wide range of temperatures and salinity simply because they evolved in the harshness of the Great Basin desert. However, the relegation of Bonneville cutthroat trout to the headwaters is likely partially influenced by the decline in habitat and water quality.

HUMBOLDT RIVER

The Humboldt River is a 6th order desert river in north-central Nevada. Mary's River, beginning in the Jarbidge Mountains (north of Wells, Nevada), is generally considered to be the headwaters of the Humboldt River because it is the northeastern-most tributary from the river's terminus, 559 river km away at the Humboldt Sink (Fig. 14.13). It is the only major river basin (43,597 km²) completely contained within the state of Nevada. The primary source of water for the Humboldt River is snowmelt from the Jarbidge (3202 m asl), Ruby (3451 m asl), and Independence (2660 m asl) mountain ranges. Palisade Canyon, a narrow confined stretch of the river southwest of Elko, Nevada (see Fig. 14.13), separates the Humboldt River basin into upper and lower sections. Below Palisade Canyon the river begins to decline in size, with no significant input for its remaining length.

Evidence of prehistoric habitation comes from a stemmed point site in the lower Humboldt River basin, which was overlain by volcanic ash from Mount Mazama (6800 years ago). Stemmed points were in use from 11,000 to 7500 years ago. During the middle Holocene (7500 to 4500 years ago) aridity in the basin was accompanied by the abandonment of wetland sites, but a burial and an artifact cache from a site (Leonard Rockshelter) near Lovelock, Nevada, indicate that the basin was inhabited during

this period. As the late Holocene began, the frequency of occupied sites increased. The inclusion of sedges and cattails in the diet reflects the expansion of wetlands (Grayson 1993). Pinyon nuts also became an important component in the diets of the inhabitants of the Humboldt River basin. At the time of first contact with Europeans, Numic-speaking tribes occupied the Humboldt River basin. Whether these people were the same as those in the basin at the beginning of the late Holocene is unknown, although several have hypothesized that the early inhabitants were replaced by Numic-speaking people about 1000 years ago.

In 1828, Peter Skene Ogden of the British Hudson's Bay Company traveled into the northern Great Basin and found a river running from east to west. The next year he followed it to its terminus southwest of present-day Lovelock, Nevada. In 1831, Ogden's successor with the Hudson's Bay Company, John Work, returned to the upper Humboldt River basin with a crew of 100 men and effectively trapped out the beaver. In 1841, the first emigrant group, the Bidwell-Bartleson Company, followed Ogden's trail along the Humboldt on their way to California, and in 1845, John Fremont's party mapped the trail and it became the main route across Nevada to California. Until that time the river had many names, including the Unknown River, the Ogden River, and Mary's River (after Ogden's wife). However, Fremont renamed the river in honor of Alexander von Humboldt, the name by which it is known today (Durham 1997).

Physiography, Climate, and Land Use

The Humboldt River lies within the Lahontan basin, a part of the Great Basin section of the Basin and Range (BR) physiographic province (see Fig. 14.13). The western borders of the Humboldt River basin include the desiccated bed of Lake Lahontan, the Blackrock Desert, and the Trinity Range (118°45'W longitude). The Jarbidge, Santa Rosa, and Independence mountains form the high northern border of the basin (41°50'N latitude), and the Owyhee Bluffs and the Snake Mountains form the lower-elevation northern border. These are predominantly igneous rock. The northeastern edge of the basin is comprised of a series of low ranges (2100 to 2700 m asl) and highlands (1890 to 2050 m asl; 114°50'W longitude). The East Humboldt Range and the Ruby Mountains (3050 to 3470 m asl) form the southeastern border of the basin. About 10 smaller mountain ranges, with

FIGURE 14.5 Humboldt River downstream of Tonka siding, east of Carlin, Nevada (downstream from Elko, Nevada) (PHOTO BY D. K. SHIOZAWA).

peaks between 2500 and 3000 m asl, form the southern border (38°45'N to 40°00'N latitude), with the Toiyabe Range and Shoshone Mountains bordering the southern extension of the Reese River (south of Battle Mountain, Nevada). The basin relief, from Ruby Dome Peak (33,470 m asl) to the Humboldt Sink (1186 m asl), is 2283 m.

The Humboldt River basin supports two terrestrial ecoregions. The low-altitude volcanic rock, plains, and valleys, which comprise most of the watershed, are in the Great Basin Shrub Steppe ecoregion, with sagebrush, bunch grasses, and inva-

sive nonnative cheat grass. Shadscale and black greasewood dominate in the lower basin. Mountain ranges, most notably the Ruby, Independence, Santa Rosa, and Jarbidge mountains, are in the Great Basin Montane Forests ecoregion in their upper elevations (Ricketts et al. 1999) and are comprised of quaking aspen, juniper, singleleaf pinyon pine, limber pine, bristlecone pine, white fir, and whitebark pine.

Although located in the center of the Great Basin, climate is surprisingly variable in the Humboldt drainage. Wells and Elko, Nevada, in the upper basin have lower average annual temperatures (6.6°C and

8.2°C) than cities in the lower basin (e. g., Lovelock, Nevada, average annual temperature 11.2°C). The average basin temperature peaks at 21.7°C in July and the average low temperature is -1.7°C in January (Fig. 14.14). Precipitation is at its minimum in August, is greater in the higher elevations of the upper basin, and decreases as elevation drops and as the river moves closer to the rain shadow of the Sierra Nevada. Elko and Wells, Nevada, average over 25 cm of precipitation annually. Valleys of the lower basin only average 15 to 20 cm of precipitation per year, and their evaporation rates exceed 100 cm per year (<http://water.nv.gov/Water%20planning/humboldt/hrchrono.htm> 1999).

Agriculture, primarily livestock grazing, is by far the most extensive land use in both the upper and lower basins. During the 1870s and 1880s the entire basin was heavily grazed. Initially this included open-range winter grazing, but following a severe winter in 1889 to 1890, when many cattle died, ranchers began supplementing grazing with hay crops. This led to increased irrigation and thus conflicts over water. By the early 1900s grazing-induced vegetation destruction and subsequent erosion in the upper basin caused the federal government to include a number of the mountain headwater areas as part of the National Forest system. Today National Forests cover 12% of the drainage. The remaining open rangelands, which were lower-elevation federal lands, began to be managed in 1935, again in response to habitat degradation from overgrazing. These lands, 54% of the basin, are now managed by the Bureau of Land Management. Private lands compose 32% and reservations, state lands, and other federal holdings make up the remaining 2% of the land ownership in the Humboldt River basin. Essentially all federal lands are still grazed.

Mining, especially in the lower basin, has been a dominant economic activity since the 1860s. Mining, mostly for silver in the late 1800s, led to deforestation as timber was cut for ties and beams. Water was utilized for processing ore. One company even claimed all of the water in the Humboldt River for its mining operations, but subsequent vigilante action by local residents eliminated that claim by dynamiting the company's dam. In the early 1900s, gold was discovered in the Humboldt River basin, and gold mining continues today, accounting for about a quarter of the basin's employment (<http://water.nv.gov/Water%20planning/humboldt/hrchrono.htm> 1999).

River Geomorphology, Hydrology, and Chemistry

The upper basin above Palisade Canyon composes less than 30% of the drainage area but provides all of the water for the lower basin. The Mary's River from its headwaters to the Humboldt is 92 km in length. From its confluence with the Mary's River the Humboldt River flows 116 km past the towns of Elko and Carlin, Nevada, to Palisade Canyon (Fig. 14.5). Along this reach the Humboldt River receives water from tributaries draining the Ruby Mountains to the south and the Independence Mountains in the north.

The hydrology of the Humboldt is unusual in that discharge currently peaks near Palisade Canyon, well upstream of its terminus, at 11.4 m³/s. Streams in the lower Humboldt River basin stop flowing a considerable distance from the river. The Little Humboldt River, whose subbasin comprises over 10% of the Humboldt River basin, dries 10 km from the Humboldt River, and the Reese River, comprising almost 21% of the basin, stops flowing 16 to 32 km short of the Humboldt River. Below Rye Patch Reservoir the river discharge has fallen to 7.2 m³/s (<http://water.nv.gov/Water%20planning/walker/wrchrono.htm> 1999) and it still has to flow 80 km through irrigated land before reaching the Humboldt Sink. After evaporation, irrigation, and influent losses to depleted groundwater aquifers, little water remains to enter the sink. An average discharge of 0.9 m³/s was recorded between 1900 and 1960, but no discharge data are available for the terminus of the Humboldt River prior to water diversions. We therefore used the Humboldt River's estimated percentage of total Lahontan basin flow (Grayson 1993) to generate a prediversion discharge of 25.8 m³/s. Based on available data, prediversion runoff was still very low, peaking in June as the result of spring snowmelt from the mountains, with extremely low runoff from August through February due to evapotranspiration losses (see Fig. 14.14).

Most of the upper basin headwaters consist of mountain streams with clear water, unembedded rocky bottoms (gravel, cobbles, rubble), and mixed riffle-pool habitat. The gradient of the Mary's River is 15.1 m/km. From the confluence of Mary's River and the Humboldt River to Palisade, the river falls at 1.5 m/km. It meanders through a broad valley and habitat heterogeneity decreases, with patchy rubble and gravel substrates embedded in sand and silt.

Below the Palisade Canyon the river enters the lower basin and flow decreases as evaporative losses and agricultural diversions exceed inflows. From Palisade to the Humboldt Sink the river gradient averages about 0.7 m/km. Sand and silt become predominant. The mountains of the lower basin are far from the main channel and most of the tributaries only reach the main river during extreme flood events. Rye Patch Reservoir, the only reservoir on the main-stem Humboldt River, is located south of Winnemucca, Nevada. It was constructed in 1936 to provide irrigation water for Lovelock Valley. From Rye Patch Reservoir the river flows 70 km past a number of low-head irrigation-diversion dams to a series of canals that divert water to the Humboldt Lakes (Toulon and Humboldt lakes). Prior to European settlement the main stem of the Humboldt River annually flooded its terminus 10 km below the Humboldt Lakes, the Humboldt Sink. In 1829, Peter Skene Ogden described the sink as a 13 km long and 3.5 km wide lake, with dense vegetation (Egan 1977). Now, because of water diversions, the Humboldt River reaches the sink only during high-water years. The Humboldt Sink is about 10 km from the Carson Sink, the endpoint of the Carson River, which flows from the southwest. In extremely wet years water in the Humboldt Sink can flow into the Carson Sink, which is about 6 m lower in elevation.

Basalt, rhyolite, and other volcanic rocks dominate the Humboldt River basin, and these influence the water chemistry of the basin. Calcium concentrations are similar in the upper and lower basin. At Elko, Nevada, in the upper basin, calcium is 46 mg/L, and this changes very little in the lower basin (47 mg/L). However, sodium, chloride, and sulfate are consistently two to three times greater in the lower basin (126 mg/L, 128 mg/L, and 93 mg/L, respectively).

River Biodiversity and Ecology

The Humboldt River is part of the Lahontan freshwater ecoregion of the Great Basin complex (Abell et al. 2000). Although the Humboldt River is not well studied in terms of its biology and ecology, there is probably more known about its fishes than anything else.

Plants

The riparian community of the upper mountainous portion of the basin (Manning and Padgett 1995) is dominated by various conifers (white fir, lodgepole pine, ponderosa pine, Engelmann spruce), some

deciduous trees (river birch, narrowleaf cottonwood, quaking aspen), willow, and shrubs (e.g., red-osier dogwood, wild rose, sedges, rushes, and grasses). Forbs are common but rarely abundant. Riparian vegetation of the lower portion of the basin is relatively unstudied and poorly understood. It is less diverse than in the upper basin, and conifers are rare, whereas cottonwoods, some species of willow, sedges, and grasses are common. Two nonnative species, halogeton and cheatgrass, are often the most abundant plants (riparian and otherwise) in the lower basin. Halogeton, which favors high sodium levels in the soil, made its first appearance in North America in the Humboldt River basin in the 1930s. It produces toxic oxalates and has been responsible for thousands of livestock deaths.

Invertebrates

Although little information is available, invertebrate diversity in the upper basin is probably quite high and similar to other mountainous portions of the Great Basin. A decline in habitat heterogeneity in the lower basin is reflected in low invertebrate diversity where abundances are dominated by dipterans (true flies), some caddisflies, and beetles. Mayflies are primarily represented by *Baetis* but also include *Acentrella*, *Camelobaetidius*, *Centroptilum*, *Baetisca*, *Ephemerella*, *Ephemerella*, *Hexagenia*, *Heptagenia*, *Rhithrogena*, *Tricorythodes*, *Paraleptophlebia*, *Traverella*, and *Ephoron*. Stoneflies include *Capnura*, *Taenionema*, *Isogenoides*, *Isoperla*, and *Acroneuria*, and caddisflies include *Cheumatopsyche*, *Hydropsyche*, *Micrasema*, *Anagapetus*, *Hydroptila*, *Brachycentrus*, *Chyranda*, *Limnephilus*, *Rhyacophila*, and *Nectopsyche albida* (Baumann and Kondratieff 2000). Dipterans (e.g., *Tipula*, Chironomidae, Empididae) and beetles (Hydraenidae, Elmidae, Hydrophilidae) are the most diverse groups. True bugs (*Ambrysus*) and odonates (dragonflies) are also present. The signal crayfish, native to the Humboldt River basin, is present in the Mary's River.

Vertebrates

Only seven fishes are native to the Humboldt River. These are the Lahontan cutthroat trout (threatened), Paiute sculpin, tui chub, Lahontan redbelly, speckled dace, Tahoe sucker, and mountain sucker. The low number of native fishes reflects the isolated nature of the basin and the associated harsh environment. At least 19 nonnative taxa occur in the basin, including common carp, goldfish, brook trout, brown trout, rainbow trout, Yellowstone cutthroat trout, black bullhead, channel catfish, walleye,

bluegill, green sunfish, black crappie, Sacramento perch, largemouth bass, smallmouth bass, and western mosquitofish.

Among the other aquatic vertebrates, Northern leopard frog, boreal toad, and Columbia spotted frog occur in parts of the Humboldt River basin, as does the Great Basin spadefoot toad. Bullfrogs have been introduced into springs within the basin. The common garter snake occurs throughout the basin, feeding in the river on fishes and invertebrates. Beaver, which attracted trappers as the first Europeans in the region and were commercially trapped out by those trappers, are still present in the Humboldt River system, as are muskrat.

Ecosystem Processes

Little has been done concerning ecosystem processes, although a number of studies have been conducted on Lahontan cutthroat trout metapopulation in the Mary's River (e.g., Dunham et al. 1999). The Humboldt River heads in montane forests and high-elevation desert scrub. Many stream riparian zones in these upper reaches are lined with willows and cottonwoods, which indicate a significant role of allochthonous detritus in low-order systems. As the streams leave the mountainous regions the banks become down-cut and both silt and turbidity increases. The main Humboldt River has little riparian cover other than patches of willows, and often has steeply cut banks. In these reaches it is likely that autochthonous input is significant and perhaps dominant. In late summer attached filamentous algae can be seen in the riffles. Daily and seasonal fluctuations in temperature are more extreme in the lower basin and are important factors associated with the structuring of the aquatic community of the main river system.

Human Impacts and Special Features

The Humboldt River is a desert river that once terminated in a large wetland, the Humboldt Sink. Of the major rivers in the Great Basin, the Humboldt River is the most strongly influenced by the Great Basin climate, having its headwaters in central Great Basin mountains and the majority of its length in the Great Basin Shrub Steppe covered valleys. The Humboldt River provided a low-elevation path from eastern Nevada to the Humboldt Sink in west central Nevada, which made the overland wagon trek to California possible. Immigrants traveling the California Trail in the mid 1800s looked negatively at the Humboldt River and allowed their cattle herds to denude much of the land along the river valley.

The Humboldt River basin has a long history of agriculture (primarily grazing of cattle and sheep) and mining. Both industries have impacted the natural flow regime, riparian vegetation, rates of erosion, and water quality in the Humboldt River. The Humboldt River basin generates about 43% of the total crops and almost 45% of the livestock production in Nevada. Both operations rely heavily on the water in the Humboldt River. During the mid to late 1800s ranchers in the Humboldt River basin gained ownership of land along valley streams and springs, which in turn gave them control of many times that amount of adjacent public lands. Several ranches owned over 800 km² within the Humboldt River basin. Farming in the lower basin was impacted by upstream water diversions, and the problem was brought to a head by a drought in 1888–1889 and a severe winter in 1889–1890. Upper basin ranchers, especially in the Elko region, realized that the open range could not support their herds over the winter and they increased water diversions to raise feed. This reduced the amount of water reaching the lower basin. Because of this conflict Nevada passed and repealed several water-rights laws over the next three decades, finally settling the conflict in the early 1930s. The construction of Rye Patch Reservoir in the 1930s allowed spring runoff to be stored for later use in the lower basin. In addition, a number of ranches in the Battle Mountain area were purchased and their water rights transferred to the lower basin.

Much of the gold is extracted from open-pit mines and groundwater is pumped to prevent flooding. The state of Nevada requires that the water be returned to the groundwater or that it be utilized in lieu of existing groundwater allocations (such as irrigation of crops). If the water is discharged as surface flow, federal requirements designate the acceptable levels of contaminants in the water. A major unknown associated with mining operations is the future filling of the open pits with water once mining operations have ceased. One mine, for example, when filled will become the third-largest lake fully contained within Nevada (exceeded only by Pyramid Lake and Walker Lake). Such pit lakes may have great recreational value, but the water quality in the lakes, the impact on groundwater flow, the impact of evaporative losses, and the ultimate effect on Humboldt River discharge are unknown. These pits will eventually hold an estimated 1.9 to 2.5 km³ of water (<http://water.nv.gov/Water%20planning/walker/wrchrono.htm> 1999).

FIGURE 14.6 Truckee River near Reno, Nevada (PHOTO BY D. K. SHIOZAWA).

TRUCKEE RIVER

The Truckee River of the Lahontan basin is a 5th order river with a drainage basin of 7925 km². It heads in the Sierra Nevada of California, near Lake Tahoe, and terminates in Pyramid Lake, Nevada (Fig. 14.15). The basin is divided into upper and lower parts. The upper Truckee River basin includes the headwaters above Lake Tahoe and the tributaries to the Truckee River above Reno, Nevada. The lower Truckee River basin begins just above Reno and extends to Pyramid Lake (Fig. 14.6). The upper Truckee River feeds Lake Tahoe from the south. The main-stem Truckee River begins as the outflow from Lake Tahoe. It flows northeast, is joined by the Little Truckee River and several other streams, and descends the Sierra Nevada to Reno, on the edge of the Nevada desert. Once past Reno the river continues east, and at Wadsworth, Nevada, within the Pyramid Lake Indian reservation, it then turns north, eventually entering Pyramid Lake. Pyramid Lake, 48 km long and 17 km wide (574 km²), has a maxi-

mum depth of 102 m. The Truckee River's total length, including the upper Truckee River, is 225 km.

The upper basin was originally occupied by the Washoe Indians, whereas the Northern Paiute occupied the lower basin around Pyramid Lake. The Pyramid Lake tribe was known as the Kuyuidokado (fish eaters) after the planktivorous cui-ui that provided a major part of their diet. The government explorer John Fremont named the lake on January 10, 1844, after its pyramid-shaped island (Egan 1977). Paiutes camping at the mouth of the Truckee River shared their catch of large trout with the expedition and Fremont named the river the Salmon Trout River (James 1978). After leaving Pyramid Lake Fremont traveled south, crossed the Carson River, and followed the Walker River into the Sierra Nevada (Egan 1977). On February 14, 1844, he and his cartographer climbed Red Lake Peak in the headwaters of the Carson River. About 30 km to the north they saw a large lake that Fremont described as being surrounded by mountains (James 1978). They were the first Europeans to see Lake Tahoe

(Egan 1977) and, unknowingly, were just a kilometer southwest of the head of the upper Truckee River.

In the late fall of that same year, the California-bound Stevens–Townsend emigrant party followed the Humboldt River to the Humboldt Sink and crossed the desert to the Salmon Trout River (the Truckee River). They followed the river upstream into the Sierra Nevada and crossed into California. They named the river the Truckee after their Paiute guide (James 1978, Durham 1997) and their route became the preferred trail to California. The next fall another pioneer party used the Stevens–Townsend trail but became stranded by snow. That group, the Donner–Reed party, resorted to cannibalism to survive and brought notoriety to the pass.

Physiography, Climate, and Land Use

The Truckee River basin extends from southwest of Lake Tahoe northeast 80 km to Pyramid Lake. The crest of the Sierra Nevada (2400 to 2700 m asl) forms the western border and the Carson Range east of Lake Tahoe forms the eastern border of the upper basin. The upper basin drainages of the Truckee River extend 30 km south and 44 km north of Lake Tahoe. The lower basin's western borders are the east side of the Carson Range. The Lake and Fox ranges, the Terraced Hills, and the Virginia Mountains form the northeastern basin border (1500 to 2300 m asl) at about 40° 25' N latitude. The southeastern border of the lower basin is formed by the low-elevation (2100 m asl) Truckee and Virginia ranges.

The Truckee River basin includes two physiographic provinces (Hunt 1974) and two terrestrial ecoregions (Ricketts et al. 1999) that roughly correspond. The montane forests on the west shore of Lake Tahoe are typical of the Sierra Nevada Forests ecoregion but the Carson Range to the east of Lake Tahoe is dryer, and Jeffrey pine and white fir predominate. These mountainous areas are within the Cascade Sierra (CS) physiographic province (see Fig. 14.15). Patches of montane chaparral (curl-leaf mountain mahogany, green leaf manzanita, and huckleberry oak) occur between 1830 to 2900 m asl. Pinyon–juniper woodlands occur between 1520 to 2740 m asl, especially in well-drained gravelly soils (Howald 2000). The lower basin is in the Great Basin Shrub Steppe ecoregion, which roughly corresponds to the Great Basin section of the Basin and Range (BR) physiographic province. Big sagebrush, rubber rabbitbrush, and antelope bitterbrush dominate the

alluvial reaches. In the driest, most saline and alkaline sites the community is dominated by shadscale (Howald 2000).

Temperature and precipitation vary greatly across the basin. Only 25% of the Truckee River basin lies in California, but it captures the majority of the precipitation, mostly as snowfall. Tahoe City, California, on the west side of Lake Tahoe, receives an average of 82 cm/yr of precipitation, but Glenbrook, Nevada, just across the lake to the east, receives only 40 cm/yr, and the lower basin receives <20 cm/yr. The average precipitation for the entire basin is 43 cm/yr, with 5 to 6 cm/mo falling in winter and <1 cm/mo in July and August (Fig. 14.16). Tahoe City has a mean annual temperature of 6.4°C, similar to other parts of the upper basin. In the lower basin, Reno, Wadsworth, and Nixon, Nevada, all have mean annual temperatures near 10°C (www.ncdc.noaa.gov 2004). Although the upper basin mean annual high temperature is 4°C to 9°C cooler than the lower basin (mean July temperature 18.6°C), the mean annual low temperatures are similar throughout the entire basin, at about 0°C from December to February (see Fig. 14.16).

Lake Tahoe in the upper basin and Pyramid Lake at the basin terminus dominate the basin today. Lake Tahoe, 20 km wide and 35 km long, is a graben lake, the third-deepest lake in North America and the tenth deepest in the world, with a maximum depth of 501 m (Horne and Goldman 1994). An additional 790 m of sediments underlay the lake. Pyramid Lake is 48 km long and 17 km wide and has a surface area of 446 km² and a maximum depth of 102 m. Twelve major tributary streams enter Lake Tahoe, but only three minor streams and the Truckee enter Pyramid Lake. During the arid mid-Holocene (7000 to 4500 years ago), Lake Tahoe was 6 or 7 m lower than today and was not flowing into the Truckee River. Submerged trees up to 1 m in diameter, dating to about 4500 years ago, have been found in the south end of the lake. Based on archaeological sites, modern shores were established by 3500 years ago (Grayson 1993). Pyramid Lake, with a volume of 25.3 km³, has an average evaporative rate of 120 cm/yr.

The BLM manages 42% of the Truckee River basin, the U.S. Forest Service manages 9%, and 9% is Indian reservation. State lands constitute less than 7% of the land area. Private holdings comprise 33% of the land, including urbanized areas, especially around Lake Tahoe. The Lake Tahoe region is a major recreation center. Ski resorts, vacation

housing, and gambling combine to make this area a year-round recreational destination.

River Geomorphology, Hydrology, and Chemistry

The Truckee River drops 1603 m in its 225 km length, for an average gradient of 7.1 m/km. The upper Truckee River begins at 2757 m asl and descends to Lake Tahoe (1899 m asl) over a distance of 37 km for a 23.2 m/km gradient. From Lake Tahoe to Reno, Nevada, the Truckee drops 528 m in 91 km, with an average gradient of 5.8 m/km. The river enters the Great Basin desert at Reno, flows east 53 km, and then turns north for another 44 km to Pyramid Lake (1156 m asl). It descends 215 m for a gradient of about 2.2 m/km. Higher-gradient sections of the Truckee River have rubble to boulder substrates, including the Reno area. Downstream of Reno large substrates occur in confined river reaches, but siltation is noticeable in the summer.

Discharge varies seasonally (see Fig. 14.16). Average annual flow for the Truckee River at the Lake Tahoe outlet is 6.3 m³/s but in high-water years it reaches 32.6 m³/s and has been as low as 0.004 m³/s. The outlet is regulated by a dam so that water can be stored in the lake. Initially established for use in hydropower generation, it is now controlled by the Bureau of Reclamation, but flows are still regulated for downstream power-generation facilities. At the California–Nevada border the average annual flow is 21.2 m³/s, ranging from 5.2 to 69.2 m³/s. Nine streams enter the Truckee River in the upper basin. None of these exceed the Truckee River outflow from Lake Tahoe, but collectively they provide 68% of the flow at the California–Nevada border. The largest of these are Donner Creek with 12% of the discharge, Prosser Creek with 13%, and the Little Truckee River with 25%. At Reno the average annual discharge drops to 18.7 m³/s, and below Derby Dam, 64 km upstream of Pyramid Lake, the flow is reduced to 10.5 m³/s. By the time the river reaches Nixon, Nevada, near Pyramid Lake the average annual discharge is 14.2 m³/s. Irrigation return flows boost the river volume.

Although no records exist to directly give the discharge of the Truckee River into Pyramid Lake prior to water diversions, it is known that the lake fluctuated about 6 m annually and, based on its surface area at that time, that represents the evaporation of almost 586 million m³ of water annually. This suggests a prediversion average annual discharge of

18.6 m³/s from the Truckee River into Pyramid Lake. The greatest precipitation in the basin occurs in February and runoff in the Truckee River peaks in May with snowmelt (see Fig. 14.16).

The exposed Sierra batholith in the upper basin is low in nutrient content, so the water is soft. In the upper Truckee River, calcium is 4.9 mg/L, magnesium 1.2 mg/L, sodium 4.6 mg/L, chloride 4.8 mg/L, alkalinity 24.3 mg/L as CaCO₃, and sulfate 0.8 mg/L. By the time the river reaches Reno these values have increased to 28 mg/L, 8.1 mg/L, 37 mg/L, 31.8 mg/L, 56 mg/L as CaCO₃, and 6.6 mg/L, respectively. At Wadsworth, Nevada, the same six variables are 64 mg/L, 27 mg/L, 92 mg/L, 86.5 mg/L, 174 mg/L as CaCO₃, and 160 mg/L. Alkalinity and calcium concentrations increase seven- to thirteenfold, sodium and chloride about twentyfold, and sulfates by seventy-fivefold. These increases are much lower than in Bonneville basin rivers, where sedimentary rocks dominate. This is likely the reason Pyramid Lake has been able to maintain fishes while the Great Salt Lake has not. Nevertheless, tufa deposits in Pyramid Lake reflect the high TDS. Nitrate and orthophosphate increase downstream. In the early 1980s, these two ions were 0.02 and 0.007 mg/L, respectively, at the outflow of Lake Tahoe, and 0.02 and 0.198 mg/L at Reno. Near the river's terminus at Nixon, Nevada, NO₃-N was 0.32 mg/L and orthophosphate was 0.593 mg/L. The Reno-Sparks sewage treatment plant installed equipment to remove phosphorus in 1982 and denitrification towers in 1988. By the 1990s both NO₃-N and orthophosphate at Nixon had decreased to 0.01 mg/L.

River Biodiversity and Ecology

The Truckee River is part of the Lahontan freshwater ecoregion of the Great Basin complex (Abell et al. 2000). Several tributaries to the Truckee River have been the sites of studies. One of the most notable was a study on the variability of invertebrates sampled in a single riffle (Needham and Usinger 1956), which has influenced the design of macrobenthos sampling since it was published. The Sagehen Creek Field Station, operated by the University of California, Berkeley, is located on a tributary to the Truckee River. This station has facilitated a number of studies that relate to the Truckee River basin, from fish life histories (Jones 1972, Erman and Hawthorn 1976), to the role of beaver in aquatic systems (e.g., Beier and Barrett 1987), to the importance of peat fens in stream energetics (Erman and Chouteau 1979).

Plants

The riparian plant community varies with elevation. In the high elevations of the Sierra Nevada, mountain alder, black cottonwood, quaking aspen, narrowleaf cottonwood, willow, and red-osier dogwood are present. At lower elevations river birch, willow, and Fremont cottonwood can form the riparian overstory (Manning and Padgett 1995, Howald 2000).

Invertebrates

Collections in the Monte L. Bean Life Science Museum at Brigham Young University include stoneflies and caddisflies, mostly from tributaries in the Truckee basin. Stoneflies are represented by *Alloperla*, *Haploperla*, *Suwallia*, *Sweltsa*, *Capnia*, *Mesocapnia*, *Utacapnia*, *Megaleuctra*, *Paraleuctra*, *Nemoura*, *Zapada*, *Doroneuria*, and *Isoperla*. Caddisflies include *Apatania*, *Hydroptila*, *Polycentropus*, *Psychomyia*, *Ochrotrichia*, *Psychoglypha*, *Wormaldia*, and *Rhyacophila*. The mayfly genera *Ephemerella*, *Heptagenia*, *Rhithrogena*, and *Baetis* are also present in the drainage (Allen and Murvosh 1991). The mayflies *Ameletus*, *Caenis*, *Leptophlebia*, *Anthopotamus*, and *Choroterpes* are in Lake Tahoe.

Lake Tahoe is possibly late Pliocene in age, and a number of unique endemic native organisms are present. The benthic invertebrates are dominated by oligochaetes, amphipods, and dipterans. The oligochaete *Rhyacodrilus* occurs from the deepest waters to 30 m depth, whereas the oligochaetes *Arcteonais* and *Uncinaiis* occur in water depths less than 30 m. Crustaceans include *Hyaella azteca* in the shallow waters and two endemic species of *Stygobromus* in deeper waters. Perhaps most interesting are two species of endemic flightless stoneflies. A shallow-water species, *Utacapnia taboensis*, emerges along the lake shore, but the deep-water species, *Capnia lacustra*, spends its entire life cycle underwater at depths down to 274 m (Frantz and Cordone 1996). In 1963 the opossum shrimp was introduced to Lake Tahoe and by 1971 the major zooplankton species in the lake had crashed (Richards et al. 1975). From 1985 to 1986 an attempt to recollect the deep-water stonefly failed, a serious concern, as this species had been in densities of 38/m² in the 1960s (Frantz and Cordone 1996). The signal crayfish may also be native to the drainage, although populations in Lake Tahoe are thought to be introduced.

Vertebrates

The native fishes of the Truckee River include Lahontan cutthroat trout, mountain whitefish, Paiute

sculpin, speckled dace, tui chub, Lahontan redbreast, Tahoe sucker, and mountain sucker. A ninth species, the cui-ui, listed as endangered in 1967, occurs only in Pyramid Lake and spawns in the Truckee River. Lahontan cutthroat trout were listed as threatened in 1970.

One of the most recognized human impacts on the Truckee River is the extinction of the Pyramid Lake strain of the Lahontan cutthroat trout. This piscivorous trout reached 1.2 m long. The record sport catch weighed 18.6 kg, and the record commercial catch was estimated at 27.3 kg. Although the trout survived the high salinity and temperature in Pyramid Lake, the low-elevation reaches of the Truckee River were probably too warm for good fry survival. In the late winter and early spring, the trout would swim up the Truckee from Pyramid Lake to tributaries and lakes in the Sierra Nevada to spawn (e.g., Lake Tahoe and Donner Lake). Dams blocked trout access to the upper Truckee River, and with reduced discharge due to irrigation diversions Pyramid Lake fell in elevation. A bar developed across the mouth of the river, preventing upstream fish movement after 1938 (Gerstung 1988). With that final impact, the largest cutthroat trout in North America went extinct. The cui-ui in Pyramid Lake was also unable to spawn, but its long lifespan allowed it to survive the obstruction.

A number of nonnative fishes are established in the basin (Sada 2000). These include rainbow trout, brown trout, lake trout, sockeye salmon, common carp, channel catfish, black bullhead, white bass, and Sacramento perch. The impacts of nonnative fishes are the same as elsewhere in the Great Basin. They are slowly destroying the native fish communities. Fortunately, Pyramid Lake's high salinity has prevented nonnative fishes from invading there.

The endangered mountain yellow-legged frog and foothill yellow-legged frog are part of the native Sierra Nevada fauna in the upper Truckee River basin. The Pacific tree frog and boreal toad occur in the upper basin as well. In the lower basin, Woodhouse's toad and the northern leopard frog are native. The common garter snake and the Western aquatic garter snake are both found in the Truckee basin, as are beaver and muskrat.

During wet years the Truckee River would overflow a small divide a few kilometers upstream from Pyramid Lake into the large, marshy Winnemucca Lake (see Fig. 14.15). This wetland once offered important habitat to waterfowl on their migratory flights along the Pacific Flyway. However, once water diversion into the Carson basin via Derby Dam

began, Lake Winnemucca completely dried and has remained dry since 1938.

Ecosystem Processes

Prosser Creek, California, in the Truckee River drainage, is the site of Needham and Usinger's (1956) classic study of the variability among invertebrate samples taken from a single riffle. Their results have been influential in the design of quantitative stream sampling programs. Sagehen Creek, another tributary, has been a focal area for a number of studies of the Truckee River drainage. Erman and Hawthorn (1976) showed that an intermittent stream entering Sagehen Creek was important spawning habitat for rainbow trout. About 40% of the rainbow trout utilized it for reproduction, although brook trout could not because the stream was dry in the fall. The influence of such ephemeral habitats on life histories could also be reflected in the outcomes of interactions between the two species. Erman and Chouteau (1979) showed that fine particulate organic matter input from fens (small peatlands) into Sagehen Creek varied from 5 to 20 mg m⁻² yr⁻¹. The input fluctuated daily, with the lowest occurring in the afternoon. Black flies increased in densities below the fens, although other macroinvertebrates did not. Beaver colonies in the Truckee River system above Verdi at the Nevada-Californian border were more successful in river reaches with lower gradients and abandoned sites were more common in reaches with narrow channels and steep gradients (Beier and Barrett 1987). Beaver also significantly reduced or eliminated stands of both black cottonwood and quaking aspen, which reduced the input of leaves into the river. But woody debris input was increased by the dams, and both sediments and particulate organic material were retained by the dams. These studies suggest that overall detrital dynamics in the river can be influenced by import (fens, streamside vegetation) and the presence of instream structures (beaver dams), which in turn are related to the gradient of the river.

Human Impacts and Special Features

The Truckee River begins in Lake Tahoe, one of the deepest lakes in North America, and terminates in the Nevada desert in Pyramid Lake, the largest remnant of Pleistocene Lake Lahontan. Pyramid Lake, despite being a terminal basin lake, still has a freshwater fauna, although its total dissolved solid loading is very high. Prior to watershed development spawning fishes from Pyramid Lake could swim the entire river, to Lake Tahoe as well as surrounding lakes.

The Truckee River basin is the center of western Nevada's urbanization, it provides a major route over the Sierra Nevada into California (the California Trail, the Central Pacific Railroad, Interstate 80), and it includes a major recreation area in the Lake Tahoe region. As the Truckee River basin was settled demands increased on the region's resources. In the late 1800s between 45 to 90 metric tons of trout were shipped annually from the Pyramid Lake fishery (Gerstung 1988). Trees in the watershed were cut for timbers for the mining industry, wastes from mills increased pollution, and grazing increased sediment loadings.

Like all rivers of the Great Basin, the Truckee River is a highly regulated drainage. Most of the water in the Truckee River originates from snowmelt in the Sierra Nevada. Very little input comes from the Truckee Valley in Nevada. The majority of the water-storage reservoirs are on previously free-flowing tributaries to the Truckee River, but the outflows from Lake Tahoe and most of the smaller natural lakes in the upper part of the basin (e.g., Donner Lake) are also regulated by dams. Furthermore, four hydroelectric facilities are located at or near the California-Nevada border and water diversions to these facilities dewatered reaches of the Truckee River, significantly fragmenting the system. Two small diversion dams exist on the lower Truckee within the Pyramid Lake reservation.

Seven diversions take water out of the Truckee River basin. The Tahoe basin exports approximately 0.36 m³/s of treated wastewater to Alpine County, California, and the Carson River basin, Nevada. In the 1950s, nitrates leaching from septic systems were causing eutrophication in Lake Tahoe and by late 1960 wastewater began to be exported. Yet in 1995 the Tahoe Regional Planning Agency reported that algal primary productivity was still over 3.5 times greater than in 1968 (<http://water.nv.gov/Water%20planning/truckee/trchrono.htm> 1997). In 1905 the U.S. Bureau of Reclamation began the Newlands Project, constructing Derby Dam on the Truckee River (Coleman and Johnson 1988). This dam facilitated transport of up to 50 million m³/yr (1.6 m³/s) of water from the Truckee to the Carson River basin, where it has been used to augment agricultural water supplies. As a result, Pyramid Lake has fallen 26 m (Coleman and Johnson 1988), losing 33% of its total volume and increasing in salinity to 5100 mg/L. Since 1970 the diversion at Derby Dam has been set at 30% of the average annual Truckee River flow to reduce impacts on the remaining Pyramid Lake fishery.

FIGURE 14.7 Provo River near Midway, Wasatch County, Utah. This is the only unchannelized section of the middle reach of the Provo River (PHOTO BY D. K. SHIOZAWA).

ADDITIONAL RIVERS

The 119 km long Provo River heads in Utah in small alpine and subalpine lakes in the Uinta Mountains, flows southwest, and terminates in Utah Lake (Fig. 14.7, Fig. 14.17). Mean annual precipitation ranges from 102 cm in the mountains (Wasatch and Uinta Montane Forests ecoregion) to 25 to 30 cm around Utah Lake (Great Basin Shrub Steppe ecoregion). Snowmelt feeds the river, resulting in peak runoff in May (Fig. 14.18). The Provo River has two major reservoirs, Jordanelle and Deer Creek, three major diversions to Heber Valley, Provo City, and Salt Lake City, plus numerous smaller diversions. The largest consumptive use of surface water is irrigation (78%). The Provo River provides one of the top trout fisheries in the western United States and minimum flows from the reservoirs protect these tailwater fisheries. The lower 7.8 km of the river is critical habitat for the endangered June sucker. The most serious threats to water quality of the Provo River are nutrient enrichment and pesticides associated with agriculture

in Heber Valley, pollutants attributed to recreational activities in the reservoirs (500,000 people visit Jordanelle and Deer Creek reservoirs annually), and nonpoint-source pollutants associated with runoff from Provo City.

The Weber River is the second-largest tributary to the Great Salt Lake. Mountainous terrain, above 1515 m asl, accounts for 84% of the Weber River basin (Fig. 14.8). It flows northwest and is joined by the Ogden River, the largest of four major tributaries, just before it enters the Great Salt Lake (Fig. 14.19). Mean annual precipitation, enhanced by evaporation from the Great Salt Lake, ranges from 25 to 87 cm in the mountains and from 10 to 19 cm near the Great Salt Lake. Seasonal runoff is strongly influenced by snowmelt, which peaks in May (>5 cm/mo) and declines to ≤ 0.3 cm/mo from July to September (Fig. 14.20). The Weber River, approximately 200 km long, is within the Wasatch and Uinta Mountain Forests terrestrial ecoregion from its headwaters to the mouth of Weber Canyon. Upon leaving Weber Canyon it enters the Great Basin Shrub Steppe

FIGURE 14.8 Weber River, west of Coalville, Summit County, Utah (PHOTO BY D. K. SHIOZAWA).

ecoregion in the bed of Lake Bonneville. It terminates in the Ogden Bay Wildlife Management Area. Mountainous areas are used for limited crop production, livestock grazing, timber harvest, and winter recreation. Mountain communities are mostly small rural towns, with the exception of Park City, which is the fastest-growing area in Utah. Reservoirs store 54% of the basin's total average annual runoff. Five inter-basin transfers have been developed, two to the Provo River, one to the Bear River, and one each from the Jordan and Provo rivers back into the Weber River.

The Walker River is formed by the confluence of the East and West Walker rivers about midway in the drainage basin south of Yerington, Nevada (Fig. 14.1, Fig. 14.21). Both of these tributaries head in the Sierra Nevada of California at a maximum elevation of 3420 m asl. The upper 25% of the drainage supplies over 90% of the basin's total surface water. The highest precipitation occurs from December through March, but it is stored as snow before being released in the late spring and early summer (Fig. 14.22). Cattle grazing and agriculture are the primary land uses in the lower basin and timber

harvest and agriculture dominate the upper basin. The surface waters of the Walker River are over-appropriated, resulting in heavy groundwater pumping. Walker Lake, the terminal lake in the basin, supports a major recreational fishery for Lahontan cutthroat trout and is an important waterfowl stopover area. Since 1882 the lake has fallen 40 m in elevation and 77% in volume. TDS concentrations (primarily sodium chloride, sulfate, and bicarbonate) have increased from 2560 mg/L to 13,000 mg/L. With current water availability ($3.5 \text{ m}^3/\text{s}$), Walker Lake is projected to stabilize at 9.7% of its 1882 volume in the year 2046. An average inflow of $4.2 \text{ m}^3/\text{s}$ would stabilize the lake at its 1994 volume. In 1996 the conservation organization American Rivers designated the Walker River one of thirty threatened or endangered rivers in the United States.

ACKNOWLEDGMENTS

We would like to acknowledge R. W. Baumann, M. L. Bean Life Science Museum, Brigham Young University, for allowing us to examine the insect collection and for

providing information, especially on the Humboldt River. Mark Vincent, Utah State University, provided species lists from the Sevier and Bear rivers. Chris Rosamond, University of Nevada, Reno, provided a list of invertebrates from the Truckee River system. Patrick Collins, Mount Nebo Scientific, Inc., kindly reviewed the plant community information. Kent Hatch and Riley Nelson of Brigham Young University provided information about Lahontan basin species. M. McKell, E. McLaughlin, K. Redlin, J. Hansen, S. Piper, B. Florence, A. Pace, A. V. Bell, and A. R. Bell aided in compiling data.

FIGURE 14.10 Mean monthly air temperature, precipitation, and runoff for the Bear River basin.

BEAR RIVER

Relief: 2593 m

Basin area: 19,631 km²

Mean discharge: 71.2 m³/s (virgin); 52.0 m³/s (present)

River order: 6

Mean annual precipitation: 55.9 cm

Mean air temperature: 6.5°C

Mean water temperature: 10.1°C

Physiographic provinces: Middle Rocky Mountains (MR), Basin and Range (BR)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Bonneville

Terrestrial ecoregions: Great Basin Shrub Steppe, Wasatch and Uinta Montane Forests, South Central Rockies Forests

Number of fish species: 33 (17 native)

Number of endangered species: 0

Major fishes: Bonneville cutthroat trout, mountain whitefish, Bonneville whitefish, Bear Lake whitefish, Bonneville cisco, speckled dace, longnose dace, redbreast shiner, leatherside chub, Utah chub, Utah sucker, mountain sucker, bluehead sucker, Paiute sculpin, mottled sculpin, Bear Lake sculpin

Major other aquatic vertebrates: Columbia spotted frog, boreal toad, Woodhouse's toad, northern leopard frog, tiger salamander, common garter snake, muskrat, beaver, dipper

Major benthic invertebrates: mayflies (*Baetis*, *Drunella*, *Ephemerella*, *Epeorus*, *Rhythrogena*, *Stenonema*), stoneflies (*Sweltsa*, *Claassenia*, *Isoperla*, *Zapada*, *Skwala*), caddisflies (*Brachycentrus*, *Micrasema*, *Helicopsyche*, *Arctopsyche*, *Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Lepidostoma*, *Nectopsyche*, *Oecetis*, *Chyranda*, *Dicosmoecus*, *Hesperophylax*, *Limnephilus*, *Polycentropus*, *Rhyacophila*, *Oligophlebodes*)

Nonnative species: common carp, brown trout, rainbow trout, brook trout, lake trout, Yellowstone cutthroat trout, sockeye salmon, black bullhead, channel catfish, bluegill, green sunfish, yellow perch, walleye, largemouth bass, western mosquitofish, fathead minnow

Major riparian plants: Fremont cottonwood, narrowleaf cottonwood, river birch, red-osier dogwood, willow, box elder, wild rose

Special features: Bear Lake, Bear River Bay Bird Refuge, Uinta Mountains, Thatcher basin, Red Rock Pass, Oneida narrows

Fragmentation: 6 dams on main stem

Water quality: pH = 8.2, conductivity = 816 μS/cm, alkalinity = 225 mg/L as CaCO₃, Ca = 53 mg/L, Mg = 30 mg/L, Na = 59 mg/L, Cl = 83 mg/L, SO₄ = 53 mg/L, NO₃-N = 0.5 mg/L, PO₄-P = 0.2 mg/L

Land use: agriculture, recreation, grazing. Land ownership 55% private, 7% state land, 18% National Forest, 18% BLM, 2% refuges etc.

Population density: 9.0 people/km²

Major information sources: Haws and Hughes 1973, Utah Board of Water Resources 1992, <http://waterdata.usgs.gov> 2004, <http://www.ncdc.noaa.gov> 2004

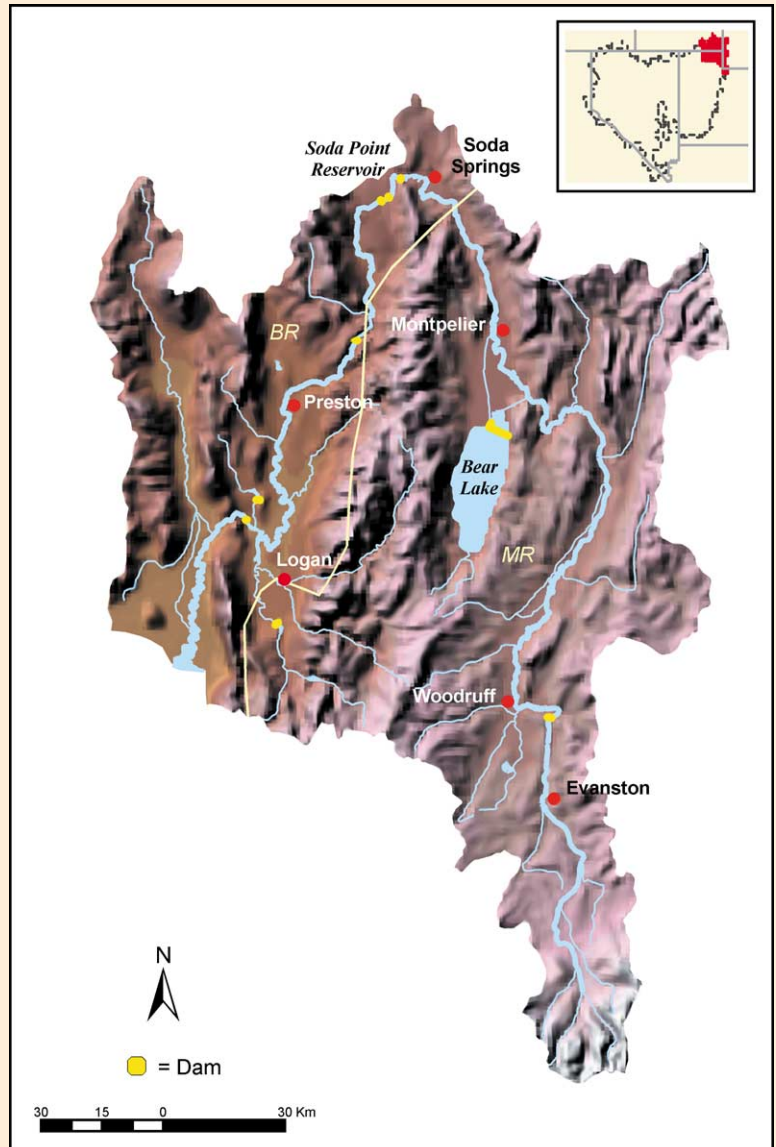

FIGURE 14.9 Map of the Bear River basin. Physiographic provinces are separated by a yellow line.

FIGURE 14.12 Mean monthly air temperature, precipitation, and runoff for the Sevier River basin.

SEVIER RIVER

Relief: 2341 m

Basin area: 42,025 km²

Mean discharge: 32.2 m³/s (virgin); 1.3 m³/s (present)

River order: 5

Mean annual precipitation: 36 cm

Mean air temperature: 9.3°C

Mean water temperature: 11.3°C

Physiographic provinces: Colorado Plateaus (CO), Basin and Range (BR)

Biome: Desert

Freshwater ecoregion: Bonneville

Terrestrial ecoregions: Colorado Plateau Shrublands, Great Basin Shrub Steppe, Wasatch and Uinta Montane Forests

Number of fish species: 21 (9 native)

Number of endangered species: 0

Major fishes: Bonneville cutthroat trout, speckled dace, reddsider, leatherside chub, least chub, Utah chub, mountain sucker, Utah sucker, mottled sculpin

Major other aquatic vertebrates: boreal toad, Woodhouse's toad, northern leopard frog, tiger salamander, common garter snake, muskrat, beaver, dipper

Major benthic invertebrates: mayflies (*Baetis*, *Rhythrogena*), stoneflies (*Capnia*, *Utacapnia*, *Alloperla*, *Claassenia*, *Hesperoperla*, *Diura*, *Isogenoides*, *Isoperla*, *Megarcys*), caddisflies (*Brachycentrus*, *Hydropsyche*, *Hydroptila*, *Ochrotrichia*, *Nectopsyche*, *Oecetis*, *Amphicosmoecus*, *Hesperophylax*, *Limnephilus*, *Onocosmoecus*, *Rhyacophila*, *Oligophlebodes*)

Nonnative species: Asiatic clam, common carp, brown trout, rainbow trout, brook trout, Yellowstone cutthroat trout, mountain whitefish, channel catfish, black bullhead, walleye, yellow perch, fathead minnow, western mosquitofish, tamarisk, Russian olive

Major riparian plants: Fremont cottonwood, narrowleaf cottonwood, river birch, red-osier dogwood, willow, box elder, wild rose

Special features: desert river through much of length; usually dries before reaching Sevier Lake, which is itself usually dry because of diversions; National Parks in high plateaus

Fragmentation: 8 dams on main stem

Water quality: pH = 8.1, conductivity = 1340 mS/cm, alkalinity = 263 mg/L as CaCO₃, Ca = 78 mg/L, Mg = 57 mg/L, Na = 170 mg/L, Cl = 235 mg/L, SO₄ = 240 mg/L, PO₄-P = 0.2 mg/L

Land use: 4.5% irrigated agriculture, 80% rangeland grazing; land ownership 21% private, 8% state, 23% National Forest, 48% BLM

Population density: 1.4 people/km²

Major information sources: Utah Board of Water Resources 1999, <http://waterdata.usgs.gov> 2004, <http://www.ncdc.noaa.gov> 2004

FIGURE 14.11 Map of the Sevier River basin. Physiographic provinces are separated by a yellow line.

FIGURE 14.13 Map of the Humboldt River basin.

HUMBOLDT RIVER

Relief: 2036 m

Basin area: 43,597 km²

Mean discharge: 25.8 m³/s (virgin, estimated); 0.9 m³/s (present)

River order: 6

Mean annual precipitation: 22 cm

Mean air temperature: 9.4°C

Mean water temperature: 12.3°C

Physiographic province: Basin and Range (BR)

Biome: Desert

Freshwater ecoregion: Lahontan

Terrestrial ecoregions: Great Basin Montane Forests, Great Basin Shrub Steppe

Number of fish species: 23 (7 native)

Number of endangered species: 1 threatened

Major fishes: Lahontan cutthroat trout, Paiute sculpin, tui chub, Lahontan redbreast, speckled dace, Tahoe sucker, mountain sucker

Major other aquatic vertebrates: Columbia spotted frog, northern leopard frog, boreal toad, Great Basin spadefoot toad, common garter snake, western aquatic garter snake, muskrat, beaver

Major benthic invertebrates: mayflies (*Baetis*, *Acentrella*, *Camelobaetidius*, *Centroptilum*, *Baetisca*, *Ephemerella*, *Ephemera*, *Hexagenia*, *Heptagenia*, *Rhithrogena*, *Tricorythodes*, *Paraleptophlebia*, *Traverella*, *Ephoron*), stoneflies (*Isogenoides*, *Isoperla*, *Capnura*, *Taenionema*, *Acroneuria*), caddisflies (*Brachycentrus*, *Micrasema*, *Anagapetus*, *Cheumatopsyche*, *Hydropsyche*, *Hydroptila*, *Chyranda*, *Limnephilus*, *Nectopsyche albida*, *Rhyacophila*), crustaceans (signal crayfish)

Nonnative species: common carp, goldfish, brook trout, brown trout, rainbow trout, Yellowstone cutthroat trout, black bullhead, channel catfish, walleye, bluegill, green sunfish, black crappie, Sacramento perch, largemouth bass, bullfrog

Major riparian plants: quaking aspen, Fremont cottonwood, black cottonwood, narrowleaf cottonwood, willow, river birch

Special features: desert river traversing Great Basin east to west; longest river in Great Basin; terminates in Humboldt Sink, once a large wetland, now usually dry due to diversions; most tributaries in lower basin do not reach main stem

Fragmentation: 1 dam on main stem, numerous diversions in lower basin

Water quality: pH = 8.5, conductivity = 695 µS/cm, alkalinity = 238 mg/L as CaCO₃, Ca = 46 mg/L, Mg = 15 mg/L, Na = 82 mg/L, Cl = 61 mg/L, SO₄ = 72 mg/L, NO₃-N = 0.04 mg/L, PO₄-P = 0.4 mg/L

Land use: agriculture, grazing, mining; ownership 32% private, 2% state, reservations, etc., 12% National Forest, 54% BLM

Population density: 1.5 people/km²

Major information sources: Nevada Division of Water Resources 1999, Grayson 1993, <http://waterdata.usgs.gov> 2004, <http://www.ncdc.noaa.gov> 2004

FIGURE 14.14 Mean monthly air temperature, precipitation, and runoff for the Humboldt River basin.

FIGURE 14.16 Mean monthly air temperature, precipitation, and runoff for the Truckee River basin.

TRUCKEE RIVER

Relief: 2159 m

Basin area: 7925 km²

Mean discharge: 18.6 m³/s (virgin, estimated); 14.2 m³/s (present)

River order: 5

Mean annual precipitation: 43 cm

Mean air temperature: 8.4°C

Mean water temperature: 11.4°C

Physiographic provinces: Cascade–Sierra Mountains (CS), Basin and Range (BR)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Lahontan

Terrestrial ecoregions: Sierra Nevada Forests, Great Basin Shrub Steppe

Number of fish species: 21 (8 native)

Number of endangered species: 1 fish, 1 frog, 1 threatened fish

Major fishes: Lahontan cutthroat trout, Paiute sculpin, tui chub, Lahontan redbreast, speckled dace, Tahoe sucker, mountain sucker, cui-ui

Major other aquatic vertebrates: Pacific tree frog, boreal toad, Great Basin spadefoot toad, mountain yellow-legged frog, foothill yellow-legged frog, northern leopard frog, river otter, muskrat, beaver

Major benthic invertebrates: mayflies (*Ephemera*, *Drunella*, *Epeorus*, *Heptagenia*, *Rhythrogena*, *Cinygmula*, *Baetis*), stoneflies (*Capnia*, *Utacapnia*, *Skwala*, *Malenka*, *Kogotus*, *Paraleuctra*, *Perlomyia*, *Prostoia*, *Soyedina*, *Zapada*, *Claassenia*, *Cultus*, *Isoperla*), caddisflies (*Glossosoma*, *Arctopsyche*, *Hydropsyche*, *Parapsyche*, *Lepidostoma*, *Limnephilus*, *Wormaldia*, *Rhyacophila*), crustaceans (signal crayfish)

Nonnative species: common carp, brook trout, brown trout, rainbow trout, Yellowstone cutthroat trout, sockeye salmon, black bullhead, channel catfish, bluegill, green sunfish, Sacramento perch, smallmouth bass, western mosquitofish, bullfrog

Major riparian plants: mountain alder, quaking aspen, black cottonwood, Fremont cottonwood, narrowleaf cottonwood, willow, red-osier dogwood, river birch

Special features: desert river flowing through Lake Tahoe and terminating in Pyramid Lake; Lake Tahoe recreation area; major transportation corridor from Nevada to California

Fragmentation: four hydroelectric diversion dams, one diversion dam in lower basin (Derby Dam), several small diversion dams on main stem; most large tributaries and lakes, including Lake Tahoe, regulated by dams

Water quality: pH = 8.0, conductivity = 226 µS/cm, alkalinity = 76 mg/L as CaCO₃, Ca = 23 mg/L, Mg = 8 mg/L, Na = 32 mg/L, Cl = 32 mg/L, SO₄ = 45 mg/L, NO₃-N = 0.04 mg/L, PO₄-P = 0.07 mg/L

Land use: recreation, agriculture, grazing, urban; land ownership 33% private, 7% state, 9% National Forest, 42% BLM, 9% reservation

Population density: 46.9 people/km²

Major information sources: Nevada Division of Water Resources 1997, Smith 2000, <http://waterdata.usgs.gov> 2004, <http://www.ncdc.noaa.gov> 2004

FIGURE 14.17 Map of the Provo River basin. Physiographic provinces are separated by a yellow line.

PROVO RIVER

Relief: 2294 m

Basin area: 1761 km²

Mean discharge: 18.1 m³/s (virgin, estimated); 9.9 m³/s (present)

River order: 5

Mean annual precipitation: 64.2 cm

Mean air temperature: 9.3°C

Mean water temperature: 7.7°C

Physiographic provinces: Middle Rocky Mountains (MR),
Basin and Range (BR)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Bonneville

Terrestrial ecoregions: Great Basin Shrub Steppe, Wasatch and
Uinta Montane Forests

Number of fish species: 28 (13 native)

Number of endangered species: 1 fish

Major fishes: Bonneville cutthroat trout, mountain whitefish, reddsie
shiner, leatherside chub, Utah chub, speckled dace, longnose dace,
mountain sucker, Utah sucker, June sucker, mottled sculpin, Paiute sculpin, Utah Lake sculpin (extinct)

Major other aquatic vertebrates: Columbia spotted frog, northern leopard frog, Pacific chorus frog, Woodhouse's toad, boreal
toad, tiger salamander, beaver, muskrat, mink, river otter, water vole, dipper

Major benthic invertebrates: mayflies (*Baetis*, *Paraleptophlebia*, *Drunella*, *Rhithrogena*), stoneflies (*Pteronarcys*, *Claassenia*,
Hesperoperla, *Diura*, *Isogenoides*, *Isoperla*, *Megarcys*), caddisflies (*Brachycentrus*, *Hydropsyche*, *Hydroptila*, *Oecetis*,
Hesperophylax, *Limnephilus*, *Onocosmoecus*, *Rhyacophila*), true flies (*Atherix*), crustaceans (*Gammarus*, *Hyaella*)

Nonnative species: virile crayfish, common carp, brown trout, rainbow trout, brook trout, Yellowstone cutthroat trout, channel
catfish, black bullhead, largemouth bass, smallmouth bass, green sunfish, bluegill, black crappie, white bass, yellow perch,
western mosquitofish, tamarisk, Russian olive

Major riparian plants: Fremont cottonwood, narrowleaf cottonwood, river birch, red-osier dogwood, willow, box elder

Special features: one of top trout streams in North America; middle reach undergoing restoration; recreation in Uinta Mountain

Fragmentation: two dams on main stem, numerous diversion structures

Water quality: pH = 7.8, alkalinity = 127 mg/L as CaCO₃, Ca = 54.1 mg/L, Mg = 11.8 mg/L, Na = 7.0 mg/L, Cl = 8.7 mg/L,
SO₄ = 54.4 mg/L, NO₃-N = 0.18 mg/L, PO₄-P = 0.8 mg/L

Land use: urban, agriculture, grazing, recreation; land ownership 46.5% private, 7.5% state (including state parks),
45.5% National Forest, 1.0% BLM

Population density: 158.7 people/km²

WEBER RIVER

Relief: 2358 m

Basin area: 6070 km²

Mean discharge: 38.3 m³/s (virgin, estimated); 12.2 m³/s (present)

River order: 5

Mean annual precipitation: 53.3 cm

Mean air temperature: 7.7°C

Mean water temperature: 10.0°C

Physiographic provinces: Middle Rocky Mountains (MR),
Basin and Range (BR)

Biomes: Temperate Mountain Forest, Desert

Freshwater ecoregion: Bonneville

Terrestrial ecoregions: Great Basin Shrub Steppe, Wasatch and
Uinta Montane Forests

Number of fish species: 26 (11 native)

Number of endangered species: 0

Major fishes: reidside shiner, Utah chub, speckled dace, longnose dace,
mottled sculpin, Paiute sculpin, Bonneville cutthroat trout,
mountain whitefish, mountain sucker, Utah sucker, bluehead sucker

Major other aquatic vertebrates: Woodhouse's toad, tiger salamander, northern leopard frog, boreal toad, Pacific chorus frog,
Columbia spotted frog, Great Basin spadefoot toad, water vole, muskrat, beaver, mink, river otter

Major benthic invertebrates: mayflies (*Baetis*, *Rhithrogena*, *Drunella*), stoneflies (*Capnia*, *Utacapnia*, *Alloperla*, *Pteronarcys*,
Amphinemura, *Podmosta*, *Prostoia*, *Claassenia*, *Hesperoperla*, *Diura*, *Isogenoides*, *Isoperla*), caddisflies (*Brachycentrus*,
Hydropsyche, *Hydroptila*, *Hesperophylax*, *Limnephilus*, *Oligophlebodes*), crustaceans (*Pacifastacus gambelii*)

Nonnative species: tamarisk, Russian olive, common carp, rainbow trout, Yellowstone cutthroat trout, brown trout, brook
trout, yellow perch, smallmouth bass, largemouth bass, black bullhead, channel catfish, green sunfish, bluegill, black
crappie, walleye, western mosquitofish

Major riparian plants: Fremont cottonwood, narrowleaf cottonwood, river birch, red-osier dogwood, willow, box elder

Special features: mountainous river system with most of basin privately owned; second-largest tributary of Great Salt Lake

Fragmentation: seven major dams, two on main stem

Water quality: alkalinity = 97 mg/L as CaCO₃, Ca = 58.9 mg/L, Mg = 17.6 mg/L, Na = 33.1 mg/L, Cl = 45.0 mg/L, SO₄ =
34.5 mg/L, PO₄-P = 0.65 mg/L

Land use: urban, agriculture, grazing, recreation; land ownership 80.9% private, 2.5% state, 15% National Forest, 1.6% BLM,
Bureau of Reclamation, and Department of Defense

Population density: 80.7 people/km²

WALKER RIVER

Relief: 2576 m

Basin area: 7894 km²

Mean discharge: 9.7 m³/s (virgin); 3.5 m³/s (present)

River order: 6

Mean annual precipitation: 37.6 cm

Mean air temperature: 23.7°C

Mean water temperature: 10.8°C

Physiographic provinces: Cascade–Sierra Mountains (CS), Basin and Range (BR)

Biomes: Pinyon–Juniper, Basin Sagebrush

Freshwater ecoregion: Lahontan

Terrestrial ecoregions: Sierra Nevada Forests, Great Basin Shrub Steppe

Number of fish species: 15 (7 native)

Number of endangered species: 1 frog, 1 threatened fish

Major fishes: Lahontan redbreast, speckled dace, tui chub, Paiute sculpin, Lahontan cutthroat trout, mountain sucker, Tahoe sucker

Major other aquatic vertebrates: mountain yellowlegged frog, Yosemite toad, northern leopard frog, boreal toad, Great Basin spadefoot toad, beaver, muskrat, mink, common loon

Major benthic invertebrates: mayflies (*Baetis*, *Heptagenia*, *Rhithrogena*, *Ephemerella*), stoneflies (*Capnia*, *Pteronarcys*, *Utacapnia*, *Sweltsa*, *Isoperla*, *Prostoia*, *Paraleuctra*, *Claassenia*, *Kogotus*), caddisflies (*Brachycentrus*, *Micrasema*, *Lepidostoma*, *Hydropsyche*, *Hydroptila*, *Nectopsyche*, *Limnephilus*, *Rhyacophila*, *Glossosoma*), crustaceans (signal crayfish)

Nonnative species: Russian olive, common carp, channel catfish, black bullhead, Sacramento perch, white bass, brown trout, rainbow trout, Yellowstone cutthroat trout

Major riparian plants: narrowleaf cottonwood, Fremont cottonwood, river birch, red-osier dogwood, willow, mountain alder

Special features: best-studied basin in Lahontan basin; terminates in Walker Lake, which has major cutthroat trout fishery; lake faces destruction from increased salinity due to diversions and groundwater pumping

Fragmentation: nine major reservoirs, four on East Walker River, four on West Walker River, one on main Walker River

Water quality: pH = 8.2, alkalinity = 99.9 mg/L as CaCO₃, Ca = 24.8 mg/L, Mg = 6.1 mg/L, Na = 35.3 mg/L, Cl = 9.6 mg/L, SO₄ = 21.3 mg/L, NO₃-N = 0.11 mg/L, PO₄-P = 0.21 mg/L

Land use: agriculture, grazing, rangeland; land ownership 9.6% private, 0.5% state, 25.8% National Forest, 52.4% BLM, 4.1% Bureau of Reclamation and Department of Defense, 7.7% reservation

Population density: 2.3 people/km²

THOMPSON RIVER

NECHAKO RIVER

STUART RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

The Fraser River, with its headwaters in the Rocky Mountains, flows across the dry Fraser Plateau through coastal mountain ranges to the Pacific Ocean (Fig. 15.2). This river has been the primary trade route through southern and central British Columbia for millennia. In recent times it has been the focus of settlement and industry and sustains Vancouver as one of North America's great cities. By any measure the Fraser is one of Canada's great rivers, with an abundance and diversity of natural resources that rivals almost any other river in the world. Of Canadian rivers it has the third-highest mean flow (3972 m³/s), it is the fifth longest (1375 km), and its drainage basin is the fifth largest (234,000 km²). The diversity of geology, climate, and the landscape is so great that it includes 11 of the 14 biogeoclimatic zones identified in British Columbia, and from its headwaters the river discharges to the Straits of Georgia in the city of Vancouver, the most densely populated region of the province.

The Fraser River was named after Simon Fraser, who while working for the North West Company was the first nonnative North American to reach the mouth of the river in 1808. The Fraser is far more

than a single watercourse. Beyond the main-stem river is a vast and intricate network of tributary rivers that reach out to envelop more than a quarter of British Columbia. The entire catchment area of the Fraser River reaches as far north as Bulkley House on the Stuart River system and stretches westward from the highest summits of the Coast Mountain range to the heights of the Rocky Mountains in the east. It is the water flowing through these tributaries that links the massive Fraser basin system, providing essential nutrients, migration routes, and habitat that support the diverse ecosystems within it.

The river and its basin occupy a special historic and political place in the development of North America. For at least 10,000 years native peoples have occupied the Fraser River basin and used its resources (Kew and Griggs 1991). Within British Columbia there is a greater degree of indigenous cultural and linguistic diversity than in any other region of Canada. The Fraser basin itself was and remains inhabited by native peoples speaking six separate and distinct languages belonging to two great language families. Within the basin can be distinguished both Northwest-coast cultures on the lower part of the river and adjoining sea coast and Plateau cultures in the middle and upper parts of the basin. This remark-

FIGURE 15.2 The Fraser River and its tributaries covered in this chapter.

able variety and diversity is consistent with the 10 millennia of human presence in the basin, and it indicates a large degree of stability. It also suggests that to a large degree, with the notable exception of occasional trade and barter or raids, each language group remained independent of its neighbors and was largely self-contained and self-sufficient within its traditional territories. Prior to contact with European explorers, an estimated 50,000 people lived in the basin (Dorcey 1991). However, these numbers were likely already half the original population after the ravages of disease introduced by earlier explorers of the continent by the time Simon Fraser canoed the river some 200 years later in 1808. Although salmon fishing and fur trading led to minor settlement and agricultural development around Fort Langley and

New Westminster before 1855, it was not until the discovery of gold on the Thompson tributary in 1857 that the consequent influx of people raised the total population to precontact levels. The gold strikes at Barkerville in the headwaters of the Willow River resulted in the development of famous land and water routes up the Fraser, including the Harrison Trail and Cariboo Road, and provided the impetus to use the river as a path through the coastal mountain barrier.

In this chapter, we describe the main-stem Fraser River as well as eight major tributaries that illustrate the wide range of geologic, climatic, and biological diversity in the basin (see Fig. 15.2). The main-stem Fraser, Thompson, Nechako, and Stuart rivers are described in some detail. Abbreviated descriptions of

physical and biological characteristics are provided for the West Road, Quesnel, Chilcotin, and Lillooet and Harrison rivers on the Fraser and the Clearwater River on the Thompson.

Physiography and Climate

The basin is contained within two physiographic provinces (Fig. 15.5). A portion of the Fraser drains from the Rocky Mountains in Canada (RM) province in the east and a portion drains from the Coast Mountains of British Columbia and Southeast Alaska (PM) province. Thus, the basin is dominated by rugged, mountainous terrain that incorporates several major interior plains. The plains are more extensive in the north and extend out as intermontane valleys toward the southern half of the basin. Most of these plains and valleys are covered by glacial moraine and to some degree fluvial and lacustrine deposits, whereas the mountains consist largely of colluvium and rock outcrops. The soils of the lower valley floors to the south are often chernozems and support grasslands. These grade into arid environments in the Okanagan area toward the Canada–United States border.

The climate of the basin ranges from subarid to arid and mild in southern lower valleys to humid and cold at higher elevations in the northern reaches, reflecting the interaction of the dominant westerly circulation with the mountain ranges. Moist Pacific air and the effect of orographic rainfall control the precipitation pattern such that both rain shadows and wet belts are generated within the basin, often in close geographic proximity to each other. The rain shadow cast by the massive Coast Mountains results in some of the driest climates in Canada in the valley bottoms of the south-central part of the basin. During winter a relatively steady succession of low-pressure systems move eastward from the Pacific Ocean, bringing wet conditions associated with cyclonic, frontal, and, in the mountains, orographic uplift. Outbreaks of arctic air occasionally occur during the winter, bringing cold conditions and brisk winds, particularly in the Lower Fraser Valley. In summer the westerly circulation weakens and a persistent high-pressure area develops off the coast, resulting in a decreasing frequency of storms and frequent periods of fine weather. The Rocky Mountains also impede the westward flow of cold continental Arctic air masses. For most of the basin mean annual temperatures range between 0.5°C in the northwest (Skeena Mountains) and 7.5°C in the Okanagan area along the Canada–United States border. Mean

summer temperatures range from 11°C to 16.5°C. Mean winter temperatures range from –11°C to –1°C. The coastal portion of the basin has some of the warmest and the wettest climatic conditions in Canada. Mean annual temperatures along the coast range from 4.5°C in the north to 9°C in the Georgia–Puget basin–Lower Mainland regions. Mean summer temperatures range from 10°C in the north to 15.5°C in the south. Mean winter temperatures range from –0.5°C to 3.5°C, and relative to the rest of Canada there is little variation between the mean monthly temperatures through the year.

Basin Landscape and Land Use

The basin lies between latitudes 49°N and 56°N and longitudes 118°W and 125°W and encompasses six terrestrial ecoregions (Ricketts et al. 1999): North Central Rockies Forests, Fraser Plateau and Basin Complex, Okanagan Dry Forests, Cascade Mountains Leeward Forests, British Columbia Mainland Coastal Forests, and Puget Lowland Forests. These are some of the most diverse of all the Canadian ecoregions, ranging from alpine tundra to dense conifer forests to dry sagebrush and grasslands.

Vegetative cover is extremely diverse; alpine environments contain various herb, lichen, and shrub associations, whereas the subalpine environment has tree species such as lodgepole pine, alpine fir, and Engelmann spruce. With decreasing elevation the vegetation of the mountainous slopes and rolling plains separates into three general groups: a marginal band of forests characterized by Engelmann spruce, alpine fir, and lodgepole pine; forests characterized by ponderosa pine, interior Douglas fir, lodgepole pine, and trembling aspen in much of the southwest and central portions; and forests characterized by western hemlock, western red cedar, interior Douglas fir, and western white pine in the southeast. Shrubs found in the dry southern interior include sagebrush, rabbitbrush, and antelope bush. Most of the natural grasslands that existed in the dry south have vanished, to be replaced by urban settlement and agriculture. In the western coastal zone the temperate coastal forests are composed of mixtures of western red cedar, yellow cedar, western hemlock, Douglas fir, amabilis fir, mountain hemlock, Sitka spruce, and alder. Many of these trees reach very large dimensions and grow to great ages, and formed ancient or old-growth forests in this region, although these are now restricted to watersheds to the north of the Fraser River. Mountain hemlock is usually associated with higher elevations. Variations in altitude account

for the presence of widely contrasting ecosystems within the coastal region, ranging from mild humid coastal rainforest to cool boreal and alpine conditions at higher elevations. Characteristic mammals include woodland caribou, mule, blacktail and white-tailed deer, moose, mountain goat, bighorn sheep, otter, raccoon, coyote, wolf, black and grizzly bear, hoary marmot, and Columbian ground squirrel. Typical bird species include blue grouse, Steller's jay, and black-billed magpie. In coastal areas American black oystercatcher, California and mountain quail, tufted puffin, and chestnut-backed chickadee occur, as well as pygmy owl, Steller's jay, and northwestern crow.

Following the discovery of gold in the 1850s most new immigrants arrived by sea at the mouth of the river. Prospectors and miners could travel inland to the gold fields by riding steamboats that operated as far as Yale just below the canyon and again on the river between Soda Creek and Quesnel. Following the gold rush, settlement expanded and development rapidly began to shape the basin to the resource uses and communities seen at present. Valley bottom forests were cleared for agriculture and the forest industry that is now the core of the provincial economy soon began to increase timber exports. Salted and canned salmon were also part of the initial export economy. With the completion in 1886 of the transcontinental railway that ran beside the Fraser and Thompson rivers, access was opened not only to the interior of the basin but also to the rest of Canada east of the Rockies. Growing east-west trade led to the construction of grain elevators in Vancouver to export grain from the prairies, and the completion of the Panama Canal in 1914 opened new markets in Europe for many industries and led to further expansion after World War 1. In 1894 the largest freshet on record caused major flooding in the Lower Fraser Valley, prompting construction of a dyking and drainage system that consolidated the patterns of both the river channel and delta for agricultural and urban development. At the present time greater Vancouver is the third-largest metropolitan area in Canada, with 2.1 million people at the 2001 census, representing two-thirds of the provincial population, and more than three-quarters of the basin's population is concentrated in the Lower Fraser Valley. In the interior only Kelowna (96,288), Kamloops (77,281), and Prince George (72,406) have similar populations to the medium-size lower Fraser Valley municipalities (e.g., Coquitlam 112,890 and Chilliwack 62,927). Other interior basin towns are quite small; in the middle Fraser region the major centers are Williams

Lake (11,153) and Quesnel (10,044), and in the Thompson basin Salmon Arm (15,210). The basin economy has grown with these communities but retains its resource dependence despite significant changes taking place in recent decades.

Commercial forest operations have been established in many parts of the basin, particularly in the northern interior sections. Forest productivity in some coastal areas is the highest in Canada and commercial forest operations are of major economic importance to Canada's forest industry. British Columbia accounts for 60% of Canada's lumber exports, almost half of its chemical pulp exports, and 36% of its kraft paper exports. The forest industry continues to be of major importance in the basin, with harvesting and processing in the interior increasingly significant in the past two decades. The Fraser River estuary, where the coastal forest industry collects, sorts, processes, and exports water-borne logs, is still of critical importance to the international competitiveness of the industry. The lowlands of the Fraser Valley possess the area's main expanse of highly productive agricultural soils, as well as urban lands. Mining, oil and gas production, and tourism are the other significant activities.

The mining industry, historically the second most important contributor to the gross provincial product, operates in many parts of the basin. The province produces almost 70% of Canada's coal exports and over 98% of its copper and molybdenum ore exports and potential exists for mining small high-grade ore deposits and anthracite.

Recreation and tourism has overtaken mining as the second most important provincial economic sector. The recreational freshwater and saltwater fisheries associated with the Fraser are a major component of this, along with other water-related attractions throughout the basin. Already a major world exporter of canned and frozen salmon, British Columbia has a growing aquaculture industry that is now a significant contributor to the provincial economy. In 2002 the farmgate value of the salmon, shellfish, and trout sectors combined was \$304.5 million, with farmed salmon British Columbia's largest agricultural export product. The commercial fishing fleets find moorings in the estuary and depend heavily on the Fraser River salmon runs, which they share with the native and recreational fisheries.

In the eastern Rocky and Columbia mountains, national and provincial parks have been established for recreational use or as reserves for wildlife habitat. It is mainly in the valleys that areas have been improved for range or are farmed; near streams,

where water is available for irrigation, row crops and hay are grown. The southern valleys are nationally important for their orchards and vineyards.

British Columbia's agriculture industry is the third-largest component of its resource-based sector. Agriculture is an important activity in the Lower Fraser Valley, where crop production utilizes some of the most productive lands in Canada, and in the interior subbasins, where ranching is of greater significance.

The Rivers

The entire Fraser basin is contained within the North Pacific Coastal freshwater ecoregion (Abell et al. 2000). This ecoregion extends from southeastern Alaska through the southwestern portion of the Yukon Territory and western and central portions of British Columbia to northwestern Washington. It is considered a cool, high-rainfall area, formerly covered by rain forests on the coast and drier forest and grasslands in the interior. The ecoregion is considered continentally outstanding with regard to biological distinctiveness.

Because the various tributaries across the basin experience a great range of topographic features and precipitation patterns, they are highly variable in their monthly stream flows. Low-elevation coastal basins are dominated by autumn and winter rainfall, with high autumn and winter flows and low summer flow when rainfall is low and evaporation losses are high. However, most of the other basin types respond to melting of winter snow, with the bulk of the runoff occurring in spring and summer and low flows occurring in winter when most of the precipitation falls as snow and is stored in the snowpack. Runoff is greater in basins dominated by mountainous terrain and/or near the coast (Lillooet, Coquihalla, McGregor, Salmon, North Thompson, and South Thompson) than basins that dominantly drain the interior plateau (Nautley, Nicola, West Road, and Salmon near Prince George).

Although British Columbia ranks third nationally in hydroelectricity generation and second in natural gas production, only a small proportion of the basin's total energy supply is produced from tributaries of the Fraser, which remains one of the few minimally impounded great rivers of North America (with the exception of the Nechako River). However, the basin acts as a major conduit of energy for the entire province. The human population largely resides in the last few 100 km of the river, hemmed in between mountain barriers. The basin, compared to other

large North American river systems, is relatively unimpacted by human activities. The two major activities in the basin are logging and mining. Effects from tree removal and pulp and paper mills have been of most concern. The impacts of pulp mill discharges are generally small, as they are located on the major rivers and the impacts from harvesting tend to be local. Mining activities do have local impacts.

FRASER RIVER MAIN STEM

The Fraser is one of four major North American river systems arising within a few kilometers of each other in the Canadian Rocky Mountains. The others include the northward-flowing Athabasca River, part of the Peace–Mackenzie system; the North Saskatchewan, part of the Nelson system; and the Columbia River. The Fraser River begins in Mount Robson Provincial Park in the Rocky Mountains on the British Columbia–Alberta border, initially flowing in a northwesterly direction (see Fig. 15.5). Just northeast of Prince George it turns sharply south until it reaches Hope (Fig. 15.3), in southern British Columbia, and then turns west before emptying into the Straits of Georgia. The Fraser River is the second-largest river in North America with no main-stem dams, after the Yukon River in Alaska (Dynesius and Nilsson 1994). The Fraser is also one of the greatest salmon rivers in the world (Northcote and Larkin 1989).

Physiography, Climate, and Land Use

The headwaters of the Fraser River are in the Rocky Mountains in Canada (RM) physiographic province of southeastern British Columbia (see Fig. 15.5). Elevations rise to over 3000 m asl along the continental divide and include the highest mountain in the Canadian Rocky Mountains, Mount Robson, at just over 3600 m asl. The river first flows northwest for approximately 250 km through the Rocky Mountain Trench and drains a relatively narrow and steep valley that is hemmed in by the Rocky Mountains (3950 m asl) to the east and the Cariboo Mountains to the west (2590 m asl). The Southern Rocky Mountain Trench is a linear, steep-walled, faulted valley about 480 km long. The valley floor is relatively level and can vary in width from less than 1 km to 20 km. The rivers that drain into and meander along the valley floor of the trench have formed large floodplains and wetlands. At Prince George is the confluence of the Nechako–Stuart systems with the Fraser River. In this

FIGURE 15.3 Fraser River at Hope, British Columbia (PHOTO BY TIM PALMER).

middle region the river has entered the Coast Mountains of British Columbia and Southeast Alaska (PM) physiographic province. Before actually reaching the Coast Mountains, however, the river flows across a high plateau with a dry continental climate bordered by the Coast Mountains (3000m asl) to the west and the Cariboo Mountains to the east. In succession, the river flow is augmented by the West Road, Quesnel, Chilcotin, and Bridge rivers. In the lower sections of this region, the river drops rapidly and enters a very arid area. Here, the silt-loaded waters of the Fraser are joined by the clear water of the Thompson, another great river system, before entering the long narrow Fraser Canyon that cuts through the barrier

of the Coast Range. Below the canyon the river turns west into the more humid coastal region and flows through the lower Fraser Valley in a widening V bordered by the Coast Mountains to the north and the Cascades on the U.S. border to the south. Entering into the Fraser River estuary the river then divides, with 85% of its flow going down the Main Arm and the remainder down the North Arm, dividing again to form the Fraser Delta.

The Coast Mountains receive the main westerly weather systems and experience heavy precipitation during the autumn and winter. Mean annual precipitation can exceed 300cm in some areas. At higher elevations much of the precipitation is in the form of

snow and remains in storage until the spring melt. The windward slopes of the mountain ranges experience the heaviest precipitation, whereas the leeward slopes tend to exhibit a rain-shadow effect; precipitation also generally increases with elevation. The interior plateau lies in the rain shadow of the Coast Mountains and mean annual precipitation ranges from about 40 to 80 cm. In contrast to the Coast Mountains, stations in the interior plateau experience a precipitation peak in the summer, reflecting the influence of summer convective storms, and most of the winter precipitation falls as snow. The mean annual temperature for the area is approximately 3°C, with a summer mean of 12.5°C and a winter mean of -8°C. As easterly moving air masses encounter the Eastern Mountains they produce precipitation. However, having already lost moisture over the Coast Mountains the air masses are not as productive and mean annual precipitation in the region ranges from 100 to perhaps over 200 cm. As in the Coast Mountains, elevation and exposure to the prevailing winds influence precipitation. The autumn precipitation peak is not as marked as in the Coast Mountains. In the headwaters the lower-elevation valleys are marked by warm, showery summers and mild, snowy winters. Subalpine summers are cool, showery, and prone to frosts. Winters are moderately cold and snowy. The mean annual temperature for the headwater valleys is approximately 3.5°C, with a summer mean of 13°C and a winter mean of -6.5°C. The mean annual precipitation in the major valleys is 70 to 80 cm. In the subalpine zone the annual precipitation climbs to 120 cm. Approximations of mean annual precipitation and temperature are 80 cm and 6.1°C, respectively, based on nine stations throughout the basin. The high autumn-winter precipitation in the mountainous areas has the predominant influence on the basin average (Fig. 15.6).

The main stem of the Fraser River flows through five terrestrial ecoregions: North Central Rockies Forests, Fraser Plateau and Basin Complex, Cascade Mountains Leeward Forests, Mainland Coastal Forests, and Puget Lowland Forests (Ricketts et al. 1999). The upper reach of the Fraser flows through the North Central Rockies Forests ecoregion, which is predominantly composed of subalpine and alpine ecosystems and, in the major valley systems, is covered by montane forests. Montane forests are composed of western hemlock and western red cedar in the north, trending to white spruce and alpine fir forests in the south. Subalpine forests are composed of Engelmann spruce, alpine fir, and lodgepole pine.

Valley bottom vegetation ranges from bunchgrass, ponderosa pine, and Douglas fir in the south, to western red cedar and western hemlock in the central portion, to white and black spruce and lodgepole pine in the northern portions of the region. Just north of Prince George the main stem enters the Fraser Plateau and Basin Complex. In this interior plateau the forests are characterized by mixed stands of trembling aspen, paper birch, lodgepole pine, and the climax species, white and black spruce. The subalpine zone that occurs above 1200 m asl supports forests of lodgepole pine, which develop after fires, as well as Engelmann spruce and alpine fir. The plateau is a drier region where the annual precipitation range is 25 to 30 cm in the area around the junction of the Chilcotin and Fraser rivers. Here, bunchgrass-dominated grasslands occur at valley bottom elevations along the Fraser and Chilcotin rivers. Upon leaving the plateau the Fraser enters the Cascade Mountains Leeward Forests ecoregion. In this area, where the river passes through the Interior Transition Ranges between Williams Lake and Lillooet, there are ecosystems ranging from alpine at the highest elevations, to subalpine forests of Engelmann spruce, alpine fir, and lodgepole pine, to montane forests of lodgepole pine, trembling aspen, white spruce, and Douglas fir. At the lowest elevations there is a parkland of scattered ponderosa pine in a matrix of bluebunch wheat grass and sagebrush grasslands. The Fraser then passes through the British Columbia Coast Forests ecoregion. The Pacific Ranges of this ecoregion are high, irregular, steeply sloping mountains that form the main southern part of the rugged Coast Mountains. The area incorporates three main ecological zones: the coastal forest zone, which ranges from sea level to about 900 m asl, the subalpine zone, from about 900 to 1800 m asl, and the alpine zone above 1800 m asl. Vegetative cover of the low-elevation slopes includes very productive stands of western hemlock, western red cedar, and amabilis fir. Drier sites support stands of western hemlock and Douglas fir. The subalpine zone is dominated by forests of mountain hemlock and amabilis fir with some yellow cedar. Finally, the river flows through the Puget Lowland Forests ecoregion (Lower Mainland region), where native vegetation is characterized by forests of Douglas fir with an understory of salal, Oregon grape, and moss. Mixed stands of Douglas fir and western hemlock with some dogwood and arbutus are common on drier sites. Red alder is common where sites have been disturbed. Wet sites support Douglas fir, western hemlock, and western red cedar.

In the upper reaches, as in the rest of the basin, the primary land use is forestry (97.2% for the whole basin), with water impoundment, grazing, hunting, recreation, livestock, forage-crop production, and tourism. Forestry and ranching are the main land uses in the interior plateau, along with outdoor recreation, including hunting and fishing. Passing out of the interior plateau to the interior ranges, land use reflects high recreational and wildlife values in alpine and subalpine zones, whereas forestry and agriculture tend to become more important in lower, warmer zones. Mineral exploration occurs throughout this region. There are 50,000 ha of farmland in the region, the most productive of which are the irrigated forages, mainly alfalfa, on the benches of the river, which is also an important transportation corridor. In the Pacific Ranges land uses reflect high recreational and wildlife values at upper elevations and forestry values at lower elevations. This area contains some of the most productive forestlands in Canada. Important land uses include pulp and sawlog forestry, production of hydroelectric power, water-oriented recreation, and tourism. Much of the forestland is under Tree Farm License. The Lower Mainland region is an urban and agricultural region, containing the largest population center in British Columbia, although compared to the total basin area both urban (2.2%) and agriculture (0.6%) land use is small. Intensive agriculture does occur on the valley bottoms of the Fraser River valley, where it competes with urban development. Forestry operations occur on higher slopes along the mountains. There are about 87,000 ha of highly productive farmland in the area. Coastal salt marshes are important wildlife habitat on the Fraser River delta and adjacent Boundary Bay. Urban and suburban development continues in the Vancouver area and is scattered among many communities in the Fraser River valley and Sunshine Coast.

River Geomorphology, Hydrology, and Chemistry

In the headwaters the mountain ranges are composed of Paleozoic limestones and quartzites. Glaciation has sculpted great U-shaped valleys and left valley floors filled with glaciofluvial and morainal sediments. Rock outcrops predominate at the highest elevations. Permafrost occurs in isolated patches in alpine areas. Underlain by Paleozoic and Proterozoic strata, the trench is covered with a variety of glacial deposits, including ground moraine, outwash plains

and terraces, drumlins, eskers, glacial lake terraces, and recent alluvium. The average slope of the upper river from the headwaters to Prince George is about 2.1 m/km. In the interior plateau the region is underlain by flat-lying Tertiary and volcanic bedrock that generally lies below 1000 m asl. It has a gently rolling surface covered by thick glacial drift into which the Fraser River and its major tributaries are commonly incised. The glacial deposits include moraine with well-developed drumlin features, glaciofluvial terraces, eskers, and large areas of glacial lake deposits. From Prince George to Quesnel the average slope is 1.58 m/km. Below Quesnel the river enters a broad rolling plateau, which generally lies 1150 to 1800 m asl. Surface deposits include glacial till with well-developed drumlinoid features, pitted terraces, simple and compound eskers, and areas of glacial lake (lacustrine) deposits. The average slope from Quesnel to Williams Lake is also 1.58 m/km but increases to 2.45 m/km from Williams Lake to Lillooet. The river cuts through the rugged Coast Mountains in the spectacular Fraser Canyon. Finally, the river flows through the Lower Mainland region, which is underlain by unconsolidated glaciofluvial deposits, silty alluvium, silty and clayey marine sediments, and glacial till. Below Lillooet the average slope decreases to 0.92 m/km.

The hydrology of an area reflects interactions between climatic, physiographic, geologic, and vegetative factors as well as human activity. Hydrologically the Fraser River can be divided into three zones: the Coast Mountains, the interior plateau, and the eastern mountains (Columbia and Rocky mountains) (Slaymaker 1990). Rainfall, snowmelt, and glacier melt contribute varying amounts of water to the Fraser basin. The magnitude and timing of snowmelt varies through the basin depending on the interaction of snow accumulation and melt processes. At lower elevations, especially in the Coast Mountains, mid-winter melt events are common and decrease the amount of snowpack, which can be released during the spring melt. At higher elevations with cooler temperatures, midwinter melt events occur less frequently, and more of the precipitation falls as snow. The timing of the main spring thaw varies according to location and elevation. Runoff in the Fraser basin is predominantly determined by the melt of the snowpack in the headwaters and can produce great variation within and between years.

Mean annual discharge at the Mission hydrometric gaging station is 3370 m³/s, with mean monthly flow varying from 1400 m³/s in winter to over 8000 m³/s in summer. With great between-year varia-

tion, however, monthly flows range from as low as 450 m³/s to as high as 20,000 m³/s. Mean runoff at Mission averages less than 2 cm/mo from January through March, but runoff from the spring snowmelt peaks in June at about 9 cm/mo (see Fig. 15.6). Mean discharge estimated at the mouth (3972 m³/s) is somewhat higher than at the Mission station. The tidal effect on water level reaches as far inland as Chilliwack, 120 km from the mouth, at low flow and 75 km upstream (Mission) during the spring freshet. The salt wedge ranges from 22 km upstream (low flow) to just to the river mouth (high flow). It is estimated that sediment is added to the river delta at a rate of 12 million m³/yr, and the Sturgeon Bank at the delta is advancing seaward at a rate of 25 m/yr.

Glacier melt is also an important source of water, mainly in the headwater basins in the Coast, Cariboo, and Rocky mountains. The melt normally begins in May in higher elevations in the Coast Mountains. The Fraser River in this region is sufficiently large that only spatially widespread and prolonged seasonal melting of snow and ice produces peak flows. In the interior plateau, the main melt begins in March (e.g., Prince George), as reflected in the hydrograph, and flow begins to increase almost a month earlier than in the eastern mountains. Because the temperature decreases both with elevation and latitude the relative importance of snow as winter precipitation and its consequent effects on runoff and hydrology is affected by these two factors. Upstream of Prince George the melt varies from March (low altitude) to May (high altitude). Glacier melt is also an important source of water in the headwater basins of the Rocky Mountains.

The most noticeable feature of the water chemistry in the Fraser River is the high sediment load, which is a natural phenomenon of the river and was noted by Simon Fraser in the spring of 1808 (Slaymaker 1991). This results from natural erosion processes as the river flows through the glacial deposits and drift material in the central plateau. However, extensive logging occurs throughout the basin, and although it does not affect sediment loads in the main stem, it may be an issue on smaller tributaries. Water chemistry along the length of the main stem in different seasons shows changes in turbidity, total phosphorus, and iron are positively related to discharge, and five variables (chloride, calcium, sodium, reactive silica, and sulphate) are negatively associated with discharge (Whitfield 1983, Whitfield and Schreier 1982). Three zones have been identified from the water chemistry: a headwaters zone that extends only as far as Red Pass, only 70 km from the

source, a midstream zone from Red Pass to between Prince George and Quesnel, and a downstream zone (Whitfield 1983). The mean ranges in these three zones, respectively, are turbidity 1.0 to 6.0 JTU, 6.0 to 10.0 JTU, and 19.0 to 25.0 JTU; specific conductance 100 to 145 µS/cm, 133 to 146 µS/cm, and 114 to 139 µS/cm; alkalinity 35 to 60 mg/L as CaCO₃, 51 to 65 mg/L as CaCO₃, and 47 to 61 mg/L as CaCO₃; hardness 50 to 73 mg/L as CaCO₃, 65 to 74 mg/L as CaCO₃, and 53 to 67 mg/L as CaCO₃; chloride 0.2 to 0.5 mg/L, 0.4 to 1 mg/L, and 1.1 to 1.5 mg/L; silica 2.6 to 3.8 mg/L, 3 to 4 mg/L, and 3.9 to 5.6 mg/L; and sodium 0.6 to 0.9 mg/L, 0.8 to 1.5 mg/L, and 2.1 to 2.7 mg/L.

River Biodiversity and Ecology

The Fraser is the largest river system within the North Pacific Coastal freshwater ecoregion (Abell et al. 2000). In spite of its size, it is probably the best studied in terms of its biodiversity and ecology, both in the main stem and in several of its tributaries.

Algae and Cyanobacteria

In the main stem above Prince George between 11 and 15 taxa have been recorded in the Fraser River, primarily diatoms, but with two species of Cyanobacteria (*Lyngbya* spp.) and one green algal species (*Scenedesmus* sp.) (Rosenberg et al. 1998). There is generally more variability in the dominant taxa upstream of Prince George, with three dominant species, the green alga *Ulothrix* sp. and the diatoms *Synedra ulna* and *Achnanthes minutissima*. Other common species are *Amphipleura pellucida*, *Fragilaria vaucheriae*, *Gomphonema olivaceum*, *Hannaea arcus*, and *Navicula* sp. There is a trend to increased species richness downstream of Prince George, with up to twice as many taxa observed (5 to 12 upstream and 15 to 23 downstream). Downstream of Prince George the diatom *Cymbella* sp. is most abundant at all but one site, and other diatoms, such as *Achnanthes minutissima*, *Fragilaria capucina*, *Gomphonema olivaceum*, *Melosira varians*, *Melosira* sp., *Navicula radiosa*, *Nitzschia palea*, and *Synedra ulna*, are also common (more than 10% of sample) (Rosenberg et al. 1998).

Plants

There is little in the way of macrophyte development in the fast-flowing Fraser River. Riparian vegetation shifts from domination by conifers such as white spruce, lodgepole pine, and Douglas fir upstream of Prince George to birch, cottonwood,

various willows, and various grasses in the downstream reaches.

Invertebrates

According to Reece and Richardson (2000), little research has been done on benthic communities in streams of noncoastal regions of British Columbia. Rosenberg et al. (1998) examined changes in invertebrate communities along the length of the Fraser River from the headwaters to Agassiz, near the mouth, and identified over 50 families at 28 sampling sites. Of these, 11 families represented more than 90% of the invertebrates found. The most widely distributed and abundant were Chironomidae (midges), which were present at 97.5% of sites. Also abundant and common were stoneflies (Capniidae, Taeniopterygidae, and Perlodidae), mayflies (Heptageniidae, Ephemerellidae, and Baetidae), annelid worms (Naididae and Enchytraeidae), caddisflies (Hydropsychidae), and true flies (Empididae). There was a general trend of increasing abundance from the headwaters (300 to 400 organisms per minute of sampling) to Quesnel (1200 to 1500 organisms per minute of sampling), followed by a region of low abundance to Lillooet (<100 organisms per minute of sampling) and then a gradual increase in abundance to Agassiz, furthest downstream. Diversity (number of taxa) decreases from the headwaters to the lower reaches. The changes in abundance and diversity are partially reflected by the major families. Upstream sites are dominated by mayflies. The baetid mayflies occur primarily in the headwaters and the ephemereiid mayflies occur in the headwater and upstream sections. Chironomid midges are particularly abundant in the middle reaches. Common genera in the Fraser River are the stoneflies *Capnia* and *Isogenoides*, the mayflies *Rhithrogena*, *Ameletus*, *Ephemerella*, and *Baetis*, and two naidid oligochaetes, *Nais* and *Specaria*.

Vertebrates

Three major assemblages have been proposed (McPhail 1998) based on the distribution of native freshwater fish species and the eight marine species that regularly enter the river. First, an estuarine assemblage occupies the estuary as far as Sturgeon Bank and the river to the upper limits of tidal influence at Mission. This assemblage is comprised of six abundant salmonid species (pink, chum, coho, sockeye, and Chinook salmon and rainbow trout) as well as marine species, such as starry flounder, and many small forage fishes, such as peamouth chub, reidside shiner, and sticklebacks (Richardson et al.

2000). Second, a lower-river assemblage occupies the river from Mission upstream to the Fraser Canyon and is characterized by eight native species (river lamprey, western brook lamprey, green sturgeon, longfin smelt, eulachon, coastal cutthroat trout, chum salmon, and threespine stickleback) that do not occur upstream of this reach of the Fraser. Finally, a distinctive upper-river assemblage occupies the river upstream of the Fraser Canyon, characterized by six species (chiselmouth, lake chub, white sucker, pygmy whitefish, slimy sculpin, and torrent sculpin) and one subspecies (westslope cutthroat trout) that do not occur below the canyon. Two species were formerly restricted to the upper basin (lake trout and lake whitefish) but have been transplanted to the lower basin. This upper-river assemblage has been separated by McPhail (1998) into a lower and upper community, with the geographic boundary the confluence of the Fraser and Bowron rivers. Upstream of the Bowron the community is characterized by the loss of species and is dominated by species adapted to swift glacial rivers.

The main-stem Fraser River is noteworthy for providing spawning habitat for at least three species of Pacific salmon: pink, chum, and chinook (Northcote and Burwash 1991). From 1957 to 1989 an annual average of 765,000 pink salmon spawned in the main stem in the area of Hope, representing 90% of the total pink salmon production to the lower Fraser subbasin. Chinook salmon use the headwater reaches of the main stem and make up 32% of the salmon escapement to the drainage basin.

Other aquatic vertebrates in the basin include birds and mammals, as well as several amphibian species. Aquatic mammals found in the river drainage include beaver, common muskrat, and river otter. The South Arm Marshes and Ladner Marsh in the Fraser River delta together make up internationally important stopovers for hundreds of thousands of migratory birds on the Pacific Flyway. The area provides breeding and feeding habitat for one of the largest overwintering waterfowl populations in Canada, comprising some 40 species of ducks, geese, and swans. The entire range of the coastal giant salamander in Canada (red-listed in Canada) is within the Fraser River drainage.

Ecosystem Processes

Although considerable information exists for water chemistry, fisheries, and other biological features, there have been few studies on ecological processes on the main-stem Fraser River. Calculations of the organic loading of the lower Fraser River,

primarily from agricultural and municipal sources, suggest large increases in ecosystem productivity during the twentieth century (Healey and Richardson 1996). However, much more information on ecosystem processes is available on its largest tributary, the Thompson (as will be discussed later in this chapter).

Human Impacts and Special Features

The Fraser River has to be considered one of the less-impacted major river systems in North America. Along most of its length there are few urban centers. Municipal and pulp mill discharges are the major point-source discharges and seem to be generally producing mild enrichment for a short distance. The main stem provides passage to some of the world's most famous salmon fisheries. The major nonpoint-source effects are from forestry and these tend to be localized and to affect only small streams. The major effects are observed in the major urban area, Vancouver, at the mouth of the river. One of the most notable features of the Fraser is its dramatic transition as the river flows through the spectacular Fraser Canyon and Hell's Gate as it breaks through the Coastal Range. Gold prospector W. Champness described this in 1863:

In other parts of the journey especially in the river gorges, our track conducted us along the most frightful precipices. There was no help for this, as we could select no route more passable. The river flows often through dark and awful gorges whose rocky sides tower perpendicularly from a thousand to fifteen hundred feet. By a series of zigzag paths, often but a yard in width, man and beast have to traverse these scenes of grandeur. Sad and fatal accidents often occur, and horses and their owners are dashed to pieces on the rocks below, or drowned in the deep foaming waters rushing down the narrow defiles from the vast regions of the mountain snow melting in the summer heat. (www.barkerville.ca/barkerville/documents 2004)

The major potential sources of human impact are effluents from point sources such as pulp and paper mills located at Prince George and Quesnel. Also, there are nonpoint sources of contaminants in the urbanized lower Fraser Valley and agricultural sub-basins in the lower Fraser, and exposures to effluents in the delta foreshore from large municipal wastewater treatment plants. The main-stem river upstream of the estuary and its major tributaries does not exhibit significant concentrations of contaminants at most locations, and low levels of contaminants have been recorded in wildlife (Wilson et al.

1998) and benthic invertebrates (Richardson and Levings 1996). Mesocosm experiments (Culp and Lowell 1998) have shown that pulp mill effluents stimulate growth of invertebrates at the lowest dilution levels currently observed in the Fraser River, but that an increase in effluent concentration could induce toxic effects. Analyses of fish (Raymond et al. 1998) and bird (Wilson et al. 1998) tissue show a greater induction of the detoxifying enzyme, mixed-function oxygenase, downstream of urban centers and pulp mill discharges. Furthermore, two fish species, peamouth chub and mountain whitefish, had a relatively high incidence of abnormalities throughout the basin and highly pigmented livers and kidneys and reduced gonad development at sites downstream of pulp mills. However, the ecological significance of these observations is not known. Contamination is also evident in the Fraser River estuary, where the levels of chemicals such as PAHs and some dioxin and furan congeners in sediment exceeded guidelines or draft guidelines established for the protection of aquatic life (Brewer et al. 1998). Runoff from agricultural and urban areas is now a significant source of contaminants to the basin, and the lower Fraser Valley is one of the most important agricultural regions in British Columbia. The key issues are excess nitrogen, ammonia, eutrophication, and coliform problems in small streams, as well as elevated nitrate values in groundwater and high Zn in sediment (Schreier et al. 1998). Results have shown that water-quality conditions are limiting the distribution and breeding success of native amphibians in areas of the Sumas watershed. Finally, persistent organic pollutants have been found in the rivers headwaters. The likely source of PCBs, DDT and its metabolites, and toxaphene found in fishes from headwater lakes is long-range atmospheric transport and deposition coupled with the release of historic deposits of contaminants from melting glaciers and permanent snowfields.

THOMPSON RIVER

Rising near the continental divide in cold headwater streams of the Cariboo Mountains, the Thompson River flows 300km as the North Thompson River until it joins the flow of the South Thompson from Shuswap Lake (Fig. 15.7). The Thompson River then travels approximately 40 km through Kamloops Lake before exiting as one of the larger rocky-bottom rivers in North America. At its confluence with the Fraser River the 7th order Thompson River

is more than 500 km long and drains approximately 55,000 km². As the Thompson cuts across south-central British Columbia it dissects the diverse montane cordillera, with alpine tundra and dense conifer forests in the upper basin; dry sagebrush grasslands and ponderosa pine forests cover the lower basin.

Simon Fraser named the Thompson River during his 1808 exploration of the Fraser River to honor David Thompson. Thompson explored passes west of the Saskatchewan and Athabasca rivers, as well as the Columbia River from 1806 to 1811, in search of new trade routes, but never reached as far northwest as the river system that bears his name. The Shuswap tribe of the Salish nation named the confluence of the North and South Thompson rivers near present-day Kamloops “cume-loups,” apparently meaning “meeting of the waters.” Between 1810 and the 1850s, fur traders and then gold seekers and farmers developed the area around the lower Thompson River as an important regional trade center. Although the river was not of great importance as a navigational route because of dangerous rapids, terraces along its banks provided natural roadways. Today the Thompson is an important transportation corridor, with highways and railways following the river from Kamloops to its confluence with the Fraser River.

Physiography, Climate, and Land Use

The Thompson River flows south to join the South Thompson River at Kamloops, British Columbia, then travels southwest to its confluence with the Fraser River. Lying between latitudes 50°N to 53°N and longitudes 122°W to 118°W, this large drainage lies within the Coast Mountains of British Columbia and Southeast Alaska (PM) physiographic province (see Fig. 15.7). Much of the basin is composed of folded sedimentary and volcanic strata, with metamorphic rocks of Paleozoic and Mesozoic age covered by a thick mantle of glacial drift. Soils across the region are quite varied, with luvisols and brunisols the most common; podzols occur in the mountain ranges of the wetter, eastern portion of the basin and chernozems form the soils of lower valley floors to the south. Plains and valleys are covered by glacial moraine and fluvial and lacustrine deposits, whereas mountains consist largely of colluvium and rock outcrops.

The Thompson basin encompasses three terrestrial ecoregions: the North Central Rockies Forests, the Okanagan Dry Forests, and the Cascade Mountains Leeward Forests (Ricketts et al. 1999). The

basin is an incredibly diverse region, with habitats ranging from alpine tundra to sagebrush grassland. The diverse landscape varies with elevation from alpine environments containing herbs, lichens, and shrubs to well-treed subalpine forests. With decreasing elevation, forests are characterized by ponderosa and lodgepole pine, Douglas fir, and trembling aspen in the southwest and central portions of the basin and western hemlock, western red cedar, and Douglas fir in the southeast. In the driest areas west of the North and South Thompson confluence, grasslands of bluebunch wheat grass, blue grass, june grass, sagebrush, rabbitbrush, and antelope bush occur.

Mean annual air temperature for the area is 9.7°C, with mean monthly temperatures ranging from -2.3°C in January to 21.4°C in July and August (Fig. 15.8). Kamloops has the highest average daytime maximum temperature of all Canadian cities at 28°C. The lower portion of the basin is one of the driest regions in Canada. Indeed, annual precipitation exhibits a strong gradient across the basin, ranging from 27 cm in the lower Thompson Valley at Kamloops to more than 100 cm in mountain headwaters. Mean monthly precipitation at Lytton ranges from 6.7 cm in December to 1.4 cm in July (see Fig. 15.8). Approximately 30% to 40% of the precipitation arrives as snowfall in winter.

Many of the natural grasslands have been replaced by urban settlement and irrigated agricultural operations. Land uses reflect high recreational and wildlife values in alpine and subalpine zones, whereas forestry and agriculture tend to become more important in lower, warmer zones. The majority of the basin is managed for sustainable forest harvesting, although river valleys generally contain sparsely populated rural districts and forage agriculture is common along the terraces of the lower Thompson River. Forest and shrubs cover approximately 75% of the basin and agricultural lands less than 3%. Mineral exploration occurs throughout the region. Population density across the basin is sparse and varies considerably, with less than 3 people/km². Approximately 70% of the population resides in Kamloops, the main urban area within the basin (estimated population of 85,000 in 1996).

River Geomorphology, Hydrology, and Chemistry

The North Thompson is a high-velocity erosional river flowing over a gravelly bottom, ranging to boulders and bedrock in some reaches (Fig. 15.1). The upper part of the North Thompson between the

Clearwater and Blue rivers is fairly steep, with an average slope of 2.90 m/km. The lower part of the North Thompson between the Clearwater and the confluence with the South Thompson has an average slope of 0.54 m/km. The North Thompson comprises 38% (20,700 km²) of the total drainage area of the whole Thompson River basin, but contributes 55% (428 m³/s) of the mean annual flow for the whole river (787 m³/s). In contrast to the South Thompson, the North Thompson is a free-flowing river, without intervening lakes, and can be greatly affected by heavy rains and sudden snowmelt. Mean monthly discharge ranges from 81 m³/s in February to 1360 m³/s during the freshet peak in June.

The South Thompson between Shuswap Lake and the North Thompson is slow flowing. It is typified by a sand-gravel bottom and has an average slope of 0.24 m/km. The South Thompson drainage area (17,800 km²) is 32% of the basin total for the Thompson River and contributes 37% (289 m³/s) of the mean annual flow. The flow in the South Thompson is modulated by upstream lake storage, most notably Shuswap Lake. Mean monthly discharge ranges from 88 m³/s in March (late winter) to 855 m³/s in June. Thus, although only comprising 69% of the whole Thompson River drainage, the North and South Thompson subdrainages contribute 92% of the total discharge, reflecting the arid conditions in the lower Thompson. Both the North and South Thompson can be ice covered for several months of the year.

Water chemistry is quite similar in the North and South Thompson rivers. In the North Thompson, specific conductance is 91 µS/cm, alkalinity 36 mg/L as CaCO₃, hardness 91 mg/L as CaCO₃, chloride 0.3 mg/L, silica 5.4 mg/L, sodium 1.5 mg/L, and pH 7.6. In the South Thompson, specific conductance is 101 µS/cm, alkalinity 38 mg/L as CaCO₃, hardness 91 mg/L as CaCO₃, chloride 0.5 mg/L, silica 5.3 mg/L, sodium 2.0 mg/L, and pH 7.7 (Nordin and Holmes, 1992). The North Thompson, however, is more turbid (3.9 NTU), with more suspended sediments (30 mg/L) than the South Thompson (1.7 NTU, 15 mg/L). Both the North and South Thompson are fairly pristine and nutrient poor. Whereas levels of inorganic nitrogen do not appear to be limiting (~70 to 130 µg/L), phosphorus levels are quite low (soluble reactive phosphorus 0.7 to 1.1 µg/L, total dissolved phosphorus 2.7 to 3.5 µg/L), resulting in phosphorus limitation (Bothwell 1985). The 15 km length of the lower Thompson from the confluence of the North and South Thompson to Kamloops Lake is the major point source of phosphorus loading to the river

system; this is the location of the outfalls for the bleached kraft pulp mill and the city of Kamloops municipal sewage treatment plant. Increased algal growth below Kamloops Lake has been attributed to this phosphorus loading (Lowell et al. 2000).

An unusual eutrophication pattern is apparent in the lower Thompson River. Whereas the main point sources of phosphorus loading are located just upstream of Kamloops Lake and there is evidence of nutrient enhancement downstream of the lake, the lake itself remains oligotrophic. This appears to be a result of the circulation patterns in the lake (Carmack et al. 1979). Kamloops Lake is fairly long (25 km), narrow (mean width 2.1 km), and deep (mean depth 71 m). The annual mean flushing time is only 60 days, which helps to prevent nutrients from accumulating in the lake. Furthermore, periods of high river flow into the lake during the spring and summer are associated with high suspended sediment load, restricting light penetration. In combination with deep mixing in the water column this keeps algal production in the lake within the oligotrophic range. During the warmer months of the year thermally driven differences in river inflow density versus lake water density results in mixing of river water in the lake, which, together with greater river flow and dilution, leads to lesser nutrient inputs to the river downstream of the lake. During the limnological winter, however, river inflows of less-dense 0°C water tend to flow across the surface of the more-dense 4°C lake water and exit the lake with relatively little intermixing. Because this is also the period of lowest flow, dilution is minimal and greater levels of nutrients are delivered to the river downstream of the lake in the winter.

The remaining 100 km of the lower Thompson from Kamloops Lake to the Fraser River is fairly fast flowing, with a substratum consisting of boulders, cobbles, and gravel. Unlike the North and South Thompson, this section of the Thompson is usually ice free, due in part to the lake's thermal inertia. Levels of soluble reactive phosphorus (3 to 4 µg/L) are often three or more times those in the North and South Thompson (Bothwell 1985). The final section of the lower Thompson from Spences Bridge to the Fraser River passes through steep-sided gorges and is a well-known white-water rafting area. Despite the fact that precipitation is highest from November through February, discharge in the lower river peaks annually during mountain runoff between May and July and reaches the annual minimum in late winter between January and March (see Fig. 15.8). Thus, the annual discharge pattern is driven by snowmelt in spring.

River Biodiversity and Ecology

As with the rest of the Fraser system, the Thompson is within the North Pacific Coastal freshwater ecoregion (Abell et al. 2000). The river is relatively well studied in terms of its biodiversity and ecology, including studies on ecosystem processes.

Algae

The Thompson River system is naturally oligotrophic and primary producers of the river respond rapidly to nutrient additions (Bothwell 1985). Food webs in the Thompson main stem appear to be based largely on epilithic algal production (Bothwell et al. 1992, Wassenaar and Culp 1996), although the importance of allochthonous detritus probably increases toward the headwaters. Epilithic algal communities are dominated by several diatom genera in the South, North, and main-stem Thompson rivers, including *Achnanthes*, *Cymbella*, *Diatoma*, *Fragilaria*, *Gomphonema*, *Hannaea*, *Nitzschia*, *Synedra*, and *Tabellaria* (Federal-Provincial Thompson River Task Force 1976, Bothwell 1985). Species diversity is highest in the South Thompson River, where algal biomass is low. Algal biomass increases downstream of effluent discharges at Kamloops Lake, and the filamentous diatom *Gomphonema olivaceum* often dominates the species composition of the lower river.

Plants

Macrophytes are seldom abundant in the Thompson River. Riparian vegetation in the heavily forested North Thompson and South Thompson rivers consists of various willow species, trembling aspen, and conifers such as lodgepole pine or Douglas fir. Along the lower Thompson River the riparian vegetation is sparse and is composed mostly of grasses, shrubs (e.g., sagebrush), and the occasional balsam poplar or ponderosa pine.

Invertebrates

Early river-monitoring studies (1973 to 1975) showed that the benthic macroinvertebrate faunal composition of the North and South Thompson rivers was dominated by families of mayflies (Baetidae, Ephemerellidae, Siphonuridae, Heptageniidae), stoneflies (Chloroperlidae, Nemouridae, Perlodidae), caddisflies (Hydropsychidae, Leptoceridae), and midges (Chironomidae) (Federal-Provincial Thompson River Task Force 1976). In contrast, taxonomic richness in the main-stem Thompson below major effluent sources was greatly reduced and comprised mostly of chironomids, oligochaetes, and nematodes

but recovered to more pollution-intolerant forms by the 1990s (Lowell and Culp 2002).

The annual freshet appears to be an important reset mechanism for the benthos, as many insects emerge prior to its onset. Insect abundance (density and biomass) is lowest in late summer following the annual freshet and early larval instars are common. Abundance of most taxa (i.e., mayflies, midges, caddisflies) increases to an annual maximum by late winter during the period of high algal biomass and low, stable discharge. Total densities during this period often exceed 20,000 individuals/m² and the river is dominated by taxa belonging to the collector-gatherer, filterer, scraper, and predator functional feeding groups. Insects present in late winter are generally late instars nearing emergence. Common genera in the Thompson River are the mayflies *Baetis*, *Ephemerella*, *Paraleptophlebia*, and *Rhithrogena*; the caddisflies *Arctopsyche*, *Brachycentrus*, *Cheumatopsyche*, *Glossosoma*, *Hydropsyche*, and *Hydroptila*; the stoneflies *Arcynopteryx* and *Skwala*; and the midges *Cardiocladius*, *Cricotopus*, and *Eukiefferiella*. Bothwell and Culp (1993) report a clear seasonal pattern of insect abundance in the Thompson River, which they summarized for two taxa, *Baetis tricaudatus* mayflies and Orthoclaadiinae midges.

Vertebrates

The Thompson River basin provides important spawning, rearing, and migratory habitat for several species of Pacific salmon (coho, chinook, sockeye, and pink) as well as steelhead. Of special importance is the Adams River sockeye migration, the largest in North America, and the Thompson River steelhead run (Hume 1992). At least 40 streams and rivers in the Thompson drainage provide spawning habitat for coho salmon. Over the last decade abundance of coho returning to the Thompson River watershed has declined by 90% due to a combination of factors, such as changes in land use, fishing, and climate change (Bradford and Irvine 2000). Pink salmon spawn extensively in the Thompson River below Kamloops Lake (Federal-Provincial Thompson River Task Force 1976). Recent surveys found that juvenile chinook salmon also use the main stem as winter habitat, where they feed on benthic macroinvertebrates such as caddisflies and stoneflies. In fact, electrofishing surveys revealed that the lower Thompson had the highest winter densities of juvenile sockeye in the Fraser basin. Finally, recent studies indicate that the Thompson River stocks of chinook and coho salmon form evolutionarily significant units of

importance for biodiversity conservation (Small et al. 1998, Teel et al. 2000, Nelson et al. 2001).

Although Pacific salmon are the charismatic component of the basin fish fauna, the Thompson River watershed contains a total of 24 species. These include round whitefish, largescale sucker, bridgelip sucker, northern squawfish, longnose dace, and slimy sculpin. Although there is little information on most of the fish species of the Thompson other than salmon, Bothwell and Culp (1993) reviewed the seasonal cycles of growth and abundance of longnose dace, a key benthic predator in the lower Thompson River. This minnow spawns in summer with young-of-the-year (YOY) appearing in August along the river margins. YOY dace grow rapidly through the fall, attaining body lengths of 30 to 40mm by November. Over this period YOY dace densities decline, indicating that autumn is a period of high mortality for this age class. Densities of older year classes are also highest in late summer and decrease through late winter (March and April).

Other aquatic vertebrates in the basin include birds and mammals, as well as several amphibian species. Only four species of amphibians are associated with flowing waters or ponds adjacent to streams in forested landscapes: long toed salamander, Pacific tree frog, Great Basin spadefoot, and the Columbia spotted frog (Corkran and Thoms 1996). Aquatic mammals found in the river drainage include beaver, muskrat, and river otter. The South Thompson River is an important winter habitat for waterfowl. Winter surveys of this stretch of the river have recorded 100 to 400 trumpeter swans, which represents as much as 2% of the global population. Breeding birds of the Thompson River include wood ducks, osprey, common merganser, and dipper.

Ecosystem Processes

Primary production in the Thompson River is limited by soluble reactive phosphorus (SRP) availability, as the river is extremely sensitive to nutrient dynamics (Bothwell 1985). Nutrient-saturated growth rates of benthic diatoms in the lower Thompson River occur near $1\mu\text{g SRP/L}$. However, areal biomass accumulated on epilithic surfaces increases with elevation of phosphorus concentration to at least $30\mu\text{g SRP/L}$ (Bothwell 1989). Nutrient limitation varies with season in the lower Thompson River: Periphytic communities are nutrient limited in the autumn but relatively insensitive to elevation in phosphorus during the winter (Bothwell and Culp 1993, Dubé et al. 1997). Chlorophyll *a* varies about twenty-

fivefold during the year in the Thompson main stem, with the lowest levels ($2\mu\text{g/cm}^2$) occurring after the spring freshet (Bothwell and Culp 1993). Algal biomass increases from summer through late winter as a result of complex mixing patterns in Kamloops Lake (described previously) that produce conditions of nutrient limitation in the fall and eutrophication in the winter (Dubé et al. 1997). Late-winter biomass values can peak as high as $40\mu\text{g/cm}^2$ prior to the algal mat sloughing as it becomes thick and physically unstable. Although grazers such as midges can reduce the amount of benthic algae, particularly in the autumn when water temperatures are warm, the effectiveness of insect grazing is reduced by the presence of predatory benthic fishes.

The lower Thompson River is an open-canopy river and would be predicted to have a food web based on carbon derived from algal production. However, stable isotopic analyses indicate that both the carbon and nitrogen isotopic signatures of insects collected 50 to 100km downstream of the pulp mill contained 50% to 80% of mass derived from terrestrial sources (Wassenaar and Culp, 1996). This carbon is most likely material from pulp mill effluent and indicates that the discharge contributes directly and significantly to the lower Thompson food chain. Filter-feeding caddisflies contained the greatest percentages of terrestrial carbon. Like their insect prey, the fish isotopic signatures downstream of the mill were correlated to that of the effluent.

Human Impacts and Special Features

The Thompson River is one British Columbia's most important rivers, as it provides water to municipalities, industry, and agriculture as well as providing important habitat for commercial and recreational fisheries. The Thompson is the spawning route for millions of sockeye, chinook, coho, and pink salmon and is home to some of the largest steelhead found in North America. The North Thompson River has few sections of wild water with chinook salmon and Dolly Varden the primary targets for anglers. The South Thompson River is relatively slow moving and is the passageway for the famous Adams River run of sockeye salmon. Below Kamloops the landscape surrounding the Thompson River changes from forest to a semiarid landscape of grass and sagebrush. Many of the river terraces along this stretch of the river are used for cattle grazing and fodder crops. Both the Canadian Pacific and Canadian National transcontinental railroad lines follow the river from Kamloops to Lytton. The river reach from Kamloops

Lake to the Spences Bridge area is famous for steelhead fishing, with fish sometimes reaching 8 to 10 kg. The river section downstream of Spences Bridge to Lytton is wild and fast, traveling through steep-sided canyons and gorges. This section of the river features 18 Class III (or greater) rapids, beginning with Frog Rapid, a turbulent river section that squeezes around a house-sized rock that resembles its namesake at base flow. Thousands of people raft this section of the river each summer to experience huge standing waves, the hot climate, and desert-canyon scenery.

The primary human impact on the Thompson River is the effect of the bleached kraft pulp mill and municipal sewage effluent discharged at Kamloops. Coincident with increases in effluent loading from the pulp mill in the early 1970s were reports of excessive algal growth and changes in water quality downstream of Kamloops Lake. This raised concern about effects on Pacific salmon stocks and led to studies by the Federal–Provincial Thompson River Task Force (1976). Phosphorus was identified as the nutrient most likely responsible for the excessive increase of attached algae (later confirmed experimentally by Bothwell et al. [1992] and others). Recommendations prompted the city of Kamloops and provincial regulators to initiate tertiary treatment of the municipal effluent by alum flocculation as a routine treatment in 1977. Although phosphorus in the sewage effluent was reduced by 90%, scientists at the National Water Research Institute devised an additional “winterholdback” strategy to further reduce phosphorus discharge to the river. This plan calls for storage of all municipal effluent during the low-flow period (December to March) in order to reduce nutrient enrichment in the lower Thompson River. Discharge commences again during the spring freshet, when high dilution and mixing within Kamloops Lake minimize nutrient impact in the river.

This strategy for reducing nutrient loading markedly lowered phosphorus discharge from the sewage plant throughout the year. Abundances of several key invertebrate taxa (mayflies [Heptageniidae, Baetidae, Ephemerellidae], stoneflies [Perlodidae], and caddisflies [Hydropsychidae]) were greater in later years during which mill output of effluent solids and phosphorus was greater. However, these effects were not pronounced enough to produce increased abundances of more pollution-tolerant taxa, such as nematodes and oligochaetes, as was observed in the 1970s prior to improved effluent treatment. Outdoor artificial stream experiments set up alongside the river demonstrate that effluent con-

centrations from 1% to 10% increase the growth of algae and the biomass of mayflies (*Baetis tricaudatus*) and chironomids, although some inhibitory effects on the invertebrates occurred at effluent concentrations $\geq 5\%$ (Lowell et al. 1995, Dubé and Culp 1996, Culp and Lowell 1999, Lowell and Culp 1999).

NECHAKO RIVER

The Nechako River flows northeast from the Coast Mountains, and after it joins its major tributary, the Stuart River, flows east to join the Fraser River at Prince George (Fig. 15.9). This is the most regulated of the basins within the Fraser River catchment, with a 906 km² reservoir stored behind the rock-filled Kenney Dam. The river from the dam to the confluence with the Fraser River is now 290 km long, but prior to the dam installation was approximately 440 km in length (Fig. 15.4). The river, along with its tributaries, the Stuart and Nautley rivers, now makes up about 8% of the total flow of the Fraser River.

Native Americans have lived in the catchment for thousands of years, and include the Carrier (Dakelhne) and Wet’suwet’en peoples, part of the Athapaskan language group. Prior to European contact one of the largest settlements of native people in the basin was at the confluence of the Nechako and Stuart rivers in a place known as Chinlac, site of an intertribal massacre of Carrier people in 1745. The earliest recorded European movement into the basin is attributed to Simon Fraser, one of the early British explorers, who established trading posts and forts in 1806, one of which was Fort Fraser. The earliest farming in the area began in about 1811. The first major wave of settlement in the region occurred in 1903, when news that the Grand Trunk Pacific Railway would be built through the area, which was completed at Vanderhoof in 1914.

Physiography, Climate, and Land Use

The Nechako sits in the Coast Mountains of British Columbia and Southeast Alaska (PM) physiographic province, although most of the basin is actually eastward of the Coast Mountains (see Fig. 15.9). The headwaters of the Nechako River in the west of the basin drain a mostly igneous, granitic batholith with low solute concentrations that makes up the Coast Mountains. These headwaters are on the eastern edge of the British Columbia Mainland Coastal Forests terrestrial

FIGURE 15.4 Nechako River at Highway 16, British Columbia (PHOTO BY TIM PALMER).

ecoregion. The areas near the mountains are steep and consist of boreal, temperate forest and tundra biomes. The majority of the basin has a gently rolling topography. About 85% of the basin drains the Nechako Plateau, made up primarily of volcanic rock, with some sedimentary areas and higher solute concentrations (Hall et al. 1991). This plateau is part of the Fraser Plateau and Basin Complex terrestrial ecoregion, typified by deep, postglacial lacustrine soils.

The forests of the basin are predominantly a sub-boreal type characterized by lodgepole pine, white spruce, and aspen. At higher elevations these forests grade into subalpine zones along the leeward side of the Coast Mountains, with subalpine fir, mountain hemlock, and Engelmann spruce most common. These forests experience large-scale disturbances from fire and insect outbreaks. In recent years outbreaks of mountain pine beetle have resulted in extensive damage to forests.

The main portion of the basin is in the rain shadow of Coast Mountain range and gets only about 40 to 60 cm/yr of precipitation (Fig. 15.10).

Rainfall through the basin varies with proximity to the mountains and with elevation. Near the Coast Mountains at the west end of the catchment, average annual precipitation is 196 cm/yr, whereas in the eastern portion of the basin it averages only 20 to 40 cm/yr. Precipitation falls throughout the year without any distinct seasonal pattern, with the exception of slightly lower winter precipitation. During winter the low temperatures result in storage of precipitation as snow throughout the basin. The annual temperature pattern is characteristic of the northern continental climate, with freezing winter temperatures and mean summer temperatures of about 15°C (see Fig. 15.10), but summer temperatures can reach the mid-30s. Summer rainfall is often cyclonic in nature and results in frequent thunderstorms.

The major land use in the area is timber harvesting. Forest covers about 88% of the basin (Revenga et al. 1998). Agriculture, mostly ranching, occupies about 6% of the basin, and very little of that is irrigated farming. Forest cover and soils are similar to those in the Stuart River basin (which will be

discussed later in this chapter). The largest towns in the catchment, which occupy only about 0.2% of the basin area, are Vanderhoof, Burns Lake, and Fraser Lake, with a combined population of about 7800 (2002 figures). Most water for domestic use comes from groundwater sources. There are no pulp mills in the basin.

River Geomorphology, Hydrology, and Chemistry

The river has a cobble bottom through much of its course downstream of the Kenney Dam, almost to the town of Vanderhoof. Chinook salmon spawn in the reaches upstream of the confluence with the Stuart River and can have enough influence on the bed during their digging of redds that dunes of up to 15 m in period and amplitude of 0.75 m form in large sections (Tutty 1986). Downstream of Vanderhoof until the confluence with the Fraser River the gradient is lower and the river takes on a slow, meandering form, with many backwaters (sloughs) and a main channel depth approaching 10 m.

The biggest tributary of the Nechako River is the Stuart River, which joins the Nechako downstream of Vanderhoof, 92 km before its confluence with the Fraser River at Prince George. The other major tributary of the Nechako River is the Nautley River, joining near the town of Fort Fraser. The Nechako drains a catchment area of 52,000 km². The river at the mouth is 7th order and now contributes, along with its major tributaries, the Stuart and Nautley rivers, about 8.3% of total Fraser River flow. The predam discharge from the river was approximately 434 m³/s. The 93 m high Kenney Dam was completed in 1952 to impound the Nechako River and diverts 60% to 70% of the average annual flow of the basin above the dam from the west end of the reservoir to the Aluminum Company of Canada's power plant on the Pacific coast near Kemano. The withdrawal of water is equivalent to about 3% of the total flow of the Fraser River at its mouth. The surface of the reservoir is at 853 m asl, and it has live storage of 7.1×10^9 m³. The elevation drop from the reservoir surface to the penstock of the power generating plant at 61 m asl is 792 m along a 16 km tunnel through the Coast Mountains (Mundie and Bell-Irving 1986). The power is used for aluminum smelting operations in Kitimat. One of the primary considerations in the management of the Nechako Reservoir is the provision of cool water for salmon migrations. The two salmon species of most concern are chinook salmon

that spawn in the Nechako River downstream of the dam and the Stuart River stock of sockeye salmon that migrates up the lower Nechako, as sockeye are particularly sensitive to the higher summer temperatures resulting from flow regulation (Mundie and Bell-Irving 1986).

Although only 15% of the drainage area flows from the Coast Mountains, it contributes more than 15% of the discharge of the river, given the higher rainfall amounts in the mountains. Snowmelt peaks in late spring or early summer dominate the annual hydrograph (Moore 1991). A second peak in the hydrograph is sometimes evident from autumn rains prior to freezing.

The hydrology is heavily regulated by impoundment by the Kenney Dam. There is no direct release of water from the Kenney Dam and water released from the reservoir is regulated at the Skins Lake Spillway, passing through Cheslatta Lake and River to enter the Nechako River about 9 km downstream of the dam. The hydrograph upstream of Fort Fraser has been shifted to reduce the spring and summer snowmelt peaks that characterized the natural pattern of flow (see figures in French and Chambers 1995). Nonetheless, the runoff near Prince George still peaks in June and July (about 3 cm/mo), and is ≤ 1 cm/mo during winter (see Fig. 15.10). In contrast, peak discharge in the Stuart River is >5 cm during July. The provincial government has forced the additional release of water when migrating fish stocks are moving up the Nechako River from Prince George, primarily the early Stuart River run, but also those of the Nadine and Stellako catchments. The high flow released during mid to late summer is to provide sufficient water depth for migration, but especially to provide water of a particular temperature to protect the sockeye salmon. There has been very careful modeling of predicted temperatures to ensure target upper temperatures of the Nechako River. The typical temperature peak is about 19°C (Russell et al. 1983), and the temperature is regulated to ensure it rarely exceeds 20°C. The low winter flows typical of rivers in the region lead to formation of frazil and anchor ice, and ice may form into the substrate (Blachut 1988).

This is a clearwater river, and total dissolved solids range from 1 to 100 mg/L. The large influence of lakes and reservoirs, as well as a large portion of the water coming from the granitic batholith of the Coast Mountains, probably contribute to the low turbidity. The water is typically low in Ca⁺⁺ (13 to 17 mg/L) and SO₄ (3.3 to 5.3 mg/L). Total phosphorus ranges from 17 to 36 µg/L, and NO₃-N values are 216 to 295 µg/L

(Hall et al. 1991). Groundwater is the primary source of drinking water in the basin, and is mostly hard water ($>150\text{mg/L}$ as CaCO_3) with elevated Fe ($>0.3\text{mg/L}$) and Mn ($>0.05\text{mg/L}$) concentrations (Hall et al. 1991). Copper has sometimes been reported to be at concentrations exceeding water-quality guidelines, and the source is presumed to be natural mineralization.

The primary sources of pollution in this catchment come from domestic waste, particularly the town of Vanderhoof. Concentrations of $\text{NO}_3\text{-N}$ typically double and orthophosphorus is four to eight times higher below the Vanderhoof sewage treatment plant than upstream (Slaney et al. 1994).

River Biodiversity and Ecology

As part of the Fraser River system the Nechako River belongs to the North Pacific Coastal freshwater ecoregion (Abell et al. 2000). There has been concerted study of the postimpoundment conditions in the river because of concern for the chinook salmon stock and the possibility of nutrient-enrichment impacts on macrophyte growth in reaches near Vanderhoof. As a major corridor for passage of salmon, especially sockeye salmon, to their spawning areas, there has been continued evaluation of those fish stocks relative to river temperatures and other changes.

Algae and Cyanobacteria

The periphyton in the Nechako River was mostly comprised of the diatoms Bacillariophyceae (~80% by area) (*Synedra*, *Fragilaria*, *Tabellaria*, *Hannaea*) and Chlorophyta (*Zygnema* and *Ulothrix*), with traces of Cyanobacteria (Slaney et al. 1994, Perrin and Richardson 1997). Estimates of algal biomass varied from about 3 to $20\text{mg chl } a/\text{m}^2$ in the main channel of the river (Slaney et al. 1994). Experimental additions of inorganic nutrients resulted in a large increase in the accrual of algal biomass in the main channel of the river, indicating the oligotrophic status of the upper part of the river (Slaney et al. 1994). A set of 12 wadeable streams in the Cheslaslie drainage in the central part of the basin were sampled for algae by Rosenberg et al. (1998) and they found at least 68 species of algae. The most abundant of the algal species in those smaller streams were *Achnanthes minutissima*, *Tabellaria flocculosa*, *Gomphonema olivaceum*, *Tabellaria fenestrata*, *Synedra ulna*, *Hannaea arcus*, *Epithemia turgida*, *Cymbella ventricosa*, *Cymbella turgida*, and *Melosira granulata* (in order of abundance). Estimates of algal biomass from

these small streams within the basin were $0.09\text{mg chl } a/\text{cm}^2$ (Rosenberg et al. 1998).

Plants

There is a diverse macrophyte assemblage in the river consisting of several species of pondweed (e.g., sago pondweed, Richardson's pondweed), spiked watermilfoil, elodea, water buttercup (whitewater crowfoot), and coontail (French and Chambers 1996). Elodea is the most abundant of the river macrophytes and at times creates a nuisance for users of the river. Most of these vascular plants are found in the slower-velocity reaches of the river, particularly downstream of Fort Fraser, where the river gradient is lower and velocities slower. Mosses were the primary macrophyte in waters with current speeds in excess of 60cm/s (French and Chambers 1996). The riparian forest surrounding the Nechako River includes black cottonwood, balsam poplar, aspen, Sitka alder, and willows. Thimbleberry, American fly honeysuckle, and cowparsnip are common understory plants near the riparian margins of smaller streams.

Invertebrates

In one study of macroinvertebrates in the Nechako River, estimates of benthic densities were $400/\text{m}^2$ (range 200 to 1600), with a biomass estimate of about $200\text{mg}/\text{m}^2$ (range ~50 to 800) depending upon site and date (Russell et al. 1983). In mesocosm studies estimates from the Nechako were $14,800 (+1141\text{ SE})/\text{m}^2$ based on sorting down to $250\mu\text{m}$ size (Perrin and Richardson 1997). Orthoclaadiinae chironomids were the most numerically abundant invertebrates, followed by the mayflies *Serratella tibialis* and *Baetis* spp. Some other large species included the stoneflies *Pteronarcys* sp. and *Hesperoperla pacifica* and hydroptychid caddisflies.

Vertebrates

Twenty-six species of fishes are found in the Nechako River basin. Prior to construction of the dam the canyon where the dam is located created a natural barrier to fish dispersal. The most abundant fish species in the river include cyprinids (e.g., northern pike minnow, redbreast shiners), largescale suckers, burbot, and slimy sculpin. There is a substantial run of chinook salmon that spawn in the upper part of the Nechako River in the section below the dam and upstream of the confluence with the Nautley River. There are also small populations of rainbow trout and Dolly Varden trout in the river. In the reservoir the most abundant of the fish species include kokanee

(a landlocked form of sockeye salmon), rainbow trout, mountain whitefish, and northern pikeminnow (squawfish). Less-abundant species of fishes in the reservoir include longnose and largescale suckers, prickly and slimy sculpins, burbot, and peamouth chub.

The white sturgeon population in the Nechako and Stuart rivers is isolated from other populations in the Fraser River downstream. Sturgeon number about 600 individuals and are apparently declining in numbers (Ted Downs, personal communication), perhaps because of flow regulation and diminished habitat as a result of the Kenney Dam. Few to no sturgeon under the age of 15 years have been captured from the population during intensive surveys, suggesting serious impairment of the population. The population has been designated vulnerable to critically imperiled. Recent studies have confirmed that the Nechako River population showed genetic divergence from downstream populations in the Fraser River main stem. The low-gradient reach of the river in the 60km upstream of the confluence with the Fraser River lacks deep pools and is considered a dispersal barrier to white sturgeon.

Two other fish species are of concern in the Nechako River basin. One is the bull trout, which is considered vulnerable throughout its British Columbia range and is on the province's blue list. The brassy minnow has a disjunct population in the basin, isolated from the remainder of the species' range.

Substantial populations of sockeye salmon migrate through the Nechako River's downstream reaches from the Fraser River to the Stuart River system each year. The management of flows and water temperatures of water released from the dam are based around the protection of the summer runs of sockeye (July and August).

The chinook salmon is the most commercially important of the Nechako fishes and escapements to the upper river have been in the range of 600 to 2000 adult spawners. Chinook salmon have juveniles of two sorts, one of which overwinters in the river as 0+ age fish and another that migrates soon after hatching. Chinook salmon numbers have apparently declined in the period following construction of the Kenney Dam. The reduced numbers have been attributed in part to changes in flow, modification of temperature patterns speeding in-gravel development, and changes in predator numbers (Bradford 1994).

There are many riparian-dependant vertebrates in the basin. Common mammals are beaver, muskrat, river otter, moose, and mink. There are many birds

associated with the river, including osprey, merganser, bald eagle, and goldeneye duck.

Ecosystem Processes

The Nechako River basin is influenced by cold winter temperatures that freeze over most of the water bodies in the catchment. Late in the autumn, freezing temperatures and dark nights can result in re-radiation, causing the formation of anchor ice that can have negative impacts on benthic life, including incubating salmon eggs. The influence of the dam has changed the nature of many processes, including reducing the movement of bed sediments both through blocking transport and by reducing peak flows in the spring. Whole-river fertilization experiments in the upper Nechako River (below the dam) showed strong responses of periphyton to additions of nitrogen and phosphorus, and the periphyton growth acceleration was noted up to 50km downstream with a lag of several months, demonstrating the slow spiraling of nutrients within this oligotrophic river (Slaney et al. 1994). However, despite the increase in periphyton production through the upper river there was no evidence of enhanced growth of fishes there (Slaney et al. 1994), suggesting other sinks for production within the river food web.

Human Impacts and Special Features

The Nechako River catchment includes several large wilderness areas, some now isolated by the waters of the reservoir. It provides some productive trout and other game fishing areas, which supply recreational opportunities to the region. The limited access to the basin has preserved most of its wildlife populations. Most of the Nechako basin is sparsely settled but has been exploited for timber production and agriculture for over a century. The major town in the catchment is Vanderhoof, along with a number of smaller towns, such as Burns Lake, Fort Fraser, and Fraser Lake. Agriculture is mostly restricted to the lower part of the basin in the plateau areas west of Prince George and includes cattle production and some cereal crops. A large open-pit molybdenum mine, the Endako Mine, is in the basin east of Fraser Lake.

There have been large changes to the hydrology as a consequence of the Kenney Dam built in the mid-to late 1950s about 280km upstream of the confluence with the Fraser River. About 60% of the inflow to the 906km² reservoir in most years is diverted westward directly to the turbines on the Pacific Coast

through 16km long tunnels through the Coast Mountains. Attempts to mitigate some of the effects of the dam have employed flow regulation, temperature controls (deep release), and fertilization (Perrin and Richardson 1997). A second phase to raise the dam and divert another river into the reservoir was stopped by the British Columbia government prior to development.

STUART RIVER

The Stuart River drains a 14,600km² catchment that represents the northernmost part of the Fraser River basin. It is an unregulated 280km long lake and river system draining southeast from high on the leeward side of the Coast Range Mountains, and joins the Nechako River just before the latter empties into the Fraser (Fig. 15.11). The northern half of the catchment is tightly confined by mountains on both sides, yielding to a relatively flat plateau south of Stuart Lake in the southern half of the basin. There are a series of large, natural lakes in the drainage, all important sockeye nursery areas. The northern half of the basin is largely forested, with limited amounts of forest harvesting. The southern half of this catchment has had more extensive forest harvesting, and a small portion is used for agriculture.

Native Americans make up the largest proportion of the residents in the basin, largely members of the Carrier–Sekani Tribal Council, and they have occupied the area for thousands of years. The first European contact is considered to have been with Simon Fraser, one of the early explorers seeking a route to the Pacific Ocean overland. He established a post called Fort St. James in 1806, and a Hudson Bay Company trading post constructed to trade with the native people. Farming in the southern portion of the basin began in the early 1800s. The town of Fort St. James remains the largest settlement in the catchment.

Physiography, Climate, and Land Use

The Stuart River basin sits in the Coast Mountains of British Columbia and Southeast Alaska (PM) physiographic province (see Fig. 15.11) (Hunt 1974). Most of the basin is on the Nechako Plateau and is primarily underlain by volcanic rock, with some clastic subbasins (Gabrielse and Yorath 1991). This region is part of a series of terranes known as the Intermontane Belt and the Omineca Belt (Gabrielse and Yorath 1991). The surface of much of the basin

consists of fine lacustrine deposits from postglacial lakes and basal tills. The soil types of this area are primarily luvisols (Canadian classification system), having a large clay component in the subsoil derived from leaching above (Farley 1979).

The climate of the Stuart River basin is continental. Mean annual temperature is only about 3°C, with the lowest mean monthly temperature reaching –11.7°C in January and the highest mean monthly temperature about 15°C in July (Fig. 15.12). Sitting in the rain shadow of the Coast Mountains the basin receives about 35 to 60cm of precipitation per year, depending on elevation and aspect (Moore 1991). Mean annual precipitation is about 49cm and is distributed fairly evenly throughout the year, although it is lowest from February through April (see Fig. 15.12). Low winter temperatures result in fall and winter precipitation being stored as snow. Summer rainfall often occurs as late-afternoon thunderstorms in the basin.

The Stuart basin is within the Fraser Plateau and Basin Complex terrestrial ecoregion. The primary forest type is the Subboreal Spruce zone, with areas of Engelmann spruce–subalpine fir forest at higher elevations. The primary forest tree species are lodgepole pine, Engelmann spruce, hybrid Engelmann x white spruce, and subalpine fir.

Over 90% of the land area is covered by forest, with forest harvesting and farming the two biggest land uses in the basin. Only about 1% of the catchment is in agricultural use of any sort, and the amount of that that is irrigated is negligible, mostly for hay production. Urban land use accounts for <0.1% of the catchment area and the biggest town in the catchment is Fort St. James.

River Geomorphology, Hydrology, and Chemistry

The sources of the river begin in the Driftwood River between the Omineca Mountains and the Bait Range of the Skeena Mountains (elevations up to 2000m asl). The river flows in a narrow valley between these two ranges and then through a series of large lakes: Takla Lake, Trembleur Lake, and, finally, Stuart Lake (see Fig. 15.11). Takla Lake and Trembleur Lake are connected by the Middle River, which has more characteristics of a lake than a river. Many of the tributary streams flowing into the lakes in the northern half of the catchment are relatively short (most <20km) and steep. The basin also has a great many lakes and wetlands, which affect flow and temperature conditions in many of the tributary streams.

After leaving Stuart Lake the river flows through part of the Nechako Plateau, a relatively flat area, resulting in a lower gradient as it flows toward its confluence with the Nechako River downstream of the town of Vanderhoof.

The rivers in the northern half of the basin are cobble-bottom. The smallest tributaries have step-pool morphologies, formed by imbricated boulders as steps. Further downstream in these tributaries, where gradients drop, gravels are the appropriate size for spawning fishes, including sockeye salmon, and there are large amounts of large woody debris, about 31 pieces/100m of stream (Fuchs et al. 2003). Sockeye spawn in the tributaries of the large lakes and estimates of bedload and suspended loads in these small tributaries suggest sockeye can be a major agent of sediment transport. These areas have sufficient groundwater inflows to prevent low winter temperatures freezing all the way into the substrate, where developing sockeye salmon eggs spend the winter.

The hydrology of the Stuart River exhibits pronounced snowmelt peaks, usually in June, July, and August, when runoff typically exceeds 4 cm/mo (see Fig. 15.12). Runoff is lowest from October through April, when much of the precipitation falls as snow and remains on the land until late spring. Smaller streams in the lower part of the valley may have their peak runoff in May and June (Moore 1991). The topographic variation from high mountains to the valley bottoms makes it difficult to characterize the whole basin, but the runoff from the Stuart River integrates the flows of all the smaller drainages. The average annual discharge is about 128 m³/s near Fort St. James.

Water quality of the Stuart River is good, and turbidity levels are in general low, in part due to several large and deep lakes in the basin. There is no glacial source for any part of the Stuart River basin. The levels of total dissolved solids are in the range from 1 to 100 mg/L but mostly toward the lower end of the range (Hall et al. 1991). Average total phosphorus concentrations are 8 to 9 µg/L, NO₃-N 39 to 49 µg/L, Ca⁺⁺ 14 to 15.5 mg/L, and SO₄ 4.1 to 5 mg/L (Hall et al. 1991). Copper is sometimes in excess of criterion guidelines, probably from natural mineralization (Hall et al. 1991). Groundwater hardness is generally hard to very hard, usually >150 mg/L as CaCO₃, and often with iron and manganese exceeding drinking water standards (Fe >0.3 mg/L and Mn >0.05 mg/L) (Hall et al. 1991).

The water temperatures in the river have an average of about 6.8°C (based on a single year). The

water reaches 0°C in the winter and the river and lakes are ice covered for several months each year. Summer maximum temperature is around 20°C (range over 7 years, 18.7°C to 20.5°C), which is typically attained in late July or early August (July 6 to August 16, depending on year). Studies in some of the small tributary streams (2nd to 3rd order) in the area have recorded water temperatures from 0°C to 18°C, with a daily summer average of ~13°C (MacDonald and Herunter 1998).

Stuart Lake is the most downstream lake in the river and lake system. The lake has a water residence time of about 2.3 years, despite being relatively shallow, with a mean depth of only 26m (Macdonald et al. 1998). Sedimentation is primarily of organic materials, as the chain of upstream lakes restricts transport of heavier materials. The lake has good water quality, but cores of its sediments indicate a pulse of elevated mercury during the middle part of the twentieth century, peaking in about 1950 (now returned to background levels), as a consequence of a mercury mine in the basin at Pinci Lake that operated in the 1940s (Macdonald et al. 1998).

River Biodiversity and Ecology

The Stuart River is part of the North Pacific Coastal freshwater ecoregion, as are all Fraser River tributaries (Abell et al. 2000). Information on algae and invertebrates is primarily available from small tributaries, but more extensive information is available on anadromous fishes, particularly sockeye salmon.

Algae

Estimates of algal biomass from small streams in the Driftwood River basin at the north end of the Stuart catchment were 7.0 mg chl *a*/cm² (Rosenberg et al. 1998). There were a total of 38 species of algae identified in those streams. Among the most abundant of the algae species were *Achnanthes minutissima*, *Gomphonema olivaceum*, *Diatoma tenue*, *Fragilaria vaucherie*, *Synedra ulna*, and *Gomphonema parvulum* (Rosenberg et al. 1998). In some smaller streams near the Middle River, estimates of algal biomass were 0.011 µg/m² as chlorophyll *a* and 3.04 mg/m² as ash-free dry mass (Shirley Fuchs, personal communication).

Plants

Sitka alder, various willows, black cottonwood, and balsam poplar are the common trees in the riparian areas. Thimbleberry, black twinberry, and

cowparsnip are common understory plants near the riparian margins of smaller streams.

Invertebrates

Macroinvertebrates have been sampled in two sets of streams, one near the Middle River and another further north in the Driftwood River sub-basin. In the Middle River area, macroinvertebrate densities were in the range of 3000 to 8100 individuals/m² and biomass ranged from 1.8g/m³ (under forest cover) to 3.0g/m² (recent clearing) (Fuchs et al. 2003). Some of the common taxa reported included the mayfly *Drunella*, the caddisflies *Glossosoma* and *Rhyacophila*, the stonefly *Despaxia*, chironomid midges (Orthocladiinae and Tanytarsini), oligochaete worms, and mites (Acari) (Fuchs et al. 2003). In small streams of the Driftwood River basin, other taxa predominated, such as the mayflies *Ephemerella*, *Rhithrogena*, and *Dipheter*, the stoneflies *Capnia*, *Paraleuctra*, *Sweltsa*, and *Taenionema*, and chironomids (e.g., *Micropsectra*, *Polypedilum*, and *Rheocricotopus*) (Rosenberg et al. 1998).

Vertebrates

There are major early and late runs of sockeye to the Stuart system, distinguished as separate stocks. These stocks differ in their timing of entry to the Fraser River. Both spawn in the streams and rivers of the Stuart River system and rear in Trembleur Lake or Takla Lake. The early Stuart run reaches the spawning grounds in late July to early August, making them vulnerable to warm summer temperatures during the long migration, and making them the primary focus of temperature manipulation from the regulated Nechako River (see Nechako discussion). The early Stuart run has a four-year dominant cycle, with average numbers in peak years (e.g., 1993, 1997, 2001) of over 300,000 adults and in the three other years of the cycle adult numbers of about 60,000. The late Stuart run spawns further upstream on average, making it the longest migrating sockeye salmon population in the Fraser River basin, with a migration of about 1200 km from the ocean. The late run spawns in mid-September. The nonmigratory form of sockeye salmon known as kokanee lives its entire life in the freshwater environment but produces fertile hybrids with anadromous sockeye (Foote et al. 1989).

As with many streams of the north with continental climates, low flows in winter and freezing into the gravel is a hazard for fishes, especially for eggs deposited in the substrate to overwinter. Spawning sockeye select upwelling areas for their redds (spawn-

ing areas), which are less likely to freeze. The timing of development for fishes that lay their eggs late in the season seems to result in eggs hatching before intense freezing. Sockeye eggs hatch during the winter and there is evidence that the alevins (larvae) are capable of moving deeper within the substrate to avoid ice formation near the surface. Sockeye fry move from the spawning streams out to the lakes soon after emerging from the gravels.

The white sturgeon found in the Stuart River system are part of the Nechako River population, which are considered distinct from other Fraser River populations (see Nechako discussion). The current estimate of total population numbers, including immatures, is about 600 individuals, and the species is considered vulnerable in British Columbia. Recent evidence shows that there has been negligible recruitment in the past 15 years, for unknown reasons (Ted Downs, personal communication).

There are many other species of fishes found in the Stuart River system. Lake trout and rainbow trout are popular sport fishes in the lakes and the Middle River part of the basin. Most of the other species are not sought after by recreational or commercial fishers, so there is much less known about their populations in the Stuart River. These include mountain whitefish, largescale sucker, and a number of common cyprinid fishes, such as northern pikeminnow, peamouth chub, lake chub, and redbside shiner. These species occupy the larger river and lake systems. There are few species that reside year-round in the small streams of the basin, presumably because of the risk of winter freezing.

Beaver densities are high and provide an important alteration of sediment transport processes in smaller streams. Newly created beaver dams can result in smothering of eggs and alevins of salmonids by sedimentation of fine sediments. Meanwhile, beavers create habitat diversity important to some fish and invertebrate species, and beaver ponds are regularly used as rearing habitat by salmonids. Most riparian-dependant wildlife populations in the basin, such as moose, river otter, muskrat, merganser, osprey, and bald eagle, have relatively stable numbers.

Ecosystem Processes

Although no studies of basic ecosystem processes have been done in the Stuart River, it is clear that a number of processes have large ecosystem effects. The sediments, either as bedload or suspended load, are highly mobile, with movement driven by spring freshet and by the actions of spawning salmon. One

estimate has sockeye salmon contributing to 10% to 39% of the bedload movement (Scrivener and Macdonald 1998). Freezing temperatures also have several effects on these river systems, including storage of snow through the winter, ice cover of most water bodies, and early season potential for anchor ice formation deep into the substrate. This river system is relatively productive in contrast to some other drainages of the Fraser catchment, perhaps in part due to the large amounts of marine-derived nutrients delivered by returning Pacific salmon (Naiman et al. 2002).

Human Impacts and Special Features

This is a relatively pristine river system and is somewhat unusual in being a narrow lake-dominated system with short tributary streams flowing into its major lakes, Takla and Stuart. Furthermore, it is special in being the most distant tributary from the Fraser's mouth and supporting the longest migration of sockeye salmon populations in the system. The Canadian Department of Fisheries and Oceans has a large-scale experimental forestry-fisheries study underway in a set of small streams in the Stuart River catchment.

Human impacts to the river are minor. Most water withdrawal is for human use and almost all of that is from pumped groundwater. The largest town in the catchment is Fort St. James, with a population slightly greater than 2000. Forest harvesting and wood processing (milling and manufacture) are the main industrial activities in the basin, but there are no pulp mills.

ADDITIONAL RIVERS

The West Road (Blackwater) River flows eastward before joining the Fraser River north of Quesnel (Fig. 15.13). It is contained entirely within the Fraser Plateau and Basin Complex rising in the Ilgachuz Mountains, and with a slight gradient it forms numerous lakes along the way. The basin is very sparsely populated (<1 person/km²), and its even terrain and easy canoeing are the reasons for its name. The West Road River was a major path for travel between the coast and the interior. In 1793 it was the route chosen by Sir Alexander MacKenzie, and it is now a heritage hiking trail to Bella Coola. Although it has relatively low discharge, the West Road River is one of the finest trout streams in British Columbia.

The Quesnel River begins in Quesnel Lake on the western slopes of the Cariboo Mountains and flows in a northwest direction before joining the Fraser River at Quesnel (Fig. 15.15). Historically, the Quesnel River produced the Fraser River's largest sockeye salmon runs. With the construction of the Quesnel River dam—built for placer mining in 1896–1897—and the Hell's Gate slide on the Fraser in 1913, the Horsefly and Mitchell river populations (the two most productive tributaries for sockeye in the Quesnel system) had declined to a total run of about 5000 fish and less than 1000 spawners by 1941. The Quesnel River sockeye stocks began to rebuild in the 1950s under the watchful eye of the Pacific Salmon Commission's recovery strategy, which included the construction of fish passage structures. From 1958 to 1977 the Quesnel River sockeye made a remarkable comeback. The last dominant year for Quesnel River sockeye occurred in 1993, producing a run of 12.2 million fish, with 2.5 million fish making it to the Quesnel River headwater tributaries to spawn. The Quesnel River has now surpassed the world-famous Adams River for sockeye production and is, once again, the Fraser's greatest sockeye producer.

The Chilcotin River, with headwaters in the wilderness region near the Ilgachuz Range, winds its way through mountains, open valleys, grasslands, and canyons as it flows in a generally eastward direction to the Fraser (Fig. 15.17). Major tributaries are the Chilanko and Chilco rivers. The watershed includes a wide range of habitats, from high alpine to desert canyons, and the river has major rapids, eddies, rocks, narrow spots, standing waves, and boulder gardens. The Chilcotin is rated among the best and most challenging in North America for kayaking and white-water rafting, and has some of the most spectacular scenery in the basin.

The Clearwater River begins in Wells Gray Provincial Park, a 522,000 ha wilderness area, and flows south to its confluence with the North Thompson River (Fig. 15.19). The basin includes volcanic formations, splendid alpine meadows, six major lakes, excellent fishing and rafting, superb waterfalls, and countless prominent topographical features. The area is known worldwide for spectacular mountain scenery and hiking trails. One of the most spectacular views is Helmcken Falls, which plunges 141 m down a narrow canyon. This is a clearwater river, as it flows through igneous rocks and silt is deposited in upstream ponds.

The Lillooet River arises in the Coast Mountains at the foot of Mount Dalglish and flows in a south-

easterly direction for 209 km before entering Harrison Lake (Fig. 15.21). The headwater Lillooet River system runs for about 190 km of white-water paddling and with spectacular autumn Sockeye salmon runs. Harrison Lake is famous for being the largest lake in southwestern British Columbia, with over 72 km of beautiful lake settings and hot springs. The outlet from Harrison Lake is known as the Harrison River and discharges to the Fraser River. This is a very sparsely populated catchment encompassing a wide range of habitats, from alpine to desert to coastal rain forest. High precipitation in the basin results in extremely high annual runoff (>160 cm; Fig. 15.22).

ACKNOWLEDGMENTS

The authors would like to acknowledge the Fraser River Action Plan (Environment Canada), without which much of this information would not be available, and also the Water Survey of Canada and the Meteorological Service of Canada, which provided much of the site-specific information. Finally, Taina Tuominen of Environment Canada was extremely helpful in acquiring much of data for this chapter.

FIGURE 15.6 Mean monthly air temperature, precipitation, and runoff for the Fraser River basin.

FRASER RIVER

Relief: 3954 m

Basin area: 234,000 km²

Mean discharge: 3972 m³/s

River order: 8

Mean annual precipitation: 80 cm (approx. basin mean)

Mean air temperature: 6.1°C (approx. basin mean)

Mean water temperature: NA

Physiographic Provinces: Coast Mountains of British Columbia and Southeast Alaska (PM), Rocky Mountains in Canada (RM)

Biomes: Temperate Mountain Forest, Tundra

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: North Central Rockies Forests, Fraser Plateau and Basin Complex, Okanagan Dry Forests, Cascade Mountains Leeward Forests, British Columbia Mainland Coastal Forests, Puget Lowland Forests

Number of fish species: 40 freshwater (native), 8 marine

Number of endangered species: 7 fishes

Major fishes: starry flounder, coho salmon, chinook

salmon, sockeye salmon, pink salmon, chum salmon, rainbow trout, river lamprey, pacific lamprey, eulachon, surf smelt, longfin smelt, northern squawfish, peamouth chub, reddsider shiner, longnose dace, largescale sucker, longnose sucker, white sucker, bridgelip sucker, prickly sculpin

Major other aquatic vertebrates: great blue heron, bald eagle, river otter, mink

Major benthic invertebrates: mayflies (*Baetis*, *Ephemerella*, *Drunella*, *Rhythrogena*), stoneflies (*Capnia*, *Sweltsa*, *Taenionema*, *Zapada*), chironomid midges (*Eukiefferiella*, *Micropsectra*, *Tvetenia*), caddisflies (*Rhyacophila*)

Nonnative species: American shad, common carp, brown bullhead, goldfish, fathead minnow, Atlantic salmon, brook trout, yellow perch, pumpkinseed, largemouth bass, black crappie

Major riparian plants: white spruce, lodgepole pine, trembling aspen, Douglas fir, Engelmann spruce, alpine fir, common paper birch, black cottonwood, trembling aspen, various willows, various grasses

Special features: Canadian Heritage river; Fraser Canyon between Yale and Boston Bar

Fragmentation: none except for dam in Nechako River

Water quality: alkalinity = 47 to 61 mg/L as CaCO₃, pH = 7.8 to 7.9, NO₃-N = 0.13 to 0.21 mg/L, total phosphorus = 0.07 to 0.11 mg/L

Land use: 2.2% urban, 0.6% agriculture, 97.2% forest and park

Population density: <10.7 people/km²

Major information sources: Dorcey 1991, Gray and Tuominen 1998, Rosenberg et al. 1998, Richardson et al. 2000, Whitfield 1983, Northcote and Larkin 1989

FIGURE 15.5 Map of the Fraser River basin. Physiographic provinces are separated by a yellow line.

FIGURE 15.8 Mean monthly air temperature, precipitation, and runoff for the Thompson River basin.

THOMPSON RIVER

Relief: 3250 m

Basin area: 55,400 km²

Mean discharge: 787 m³/s

River order: 7

Annual mean precipitation: 43.2 cm

Mean air temperature: 9.7°C

Mean water temperature: 9.0°C

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biome: Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: North Central Rockies Forests, Okanagan Dry Forests, Cascade Mountains Leeward Forests

Number of fish species: 24

Number of endangered species: 2 fishes

Major fishes: round whitefish, coho salmon, chinook salmon, sockeye salmon, pink salmon, largescale sucker, bridgelip sucker, northern squawfish, longnose dace, slimy sculpin

Major other aquatic vertebrates: beaver, muskrat, dipper, merganser, osprey

Major benthic invertebrates: mayflies (*Baetis*, *Ephemerella*, *Paraleptophlebia*, *Rhytrogena*), caddisflies (*Arctopsyche*, *Brachycentrus*, *Cheumatopsyche*, *Glossosoma*, *Hydropsyche*, *Hydroptila*), stoneflies (*Arcynopteryx*, *Skwala*), chironomid midges (*Cardiocladius*, *Cricotopus*, *Eukiefferiella*)

Nonnative species: carp

Major riparian plants: common paper birch, black cottonwood, trembling aspen, various willows, various grasses

Special features: white-water rapids between Spences Bridge and the confluence with the Fraser River; Adams River run of Sockeye salmon

Fragmentation: none

Water quality: alkalinity = 38.2 mg/L as CaCO₃, pH = 7.7, NO₃-N = 0.08 mg/L, orthophosphate = 0.004 mg/L, total dissolved phosphorus = 0.005 mg/L, total phosphorus = 0.012 mg/L, total dissolved nitrogen = 0.16 mg/L

Land use: 0.3% urban, 2.4% agriculture, 5.1% alpine, 4.3% freshwater, 41.0% young forest, 25.9% old forest, 8.2% recently logged, 4.5% rangeland, 8.6% other

Population density: <3 people/km²

Major information sources: Bradford and Irvine 2000, Bothwell 1985, Culp and Lowell 1999, Dubé et al. 1997, Federal-Provincial Thompson River Task Force 1976

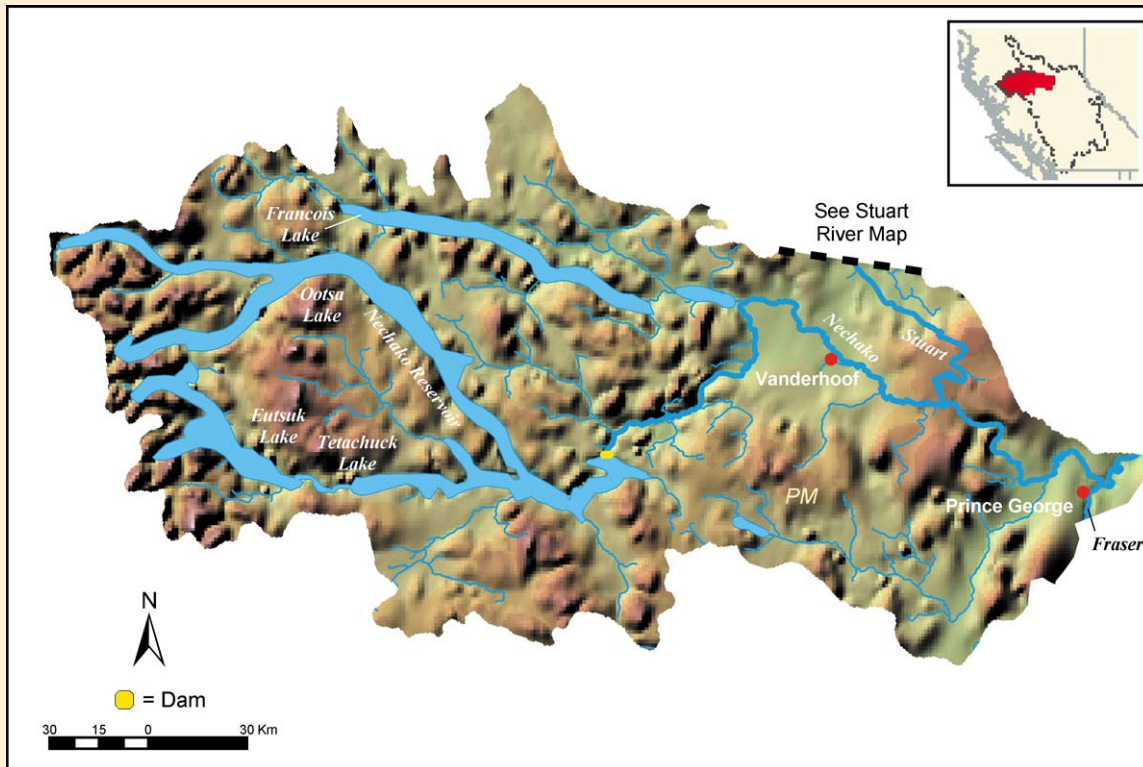

FIGURE 15.9 Map of the Nechako River basin.

NECHAKO RIVER

Relief: ~1400m

Basin area: 42,500km²

Mean discharge: 434 m³/s (virgin, estimated); 284 m³/s (present)

River order: 7

Mean annual precipitation: 60.1 cm

Mean air temperature: 3.7°C

Mean water temperature: NA

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biome: Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: Fraser Plateau and Basin Complex, British Columbia Mainland Coastal Forests

Number of fish species: 26

Number of endangered species: 2 fishes

Major fishes: burbot, mountain whitefish, lake whitefish, lake trout, chinook salmon, sockeye salmon (kokanee), rainbow trout, prickly sculpin, largescale sucker, longnose sucker, redbside shiner, peamouth chub, lake chub

Major other aquatic vertebrates: beaver, moose, merganser, goldeneye duck

Major benthic invertebrates: mayflies (*Baetidae*, *Ephemerella*, *Serratella*), stoneflies (*Capniidae*, *Chloroperlidae*, *Hesperoperla pacifica*, *Pteronarcys*), caddisflies (*Hydropsychidae*), chironomid midges (*Tanytopodinae*, *Tanytarsini*, *Orthocladiinae*)

Nonnative species: goldfish, brook trout

Major riparian plants: willows, black cottonwood, balsam poplar, alder, aspen

Special features: remote basin with large areas of pristine forest in the western part of its basin near the Coast Range

Fragmentation: major dam with large influence on river regulation and diversion of water to a power generating station on the Pacific coast

Water quality: alkalinity = 40.4mg/L as CaCO₃, pH = 7.6, NO₃-N + NO₂-N = 0.2mg/L, PO₄-P = 0.029mg/L

Land use: in 1996, 0.2% urban, 2.5% agriculture, 11.6% freshwater, 8.3% recently logged, 28.4% old forest, 42.4% new forest, 6.3% other

Population density: <0.1 person/km²

Major information sources: www.statcan.ca 2002, Environment Canada 2002, Rosenberg et al. 1998, McPhail et al. 1998, Perrin and Richardson 1997

FIGURE 15.12 Mean monthly air temperature, precipitation, and runoff for the Stuart River basin.

STUART RIVER

Relief: 1097 m

Basin area: 14,600 km²

Mean discharge: 128 m³/s

River order: 6

Mean annual precipitation: 48.7 cm

Mean air temperature: 2.8°C

Mean water temperature: 6.8°C

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biome: Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregion: Fraser Plateau and Basin Complex

Number of fish species: 23

Number of endangered species: 2 fishes

Major fishes: mountain whitefish, lake whitefish, lake trout, sockeye salmon, rainbow trout, largescale sucker, slimy sculpin, northern pikeminnow, reidside shiner, peamouth chub, lake chub

Major other aquatic vertebrates: beaver, river otter, muskrat, moose, merganser

Major benthic invertebrates: mayflies (*Dipheter hageni*, *Ephemerella*, *Leucocuta*, *Rhithrogena*), stoneflies (*Capnia*, *Paraleuctra*, *Sweltsa*, *Taenionema*), chironomid midges (*Micropsectra*, *Polypedilum*, *Rheocricotopus* [*Rheocricotopus*] *eminellobus*, *Tanytarsus*, *Tvetenia bavarica* group)

Nonnative species: none

Major riparian plants: black cottonwood, Sitka alder, willows

Special features: lake-dominated system with short tributary streams flowing into Takla and Stuart lakes; system supports sockeye salmon populations with longest migration in Fraser River system

Fragmentation: none

Water quality: median of 10 sites, alkalinity = 38.4 mg/L as CaCO₃, pH = 7.7, NO₃-N + NO₂-N = 0.003 mg/L, total Kjeldahl nitrogen = 0.091 mg/L, total phosphorus = 0.004 mg/L

Land use: 0.1% urban, 0.4% agriculture, 12.3% freshwater, 8.2% recently logged, 29.8% old forest, 43.6% new forest, 5.6% other

Population density: <0.1 person/km²

WEST ROAD RIVER

Relief: 2000 m

Basin area: 12,400 km²

Mean discharge: 38 m³/s

River order: 7

Mean annual precipitation: 64.1 cm

Mean air temperature: 4.7°C

Mean water temperature: NA

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biome: Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregion: Fraser Plateau and Basin Complex

Number of fish species: 21

Number of endangered species: none

Major fishes: burbot, mountain whitefish, bull trout, Chinook salmon, sockeye salmon, rainbow trout, largescale sucker, longnose sucker, reidside shiner, northern squawfish, peamouth chub

Major other aquatic vertebrates: great blue heron, bald eagle, river otter, mink

Major benthic invertebrates: mayflies (*Baetis tricaudatus*, *Paraleptophlebia*, *Leucrocota*, *Serratella*), stoneflies (*Capnia*, *Sweltsa*, *Zapada cinctipes*), chironomid midges (*Micropsectra*, *Polypedilum*, *Tanytarsus*, *Tvetenia bavarica* group, *Zavrelimyia*)

Nonnative species: brook trout

Major riparian plants: willows, black cottonwood, alder, aspen

Special features: one of the finest trout streams in British Columbia; route chosen by Sir Alexander Mackenzie in 1793—now a heritage hiking trail to Bella Coola

Fragmentation: none

Water quality: median of 38 sites, alkalinity = 54.8 mg/L as CaCO₃, pH = 7.9, NO₃-N + NO₂-N = 0.003 mg/L, total Kjeldahl nitrogen = 0.269 mg/L, total phosphorus = 0.021 mg/L

Land use: 0.7% agriculture, 9.4% freshwater, 16.9% old forest, 10.8% recently logged, 60.3% young forest, 1.9% other

Population density: <1 person/km²

QUESNEL RIVER

Relief: 2500 m

Basin area: 11,500 km²

Mean discharge: 239 m³/s

River order: 6

Mean annual precipitation: 53.9 cm

Mean air temperature: 4.9°C

Mean water temperature: NA

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biome: Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: North Central Rockies Forests, Fraser Plateau and Basin Complex

Number of fish species: 23

Number of endangered species: none

Major fishes: sockeye salmon, rainbow trout, largescale sucker, longnose sucker, reddsider shiner, northern squawfish, peamouth chub, lake chub

Major other aquatic vertebrates: moose, beaver, merganser

Major benthic invertebrates: NA

Nonnative species: none

Major riparian plants: white spruce, lodgepole pine, trembling aspen, Douglas fir

Special features: remarkable comeback of Quesnel River sockeye; run of 12.2 million fish in 1993, with 2.5 million fish making it to Quesnel headwaters to spawn; once again the Fraser's greatest sockeye producer, surpassing world-famous Adams River for sockeye production

Fragmentation: none

Water quality: alkalinity = 53.8 mg/L as CaCO₃, pH = 7.9, orthophosphate = 0.003 mg/L, total phosphate = 0.3 mg/L

Land use: 0.03% urban, 1.5% agriculture, 9.8% alpine, 6.8% freshwater, 11.2% recently logged, 29.1% old forest, 34.2% young forest, 7.4% other

Population density: 2.2 people/km²

CHILCOTIN RIVER

Relief: 3250 m

Basin area: 19,300 km²

Mean discharge: 102 m³/s

River order: 6

Mean annual precipitation: 33.5 cm

Mean air temperature: 2.2°C

Mean water temperature: NA

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biome: Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregion: Fraser Plateau and Basin Complex

Number of fish species: 16

Number of endangered species: none

Major fishes: mountain whitefish, rainbow trout, sockeye salmon, bull trout, longnose sucker, reidside shiner, largescale sucker, northern squawfish, peamouth chub, lake chub

Major other aquatic vertebrates: beaver, moose, merganser

Major benthic invertebrates: mayflies (*Baetis tricaudatus*, *Epeorus deceptivus*, *Paraleptophlebia*, *Rhithrogena*), stoneflies (*Capnia*, *Sweltsa*, *Taenionema*, *Zapada cinctipes*, *Zapada columbiana*), chironomid midges (*Brillia retifinis*, *Eukiefferiella brehmi* group, *Micropsectra*, *Orthocladius* [*Eudactylocladius*])

Nonnative species: brook trout

Major riparian plants: white spruce, lodgepole pine, trembling aspen, Douglas fir, Engelmann spruce, alpine fir, bunchgrass

Special features: among best and most challenging river in North America for kayaking and white-water rafting; spectacular scenery, such as Farwell Canyon, where river cuts deeply into sandstone cliffs with native pictographs on overhang

Fragmentation: none

Water quality: alkalinity = 51 mg/L as CaCO₃, pH = 7.7, NO₃-N + NO₂-N = 0.002 mg/L, total Kjeldahl nitrogen = 0.060 mg/L, total phosphate = 0.042 mg/L

Land use: 0.05% urban, 0.53% agriculture, 0.9% alpine, 7.9% water, 7.1% recently logged, 18.3% old forest, 49.7% new forest, 1.8% rangeland, 13.7% other

Population density: <1 person/km²

LILLOOET AND HARRISON RIVERS

Relief: 2750 m

Basin area: 7870 km²

Mean discharge: 445 m³/s

River order: 5

Mean annual precipitation: 172.6 cm

Mean air temperature: 10.2°C

Mean water temperature: NA

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biome: Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: Cascade Mountains Leeward Forests, British Columbia Mainland Coastal Forests

Number of fish species: 20

Number of endangered species: none

Major fishes: chinook salmon, sockeye salmon, coho salmon, chum salmon, pink salmon, rainbow trout, cutthroat trout, largescale sucker, reddsider shiner

Major other aquatic vertebrates: beaver, moose, merganser

Major benthic invertebrates: mayflies (*Drunella doddsi*, *Rhithrogena*), stoneflies (*Megarcys*, *Taenionema*), caddisflies (*Oligophlebodes*)

Nonnative species: brown bullhead

Major riparian plants: white spruce, lodgepole pine, trembling aspen, Douglas fir, Engelmann spruce, alpine fir

Special features: headwater Lillooet River runs for almost 200km of white-water paddling with spectacular autumn sockeye salmon runs; Lillooet empties into Harrison Lake, the largest lake in southwestern British Columbia

Fragmentation: none

Water quality: alkalinity = 19.0 mg/L as CaCO₃, pH = 7.1, NO₃-N + NO₂-N = 0.017 mg/L, total Kjeldahl nitrogen = 0.031 mg/L, total phosphorus = 0.015 mg/L

Land use: 0.15% urban, 0.6% agriculture, 25.3% alpine, 4.5% freshwater, 6.1% recently logged, 31.3% old forest, 14.7% young forest, 12.3% other

INTRODUCTION

KUSKOKWIM RIVER

SUSITNA RIVER

KENAI RIVER

STIKINE RIVER

SKEENA RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

The Pacific coast rivers of Canada and Alaska (Fig. 16.2) cover the region extending from British Columbia's north coast (north of the Fraser River, Chapter 15) to north of the Aleutian Islands (south of the Yukon River, Chapter 17), and have a latitudinal range from 54°N to 64°N. The southernmost rivers in this region have their catchments entirely within British Columbia, and the northernmost rivers have their basins within Alaska. In 1867 the United States purchased Alaska from Russia, creating a situation whereby the northern half of British Columbia is isolated from the ocean by the Alaskan panhandle. Thus several rivers of this region have a large portion of their catchment within Canada before flowing through Alaska to the Pacific Ocean; these rivers are known as transboundary rivers.

Most of the coastal rivers of the northeastern Pacific and southern Bering Sea are characterized by catchments originating at high elevations within a series of mountain ranges. These are the classic wild salmon rivers of the West Coast and include some of the most pristine drainages in the north temperate region (Dynesius and Nilsson 1994). Each one of the

basins described here has its upper drainages in mountainous terrain, some originating from glaciers, and discharge to the ocean. Several have their highest points well above 3000m asl within the Alaska Range (including Mount McKinley), the Wrangell Mountains, the St. Elias Mountains, and the Coast Mountains. All the basins have considerable topographic relief from highest source to mouth.

Native peoples have a close association with most of these large rivers, which provided important food resources, notably salmon. There are different views of when people arrived in western North America, but it seems most likely that human settlement dates from at least the end of the Wisconsinan glacial period (approximately 11,000 years ago) when the Bering land bridge between Asia and Alaska (Beringia) still existed (McGhee 1996). Rich aquatic resources and abundant wildlife supported subsistence living in these coastal regions of North America. Large winter villages and a dependence on salmon appear to be among the factors leading to the rich set of traditions and culture associated with coastal peoples (Muckle 1998). There are many native groups in the region, largely differentiated on the basis of language, but there are differences of opinion, even among native

FIGURE 16.2 Pacific Coast rivers of Alaska and Canada covered in this chapter.

peoples, as to how the different bands or tribes should be grouped (Muckle 1998). Some of the native groups associated with the area covered in this chapter include the southern Eskimos, the Yuit of the Yukon–Kuskokwim delta and southwest Alaska (McGhee 1996), and the Athabaskan, Haida, Tsimshian, Tlingit, Tahltan, and Nisga’a Indians, to name a few. Some “nations” have traditional areas defined in part by catchment boundaries, which partly reflects their association with the rivers. Europeans reached coastal areas of British Columbia and Alaska during the late 1700s and trading posts and fishing ports were established during the early 1800s. It was not until the gold rushes (especially the Klondike gold rush) of the mid-1800s that large numbers of European settlers moved inland. Today

the populations of much of this region (villages or smaller communities) are still well represented by aboriginal peoples with many traditional occupations, such as trapping and fishing.

We will discuss 10 major rivers from this region, several of which are among the 30 largest rivers in North America (Leopold 1994; see Fig. 16.2). The five focus rivers to be covered were selected to illustrate the diversity of drainages, although many similarities among rivers in this sparsely populated and relatively “wild” part of North America exist. The focus rivers (with their world rank in terms of average annual discharge) are Kuskokwim (40th), Susitna (60th), Kenai, Stikine (48th), and Skeena (46th). Although the Kenai River is not as large as some rivers in the region, it is very important eco-

nomically, supporting significant commercial and sports fisheries. Abbreviated physical and biological descriptions of five additional rivers are also provided: Nushagak (57th), Copper (45th), Alsek, Taku, and Nass (69th).

Physiography and Climate

The region includes parts of three physiographic provinces, Yukon Basin, South Central Alaska, and Coast Mountains of British Columbia and Alaska. The latter two are provinces within the Pacific Mountain System physiographic division. These coastal areas of British Columbia and Alaska are tectonically active where the convergence of the Pacific plate and the North American plate results in extensive deformation of the crust and marked topographic relief. A series of mountain ranges run approximately parallel to the margin of the intersection of these two main plates. The Pacific Mountain System, which incorporates the Alaska Range, the Chugach Mountains, the Wrangell Mountains, the St. Elias Mountains, and the Coast Mountains extends south to Baja California in Mexico. Some of the largest mountains in North America (some >4000 m asl, including Mount McKinley, Mount Logan, and Mount St. Elias) occur in these mountain ranges. These ranges heavily influence the weather and other attributes of coastal catchments. Other legacies of the tectonic activity are the large number of earthquakes and the resulting changes to some river drainages. There are several geothermal areas where hot springs are common, particularly within the Stikine River basin (Farley 1979). There are also many ancient and recent volcanoes along the coastal mountain ranges throughout the region (recent volcanoes principally in the Aleutian Range apart from Mount Wrangell and Mount Edgumbe near Sitka).

From the Rocky Mountains westward are land areas, or terranes, that have been added to the original North American plate during or since the Phanerozoic era. Large portions of the region are underlain by rocks of volcanic origin, intermixed with igneous intrusives and some sedimentary formations (Gabrielse and Yorath 1991). The coastal mountains are formed by an extensive intrusive granitic and crystalline gneiss batholith from late Cretaceous to early Tertiary age (Farley 1979), which is highly resistant to weathering.

Most of the region included in this chapter has been subject to glaciation over the past million years and was covered by ice during the Wisconsin glacial period (75,000 to 10,000 years ago), with the

exception of the “Beringian refuge” and some small coastal areas (Hunt 1974). The Beringian refuge includes much of the Yukon and Kuskokwim lowlands, which receive very low amounts of precipitation in contrast to coastal regions and higher elevations. Recolonization of previously glaciated regions by freshwater species following ice retreat was predominantly from the Beringian and Pacific refuges, and, for a few species, the Mississippi refuge (McPhail and Lindsay 1970, Oswald et al. 2000).

The mountains show signs of glacial scouring, with U-shaped valleys and basal till forming a thin layer over bedrock in many parts of the region. The thin ground layer means that there is relatively low groundwater storage in many areas compared to unglaciated regions. Most of these systems also respond rapidly to precipitation events because of their low storage capacity. This till contributes to high bedload transport and is actively reworked to create alluvial structures in river sections with lower gradients. Broad, braided reaches of these rivers are common where the gradient permits. There are no extensive limestone deposits, and thus no cave systems in this region.

The soils of the area are predominantly podzols. There is a broad band of ferro-humic podzols (in the Canadian series, and the equivalent United States classes are humic cryorthod and humic haplorthod) along the coastal regions of about 150 km width (Farley 1979). Further inland there is a wide expanse of humo-ferric podzols (cryorthod, haplorthod). Some parts of the Skeena River basin originate in a wide, interior, postglacial plateau characterized by gray luvisols (boralf). In the more northerly basins, cryosols (permafrost areas) and brunisols are more extensive.

Given the northern location and the extensive area of high mountains in this region, a large portion of the annual precipitation falls as snow. The wide altitudinal relief in these basins and sparse distribution of monitoring stations (mostly in valley bottoms) results in severe underestimation of catchmentwide precipitation. Climate varies throughout these large basins and simple measures cannot adequately characterize entire catchments. All of the catchments included in this chapter have some glacial influence, with the Nass and Skeena rivers to the south having the lowest contributions. The dominant weather systems along these coastal areas are Pacific westerlies that bring extensive moisture to the coast, as well as moderating temperatures, creating a relatively mild maritime climate. Precipitation is highest along the coast, and especially in mountainous areas,

but diminishes rapidly inland. This is a very cold region, with mean monthly temperatures in January for the Copper and Alsek basins as low as -21°C and July mean temperatures for any of the basins not exceeding 16°C . Temperature patterns inland of the Coast Mountains and the other mountain ranges are more continental, with wider seasonal fluctuations in temperature.

Basin Landscape and Land Use

The region includes 14 terrestrial ecoregions (see river descriptions), including coastal, temperate rainforests, interior coniferous forests, taiga, tundra, and alpine tundra (Ricketts et al. 1999). Most of the dominant forest trees are conifers. The Northern Pacific Coastal Forests ecoregion encompasses a band reaching a maximum width of 200 km that borders coastal regions. The dominant coastal forest tree species include western red cedar, Sitka spruce, western hemlock, Douglas fir, and Pacific silver fir, and further north, yellow cedar (also known as Alaska cypress) and mountain hemlock. Other species found in these forests include red alder, other alder species, vine maple, and western yew. These coastal temperate forests of British Columbia and southeastern Alaska are considered a globally outstanding habitat (Ricketts et al. 1999). The treeline in Alaska is about 800 to 1000 m asl and is higher further south. Interior forests of northern British Columbia are boreal (Northern Cordillera Forests ecoregion) and dominated by white spruce, lodgepole pine, black spruce, subalpine fir, and quaking aspen. In northern British Columbia, the southern part of the Yukon Territory, and Alaska the coastal forest grades into the boreal forest or taiga (white spruce, black spruce, quaking aspen, balsam poplar, Sitka spruce, cottonwood, and paper birch), then into tundra. The tundra ecoregions (Pacific Coastal Mountain Tundra and Ice Fields, and Alaska/St. Elias Range Tundra) are characterized by dwarf shrubs, including species of the family Ericaceae, birch, willows, and alders. Additional ground cover in the tundra is provided by other ericaceous species (e.g., mountain heath) and a range of herbaceous species, such as mountain aven. Additional forest types occur in the more southerly basins, as described in this chapter.

Historically, land use in the region was subsistence hunting and fishing by indigenous peoples. Current land use throughout the region continues to predominantly involve resource extraction, namely timber harvest, mining for minerals, and fisheries. Many areas are sufficiently remote from markets,

mills, and other infrastructure, or timber is of lower quality, such that forestry is still a minor activity and there are extensive tracts of original forest. Parts of the region have fewer than 60 frost-free days per year (Farley 1979), and thus permafrost dominates here. Agriculture is thus not viable in most areas, except in the Matanuska Valley in south-central Alaska and in the southernmost part of this region in British Columbia. Trapping for furs remains an important activity for native and nonnative inhabitants.

Most of the region is sparsely populated, with the major population centers on the coast. Most of these towns and cities (e.g., Anchorage and Prince Rupert) occur at the ocean mouths of the large rivers. Most other towns and villages are small (<1000 inhabitants), often associated with forestry activities or native settlements. Even so, these villages are tied to the rivers for their fisheries value and other resources.

Sport fishing and hunting are two important economic activities in these catchments. Tourism is also a major force that continues to increase and is now the second most important activity for the Alaska economy after oil. One of the commercially dominant tourism activities is the cruise ship industry, taking passengers from Vancouver to southeast Alaska, including Juneau and Glacier Bay National Park and Preserve. Rafting, kayaking, and wildlife viewing (e.g., grizzly bear, Kermode bear [variety of black bear], and other species) are also popular activities in the area. The Alsek, Tatshenshini, and Taku rivers are popular for float trips with rafts.

The region includes several large parks and protected areas. These parks are largely wilderness areas, further evidence of the region's low level of development. Among those parks is an extensive, contiguous U.S.–Canada protected area of 13,926 km², which includes Wrangell–St. Elias National Park and Glacier Bay National Park in Alaska, Kluane National Park in Yukon Territories, and Tatshenshini–Alsek Park in British Columbia (the Kluane and Tatshenshini parks protect most of the Alsek River basin). Much of this area was designated a World Heritage Site by the United Nations in 1979. Other protected areas in the region include Denali National Park (Alaska), Spatsizi Wilderness Park (British Columbia), and the Tongass National Forest (Alaska), although some forest harvest is allowed therein.

The Rivers

Two freshwater ecoregions are represented by the rivers covered in this chapter: the North Pacific

Coastal and the Yukon (Abell et al. 2000). The Kuskokwim and Nushagak Rivers are part of the Yukon ecoregion, and the others belong to the North Pacific Coastal ecoregion. These rivers share similar properties: snowmelt- and/or glaciermelt-dominated hydrology (large storage of precipitation as ice or snow), influence of past glaciation on landforms, low conductivity, and at least some portion of each basin draining steep, mountainous areas. Although runoff is largely based on snowmelt, glaciermelt, or both, there is also a rainfall-driven signal in the hydrology as a consequence of the mild westerly flow of moist air across the Pacific falling as rain in the low-lying portions of the basins and especially coastal areas. Few meteorological stations exist on these rivers, and the ones that do are often associated with population centers in valley-bottom sites, whereas the majority of the basin areas are at elevation. Hence, precipitation records do not accurately represent inputs to each basin. Two factors that underestimate inputs are the well-known effects of orographic influence, with rainfall increasing from 50% to 400% across the elevations of 1000s of m asl in the region, and the predominance of snow as input, which is difficult to accurately measure (e.g., Jones 1997, Dingman 2002). The set of rivers here represent a latitudinal gradient in terms of forest types, from coastal temperate rainforests to tundra. That latitudinal gradient is also inversely correlated with gradients in human use.

A unique aspect of the glacial influence on some of these rivers is the periodic occurrence of outburst floods, also known by their Icelandic name, *Jökulhlaup* events. Outburst floods take place when lake discharge is restricted by glacial activity, which eventually releases suddenly through the glacier during summer. This typically occurs as a result of the ice barrier becoming raised or water tunneling through the ice as it warms. An outburst flood can raise instantaneous discharges twofold to fivefold above the already swollen late-summer flood stage (e.g., Brabets 1997). Examples include Miles Lake on the Copper River, Lake Nolake and Tulsequah Lake in the Taku River drainage (the latter being close to a proposed mine site), and the Snow River basin within the Kenai River system, which is discussed in this chapter. These outburst floods can take place in the course of a few days and the large flows play a major role in reshaping channel geomorphology, as well as disturbing floodplain vegetation and potentially damaging bridges, roads, and other structures.

All rivers sustain important spawning and rearing areas for Pacific salmon (sockeye, chinook, coho, chum, and pink) and steelhead. Rainbow trout (the

nonanadromous form of steelhead), cutthroat trout, and Dolly Varden (char) also have many resident populations that remain entirely in freshwater. Studies indicate that less than 5% of salmon stocks in southeastern Alaska are in decline, with <1% rated at moderate to high risk of extinction (Baker et al. 1996). The species in British Columbia waters are more threatened (mostly toward the south), with 1.5% of stocks listed as extinct and 7.3% of stocks classed at moderate to high risk of extinction (Slaney et al. 1996). Abundance data are not available for many salmon stocks (57% of stocks in Alaska, 43% in British Columbia), so complete assessments are not possible.

The Canadian and U.S. governments frequently debate the allocation of salmon fisheries along the southeast Alaska coast. Salmon stocks primarily spawn and rear in Canadian waters, but juvenile fishes spend time in river habitats and estuaries in Alaskan waters before migrating to sea for one to four years, depending upon species (Murphy et al. 1997). Debates persist over salmon entitlements, particularly the commercial catch in Alaskan waters of salmon migrating to natal areas in Canada. Currently the Pacific Salmon Treaty determines allocations between the two nations.

A freshwater fish fauna of 44 species in the Pacific drainages of Canada and Alaska is depauperate compared to other regions due to the legacy of glaciation (Scott and Crossman 1973). As noted earlier, all rivers covered in this chapter have large, self-sustaining populations of the seven Pacific salmon and trout species (*Oncorhynchus* spp.). Of the 44 freshwater species, 18 are common to the river drainages discussed in this chapter, or at least should be within their range. It is also worth noting that 19 of the species are salmonids (including salmon, trout, char, and whitefish).

Few aquatic species in this region of North America are considered at risk. Crayfishes are widely distributed throughout much of North America, but the coast of British Columbia supports only a single species, the signal crayfish. However, its range may not extend as far north as the Skeena River, and there are no crayfish in Alaska (Taylor et al. 1996). There are 25 species of mollusks listed for the region (Clarke 1981), many of which have widespread distributions across northern North America. Some species are found only in the northern Pacific region, such as the Alaskan pond snail, the muskeg stagnicola, the subarctic lake stagnicola, the giant northern pea clam, and the Arctic-alpine pea clam; however, the ranges of these species are not well described. One species of mussel, the Yukon floater, is endemic

to the Yukon basin, including the Kuskokwim River (Clarke 1981).

A corollary of the predominance of Pacific salmon in the trophic ecology of most of these rivers and their tributaries and lake systems is the contribution of marine-derived nutrients to these mostly oligotrophic systems following salmon spawning (e.g., Helfield and Naiman 2001, Naiman et al. 2002). Some of these systems have broad and shallow alluvial channels, with riparian vegetation set back from the channels, and thus a predominance of algal-based food webs, excepting those with high degrees of glacially influenced turbidity (Oswood et al. 2000). Tributary systems, especially toward the southern portion of the region, have a greater dependence upon allochthonous sources of energy.

The sources of water impose various characteristics on these systems. For instance, water that varies in terms of organic staining, glacially derived turbidity, or clear water, has different thermal properties. Backscattering from suspended particles was shown by Edmundson and Mazumder (2002) to result in water temperatures of 5.9°C in turbid lakes compared to 7.2°C to 7.4°C in stained or clear lakes. This kind of variation in turbidity and staining likely has impacts on river thermal properties and other characteristics, but there has been little detailed study of variation caused by these sources.

Populations of most wildlife species are not threatened in this region. Some of the species commonly associated with the majority of rivers in this region include those that depend on fishes for parts of their diet, including grizzly bear, black bear, American mink, and river otter. Many other species are common throughout much of the region and associated in some ways with the rivers, including moose, beaver (except southwest Alaska), and muskrat. Among river-associated birds, merganser, belted kingfisher, and American dipper are species common to the rivers of the region (Oswood et al. 1995).

The rivers in this chapter are unaffected by fragmentation or flow regulation (Dynesius and Nilsson 1994). Minor amounts of water extraction occur for domestic use, and some small reservoirs exist on tributaries to a couple of these rivers. Rivers of this region represent one of the few remaining places in the world to contain the possibility of an “international preservation network of representative, unregulated and unfragmented” large-river systems (Dynesius and Nilsson 1994). Only three rivers in the northern hemisphere with discharge $>350\text{ m}^3/\text{s}$ are unregulated and drain areas other than boreal forest and taiga (i.e., the Kamchatka River of Russia and

the Stikine and Skeena rivers of British Columbia; Dynesius and Nilsson 1994), the latter two of which are discussed in this chapter.

Major current and future threats to rivers within this region are impoundments to generate hydroelectric power (especially on the Stikine River), contamination from mining effluents and sediments, timber harvest, and introduced (nonnative) species. Less than 0.1% of the length of Alaska rivers are listed as National Wild and Scenic, but at 5165 km, Alaska contains nearly one-third of the protected rivers in the United States (Karr et al. 2000). Many of these rivers have a large potential for generating electricity, and there is little protection from that fate in the future for most rivers. The rate of timber harvesting is increasing throughout the region, although some of the forests are not currently viable because of distance from mills and markets. Atlantic salmon escaped from sea-pen farming operations have been found as far north as the Bering Sea (Brodeur and Busby 1998), but potential impacts of these escaped fish on native, anadromous salmonids remain unclear. To date these threats remain relatively minor pressures on the rivers covered in this chapter.

Global climate change is predicted to significantly influence rivers within the region. Current predictions are that warmer temperatures will cause earlier snowmelt and higher peak flows from more rapid melting. Flows will be potentially lower in late summer and autumn (McCarthy et al. 2001). In rivers dominated by glacial flow, climate changes will likely cause increased glacial melt and increase the peak summer flow. Colder temperatures are likely to occur further downstream from the glacier margin (McGregor et al. 1995, Milner et al. 2001). These effects may put stress on riverine fish, as well as cause changes to river channels, estuaries, and coastal wetlands from changes in hydrographs. Climate warming could also alter turbidity and concentrations of dissolved organic carbon, which would alter stream food webs further (Milner et al. 2000, Edmundson and Mazumder 2002). Oswood et al. (1995) reported that dissolved organic carbon levels have increased and will continue to increase in permafrost-rich catchments in Alaska.

Much less is known about the biodiversity and ecology of most of these rivers than rivers in more populated and anthropogenically influenced basins of North America. Salmon production in all of these river systems supports a large industry, and thus comprehensive data on Pacific salmon numbers have been recorded. Knowledge of many aspects of the biology of some basins is sparse.

KUSKOKWIM RIVER

The Kuskokwim is a large subarctic river that drains mostly wilderness, including the north side of the Alaska Range, and then flows to the southwest into Bristol Bay in the Bering Sea (Fig. 16.9). On the basis of average annual discharge, the Kuskokwim River is ranked fortieth largest in the world (Leopold 1994) and the ninth in the United States. The Kuskokwim is the second-largest and second-longest river in Alaska (at 1130 km) after the nearby Yukon River (see Chapter 17), the latter of which has three times the average annual flow of the Kuskokwim. Large portions of the Yukon basin, including much of the Kuskokwim basin, were not glaciated during the most recent ice age, leaving an area known as Beringia, which acted as a refugium for terrestrial and aquatic organisms that later recolonized those areas that were glaciated (Oswood et al. 2000).

The area has been occupied for thousands of years by the Yuit or southern Eskimos (speakers of the Yupik language) near the coast and the Athabaskan Indians (or Athapaskan) of the Ingalik and Upper Kuskokwim tribes in the interior of the basin. The Eskimos used distinct winter villages and summer camps as appropriate to the resources available. The Athabaskan Indians are believed to have been nomadic. The area is thought to have been first visited by Europeans as part of Captain Cook's third voyage in 1778. Russian traders soon followed at the end of the eighteenth century, and trading posts were established in the early nineteenth century. Later growth of towns was a result of missionary settlements, first Russian Orthodox, then others. The territory was sold to the United States in 1867. The 1898 Yukon gold rush brought major changes associated with the large numbers of people seeking their fortune in gold in the Yukon and other large Alaskan rivers.

Physiography, Climate, and Land Use

The basin has a variety of landforms, with tributaries originating from the northern flanks of the Alaska Range at elevations exceeding 3000 m asl. It also drains the Kuskokwim Mountains to the northwest. The Kuskokwim basin is made up of the South Central Alaska (SC) and Yukon Basin (YB) physiographic provinces (see Fig. 16.9).

The Kuskokwim basin includes four terrestrial ecoregions (Ricketts et al. 1999). The Beringian Lowland Tundra and the Beringian Upland Tundra ecoregions are found along the coast near Bristol Bay,

much of which is in the Kuskokwim delta. The delta is a large wetland complex formed by low topographic relief and permafrost that restricts drainage and results in extensive areas of thaw lakes (Oswood et al. 1995). Vegetation includes sedges and shrubs, as well as alder and willow trees. Much of the upper basin is within the Interior Alaska/Yukon Lowland Taiga and the Alaska/St. Elias Range Tundra terrestrial ecoregions. Vegetation includes open taiga, mountain tundra, and even areas of moderately productive closed taiga forest. The predominant tree species include black spruce, white spruce, aspen, larch, birch, and poplars (Oswood et al. 1995), giving way to alpine tundra shrubs, rocky slopes, and glaciers at higher elevations (Ricketts et al. 1999).

Climate in the basin is described from only two weather stations. At Bethel, at the head of the estuary, monthly average temperatures reach 12.9°C in July and -14.5°C in January (Fig. 16.10). The average annual temperature at Bethel, probably the warmest point in the basin, is -1.6°C. About 63% of precipitation falls from June through October, and August is the wettest month, although this may underestimate inputs from snow, which are difficult to accurately measure (see Fig. 16.10).

At least 99% of the basin is undeveloped tundra, taiga forest, and wetlands. Most of the land use in the region is subsistence fishing, hunting, and trapping. There is a minor amount of forestry in the upper part of the basin. Mining for gold (mostly placer mining) and mercury occurred in the eastern part of the river basin, although most of the mercury mining has ceased. The Kuskokwim River basin is populated by about 14,000 people distributed among 56 towns and villages. The largest center is Bethel, with a population exceeding 5200, with smaller settlements at McGrath, Crooked Creek, Aniak, and Akiak.

River Geomorphology, Hydrology, and Chemistry

The Kuskokwim flows approximately 1300 km from its source in the interior of Alaska to its mouth at Bristol Bay. Many portions of the river are wide, braided, cobble-bottom channels with low gradients. The gradient of the river up to McGrath, about 455 km upstream from Bethel, is only about 20 cm/km. Many sections flow through thick alluvial terraces. The source of this river and many of its tributaries is glaciers at high elevation on the north side of the Alaska Range. The lower portion up to Bethel is tidal or tidally influenced.

The main tributaries include North Fork, East Fork, and South Fork upstream of McGrath, as well as Holitna River, Stony River, Swift River, Kisaralik River, and Kwethluk River (all upstream of Bethel). The most downstream water-sampling station from which the most water-quality and discharge data are available is the confluence with Crooked Creek, some 350 km from the mouth (Wang 1999). Mean width at the confluence with Crooked Creek is 340 m.

The average annual discharge at Crooked Creek is 1145 m³/s. The discharge is relatively low for the size of the basin as a result of most of the basin receiving relatively low amounts of precipitation because it is in the rain shadow of the Alaska Range. Other tributaries contribute to the discharge of the river to Bristol Bay, so the river discharge is much higher than that at Crooked Creek; Dynesius and Nilsson (1994) have estimated annual discharge to be 1900 m³/s. Winter discharge is very low, as precipitation falls mostly as snow and is locked up in snowpack and glaciers throughout the basin (see Fig. 16.10). Peaks in discharge occur from snowmelt and glaciermelt and can occur from May through August, depending upon year. Peak flows of 7362 to 11,100 m³/s have been recorded in some years (record period 1952 to 2000, USGS data, Crooked Creek station [<http://waterdata.usgs.gov/nwis/sw>]). A very minor amount of water is withdrawn from the river for power generation and domestic consumption.

Several aspects of water quality vary throughout the Kuskokwim River basin depending upon elevation, degree of glacial influence, and underlying parent materials. The mean annual water temperature was about 5°C (based on sparse data records from 1951 to 1999 by the USGS [<http://waterdata.usgs.gov/nwis/qw>]). The temperature usually remains at 0°C from December through March, when most of the river is covered by ice. The river warms quickly in May and June to reach a summer maximum of up to 20°C in July (range of summer maxima from 13.6°C to 20.6°C at the Crooked Creek station). Turbidity shows a strong seasonal pattern as glacier water melts in summer. Turbidity increases from 2 NTU (monthly average) during the cold part of the year (November through April) to a peak of 124 NTU in July (long-term July average; Fig. 16.3). Suspended solids show a similar pattern, averaging 112 mg/L. Average conductivity is 175 µS/cm (maximum 317), and hardness is 86.9 mg/L as CaCO₃. Some tributaries of the Kuskokwim River drain from a naturally elevated source of mercury (Wang 1999). Nitrate-N is 210 µg/L and PO₄-P is 123 µg/L.

FIGURE 16.3 Annual variation in turbidity (NTUs) of the Kuskokwim River based on data from the USGS for the Crooked Creek monitoring site. This seasonal pattern of high turbidity in summer is characteristic of glacier-influenced discharge, a feature common to a large proportion of streams in this region.

River Biodiversity and Ecology

The Kuskokwim River is within the Yukon freshwater ecoregion, which includes rivers draining into the Bering and Beaufort seas (Abell et al. 2000). Besides the Kuskokwim and Yukon rivers, these are the Kuzitrin, Colville, Sagavanirktok, Kuparuk, and Nushagak, among others of northern Alaska. Unfortunately, the ecology of the Kuskokwim River has been little studied, aside from salmon escapement estimates. The larger Yukon ecoregion is considered continentally outstanding in biological distinctiveness, but much remains to be learned of this region. It includes at least two species endemic to the Beringian refuge, the Alaskan blackfish (McPhail and Lindsay 1970) and a freshwater mussel, the Yukon floater (Clarke 1981). Other species endemic to the Beringian refuge (Squanga whitefish, Bering cisco, and Angayukaksurak char) may also be found in the Kuskokwim (Abell et al. 2000), although we have found no mention of their occurrence there.

Algae and Cyanobacteria

Little is known about algae and cyanobacteria in the Kuskokwim, but there have been some studies in small tributaries of the nearby Nushagak basin to the south, which are similar to many of those in the Kuskokwim (Peterson and Foote 2000). Summer algal biomass ranged from negligible to >10 mg/m² and showed generally higher levels following salmon spawning.

Plants

Riparian vegetation includes alders and willows. Most of the riparian vegetation is set back on river terraces away from the active channel.

Invertebrates

As with algae, little is known about invertebrates in the Kuskokwim. Studies in the small Nushagak tributary streams found benthic invertebrate densities at approximately 5500/m² (Peterson and Foote 2000).

Vertebrates

The main stem of the Kuskokwim and the north side of its basin in the Yukon plains was unglaciated during the Wisconsinan glaciation, forming a part of the Beringian refuge. The fish communities of the Kuskokwim basin differ from those of south-central and southeastern Alaska, from which it is isolated by the high peaks of the Alaska Range, but are similar to those of the nearby Yukon basin (Oswood et al. 2000; see Chapter 17).

Pacific salmon (sockeye, chum, chinook, coho, and pink) and steelhead are the most commercially valuable fishes in this river and spawn in various parts of the basin. The single biggest commercial sockeye fishery in the world is based in Bristol Bay (one-third of Alaska's total commercial salmon catch). Bristol Bay fisheries are based on fishes originating from the Kuskokwim, Nushagak, Kvichak, and other southwest Alaska rivers. Other fish species found in the river include Pacific lamprey, humpback whitefish, lake trout, Dolly Varden, longfin smelt, boreal smelt, eulachon, longnose sucker, burbot, three-spine stickleback, and coastrange sculpin.

The abundant salmon support large populations of vertebrates that come to the river to feed, including grizzly and black bears, mink, and river otters. Moose and muskrat are common to the wetlands of the basin, although moose were considered rare in the early period of Russian exploration in the late eighteenth century. Many predatory birds spend summers around the river and its tributaries, including mergansers, belted kingfishers, and dippers. Large breeding populations of many wetland birds are found in the delta (e.g., emperor goose, spectacled and common eiders, other geese, ducks, and shorebirds; Sedinger 1997). This area is thus critical habitat for many breeding waterfowl and many other kinds of wildlife.

Ecosystem Processes

Relatively few ecosystem processes have been studied in the Kuskokwim River. However, because of the importance of contaminant sources in the catchment, details of sediment transport have been determined (Nelson et al. 1977, Duffy et al. 1999). The bedform of the river is highly mobile and strongly influenced by summer freshet from snowmelt and glaciermelt. Furthermore, temperatures at these latitudes have important influences on ice cover and formation of anchor ice, which have important biological consequences. As noted, in rivers in southeast Alaska, the relatively less turbid periods toward the end of summer and into autumn may be important to primary production given the lack of canopy cover along most of the river and its tributaries (Milner et al. 2001).

Human Impacts and Special Features

The Kuskokwim River, like the larger Yukon River on its northern border, is largely pristine and shares many of the unique characteristics of the Beringian refuge. The Kuskokwim remains free flowing and is largely unaltered by humans. It does, however, have some contaminant problems, and could be in danger of future development. The river has an anomalous problem with mercury, which originates from natural sources in some basin tributaries (Nelson et al. 1977). There was some limited mining for mercury, but erosion of natural sediments (partly exacerbated by mining) has contributed mercury to the river system. The concentrations in tributaries can average 570 mg/kg of channel sediments, but these values are diluted downstream to levels closer to an average of 0.5 mg/kg of sediment in the main stem (Nelson et al. 1977). Levels of mercury in fishes consumed by native peoples are elevated and frequently exceed the EPA's reference dose, and this has motivated continuing studies of the sources and fates of mercury (Duffy et al. 1999).

The Iditarod trail, famous for its annual dogsled race, traverses the river basin to provide winter access to the upper part of the catchment.

SUSITNA RIVER

The Susitna River is an unregulated river in south-central Alaska, fed by glaciers on the southern slopes of the Alaska Range (Fig. 16.11), with a drainage area of approximately 51,800 km², the sixth largest in Alaska (Alaska Power Authority 1985). It flows

west and then southwest before emptying into the Cook Inlet to the west of Anchorage, Alaska's largest city at 260,000. Glaciers cover 11% of the basin, and 58% of the catchment is considered to be in high mountains (Kyle and Brabets 2001). The Susitna valley is a major transportation corridor for road and railway links between the cities of Anchorage and Fairbanks (Fig. 16.1). This river makes for a nice comparison to the Kenai River on the Kenai Peninsula, both of which drain through the Cook Inlet Taiga terrestrial ecoregion before emptying into Cook Inlet.

Prehistoric humans probably invaded the Susitna valley soon after the glaciers receded about 9000 years ago. Several eras of native settlements followed, with the Pacific Eskimos being displaced by the Athabaskan Dena'ina Indians of the Tanaina tribe at least several hundred years ago. Talkeetna, where the three main tributaries meet, means "river of plenty" in the Dena language, and was a major center for the native Indians living in the catchment. James Cook is reportedly the first European to explore the coastal area near the mouth of the river close to Anchorage in 1778. Russians explored and traded in the area beginning in the late eighteenth century and established trading posts before the sale of Alaska in 1867 from Russia to the United States. Discovery of gold in the Susitna River in 1886 lured nonnative prospectors far inland along the Alaskan rivers in the late 1800s, including deep into the Susitna River valley. In the early 1900s, the Alaska Railroad was built along the east side of the lower Susitna, leading to the establishment of towns such as Willow and Anchorage.

Physiography, Climate, and Land Use

The Susitna River lies within the South Central Alaska (SC) physiographic province. The drainage basin lies in a zone of discontinuous permafrost, where well-drained upland soils support white and black spruce and poorly drained valley bottoms support muskeg. The headwaters of the Susitna begin in the Copper Plateau Taiga terrestrial ecoregion to the east (see Fig. 16.11), a relatively flat area that was the site of a large Pleistocene lake (Ricketts et al. 1999). At a relatively low elevation (<1000 m asl), this plateau contains coniferous forest dominated by black spruce. The river then passes through the Alaska/St. Elias Range Tundra ecoregion, a long region of rugged mountains where elevations are often >4000 m asl. Some tributaries to the north (Chulitna River) drain from Mount McKinley at an

elevation of >6100 m asl. These mountains mostly consist of rocky slopes, ice fields, and glaciers. The Susitna (and many of its tributaries, such as the Yentna River) then enter the relatively flat, low-elevation Cook Inlet Taiga ecoregion. Here the vegetation includes various combinations of black and white spruce, Sitka spruce, quaking aspen, balsam poplar, black cottonwood, and paper birch (Ricketts et al. 1999).

The Susitna River originates in the continental climate zone and then flows south into the transitional climate zone. Due to maritime influence, temperatures are more moderate at the lower elevations of the basin (within the Cook Inlet Taiga) than in the interior mountains. In these more mild lowlands (where records are available), mean monthly air temperatures range from -12°C in January to 15°C in July (Fig. 16.12). Precipitation in the lowlands is quite seasonal, with maximum values of 12 cm/mo in August, but values of only 4 cm/mo or less from January through April (see Fig. 16.12). This precipitation pattern is an obvious underestimation of total precipitation for the basin, because precipitation is less than total runoff, an anomaly that is too large to be explained by the melting of glaciers.

The basin is almost entirely pristine wilderness, with no major land-use activities or settlements within the drainage. There are a number of remote cabins used for recreation and a number of homestead sites. There is no mining or timber harvest of note. Talkeetna is the largest settlement in the drainage at the junction of the Susitna, Talkeetna, and Chulitna rivers. It has a permanent population of <300 and serves primarily as an aircraft access point for climbers and sightseers to Denali National Park and Mount McKinley and for sports fishing.

River Geomorphology, Hydrology, and Chemistry

The 510 km long river (Alaska Power Authority 1985) originates as a number of small tributaries draining the East Fork, Susitna, West Fork, and MacLaren glaciers. This upper river flows in a braided channel across the alluvial floodplain of the Copper Plateau Taiga ecoregion for the first 80 km, with an average gradient of 2.6 m/km. Downstream from there the river flows for 115 km through a steep-walled canyon of the Alaska Range, known as Devil Canyon, with a gradient of 5.8 m/km. For the next 155 km, known as the middle river, it flows south through a well-defined and relatively stable series of

channels until its confluence with the Talkeetna and Chulitna rivers (both glacier fed) about 160 km from the river mouth. This confluence near the settlement of Talkeetna is frequently termed the “three-rivers” confluence. Below Devil Canyon the gradient decreases from 2.6 m/km above Talkeetna to 1.52 m/km at Talkeetna. Downstream of this confluence the Susitna River valley broadens into a large coastal lowland, where the lower river is heavily braided with negligible riparian vegetation. As the river braids below Talkeetna the gradient further decreases to 1.05 m/km and in the last 70 km falls to 0.3 m/km (Schoch and Bredthauer 1983). The Yentna (a glacier-fed river) is the largest tributary joining the Susitna River from the west, with its confluence 45 km from the Susitna mouth, below Willow.

Six principal habitat categories were identified by the Alaska Department of Fish and Game (1984a) in the middle river section of the Susitna River based on similar morphologic, hydrologic, and hydraulic characteristics: main stem, side channel, side slough, upland slough, tributary, and tributary mouth. Some habitats may shift from one category to another depending upon main-stem discharges (Klinger and Trihey 1984); for example, turbid side channels at summer high flow to clear side sloughs at lower flows in the fall or spring. These habitats support characteristically different fishes and benthic macroinvertebrate communities.

The main water sources to the Susitna River—glacier melt, tributary inflow, surface runoff, and groundwater input—change seasonally, with approximately 25% of flow being glacial in the middle river during summer, falling to less than 3% in winter when flows are dominated by groundwater. Consequently, the Susitna River is characterized by highly turbid streamflow in the summer and low clearwater flow in the winter and early spring (see Fig. 16.12). There are scattered open areas of water where the river is not frozen over due to groundwater upwelling or high current velocity. Mean discharge just below the confluence with the Yentna River is 1427 m³/s. Peak flows typically occur in July, exceeding 1400 m³/s at Gold Creek in the middle river and averaging 5432 m³/s (1975 to 1992) toward the river mouth. The record peak of 8839 m³/s was recorded at Susitna Station in October 1986 following heavy rains. The river below the confluence with the Chulitna River regularly experiences flooding during summer storms, which add to the snowmelt and icemelt flows (Schoch and Bredthauer 1983).

Winter has a major effect on the Susitna River, with ice generation, staging, ice jamming, and break-

up processes all having a major impact on aquatic habitat and biotic communities (Schoch and Bredthauer 1983). The size and configuration of existing sloughs along the river is dependent on the frequency of ice jamming in the adjacent main stem. Ice jamming creates floes that can modify the elevation of entrance berms to the sloughs or enlarge sloughs or side channels by scouring the banks and bed material. Ice processes do not appear to play such an important role in the morphology of the Susitna River below the Chulitna confluence. Frazil ice can scour surfaces and move organisms and stored organic matter downstream (Oswood 1997).

At Gold Creek in the Middle River, pH is circumneutral at 7.3, with alkalinity 50 mg/L as CaCO₃, NO₃-N 0.15 mg/L, and total phosphorus 0.12 mg/L. Turbidity values reach 200 NTU in the summer but fall to <1 NTU in winter.

River Biodiversity and Ecology

The Susitna River represents the upper end of the North Pacific Coastal freshwater ecoregion (Abell et al. 2000). This ecoregion stretches down the Pacific coast until it reaches (but does not include) the Columbia River. The region is considered continentally outstanding in biological distinctiveness.

Plants

Upstream of Talkeetna the riparian vegetation is relatively well established along the main channel and on island bars and includes black and white spruce, alder, and willow. Downstream of Talkeetna the river migrates markedly across a wide floodplain and riparian vegetation is limited due to the instability of the substrate.

Invertebrates

Studies of macroinvertebrates are limited to the middle river in association with a proposed hydroelectric project (as discussed in this chapter). Macroinvertebrates in the main channel during summer are low in diversity and abundance, limited principally to Diamesinae and Orthocladiinae chironomid midges. In side channel and side slough habitats, diversity increased, and in addition to chironomids, the principal taxa found were oligochaete worms, capniid stoneflies, baetid mayflies (principally *Baetis*), and heptageniid mayflies (principally *Cinygmula* and *Epeorus*) (Hansen and Richards 1985). When side channels and side sloughs were breached by mainstem water, drifting organisms increased, providing an

important food source for rearing juvenile chinook salmon (principally chironomids).

Vertebrates

Pacific salmon are the most prominent of the fish species in the Susitna River and the group of fishes about which the most is known. The primary spawning habitat of chinook, coho, and pink salmon within the Susitna River drainage is in the tributaries, whereas sockeye and chum salmon spawn mainly in side slough habitats. Upwelling water is an important factor for the selection of sites by chum and sockeye salmon to enhance egg survival (Alaska Department of Fish and Game 1984b).

Depending upon the season, juvenile rearing salmon are found within all aquatic habitat types. Rearing juvenile coho salmon utilize tributary and side slough habitat, whereas juvenile sockeye salmon are found principally in side slough and upland slough habitats. Side channels are used by juvenile king (chinook) salmon, and the turbidity and invertebrate drift into these channels can provide cover and food sources. Juvenile chinook overwinter in these habitats. Some resident species, such as rainbow trout and Arctic grayling, use the main-stem channel for overwintering. Burbot are found exclusively in the main stem and side channels due to their preference for turbid water (Alaska Department of Fish and Game 1984c). Other fish species known from the river basin are Pacific lamprey, humpback whitefish, lake trout, Dolly Varden, longfin smelt, boreal smelt, eulachon, longnose sucker, threespine stickleback, and coastrange sculpin.

The majority of the upper Cook Inlet chum and coho commercial fishery originates in the Susitna River basin, and in the mid-1980s the estimated contribution of the river to the important and most valuable species, sockeye, was between 10% and 30% of the total upper Cook Inlet sockeye fishery (Alaska Department of Fish and Game 1984a).

The seasonal spawning migration of Pacific salmon lures many species of wildlife to the river, including bears (grizzly and black), bald eagles, and scavengers. Many other piscivorous species are found, including mink, river otter, osprey, merganser, and kingfisher. Dippers are also found in the basin. Moose, beaver, and muskrat are common species associated with the river margins and wetlands.

Ecosystem Processes

The ecology of the river in the main stem and side channel habitats is dominated by the hydrology and

the influence of turbidity and sediment from glacial runoff. During the window of late winter–spring, when turbidities are low, algal growth and consequent macroinvertebrate production may be high. As discharges start to rapidly rise during late May and sediment concentrations increase, scouring removes the majority of algal production in these habitats and, with light penetration decreasing to <0.15 m, primary production is limited (Van Nieuwenhuyse 1984). A second algal bloom typically occurs in autumn as stream flows moderate and turbidities fall below 20 NTU. Some of this production may be lost due to the detrimental effects of ice regimes during freeze-up. In the summer, the main stem serves principally as a migratory corridor for adult salmon and outmigrating smolts.

Human Impacts and Special Features

The Susitna River is one of the most pristine basins in North America and is unique in draining some of the highest glacial mountains, including Mount McKinley and others in the Denali National Park of Alaska. However, with its mouth at Cook Inlet just west of Anchorage the river has and will probably continue to be threatened by human development.

At present there is relatively little impact from human population within the Susitna drainage, as the largest town is Talkeetna, near the three-rivers confluence, with a population of <300. Otherwise the settlement of the drainage is principally cabins and homestead sites, with a few small settlements along the Parks Highway bordering the Susitna downstream of Talkeetna. The highway does not appear to have much influence on the river. No major industries are present in the basin. In the early 1980s, however, a series of dams were proposed at Watana (294 Rkm) and Devil's Canyon (243 Rkm), which were scheduled for completion in 1994 and 2002 with a generating capacity of 1600 megawatts. Due to an economic downturn in oil prices in the 1980s the project was cancelled. It seems safe to say that the threat of damming of this pristine wilderness will always be present.

KENAI RIVER

The Kenai River is located on the northern portion of the Kenai Peninsula, just south of Anchorage. The Kenai River has a drainage area of approximately 5206 km² and is an unregulated river in south-central

FIGURE 16.4 Kenai River, Kenai Peninsula, Alaska, at low flow in May (PHOTO BY A. MILNER).

Alaska fed by glaciers on the western slopes of the rugged Kenai Mountain Range. The river flows westerly through two large lakes and across lowlands before emptying into the Cook Inlet at the town of Kenai (Fig. 16.13). It is one of the most productive and economically important rivers in Alaska due to its support of commercial and sports fisheries, including its world-renowned king salmon fishery (Fig. 16.4).

The Kenai Peninsula has been occupied by humans for many thousands of years. From about 3000 to 1000 years ago the area along the river was occupied by the Kachemak Riverine culture. About 1000 years ago they were replaced by the Kenaitze Indians, Athabascans of the Tanaina tribe (Boggs et al. 1997) who built settlements along the major rivers. At least 20 settlements are estimated to have existed on the Kenai Peninsula, with a maximum population in 1805 of 3000 people (Pederson 1983). The Kenai River was a major source of fishes, and summer camps were established to catch and dry salmon, and also to hunt muskrat, waterfowl, and caribou (Langdon 1987). The river and some of its

tributaries would also be used for transportation through the wetland areas of the low-lying Kenai Peninsula. Indians occupied the area when, in 1778 in search of the Northwest Passage, the English naval Captain James Cook sailed up the inlet that is now named after him. By this time Russian fur traders had been visiting the region, and a fortified Russian trading post, Fort St. Nicholas (Kenai), was established in 1791. Interactions between natives and traders were not always peaceful, and several battles between the Russians and Indians in the Kenai area resulted in many deaths. When the United States purchased Alaska in 1867 from Russia, the post was renamed Fort Kenai for the local Indians. Nonaboriginal American expansion into the catchment was spurred on by the discovery of gold near Cooper Landing in the 1880s. Kenai and the surrounding areas were opened to homesteading in 1947. Since that time the recreational value of the basin has attracted development, particularly in recent times. Most of this development has occurred along the main highway, which is in close proximity to the river for much of its length to Skilak Lake.

Physiography, Climate, and Land Use

The Kenai River basin is located in the South Central Alaska (SC) physiographic province (see Fig. 16.13). It is dominated by headwaters originating in the rugged Kenai Mountains rising up to 1500 m asl, two large lakes, and the river flowing for a great part of its length across lowlands dominated by wetlands. The drainage incorporates two terrestrial ecoregions. In the mountainous uplands to the east is the Pacific Coastal Mountain Tundra and Ice Fields. The lowlands to the west are within the Cook Inlet Taiga ecoregion. The lowland geology is dominated by unconsolidated Quaternary deposits (Brabets et al. 1999). The vegetation in the lowlands is dominated by closed spruce forest, closed mixed forest, and tall shrub.

The climate is classified as transitional and rainfall averages 48 cm in the coastal town of Kenai. The highest precipitation occurs in late summer, with a mean monthly accumulation of 8 cm in September (Fig. 16.14). Mean air temperature is only 0.9°C, with a minimum monthly mean of -11°C in January and a maximum of 12°C in July (Milner et al. 1997; see Fig. 16.14). Toward the mountains more precipitation and wider temperature fluctuations typically occur.

The land within the Kenai lowlands is predominantly state or native owned, except along the river in the lower reaches, where private ownership dominates. Above and in the environs of Skilak Lake the land is federally owned, the majority within the Kenai National Wildlife Refuge, which has 61 km of river frontage. Three main communities occur along the main river: Sterling (60 km from the mouth) at its junction with the Moose River, with a population of approximately 6000; Soldotna (40 km from the mouth), with 4000; and Kenai (at the river mouth), with 7000. The Borough of Kenai had a censused population over 51,000 in 2002. Most of the basin is uninhabited, except for numerous remote cabins and lodges along the lower river. Most of the Kenai River basin has been infested by the spruce bark beetle, and hence some salvage logging has occurred in these areas.

River Geomorphology, Hydrology, and Chemistry

Approximately 10% of the basin is glacierized (Dorava and Milner 2000). The Kenai River is similar to the other large rivers in the region in being

dominated by glacial runoff, with many tributaries, both glacial and clearwater. However, none of the tributaries attain the size of those within the Susitna drainage, which accounts for the Kenai River's relatively lower discharge. Another major feature of the Kenai drainage is the presence within the catchment of two large glacial lakes, Kenai and Skilak (see Fig. 16.13), which have a significant influence on river hydrology and the associated river ecology (as discussed later in the chapter). Kenai Lake is 55.9 km², with a mean depth of 91 m and a maximum depth of 165 m, whereas Skilak Lake is 100 km², with a mean depth of 73 m and a maximum depth of 160 m. Many of the streams and rivers flowing into Kenai Lake, most notably the Snow River, are fed by lakes and glaciers. Many of the tributaries upstream of and including the Killey River (10 km downstream of the outlet of Skilak Lake) are principally glacial in origin. However, between Skilak and Kenai Lake, the Russian River is a clearwater tributary fed by lakes well known for their sport sockeye salmon fishery. A major input into Skilak Lake is the Skilak River from Skilak Glacier, a major outflow from the Harding Ice Field. Downstream of the Killey River various clearwater tributaries, fed by snowmelt and rainfall, drain the Kenai Lowlands and frequently flow through wetlands and lakes.

The series of transitions of the Kenai River from glacial mountains to the Cook Inlet result in it being divided into five distinct reaches based on geomorphology (Liepitz 1994): (1) an intertidal reach from the mouth to Rkm 16, (2) a transitional reach from Rkm 16.0 to Rkm 28.3, (3) an entrenched reach from Rkm 28.3 to Rkm 68.3 where the river is confined within the Soldotna terrace, (4) an upper reach from the glacial moraine to the outlet of Skilak Lake, and (5) the interlake reach between Kenai and Skilak lakes. The entrenched reach resulted from the river down-cutting due to sea-level decline and plays a major factor in the stability of the channel. The bed is armored in this reach, with 38% of the substrate between 6.4 and 12.7 cm and 41% between 12.7 and 25.4 cm (Scott 1982). Upstream the substrate is generally larger. In the lower reaches the substrate is markedly smaller, with 40% sand and silt (<0.6 cm) and 51% gravel (0.6 to 6.4 cm; Bendock and Bingham 1988). Because of the large lakes, the Kenai River has a lower width-to-depth ratio (57) than three other glacier-fed rivers in Alaska without lakes (ratio of 85) (Dorava and Milner 2000). These lower ratios in the Kenai River create deeper water habitats, which is important for fish production. Gradient from Kenai Lake to Skilak Lake is relatively steep

at 6.8 m/km, but from Skilak Lake to Cook Inlet it is typically <3 m/km.

Continuous discharge data for the main-stem Kenai River are available from two stations, Cooper Landing located downstream of Kenai Lake (since 1948) and Soldotna, 40 km from the mouth with a drainage area of 5206 km² (from 1966). Minimum mean monthly discharge occurs from February to April, falling to <51 m³/s, with maximum discharges in August with a monthly mean of 410 m³/s (1966 to 1994 measured at Soldotna), fed predominantly by snowmelt and glaciermelt (see Fig. 16.14). The two large lakes buffer flow variations such that the river channel downstream of Skilak Lake is not braided and multichanneled, as is so typical of many glacier-fed rivers in Alaska (e.g., the Susitna River). Instead, a single meandering or sinuous channel occurs, with relatively stable banks and riparian vegetation. Nevertheless, major floods can still occur in the Kenai River, as evidenced by flows in October 1999 after a period of sustained rainfall, with discharges reaching >1000 m³/s at Soldotna. Floods may also occur due to sudden discharges from ice-dammed lakes in the drainage, a *Jökulhlaup* event. This frequently occurs at a glacial lake within the Snow River basin (every two to four years), and on one occasion caused a flood peak of 954 m³/s at Soldotna (Scott 1982).

The presence of the large lakes in the Kenai River system markedly reduces the average sediment load carried by this major glacier-fed river. The average load in the Lower Kenai River is 0.09 tons d⁻¹ km⁻². This can be compared with an average of 2.16 tons d⁻¹ km⁻² for glacier-fed rivers in south-central Alaska without major lakes in their systems (Dorava and Milner 2000).

In the main-stem Kenai River, water temperature ranges from near 0°C to 13°C, with a mean of 6.4°C (Litchfield and Kyle 1992). Maximum water temperature typically occurs in July. Dissolved oxygen in Kenai River water is always close to saturation, although it can be lower in some of the shallow slow-flowing tributaries on the Kenai Lowlands. Litchfield and Kyle (1992) reported turbidities in the main stem from 2 to 18 NTU and suspended sediment concentrations between 10 and 100 mg/L. Conductivity ranges from 30 to 81 µS/cm, with pH close to neutral. Alkalinities are low, typically averaging 25 mg/L as CaCO₃. Studies in 1991 and 1992 indicated that nitrate and nitrite decreased downstream, with values in 1991 exceeding 230 µg/L below Skilak Lake but 150 µg/L near the mouth. Orthophosphate increased near the mouth but still remained below 10 µg/L.

River Biodiversity and Ecology

Like the Susitna River, the Kenai River is one of the most northern rivers within the North Pacific Coastal freshwater ecoregion (Abell et al. 2000). Although the fisheries of the Kenai are extremely well studied, less attention has been given to its lower trophic levels and general ecology. Nonetheless, more is known about this system than most of the northern Pacific rivers.

Plants

Due to the stability of the river channel below Skilak Lake there is extensive growth of riparian vegetation along the river, largely made up of alders and willows. Where wetland areas adjoin the river, typical wetland communities of sedges and mosses occur. Macrophytes are not extensive in the main-stem river due to low water clarity in the summer and high velocities.

Invertebrates

By attenuating peak flows, sustaining high flows throughout the summer, supplementing winter flows, settling bedload and suspending sediment, and enhancing downstream water temperature, the lakes have a major influence on the biotic productivity of the Kenai River system (Dorava and Milner 2000). The macroinvertebrate fauna of the Kenai River is dominated by chironomid midges, particularly the subfamilies Diamesinae and Orthoclaadiinae. Other dipterans, such as crane flies (*Dicranota*), dance flies (Empididae), and black flies, have also been reported (Burger et al. 1983, Milner and Gabrielson 1994). Densities have been found to increase downstream and range from 592 organisms/m² to 11,050 organisms/m² (Milner and Gabrielson 1994). The mayflies were dominated by *Baetis*, *Cinygmula*, *Drunella*, and *Ephemerella*; stoneflies by *Capnia*, *Plumiperla*, *Paraleuctra*, and *Isoperla*; and caddisflies by *Glossosoma* and *Brachycentrus*. Richness of nondipteran taxa was typically between 10 and 15 species. Macroinvertebrate richness is typically higher in the clear-water tributaries. However, due to the stabilizing influence of the lakes on the Kenai River, overall abundance and macroinvertebrate diversity in the main-stem river is an order of magnitude higher than in a glacial system without lakes. For example, macroinvertebrate densities in the Johnson River, a glacier-fed river without lakes on the west side of Cook Inlet, averaged only 460 organisms/m² (Dorava and Milner 1999).

Vertebrates

All five species of Pacific salmon (chinook, coho, sockeye, chum, and pink) use the Kenai River, which supports extensive commercial and sports fisheries. Dorava and Scott (1998) compared the salmon escapement per unit length of river, normalized for catchment area, and found the Kenai River to be 2.3 times higher than the Deshka River, a well-known clearwater salmon river in south-central Alaska. The availability of suitable overwintering habitat is critical to the survival of juvenile salmon to smolts in coastal Alaska and British Columbia (Tschaplinski and Hartman 1983). Glacial lakes provide important overwintering habitat for juvenile fishes, thereby reducing mortality and enhancing production (Reynolds 1997). A large percentage of 0+ juvenile chinook salmon were found to move over 50 km upstream to overwinter in or near the outlet of Skilak Lake (Bendock 1989).

Chinook salmon have two major runs into the Kenai River, an early run entering the Kenai River before June 30 and spawning principally in tributaries, with about 15% spawning in the main stem. Late-run chinook salmon enter the Kenai River after June 30 and spawn in the main stem, principally in the transitional and middle river reaches (Burger et al. 1983). Early chinook runs typically range between 10,000 to 27,000 fish, whereas late runs are between 39,000 and 80,000, with a mean of 58,360 (1984 to 1994) (Hammarstrom 1995). Of these, an average of 16,570 were caught in the commercial harvest in Cook Inlet and 10,800 were taken by sports fishermen in the river, giving an average escapement of 30,990 (19,580 to 48,040). Juvenile chinook salmon typically remain in fresh water for one year and rear in the margins of the main river.

Coho salmon also have two overlapping runs, with the early run beginning in late July and running until late August and the late run extending into November. Similar to chinook, early-run coho spawn primarily in tributary streams from September through early October, whereas the late-run fish spawn primarily in the main stem from October through February. Juvenile coho salmon typically spend two years in fresh water before going to the ocean as smolts, principally in low-velocity areas in the main stem or side sloughs. However, these juveniles can migrate extensively within the drainage and may emigrate from the main-stem Kenai River to overwinter in tributaries and lakes.

The species of most commercial value is the sockeye salmon. Similar to the other two species, sockeye possess two distinct stocks, an early run

entering the river in mid-May and a late run that typically peaks in mid July. The early run supports an important sports fishery at the confluence of the Russian River and the main-stem Kenai, with an average catch of 22,530 or 42% of the river return (1963 to 1993) (Nelson 1985). The Russian River escapement has usually exceeded 30,000, with an average of over 23,000 fishes (1968 to 1993). These fishes spawn in the Russian River and rear exclusively in Upper Russian Lake.

The late run of sockeye salmon enters the Kenai River in early July, and the run is usually completed by early August. The escapement goal is for between 400,000 and 700,000 spawners. The average (1968 to 1992) has been 635,000, with a minimum of 53,000 and a maximum of 1.6 million following the Exxon Valdez oil spill in 1989, when commercial fishing was closed down due to possible tainting of flesh from oil. Sockeye salmon spawn in the main stem below Skilak Lake and several tributary streams, including the Russian River and Hidden Lake. The majority of main-stem and tributary sockeye salmon rear principally in Kenai and Skilak lakes, with about 20% in Kenai Lake. Sockeye salmon juveniles typically spend one year in fresh water, but high winter mortality is typical. Tarbox and Brannian (1994) estimated about 10% survival, which is positively correlated to fall copepod density and fry condition (Schmidt et al. 1995).

Other fishes known from the Kenai River catchment include Pacific lamprey, humpback whitefish, lake trout, Dolly Varden, longfin smelt, boreal smelt, eulachon, longnose sucker, burbot, threespine stickleback, and coastrange sculpin.

Wildlife within the basin is abundant, and the availability of upstream-migrating salmon and eulachon (hoolican) provides a short-lived but critical resource to grizzly bears, black bears, bald eagles, and many scavengers. The river supports river otter, mink, merganser, kingfisher, osprey, and dipper. Beaver and muskrat are common within the catchment, and moose are abundant and associated with the river margins and wetlands.

Ecosystem Processes

Turbidity is likely to limit primary production during the high summer discharges, but when water clarity increases in late spring and early fall, windows for primary production exist when the river is not ice covered, and mats of filamentous algae have been observed. However, we have no indication of the role of primary production relative to the energetics of the main-stem Kenai River and its tributaries. Indeed,

there is a lack of studies of lower trophic levels in the Kenai River and their interactions, as most of the focus has been on fisheries populations for management objectives. We have no indication of the role of benthic organic matter in the Kenai River, whether the lakes are a sink or source of organic carbon, or the role of tributaries in supplying organic carbon. Nutrient dynamics are poorly understood, particularly the role of salmon carcasses and wetland areas.

Human Impacts and Special Features

The Kenai River is unique, with its rugged undeveloped catchment, its strong influence of lakes and glaciers, and its low-elevation wetlands, all within the Kenai Peninsula. It is also the most important sport fishing river in Alaska, with many fishermen seeking out the mighty king (chinook) salmon because of the size reached in the Kenai River. The state record for a king salmon is 44 kg in the Kenai River. The river is also important in providing sockeye salmon to the commercial fishery in Cook Inlet, both by set nets along the beach and drift gill netting by boat. The intense recreational use has potentially damaged riparian habitat and spawning areas by increased bank erosion due to trampling and boat wakes, principally from fishing guides in the lower river (Dorava and Moore 1997). Development near the river, the infilling of wetlands, and construction of structures within the river have added to habitat effects (Dorava 1995). Instream structures like jetties and groins may increase velocities and sheltered areas reduce velocities, which are outside the preferable range of juvenile chinook salmon (Burger et al. 1983). High velocities may hinder juvenile salmon migration, which is essential for overwinter survival.

Commercial and recreational fisheries have the most direct impact on Kenai River salmon. Early-run chinook and sockeye are not targeted by the commercial fishery, but some late-run chinook are removed as incidental by-catch of the commercial sockeye fishery in Cook Inlet, creating conflict with the sports fishermen. Similar conflicts can occur when the sports fishery for sockeye is restricted due to lower bag limits or hours of fishing as a result of low catches within the commercial fishery. Commercial sockeye salmon harvests typically range from 500,000 to 3 million fish. Additional pressure has occurred since 1989 from a subsistence dip-net fishery at the mouth of the river that permits Alaska residents to remove 35 sockeye salmon for personal use.

STIKINE RIVER

The Stikine River is a transboundary river originating within and having most of its basin in Canada but reaching the Pacific through the Alaska panhandle (southeast Alaska). The 539 km long river initially flows west and then southwesterly from its source east of the Coast Range Mountains, and is joined by its major tributary, the Iskut River, close to its mouth (Fig. 16.15). This largely pristine system is one of only three (together with the Skeena River of British Columbia and the Kamchatka River of Russia) large (>350 m³/s) free-flowing rivers in the Northern Hemisphere that drain a biome (Temperate Mountain Forest) other than the Boreal Forest and Tundra (Dynesius and Nilsson 1994) (Fig. 16.5). As with all the rivers covered in this chapter, the Stikine River has a large component of glacial influence. However, less of the basin is influenced by glaciers compared to the more northerly rivers.

Two native groups have occupied the river basin for more than a thousand years, the Tlingit on the coast and the Tahltan in the interior. The Tahltan claimed winter hunting grounds down the frozen Stikine River but were not great river travelers in the summer, whereas the Tlingit claimed the Stikine salmon-spawning tributaries. In the summer the Tahltan would trade products of the interior with the items the Tlingit would bring along before they returned to the coast. The Stikine River, meaning “great river” in the native Tlingit language, was missed by Captain Vancouver but “discovered” by American fur traders. European contact was first recorded in the late 1700s, when the Russian-American Company began trading with Tlingit peoples in the delta of the Stikine River. The Russian-American Company operated there from 1799 to 1839. About 1834, the Hudson Bay Company established a trading post in the interior of the Stikine basin and eventually took over trading operations, including the coast. The Stikine provided a transportation corridor to the gold rushes of the north: the Stikine gold rush in 1862, followed by the Cassiar gold rush of 1874–1876, and finally in the Yukon in 1897. Steamboats were a common mode of transport and between 1862 and 1969, 107 commercial boats operated on the river. The head of navigation was Telegraph Creek, 250 km from the mouth, which connected to trails and later roads. The population of Telegraph Creek is 300, mostly Tahltan Indians. The Stikine was also surveyed as a potential route for a telegraph line in the 1860s. The area was also used as a staging and supply post for construction of part

FIGURE 16.5 Stikine River, British Columbia (PHOTO BY TIM PALMER).

of the Alaska Highway in 1941–1942. Today the Cassiar Highway passes through the basin, but it is still a sparsely settled and remote location. The Tahltan nation claims most of the catchment as its traditional territory and remains the primary occupants of the area, relying on the river fishery (BC-LUCO 2000).

Physiography, Climate, and Land Use

The Stikine River belongs to the Coast Mountains of British Columbia and Southeast Alaska (PM) physiographic province (see Fig. 16.15). The Stikine basin includes several forest types from the coastal temperate forest (western red cedar, Sitka spruce, western hemlock), part of the Northern Pacific Coastal Forests terrestrial ecoregion, to the eastern extent of the basin. Upstream of the coast range the river passes through a cold, wet forest type, known in British Columbia as the Interior Cedar–Hemlock zone, and is part of the Northern Cordilleran Forests ecoregion (includes western red cedar, western hemlock, “interior” spruce [*Picea engelmannii* ×

glauca], and lodgepole pine in drier sites). At higher elevations along the coast is the mountain hemlock zone, replaced away from the coast by the Engelmann spruce–subalpine fir zone. Two other forest types that cover small portions of the basin in drier, lower-elevation zones are known as the subboreal spruce (Engelmann–White spruce hybrid, subalpine fir) and the boreal white and black spruce (black spruce, white spruce, trembling aspen) zones, part of the Northern Cordillera Forests ecoregion. The mid-course of the Iskut River, the Stikine’s main tributary, flows through the Northern Transitional Alpine Forests ecoregion, representing a mix of forest types from rainforest in the valley bottoms to tundra and permafrost at higher elevations. The largest portion of the basin includes alpine tundra (40%; Pacific Coastal Mountain Tundra and Ice Fields ecoregion) and spruce–willow–birch forests (28%).

The Stikine River basin had a mean annual air temperature of only 2°C (1951 to 1980) at the one valley-bottom recording station of Telegraph Creek. Mean monthly temperature was lowest (−18°C) in January and highest (16°C) in July (Fig. 16.16). Most

of the basin would be cooler on average. The average annual precipitation at Telegraph Creek in the rain shadow of the coast range was about 40 cm, likely an underestimate of the average for the basin. The rate of precipitation was highest from October through December and lowest in spring, but did not vary greatly throughout the year (see Fig. 16.16).

Only about 50% of this basin is forested, with much of the remainder covered by alpine tundra and ice fields. About 73% is considered to be in wilderness or near-wilderness condition (BC-LUCO 2000). Only about 1300 people reside within the catchment, centered on the towns of Telegraph Creek and Dease Lake.

River Geomorphology, Hydrology, and Chemistry

The two main rivers of the Stikine drainage, the Iskut and Stikine, join near the coast. Both rivers are glacially influenced and have large braided channels in their lower reaches, which in the Stikine is nearly 130 km long before entering the Pacific Ocean. The primary tributaries to the Stikine River include the Tahltan, Spatsizi, Klappan, and Tuya rivers. The catchment has its origins in the extensive mountain areas, with the highest point (2938 m asl) being Amaman Mountain in the Coast Range Mountains. Extensive lava beds in the basin are evidence of the past volcanic history of the region. The river substrate includes clasts up to house size in some of the canyon reaches. One spectacular feature of the 540 km long river is the 95 km long Grand Canyon of the Stikine, with gradients between 2.5 and 7 m/km. This gorge (up to 300 m deep) separates the inland and coastal portion of the river. Below the canyon the river is navigable and has an average gradient of 1 m/km from the settlement of Telegraph Creek to the border with Alaska some 180 km downstream. From Telegraph Creek to the border the river width expands from 100 m to about 250 m across the active channel. The Iskut River has a gradient of 1.5 to 2.5 m/km upstream of the confluence with the Stikine, but in the 5 km reach downstream of its confluence with the Forrest Kerr River the river goes through a canyon section up to 120 m deep and with a 27 m/km gradient. The Stikine is considered one of only three large free-flowing rivers in the Northern Hemisphere that drain biomes (Temperate Mountain Forest) other than Boreal Forest and Tundra (Dynesius and Nilsson 1994). Nevertheless, there is continuing pressure to consider development of the

enormous potential for hydroelectric power generation from the basin.

Mean discharge for the Stikine River is 1587 m³/s. Runoff is highest during June and July (>19 cm/mo) due to the domination of the hydrograph by snowmelt and to a lesser extent glaciermelt (mostly from the Coast Range Mountains) (see Fig. 16.16). Runoff appears to be higher than precipitation, but this is caused by the underestimation of precipitation for the basin as a whole, as seen for most northern Pacific rivers with few valley-bottom weather stations. Winter precipitation is mostly stored as snow throughout the basin, and the mountains hold snow until the middle of spring before melting.

Water quality of the Stikine River has been measured at a station about 8.2 km upstream of its confluence with the Iskut River (Jang and Webber 1996). There were no significant trends in the water quality. Most parameters varied seasonally along with flow conditions. As with other glacially influenced rivers, turbidity has a considerable range, with fall and winter values of 1 to 5 NTUs and summer peaks between 50 to 350 NTUs, depending upon year. Metal concentrations were relatively high, suggesting natural sources: Copper regularly exceeded the criterion for protection of aquatic life, with concentrations frequently >10 µg/L and up to 60 µg/L; iron regularly exceeded the criterion for aquatic life of 0.3 mg/L (range 0.2 to 11 mg/L); average zinc concentrations were 15 µg/L; aluminum was ~2 mg/L; and calcium concentrations were 15 to 32 mg/L (suggesting low sensitivity to acid inputs). Alkalinity was 45 to 90 mg/L as CaCO₃ and hardness had a range of 50 to 110 mg/L as CaCO₃, with higher values during high-flow periods. Nitrate-N and NO₂-N both averaged 0.1 mg/L (range 0.02 to 0.35 mg/L) and total phosphorus was ~0.2 mg/L (range 0.005 to 1.0 mg/L). Conductivity ranged from 100 to 240 µS/cm (at 25°C) and pH was ~7.8 (range 7.5 to 8.3). Temperatures were not continuously measured, but summer peak temperatures were between 11°C and 12°C (Jang and Webber 1996), peaking from late June to mid July.

River Biodiversity and Ecology

Like most of the rivers in this chapter, the Stikine is located within the North Pacific Coastal freshwater ecoregion (Abell et al. 2000). In spite of the size and pristine nature of this Pacific river, relatively few biological and ecological studies have been done, particularly for algae and invertebrates.

Plants

In the lower reaches of the Stikine River, riparian vegetation includes cottonwood, alder, and willow trees. Sitka spruce and hemlock are found at somewhat higher elevations.

Invertebrates

We are not aware of any published reports on the Stikine or its tributaries. However, samples taken in the Iskut River near the Forrest Kerr River show this river to have similar assemblages to many other glacially influenced rivers. The predominant taxa were the mayfly *Baetis*, the stoneflies *Capnia*, *Doddsia*, *Suwallia*, *Podmosta*, and *Zapada*, and the chironomid genera *Diamesa*, *Cricotopus*, and *Orthocladius* (L. Fanning, unpublished data).

Vertebrates

The Pacific salmon are all large contributors to the fish assemblages of the Stikine River system, and all are commercially exploited. Sockeye and chinook salmon populations are substantial. The sockeye salmon populations are unique because they rear in the main-stem Stikine and not in lakes; this also occurs in other rivers in southeast Alaska, the Taku River (Murphy et al. 1997). Escapements of sockeye salmon to the basin are approximately 38,000 per year (range 6400 to 90,600 from 1979 to 1999). Despite the importance of anadromous fishes in this system, reliable population data are limited (available for <10% of the individual stocks). Of the stocks that are sufficiently well documented, none appear to be at risk (Slaney et al. 1996).

Sockeye salmon in this glacial system were thought to come primarily from Tahltan Lake, one of the few clearwater lakes in the basin. However, there is evidence that >30% of sockeye from the Stikine may spend their freshwater time in glacial rivers (“river type”) or even go to sea immediately after fry emerge from the gravels (“sea type”). This is partly attributed to life history plasticity and the need for alternative rearing strategies in northern rivers (Wood et al. 1987). The bull trout, found in most of the Taku, Stikine, Nass, and Skeena catchments but not further north, is the only fish in the Stikine River basin on British Columbia’s blue list (Williams et al. 1989). Other fish species found in the catchment are Pacific lamprey, humpback whitefish complex, lake trout, Dolly Varden, longfin smelt, boreal smelt complex, eulachon, longnose sucker, burbot, threespine stickleback, and coastrange sculpin.

Bears (grizzly and black) are drawn to the migrating adult salmon. There are many other piscivorous species, including bald eagle, river otter, mink, kingfisher, merganser, and osprey. Other species common to the river and its margins are beaver, muskrat, dippers, and moose. Wildlife within the basin is abundant and many species found here in abundance are considered threatened or endangered in other parts of their range.

Ecosystem Processes

There have been no ecosystems studies to date in the basin. Most of the work that has been done is related to hydrology for estimation of hydroelectric power potential.

Human Impacts and Special Features

As a very large river flowing through a rugged mountainous wilderness, there is very little human development in the Stikine River basin. About 17% of the basin is currently under protected status, which will likely increase to over 25% with the implementation of a proposed land-use plan. The Spatsizi Wilderness Area is a large protected area (6568 km²). The Stikine River Recreation Area (2170 km²) borders the upper Stikine River, primarily serving as a rafting and canoeing area. Further protected areas include Mount Edziza Provincial Park (2302 km²) and the Stikine–LeConte Wilderness Area within the Tongass National Forest (Alaska).

Despite the extensive forest cover of the region, <1% is considered commercially viable, partly because of the remote location, which makes harvesting uneconomical. Forestry accounts for only 2% of employment within the basin (BC-LUCO 2000). Mining accounts for 5% of employment and includes the Eskay Creek mine (silver and gold), which is the world’s fifth-largest producer of silver. Large high-grade coal deposits occur in the basin, notably at Mount Klappen, but these are not currently being mined (BC-LUCO 2000). Government and other services account for over 50% of employment within the basin. Guide outfitting and ecotourism are other sources of employment. Contentious and largely unresolved issues over fisheries values remain, but these are partly addressed by the Pacific Salmon Treaty and similar legislation. This currently unimpounded river has enormous hydroelectric potential and the river remains at risk of being developed for energy in several reaches, including the Grand Canyon of the Stikine and the gorge on the Iskut River.

FIGURE 16.6 Skeena River below Terrace, British Columbia (PHOTO BY TIM PALMER).

SKEENA RIVER

The Skeena River arises in the interior plateau of British Columbia and the central mountains and flows west 579 km through the Coast Range Mountains to the Pacific (Fig. 16.17). This is the third-largest catchment within British Columbia (after the Fraser River [Chapter 15] and the Stikine River) at 42,200 km² (Fig. 16.6). Like the Stikine River, the Skeena is one of only three (also the Kamchatka River of Russia) large (>350 m³/s), free-flowing rivers in the Northern Hemisphere that drain a biome (Temperate Mountain Forest) other than the Boreal Forest and Tundra (Dynesius and Nilsson 1994).

The Skeena River catchment is the southernmost among the Pacific Coast rivers covered in this chapter. Like most of the coastal rivers, the Skeena River is a large producer of Pacific salmon. This basin supports the greatest diversity of forest types within the basins covered in this chapter and the highest intensity of land use, although still relatively low.

The area of the Skeena (the “river of mist”) has been settled by Native Americans for several thousand years, with the Tsimshian people near the coast and the Gitksan in the interior of the basin. These peoples developed a rich culture and permanent settlements based on the resources provided by returning salmon and eulachon, plants, abundant wildlife,

and, for the Tsimshian, the sea. The British Captain Vancouver is thought to be the first European to make contact with the Tsimshian in 1793 during surveying of the Pacific Coast. The first trading post was established by the Hudson's Bay Company in 1834 at Port Simpson on the coast, and in 1879 they established a trading post near Hazelton to serve the interior of the basin using the lower Skeena River as the transportation corridor from the coast. The Grand Trunk Railway, completed to the coast in 1913, opened the basin to further development.

Physiography, Climate, and Land Use

The Skeena River sits in the Coast Mountains of British Columbia and Southeast Alaska (PM) physiographic province (see Fig. 16.17). The basin drains from many mountain ranges, including parts of the east side of the Coast Range Mountains, the Nass Ranges, the Bulkley Ranges, the Babine Range, and the Skeena Mountains. Many peaks in the catchment exceed 2000 m asl and most of the basin is mountainous.

The different forest types found in the Skeena River basin are somewhat similar to the Stikine River (previously discussed). The British Columbia Mainland Coastal Forests terrestrial ecoregion penetrates almost 180 km from the coast along the Skeena River. This lowland portion of the basin includes western hemlock, western red cedar, and amabilis fir in the low elevations, and mountain hemlock, subalpine fir, and yellow cedar in the subalpine zone (Ricketts et al. 1999). At higher elevations is the Northern Transitional Alpine Forests ecoregion, which is dominated by subalpine fir and mountain hemlock. There is also the Fraser Plateau and Basin Complex ecoregion, which is characterized by Engelmann spruce, lodgepole pine, and subalpine fir. The highest portion of the Skeena basin drains from the Central British Columbia Mountain Forests ecoregion. This region includes Engelmann spruce, alpine fir, lodgepole pine, quaking aspen, white and black spruce, and a small amount of alpine tundra (<0.3% of catchment area).

The climate of the Skeena basin is modified by the rain shadow imposed by the Coast Range, and annual precipitation in the valley bottom averages 62 cm. Precipitation is not highly seasonal in the valley, but is lowest (<4 cm/mo) from February through May and highest (up to 8 cm/mo) from October to January (Fig. 16.18). As with many of the northern basins in western North America, there are relatively few weather recording stations. Most are in the valleys, associated with airports and towns,

and do not reflect adequately the overall conditions in the majority of the basin, which is at higher elevation and receives more precipitation and is colder than the recording stations. Average air temperature for the towns in the valley is about 4°C, with a low of -11°C in January and a high of 16°C in July (see Fig. 16.18). However, there is a large amount of variation across a catchment of over 50,000 km².

Most of the basin remains in forest (>90%). There are several industries in the basin, including forestry, mining, recreation, and service providers. Forestry is a major industry within the basin, accounting for >20% of employment within the region (Tamblyn and Horn 2001). However, only 39% of the catchment is considered productive forestland, and only 6% is considered operable timber-producing area because of steep terrain and other limitations (Tamblyn and Horn 2001). The primary tree species harvested are western hemlock, western red cedar, amabilis fir, Sitka spruce, yellow cedar, and cottonwood.

The primary mineral resources are gold, silver, copper, zinc, and lead. There are at least 14 active sites for mineral exploration or extraction in the catchment. Most of these are small operations. Sport fishing, hunting, and other outdoor recreation in the basin are popular due to its wilderness setting (Tamblyn and Horn 2001). Agriculture is very scarce in the area and the potential for agriculture is low. Thus, there is no irrigation use of water from the river or its tributaries.

River Geomorphology, Hydrology, and Chemistry

The Skeena River reaches the ocean in a broad, braided alluvial channel as it passes through the Coast Mountain Range. The majority of the river's basin is inland of the Coast Range, with only minor tributaries west of the city of Terrace (see Fig. 16.17). The river gradient up to Terrace from the estuary is only 0.63 m/km and navigable (see Fig. 16.6). Two large tributaries, the Bulkley and Kispiox rivers, meet the Skeena River near the town of Hazelton. Several other large tributaries to the river include the Morice, Babine, and Kitsumkalum rivers. Upstream of Terrace the gradient of the river through the 180 km to the confluence with the Babine River is about 1.42 m/km and alternates between reaches with gravel bars and alluvial development and strongly constrained sections with steep margins, such as the reach adjacent to the Skeena Mountains. Upstream of the confluence with the Babine River the river

gradient reaches 4.0 m/km until the junction with the Sustut River, and even steeper upstream of that. The river is cobble bottom throughout and gravel bars in alluvial reaches are common in many segments of the river downstream of the Babine River.

The hydrology of the river is snowmelt dominated, although coastal areas receive a large amount of rain in winter, but this includes only a small portion of the basin. The Skeena basin has the least glacier influence of any of the rivers treated in this chapter. The Skeena River system has a reservoir on one of its tributaries, with a gross capacity of about 0.2% of its flow (Dynesius and Nilsson 1994). Runoff is dominated by snowmelt and peaks in May and June (see Fig. 16.18), earlier than the other rivers in this chapter. Parts of the Skeena River basin in the Nechako Plateau have greater groundwater storage than other parts of the region and can supply up to 90 L/min through pumping.

Water chemistry has been measured by Environment Canada nearly every two weeks (1984 to 2000) at Usk near the Pacific Ocean (www.ec.gc.ca/water). Like most rivers in the region the water temperature is near 0°C for nearly six months of the year, with an approximate average annual temperature of 6°C (based on unweighted data from biweekly samples). Summer maximum temperature at that station is about 14°C to 16°C in most summers, peaking about late July to early August, but temperatures as high as 24°C and 26°C have been recorded during that interval. Turbidity does not have the regular seasonal extremes of more northern and glacial-influenced rivers, but peaks in excess of 200 NTUs have been recorded a couple of times during the period of record. Mean values for other standard water-chemistry values include alkalinity 41 mg/L as CaCO₃, pH 7.6, NO₃-N 0.08 mg/L, and total phosphorus 0.057 mg/L.

River Biodiversity and Ecology

The Skeena is the southernmost river from this chapter located within the North Pacific Coastal freshwater ecoregion (Abell et al. 2000). As with many of these rivers, the biological and ecological information is relatively sparse, with the exception of the salmon populations.

Plants

Riparian plants associated with the margins of the river include alders, willows, black cottonwood, and trembling aspen. Thimbleberry and black twinberry provide an important shrub layer in the understory.

Invertebrates

We are unaware of any published studies of invertebrates in the Skeena, but some unpublished data have been collected by Shauna Bennett (University of British Columbia) and Ian Sharpe (British Columbia Ministry of Water, Land, and Air Protection). The most common mayfly genera are *Baetis*, *Rhithrogena*, *Epeorus*, *Cinygmula*, *Drunella*, *Serratella*, and *Paraleptophlebia*. Caddisflies include hydropsychids and *Rhyacophila*, and stoneflies include *Sweltsa* and *Zapada*. As in most riverine systems, oligochaete worms are present, and the dipterans are well represented by chironomid midges and black flies.

Vertebrates

As with all the rivers in this chapter, this is a major salmon-producing river, with the five species of Pacific salmon (chinook, coho, sockeye, chum, and pink) and steelhead present. About half of the stocks in this river lack sufficient data to determine trends. From the 515 individual stocks (species and breeding populations) for which data are available, 2 are known to have gone extinct and 45 more are considered to be at moderate to high risk of extinction (Slaney et al. 1996). The nonanadromous form of sockeye (kokanee) is found in some lakes of the region, notably Babine Lake.

The rest of the fish community includes Pacific lamprey, humpback whitefish complex, lake trout, Dolly Varden, longfin smelt, boreal smelt complex, eulachon, longnose sucker, burbot, threespine stickleback, and coastrange sculpin. Bull trout, found in most of the Taku, Stikine, Nass, and Skeena catchments but not further north, is on British Columbia's blue list (Williams et al. 1989). Giant pygmy whitefish (*Prosopium* sp. nr. *coulteri*) is found in only two lakes in the world, one of which is in the Skeena drainage, and appears to have diverged from *P. coulteri* (Cannings and Ptolemy 1998). This species has not been formally described, but as a distinct form is listed on British Columbia's red list.

The tailed frog is found in some of the tributaries of the Skeena and Nass river systems, mostly in the Coast Mountains, and is listed as vulnerable (blue list) in British Columbia. It is the only amphibian or reptile associated with the rivers in this chapter, which are past the northern limits of most species of these groups of organisms.

Grizzly bears typically occur at higher densities in coastal areas and are thought to be secure in the catchment, with densities of approximately 0.035 per km² (Tamblyn and Horn 2001). Salmon form an

important food resource for coastal grizzly bear (also known as brown bears). Fishes also sustain good populations of river otter, mink, bald eagle, osprey, kingfisher, and merganser. Dippers and spotted sandpiper are common in the catchment. Beaver reach high densities and are thought to still be recovering from heavy exploitation during the fur-trading days of the early nineteenth century in this part of the continent. Muskrat and moose are also common inhabitants of riparian areas of the streams and wetlands of the catchment.

Ecosystem Processes

Studies of ecosystem processes are lacking, except for assessments of salmonid production. The Skeena system is considered to be among the three greatest salmonid-producing rivers in the world, after the Fraser and Columbia rivers (Northcote and Larkin 1989). Pink salmon is the most abundant of the anadromous fishes in the Skeena River system, with escapements numbering from 0.5 to 3 million fish per year (Tamblyn and Horn 2001). Pink salmon have an odd-even year alternation of dominant runs, with odd years being higher. Adult sockeye salmon escapements to the river number up to 1.6 million fish per year, of which the Babine Lake stock makes up the largest proportion in the Skeena system. The Babine Lake sockeye run numbers from 0.5 to 1.5 million fish per year. Numbers of adult Chinook salmon range from 40,000 to 50,000 per year, and chum salmon about 10,000 to 20,000 per year (Tamblyn and Horn 2001). Numbers of most stocks appear to be improving after lower numbers during the 1980s and early 1990s. Annual harvests of salmon returning to the Skeena system have averaged 5.8 million pink salmon, ~2 million sockeye, 0.5 million chum, 300,000 coho, and about 80,000 chinook (Tamblyn and Horn 2001).

Human Impacts and Special Features

Although the Skeena River basin is the most populated basin covered in this chapter, with towns mostly based on service industries to resource extraction, population densities in the drainage are still relatively low. Much of the Skeena basin is still largely a forested wilderness area, and the main-stem river is undammed. The major population centers include Terrace, Smithers, and Houston. The city of Prince Rupert is not within the basin proper but lies at the mouth of the river where it enters the Pacific Ocean and is thought to have been the largest Native

American center north of Mexico because of its rich resources and strategic location (Tamblyn and Horn 2001). Overall population densities in the drainage are low relative to other parts of North America.

Forestry and mining occur in the basin, with a minor amount of agriculture. Forest harvesting occurs in areas around the Skeena basin and other coastal areas and generates the highest rates of timber harvest for basins within this region. A plan to divert part of the Skeena basin into the Nechako Reservoir (Fraser basin) was stopped by the government in the early 1990s. At present the Skeena River basin appears to be free of proposals for major dams.

ADDITIONAL RIVERS

The Nushagak River drains a nearly pristine area of southwest Alaska south of the Alaska Range, and near the town of Dillingham flows into Bristol Bay in the south Bering Sea (Fig. 16.19). The lower 100 km of the river has a low gradient and meanders through a large wetlands complex. There are many lakes in the catchment supporting a large sockeye salmon production, and the basin also produces many other salmon. There is less glacial influence on turbidity in this river system because of the low elevation of most of the basin and the presence of many lakes, which themselves are still turbid with glacial “flour.” The basin is sparsely populated, largely by Native Americans with a fishing- and hunting-based economy. The University of Washington has maintained a research station at Woods Lakes in the basin for many years. There are two National Wild and Scenic Rivers in the basin, the Mulchatna River and the Chilikadrotna River.

The Copper River is a large braided river flowing south into the Gulf of Alaska just east of Cordova (Fig. 16.21). The river is highly influenced by glaciers from which it originates in the Alaska Range to the north and east parts of the basin. The catchment has little development, but the highways connecting Anchorage and Valdez to the interior parts of the state, including Fairbanks, follows the river north. Most study of the river has been devoted to examining the geomorphology and hydrology of the river to safeguard highway construction, especially bridges associated with the highways, as it has a highly mobile river bed and high rates of bedload movement. The Copper River is also prone to outburst floods (*Jökulhlaup* event) from the sudden release of glacier-dammed lakes, which can cause large flood peaks, potentially causing damage to developments

FIGURE 16.7 Copper River (left to right) at confluence with Chitina River (center in distance), its largest tributary, at Chitina, Alaska (PHOTO BY M. C. T. SMITH).

downstream (Brabets 1997). The river exports an average of 70 million tonnes of suspended sediment per year, as much as the Yukon River, which drains an area >10 times larger (Brabets 1997) (Fig. 16.7). As with other rivers in the region, it helps support a productive fishery for Pacific salmon.

The Alsek River and its major tributary, the Tatshenshini River, are highly braided and geomorphically active glacial rivers, parts of which are in the Canadian Heritage Rivers system. The dramatic mountain landscape of the basin shows the effects of glacial advance and retreat, including the periodic breaking of glacier ice dams, even in modern times

as glaciers have retreated during the past century (Fig. 16.8). The tributaries of the rivers arise from high in the Alaska Range in the Yukon Territories and British Columbia and flow southwest into the Gulf of Alaska (Fig. 16.23). The lower part of the Alsek River passes between high mountains on its way to the ocean. This pristine basin is almost entirely protected in the Kluane National Park in the Yukon Territories and Tatshenshini–Alsek Park in British Columbia. These parks, along with the adjacent Wrangell–St. Elias National Park and Glacier Bay National Park of Alaska, make up the world's largest protected area and have large populations of

FIGURE 16.8 Alsek River (top) at confluence with Tatshenshini River (right), its largest tributary, in British Columbia (PHOTO BY M. C. T. SMITH).

wildlife, including grizzly bear, golden eagle, moose, Dall sheep, and many others. This is another wild salmon river, and the productivity of the Pacific salmon has long been part of the subsistence basis of the native Tlingit people. The river is a world-class destination for river rafting, and recreational tourism is the main activity in the basin.

The Taku River is a highly braided, glacially influenced river flowing from glaciers in the Alaska Range southwest through British Columbia, then flowing westward to enter the Gulf of Alaska near Juneau (Fig. 16.25). This turbid river also experiences outburst floods nearly every year from Tulsequah Lake, which cause sudden increases in flow as glacier-dammed lakes empty and may cause damage downstream. The river supports substantial populations of all the Pacific salmon and steelhead. The highly active riverbed and high amounts of suspended load cause unstable channels and fine sediment deposition in lower-gradient sections but highly productive spawning habitats for salmon in other reaches. Down-

stream of the U.S.–Canada border the river becomes wide for 28 km, and the lower 30 km of the river is broad and tidally influenced, providing nursery habitat for juvenile salmonids prior to going to the ocean (Murphy et al. 1997).

The Nass River originates in the high mountains in the Coast Range Mountains and Hazelton Mountains of British Columbia and flows into the Portland Canal, a fjord of the Pacific Ocean (Fig. 16.27). The braided river has a variety of sources, some highly influenced by glacier melt and others predominated by snowmelt. The basin is the traditional territory of the Nisga'a people. The land is mostly pristine and as with most rivers in this chapter has no regulation of flows; however, there has been logging and mining activity in the catchment. The basin shows signs of volcanic activity, including more than 15 km² of Nisga'a lava beds, formed within the past 300 years, and other earlier flows from the Tseax cone. This is another of the productive salmon rivers of the north Pacific.

ACKNOWLEDGMENTS

We are grateful to the many people who provided information in response to our inquiries, particularly Jim Edmondson from the Alaska Department of Fish and Game, and others from the U.S. Geological Survey and B.C. Ministry of Water, Land, and Air Protection. We thank Shauna Bennett, Ian Sharpe, Benoit Godin, and Len Fanning for use of unpublished invertebrate data. We greatly appreciate the considerable efforts of Art Benke and Colbert Cushing in reviewing and editing this chapter.

FIGURE 16.9 Map of the Kuskokwim River basin. Physiographic provinces are separated by the yellow line.

KUSKOKWIM RIVER

Relief: >3550m

Basin area: 124,319km²

Mean discharge: 1900m³/s

River order: 9 (approximated)

Mean annual precipitation: 42.0cm

Mean air temperature: ~-1.6°C

Mean water temperature: ~-5°C

Physiographic provinces: Yukon Basin (YB), South Central Alaska (SC)

Biomes: Tundra, Boreal Forest

Freshwater ecoregion: Yukon

Terrestrial ecoregions: Beringian Lowland Tundra, Beringian Upland Tundra, Alaska/St. Elias Range Tundra, Interior Alaska/Yukon Lowland Taiga

Number of fish species: 27 to 31

Number of endangered species: none

Major fishes: sockeye salmon, chinook salmon, coho salmon, chum salmon, pink salmon, Pacific lamprey, humpback whitefish, lake trout,

Dolly Varden, longfin smelt, boreal smelt, eulachon, longnose sucker, burbot, threespine stickleback, coastrange sculpin

Major other aquatic vertebrates: river otter, muskrat, moose, mink, merganser, belted kingfisher, American dipper

Major benthic invertebrates: NA

Nonnative species: none

Major riparian plants: willows, alder

Special features: globally important wildlife area in Yukon–Kuskokwim delta, especially for breeding waterfowl; part of Beringian glacial refuge and home to several endemic species; a variety of water sources, including glacier runoff, snowmelt, wetlands, and forest; mostly pristine wilderness

Fragmentation: none

Water quality: generally high suspended sediment loads; nutrient concentrations low; NO₂-N + NO₃-N = 0.04 to 0.08 mg/L, total phosphorus = 0.01 to 0.05 mg/L; mercury elevated in much of basin from natural sources and past mining

Land use: >99% taiga, tundra, or ice fields, with <1% of the basin developed; subsistence hunting and fishing; Bethel is the primary settlement in basin

Population density: ~0.1 people/km²

Major information sources: Nelson et al. 1977, Wang 1999, Dynesius and Nilsson 1994

FIGURE 16.10 Mean monthly air temperature, precipitation, and runoff for the Kuskokwim River basin.

FIGURE 16.11 Map of the Susitna River basin.

SUSITNA RIVER

Relief: >4000 m
Basin area: 51,800 km²
Mean discharge: 1427 m³/s
River order: 7
Mean annual precipitation: 70.8 cm (underestimate)
Mean air temperature: 0.8°C
Mean water temperature: 4.3°C
Physiographic province: South Central Alaska (SC)
Biomes: Tundra, Boreal Forest
Freshwater ecoregion: North Pacific Coastal
Terrestrial ecoregions: Cook Inlet Taiga, Alaska/St. Elias Range
 Tundra, Copper Plateau Taiga
Number of fish species: 25 to 29
Number of endangered species: none
Major fishes: chinook salmon, coho salmon, chum salmon, pink salmon, sockeye salmon, Bering cisco, round whitefish, rainbow trout, Dolly Varden, Arctic grayling, Arctic lamprey, burbot
Major other aquatic vertebrates: river otter, muskrat, moose, mink, merganser, belted kingfisher, American dipper
Major benthic invertebrates: chironomid midges, oligochaete worms, stoneflies (capniids), mayflies (*Baetis*, *Cinygmula*)
Nonnative species: none
Major riparian plants: willow, alder, cottonwood
Special features: major glacier-fed system that dominates landscape to the southwest of Alaska Range with many complex, off-channel habitats; drains from Mount McKinley, highest point in North America, and other glaciated peaks of the Alaska Range (U.S.)
Fragmentation: none
Water quality: no major pollutants; middle river (Gold Creek) pH = 7.3, alkalinity = 50 mg/L as CaCO₃, NO₃-N = 0.15 mg/L, total phosphorus = 0.12 mg/L, turbidity (summer) = 200 NTU
Land use: 95% forest and tundra, 5% glaciers; mostly wilderness
Population density: ~0.01 people/km²
Major information sources: Kyle and Brabets 2001; Alaska Department of Fish and Game 1984a, 1984b, 1984c; Alaska Power Authority 1985

FIGURE 16.12 Mean monthly air temperature, precipitation, and runoff for the Susitna River basin.

FIGURE 16.14 Mean monthly air temperature, precipitation, and runoff for the Kenai River basin.

KENAI RIVER

Relief: >1500 m

Basin area: 5206 km²

Mean discharge: 167.7 m³/s

River order: 6

Mean annual precipitation: 48.8 cm (underestimate)

Mean air temperature: 0.9°C

Mean water temperature: 6.4°C

Physiographic province: South Central Alaska (SC)

Biome: Temperate Coniferous Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: Northern Pacific Coastal Forests, Pacific Coastal Mountain Tundra and Ice Fields

Number of fish species: 28

Number of endangered species: none

Major fishes: Dolly Varden, Arctic grayling, chinook salmon, sockeye salmon, coho salmon, pink salmon, chum salmon, rainbow trout, steelhead, Pacific lamprey, humpback whitefish, lake trout, longfin smelt, boreal smelt, eulachon, longnose sucker, burbot, threespine stickleback, coastrange sculpin

Major other aquatic vertebrates: river otter, muskrat, beaver, moose, mink, merganser, belted kingfisher, American dipper

Major benthic invertebrates: chironomid midges (*Diamesa*, *Cricotopus/Orthocladius*, *Pagastia*, *Parakiefferiella*, *Eukiefferiella*, *Rheotanytarsus*), mayflies (*Baetis*, *Cinygmula*, *Ephemerella*), stoneflies (*Paraleuctra*, *Plumiperla*, *Isoperla*), caddisflies (*Brachycentrus*, *Ecclisocosmoceus*, *Glossosoma*, *Hydropsyche*)

Nonnative species: none

Major riparian plants: willow, alder

Special features: diversity of clearwater, glacier-influenced, and wetland-stained river systems; very productive salmon river; large tourism industry based on freshwater and tidal zone fishing; valuable economies through commercial and sports fisheries

Fragmentation: none

Water quality: no major pollutants except possible organic enrichment around Soldotna; pH = ~7.0, alkalinity = 25 mg/L as CaCO₃, conductivity = 30 to 81 μS/cm, NO₃-N + NO₂-N = 150 to 250 μg/L, total phosphorus = <10 μg/L, turbidity = 2 to 18 NTU

Land use: >95% forest and wetlands, with small amounts of development; primarily undeveloped with many wetland areas; recreational cabins along river with some guiding/tourist facilities, mostly on main stem

Population density: ~3.3 people/km²

Major information sources: Boggs et al. 1997, Brabets et al. 1999, Litchfield and Kyle 1992

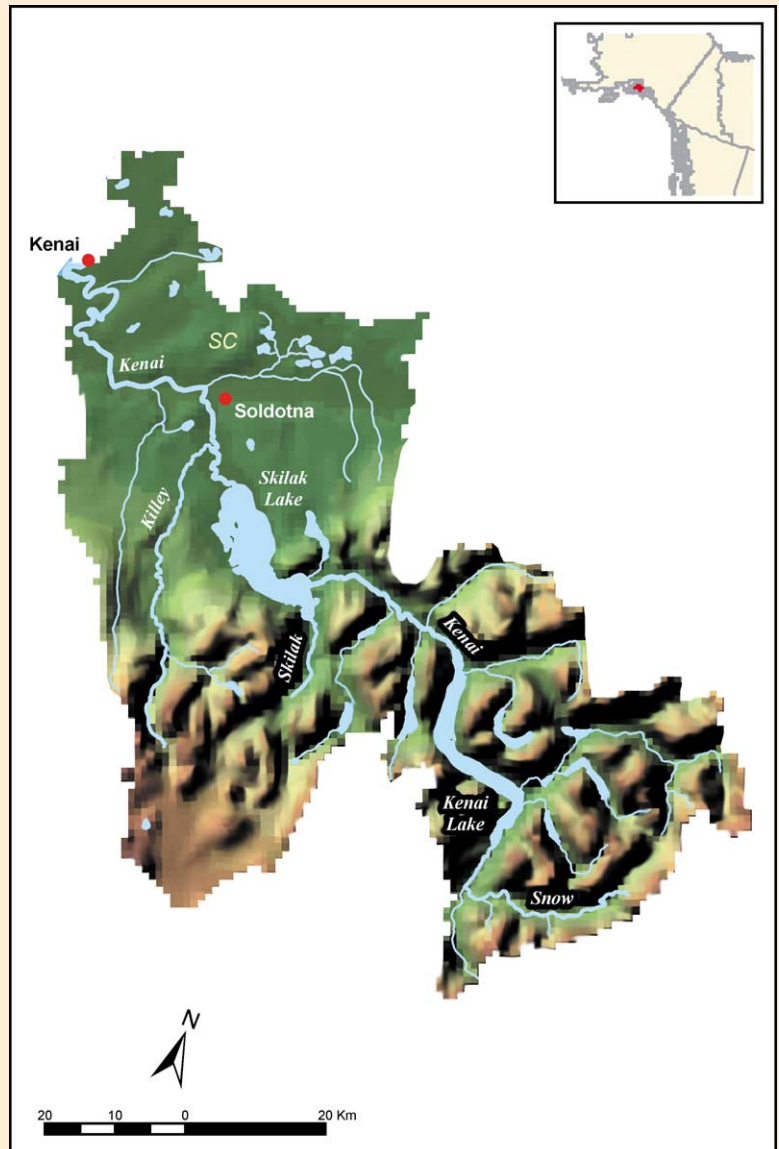

FIGURE 16.13 Map of the Kenai River basin.

FIGURE 16.15 Map of the Stikine River basin.

STIKINE RIVER

Relief: >2900m

Basin area: 51,592 km²

Mean discharge: 1587 m³/s

River order: 8

Mean annual precipitation: 37.7 cm (underestimate)

Mean air temperature: 2.0°C

Mean water temperature: 6.6°C

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biomes: Temperate Mountain Forest, Boreal Forest, Tundra

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: Northern Cordillera Forests, Pacific Coastal Mountain Tundra and Ice Fields, Northern Pacific Coastal Forests, Northern Transitional Alpine Forests

Number of fish species: 22 to 26

Number of endangered species: 1 fish (threatened)

Major fishes: sockeye salmon, chinook salmon, Arctic grayling, burbot, chum salmon, coho salmon, cutthroat trout, longnose sucker, mountain whitefish, rainbow trout, lake chub, pink salmon, threespine stickleback, sculpins

Major other aquatic vertebrates: river otter, muskrat, beaver, moose, mink, merganser, belted kingfisher, American dipper

Major benthic invertebrates: mayflies (*Baetis*, *Cinygmula*, *Rhithrogena*, *Ameletus*), stoneflies (*Suwallia*, *Capnia*, *Doddsia*, *Isoperla*, *Podmosta*, *Zapada*), chironomid midges (*Diamesa*, *Cricotopus*, *Orthocladius*, *Euryhopsis*, *Eukiefferiella*), Acarina

Nonnative species: none; threats of Atlantic salmon; historical records of American shad

Major riparian plants: willows, alders, cottonwood

Special features: one of the largest free-flowing rivers draining a temperate biome; largely pristine wilderness with some glacial drainage; drains Edziza Provincial Park and Spatsizi Plateau Wilderness Provincial Park

Fragmentation: none

Water quality: naturally elevated metals, copper usually = >10 µg/L (5 to 60 µg/L), iron usually = >0.3 mg/L (0.2 to 11 mg/L), zinc = ~15 µg/L; alkalinity = 45 to 90 mg/L as CaCO₃, pH = 7.8, NO₃-N = 0.1 mg/L, total phosphorus = 0.2 mg/L, turbidity (summer maximum) = 50 to 350 NTU

Land use: subsistence hunting and fishing, mining, and low levels of timber extraction; over 95% of the basin is covered by forest, alpine tundra, and ice fields

Population density: <0.025 people/km²

Major information sources: www.dfo-mpo.gc.ca 1999, L. Fanning, unpublished data

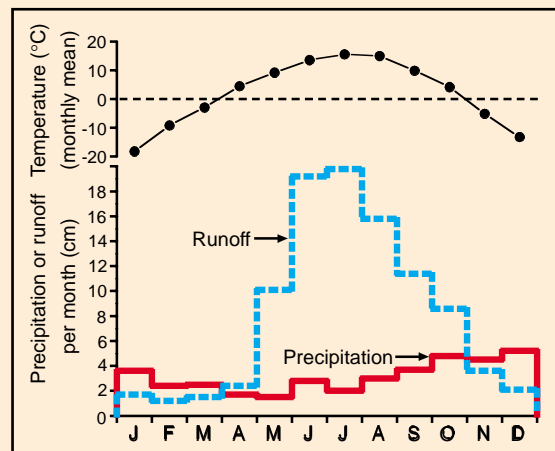

FIGURE 16.16 Mean monthly air temperature, precipitation, and runoff for the Stikine River basin.

FIGURE 16.18 Mean monthly air temperature, precipitation, and runoff for the Skeena River basin.

SKEENA RIVER

Relief: 2755 m

Basin area: 54,400 km²

Mean discharge: 1760 m³/s

River order: 8

Mean annual precipitation: 62.5 cm (underestimate)

Mean air temperature: 4.3°C

Mean water temperature: -6.0°C

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biomes: Temperate Mountain Forest, Boreal Forest, Tundra

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: British Columbia Mainland

Coastal Forests, Northern Transitional Alpine

Forests, Fraser Plateau and Basin Complex,

Central British Columbia Mountain Forests

Number of fish species: 33

Number of endangered species: 1 fish

Major fishes: pink salmon, sockeye salmon, chinook salmon, coho salmon, steelhead, rainbow trout,

cutthroat trout, Dolly Varden, eulachon, burbot, mountain whitefish, chum salmon, prickly sculpin, Pacific lamprey, burbot, largescale sucker, peamouth chub, pygmy whitefish, white sucker, white sturgeon, northern pikeminnow

Major other aquatic vertebrates: river otter, muskrat, beaver, moose, mink, merganser, belted kingfisher, American dipper, tailed frog

Major benthic invertebrates: chironomid midges, black flies, Oligochaete worms, mayflies (*Baetis*, *Rhithrogena*, *Epeorus*, *Cinygmula*, *Drunella*, *Serratella*, *Paraleptophlebia*), stoneflies (*Sweltsa*, *Zapada*), caddisflies (*Hydropsychidae*, *Rhyacophila*)

Nonnative species: none; threats of Atlantic salmon; historical records of American shad

Major riparian plants: willows, alders, vine maple, western red cedar, western hemlock

Special features: largest free-flowing river in North America draining a temperate biome; productive salmon river

Fragmentation: very low; dam in tributary affects about 0.2% of total flow

Water quality: alkalinity = 41 mg/L as CaCO₃, pH = 7.6, NO₃-N = 0.08 mg/L, total phosphorus = 0.057 mg/L, turbidity = 16.9 NTUs (summer maximum up to 250)

Land use: >95% forest; moderate levels of timber extraction, some mining, limited agriculture

Population density: <3 people/km²

Major information sources: McPhail and Carveth 1999, Shauna Bennett and Ian Sharpe, personal communication, Dynesius and Nilsson 1994

FIGURE 16.17 Map of the Skeena River basin.

FIGURE 16.19 Map of the Nushagak River basin. Physiographic provinces are separated by the yellow line.

NUSHAGAK RIVER

Relief: ~600 m
Basin area: 34,706 km²
Mean discharge: 1000 m³/s
River order: 8
Mean annual precipitation: 66.3 cm (underestimate)
Mean air temperature: 0.9°C
Mean water temperature: NA
Physiographic provinces: Yukon Basin (YB), South Central Alaska (SC)
Biomes: Tundra, Boreal Forest, Temperate Mountain Forest
Freshwater ecoregion: Yukon
Terrestrial ecoregions: Beringia Lowland Tundra, Interior Alaska/Yukon Lowland Taiga, Alaska/St. Elias Range Tundra
Number of fish species: 27 to 31
Number of endangered species: none
Major fishes: sockeye salmon, chinook salmon, coho salmon, chum salmon, pink salmon, Alaska blackfish, Dolly Varden, northern pike, rainbow trout, slimy sculpin, Arctic grayling, lake trout, threespine stickleback, rainbow smelt, humpback whitefish, Pacific lamprey, burbot
Major other aquatic vertebrates: river otter, muskrat, moose, mink, merganser, belted kingfisher, American dipper
Major benthic invertebrates: mayflies (Ephemeroptera), chironomid midges, triclad flatworms, stoneflies (Chloroperlidae, Nemouridae), crustaceans (ostracods), caddisflies (Hydroptilidae, Glossosomatidae), bivalves
Nonnative species: none
Major riparian plants: grasses, willow, alder
Special features: pristine wilderness; Mulchatna and Chilikadrotna tributaries are U.S. National Wild and Scenic Rivers; large glacial lakes are predominant feature of basin; long-term studies of salmon and their food webs by University of Washington at Woods Lakes research station
Fragmentation: none
Water quality: high quality, no pollution
Land use: >99% of the basin is forest, taiga, and tundra; mostly wilderness; subsistence hunting and fishing by native population; Dillingham is largest settled area, with ~2500 people
Population density: <0.1 people/km²
Major information source: Peterson and Foote 2000

FIGURE 16.20 Mean monthly air temperature, precipitation, and runoff for the Nushagak River basin.

FIGURE 16.22 Mean monthly air temperature, precipitation, and runoff for the Copper River basin.

COPPER RIVER

Relief: >2500 m

Basin area: 63,196 km²

Mean discharge: 1785 m³/s

River order: ~7

Mean annual precipitation: 28.4 cm (underestimate)

Mean air temperature: -2.7°C

Mean water temperature: NA

Physiographic province: South Central Alaska (SC)

Biomes: Tundra, Boreal Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: Copper Plateau Taiga, Pacific Coastal Mountain Tundra and Ice Fields, Alaska/St. Elias Range Tundra

Number of fish species: 24 to 27

Number of endangered species: none

Major fishes: coho salmon, longnose sucker, arctic grayling, Dolly Varden, chinook salmon, sockeye salmon, chum salmon, round whitefish, slimy sculpin

Major other aquatic vertebrates: river otter, muskrat, beaver, moose, mink, merganser, belted kingfisher, American dipper

Major benthic invertebrates: chironomid midges (particularly *Diamesa*), black flies, crane flies, mayflies (Baetidae, Ameletidae, Ephemerellidae, Heptageniidae), stoneflies (Nemouridae, Chloroperlidae), caddisflies (Lepidostomatidae)

Nonnative species: none

Major riparian plants: willows, alders

Special features: Gulkana River, a tributary, is a U.S. National Wild and Scenic River; drains from Wrangell–St. Elias National Park (U.S.) and Kluane National Park (Canada)

Fragmentation: none

Water quality: no pollution

Land use: >99% of the basin is in forest, tundra, or ice; undeveloped

Population density: <0.05 people/km²

Major information source: Mount et al. 2002

FIGURE 16.21 Map of the Copper River basin.

FIGURE 16.24 Mean monthly air temperature, precipitation, and runoff for the Alsek River basin.

ALSEK RIVER

Relief: >3000 m

Basin area: 28,023 km²

Mean discharge: 862.6 m³/s

River order: 6

Mean annual precipitation: 30.6 cm (underestimate)

Mean air temperature: -2.9°C

Mean water temperature: NA

Physiographic provinces: South Central Alaska (SC), Coast Mountains of British Columbia and Southeast Alaska (PM), Yukon Basin (YB)

Biomes: Tundra, Boreal Forest, Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: Pacific Coastal Mountain Tundra and Ice Fields, Alaska/St. Elias Range Tundra, Northern Cordillera Forests

Number of fish species: ≥32

Number of endangered species: none

Major fishes: Arctic grayling, chinook salmon, coho salmon, cutthroat trout, Dolly Varden, sockeye salmon, steelhead, chum salmon, burbot, northern pike, lake trout

Major other aquatic vertebrates: river otter, muskrat, beaver, moose, mink, merganser, belted kingfisher, American dipper

Major benthic invertebrates: chironomid midges (*Diamesa*, *Cricotopus*, *Rheotanytarsus*, *Eukiefferiella*, *Thienemannimyia*), mayflies (*Cinygmula*, *Baetis*, *Ephemerella*, *Rhithrogena*, *Drunella*), stoneflies (*Sweltsa*, *Capnia*)

Nonnative species: none; threats of Atlantic salmon; historical records of American shad

Major riparian plants: willows, alders

Special features: most of basin protected within wilderness areas and National Parks; Alsek and its major tributary, the Tatshenshini River, are part of Canadian Heritage River system and part of World Heritage Site (UNESCO); popular for river rafting

Fragmentation: one tributary has dam affecting ~2% of Alsek flow in live storage

Water quality: sparse data for Alsek River above Bates River; alkalinity = ~70 mg/L as CaCO₃, hardness = ~90 mg/L as CaCO₃, conductivity = ~180 μS/cm, NO₃-N = ~0.08 mg/L, total phosphorus = ~0.2 mg/L, pH = 8.2, turbidity (summer) peaks = 65 to 175 NTU

Land use: largely pristine and protected in parks and reserves, such as Kluane National Park in the Yukon Territories; minor amounts of development; >95% of the basin is covered in forest, taiga, tundra, and ice

Population density: <0.01 people/km²

Major information sources: Benoit Godin, personal communication, Dynesius and Nilsson 1994

FIGURE 16.23 Map of the Alsek River basin. Physiographic provinces are separated by yellow lines.

FIGURE 16.25 Map of the Taku River basin.

TAKU RIVER

Relief: >2300 m

Basin area: 29,800 km²

Mean discharge: 600 m³/s

River order: 8

Mean annual precipitation: 33.8 cm (underestimate)

Mean air temperature: 0°C

Mean water temperature: NA

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biomes: Tundra, Boreal Forest, Temperate Mountain Forest

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: Pacific Coastal Mountain Tundra and Ice

Fields, Northern Cordillera Forests, Yukon Interior Dry Forests

Number of fish species: ≥32

Number of endangered species: none

Major fishes: sockeye salmon, pink salmon, coho salmon, chinook salmon, Dolly Varden, cutthroat trout, steelhead, chum salmon, eulachon, longfin smelt, Pacific lamprey, round whitefish, slimy sculpin, threespine stickleback

Major other aquatic vertebrates: river otter, muskrat, beaver, moose, mink, merganser, belted kingfisher, American dipper

Major benthic invertebrates: NA

Nonnative species: none; threats of Atlantic salmon; historical records of American shad

Major riparian plants: alders, willows

Special features: primarily wilderness basin; peak flows fill Tulsequah Lake and cause lake outburst events most years (as lake swells the water can float the glacier or melt it sufficiently to cause sudden releases); popular river for rafting; very productive salmon river

Fragmentation: none

Water quality: elevated Cu, Pb, and Zn concentrations; turbidity = 200 NTUs (summer peak); very little “clear” water (not glacier influenced) in basin

Land use: basin is covered by forest, tundra, and ice fields, with <1% of basin developed; subsistence hunting and fishing, ecotourism, forestry, some placer mining; threats from mine developments, especially proposed reactivation of Tulsequah Chief mine (copper and other metals)

Population density: <0.025 people/km²

Major information source: McPhail and Carveth 1999

NASS RIVER

Relief: 2368 m

Basin area: 21,100 km²

Mean discharge: 892 m³/s

River order: 7

Mean annual precipitation: 129.5 cm

Mean air temperature: 6.1°C

Mean water temperature: NA

Physiographic province: Coast Mountains of British Columbia and Southeast Alaska (PM)

Biomes: Temperate Mountain Forest, Boreal Forest, Tundra

Freshwater ecoregion: North Pacific Coastal

Terrestrial ecoregions: British Columbia Mainland Coastal Forests, Northern Transitional Alpine Forests, Pacific Coastal Mountain Tundra and Ice Fields

Number of fish species: 27

Number of endangered species: none

Major fishes: chinook salmon, steelhead, chum salmon, coho salmon, sockeye salmon, pink salmon, cutthroat trout, eulachon, mountain whitefish, Dolly Varden, Pacific lamprey, threespine stickleback

Major other aquatic vertebrates: river otter, muskrat, beaver, moose, mink, merganser, belted kingfisher, American dipper

Major benthic invertebrates: NA

Nonnative species: none; threats of Atlantic salmon; historical records of American shad

Major riparian plants: willows, alders, cottonwood

Special features: largely pristine catchment draining extensive areas in lee of Coast Range Mountains; flows 380 km from most inland source to Pacific; drains large areas of high-elevation forest and tundra; productive salmon river

Fragmentation: none

Water quality: high quality

Land use: >95% forest, tundra, and a small amount of ice fields; largely wilderness; low levels of timber harvest and subsistence fishing, hunting, and trapping

Population density: ~0.14 people/km²

Major information source: McPhail and Carveth 1999

YUKON RIVER BASIN

ROBERT C. BAILEY

INTRODUCTION

YUKON RIVER MAIN STEM

TANANA RIVER

KOYUKUK RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

The Yukon basin is the 7th largest in North America (after the Mississippi, Missouri, St. Lawrence, Nelson, Mackenzie, and Rio Grande), with an area of 839,200 km². Approximately 61% of the basin is in Alaska and 39% is in Canada (Fig. 17.2). Most (>90%) of the Canadian portion of the basin is in the Yukon Territory, although many of the headwater lakes and streams are in northern British Columbia. The Yukon River is one of the wildest and is by far the longest free-flowing river in North America (Dynesius and Nilsson 1994), with only a single dam at its headwaters and one each on two of its major tributaries. From its headwater lakes less than 30 km from the Pacific Ocean in British Columbia to its outflow into the Bering Sea 3200 km downstream in Alaska, the vast Yukon River and its basin encompass a heterogeneous collection of often spectacular ecosystems, from ephemeral mountain streams to minideserts, from opaque glacial runoff rivers to clear boreal forest creeks, from torrential running waters to productive wetland “flats” of thousands of km² of small lakes and ponds. The southern origin of the Yukon River, draining the eastern side of the Coast Mountains and the west side of the Rockies in

northern British Columbia, is at a latitude of 59°N and a longitude that is about 15° west of Los Angeles (133°W). The Bering Sea outflow of the river at 63°N is 30° west (164°W) of the headwaters, and the river basin itself extends to a northern limit of about 68°N in the Porcupine River watershed.

Although sparsely populated, the Yukon River basin has been prehistorically and more recently very important to the human population of North America and the world. Most anthropologists agree that the first human colonization of North America was via a land bridge that crossed what is now Bering Strait >12,000 years ago (Yesner 2001). Subsequent to the colonization, the basin became an important resource-rich environment for the development and evolution of northern aboriginal communities. In the last 300 years the Yukon River basin has attracted fur traders and gold miners from Russia, southern North America, and around the world. More recently, and not without controversy, the basin has been part of a transportation route to the south for oil and gas rather than humans.

This chapter discusses the major features of the main-stem Yukon River, as well as two of its major tributaries, the Tanana and Koyukuk rivers (see Fig. 17.2). Abbreviated physical and biological descriptions are included for several smaller tributary rivers,

◀ **FIGURE 17.1** South Fork of the Koyukuk River, from the Dalton Highway along the Trans-Alaskan pipeline, Alaska (PHOTO BY D. SHIOZAWA).

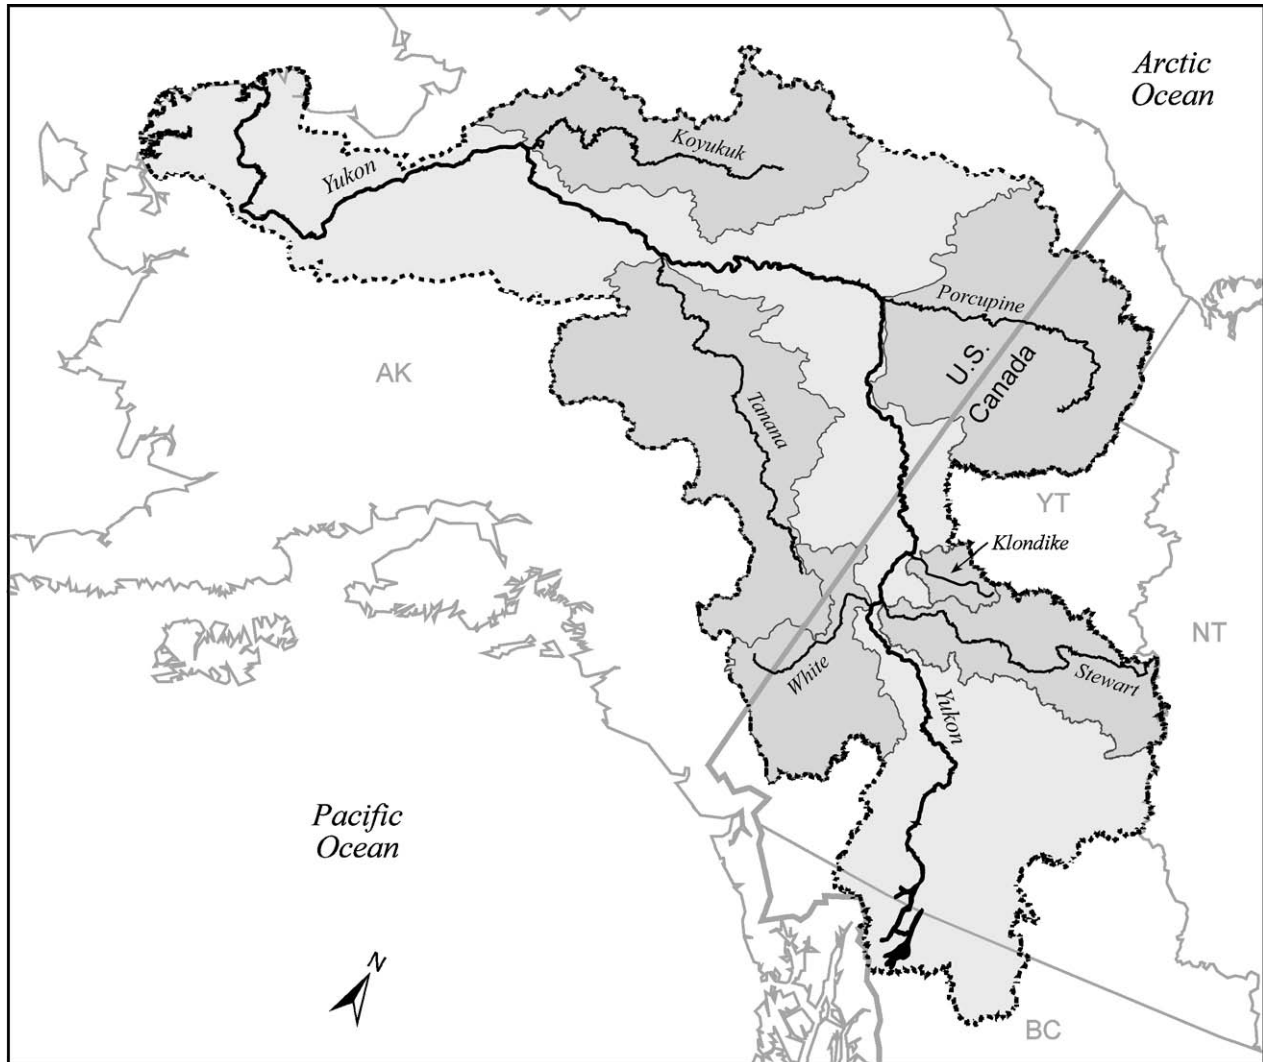

FIGURE 17.2 Rivers of the Yukon River basin covered in this chapter.

including the historically and economically important Klondike River and Stewart River, as well as the largely glacial meltwater White River and the tundra-draining Porcupine River.

Physiography and Climate

With the exception of its headwater lakes, which are in the Coast Mountains of British Columbia and Alaska (PM) physiographic province to the southeast, most of the body of the Yukon River's catchment area is in the Yukon Basin province (YB) (Fig. 17.7). The Mackenzie Mountains (MM), Brooks Range (BR), Seward Peninsula and Bering Coast Uplands (SB), and South Central Alaska (SC) physiographic provinces define the watershed in the

northeast, north, northwest, and southwest, respectively. As Hunt (1974) describes, the Yukon Basin is structurally the highest part of Alaska, exposing the oldest (Precambrian) rock in northwestern North America. Its watershed is largely defined by a south-to-north divergence of the Rocky Mountains. This divergence includes the Cassiar, Selwyn, Ogilvie, Richardson, and British mountains and Brooks Range to the east and north, and the larger Coast Mountains, including the St. Elias (with Mount Logan, Canada's highest peak at 5959 m asl) and Alaska ranges (with Mount McKinley, North America's highest peak at 6194 m asl), to the south of the basin.

Except for the outflow of the basin on the west coast of Alaska, which has a Transitional-

Continental climate, the Yukon River basin lies in the Continental climate zone (National Climate Center 1982), characterized by cool summers and very cold winters but perhaps best described as seasonally variable (Wahl et al. 1987). Temperature and particularly precipitation are affected by the mountain ranges that line the southern portion of the basin, where the moist warm air from the Pacific Ocean is often stalled. Areas directly east of the St. Elias Mountains, in the White River subbasin and headwater lakes of the Yukon River, receive as little as 20 cm/yr precipitation (Wahl et al. 1987). The famous Carcross Desert, near Bennett and Tagish lakes (part of the headwaters of the Yukon River), is a striking example of a rain shadow in the region. Although there is more precipitation in the central and lower parts of the basin, it generally totals less than 50 cm, considerably lower than the continental, temperate part of North America (75 to 100 cm) and much lower than maritime areas (>100 cm) but similar to southern rain-shadow areas, such as Alberta in Canada (40 to 50 cm).

Basin Landscape and Land Use

It is ironic that much of the lower (downstream of the Canada–U.S. border) Yukon River basin, with a climate that is cold relative to most of North America, was largely unglaciated during the various advances of the Cordilleran ice sheet in the Wisconsin glaciation of the Pleistocene (Hopkins et al. 1982). Hunt (1974) points out that both cold and precipitation are necessary for glaciation, and the relative dryness of the Yukon basin spared most of it from the ice front. Approximately 18,000 years ago sea level was low enough to expose a 1500 km wide land bridge across the Bering Sea, and populations of large herbivorous mammals, such as woolly mammoth, horse, and bison, colonized East Beringia, or what is now the Yukon River basin (Hopkins et al. 1982). The periodically emerging land bridge is considered very significant in the biogeographical history of North American fauna, whereas the Bering Strait is a key marine biogeographic linkage between the Pacific and Atlantic oceans during periods when the land bridge is submerged.

Debate about the specific nature of the ecosystems of the Yukon River basin between 8000 and 20,000 years ago has raged for many years. Divergent views on the nature of the “steppe-tundra” vegetation community, in particular its ability to support a diverse megafauna of herbivores, have been proposed and defended, often with some rancor (Yurtsev 2001). It

is clear, at any rate, that the Beringean refugium from the most recent glaciations provided an opportunity for evolutionary divergence while much of temperate North America was “shut down” by ice cover. However, climatic conditions in the basin were even harsher than at present, with the consequence that we do not see much evidence of evolutionary radiation of aquatic or terrestrial taxa during this period. The unique evolutionary opportunity was largely unrealized, such that the region has been far more important from a biogeographic than an evolutionary perspective.

The Yukon River basin encompasses several terrestrial ecoregions within the Boreal Forest and Tundra biomes, including Yukon Interior Dry Forests in the headwater area, Interior Yukon/Alaska Alpine Tundra in the middle part of the basin, Interior Alaska/Yukon Lowland Taiga in the most northerly part of the basin (including the significant and productive Yukon Flats area), and the Beringia Lowland Tundra at the deltaic outflow of the Yukon River into the Bering Sea (Ricketts et al. 1999). Ecoregions in the mountain ranges defining the basin include Ogilvie/MacKenzie Alpine Tundra, Brooks/British Range Tundra, Beringia Upland Tundra, and Alaska/St. Elias Range Tundra (Ricketts et al. 1999). Tundra shrubs and sedges occur throughout much of the Yukon basin, depending on the elevation and microhabitat. White and black spruce are common throughout the basin, and alpine fir and lodgepole pine are quite common in the southern headwaters. Alaska larch is fairly abundant in the middle reaches of the Yukon River and its tributaries in central Alaska. Lowland areas throughout the basin are characterized by several species of willows, as well as balsam poplar, quaking aspen, white birch, Alaska paper birch, and green alder. Riparian tree vegetation often includes mountain and water birch (Farrar 1995).

Not surprising for an area almost entirely above 60°N latitude, the basin has much lower species richness in both aquatic (fishes, mussels, crayfishes, and herpetofauna; Abell et al. 2000) and terrestrial (birds, mammals, butterflies, reptiles, land snails, and vascular plants; Ricketts et al. 1999) communities than similar-size areas in southern North America, although it harbors considerably more biodiversity than similar latitudes of eastern North America. There have been many hypotheses proposed to account for the often-observed pattern of decreasing diversity as one moves from the equator toward the poles, including a harsher physical-chemical environment, less predation pressure, lower primary

productivity, more intrayear climatic variation, and younger evolutionary “age” in the far north than in the tropics (Begon et al. 1996). Wiggins and Parker (1997), in discussing the caddisflies in particular, note not only a decline in diversity as one moves north but a decline of lotic species with a proportional increase of lentic species, and propose that lentic species were better at crossing the Bering land bridge than lotic species. Cobb and Flanagan (1980) attribute the low diversity of mayfly fauna in northern latitudes to constrained dispersal of adults in cold weather and increased reliance on dispersal of nymphs in the aquatic environment. None of these explanations has been thoroughly refuted or supported, but it is reasonable to assume that some combination of them is responsible for the low biodiversity of the Yukon River basin. Many of the relatively small number of species that occur in the Yukon River basin have adaptations to arctic or subarctic environment (e.g., insects; Downes 1965, Danks et al. 1997).

In addition to its importance for North American biogeography in general, Beringia (Yukon Territory, Alaska, eastern Siberia) has played a key role in the establishment and dispersal of humans into and throughout North America (Clark 1991, Yesner 2001). About 25,000 years ago humans in Eurasia learned how to live in the far north. Although there is much debate among archaeologists about the specific date, humans dispersed from Eurasian into North American Beringia at least 12,000 years ago (Yesner 2001). Following the Wisconsin glaciation, some humans dispersed up the Yukon River basin, south and east into central North America. The first peoples who stayed in the Yukon basin, largely descendants of the Athapaskans, have maintained small but persistent and increasingly powerful populations. They have in recent decades achieved a measure of self-government through land-claim settlements in both Alaska and Yukon Territory. Traditional territories of aboriginal peoples within the Yukon River basin include the nations derived from eighteenth-century Tlingit, Tagish, Tutchone, Han, Tanana, Gwichin, Tanana, Tanacross, Koyukon, Kolchan, and Ingalik tribes of what is now Yukon Territory and Alaska (Clark 1991).

Secondary human colonization of northwestern North America by Russia began during the reign of Peter the Great in the early eighteenth century but was mainly focused on the coast rather than the Alaskan interior. In 1724, the tsar decided that he wanted to know whether and where Russia and America were separated, so he sent Danish captain Vitus Bering on his first voyage (Hayes 1999). Bering

actually reached the strait that bears his name by 1728, but the proximity (and separation) of North America and Asia was first elucidated by Mikhail Gwosdev in 1732 (Hayes 1999). The British, Spanish, Americans, and others joining in the search for the northwest passage and exploitation of abundant wildlife and fisheries resources in and off the coast of Alaska followed throughout the late eighteenth and nineteenth centuries. In 1825, the Russians and British established 141°W longitude as the boundary between Russian and British North America, in addition to what is now known as the Alaskan panhandle (Hayes 1999). In 1867, a treaty was negotiated by Secretary of State William H. Seward by which the United States purchased Alaska for \$7.2 million, or about 5 cents/ha.

There had been modest gold discoveries within the Yukon River basin when, in 1896, gold nuggets were found in Rabbit (later Bonanza) Creek, a tributary of the Klondike River just outside of Dawson City, Yukon. A gold rush began in 1897 and swelled in 1898, as miners and adventurers poured in, mainly from the United States. Placer mining continues to this day in the Klondike River, Stewart River, and adjacent basins, and to a lesser degree in parts of the headwater lakes basin. Although placer mining is usually a relatively small-scale activity, the effluent from the process can have significant impacts on downstream ecosystems (Bailey et al. 1998, Laperriere and Reynolds 1997, Pentz and Kostaschuk 1999). There are also several larger-scale mining developments (mainly zinc, silver, and copper) that operate with varying amounts of activity, depending on the metal markets (Burke 2002, Swainbank et al. 2002).

Although the first oil claims were staked in the Cook Inlet area of southern Alaska (near Anchorage) in the nineteenth century, the modern Alaskan oil and gas era began in the mid-1950s, just prior to statehood in 1958. A major oil discovery in the mid-1960s in the north slope of Alaska led to plans for a pipeline. Oil transportation became significant to the Yukon River basin with the construction of the Trans-Alaskan Pipeline, completed in 1977. The 122 cm diameter pipeline allows movement of about 25% of the annual crude oil production of the United States from Prudhoe Bay on the Arctic Ocean coast to Valdez in the Gulf of Alaska of the Pacific Ocean. In addition to the well-known Exxon Valdez accident of March 1989, the pipeline itself has been the subject of scrutiny from environmentalists. Its construction did, however, motivate some of the initial work on previously unstudied ecosystems north of

the Yukon River, and was deemed a “success story” with respect to environmental impact analysis, measured effects, and remediation (Alexander and Van Cleve 1983, Maki 1992). Currently there is (controversial) interest in further oil exploration in the north slope of Alaska and adjacent Porcupine River basin in and around the Arctic National Wildlife Refuge. A natural gas pipeline that may be built close to the Alaska Highway (passing through the Tanana River, White River, and headwater lakes basins of the Yukon River basin) is now in the preconstruction phase of development (“Producers to study Alaska natural gas pipeline” 2001).

Other than mining and fossil fuel developments and transportation, direct human impacts on the Yukon River basin are modest. There are about 100,000 people in the entire Yukon River basin, mostly concentrated in the small cities of Whitehorse, Yukon (20,000), on the upper Yukon River and Fairbanks, Alaska (82,000), on the lower Tanana River near its confluence with the lower Yukon River.

The Rivers

The Yukon River main stem and most of its major tributaries (Stewart, White, Tanana, and Koyukuk) begin as high-gradient rivers draining the rugged mountain ranges that define the basin (see Fig. 17.2). Beginning upstream, the east-flowing, relatively short (265 km) White River has a broad drainage basin (50,500 km²), with large inputs of turbid glacial meltwater from the steep east slope of the St. Elias and Wrangell Mountains, the highest mountain range in North America (maximum elevation 6200 m). The turbidity of the White River is also enhanced by erosion in its basin of the White River Ash, a 10 to 20 cm layer of volcanic ash that was deposited following the eruption of Mount Churchill (near the southern end of the Yukon–Alaska border) in about 700 A.D. (Clark 1991). The west-flowing Stewart River drains a basin of similar size (51,000 km²) but travels 650 km from its headwaters on the western side of the Selwyn Mountains (maximum elevation ~3000 m asl) to its confluence with the Yukon just south of Dawson City at 335 m asl. The Porcupine River, although similar in length to the Stewart, has its headwaters on the more modest north slope of the Ogilvie Mountains (maximum elevation ~1800 m asl), from which it curls counterclockwise, and meets the Yukon River well downstream of Dawson City in the labyrinth of the Yukon Flats at 130 m asl. Its flatter basin has over twice the drainage basin area (118,000 km²) of the Stewart River. Well downstream

from the Porcupine confluence, the Yukon is joined by its largest tributary, the Tanana River. The Tanana drains the north slope of the Alaska Range and flows in a northwesterly direction for about 1000 km roughly parallel to the Yukon River before joining it. The last major tributary of the Yukon is the Koyukuk River, which flows 800 km south from the Brooks Range through tundra to taiga biomes. It is a largely unstudied river at a critical interface between anadromous fish populations migrating from the Bering Sea and human development of fossil fuel transportation from the north slope of Alaska. The Yukon River culminates in a 100 km wide delta at the Bering Sea.

The entire Yukon River basin lies within the Yukon freshwater ecoregion within the Arctic Complex of the Arctic–Atlantic Bioregion (Abell et al. 2000). Rivers in the Yukon basin are not well studied but are believed to have relatively low diversity and productivity, probably due to complex interactions among a number of abiotic and biotic factors, as proposed by Oswood (1997). Schindler (1998) argued that although the lower diversity of aquatic ecosystems in northern boreal areas such as the Yukon River basin may attract less attention from those wanting to protect biodiversity (Abell et al. 2000), it also makes such ecosystems more susceptible to perturbation because of their lack of ecological redundancy. This is, of course, a restatement of the “diversity begets stability” hypothesis of ecology (MacArthur 1955), which has often been proposed and debated but rarely tested (Lehman and Tilman 2000). It is clear from modern assessments of the area at an ecoregional scale (Abell et al. 2000) that the Yukon River basin has neither the biodiversity nor the anthropogenic threats to merit the same amount of vigilance as southern areas with higher diversity and larger human populations. However, it is also clear at smaller scales, such as the Chena River, a 6th order tributary of the Tanana River near Fairbanks, Alaska, that the same kind of threats from human activity, including sewage treatment plant effluent, flood-control structures, and fish harvesting, can alter the ecosystem (Oswood et al. 1992). Whether or not these northern aquatic ecosystems are more, less, or similarly sensitive to human activity remains a testable hypothesis, but we obviously must continue to assess the effects of proposed and ongoing human stressors on northern streams.

Climate and topography of the basin are the primary determinants of the balance between glacial melt and accumulation, distribution of permafrost, and the dynamics of ice formation and breakup in

ivers and streams, which are the major structuring forces in far northern aquatic ecosystems such as the Yukon River basin (Hamilton and Moore 1996; Power and Power 1995; Prowse 1994; Prowse 2001a, 2001b; Yarie et al. 1998). Permafrost (soil or rock that remains at or below 0°C over at least two consecutive winters and an intervening summer) is spatially “sporadic” or patchily distributed in the upper Yukon basin, and occurs more frequently but is still “discontinuous” in most of the lower basin. Only in the extreme downstream Yukon Delta and far northern area of the basin in the upper Porcupine River is there continuous permafrost underlying the stream network. Even in areas of continuous permafrost, large lakes and rivers are underlain by unfrozen substrata. As Prowse (1994) describes, the spatial configuration of permafrost and unfrozen zones (“taliks”) in a northern stream’s drainage basin greatly affects the water quality in streams and essentially controls midwinter flow. The dynamics of ice within the stream also have significant effects on the structure and function of the stream ecosystem and its valley. The hydrological year in northern streams, including floods and low flows, is much more a product of the timing of freeze-up, the effects of developing ice in the channel, and the date of breakup than seasonal patterns of precipitation within the watershed. Other physical processes governed, or at least affected, by ice dynamics include erosion and deposition of sediment and the production and transport of oxygen (Prowse 2001a). Biological processes, such as seasonal movements of fishes and invertebrates as well as the dynamic creation and destruction of habitats within the stream, are also affected by ice dynamics in northern streams (Prowse 2001b).

YUKON RIVER MAIN STEM

Although the Yukon River main stem is generally considered to be the fifth-longest river in North America (Gleick 1993), it is by far the longest wild and free-flowing river on the continent (Dynesius and Nilsson 1994). It has just one dam near its headwaters in Whitehorse, Yukon, and then flows unimpeded for >3100 km through boreal forests of the Yukon Territories and Alaska to the Yukon Delta and the Bering Sea (see Fig. 17.7). There are several major inflows in the upper basin, including the Teslin, Big Salmon, Nordenskiöld, Pelly, White, Stewart, and Klondike rivers. In the lower basin, there are only a

few major inflows (albeit the largest in terms of discharge), including the Porcupine, Tanana, and Koyukuk rivers.

The earliest inhabitants of the Yukon River migrated across the Bering land bridge more than 12,000 years ago, and as the climate warmed and the Ice Age ended these Paleo-Indians continued to expand their population southward and eastward. Although doing detailed archaeological reconstruction is even more difficult in the far north than elsewhere in North America, there has been clear evidence of big-game hunting and tool use found at placer mines outside of Dawson City that has been dated to 11,350 years ago (Clark 1991). In more recent prehistory (1300 years ago to European contact), moving from upstream to downstream in the Yukon River, the Tlingit, Tagish, Tutchone, Han, Gwichin, and Koyukon tribes of the Athapaskan people established traditions and cultures that have evolved to the modern First Nations of today (Clark 1991).

Physiography, Climate, and Land Use

The main stem of the Yukon River lies primarily in the Yukon Basin (YB) physiographic province, characterized by plateaus and lowlands (see Fig. 17.7). The main stem primarily flows through two terrestrial ecoregions, the Interior Yukon/Alaska Alpine Tundra in the upper basin and the Interior Alaska/Yukon Lowland Taiga in the lower basin. White and black spruce are the most common trees of the boreal forests. Tundra vegetation at higher elevations includes shrubs and sedges.

The climate of the Yukon basin is characterized by cool summers, very cold winters, and a relatively low annual precipitation of about 33 cm. The warmest air temperatures are in July, when mean temperatures are about 12°C and rarely exceed 15°C (Fig. 17.8). January is the coldest month, with mean temperatures falling to almost –20°C and sometimes below –30°C. Daily extremes at both times of year often exceed these averages. Mayo, in the Stewart River subbasin of the Yukon, established the record high temperature for the Yukon Territory of 36°C, and the town of Snag on the White River tributary to the Yukon River, in southwestern Yukon, recorded the record low temperature in North America of –63°C. There is strong seasonal precipitation throughout much of the basin, with the highest amounts falling primarily as rain in August (see Fig. 17.8). However, as precipitation declines in the early

FIGURE 17.3 Upper Yukon River at Rink Rapids between Whitehorse and Dawson City, Yukon Territory (PHOTO BY TIM PALMER).

autumn it turns to snow and accumulates across the landscape until late spring.

The landscape along most of the Yukon River is natural tundra and boreal forest. Land use along the Yukon River main stem is largely confined to the immediate area of Whitehorse, Yukon Territory, near the headwaters. There is a hydroelectric dam on the river there, and sewage treatment facilities associated with the human population (~20,000). There is some agricultural activity (primarily hay production and livestock grazing) in the southern, upstream part of the river, just north of Whitehorse.

River Geomorphology, Hydrology, and Chemistry

The Yukon River can be more or less naturally subdivided into two regions. Upstream of its confluence with the Porcupine River, the Yukon River has a low to moderate gradient, declining in a downstream direction. The change in elevation along the Yukon River from the headwater Little Atlin Lake to the Porcupine River, a distance of 1600 km, is about 500 m, for a mean slope of 30 cm/km. The change in elevation over the remaining 1600 km to the Bering

Sea is only 130m, for a very low gradient of 8cm/km.

In the northwest corner of British Columbia in Canada, just a few kilometers over mountains and glaciers from the coast of Alaska, the headwaters of the Yukon River are collected into Teslin, Atlin, Tagish, and Bennett lakes. Teslin Lake is fairly typical of the group; a large, deep, oligotrophic lake in the boreal forest surrounded by alpine landscapes, with a linear shape on a north–south axis. All of the lakes have a relatively active recreational and subsistence (First Nations) fishery for lake trout, among other species, but there is little significant industrial activity in these lake basins and very small human populations.

Atlin Lake, the largest of the series, drains west via the Atlin River into Graham Inlet of Tagish Lake, where flow is north to the inflow from the lunar landscape of Tutshi Lake and Bennett Lake. Tagish Lake, and Marsh Lake directly downstream, form the final collecting points of the Yukon River headwater basin. The outflow of Marsh Lake, just south of Whitehorse, is where the Yukon first really defines itself as a river. In the upper basin (upstream of the U.S.–Canada border), the Shakwak Trench in the west and the Tintina Trench in the east broadly define the main Yukon River channel (Hunt 1974).

From Whitehorse to Dawson City (near the Canada–U.S. border), the Yukon is a moderate-gradient large river, as it accumulates flows from several large tributaries (Fig. 17.3). The declining gradient of the Yukon becomes apparent downstream of the international border (at 141°W), west of Dawson City. This is particularly evident as it enters the large Yukon Flats area, a web of channels and ponds that is currently protected as the Yukon Flats National Wildlife Refuge Area. It is here that the Yukon River changes substantially in character relative to its energetic nature further upstream, as it notches to its northernmost point at Fort Yukon, Alaska, at the Arctic Circle. This wetland-rich, low-relief part of the Yukon River includes the inflow of the Porcupine River.

Emerging from the Yukon Flats, the river is crossed by the 122cm diameter Trans-Alaskan Pipeline, completed in 1977. Beyond the pipeline the Yukon again becomes an inflow-structured system, flowing west and sharply south as it confronts the Nulato Hills at the base of the Seward Peninsula on the west coast of Alaska. The large Tanana River and Koyukuk River, as well as the Innoko River (draining the west slope of the Kuskokwim Mountains), meet the Yukon in this region and greatly influence

its physical, chemical, and biological nature as it moves toward the final leg of its journey.

The wetland-dominated Yukon Delta defines the final “personality” of the Yukon River as it approaches the Bering Sea. The coastal arctic tundra is the last and most extreme climate directly encountered by the river. The delta is very similar topographically to the Mississippi River Delta, although about twice as large (Hunt 1974).

For much of its length the Yukon River has cut hundreds of meters into a complex plateau, often resulting in spectacular bluffs bounding the wide valley of the river (Hunt 1974). Upstream of its confluence with the White River, just south of Dawson City, it is a clear, fast-flowing river. Its predominately sand and gravel substrate produces bars and small islands that come and go with seasons and annual variation in ice and temperature dynamics. The lower Yukon, including the Yukon Flats in Fort Yukon, Alaska, and the deltaic outflow of the river into the Bering Sea, is a relatively turbid river, with substantial inputs from melting glaciers via major inflows like the White River and the Tanana River.

Like most northern rivers, the hydrological dynamics of the Yukon River are controlled on a massive scale by a combination of seasonal and annual variations in both temperature and precipitation and their effect on the supply of glacial meltwater and the distribution of permafrost (Prowse 2001a, 2001b). Mean annual discharge is 6340 m³/s, which is the 6th highest in North America. From mid-autumn through late spring, runoff is low (<1 cm/mo), as much of the potential runoff is locked up as ice, whether in glaciers or in snow and ice on and in the river and its drainage basin (see Fig. 17.8). Spring snowmelt begins in May as mean air temperature exceeds 0°C. Runoff peaks in June (5 cm/mo) but relatively high runoff continues throughout much of the summer, as peak rainfall occurs from July through September. As would be expected in such a cold environment, evapotranspiration is relatively low and annual runoff is a high fraction of precipitation (see Fig. 17.8). The strong influence of temperature on runoff suggests that climate change would be an important factor in future changes to the river’s overall function and seasonal dynamics.

It is a truism in stream ecology that in terms of water chemistry a river is “what it catches.” The complexity and heterogeneity of the surficial geology of the Yukon River basin, combined with the seasonal dynamics of its water sources and flow, make it difficult to generalize about the river’s water quality. In most places, the river is circumneutral pH,

with moderate conductivity (~200 μ S/cm) and relatively low nutrient concentrations ($\text{PO}_4\text{-P}$ = 0.02 mg/L). Tidewater and its effect on water quality extend about 150 km upstream of the Bering Sea outflow.

River Biodiversity and Ecology

The Yukon River is contained within and largely defines the Yukon freshwater ecoregion, the largest freshwater ecoregion in North America (Abell et al. 2000). However, this ecoregion also comprises all but the southern portion of Alaska and includes several other rivers draining into the Bering and Beaufort seas (see Chapters 16 and 20). Although the ecological characteristics of the Yukon River are undoubtedly as vast and variable as its geography, biodiversity and ecology of the river are poorly known. Danks and Downes (1997) make a clear case that not enough is known about the various insect taxa in Yukon Territory; the same could be said for all other taxonomic groups outside of the narrow range of exploited fishes and wildlife. The cost of adequately studying such a large and remote area has limited detailed study in the past, as has the decline in the research resources dedicated to museum field expeditions and other taxonomic research. This is unfortunate, because the Yukon River, as rivers in other remote areas of the world, might be altered by climate change or other human stressors before it is possible to conduct adequate ecological assessments.

Plants

The upper southern Yukon River basin has alpine tundra vegetation surrounding the mountain tributary streams, with boreal forest, including white and black spruce, some lodgepole pine, and some balsam poplar, trembling aspen, and white birch bordering the main-stem river (Farrar 1995). In the riparian zone, mountain alder and various shrub willow species are very common, and some water birch is present (Farrar 1995). In the northern Yukon Flats area there is more characteristic taiga vegetation, including scattered black spruce with sedges and willow. This grades back into a boreal forest community that also includes Alaska larch, until at the coast, in the Yukon Delta, low-lying tundra vegetation is more common.

Invertebrates

As with other taxa, the overall diversity of stream invertebrates is lower in the Yukon River basin than

in similar-size temperate and subtropical basins. This is mainly attributable to the extreme climate, as well as the isolation of appropriate habitats (Danks et al. 1997, Wiggins and Parker 1997, Cobb and Flanagan 1980). The lower amounts of allochthonous CPOM provided to streams from limited riparian production (Oswood et al. 1995), autochthonous production with a limited growing season, and often turbid glacial meltwater also contribute to the lack of productivity and diversity in these streams (Hershey et al. 1997). Oswood (1997) puts these various factors together in a conceptual model that summarizes why we see the relatively low productivity and diversity of invertebrates in far-northern rivers and streams. Although this model has not really been tested in any rigorous fashion, it integrates the most probable structuring factors and provides a research plan for future improved understanding of northern running waters. Furthermore, virtually all of the invertebrate taxa that have been found and confirmed in the basin have actually been collected from the smaller tributaries of the main stem of the Yukon River (see, e.g., taxonomic and collecting-site descriptions in Danks et al. 1997 for the insects). Until the massive gaps in ecological research begin to be filled in this area, we can only hypothesize about the species that will be found in the river itself.

Mollusks are poorly represented, with just one species (albeit endemic) of Unionidae mussel (Yukon floater), and eight Sphaeriidae clams (the Arctic fingernail clam and seven pea clam [*Pisidium*] species) (Clarke 1981). There are also thirteen snail species in the families Valvatidae (*Valvata sincera*), Lymnaeidae (mostly *Lymnaea* and *Stagnicola* species), Physidae (*Physa gyrina* and *Aplexa hypnorum*), and Planorbidae (mostly *Gyraulus* species). Many of these species are primarily lentic and so would only be found in the more quiescent pool environments of the river.

Although the insect community in the Yukon River is dominated by the Diptera (true flies) (Oswood et al. 1995), our knowledge of the two major groups of Diptera in the Yukon Basin (Chironomidae and Simuliidae) is quite incomplete. Oliver and Dillon (1997) catalogued 100 species of chironomid midges collected from the Yukon “north slope” and adjacent areas (i.e., draining into the Arctic Ocean), but there is no such comprehensive list of chironomid species for the Yukon River. A clearer picture exists for the black flies (Simuliidae). Currie (1997) noted that 76 of the estimated 265 North American black fly species occur in the Yukon (some of them not yet formally described), which is

diverse relative to similar-size areas in temperate North America (e.g., Ontario has 63 species) but not in the same league as relatively small Mono County in central California, with 55 to 60 species. There are five endemic species in the Yukon River basin, including *Gymnopais dichopticus* Stone, *Gymnopais holopticus* Stone, *Gymnopais fimbriatus* Wood, *Simulium* sp. near *giganteum*, and *Simulium* (*Hellichella*) sp. (Currie 1997). Many of the chironomid and black fly species show adaptations to the colder climate, including reduced antennal brushes and, in the case of the black flies, a far greater occurrence (~25%) of autogenous (female does not require a blood meal to reproduce) species than in southern North America (~10%).

The next most abundant insect taxa in Yukon streams, including the Yukon River itself, are the mayflies and stoneflies (Oswood et al. 1995). Harper and Harper (1997) noted that of the 30 taxa (mostly species) of mayflies found in the Yukon, none are narrowly endemic to the Yukon Basin (East Beringia). The mayfly fauna is poorer than in the adjacent Mackenzie Delta (54 taxa) and is dominated by (in usual order of abundance) Baetidae (primarily *Baetis* spp.), Heptageniidae (primarily *Epeorus* spp. and *Heptagenia pulla* [Clemens]), Siphonuridae (including Ameletidae; primarily *Siphonurus* spp.), Ephemerellidae (primarily *Drunella* spp.), and Leptophlebiidae (primarily *Leptophlebia* spp.) (Oswood 1989, Harper and Harper 1997). There are 71 species (in eight families) of stoneflies in the Yukon basin. One Chloroperlidae, *Alaskaperla obivovis* (Ricker), is an endemic (Stewart et al. 1991). Only six of the species have external gills (three Taeniopterygidae, one Perlidae, and two Pteronarcyidae), and just one of these, *Hesperoperla pacifica* (Banks), is a large-bodied predator, probably reflecting the environmental challenges facing such stoneflies in the Yukon River. The most diverse and abundant families (Capniidae, Leuctridae, Nemouridae; the “winter stoneflies”) share many morphological and behavioral adaptations for a cold climate. *Capnia*, *Eucapnopsis*, *Utacapnia*, *Zapada*, *Taenionema*, *Alloperla*, *Suwallia*, and *Isoperla* are among the more common genera (Stewart and Ricker 1997). In recent distributional mapping combining about 30 years of small-scale impact-assessment studies (Doug Davidge, personal communication), *Utaperla soplandora* (Ricker) has been associated with streams near significant placer gold deposits, suggesting that its common name should be the “prospector stonefly.”

The caddisflies are less important in abundance than mayflies and stoneflies in the Yukon Basin (Oswood et al. 1995), but, with respect to diversity, Wiggins and Parker (1997) catalogued 145 species in the basin, with six endemics that include one lentic Leptoceridae (*Ylodes schmidi* Manuel and Nimmo), one Apataniidae (*Allomyia picoides* [Ross]), and four Limnephilidae (including lotic *Grammotaulius alascensis* Schmid and four lentic species). There is also a diverse but relatively rare freshwater beetle fauna in the basin, with representatives of the families Haliplidae, Amphizoidae, Dytiscidae (including the endemic *Oreodytes recticollis*), Gyrinidae, Hydrophilidae, and Elmidae. A few other insects (e.g., corixid hemipterans) are present in the Yukon River but much less abundant than in more southern rivers.

Vertebrates

Like other taxa, the fish species in the Yukon River have a reduced diversity (30 species) compared to more southern latitudes, with the species showing behavioral, morphological, or physiological adaptations to the cold climate (Reynolds 1997). Two fishes, the Arctic grayling (Salmonidae) and the Alaska blackfish (Umbridae), are in many ways icons of the Yukon River. The Arctic grayling, one of the most important sport fishes in the Yukon and Alaska, is found throughout the river (Scott and Crossman 1973, Morrow 1980). It spawns in early spring, congregates at the mouths of clear tributaries and often proceeds upstream in the channels cut into the ice by surface flow, and then in autumn heads quickly back downstream for winter residence (Reynolds 1997). The Alaska blackfish is found in weedy areas of the lower Yukon River below its confluence with the Porcupine River (Scott and Crossman 1973). Its modified esophagus, which enables it to “breathe air” in oxygen-depleted waters or dewatered, frozen side channels (Reynolds 1997), inspired a failed introduction to several farm ponds in southern Ontario (Scott and Crossman 1973).

There are several other ecologically and socially important salmonids in the Yukon River system. Lake trout are found primarily in the headwater lakes of the Yukon River upstream of its confluence with the Pelly River. Its distribution more or less matches the furthest advance of the Pleistocene glaciation (Lindsey 1964). Dolly Varden is more commonly lotic but only found in the upper reaches of the Yukon River, whereas chinook salmon are found from the mouth of the Yukon River to its head-

waters, making full use of the Whitehorse fish ladder during their summer spawning run (Scott and Crossman 1973, Morrow 1980).

Other noteworthy fish species include the endemic Arctic lamprey, found in the river as far upstream as Dawson City; the ubiquitous, winter-spawning burbot; and the inconnu (Yukon Territory), also known as the sheefish (Alaska), which causes as much debate about its palatability as its common name. Also found in the Yukon are Bering cisco, whitefish, chum salmon, coho salmon, and northern pike. Finally, it should be noted that rainbow trout is a deliberately introduced but popular nonnative species at several sites in the Yukon River and its tributaries.

Other important vertebrates that influence the river ecosystem either directly through their consumption of prey or indirectly through habitat modification in the river system include bald eagle, beaver, muskrat, brown and black bear, and moose. The role of bears and eagles, particularly in the food web and nutrient cycling of anadromous salmon in tributaries and the main stem of the Yukon River, has been explored by Kline et al. (1997).

Ecosystem Processes

There has been surprisingly (for its size and significance) little work done to understand ecosystem processes in the Yukon River. Ecological work has largely been limited to “collecting trips” in an attempt to catalogue biological diversity of plants and insects (e.g., Danks and Downes 1997), fisheries research targeted at game fishes (e.g., Beacham et al. 1989; Bradford et al. 2001), biological monitoring with benthic invertebrate communities (e.g., Bailey et al. 1998), or analyses of contaminant flux in food webs (Kidd et al. 1995, Kidd et al. 1998). Although no substantive research on ecosystem structure and function has been done in the Yukon River, there are probably useful lessons from Oswood’s (1997) model of ecosystem processes in northern rivers.

The study of contaminant flux is a good example of how applied research forces us to understand the more fundamental properties of an ecosystem. Just 35 km downstream (north) of Whitehorse the Yukon River flows into Lake Laberge (the lake made famous by Robert Service’s poem about Sam McGee). Kidd et al. (1995) and Kidd et al. (1998) found elevated levels of organochlorines in lake trout, burbot, and northern pike from Lake Laberge. They speculated that this was from long-range transport of atmos-

pheric pollutants rather than upstream (Whitehorse) human activity and showed how differences among lakes (they also looked at nearby Fox Lake and Kusawa Lake) in contaminants accumulating in fishes were at least partially explained by differences in the length of the food chains.

Human Impacts and Special Features

The size and large-scale ecological heterogeneity of the wild Yukon River, together with its context in subarctic North America and the Beringean Refugium, its historical importance to humans as a colonization route from northern Asia, and its importance as a source of valued resources from the nineteenth to the twenty-first centuries, make it one of the premier North American rivers. The wild status of the river and its landscape has been recognized by the inclusion of many of its smaller tributaries in the U.S. Wild and Scenic River system (e.g., Andreafsky River, Alatna River, North Fork of Koyukuk River, Wind River, Sheenjok River, Nowitka River, Charley River, and Forty Mile River), and the Canadian Heritage River System (Thirty Mile River). Unfortunately, no reaches of the main stem are recognized by either system.

Human impacts on the Yukon River are relatively minor at this time. Several negative impacts on the river may become substantially worse in the future. These include effects of climate change, dams, activities associated with fossil fuel development, forestry, and pollution.

Climate change is probably the most significant potential human impact on the river, as the hydrological dynamics and ecosystem processes of the river are for the most part ultimately controlled by the seasonal temperature regime. Global warming is likely to be felt most strongly in such cold climates, where organisms have adapted to the environmental conditions created by more than seven months of subzero temperatures. Warmer temperatures can dramatically change the hydrological patterns controlled by autumn freeze-up and spring snowmelt.

Activities associated with exploration for and development and transportation of fossil fuels in northern Alaska also have the potential for devastating consequences. The Trans-Alaskan pipeline crosses two of the Yukon River’s largest tributaries and crosses the Yukon River itself in central Alaska. The direct effects of the pipeline on the Yukon River have been modest so far and mostly

associated with disruption of the river and its basin, with its sensitive taiga and alpine–arctic tundra biomes. However, a major leak from the pipeline to the main-stem river or its tributaries could have an effect similar to that of major spills from oceanic tankers.

Relatively few dams have been built in the Yukon basin, with one in its headwaters near Whitehorse and one each on tributaries of the Stewart (near Mayo, Yukon) and Tanana (near Fairbanks, Alaska) rivers. The White Horse Rapids in Miles Canyon, from whence Whitehorse got its name, have disappeared because of a hydroelectric dam in the city with a summer capacity of 40 MW. The demand for electricity is inversely related to its production; as demand for electrical heat and light increases substantially in winter, freeze-up lowers the production of the generating plant to 24 MW. There are still chinook salmon and other fishes that manage to spawn upstream of the dam, thanks to what is reputedly the longest wooden fish ladder in the world. Other urban stressors on the river as it flows through Whitehorse include channelization and stabilization

of banks, as well as effluent from two sewage treatment facilities.

TANANA RIVER

The Tanana River drains the north-facing slopes of the Alaska Range and is the most developed area within the Yukon basin (Fig. 17.9). The basin, which lies almost entirely within Alaska, is 114,000 km². The headwaters of the river coalesce in the Tetlin National Wildlife Refuge, rich in small lakes and ponds, near the Yukon–Alaska border at the western edge of the White River basin. The river flows generally northwest from its origin, with several significant inflows from the Alaska Range mountains to the south, including the Chisana, Nabesna, Robertson, Gerstie, Delta, Nenana, and Kantishna rivers (Fig. 17.4). Most of these derive much of their flow from glacial meltwaters, which makes them and the Tanana River main stem quite turbid, with discharge dependent more on air temperature than precipitation (Prowse 2001a). Major inflows from the north,

FIGURE 17.4 Tanana River above Tok, Alaska (PHOTO BY TIM PALMER).

including the Healey, Goodpaster, Salcha, Chena, Chatanika, and Tolovana rivers, tend to be lower gradient and clear flowing.

Like much of the Yukon River basin on the Alaska side of the present-day international border, human colonization of the Tanana River occurred more than 12,000 years ago and progressed with the receding Cordilleran ice sheet as the Ice Age ended (Clark 1991). Evidence of the microblade people of the Paleo-Arctic tradition of about 11,000 years ago has been found at several sites in the Tanana River basin. More recently, the Tanana tribe has developed a culture and tradition over the last 1200 years in the basin that survives to the present (Clark 1991).

Physiography, Climate, and Land Use

The South-Central Alaska (SC) physiographic province defines the upper watershed of the Tanana River basin in the mountainous southwest of Alaska (see Fig. 17.9; Hunt 1974). The headwaters of the Tanana River flow from the Alaska Range to the south and east and the Yukon–Tanana Upland (Intermontane Plateau) to the north. The main-stem river is in the Yukon Basin (YB) physiographic province or, more specifically, the Tanana–Kuskokwim lowland of the Intermontane Plateaus of Alaska (Hartman and Johnson 1978). Three terrestrial ecoregions occupy the Tanana basin: Interior Alaska/Yukon Lowland Taiga, Alaska/St. Elias Range Tundra, and Interior Yukon/Alaska Alpine Tundra. As throughout much of the Yukon basin, black and white spruce are common, as well as mountain alder and quaking aspen.

Climate in the Tanana River is Continental, with large diurnal and seasonal variation in temperature and relatively low precipitation and humidity. Mean monthly air temperatures at Fairbanks range from a low of -23°C in January to a high of 17°C in July (Fig. 17.10). There is about 28 cm of precipitation, with around 40 “wet days” (>2.5 mm water precipitation) a year (Hartman and Johnson 1978). Mean precipitation ranges from <1 cm/mo in March and April to a peak of about 5 cm/mo in August (see Fig. 17.10). About 30% of precipitation falls as snow, which accumulates from mid-autumn through late spring.

The city of Fairbanks on the Tanana River has been a major center of placer gold mining for the last 150 years. It has developed into a moderate-size population center (~80,000 people) with associated infrastructure and modest industrial activity. Gold

mining has continued in the Tanana River basin since the middle of the nineteenth century and ebbs and flows depending on the price of gold. Some agricultural activity also occurs in the river valley near Fairbanks. Otherwise, the basin is largely unmodified wilderness.

River Geomorphology, Hydrology, and Chemistry

Like the Yukon River, the Tanana River is in a wide valley that cuts through a broad plain just north of the Alaska Range. It is bounded by the foothills of the Alaska Range to the south and high bluffs to the north. It has a shifting sand and gravel substrate with dynamic formation and destruction of point and mid-channel bars. Near Fairbanks the active floodplain can be as wide as 2 km.

The Tanana River, as the largest tributary of the Yukon, has an average annual discharge of $682\text{ m}^3/\text{s}$ at Nenana, which drains close to 60% of the basin. Discharge at the mouth thus has been approximated at $1185\text{ m}^3/\text{s}$. Runoff is <1 cm/mo from December through April with freeze-up and low precipitation (see Fig. 17.10). As with the Yukon, spring snowmelt begins in May and runoff peaks in July and August at more than 6 cm/mo. Thus, hydrological dynamics tend to track the freeze–thaw seasonal cycle (Prowse 2001a) more closely than seasonal patterns in precipitation. Although evapotranspiration is low, runoff appears to be higher than precipitation (see Fig. 17.10), probably due to the fact that the weather station at Fairbanks underestimates the average precipitation for the entire basin.

The river is primarily fed by glaciermelt and snowmelt from the south and groundwater from the north, so the water is moderately hard (total hardness 114 mg/L as CaCO_3). Turbidity is usually quite high in the main stem due to the collection of glacial meltwater, although some snowmelt- and spring-fed tributary streams (primarily from the north and northeast) run clear. Nutrient concentrations in the river are moderate to high in the lower river (e.g., $\text{PO}_4\text{-P}$ 0.3 mg/L), partially because of human inputs at or near Fairbanks. Metal concentrations are elevated because of the nature of the surficial geology in the basin.

River Biodiversity and Ecology

Like the Yukon River, the Tanana River is part of the Yukon freshwater ecoregion (Abell et al. 2000).

Many of the aquatic organisms found in the Yukon River as a whole are found in the Tanana River. There has been perhaps more management and manipulation of the biota in this subbasin than any other in the Yukon River basin. There is reasonably high fishing and hunting activity and there have been introductions of nonnative fish species in the past (e.g., rainbow trout).

Plants

In most of the subalpine riparian areas of the Tanana there is a typical boreal forest cover of primarily white spruce, birch, aspen, and willow. At higher elevations (above the tree line), hardier dwarf willow and other shrubs, as well as sedges and lichens, are common. The successional processes of floodplain vegetation in the Tanana basin have been studied extensively as a model for the northern boreal forest (taiga) ecosystem (Kielland et al. 1997, Kielland and Bryant 1998, Mann et al. 1995). Willow and mountain alder, as well as balsam poplar and quaking aspen, are common on the floodplain.

Invertebrates

Invertebrates of the Tanana River are poorly studied, and only a couple of more general studies have included collections of invertebrates in the Tanana and its tributaries that have found the same general pattern at the order level as described for the Yukon River (e.g., Oswood et al. 1992). Like other northern rivers, the benthos is dominated by species of chironomid midges. Stoneflies, mayflies, and caddisflies are present but not nearly as abundant as the chironomids. There are no published reports of the endemic stonefly *Alaskaperla obivovis* or endemic Yukon floater mussel having been collected in the Tanana River basin. Given the ecological parallels with the Yukon basin as a whole, it is probable that many of the invertebrate species found in tributaries of the rest of the Yukon River basin would also be found in the Tanana River basin.

Vertebrates

The Alaska Department of Fish and Game cites 18 indigenous and 2 introduced (stocked) species of fishes (rainbow trout, Arctic char). Several salmonids are common in the Tanana and its tributaries, including Arctic grayling, chinook salmon, least cisco, round whitefish, humpback whitefish, and inconnu (Oswood 1997). Additional common species include slimy sculpin, longnose sucker, northern pike, burbot, and Arctic lamprey.

There is perhaps more recreational fishing pressure in the Tanana River and its tributaries than any other part of the Yukon River basin. By far the greatest sport fishery harvest is of the Arctic grayling. As much of the river is largely glacial fed, the most significant fishery pressure comes in the clearwater sloughs and small inflow streams, although there is an active winter burbot fishery.

As in the Yukon River, other important vertebrates include bald eagles and brown bears, which can both be important in their role as part of the food web that includes the near or already dead anadromous salmon after their spawning runs (Kline et al. 1997). The Tanana has very occasionally hosted beluga whales that have migrated up the Yukon River from the Bering Sea.

Ecosystem Processes

Little work has been done on ecosystem processes of the Tanana River. However, Oswood's (1997) model of ecosystem processes in northern rivers is pertinent. The Tanana River's drainage basin is a mixture of largely glacial sources to the south with nonglacial inflows to the north, so the increase in discharge with increased seasonal temperature can result in relatively clear or turbid flow depending on variability in the weather. In citing unpublished data concerning primary production in the Chena River, a major tributary of the Tanana River just upstream from Fairbanks, Oswood et al. (1992) concluded that gross primary production rivaled that in temperate streams in the summer but was virtually nil in the long winter. Because the Chena River is a subsurface and precipitation-fed river (not glacial fed), one has to assume this represents the best conditions for primary production in terms of light availability. Allochthonous inputs of energy and nutrients to rivers such as the Tanana are also likely to be modest. This, together with the extreme seasonal disturbances of freeze-up and ice-out, would suggest a system with low productivity and diversity, but this needs to be confirmed with future ecosystem-scale research and detailed determination of species distributions.

Human Impacts and Special Features

The Tanana River, as the largest tributary of the Yukon, is an unregulated and largely wild river. As a relatively intact large and wild river with easier accessibility than most Alaskan rivers (Fairbanks), it could be a prime candidate for more detailed studies of biodiversity and ecology in an unaltered river. The southern uplands of the Tanana River basin include

part of the 2.1 million acre Denali Wilderness Area in the west and the 9.7 million acre Wrangell–Elias Wilderness Area in the east. The Delta River tributary is in the U.S. Wild and Scenic River system.

Although still a relatively wild river, the Tanana, of all the major and minor streams in the Yukon River basin, is exposed to the greatest magnitude and diversity of human stresses. Nonetheless, these impacts are likely to be small in comparison to most rivers at lower latitudes. Along with the city of Fairbanks, the river and its tributaries are traversed by the Trans-Alaskan pipeline, the Alaska Highway, the Richardson Highway, the Tok Cutoff (Highway), and the Taylor (“Top of the World”) Highway, along with associated commercial and recreational traffic of these transportation corridors. Impacts of these energy and transportation corridors are largely unknown.

Pollution impacts on the Tanana River include sewage effluent, a tributary diversion (Fairbanks Flood Control Project Chena River; Oswald et al. 1992), high levels of placer mining activity, and other development (Swainbank et al. 2002). In addition, active recreational fisheries and other tourist activity may have negative impacts. For example, overfishing may have been responsible for declines in the Arctic grayling of the Chena River tributary (Oswald et al. 1992).

KOYUKUK RIVER

The last major tributary of the Yukon River upstream of the outflow into the Bering Sea is the Koyukuk River (Fig. 17.11). Its basin (83,500 km²) is entirely within Alaska, and it is an almost pristine river, flowing from the southern edge of the Brooks Range in northern Alaska. Its headwaters are in the 3.4 million ha Gates of the Arctic Wilderness Area (established in 1980), and the eastern edge of the basin includes part of the Arctic National Wildlife Refuge, just above the Arctic Circle. The eastern branch of the headwaters of the Koyukuk River defines the pathway of the Trans-Alaskan pipeline from Prudhoe Bay to Valdez as it proceeds south over the Brooks Range, but there have been surprisingly few ecological studies done within its basin or the river itself. It enjoys some popularity as a canoeing and outfitting destination, but for such a large river, surprisingly little is known about it.

The Koyukuk River was colonized by humans early in the west-to-east Beringean migration from

what is now Asia to what is now northwestern North America (Clark 1991). There was also a south-to-north migration by humans who had previously come to North America across the Bering land bridge and then turned north. Evidence of tools used by Paleo-Indian and Paleo-Arctic cultures has been found at several sites along the Koyukuk River (Clark 1991). About 1300 years ago this developed into the Koyukon and Gwitchin tribes that developed into the First Nations present in the Koyukuk River basin in modern times.

Physiography, Climate, and Land Use

The Koyukuk River’s headwaters are in the Endicott Mountains of the Brooks Range (BR) physiographic province, whereas most of the lower two-thirds of the river’s length is in the Yukon Basin (YB) province (see Fig. 17.11). Some smaller eastward-flowing streams drain from the Seward Peninsula and Bering Coast Uplands (SB) province near the mouth of the Koyukuk River. There is quite gentle relief in the lower Koyukuk (Koyukuk Flats) area, similar to the Yukon Flats and Yukon Delta regions of the main-stem Yukon River. The basin contains parts of three terrestrial ecoregions: Brooks/British Range Tundra, Interior Yukon/Alaska Alpine Tundra, and Interior Yukon/Alaska Lowland Taiga. Besides extensive areas of tundra vegetation, including shrubs and sedges, various taiga trees are found, such as white and black spruce, lodgepole pine, quaking aspen, and alpine fir. This landscape is almost entirely intact wilderness, with few human settlements.

Climate in the Koyukuk River basin is Continental, with large diurnal and seasonal variation in temperature and relatively low precipitation and humidity. There is about 31 cm/yr of precipitation, with around 40 “wet days” (>2.5 mm water precipitation) a year (Hartman and Johnson 1978). Maximum precipitation (>5 cm/mo) occurs during the summer (Fig. 17.12). Mean monthly temperatures are very low, ranging from a high of only 10°C in July and falling to below –20°C for five months.

River Geomorphology, Hydrology, and Chemistry

The Koyukuk River drains south from the Brooks Range, more modestly dissecting the same plateau cut by the Yukon and Tanana rivers. The river’s headwater tributaries, including the John River, the South, Middle, and North forks, and the Alatna River,

collect at the north end of the Kanuti National Wildlife Refuge in the village of Bettles, Alaska (Fig. 17.1). Major inflows as the Koyukuk River flows southwest include the Kanuti, Batzu, Hogatzu, Huslia, Dubli, Kateel, and Gisasa rivers.

The Koyukuk has a relatively high average annual discharge ($664\text{ m}^3/\text{s}$), but like most rivers of the far north discharge is quite variable seasonally, as the annual hydrological cycle is determined more by temperature than precipitation patterns. Because of its smaller size and more northern drainage basin, the Koyukuk shows this annual hydrological pattern much more strongly than either the Yukon or Tanana rivers (see Fig. 17.12). The ratio of maximum to minimum monthly average discharge in the Koyukuk is about 100:1. The same ratio for the Yukon and Tanana is 10:1 and 8:1, respectively. This is because the precipitation becomes almost totally locked up in snow and ice from November through April, with very minimal runoff (see Fig. 17.12). Ironically, maximum flow occurs in May and June following the lowest months of precipitation, a clear indication of the influence of the spring snowmelt effect from ice and snow that accumulated during the previous winter.

The Koyukuk River does not predominately drain glaciers, so its maximum flow in May and June tends to be relatively clear. It has a pH of 7.6, moderate conductivity ($\sim 200\ \mu\text{S}/\text{cm}$) and hardness ($105\ \text{mg}/\text{L}$ as CaCO_3), and low nutrient concentrations ($\text{PO}_4\text{-P}$ $0.01\ \text{mg}/\text{L}$).

River Biodiversity and Ecology

The Koyukuk River is part of the vast Yukon freshwater ecoregion (Abell et al. 2000) and like the rest of the Yukon River it is poorly studied.

Plants

Skirting the Arctic Circle at relatively high altitude, much of the upper Koyukuk riparian vegetation is sparse. Spruce-lichen forest cover with dwarf willow and other shrubs, as well as sedges and lichens, are common. Tundra vegetation grades into somewhat more substantial taiga and boreal forest-plant communities in the lower Koyukuk. The Koyukuk Flats are a low-gradient, poorly drained muskeg environment with seasonally abundant populations of sedges and other herbaceous species. In the higher-gradient floodplains of the Koyukuk River, mountain alder and trembling aspen are common, as well as white and black spruce.

Invertebrates

No studies of invertebrates in the Koyukuk River and its major tributaries have been published, although very general information about some Koyukuk tributaries is included in a report associated with the pipeline construction (Johnson and Rockwell 1979). This study just reiterates the common, order-level pattern for northern rivers and streams: several common true flies, probably including several chironomid midge and black fly species, and many mayfly and stonefly species present, with a somewhat lesser abundance of caddisflies at a given location. As with other, even major tributaries within the Yukon River system (and the main stem itself), there is plenty of important ecological and taxonomic research waiting to be done in this area. Some experimental oil spills were carried out to assess their effects on biota, including benthic invertebrates, but these were done in the somewhat different north-slope tundra ecosystems (Nauman and Kernodle 1975).

Vertebrates

Because the Koyukuk River is the last major inflow into the Yukon River before its outflow into the Bering Sea, there are some fish species found here that either occur rarely or not at all further upstream in the Yukon basin. Arctic lamprey are found commonly in the lower Koyukuk. Sockeye salmon ascend to the lower Koyukuk for spawning. More commonly, some of the other anadromous salmonids, such as chinook, chum, and sockeye salmon, also make it up into the Koyukuk and its tributaries.

The upper Koyukuk's major tributaries are important migration routes for caribou, and several studies were undertaken to assess the effect of pipeline construction and operation on the caribou population, which numbers about 5000 in this area (Alexander and Van Cleve 1983). Other major aquatic or semiaquatic vertebrates include brown and black bear, beaver, mink, marten, river otter, and bald eagle. Like the Tanana River, the lower Koyukuk has very occasionally been host to beluga whales.

Ecosystem Processes

Although there was some aquatic ecosystem research done in the 1970s in preparation for the construction of the Trans-Alaskan pipeline (Alexander and Van Cleve 1983, Hobbie 1997, Milner and Oswald 1997), most of this was carried out on the north slope of the Brooks Range. No detailed

research of ecosystem processes has been carried out in the Koyukuk River system, and given its susceptibility to disturbance from human activities associated with fossil fuel exploration, development, and transportation, this is a glaring gap in our knowledge of North American rivers.

As with the other rivers in the Yukon River basin, Oswald's (1997) model of ecosystem processes in northern rivers seems an appropriate albeit untested hypothesis of how the Koyukuk River functions. There is much less glacial-source inflow to the Koyukuk relative to the Tanana and White rivers, so differences in light regime and water quality may make the relative role of these factors and their interaction somewhat different from the other major tributaries.

Human Impacts and Special Features

The Koyukuk River is undoubtedly one of the most pristine tributaries of an otherwise largely undeveloped Yukon wilderness. This has been recognized by the designation of four tributaries upstream of Allakaket (Alatna River, John River, Tinayguk and North Fork of Koyukuk River) as U.S. National Wild and Scenic Rivers. They all drain the Brooks Range within the pristine Gates of the Arctic National Park and Preserve. Thus, human impacts to date are small.

In the Koyukuk River basin, human activities include subsistence hunting and fishing by native communities, southern tourists participating in fly-in fishing and hunting, and canoe and raft tripping. There is modest placer mining activity in the basin, and virtually no hard-rock mining exploration or development (Laperriere and Reynolds 1997, Swainbank et al. 2002).

Significantly, the upper eastern portion of the Koyukuk River basin is traversed by the Trans-Alaskan pipeline, which always has the potential for impacts to the riverine environment. This renders both the headwaters and downstream areas susceptible to future exploration or development on the north slope of Alaska, or accidents during transportation of fossil fuel across Alaska.

ADDITIONAL RIVERS

The White River is a free-flowing high-gradient river that flows in a northerly direction before joining the Yukon River south of Dawson City (Fig. 17.13). This largely pristine river drains several glaciated areas in

the relatively high St. Elias and Wrangell Mountains of the southeastern Yukon (and southwestern Alaska), as well as the Donjek River outflow of the large, submontane Kluane Lake. At the headwaters of the White River in Alaska, Mount Churchill was the source of the volcanic eruption more than 1200 years ago that is thought by some to have motivated the southern migration of the Athapaskan peoples (Moodie et al. 1992), although this is controversial (Clark 1991). Because of its large burden of suspended glacier-derived sediment and a thick layer of White River Ash that underlays much of the basin (Fig. 17.5), the White River adds considerable turbidity at its confluence with the Yukon.

The Stewart River is in the Yukon Territory, with its headwaters on the western slope of the Mackenzie Mountains (Fig. 17.15). It flows in a westerly direction before joining the Yukon River just downstream of the White River confluence. The river has no dams on the main stem, but there is a small (2 MW capacity) hydroelectric dam on the Mayo River tributary near the town of Mayo, Yukon (population 500). Streams in the Stewart River system have been actively mined in the last 100 years or so, both for gold (usually in small placer mining operations) and silver (at a now dormant hard-rock mine at Elsa, Yukon). The Nacho Nyak Dun have a settled land claim encompassing a large amount of territory in the Stewart River basin and have actively pursued collaborative research on the assessment and monitoring of the stream ecosystems in the area.

The Klondike River drains a small basin just north of the Stewart River basin (Fig. 17.17). Its confluence with the Yukon is at Dawson City, "urban service center" for the famous Klondike gold rush (Fig. 17.6). At the height of the gold rush in the late nineteenth century there were about 30,000 people in Dawson. Presently, the permanent population is only about 500, although there is a significant "tourist rush" in the summer months thanks to good road access. Although the gold rush ended long ago, there is still mining activity in streams of the Klondike basin, often involving reanalysis of previously processed "waste" rock made economically feasible by the ups and downs of gold prices. Together with the adjacent Indian River basin (inflow to the Yukon River), it is still the most significant gold mining area in the Yukon, with 133,000 ounces recovered (62% of total gold production) in 1991–1992 (Placer Mining Section 1993).

The Porcupine River is the northernmost tributary of the Yukon basin and drains the largest sub-basin (118,000 km²; Fig. 17.19). The Porcupine is a

FIGURE 17.5 White River at the Alaska Highway near Koidern, Yukon Territory (PHOTO BY R. BAILEY).

FIGURE 17.6 Klondike River inflow to the Yukon River at Dawson City, Yukon Territory (PHOTO BY J. SCHWINDT).

large pristine Arctic river that has no dams. A major tributary of the Porcupine is the Sheenjek River, which drains a portion of the Arctic National Wildlife Refuge. The upper half of the Porcupine River basin is in northern Yukon Territory, where the headwater streams drain the eastern slope of the Richardson Mountains and the northern slope of the Ogilvie Mountains, from which the Porcupine River curls north to Old Crow, Yukon, and then southwest into Alaska to meet the Yukon River at Fort Yukon. Precipitation is only about half that of the Tanana basin, of similar area, and there is no glacial meltwater input into the Porcupine as there is the Tanana, so the Porcupine River has lower discharge (414 m³/s) and runoff (Fig. 17.20). The upper Porcupine basin is primarily taiga and alpine tundra, with stunted black spruce and larch. It has large patches of continuous permafrost with turbid cryosolic soils, and it is rich in peatlands (Scudder 1997). The greatest concern regarding human impacts are associated with potential oil exploration in and around the Arctic National Wildlife Refuge and the transportation of oil and gas out of this area.

ACKNOWLEDGMENTS

Many thanks to Mark Poustie and Brendan Bailey for literature and map research, and John Schwindt and John Bailey for help with field logistics and photography in an expedition to the Yukon basin in 2002 and 2003. Jim McDonald suggested several valuable references on the human prehistory of the Yukon River basin. Art Benke and Bert Cushing provided critical and patient comments throughout work on this project.

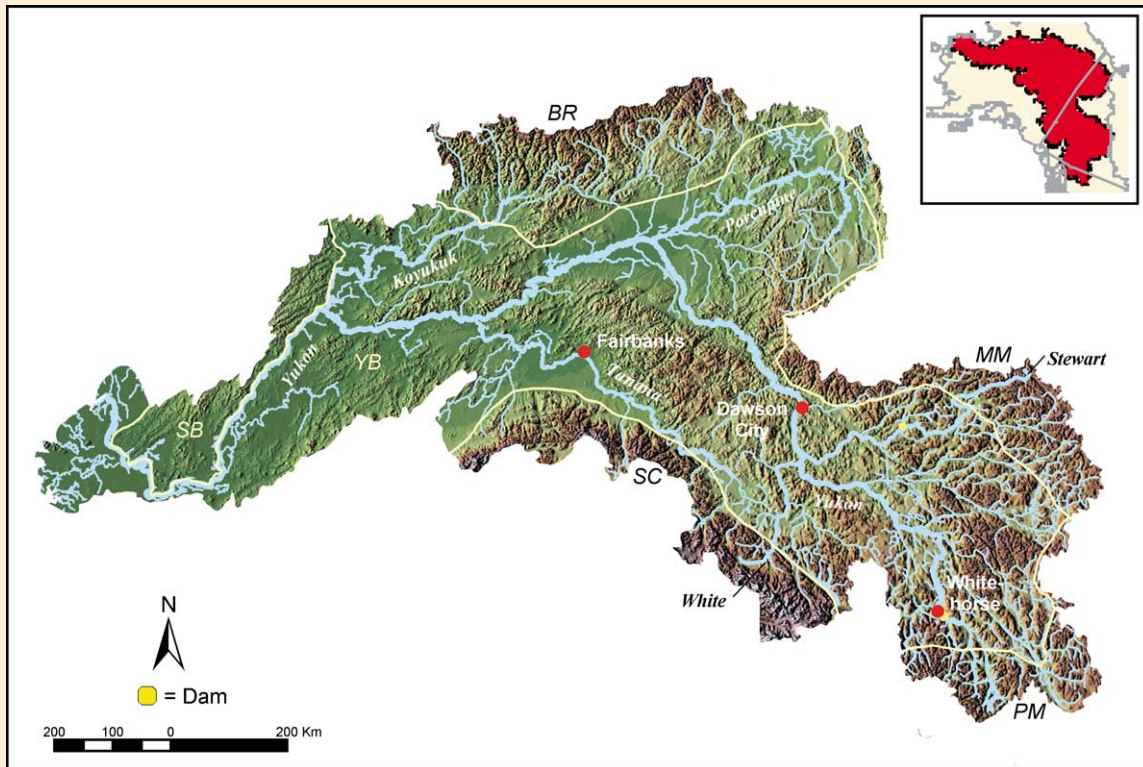

FIGURE 17.7 Map of the Yukon River basin. Physiographic provinces are separated by yellow lines.

YUKON RIVER

Relief: 6200 m

Basin area: 839,200 km²

Mean discharge: 6340 m³/s

River order: 9

Mean annual precipitation: 33 cm

Mean air temperature: -3°C

Mean water temperature: 7.7°C

Physiographic provinces: Yukon Basin (YB), Seward Peninsula and Bering Coast Uplands (SB), Brooks Range (BR), Mackenzie Mountains (MM), South-Central Alaska (SC), Coast Mountains of British Columbia and Alaska (PM)

Biomes: Boreal Forest, Tundra

Freshwater ecoregion: Yukon

Terrestrial ecoregions: Northern Cordillera Forests, Yukon Interior Dry Forests, Interior Yukon/Alaska Alpine Tundra, Ogilvie/Mackenzie Alpine Tundra, Alaska/St. Elias Range Tundra, Brooks/British Range Tundra, Interior Yukon/Alaska Lowland Taiga, Beringia Lowland Tundra

Number of fish species: 30

Number of endangered species: none

Major fishes: Bering cisco, whitefish, chinook salmon, chum salmon, coho salmon, Arctic grayling, inconnu (sheefish), lake trout, Alaska blackfish, northern pike, burbot, Dolly Varden, Arctic lamprey

Major other aquatic vertebrates: muskrat, brown bear, black bear, mink, river otter, bald eagle

Major benthic invertebrates: chironomid midges (>100 species), black flies (*Simulium*, several endemic *Gymnopsais* species), mayflies (*Baetis*, *Epeorus*, *Heptagenia pulla*, *Siphonurus*, *Drunella*, *Leptophlebia*), stoneflies (*Alaskaperla obivovis* [endemic], *Capnia*, *Eucapnopsis*, *Utacapnia*, *Zapada*, *Taenionema*, *Alloperla*, *Suwallia*, and *Isoperla*), mussel (*Pyganodon beringiana* [endemic])

Nonnative species: rainbow trout, threespine stickleback

Major riparian plants: mountain alder, water birch, black spruce

Special features: largest wild river in North America

Fragmentation: free-flowing except for dam at Whitehorse

Water quality: conductivity = 199 μS/cm; pH = 7.0; total hardness = 93.3 mg/L as CaCO₃; PO₄-P = 0.02 mg/L

Land use: <0.01% urban, agricultural, industrial, >99% forest and tundra

Population density: <0.1 people/km²

Major information sources: Danks and Downes 1997, Oswood et al. 1995, Ennis et al. 1982, Farrar 1995

FIGURE 17.8 Mean monthly air temperature, precipitation, and runoff for the Yukon River basin.

FIGURE 17.10 Mean monthly air temperature, precipitation, and runoff for the Tanana River basin.

TANANA RIVER

Relief: 6100 m

Basin area: 114,000 km²

Mean discharge: 1185 m³/s

River order: 8

Mean annual precipitation: 28 cm

Mean air temperature: -2.9°C

Mean water temperature: 6.7°C

Physiographic provinces: South-Central Alaska (SC),
Yukon Basin (YB)

Biomes: Boreal Forest, Tundra

Freshwater ecoregion: Yukon

Terrestrial ecoregions: Interior Yukon/Alaska Alpine
Tundra, Alaska/St. Elias Range Tundra, Interior
Yukon/Alaska Lowland Taiga

Number of fish species: 20

Number of endangered species: none

Major fishes: Bering cisco, whitefish, chinook salmon,
chum salmon, coho salmon, Arctic grayling,
inconnu (sheefish), lake trout, Alaska blackfish,
northern pike, burbot

Major other aquatic vertebrates: brown bear, black
bear, beaver, mink, marten, river otter, bald eagle

Major benthic invertebrates: unconfirmed; see Yukon River

Nonnative species: rainbow trout, Arctic char

Major riparian plants: black spruce, mountain alder willow, quaking aspen

Special features: mixture of turbid glacial input from the south and clear subsurface inflow from the north

Fragmentation: free-flowing except for flood-control dam on Chena River

Water quality: conductivity = 243 μS/cm, total hardness = 114 mg/L as CaCO₃, PO₄-P = 0.31 mg/L

Land use: <1% urban, agricultural, industrial; subsistence and recreational fishing and hunting; >99% tundra and boreal forest

Population density: 0.26 people/km²

Major information sources: Oswald et al. 1992, Geraghty et al. 1973, Hartman and Johnson 1978, Yarie et al. 1998

FIGURE 17.9 Map of the Tanana River basin. Physiographic provinces are separated by a yellow line.

FIGURE 17.11 Map of the Koyukuk River basin. Physiographic provinces are separated by yellow lines.

KOYUKUK RIVER

Relief: 2280 m
Basin area: 83,500 km²
Mean discharge: 664 m³/s
River order: 8
Mean annual precipitation: 31 cm
Mean air temperature: -9.5°C
Mean water temperature: 8.6°C
Physiographic provinces: Brooks Range (BR), Yukon Basin (YB), Seward Peninsula and Bering Coast Uplands (SB)
Biomes: Boreal Forest, Tundra
Freshwater ecoregion: Yukon
Terrestrial ecoregions: Interior Yukon/Alaska Lowland Taiga, Brooks/British Range Tundra, Interior Yukon/Alaska Alpine Tundra
Number of fish species: 25 (unconfirmed)
Number of endangered species: none
Major fishes: unconfirmed; see Yukon River
Major other aquatic vertebrates: see Yukon River
Major benthic invertebrates: unconfirmed; see Yukon River
Nonnative species: rainbow trout
Major riparian plants: black spruce, mountain alder, balsam poplar, quaking aspen, willow
Special features: almost pristine tundra river; important spawning areas for anadromous fishes; headwaters contact Trans-Alaskan pipeline
Fragmentation: none
Water quality: conductivity = 213 μS/cm, pH = 7.6, total hardness = 105 mg/L as CaCO₃, PO₄-P = 0.01 mg/L
Land use: subsistence and recreational fishing and hunting; pipeline right of way; >99% tundra and boreal forest
Population density: <0.01 people/km²
Major information sources: Oswood et al. 1995, Geraghty et al. 1973, Hartman and Johnson 1978

WHITE RIVER

Relief: 5635 m

Basin area: 50,500 km²

Mean discharge: 927 m³/s

River order: 6

Mean annual precipitation: 31 cm

Mean air temperature: 3.8°C

Mean water temperature: NA

Physiographic provinces: South-Central Alaska (SC),
Yukon Basin (YB)

Biomes: Boreal Forest, Tundra

Freshwater ecoregion: Yukon (Arctic Complex)

Terrestrial ecoregions: Interior Yukon/Alaska Alpine
Tundra, Alaska/St. Elias Range Tundra, Interior
Yukon/Alaska Lowland Taiga

Number of fish species: 28

Number of endangered species: none

Major fishes: Bering cisco, whitefish, chinook salmon,
chum salmon, coho salmon, Arctic grayling,
inconnu (sheefish), lake trout, Alaska blackfish,
northern pike, burbot

Major other aquatic vertebrates: see Yukon River

Major benthic invertebrates: unconfirmed; see Yukon River

Nonnative species: none

Major riparian plants: black spruce, mountain alder, quaking aspen, balsam poplar

Special features: pristine river with primarily glacial inputs; extremely turbid

Fragmentation: none

Water quality: pH = 7.8, total hardness = 122 mg/L as CaCO₃, NO₃-N = 0.3 mg/L

Land use: <0.01% urban, industrial; subsistence and recreational fishing and hunting; >99% forest and tundra

Population density: <0.01 people/km²

Major information sources: Ennis et al. 1982, Jack et al. 1983, Scudder 1997

STEWART RIVER

Relief: 2635 m
Basin area: 51,000 km²
Mean discharge: 675 m³/s
River order: 7
Mean annual precipitation: 28 cm
Mean air temperature: -2.9°C
Mean water temperature: NA
Physiographic provinces: Mackenzie Mountains (MM), Yukon Basin (YB)
Biome: Boreal Forest
Freshwater ecoregion: Yukon (Arctic Complex)
Terrestrial ecoregions: Yukon Interior Dry Forests, Interior Yukon/Alaska Alpine Tundra, Ogilvie/Mackenzie Alpine Tundra
Number of fish species: 29 (unconfirmed)
Number of endangered species: none
Major fishes: Bering cisco, whitefish, chinook salmon, chum salmon, coho salmon, Arctic grayling, inconnu (sheefish), lake trout, northern pike, burbot
Major other aquatic vertebrates: see Yukon River
Major benthic invertebrates: unconfirmed; see Yukon River
Nonnative species: rainbow trout, lake trout
Major riparian plants: see Yukon River
Special features: mostly pristine river, heavy placer activity in lower Stewart River tributaries
Fragmentation: none; one dam on tributary (Mayo River)
Water quality: pH = 7.5, total hardness = 123 mg/L as CaCO₃, NO₃-N = 0.35 mg/L, PO₄-P = 0.02 mg/L
Land use: <1% urban, agricultural, industrial; subsistence and recreational fishing and hunting; >99% forest and tundra
Population density: <1 people/km²
Major information sources: Ennis et al. 1982, Jack et al. 1983, Scudder 1997

KLONDIKE RIVER

Relief: 2200 m
 Basin area: 7800 km²
 Mean discharge: 63 m³/s
 River order: 5
 Mean annual precipitation: 32 cm
 Mean air temperature: -5.2°C
 Mean water temperature: NA
 Physiographic provinces: Mackenzie Mountains (MM), Yukon Basin (YB)
 Biomes: Boreal Forest, Tundra
 Freshwater ecoregion: Yukon
 Terrestrial ecoregions: Ogilvie/Mackenzie Alpine Tundra, Interior Yukon/Alaska Lowland Taiga
 Number of fish species: 25
 Number of endangered species: none
 Major fishes: Bering cisco, whitefish, chinook salmon, chum salmon, coho salmon, Arctic grayling, inconnu (sheefish), burbot
 Major other aquatic vertebrates: brown bear, black bear, beaver, mink, marten, river otter
 Major benthic invertebrates: unconfirmed; see Yukon River
 Nonnative species: none
 Major riparian plants: black spruce, mountain alder, balsam poplar, quaking aspen
 Special features: Klondike gold rush of 1898
 Fragmentation: none
 Water quality: pH = 7.0, total hardness = 117 mg/L as CaCO₃, NO₃-N = 0.15 mg/L, PO₄-P = 0.02 mg/L
 Land use: <1% urban, industrial; subsistence and recreational fishing and hunting; >99% tundra and forest
 Population density: 0.10 people/km²
 Major information sources: Ennis et al. 1982, Jack et al. 1983, Scudder 1997

INTRODUCTION

The catchment of the Mackenzie River basin encompasses an enormous geographic area extending over 15° of latitude and 37° of longitude from central Alberta to the Arctic Ocean, an area larger than central Europe (Fig. 18.2). Rosenberg and Barton (1986) and the Mackenzie River Basin Committee (1981a) provide a detailed description of the river's characteristics, noting that it ranks fourth in discharge relative to other Arctic Ocean rivers and is the 12th-largest drainage basin in the world. Canada's largest river basin composes 20% of the nation's territory and is the largest northerly flowing river in North America. The system includes a number of major rivers, including, from south to north, the Athabasca, Peace, Slave, Liard, Arctic Red, and Peel rivers, as well as the main-stem channel of the Mackenzie River. At the mouth the river empties through the Mackenzie Delta, the second-largest Arctic delta in the world, into the Beaufort Sea. In addition, the system contains two large freshwater deltas (the Peace–Athabasca and the Slave) and three major lakes (Lake Athabasca, Great Slave Lake, and Great Bear Lake). Both the Lower and Upper Mackenzie freshwater ecoregions of the Arctic Complex are contained within the watershed (Abell et al. 2000).

The first inhabitants in the Mackenzie watershed area were the ancestral American Indians, who moved to the area from Asia across the Bering Sea approximately 12,000 years ago. Immigration by the Inuit followed, and they eventually occupied arctic coastal areas, including the Mackenzie Delta and other tundra areas north of the tree line. Early contacts between the aboriginal peoples of the Mackenzie River basin and Europeans appear to have occurred in the late 1600s and early 1700s as a result of fur trading (Rosenberg and Barton 1986). Many of the early explorers worked for the North West Company or the Hudson's Bay Company, which were amalgamated in 1821 after years of competition (MRBC 1981a). Several of these explorers, including David Thompson and Simon Fraser, traveled through parts of the basin in search of new trade routes to the Pacific and the North. However, the river bears the name of Sir Alexander Mackenzie because he explored the main stem from Great Slave Lake to its Arctic outlet in 1789. The Mackenzie River main stem from Great Slave Lake to the Beaufort Sea has been a key transportation route for the settlement of the region, with wood-burning paddle wheelers operating on the river from the 1880s until the 1940s. Barge traffic remains an important method of transporting commodities and supplies to northern communities.

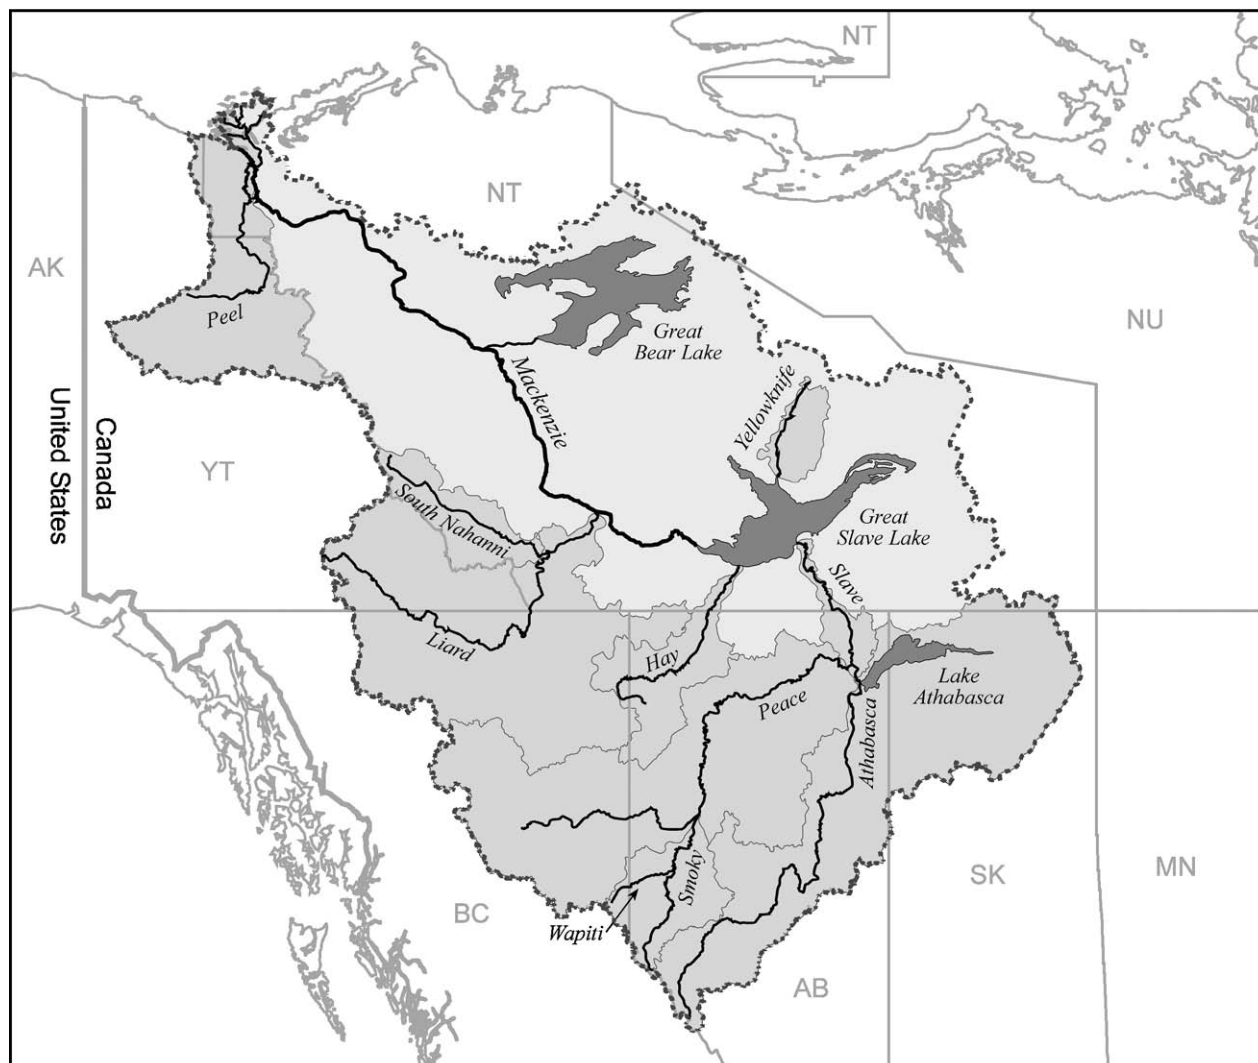

FIGURE 18.2 Rivers of the Mackenzie River basin covered in this chapter.

We discuss five major rivers of the Mackenzie River System to demonstrate the large range of natural diversity and human impacts evident within the basin. These rivers include the Athabasca, Peace, and Slave, which drain the most southern reaches of the watershed, and the Liard River and the main stem of the Mackenzie River, both of which are located north of Great Slave Lake. In addition, summary information is provided on physical, chemical, and biological characteristics and human uses of these rivers, and for five other rivers of the Mackenzie River basin (Smoky River, Hay River, Yellowknife River, South Nahanni River, and Peel River).

Physiography and Climate

During the Wisconsin time the Laurentide ice sheet covered 80% of the basin, from its eastern edge to the foothills, and western Cordillera glaciers covered many of the mountain valleys (Brunskill 1986). Glacial meltwaters formed large lakes, such as Lake McConnell, and encompassed the entire area of several present-day water bodies (Lake Athabasca, Great Slave Lake, Great Bear Lake). In addition, meltwater channels contributed to the formation of many aspects of present-day drainages. Glacial refugia extended from the South Nahanni River in the Liard basin to the Richardson Mountains in

the north, and this glacial history is thought to have greatly influenced the composition of present-day aquatic fauna (McPhail and Lindsey 1970, Rosenberg and Barton 1986).

Seven physiographic provinces are included in the Mackenzie basin: Mackenzie Mountains (MM), Coast Mountains of British Columbia and Southeast Alaska (PM), Rocky Mountains in Canada (RM), Great Plains (GP), Athabasca Plains (AT), Bear-Slave-Churchill Uplands (BC), and Arctic Lowlands (AL) (Hunt 1974). The western portion of the basin is largely underlain by sedimentary bedrock and is bounded by the Western Cordillera (MM, PM, and RM provinces), which contains numerous high mountain peaks and vast plateaus separated by wide river valleys and lowlands. This region receives the greatest amount of precipitation in the basin and thus produces all of the major tributaries to the Mackenzie River main stem. Central portions of the Mackenzie River basin lie within the GP province, an area that extends from the Athabasca River in the south to the subarctic Mackenzie Delta. Terrain in this region is flat and rolling, with occasional ranges of hills and small mountains, all underlain by sedimentary materials, such as sandstones, shales, and limestones (Brunskill 1986). Much of the area contains extensive permafrost, particularly north of 60°N latitude, and this produces vast areas of poorly drained soils and wetland habitat. To the east of the GP province the basin is bounded by AT and BC provinces, both within the Canadian (Precambrian) Shield physiographic division. Low amounts of runoff originate from this region to other parts of the basin. Bedrock here is near the surface, soils are thin, permafrost is extensive, and the landscape is a mosaic of lakes and bogs. Finally, the Mackenzie Delta, which lies within the AL province, is an extensive area of poorly developed levees formed by sediments transported from the Mackenzie River over the last 13,000 years. In addition, the delta forms a complex network of lakes, ponds, and river channels. The delta is the 10th largest in the world and provides critical summer habitat for migratory birds using the Pacific and Central flyways of North America.

Two major climatic zones, the arctic and subarctic, divide the basin at tree line. Climate is strongly influenced by continental climatic conditions, with both arctic and subarctic regions having extremely cold and long winters. Mean daily temperatures are approximately -20°C to -30°C in January and 14°C to 20°C in July. Precipitation in the basin ranges between 25 and 40 cm/yr east of the Mackenzie River and 50 to 160 cm/yr in the mountainous Cordillera

of the western basin (Brunskill 1986). Depending on the location within the catchment, from 30% to 70% of precipitation falls as snow. Southern portions of the basin receive about 8 hours of sunlight in December and 17 hours in July. At the mouth of the river Inuvik has 24 hours of darkness in December and early January and 24 hours of sunlight in early July.

Basin Landscape and Land Use

Because of the enormous size of the basin (37° of longitude, 15° of latitude), the landscape of the Mackenzie River basin is quite varied from west to east and south to north. Ricketts et al. (1999) divided the basin into 15 ecoregions within four broader categories: Temperate Coniferous Forests, Temperate Grasslands/Savanna/Shrub, Boreal Forest/Taiga, and Tundra. The forested mountains in the southwest correspond to the Central British Columbia Mountain Forests, the Alberta Mountain Forests, and the Alberta/British Columbia Foothills Forests ecoregions. To the south the basin overlaps with the Canadian Aspen Forest and Parklands ecoregion, which forms a transition to the vast midcontinental prairie grasslands. Much of the central and eastern portion of the basin is covered by the Interior Alaska/Yukon Lowland Taiga, Northwest Territories Taiga, Northern Cordillera Forests, Muskwa/Slave Lake Forests, Northern Canadian Shield Taiga, Midcontinental Canadian Forests, and Midwestern Canadian Shield Forests ecoregions. In the north, the extreme climate produces tundra, including the Ogilvie/Mackenzie Alpine Tundra, Brooks/British Range Tundra, Arctic Coastal Tundra, and Low Arctic Tundra ecoregions.

Below 60°N latitude much of the landscape of the Mackenzie River basin is closed boreal forest bordered in the south by aspen parkland (Boreal Forest biome). At higher elevations to the west forests are dominated by Engelmann and white spruce, lodgepole pine, and alpine fir (mountain provinces and ecoregions). Black spruce and tamarack occur in lower, poorly drained areas, whereas balsam poplar and white spruce are common in river valleys. Northern areas of the basin consist of open boreal forest grading into arctic tundra. The lower Mackenzie valley and delta have extensive bogs and fens, with dwarf black spruce, willow, and alder. The Arctic ecoregions are characterized by low shrubs, lichens, and mosses on drier sites, and by cottongrass-sedge meadows on poorly drained sites (MRBC 1981a).

Early development in the basin centered on fur trading, with settlements generally established at trading posts on major waterways (MRBC 1981a).

Rivers provided important transportation corridors, first for freighter canoes and later for scheduled barge service. Northern residents still rely on barge shipments for many of their commodities. Much of the basin remained relatively pristine until the early 1900s, when mineral exploration began. Mining in the basin began in the 1920s and has included the extraction of many minerals (e.g., asbestos, coal, copper, gold, silver, tungsten, and uranium). Present-day development in the Mackenzie River basin is focused around oil fields at Norman Wells, massive oil sands developments in Alberta, mineral (e.g., gold, silver, uranium) and diamond mining, hydroelectric facilities on the Peace River, and large forest harvesting operations located primarily in the Peace and Athabasca river drainages. Petroleum exploration and production continues to increase through major expansion of oil sand extraction in Alberta and oil and gas production in British Columbia and Alberta. Hydroelectric development is mostly restricted to the massive W. A. C. Bennett dam on the Peace River. Although forests have only been harvested on a large scale for pulp and paper (as well as timber) since the 1950s, southern forests have already become fragmented. Most agricultural lands are located in the Athabasca and Peace basins and are locally extensive. However, most of the basin is in a relatively pristine state, with the landscape remaining primarily as forests, shrubland, and some agricultural land. Development in the basin has progressed from the southern headwaters northward; consequently, the major cities are found in Alberta (Grande Prairie, Fort McMurray) and the southern Northwest Territories (Yellowknife). The Mackenzie River basin is very sparsely populated (<1 person/km²) and less than 350,000 people resided there in 1996.

The Rivers

The Mackenzie River basin includes the Upper and Lower Mackenzie freshwater ecoregions (Abell et al. 2000). Rivers discussed in this chapter differ mostly in basin size and mean annual temperature. Because much of the basin drains sedimentary rock, water chemistry of the rivers is similar, the exception being rivers, such as the Great Bear, that flow from the granitic bedrock of the Precambrian Canadian Shield. In addition, the flora and fauna of the rivers are quite depauperate relative to more southerly rivers in North America, largely because of recent glaciation and the severe climate. All of the major rivers are wide and moderately swift flowing.

The southern headwaters of the Mackenzie River are the Athabasca and Peace rivers, which have a unique confluence at the Peace–Athabasca Delta (PAD) where the Athabasca drains into and out of Lake Athabasca. Depending on the hydrological stage of the Peace River, waters of the delta and Lake Athabasca either flow to join the Peace at its confluence with the Slave River, or flows are reversed, resulting in flooding of PAD lakes and perched basins (Prowse and Conly 2000). The river continues flowing northward as the Slave River before emptying into Slave River Delta and Great Slave Lake. Sediments from the Peace and Athabasca rivers are mostly removed by the deltas and lake; thus the main-stem Mackenzie River is very clear when it forms at the outflow of the Great Slave Lake. The first major tributary to join the Mackenzie is the warmer and much siltier Liard River. Numerous rivers flow into the Mackenzie as it travels north to the Arctic Ocean. The major northern tributaries include the Great Bear, Peel, and Arctic Red. Finally, the Mackenzie River flows through the many channels of the Mackenzie Delta before emptying into the Beaufort Sea.

The greatest change in biota occurs in the transition from the western mountainous headwaters to the lower-gradient main stems of the major tributaries. Discharge patterns in all rivers are characterized by high flows in spring or early summer due to snowmelt (and in some cases glacial melt), followed by declining flow until the following spring, except when rainfall produces secondary flood peaks during the open-water season. Rivers are ice covered generally from sometime in the fall until late winter, and river ice breakup can have significant effects on physicochemical and biological processes (Prowse and Conly 1996, Scrimgeour et al. 1994, Prowse and Culp 2003).

Major threats to the rivers are land-use changes, including agriculture, forestry, and mining, hydrologic fragmentation through the creation of reservoirs, and point-source inputs from industry and municipalities. These developments have placed important demands on rivers as the receivers of non-point and point effluents. For example, nutrient and contaminant loadings from five pulp mills impact the Athabasca River (Chambers, Brown et al. 2000, Chambers, Dale, and Scrimgeour 2000, Culp, Cash, and Wrona 2000, Culp, Podemski, and Cash 2000). Municipal sewage effluent impacts have accompanied resource development as cities increase in size, a trend that is particularly evident in Alberta on the Athabasca and Wapiti rivers. In addition, damming

of the Peace River has caused impacts on the Peace–Athabasca Delta approximately 1200 km downstream of Williston Reservoir (Prowse and Conly 2000). Commercial fishing is important on basin lakes such as Great Slave Lake and Lake Athabasca, and aboriginal peoples of the basin continue to use wildlife resources for food and furs.

There are four tributaries of the Mackenzie River that have been designated as Canadian Heritage Rivers, including the Arctic Red, Athabasca, Bonnet Plume, and South Nahanni rivers (www.chrs.ca 2003). The Canadian Heritage Rivers System was established in 1984 by the federal, provincial, and territorial governments to conserve and protect Canada's river heritage.

MACKENZIE RIVER MAIN STEM

The Mackenzie River main stem originates at the outflow of Great Slave Lake, having drained over 970,000 km² of the Athabasca, Peace, and Lake Athabasca catchments. It then flows 1800 km northwest to the Beaufort Sea in the Arctic Ocean. At its mouth the Mackenzie River is part of an enormous 9th order system that is 4200 km long and has a drainage area of 1,787,000 km² (Fig. 18.9). The Mackenzie's most significant northern tributary, the Liard River, joins the river about 300 km downstream of Great Slave Lake at Fort Simpson (Fig. 18.3), delivering an enormous sediment load to the Mackenzie River in spring and doubling the discharge (Brunskill 1986). For many kilometers downstream the waters of the silty Liard River and the clear Mackenzie River are visually distinct (MRBC 1981a). Many other tributaries, such as the Great Bear, Arctic Red, and Peel rivers, join the Mackenzie as it flows north to the delta. Over its final 240 km the river meanders through numerous large channels in the vast Mackenzie Delta, which has an active area of 12,170 km² (MRBC 1981a, Brunskill 1986).

Early inhabitants of the main stem of the Mackenzie River were the Thule, ancestors of the Inuit of this region (Morrison and Germain 1995). They arose in Northwestern Alaska approximately 1100 years ago. Over the next two centuries they spread east throughout the Arctic to Northern Greenland. The Thule lived in permanent sod-houses in the winter, undergoing hunting based migrations during other times of the year. The transition from Thule to the Inuvialuit (Inuit of the Northwest Territories region) included adding fishing as a way of obtain-

ing food, and use of kayaks for hunting beluga whales. From archaeological records there seemed to be little cultural change from 700 years ago until the arrival of the Europeans 200 years ago. At the time of European contact the Inuvialuit were composed of six distinct territorial groups, most having a main village as a focal point. One of the larger groups were the Kittingaryumuit, who resided in a village near the mouth of the Mackenzie River. During this period there were approximately 2500 Inuvialuit.

Early contact with Europeans occurred in the 1780s, when Peter Pond established a trading post at Fort Resolution at the mouth of the Slave River (Rosenberg and Barton 1986). In 1789, Sir Alexander Mackenzie explored from Great Slave Lake to the Arctic Ocean along the length of the river that bears his name. The river became an important transportation route, so much so that the Hudson's Bay Company established a regular shipping service along the river.

Physiography, Climate, and Land Use

Although the Mackenzie basin drains seven physiographic provinces, the main-stem river flows through only three provinces (see Fig. 18.9). The main stem, situated between 60°N and 69°N latitude and 115°W and 140°W longitude, begins within the Great Plains physiographic province. As it turns north above Ft. Simpson it enters the Mackenzie Mountains province, flowing in the lowlands between the Mackenzie Mountains to the west and the smaller Franklin Mountains to the east. Near the Mackenzie Ramparts the river flows into the Arctic Lowlands province. Along its path the main stem receives runoff from tributaries of the mountain provinces to the west and the Precambrian Shield (Bear–Slave–Churchill Uplands province) to the east. Much of the region is underlain by sedimentary rock, such as limestone, shale, and sandstone. Poor drainage and widespread permafrost favors the formation of cryosolic, gleysolic, and organic soils; however, brunisolic and luvisolic soils are present in uplands. Regosols have developed within morainal, alluvial, and lacustrine landscapes. Permafrost is widespread throughout the region and is continuous in northern areas, such as the Mackenzie Delta, where it can extend to a depth of 100 m (MRBC 1981a).

Although the Mackenzie basin drains from 15 terrestrial ecoregions (Ricketts et al. 1999), the main stem flows primarily through only two. The main

FIGURE 18.3 Mackenzie River (left) at its confluence with the Liard River (right), Northwest Territories, illustrating the contrast in sediment dynamics and ice breakup. The Liard River is in active breakup and laden with sediment. The Mackenzie River is relatively clear and undergoing a thermal breakup (PHOTO BY T. D. PROWSE).

stem begins in the Muskwa/Slave Lake Forests ecoregion and then borders and eventually enters the Northwest Territories Taiga ecoregion along its path to the Mackenzie River Delta. Vegetation along the Mackenzie River Valley consists mostly of stands of black spruce and jack pine, but white spruce, balsam fir, and trembling aspen occur in warmer and moister sites to the south. The northern tree line, which has a poorly defined boundary, marks the transition zone between subarctic forests to the south and the northerly arctic tundra. The tundra is characterized by low shrubs, mosses, and lichens on drier sites and

cottongrass and sedge meadows on poorly drained sites (MRBC 1981a).

Climate of the main-stem Mackenzie River is extremely harsh, with very short and cool summers followed by bitterly cold winters. At settlements north of the Arctic Circle, such as Inuvik, Northwest Territories, mean annual temperature is about -10°C , with mean temperatures in July and January of 14° and -29°C , respectively (Fig. 18.10). Temperature extremes recorded at Inuvik are 32° and -51°C . The southern part of the region is milder; for example, annual mean temperature at Yellowknife is

–5°C, with temperatures in July and January averaging 16.5°C and –28°C. Precipitation ranges between 15 and 20 cm/yr throughout the river valley, with 50% to 70% of this moisture arriving as snow. At Inuvik mean monthly precipitation is lowest in February, at 1.1 cm/month, and increases monthly to a maximum of 4.4 cm/month in August (see Fig. 18.10). Areas in the mountains to the west have much higher precipitation (up to 70 cm/yr), which is why western tributaries, such as the Liard River, are so important to Mackenzie River discharge. The river is ice covered from October to April. In fact, public ice roads that follow the Mackenzie River are vital links between the communities of Fort Good Hope and Norman Wells.

The Mackenzie River and Valley are very sparsely populated, with <1 person/km². Excluding Yellowknife (population 17,300), which is located along the north shore of Great Slave Lake, the major communities in the basin (i.e., Fort Nelson, Inuvik, Hay River, Fort Smith, Fort Simpson) have a combined population of less than 15,000 people. Very little agriculture occurs in the region, and the primary human activities are mining, oil and gas extraction, and some forestry and tourism. In addition, hunting, trapping, and fishing are primary subsistence activities in the local economies. Land types for the main stem of the Mackenzie River include 36.5% taiga (tree crown density below 10%, may include significant shrub cover), 27.3% open land (land containing usually less than 10% of tree crown density, may contain shrubs, lichen, herbaceous vegetation cover, bare soil, rock, or small water bodies), 23.5% forest cover (trees of greater than 5 m in height with a crown density greater than 10% of the land area), 8.7% shrubland (land covered mainly by low [less than 1 m], and intermediate [less than 2 to 3 m] height woody shrubs), and 4.0% water (land covered with water in liquid form) (<http://atlas.gc.ca/site/english/index.html> 2003).

River Geomorphology, Hydrology, and Chemistry

Over its length from Great Slave Lake to the Mackenzie River Delta the main stem falls approximately 150 m, resulting in a comparatively low-gradient river (10 cm/km). The exceptions are fast-flowing reaches such as the Ramparts (downstream from Norman Wells and upstream from Fort Good Hope), where gradients can be 1.5 m/km (MRBC 1981a). The river channel is very straight and wide (1 to 2 km) and has seen little development since deglaciation

(Brunskill 1986). Rivers from the western mountains (Liard, Redstone, Arctic Red, Peel) bring silt-laden water to the west side of the Mackenzie (see Fig. 18.3), whereas eastern rivers (Great Bear) pour clear or humic-colored waters into the main stem (Brunskill 1986).

Mean monthly runoff remains below 1 cm/mo from November to April, with lowest levels of 0.5 cm/mo from February to April (see Fig. 18.10). Runoff in May and June exceeds precipitation due to the addition of snowmelt to precipitation, with a maximum of 3.1 cm/mo in June. The greatest difference between precipitation and runoff occurs in August due to evapotranspiration. Average monthly discharge of the Mackenzie River near the delta is 9020 m³/s, with peak discharge occurring in June (20,626 m³/s) and minimum values in March (3373 m³/s). Spring breakup of river ice on the upstream portions of the Mackenzie main stem occurs in late April to May and is typically triggered by flow from the Liard River (see Fig. 18.3), which can double the Mackenzie discharge in spring (Prowse 1986). Breakup advance along the main stem usually takes a month before reaching the Mackenzie Delta. More than 75% of the runoff in the Mackenzie River occurs during open water between May and October.

Water chemistry of the Mackenzie River main stem is strongly affected by Cordilleran tributary rivers that drain basins underlain by sedimentary materials (Brunskill 1986, Bodaly 1989). Thus this is an alkaline (average 93 mg/L as CaCO₃), hard-water system with basic pH (7.9) and moderate levels of cations such as calcium and potassium. Because much of the sediment load of the Peace and Athabasca rivers is trapped in deltas and lakes, the high levels of suspended sediments in the main stem during the spring and summer originate in western mountain drainages of the Yukon, Northwest Territories, and British Columbia. Although total phosphorus is high during the summer (0.24 mg/L), this is mostly due to particulate forms, as dissolved phosphorus concentration is very low (0.011 mg/L). Total nitrogen mean annual concentration is 0.37 mg/L. Metal concentrations in the water of the main stem are low (Environment Canada 1981).

River Biodiversity and Ecology

The main-stem Mackenzie is within the Lower Mackenzie freshwater ecoregion (Abell et al. 2000). Biological data on primary and secondary producers of the Mackenzie River system is very limited (Bodaly

et al. 1989). Most available information relates to fish populations and fisheries, but even these data are scarce. Authoritative reviews on the biota of the Mackenzie River include Barton (1986), McCart (1986), Rosenberg (1986), and Mackay (1995).

Algae

Most detailed information on the aquatic flora of the Mackenzie River relates to studies of delta lakes. Diatom assemblages in these lakes are dominated by benthic microflora, namely *Navicula*, *Nitzschia*, *Coccoconeis*, and *Gomphonema* (Hay et al. 2000). In addition, Wiens et al. (1975) recorded >100 species of algae from 36 genera, with *Achnanthes*, *Gomphonema*, *Navicula*, *Nitzschia*, *Pinnularia*, and *Synedra* the most diverse algal taxa.

Plants

Macrophyte growth is higher in lakes that are not strongly influenced by river flooding. Furthermore, macrophytes can be abundant in the main river channel, particularly in the less-turbid reach of the Mackenzie between Great Slave Lake and the Liard River confluence (Barton 1986). Wiens et al. (1975) provide an extensive species list of aquatic plants in the Mackenzie basin (>50 macrophyte species), with sedges, pondweed (*Potamogeton*), and the macrophytic alga *Chara* the most diverse genera.

Invertebrates

Information on benthic invertebrate assemblages of the Mackenzie River is even more limited than that for primary producers. Published data on biota of the main channel is restricted to Barton's (1986) review. He reports accumulations of large amounts of allochthonous debris and a fauna dominated by true flies (chironomid midges, black flies, biting midges), stoneflies, mayflies, and caddisflies in baskets of stones suspended in the water column. In contrast, samples collected from river channel sediments in the Mackenzie Delta contained large fractions of oligochaete worms, midges, and snails during both the summer and winter. Mean densities in the river channels of the delta were very low and ranged from 166 to 417 individuals/m². Rosenberg and Snow (1975) report that benthic invertebrate densities in Mackenzie Delta lakes were higher than in the river channel, with standing crop reduced by up to 50% when clear lakes were flooded by sediment-laden Mackenzie River waters in the spring. Benthic macroinvertebrate densities were highest in streams with low suspended sediments (<20 mg/L; Rosenberg and Snow 1975). The limited information available

for several small tributaries of the main stem indicates that these streams have a fauna typical of fast-flowing waters (i.e., mayflies, stoneflies, caddisflies, and midges; Rosenberg and Snow 1975; Rosenberg and Wiens 1976, 1978). Wiens et al. (1975) provide a list of 381 genera and 464 species of invertebrates found in the Mackenzie basin, including detailed lists for several main-stem tributaries. Common invertebrates of the main-stem Mackenzie include several true flies (biting midges, chironomid midges, black flies), mayflies (*Ametropus*, *Baetis*, *Ephemerella*, *Heptagenia*), stoneflies (*Isoperla*), and caddisflies (*Brachycentrus*).

Vertebrates

The fish fauna of the Mackenzie River basin is composed of 52 species from 14 families. The main stem of the river has 34 of these species, with the dominant fish groups consisting of the salmonids (3 families, 13 species) and cyprinids (7 species) (McCart 1986), with salmonids the most important group for subsistence and commercial fisheries. Other families include Petromyzontidae (lamprey), Hiodontidae (mooneyes), Esocidae (pike), Osmeridae (smelts), Catostomidae (suckers), Percopsidae (trout-perches), Gadidae (codfish), Gasterosteidae (sticklebacks), Cottidae (sculpins), and Percidae (perches) (McCart 1986).

Most of the Mackenzie River was covered by ice during Wisconsin glaciation and composition of the species pool is largely explained by numerous hydrological connections during deglaciation that allowed dispersal of species from the Mississippi (Rempel and Smith 1998), Bering, and Pacific refugia (McPhail and Lindsay 1970). Much of the following discussion of fish populations and fisheries in the Mackenzie River main stem is based on the reviews of McCart (1986) and Bodaly et al. (1989).

Large-scale movements of fishes are common in the Mackenzie River because of the lack of major barriers to fish movement (Bodaly et al. 1989). Anadromous fishes undertake extensive migrations in the river, with the arctic cisco traveling from the Mackenzie Delta to spawning areas in the Liard River (McLeod and O'Neil 1983). Other major anadromous fishes include Arctic char, least cisco, lake whitefish, broad whitefish, and inconnu. McCart (1986) suggests that fishes maximize their use of habitat by migrating among widely separated spawning, feeding, and overwintering habitats. For example, the broad whitefish migrates to spawning areas in the main-stem Mackenzie (e.g., Ramparts Rapids) and overwinters in the outer Mackenzie

Delta (Bodaly et al. 1989). Juveniles are hypothesized to leave the system for the Beaufort Sea with the spring flood, only to utilize shallow lake systems along the coast as summer feeding areas. Freshwater species also undertake long migrations. For example, Arctic grayling spawn in small tributaries of the Mackenzie main stem, yet feed during the summer and overwinter in Great Bear River and Great Bear Lake. In addition, inconnu, lake whitefish, and long-nose suckers appear to migrate between the Liard and Mackenzie rivers (MacDonald 1992).

There are no known reptiles that live within the Mackenzie River main-channel watershed, and only one species of amphibian, the wood frog (www.canadianbiodiversity.mcgill.ca/english/ecozones/taigaplains/taigaplains.htm 2003). The main channel of the Mackenzie River is an important route for migrating geese and other aquatic birds. Large portions of the Western Central Flyway snow geese population use the Mackenzie River as a migration route (www.ibacanada.com 2003). Other birds identified in the main channel of the river and the delta include black brant, greater white-fronted goose, tundra swan, sandhill crane, glaucous gull, Arctic tern, dabbling duck, and shorebirds (www.ibacanada.com 2003).

During the spring the Mackenzie Delta is home to a distinct stock of beluga whales, estimated at 5000 animals, which use the delta to calve and to molt (www.greatcanadianrivers.com/rivers/mack/mack-home.html 2003). The Mackenzie Delta also provides ideal habitat for muskrat, producing a thriving population in this region, which supports an active fur-harvesting industry. Other mammals found within the riparian zone include moose, mink, and beaver.

Ecosystem Processes

In general, primary productivity in these cold and turbid waters is low, such that annual phytoplankton productivity in delta lakes is $<10\text{ g C/m}^2$ and annual macrophyte production is $<30\text{ g C/m}^2$ (Bodaly et al. 1989). Production of periphyton in delta lakes is approximately equal to that of the phytoplankton. Although little information is available on allochthonous inputs to the Mackenzie River, detrital sources probably are very important to river metabolism given the substantial amount of dissolved and particulate organic matter contributed during spring breakup and flooding (Prowse and Culp 2003).

The highest amounts of primary production and algal biomass occur in clear delta lakes that have low

connectivity with the river. Bodaly et al. (1989) hypothesize that primary production in delta lakes and the river channel is light limited during the open-water season because of the high concentration of suspended sediments.

Fish production in the Mackenzie main stem and delta lakes is thought to be very low; however, only commercial fisheries yields are available to provide quantitative support for this observation (Mackay 1995). Low productivity can be attributed to high turbidity that limits primary production and unstable river substrate that restricts the growth of macrophytes (Bodaly et al. 1989). Recently, Fisheries and Oceans Canada began a multiyear study to collect information on fish populations (e.g., individual growth, age structure, contaminant body burden) in the lower Mackenzie to facilitate management of important traditional fisheries (Stewart et al. 1997).

Human Impacts and Special Features

The main channel of the Mackenzie River between Great Slave Lake and the Beaufort Sea is 1706 km long, is relatively straight, and has a relatively low gradient. There are only nine communities along this stretch of the river, including Fort Simpson, Norman Wells, Arctic Red River, and Inuvik. Thus most of the river is uninhabited and undisturbed, providing unique adventure tourism opportunities. Perhaps the most dramatic stretch of the river occurs upstream of Fort Good Hope at the Ramparts, a limestone-walled canyon approximately 2 km long and 400 to 1300 m wide (www.greatcanadianrivers.com/rivers/mack/mack-home.html 2003). There are three internationally recognized Important Bird Areas along the Mackenzie River, including the Lower Mackenzie River Islands near Fort Good Hope, the Middle Mackenzie Islands near Fort Norman, and the Mackenzie River Delta (www.ibacanada.com 2003). These areas provide important migration stopover and summer habitat areas for snow geese, Canada geese, and tundra swans, as well as many duck and shorebird species.

The Mackenzie River drains into Canada's largest and the world's 12th-largest delta. The Mackenzie Delta is 210 km in length, with an average width of 62 km. The delta consists of islands, tidal flats, ponds, and at least 25,000 shallow lakes. The moderating temperature effect of the delta allows for the tree line to continue further north in this area than other surrounding areas of the arctic. The Mackenzie Delta also contains 1500 pingos (cone-shaped ice hills

formed in areas of permafrost), the largest concentration in the world (www.greatcanadianrivers.com/rivers/mack/mack-home.html 2003). The Kendall Island Migratory Bird Sanctuary is located on the outer margins of the delta and provides summer breeding habitat for several species of geese, swans, gulls, terns, and shorebirds.

The sparse population and remote, northern location of the Mackenzie River main stem have maintained this system in a relatively unpolluted state relative to other large-river systems in Canada. Today the river remains an important corridor for barge traffic from Hay River (Canada's most northern railhead) to Tuktoyaktuk. Barge service operates between Hay River on Great Slave Lake and the Arctic Ocean during the open-water season. In addition, the Mackenzie Valley is proposed as a primary pipeline route for transporting oil and natural gas from the north to Alberta.

Although forestry, mining, and agriculture occur in several of its major tributaries, the primary effects of humans on the system are most likely related to fisheries exploitation, hydrocarbon extraction, and inputs of atmospheric pollutants (Rosenberg 1986, Bodaly et al. 1989, Muir et al. 1990). In addition, hydroelectric and pipeline developments (Rosenberg 1986, Bodaly et al. 1989), as well as climate change (Reist 1994), are anticipated to threaten the Mackenzie River in the future.

The Mackenzie basin is an important region for energy production in Canada; thus upstream developments and oil production along the main stem near Norman Wells have the potential to produce acute and chronic toxicity effects on aquatic biota. Other than through minor oil spills, the Mackenzie biota does not appear to have been seriously threatened by hydrocarbon development. Rosenberg (1986) reviews the research on oil-spill impacts that was undertaken in the 1970s as part of the Mackenzie Valley Pipeline Study. Experiments conducted in tributary streams of the Mackenzie main stem found that exposure to Norman Wells crude led to increases in periphyton biomass (Rosenberg and Wiens 1976). Increased algal production may have been an indirect response to the depletion or loss of grazers due to toxicity effects or because of oil-stimulated microflora production. Oil pollution increased chironomid abundance but reduced the density and diversity of mayflies (Rosenberg et al. 1977). These studies have renewed relevance because governments and industry are once again undertaking environmental assessments in anticipation of an oil and gas pipeline being built along the Mackenzie Valley to

bring energy reserves from the northern frontier to southern markets.

Hydroelectric power production remains an ongoing environmental threat to the Mackenzie River (Rosenberg 1986, Bodaly et al. 1989). There are no dams on the main channel of the Mackenzie River; however, there are eight dams within the greater basin, including two in Lake Athabasca, two on the Peace River, and four on the Great Slave Lake subbasin (Rosenberg 1986). Although existing dams in the Mackenzie basin do not appear to affect the Mackenzie main stem, proposed regulation of Cordilleran flows below Great Slave Lake have the potential to severely disrupt the Mackenzie River (Bodaly et al. 1989). For example, flows from the Liard River double the discharge of the Mackenzie in summer and trigger spring river-ice breakup. If the Liard is dammed, effects could be severe in the Mackenzie Delta, where spring flooding appears to be a crucial cue for migration of coregonid fishes. In addition, the spring flood serves as an environmental reset mechanism that controls delta lake biology and river channel morphology.

Global climate change is predicted to increase mean annual temperature in the Mackenzie Basin by up to 5°C by the middle of the century. Reist (1994) reviewed the possible effects of this level of change on fish species of the Mackenzie and listed several outcomes, including changes in fish distribution, effects on fish abundance and growth, and modified fisheries yields. Coolwater species at the northern edge of their distribution, such as yellow walleye and yellow perch, may increase in abundance. Arctic species with physiological intolerance to warm temperatures may experience restricted geographical ranges, with arctic coregonides (broad whitefish, least cisco, Arctic cisco) at particular risk. If fish species are below their physiological optimum temperature, higher average environmental temperature may increase growth. Thus simple fisheries models predict higher yield with increased water temperatures. McCart (1986) presents data that corroborate this prediction for Arctic grayling in the Mackenzie basin, indicating that the length of year-old fry increases with the number of growing degree days (days above 5.5°C) between latitudes 61°N and 69°N.

An obvious but poorly studied impact of humans on the ecology of the Mackenzie River is that of the commercial and subsistence fisheries (reviewed by Bodaly et al. 1989). Fishing in the river and delta lakes commences after spring spawning and extends until freeze-up. Winter fishing occurs during the

period when ice is safe for travel. Most commercial fisheries are managed by quota systems and the size of fishes caught is regulated by minimum mesh size of gill nets. Often the regulatory system for commercial operations is based on year-end questionnaires; size of the subsistence catch is more poorly documented. Bodaly et al. (1989) report that genetic stocks are not well understood; thus quotas may be inappropriate, particularly when migrating stocks are mixed, as in the Arctic Red River fishery. Despite these shortcomings, recent studies have attempted to gather the critical data necessary to facilitate fisheries management (Stewart et al. 1997).

LIARD RIVER

The Liard River arises in the Pelly Mountains in southeastern Yukon and flows through northeastern British Columbia before turning northeast to its confluence with the Mackenzie River at Fort Simpson, Northwest Territories (Fig. 18.11). The basin spans latitudes 57°N to 61°N and longitudes 121°W to 131°W and also includes parts of Alberta. With a total drainage area of 277,000 km² and a length of

1115 km, this 8th order river is the largest northern tributary of the Mackenzie River and has the seventh-largest annual river discharge in Canada. Mountains with high peaks and vast plateaus separated by large valleys and lowlands typify much of the basin. This unregulated river is quite hazardous in some stretches, particularly in the rapids between its confluence with the Trout and Toad rivers in the Grand Canyon of the Liard, a section that includes the Rapids of the Drowned and Hell Gate. Major tributaries of the Liard River include the South Nahanni and Fort Nelson rivers.

The Liard River region was occupied by aboriginals for thousands of years before the onset of European settlers. Groups included the Kaska Dene and the Slave, who were seasonal migrants in the region. The area now known as Fort Nelson was settled in 1775 by the Slave, who were driven to this area by the Cree, who had already acquired firearms, giving them a significant advantage in battle (Young 1980). Further downstream the confluence of the Liard with the Mackenzie River (known today as Fort Simpson) has for centuries been an important place to gather in the summer to celebrate after the ice breakup (www.fortsimpson.com/fshs.html 2003).

FIGURE 18.4 Liard River, Northwest Territories, illustrating ice-jam flooding, forcing backwater to overbank and develop a secondary flow channel (PHOTO BY T. D. PROWSE).

Early references to the river included the names “Courant-Fort” and “Rivière aux Liards.” Liard is a French name for poplar trees that occur along the riparian zone of the river. Surveyed by Richard McConnell in 1887 and an important route that gold prospectors used to access northern Yukon in the late 1890s, the Liard River had been an important fur-trading route for most of the century (Marsh 2001a). Fort Simpson is the oldest continuous trading post in the basin, dating back to the North West Company in 1804, and is named after Hudson’s Bay Company governor Sir George Simpson (Pool 2001).

Physiography, Climate, and Land Use

Much of the Liard River drainage comes from three Cordillera physiographic provinces: the Coast Mountains of British Columbia and Southeast Alaska (PM), the Rocky Mountains in Canada (RM), and the Mackenzie Mountains (MM) (Hunt 1974, Rosenberg and Barton 1986). A smaller part of the basin also drains from the Great Plains province, through which the lower main-stem river flows before joining the Mackenzie River at Fort Simpson (see Fig. 18.11). The basin was heavily glaciated and surface materials are primarily glacial drift, colluvium, and rock outcrops. Extensive permafrost and poor drainage in the basin have created favorable conditions for cryosolic, gleysolic, and organic soils, whereas brunisolic and luvisolic soils are common at warmer, lower-elevation locations. The dominant geology of the basin includes sedimentary materials, such as Carboniferous Paleozoic limestone, and Cretaceous shale and sandstone.

The Liard basin landscape is a mosaic of five terrestrial ecoregions (Ricketts et al. 1999). In the mountain provinces, the basin primarily drains through the Northern Cordillera Forests ecoregion but also drains portions of the Ogilvie/Mackenzie Alpine Tundra and the Alberta/British Columbia Foothills Forests. As the river enters the Great Plains it primarily flows through the Muskwa/Slave Lake Forests ecoregion but also the Northwest Territories Taiga. White and black spruce, lodgepole pine, aspen, and white birch dominate river valleys of the western Cordillera; alpine fir is abundant near tree-line. In the Great Plains portion of the Liard River basin, white spruce, balsam poplar, willow, and alder are common (MacDonald 1992).

The Liard River basin has a very cold and relatively dry Continental climate. Coastal mountains to the west prevent much of the moist Pacific air mass

from moving inland. Mean temperature decreases from -1°C in the southwestern basin to -4°C at Fort Simpson. At Fort Simpson average temperature in January is extremely cold (-27°C), with mean monthly values for July rising to 17°C (Fig. 18.12). Precipitation is low throughout the basin, with western portions receiving the most moisture (basin range ~ 35 to 50 cm). Monthly mean precipitation at Fort Simpson ranges from 1.64 cm/mo in April to 5.33 cm/mo in July (see Fig. 18.12). Approximately 60% of the precipitation falls as rain between the months of May and October.

At present the Liard River basin is relatively pristine; however, there is substantial forest harvesting and mineral resource extraction in the headwaters (MacDonald 1992). Forests of white and black spruce, lodgepole pine, and aspen are harvested, mainly in the river valleys of British Columbia. Oil and gas exploration and production in the basin occurs mostly in British Columbia in the Fort Nelson and Petitot river subbasins and has increased rapidly in the last decade. In addition, 29 mining operations, mostly for asbestos, zinc, lead, and silver, are located in the headwater subbasins of the Coal, Dease, Francis, Little Moose, Meister, Rancheria, and Toad rivers in British Columbia and the Yukon. Some placer mining activity has also occurred within the basin. There is very little commercial agriculture in the Liard River basin, and crops of hay, canola, and grains are largely used locally. Land types for the region include forest (55.4%), taiga (17.8%), open land (13.8%), shrubland (11.5%), and water (1.4%) (<http://atlas.gc.ca/site/english/index.html> 2003).

During World War II (1941) the American military constructed an airport in Fort Nelson as part of the Northwest Staging Route, and in 1942 the Alaska Highway was constructed, running right through town (Artibise 2001). These two construction projects greatly increased the size and importance of Fort Nelson as a transportation hub (Artibise 2001). Today the basin is sparsely populated, with <1 person/ km^2 , as only about 8500 people inhabit the basin. Besides forest harvesting and extraction of petroleum and other minerals, the main human activities are subsistence hunting and trapping, big game hunting and guiding, water-oriented recreation, and tourism.

River Geomorphology, Hydrology, and Chemistry

The Liard River drops more than 1200 m from its headwaters in the Yukon to the Mackenzie River

confluence. Tributary streams in the Yukon have high slopes and contain bed materials of boulder, cobble, and gravel. Immediately above its confluence with the Black River the channel of the upper Liard River is straight, with cobble and gravel substrate and a slope of 2.1 m/km. The meandering channel of the middle river reaches, located in northern British Columbia, is often braided, with a moderate slope. However, from just upstream of the Kechika River confluence the Liard River descends about 50 m over a distance of 25 km (2 m/km slope) in a series of rapids before resuming its moderate gradient. Below Liard Hot Springs the river slope increases to 1 m/km as it cascades through dangerous rapids, such as Hell Gate Rapids. In its lower reach, the river channel is both meandering and straight, depending on the location, and has numerous midchannel bars and islands (Fig. 18.4). The slope of this section ranges broadly from 10 cm/km to 60 cm/km. Bed material also exhibits a wide range, with different reaches composed of varying proportions of sand and gravel. The final 100 km of the Liard River is characterized by a single, well-incised channel with occasional small bars and islands (BC Hydro 1985). During the annual flood peak the average river width and depth within this reach is 250 to 500 m and 3 to 8 m, respectively. Substrate along this stretch of river is predominantly coarse gravel, cobbles, boulders, and bedrock sills.

Mean monthly runoff at Fort Simpson is lowest during February, at 0.39 cm/mo, and highest in June, at 6.84 cm/mo (see Fig. 18.12). For May, June, and July runoff is greater than precipitation due to increasing precipitation and increased snowmelt as the daily mean temperature rises. Discharge in the unregulated Liard River is strongly affected by mountain runoff and reaches a monthly maximum in June of 7300 m³/s. Minimum discharge occurs in late winter in March before river ice breakup (~400 m³/s). Mean monthly discharge in the Liard River is approximately 2500 m³/s. The Liard River has a major influence on the Mackenzie River and, relative to other tributary rivers, has the most impact on temperature, sediment load, and breakup of the Mackenzie (MRBC 1981a). In most years the warmer Liard River is the trigger mechanism for river-ice breakup of the Mackenzie River (Prowse 1986, 1990).

Available water quality data for the Liard River at Fort Liard and Fort Simpson was summarized by Macdonald (1992), who found very similar trends for both sites. Given the importance of sedimentary bedrock in the basin, it is not surprising that the alkaline, hard water system has a high pH (8.2) and conductivity (287 µS/cm; Macdonald 1992, Brunskill

1986). Available measurements of plant nutrients suggest the Liard River may be phosphorus limited, as annual total dissolved phosphorus at Fort Liard was 0.009 mg/L (Macdonald 1992). Mean non-filterable residue was quite high (144 mg/L), with maximum values ranging up to 865 mg/L. Suspended sediment concentrations can be extreme (>1000 mg/L) in spring during major runs of river ice (Prowse 1993). The Liard River is the single largest contributor to the Mackenzie River in terms of wash load, which includes fine material such as silt, clay, and fine sand (Carson et al. 1998). Throughout the basin metal and metalloid concentration is low; however, annual variability is large because of high suspended sediment loads in spring and early summer (MacDonald 1992). Nutrient and metal concentrations in the South Nahanni River are indicative of pristine conditions (Environment Canada 1991).

River Biodiversity and Ecology

River habitats of the Liard River are part of the Lower Mackenzie freshwater ecoregion (Abell et al. 2000). Relatively little is known about the ecological structure and function of the Liard River, and few articles about this ecosystem have been published. Most information on the biodiversity and ecology of the river is contained in unpublished government and consulting reports. Information on the benthic community of the Liard River is sparse and information on bacteria, periphyton, or macrophytes was not located. MacDonald (1992) summarizes much of this information for the basin and is an excellent reference source for available reports.

Plants

In general, there are over 700 species of vascular plants recorded in Nahanni National Park Reserve. Terrestrial vegetation is primarily boreal forest with lowland wetlands to alpine tundra. Riparian zones are dominated by white spruce and trembling aspens (<http://parkscanada.gc.ca/pn-np/nt/nahanni> 2003).

Invertebrates

A summary of benthic macroinvertebrate families recorded in the Liard River is presented by MacDonald (1992). Although no abundance data were located, longitudinal zonation of the macroinvertebrate assemblage is evident from this presence/absence information for dipterans (true flies), mayflies, stoneflies, and caddisflies. Dipteran families and subfamilies include Diamesinae, Empi-

dididae, Orthocladiinae, Simuliidae, Tanyderidae, and Tipulidae. Most mayfly (Baetidae, Ephemerellidae, Heptageniidae) and stonefly (Capniidae, Chloroperlidae, Nemouridae, Perlidae) families have been recorded throughout the river's length. However, several families have been recorded only in the Yukon headwaters of the Liard River. These include ephemereid mayflies, Isogeninae and nemourid stoneflies, and several caddisflies (Brachycentridae, Limnephilidae, Rhyacophilidae). Other caddisflies have not been sampled in the lower Northwest Territories portions of the river. Clearly, these trends are very preliminary, as there has not been a rigorous effort to collect and describe the benthic macroinvertebrate fauna of this basin.

Vertebrates

The ecology of socially and economically important fish species is much better known than other biota of the Liard River, yet the knowledge base for even this group is minimal for this basin (MacDonald 1992). Surveys of the Liard River have recorded 34 species from 12 families, with most species belonging to the Salmonidae or Cyprinidae. Two of the important anadromous species are chum salmon and Arctic cisco. Both are fall spawners and their fry move downstream in spring after ice breakup. Arctic cisco, which are important to native peoples for human consumption and sled-dog food, appear to have rearing areas in the Mackenzie River and its delta. Several other fall-spawning species are notable, such as mountain and lake whitefish, inconnu, and bull trout. Mountain whitefish is one of the most abundant species in the river, with adults and juveniles occurring throughout the main stem and upper tributaries. Bull trout are widely distributed in the river but are rare in the lower river reaches. Portions of the Liard River in the vicinity of Nahanni National Park may have been an important glacial refugium for fish species, such as the lake whitefish (Clayton et al. 1992).

Important spring-spawning species of the Liard River include longnose sucker, Arctic grayling, goldeye, northern pike, and walleye (MacDonald 1992). Longnose suckers are ubiquitous in the Liard River and appear to be the most abundant large fish species in the basin. This species is used as food for humans and dogs. The most abundant sport-fish species in the basin is Arctic grayling, which is a resident of the main stem and spawns on gravel and cobble in small streams and tributaries. The goldeye spends much of its life cycle in the main stem and is thought to be the species most dependent on

these habitats. Several surveys on tributaries failed to collect goldeye; in contrast, they are the most abundant sport fish in the lower reaches of the main-stem Liard River. Similarly, walleye are abundant in the lower river but are rare upstream of the Fort Nelson River confluence. Other species in the river system include burbot, which spawn under the ice in late winter, and many smaller forage fishes, such as various minnows and sculpins for which no information was found.

Based on surveys conducted within the Nahanni National Park Reserve, the Liard watershed area has a total of 42 species of mammals, including many that are closely associated with the river (moose, beaver, river otter, muskrat, and mink) (<http://parkscanada.gc.ca/pn-np/nt/nahanni> 2003). There are 180 species of birds, including loons, grebes, ducks, and bald eagle. In addition, Yohin Lake, which is located within the National Park Reserve, supports a small nesting population of trumpeter swans (<http://parkscanada.gc.ca/pn-np/nt/nahanni> 2003). There are no known species of reptiles in this region; however, there are a few species of amphibians, with the most common the wood frog (<http://parkscanada.gc.ca/pn-np/nt/nahanni> 2003).

Ecosystem Processes

Although studies on ecosystem function of the Liard River have not been undertaken, one can speculate that the important processes follow trends of the river continuum concept. Decomposition of terrestrial material is likely an important carbon source in headwater reaches, whereas autochthonous carbon sources likely dominate downstream. River-ice breakup is an important ecological reset mechanism in spring, as this disturbance scours the riverbed and adds large amounts of terrestrial carbon to the ecosystem (see Fig. 18.3).

Human Impacts and Special Features

The Liard River is known for its wild and rough stretches of river, with its Rapids of the Drowned and Hell Gate (Artibise 2001). Another important feature in the basin is Liard River Hot Springs, which is a British Columbia Provincial Park (http://wlapwww.gov.bc.ca/bcparks/explore/parkpgs/liard_hs/nat_cul.htm 2004). Located just off the main channel near the community of Liard River, it has thermal springs that flow into an intricate system of swamps, creating a microclimate that allows a unique vegetative community to thrive there. The South Nahanni River is a tributary of the Liard and is known for its natural

beauty. The approximately 100 m high Virginia Falls on the South Nahanni is 1.5 times the height of Niagara Falls and is part of Nahanni National Park, a U.N. World Heritage Site since 1978. Fort Nelson, the largest community in the watershed (approximately 6000 people), is home to the largest gas-processing plant in North America and the world's largest chopstick manufacturer.

Although development of forestry, mining, and petroleum resources in the upper Liard River is locally intensive, this basin remains relatively pristine and adverse environmental changes have not been observed (MacDonald 1992). Water-quality measurements throughout the system are generally well below Canadian Water Quality Guidelines (CCME 1999) for the protection of aquatic life. In addition, the very limited measurements of heavy metals in sediments and fishes from the main stem revealed levels similar to reference conditions in pristine areas throughout British Columbia and the Yukon. Nevertheless, areas of concern do exist, such as resource-extraction developments that have occurred upstream of Nahanni National Park. Of more serious concern, however, are the proposals for several hydroelectric developments along the main-stem Liard River. MacDonald (1992) outlines numerous adverse changes that these dams could cause to water quality and temperature regimes. In fact, he suggests that this hydroelectric development could cause damage to the fisheries resource through impacts to spawning and rearing habitats, as well as fragmentation of critical migration routes.

SLAVE RIVER

The 8th order Slave River is formed near the confluence of the Peace River and the outflow from Lake Athabasca, known as Rivière des Rochers, and flows north approximately 420 km to Great Slave Lake (Fig. 18.13). For its last 200 km the river meanders through the active portions of the massive Slave River Delta, which is 8300 km² in area and up to 70 km wide. It is the major southern tributary of the Mackenzie River and drains approximately 615,000 km². This area represents the combined discharge of the Peace and Athabasca rivers, the Peace–Athabasca Delta (PAD), and the Lake Athabasca drainage system. Surprisingly, the drainage area located between the Slave's origination at the confluence of the Peace and Rivière des Rochers rivers is only 15,100 km², <3% of the catchment (Alberta Environment 1987). Flow contributed to the Slave

River from the PAD originates primarily from Lake Athabasca, largely located within Saskatchewan, and the Athabasca River, fed from central portions of Alberta (Prowse and Conly 1996). Exposed bedrock occurs all along the river, with the topography of the basin consisting of rolling hills in the southeast and low scarps of limestone and small lakes in other parts of the basin.

The Slave River and Great Slave Lake are named for the Slavey peoples. The Slavey are part of the larger Dene nation, whose ancestors arrived from the Bering Strait. It is estimated that permanent residency along the Slave River occurred approximately 2500 years ago. The Slave River was a main travel route for aboriginals traveling northward. The Slavey had a seminomadic way of life due to the scattered and seasonal occurrence of the migratory animals that were their food source and harsh weather conditions (Crowe 1974). They survived primarily on fishes, moose, and caribou. The Slavey were in frequent conflict with the mountain people of the Nahanni area and today live in a number of communities of the Northwest Territories.

Early European explorations were conducted by English explorers Samuel Hearne (discovery of Great Slave Lake in 1771), Donald Alexander Smith (name-sake for the town of Fort Smith), Sir Alexander Mackenzie, and David Thompson. During the 1800s the Hudson's Bay Company established a trading post along the banks of the Slave River at Fort Smith, and this became the primary trade link to the Mackenzie River.

Physiography, Climate, and Land Use

The Slave River flows northwest between 58°N and 62°N latitude and 110°W and 114°W longitude along the boundary of two physiographic provinces, the Bear–Slave–Churchill Uplands (BC) to the east and the Great Plains (GP) to the west (Rosenberg and Barton 1986) (Fig. 18.13). Precambrian granites and gneisses in the BC province, and Devonian sedimentary rocks in the Great Plains dominate the geology of the basin. Much of the northern part of the catchment drains a flat area of lacustrine deposits through which the river meanders. Unconsolidated glacial drift, postglacial alluvial sediments, and recent organic deposits cover most of the surficial geology of the Slave River basin (Alberta Environment 1987). Eolian deposits of sand dunes, formed by wind action immediately after glacial Lake McConnell drained, are common in the southwest basin. Soils of the system include brunisols, gleysols, regosols, fibrisols,

and cryosols; however, only the brunisols have a well-developed soil horizon.

Landscape along the Slave River (excluding the upstream Peace and Athabasca basins) is composed of the Northern Canadian Shield Taiga and Mid-continental Canadian Forests terrestrial ecoregions (Ricketts et al. 1999). Vegetation includes closed stands of trembling aspen, balsam poplar, and jack pine, with white and black spruce and balsam fir dominating late successional stages. Some areas of semiopen grassland with clumps of willow and aspen are found in uplands. Sedge–grass meadows often occupy depressions on lacustrine and deltaic plains (Alberta Environment 1987). Fens and bogs are covered with tamarack, black spruce, and mosses, and up to 50% of the area is covered by wetlands. Discontinuous permafrost is occasionally evident in organic deposits. The basin contains Wood Buffalo National Park, which is the home of the world's largest bison herd.

This basin has a harsh Continental climate characterized by short cool summers and long cold winters. The mean annual temperature at Fort Smith, Northwest Territories, is approximately -3°C , with the monthly mean temperature rising to 16°C in July and falling to -25°C in January (Fig. 18.14). Daily maximum temperatures range between 23°C and -20°C . Annual precipitation in the basin is low, with approximately 60% of the 30 to 40 cm of moisture falling as rain between May and October (see Fig. 18.14). At Fort Smith monthly precipitation ranges from 1.35 cm/mo in April to a maximum of 5.68 cm/mo in July.

Currently the largest land-use activity in the Slave River watershed region is forestry; other activities include hunting, fishing, trapping, and some mineral exploration. Population of the region is $<10,000$ people (<1 person/ km^2) and contains the Northwest Territories towns of Fort Resolution and Fort Smith. Much of the west side of the Slave River watershed lies within Wood Bison National Park. Land types in the watershed consist of forest cover (40.3%), taiga (25.8%), shrubland (20.9%), agriculture (land covered with herbaceous, typically annual crops), which may contain a small proportion ($<10\%$) of trees and shrubs (1.6%), open land (1.4%), and water (9.9%) (<http://atlas.gc.ca/site/english/index.html> 2003).

Geomorphology, Hydrology, and Chemistry

The river is dominated by regional geology but has moved laterally, depositing alluvial material and

creating floodplain areas (Prowse and Conly 1996). Numerous alluvial islands and channel-bar complexes are common along the upper reaches, where the western margin of the Canadian Shield restricts river movement. At Fitzgerald the Slave River passes over a Precambrian sill of bedrock, falling 35 m over a 30 km distance. Progradation of the Slave River Delta has been occurring for 8000 years at a rate of about 20 m/yr and has progressively filled in the south arm of glacial Great Slave Lake (Prowse and Conly 1996). Scroll bars, abandoned channels, and oxbow lakes dominate river morphology within the delta.

Flow of the Slave River comes largely from the Peace River or from Lake Athabasca via the Rivière des Rochers and nearby PAD channels, depending on the hydrological stage of the Peace River (Alberta Environment 1987). During high spring flows the Peace River can act as a hydraulic dam, reversing the flow of channels of the PAD, such as the Rivière des Rochers. Thus spring floodwaters from the Peace River can be stored in the PAD–Lake Athabasca system and released later in the season (Fig. 18.5). During the remainder of the year about 90% of the outflow from the lake drains through the Rivière des Rochers or the smaller Chenal des Quatres Fourches and Revillon Coupe. Spring melt in the Peace River basin has a major influence on the Slave River hydrograph and floods are normally caused by Peace River flows (Prowse and Conly 1996).

At Fort Smith mean monthly runoff ranges from 0.82 cm/mo in February to 2.41 cm/mo in June (see Fig. 18.14). Runoff increases in May with increasing precipitation and the initiation of snowmelt. Evapotranspiration increases the precipitation-to-runoff ratio from June to October. Peak annual discharge occurs in June and July when, on average, about 25% of annual runoff is observed (see Fig. 18.14). In contrast, from August through March decrease in discharge in the Slave River is less than the Peace River due to input from the lake. Mean monthly discharge for the Slave River at Fitzgerald is approximately $3400\text{ m}^3/\text{s}$; minimum and maximum monthly discharge occur in February ($2000\text{ m}^3/\text{s}$) and June ($5600\text{ m}^3/\text{s}$), respectively (see Fig. 18.14). The normal date of freeze-up is mid-November; river ice tends to break up in mid-May.

The Peace and Athabasca rivers and Lake Athabasca strongly affect water quality in the Slave River. The water is slightly basic, with an annual mean pH of 7.8, and alkaline, with high concentrations of calcium bicarbonate, suspended sediments, and turbidity (Alberta Environment 1987). Conduc-

FIGURE 18.5 Peace–Athabasca Delta showing typical perched basin and adjacent channel system. Note contrast in sediment conditions between the basin and channel, indicating lack of flow connection at this water level (PHOTO BY T. D. PROWSE).

tivity ($253\ \mu\text{S}/\text{cm}$) and alkalinity ($82\ \text{mg}/\text{L}$ as CaCO_3) are lower than the Peace River, probably as a result of significant runoff from the Canadian Shield (Brunskill 1986, see also Peace and Slave river sections; Prowse and Conly 1996). In contrast, sodium and chloride ion concentration increases in the river near the delta as a result of inflows from the surrounding karst area. Nutrient levels in the Slave River are relatively low and similar to values for the Peace River, with average total nitrogen concentrations of $0.40\ \text{mg}/\text{L}$ and average total phosphorus concentrations of $0.21\ \text{mg}/\text{L}$.

River Biodiversity and Ecology

The Slave River lies within the Upper Mackenzie freshwater ecoregion (Abell et al. 2000). The biodiversity and ecology of the river are relatively poorly understood, with most of the information coming from surveys of McCarthy, Robertson et al. (1997), McCarthy, Stephens et al. (1997), and McCarthy, Williams et al. (1997) and reports summarized by Prowse and Conly (1996).

Plants

Although the deltaic flora of the Slave River basin is reasonably well described, little information is available on the primary producers of the river channel. Tallman (1996) speculates that high levels of suspended sediments and turbidity prevent macrophyte growth in the river channel. In contrast, willow, horsetail, and grasses are located along the frequently flooded riparian margins of the main stem (Prowse and Conly 1996). Shallow lakes and wetlands of the PAD have an abundance of emergent and submergent vegetation, as well as sedges and reed grasses. Much of the Slave River Delta is covered by emergent vegetation, such as horsetail. For a detailed description of vegetational succession in the PAD, see Prowse and Conly (2000).

Invertebrates

Recent information on benthic invertebrate communities of the Slave River is restricted to the baseline survey work of McCarthy, Robertson et al. (1997). They found that benthic environments in the river were composed of sand, silt, and clay, and sediment organic carbon was low, averaging only 2.5%. A total of 69 taxa were identified, the most abundant members of the benthic community being chironomid midges and oligochaete worms. Common chironomids were *Stictochironomus quagga*, *Procladius* sp., *Chironomus anthracinus*, and *Polypedilum scalaenum*. Oligochaetes were composed mostly of *Limnodrilus hoffmeisteri* and *Chaetogaster diaphanus*. Other common taxa included ostracods and biting midges. Total benthic density in the Slave River ranged between about 1250 and 1700 individuals/m² in 1990 and 1991, and chironomids accounted for >80% of this fauna. The primary factors correlated with benthic invertebrate distribution were water depth and organic carbon content. Furthermore, oligochaetes and ostracods were more abundant in shallow water and sediments of high organic content, and *Procladius* sp. was the only taxon exhibiting higher abundance with increasing water depth. McCarthy, Robertson et al. (1997) found that autumnal benthic communities were very similar between years. Clearly, McCarthy, Robertson et al. (1997) did not sample the complete faunal pool, as Tallman (1996) found that several other orders of benthic invertebrates comprised important proportions of fish diet in the Slave River; namely, amphipods, caddisflies, corixids, dytiscids, mayflies, and stoneflies.

Vertebrates

The fish fauna of the Slave River Basin contains 45 species, 28 of which can be found in the Slave River main stem and delta (McCart 1986). Similar to other tributaries of the Mackenzie River, most of the species are either salmonids or cyprinids. The primary information source on the Slave River fish community is Tallman (1996), who provides information on the fish fauna of the lower Slave River north of 60°N latitude. Fish species composition varies considerably among major areas in this part of the river. For example, goldeye were the most abundant fish species sampled during surveys of the main stem, whereas northern pike were common in the delta. In both the river and delta, longnose sucker and lake whitefish were present in low abundance. Most fishes in the Slave River system appear to be generalists, acting as opportunistic feeders consuming a number of different prey over the seasons (Little et al. 1998). Species such as flathead chub, goldeye, longnose sucker, and lake whitefish forage heavily on invertebrates. Top predators include the predominantly piscivorous walleye, inconnu, and large northern pike.

The Slave River is an important spawning, rearing, and feeding habitat for many fish species. Not surprisingly, spawning migrations cause seasonal changes in fish-community composition in the river. Spring spawners such as goldeye, flathead chub, longnose and white suckers, northern pike, and walleye dominate in late May shortly after river ice breakup. Fall spawners, including lake and small cisco, lake whitefish, and inconnu, become abundant between September and October. Northern pike, flathead chub, and goldeye remain relatively abundant throughout the open-water season. Radio tagging studies indicate that inconnu move from Great Slave Lake to the Rapids of the Drowned by mid-October and vacate the site before November. As ice cover forms in late fall, burbot move into the river, returning to the lake after the February spawning period (Howland et al. 2000, Tallman 1996). Based on the comparison of gillnet catches, the diversity of major fish species in the Slave River has not changed substantially since the 1970s.

The Slave River watershed contains the only known breeding habitat for the endangered whooping crane, located in the northeastern portion of Wood Buffalo National Park (www.hww.ca/hww2.asp?id=79 2003). The nesting area consists of six small areas totaling about 400 km². Most of these

areas are close to the Sass, Klewi, and Nyarling rivers, which flow into the Slave River (www.hww.ca/hww2.asp?id=79 2003). In addition, the Slave River is home to the most northerly nesting place in North America for the American white pelican. These nests are located on islands within the main channel of the Slave River. Other aquatic birds include snow geese, Canada geese, loons, grebes, mergansers, osprey, and bald eagles (www.nwtwildlife.rwed.gov.nt.ca/monitoring/speciesmonitoring 2003).

There are six known species of amphibians within the Slave River watershed, including chorus frog, wood frog, northern leopard frog, Canadian toad, boreal toad, and long toed salamander. There is one species of reptile, the red sided garter snake. Aquatic mammals found in the Slave River include beaver, muskrat, river otter, and mink (www.nwtwildlife.rwed.gov.nt.ca/monitoring/speciesmonitoring 2003).

Ecosystem Processes

Information on ecological processes of the Slave River system is limited to recent studies investigating food web structure in the main stem or the interplay of hydrologic processes and ecosystem structure and function of the PAD. First, studies of stable isotope ratios of sulphur, carbon, and nitrogen suggest that fishes in the Slave River are influenced by the pelagic food chain of Great Slave Lake and by upstream river processes (McCarthy, Robertson et al. 1997). Upstream food sources appear to be organic matter transported from the Peace and Athabasca rivers, suggesting heterotrophic processes dominate the metabolism of the Slave River. Second, ecological processes of the PAD are dependent on the hydrology of the downstream river (Prowse and Conly 1996, 2000). When ice jams or open-water floods in the Peace and Slave rivers produce water levels that are higher than those of Lake Athabasca, the connecting channels between the rivers and lake reverse their flow, filling the wetlands and perched basins of the PAD.

Human Impacts and Special Features

The Slave River drains from Lake Athabasca and the PAD in Alberta into Great Slave Lake located in the Northwest Territories. The PAD is the largest inland freshwater delta in the world and the largest alluvial-wetland habitat in the region (see Fig. 18.5) (www.ibacanada.com 2003). Its significance cannot

be overstated, as it is critical to migratory birds using the Central and Mississippi Flyways. The PAD is also important to fishes migrating between the delta lakes and the rivers, and to muskrat populations in the delta. Great Slave Lake, at 28,400 km², is the fifth-largest lake in North America and, at 618 m, the deepest (Asch 2001).

The river is the natural eastern border for Wood Bison National Park, which contains the largest free-roaming bison herd (5000 to 6000 animals) in the world (www.nwtwildlife.rwed.gov.nt.ca/monitoring/speciesmonitoring 2003). Salt Plains, located on the eastern banks of the Slave River, is an area of underground springs that transport salt from below the surface and deposit it along the flat open areas of the plain, creating unique saline microhabitats.

Historically, the Slave River has been an important transportation route to the north for the Slavey and other aboriginal groups and fur traders. Most of the river is easily boatable. However, Fort Fitzgerald and Fort Smith, the two major towns along the length of the Slave River, are located at the beginning and the end of a treacherous set of rapids spanning approximately 25 km. The towns are located in areas that have traditionally been used as portage routes. Islands located within these rapids provide the most northerly nesting habitat for the American white pelican (www.ibacanada.com 2003). Past proposals for a major hydroelectric-power dam at Pelican Rapids near Fort Smith are currently moribund.

The Slave River receives chemical compounds from several sources, including industrial, agricultural, long-range transport, and natural pathways. Concern over the threat of upstream developments in the Slave River basin, particularly the expansion of pulp mills and oil sands on the Athabasca River and damming of the Peace River, led to a multiyear monitoring program of the river in the early 1990s, which provided much of the data summarized here. Compounds in the water, such as chlorinated compounds, PAHs, and PCBs, were very low and seldom reached levels above detection limits (McCarthy, Williams et al. 1997). Furthermore, pesticides were not detected in the Slave River. In contrast, metal concentration in the Slave River often exceeded federal water-quality guidelines. Nevertheless, McCarthy, Williams et al. (1997) concluded that these relatively high levels (e.g., mercury) were most likely from natural sources rather than from upstream industrial inputs. Levels of organic and inorganic contaminants were also very low in suspended sediments. Taken together, it

was concluded that contaminant levels were unlikely to have adverse effects on the river ecosystem (McCarthy, Williams et al. 1997). This conclusion was supported by bioassay experiments that demonstrated suspended sediments from the river were not toxic to *Daphnia magna* (i.e., 48 h acute toxicity) or the bacterium *Photobacterium phosphoreum* (i.e., *Microtox* bioluminescence assays). Similarly, although benthic invertebrates occur at very low densities in the Slave River and most of the organisms are small chironomid midges, McCarthy, Robertson et al. (1997) indicate that few changes in diversity or composition occurred over the period of increased input of point and nonpoint impacts upstream (e.g., industrial effluents and forest harvesting).

Tissue from several species of fishes from the Slave River (i.e., burbot, lake whitefish, longnose suckers, northern pike, walleye) had consistently low concentrations of heavy metals, chlorinated phenolics, dioxins and furans, organochlorine pesticides, PAHs, and PCBs, indicating that fishes were fit for human consumption (McCarthy, Stephans et al. 1997). Elevated levels of toxaphene were found in the livers of burbot, which are a traditional country food, prompting Health Canada to set a human consumption limit of one burbot liver per week. Because the application of toxaphene was restricted in 1970 and its use has been banned in Canada since 1983, the source of toxaphene in the Slave River is thought to be long-range transport. Finally, biochemical indicators of contaminant exposure and effects on fishes demonstrated that contaminant effects on Slave River fish populations were minimal (Williams et al. 1997, Cash et al. 2000).

The hydrological regime of the Slave River is affected by one of the world's largest reservoirs, located more than 1200 km upstream on the Peace River, its main tributary. A major impact of flow regulation has been a reduction in the frequency and magnitude of flooding of the PAD (see Fig. 18.5) that has complex hydrological interconnections with the Slave River (Prowse and Conly 1996, 2000). Flow regulation has resulted in drying of the delta since 1968 because postreservoir discharge and ice formation are now higher in the winter, thereby leading to a reduced probability of large ice-jam flooding of the delta (Prowse and Lalonde 1996). In addition, changes in atmospheric circulation patterns and associated reductions in winter snowfall have combined to decrease the amount of snow available for spring runoff. Ultimately, decreased flooding of the delta has caused various ecological responses, including loss of wetland habitat and biota of perched basins.

Recently, flow-augmentation strategies have been proposed and successfully tested with the aim of returning the flood regime of the delta to preregulation levels and providing improved remediation strategies for wetland vegetation and wildlife (Prowse et al. 2002).

PEACE RIVER

Originating within the alpine zone of the Rocky Mountains in northeastern British Columbia, the Peace River is formed at the junction of the north-flowing Parsnip and the south-flowing Finlay rivers from headwater streams, many of which are glacial in origin (Fig. 18.15). With a drainage area of 293,000 km², the Peace River is the major tributary of the Slave River (Prowse and Conly 1996, 2000) and is regulated by a massive hydroelectric development as it feeds into the Williston Reservoir formed by the W.A.C. Bennett Dam. Regulated flow from this hydroelectric operation then passes downstream into northern Alberta and ultimately to the Peace–Athabasca Delta approximately 1200 km downstream (see Fig. 18.5). At its confluence with the PAD, one of the world's largest freshwater deltas, the Peace River is an 8th order river that is almost 2000 km in length.

Approximately 10,000 years ago the last glacial ice sheets retreated from the northern parts of the Canadian prairies. Groups of nomadic hunters probably passed through the area whenever the Rocky Mountain and Keewatin ice sheets separated briefly. There is evidence of them pausing briefly near Fort St. John, on the Peace River, around 10,000 years ago. The ice-free corridor allowed people from Asia to penetrate deep into the Americas. With the end of the Ice Age many of these groups moved back north. They followed the herds of grazing animals, which were, in turn, following the grasses northward in the warming climate. The previous introductory information and that which follows is drawn from an essay by Clare (www.calverley.ca/briefhistory.html 1998).

The arrival of the Hudson's Bay Company in Eastern Canada in 1670 eventually had a major impact in the Peace River area, as guns made their way westward as trade goods and the Cree Tribe began to push the Beaver Tribe further west. The Beaver, in turn, pushed the Sekani deep into the Rocky Mountain Trench in the mid-1700s. A truce was eventually agreed to by the Cree and the Beaver and the Peace River became the boundary between their hunting territories. Early residents of the Peace

River basin were members of the Athapaskan linguistic group.

The two rival fur-trading companies, the Hudson's Bay Company and the North West Company, pushed westward in the late 1700s. Fort Chipewyan on Lake Athabasca became the headquarters for the Northwest Company's attempts to reach the Pacific Ocean. Sir Alexander Mackenzie is thought to be the first European to explore the river during his overland search in 1793 for the Columbia River and a route to the Pacific. An era of fur trading began in the Peace with the first forts built within a few years of Mackenzie's great trip. Simon Fraser stopped over at Hudson's Hope in 1806 before he pushed south to follow the river named after him to its mouth near Vancouver. Posts such as Dunvegan, Fort Vermilion, Fort St. John, and McLeod Lake became centers of the northern fur trade. Both the Catholic and Anglican churches established missions in the Peace along with the fur traders. There was a brief flurry of gold panning in the 1870s on the Omineca and on the Peace, but it was never of much importance. Klondikers passed through the Peace in 1898 on their way to the Yukon, but this was one of the worst routes to follow to the gold fields.

Physiography, Climate, and Land Use

The Peace River basin is comprised of three major physiographic provinces (Hunt 1974) and spans latitudes 53°N to 59°N and longitudes 111°W to 127°W (see Fig. 18.15). The western Cordillera provinces include the Coast Mountains of British Columbia and Southeast Alaska (PM) and the Rocky Mountains in Canada (RM) (Rosenberg and Barton 1986, Prowse and Conly 1996). About two-thirds of the basin, however, drains the Great Plains (GP) province. Soils in the Peace basin are quite diverse and include chernozemic, brunisolic, gleysolic, luvisolic, organic, and crysollic soils. Much of the southwestern portion of the basin, including the Rocky Mountains, is composed of sedimentary rocks with deep valleys and high plateaus covered by glacial tills. However, the Great Plains is underlain by recent metamorphic and sedimentary bedrock of Devonian and Cretaceous age. The effects of Pleistocene glaciation have modified landforms here, resulting in a surficial geology consisting of glacial drift, postglacial alluvial, and aeolian deposits (Prowse and Conly 1996).

The Peace River drains from a mosaic of terrestrial ecoregions (Ricketts et al. 1999). Ecoregions in

the mountainous southwestern portion of the basin include the Central British Columbia Mountain Forests, Northern Cordillera Forests, Fraser Plateau and Basin Complex, and Alberta Mountain Forests. Within the Great Plains province the main-stem Peace River flows primarily through the Canadian Aspen Forest and Parklands ecoregion, but also drains portions of the Alberta/British Columbia Foothills Forests, Muskwa/Slave Lake Forests, and Mid-continental Canadian Forests. In the upper elevations, forests of aspen, balsam poplar, spruce, and lodgepole pine are dominant (Prowse and Conly 1996). Vegetation in most of the basin, however, consists primarily of trembling aspen and balsam poplar, and secondarily of white spruce, black spruce, lodgepole pine, and jack pine. In drier areas semiopen grasslands may also be found. Black spruce and peat lands are abundant in the Taiga regions.

The climate in the Peace River basin is relatively dry, with cool summers and cold winters. Mean annual air temperature for the area is approximately -0.9°C , with mean monthly temperatures ranging from -23°C to 17°C during the year (Fig. 18.16; data are climate normals for Fort Vermillion, Alberta, from 1908 to 1985 [www.climate.weatheroffice.ec.gc.ca/climate_normals/index_e.html 2002]). Winter temperatures can be several degrees colder in northeastern portions of the basin. Average precipitation varies from 46.8 cm/yr at Fort St. John in the upper Peace River basin to 38.1 cm/yr at Fort Vermillion in the lower river. At Fort Vermillion monthly precipitation ranges from 1.75 cm/mo to 6.44 cm/mo in July (see Fig. 18.16). Approximately 30% of this moisture arrives as snow. The main stem is ice covered from late November through early April.

The construction of the huge W.A.C. Bennett Dam at Hudson Hope and the creation of Williston Lake on the Upper Peace in the mid-1960s initiated energy extraction in the Peace River region (www.calverley.ca/Briefhistory.html 2000). Coal, oil, natural gas, and hydroelectricity provide energy sources for markets in southern Canada, the United States, and Pacific Rim countries. This region also contains an active forest industry, including pulp and paper, lumber, and particle-board mills in Chetwynd, Dawson Creek, Taylor, and Fort Nelson. In addition, there are areas of agriculture, which produce primarily oil seeds, grains, cattle, bison, and other livestock (www.calverley.ca/briefhistory.html 2000). Land type in the basin is dominated by forest cover (57.4%), followed by agriculture (16.2%), taiga (12.5%), and shrubland (11.4%) (<http://atlas.gc.ca/site/english/>

index.html 2003). Population in the basin is approximately 110,000 and population density is <1 person/km².

River Geomorphology, Hydrology, and Chemistry

The average gradient of the Peace River in the Great Plains of Alberta is only 16cm/km (Prowse and Conly 1996). The upper Peace River downstream of W.A.C. Bennett Dam is incised 200m into the surrounding Alberta Plateau. This reach has a primarily straight channel with occasional islands and gravel bars. At this point the river is approximately 500m wide and 4m deep (Prowse and Conly 1996, Kellerhals et al. 1972). The middle river reach from the confluence of the Smoky River to Fort Vermilion mostly drains the Peace River lowlands and has mean widths ranging from 500 to 650m. Intermittent islands and bar complexes are common, and the river can be characterized as partly entrenched and confined with irregular meanders (Prowse and Conly 1996). Bed materials are primarily sand and fine gravel, with silt and erodible bedrock occurring along the banks (Kellerhals et al. 1972). The lower river reach from Fort Vermilion to Peace Point cuts through the lacustrine deposits of glacial Lake McConnell. The channel is weakly sinuous, with split channels and island complexes, and channel width ranges between 700 and 1500m (Prowse and Conly 1996). Substrate composition within this reach is predominantly shallow sand with local areas of gravel.

Mean monthly runoff ranges from 1.02cm/mo in February to 3.84cm/mo in June (see Fig. 18.16). High runoff-to-precipitation ratios in May and June are due to snowmelt and increased monthly precipitation. From July through October evapotranspiration increases the difference between precipitation and runoff. Mean monthly discharge of the Peace River at Peace Point, near the mouth, is 2188m³/s. About two-thirds of this discharge originates in British Columbia. As in the Athabasca River, peak discharge is associated with snowmelt from mountain runoff, which occurs in late May to early June (~4300m³/s). Summer rainfall events can produce secondary flood peaks during most years (Prowse and Conly 1996). Minimum monthly discharge values of approximately 200m³/s occur during late winter (February to March) and are strongly regulated by the upstream dam (Peters and Prowse 2001). Spring flood peaks of the tributaries and the main-stem

Peace play a critical role in the type of river-ice breakup in the lower Peace, and thus the recharge of the Peace–Athabasca Delta as a result of ice-jam formation (Prowse and Conly 2000).

The enormous discharge of the Peace River results in considerable dilution of dissolved chemical constituents in the water. Shaw et al. (1990) indicate the Peace main stem has much higher dissolved oxygen concentration (always near saturation) and low values of most water-chemistry variables (e.g., anions, cations, nutrients) compared to tributary waters. For the main channel of the Peace River, water color is turbid, conductivity is 257µS/cm (Brunskill 1986), annual average pH is 7.9, alkalinity is 96mg/L as CaCO₃, total nitrogen is 0.52mg/L, and total phosphorus is 0.16mg/L (Shaw et al. 1990). Although tributaries can be adversely affected by anthropogenic point-source effluents (Shaw et al. 1990, Chambers, Brown et al. 2000, Chambers, Dale, and Scrimgeour 2000), synoptic surveys conducted by Alberta Environment in 1988–1989 indicate no measurable impacts of tributary discharges to the Peace main stem. Water chemistry of the main stem varies longitudinally, with upper reaches (headwaters to Smoky River confluence) characterized by low values of suspended solids (<150mg/L) and nutrients (e.g., total phosphorus 0.1mg/L). The lower reaches of the Peace River (Fort Vermilion to Peace Point) have higher concentrations of suspended solids and associated variables, including turbidity, BOD, total metals, and nutrients (Shaw et al. 1990). It is notable that many of the tributaries in this lower reach arise in peat lands and are brown-water streams. Shaw et al. (1990) also indicate that relative to the Athabasca River, the other major southern tributary of the Mackenzie, the Peace River tends to have lower and more constant concentrations of dissolved substances and higher amounts of particulate matter.

River Biodiversity and Ecology

The Peace River is a vast, sparsely populated basin and relatively little is known about its ecology and biodiversity. The Peace falls entirely within the Upper Mackenzie freshwater ecoregion (Abell et al. 2000). The available scientific literature largely originates from surveys by Alberta Environment or from studies that have examined the effects of river regulation or industrial impacts (Culp et al. 2000a, Gummer et al. 2000).

Algae and Cyanobacteria

Information on the microbial and algal communities of the Peace River is limited to data collected for the purpose of impact assessment (i.e., Shaw et al. 1990, Chambers, Brown et al. 2000, Chambers, Dale, and Scrimgeour 2000). Bacterial analyses on the Peace River in 1988–1989 indicate that total coliform counts tended to be highest in the summer and lowest in winter, often increasing downstream of point sources, such as effluents or tributaries that received large municipal or industrial loadings (e.g., Smoky River; Shaw et al. 1990). Although no information is available on algal community composition for the Peace River, diatom species probably dominate the potamoplankton and periphyton of this cold-water river. Potamoplankton biomass in the water column was low during an Alberta Environment synoptic survey, with mean concentrations ranging between 1 and 4 µg/L chlorophyll *a* along the entire river (Shaw et al. 1990). Tributary streams exhibited similar values, except for occasionally higher recordings associated with extreme sediment loads. Very few values of epilithic biomass are available for the main stem; however, observations in 1988 indicate that periphyton biomass during spring discharge was <25 mg/m² of chlorophyll *a*. Although late summer values reached levels as high as 99 mg/m² in river reaches upstream of the confluence with the Smoky River, chlorophyll *a* levels were largely <50 mg/m². Values throughout the open-water season tended to decrease along the length of the Peace River (Shaw et al. 1990). Epilithic algal biomass can be considerably higher in tributary streams receiving substantial point-source discharges. For example, algal biomass in the Wapiti River exceeded 100 mg/m² of chlorophyll *a* during fall 1994 (Scrimgeour and Chambers 2000, Chambers, Dale, and Scrimgeour 2000).

Plants

Riparian vegetation of the Peace River consists of poplar, spruce, alder, willow, and horsetail (Prowse and Conley 1996). Shoreline areas that are flooded frequently are vegetated by horsetail and grass species that tolerate high sediment deposition. With increasing distance from the channel margin, sediment- and flood-tolerant groups are replaced by willow and alder. Eventually, poplar and spruce occupy the drier and more stable portions of the upper riparian zone. Since the construction of the W.A.C. Bennett Dam, riparian vegetation has

encroached upon the channel margins as a result of reductions in large flood peaks and bank scour (Prowse and Conly 1996).

Invertebrates

An extensive longitudinal survey of benthic invertebrate communities along the Peace River main stem recorded a diverse assemblage of macroinvertebrates consisting of 106 taxa (Shaw et al. 1990). Mean taxa richness/sample was between 23 and 28 at upstream sites, but decreased to <10 taxa/sample in the lower 600 km of the river. This longitudinal trend was also evident in benthic invertebrate densities. For example, mean densities at sites along the British Columbia border exceeded 20,000 individuals/m². In contrast, densities in middle reaches of the river decreased to approximately 2000 individuals/m² and to <500 individuals/m² below Fort Vermilion. Oligochaete worms, chironomid midges (*Orthocladinae*, *Tanytopodinae*, *Tanytarsini*), and nematodes were the dominant taxa in the Peace River, their combined relative abundance making up at least 50% of the individuals at most sampling sites. Oligochaetes (*Enchytraeidae*, *Naididae*) were the most abundant groups upstream of the Smoky River confluence. Stoneflies (*Isoptera*, *Isopteroidea*, *Capniidae*, *Taeniopterygidae*) and mayflies (*Baetis*, *Ephemera*, *Heptagenia*, *Isonychia*, *Rhithrogena*) were an important component in the middle reaches of the river. Caddisflies were never abundant, with only a few genera recorded in the Peace River.

Vertebrates

The fish community of the Peace River is depauperate, containing only 31 species belonging to 12 families (McCart 1986). Eighteen of these species are either cyprinids or salmonids, and six families are represented by only one species. Most fishes in the Peace basin originate from the Mississippi–Missouri or Columbia refugia (Prowse and Conly 1996). Knowledge of the ecology of the Peace River fish community is limited but was recently updated during the Northern River Basins Study (Boag 1993). The dominant forage fishes collected in these surveys were minnows, troutperch, and sculpins. The most abundant sport fish was goldeye, followed by walleye, burbot, northern pike, and mountain whitefish. Kokanee, rainbow trout, bull trout, and lake whitefish were seldom captured. Abundance of fishes varied longitudinally, with more fishes caught

in middle and lower reaches on the main-stem Peace compared to upstream sections. However, species richness was higher in upper and middle reaches of the river. Most fishes in the main stem were concentrated in backwaters and tributary confluences, with fishes selecting areas of calm water apparently to avoid the high main-stem velocity. Boag (1993) considers the Vermilion Chutes on the Peace to be a partial barrier to upstream movement of fishes. In addition, fish surveys indicate that the Peace is used for overwintering by most of the dominant species, particularly the deep-water habitats upstream of Fort Vermilion. Goldeye and other dominant species also use the river below Peace Point for overwintering and rearing. Knowledge of the tributaries is incomplete, but spawning runs of walleye, longnose sucker, and northern pike have been observed (e.g., Wabasca River runs; Boag 1993). Furthermore, most tributaries supported populations of forage fishes, as well as juvenile longnose sucker and white sucker.

Amphibian species within the Peace River watershed include long toed salamander, western toad, spotted frog, wood frog, and striped chorus frog (PFWWCP 2000). There are only two species of reptiles: western garter snake and common garter snake. Common aquatic mammals include beaver, muskrat, river otter, and mink (PFWWCP 2000). Birds found near the river include snow goose, Canada goose, trumpeter swan, loons, grebes, merganser, osprey, and bald eagle (PFWWCP 2000).

Ecosystem Processes

Little information is available for most ecosystem processes of the Peace River. Upstream of Williston Lake attached algae are likely the most important source of autochthonous primary production. In contrast, Shaw et al. (1990) found low levels of periphytic algae (<1 mg/L chlorophyll *a*) downstream of the reservoir. In addition, this lower river reach had low values of chlorophyll *a* in the potamoplankton. The metabolism of this lower section of the river is likely based largely on decomposition of various carbon sources from upstream sources, as turbidity levels are generally high.

Human Impacts and Special Features

The Peace River is 1923 km long and one of the principal tributaries of the Mackenzie River system (Marsh 2001b). This river valley is an ancient course, which during the early Cretaceous period

(125 million years ago) was warm and lush with extensive swamps and broad bodies of fresh water, creating an ideal environment for dinosaur track formation (Currie and Sarjeant, 1979). During the construction of the W.A.C. Bennett Dam near Hudson's Hope large numbers of dinosaur fossils were unearthed (1700 tracks in >100 trackways; Currie and Sarjeant 1979). Tracks include some of the oldest records of bird footprints in the world, including a primitive shore bird, similar to killdeer, *Aquatilavipes*. Other fossils found in the area include duck-billed dinosaurs (Hadrosaurs), at least four species of carnivorous dinosaurs (including *Irenesauripus* and *Ornitholestes*), and horned dinosaurs (*Camptosaurus* and *Sauropelta*) (Currie and Sarjeant 1979). Further downstream the Peace River flows into Wood Buffalo National Park and its associated Peace-Athabasca Delta. This delta is a wetland ecosystem recognized by the Ramsar Convention on Wetlands and is listed as a U.N. World Heritage Site.

Agriculture, natural gas, forestry, and the tourism industry are the basis of the local and regional economies, which are focused in Fort St. John, the basin's largest community. The Peace valley is fertile and is the northernmost commercially important agricultural region of North America. The valley produces 85% of British Columbia's grain crops and most of the province's canola. The W.A.C. Bennett Dam located at the confluence of the Finlay and Parsnip rivers creates British Columbia's largest reservoir, Williston Lake. The Gordon M. Shrum hydroelectric power station near Hudson's Hope was built from 1968 to 1980 and at 2416 MW is the third largest in Canada.

The major impact of human activities along the Peace River main stem is regulation by the W.A.C. Bennett Dam. Filling of the Williston Reservoir between 1968 and 1972 reduced mean annual peak flows, with the magnitude of this reduction decreasing with distance downstream (Prowse and Conly 1996). Mean flood peaks at Hudson Hope near the dam outlet were reduced by about 30% relative to flows during the decade prior to regulation. Because this is a hydroelectric facility, winter flows are higher and summer flows have diminished relative to the preregulation hydrograph (Peters and Prowse 2001). For example, Prowse and Conly (1996) determined that winter flow at Peace Point, approximately 1200 km downstream of the dam, was 2.5 times greater than preregulation discharge. Although sediments appear to be transported easily through the reservoir, reductions in peak flows have reduced the capacity of the river to transport sediments below

the dam. Thus old floodplains are being transformed into new low terraces and fine sediments are accumulating along channel margins and in former back channels. As a result, semiaquatic and shoreline vegetation is prograding down the banks, leading to progressively more narrow channels (Church 1995). Timescales for establishment of new forest communities are estimated in the order of centuries, but channel geometry adjustments appear to take only a few decades.

The Peace River main stem has not been affected by point-source effluents, probably because of its large volume relative to discharges from effluents and tributaries (Shaw et al. 1990). This is not the case for several of the tributary streams. For example, the Wapiti River (a tributary of the Smoky River, which has significant data available for analysis; see Additional Rivers section later in the chapter) receives point-source discharges from a pulp mill and a municipality, with the combined volume from these treated effluents adding 125 kg/d total phosphorus and 711 kg/d total nitrogen (Chambers, Dale, and Scrimgeour 2000). These effluents average approximately 1% of the river flow during the year and increase annual total phosphorus and nitrogen concentrations in the river downstream as far as the confluence with the larger Smoky River. In fact, during the low-flow period of winter (December to April) approximately 41% of the total phosphorus and 34% of the total nitrogen in the Wapiti River originates from municipal and pulp mill inputs. Above these effluent discharges the Wapiti River is oligotrophic and periphyton biomass is less than 10 mg/m² of chlorophyll *a*. Chambers, Dale, and Scrimgeour (2000) indicate that immediately downstream of the municipal discharge algal biomass increased more than tenfold and reached a peak of approximately 140 mg/m² of chlorophyll *a* downstream of the pulp mill discharge. The bottom-up effects of nutrient enrichment are transferred to higher trophic levels as benthic invertebrate densities increase below the pulp mill (Cash et al. 1996), and longnose sucker from this reach have greater mesenteric fat storage and condition factor (Swanson et al. 1994).

The increase in BOD, as a direct result of the effluent and indirectly from decomposing algal biomass, appears to depress dissolved concentration during the period of winter ice cover in the Wapiti River (Chambers, Brown et al. 2000). Although the concentration of dissolved oxygen in the water column remains near the current Canadian guidelines, dissolved oxygen in the substrate can be more

than 3 mg/L lower than those measured in the overlying water (Lowell and Culp 1999). Thus there are concerns that winter conditions in the Wapiti River may adversely affect benthic invertebrates or egg development of fall-spawning fishes.

Environmental contamination in the Peace basin is low compared to other major river systems in Canada (Cash et al. 2000, Wrona et al. 2000). Levels of contaminants increased downstream of the pulp mill on the Wapiti River; however, improvements in the pulp mill bleaching process led to decreased levels of dioxins, furans, and chlorinated resin acids by 1996. Elevated concentrations of polychlorinated biphenyls and organochlorine pesticides were observed in burbot livers from fishes collected downstream of the pulp mill on the Wapiti River (Cash et al. 2000); however, the study concluded that the observed concentrations were not a significant risk to human health.

ATHABASCA RIVER

The Athabasca River originates in Jasper National Park in western Alberta, Canada, and is the most southerly tributary of the Mackenzie River, extending across latitudes 52°N to 58°N and longitudes 108°W to 119°W (Fig. 18.17). From its source in the Columbia Ice Field in the Rocky Mountains, this unregulated river flows northeast across boreal forests and grasslands to the Athabasca Delta and Lake Athabasca (Chambers, Dale, and Scrimgeour 2000), a natural water body covering 7940 km². With the Peace River the Athabasca forms the north-flowing Slave River. The Athabasca is approximately 1200 km in length, drains an area of 154,880 km², and is a 6th order river at its confluence with the lake. Resource extraction is advanced within the watershed, as open-pit coal mines operate in the upper basin, expansive oil sands developments are situated in the lower basin, and the boreal forest is harvested throughout the drainage. Because of this extensive development, the Athabasca River receives more point-source effluent than other rivers in the Mackenzie River basin (NRBS 1996).

Prior to the arrival of the white man, Sekani, Shuswap, Kootenay, Salish, Stoney, and Cree tribes hunted and fished along the Athabasca River (www.chrs.ca 2003). With the advent of the fur trade, Iroquois also inhabited this area. Early exploration of the Athabasca River occurred in 1778 when Peter Pond transported goods from the lower Saskatchewan River to the Athabasca in order to

FIGURE 18.6 Athabasca River in the Rocky Mountains of Canada in Jasper National Park, Alberta (PHOTO BY C. E. CUSHING).

establish trade with the First Nations peoples. One of the earliest European settlements in the basin occurred at Fort Chipewyan in 1788 on the southwestern shore of the Lake Athabasca. This settlement became an important trading post in the region, as fur traders extensively used the river as a navigation route. In 1811, David Thompson established a fur-trade route to the Pacific by following the upper Athabasca River through Athabasca Pass to Wood River, a Columbia River tributary. This pass was a primary route across the Rocky Mountains for several years. By the 1870s the Athabasca Landing Trail had been established, a route that used the site of the present-day town of Athabasca on the river as the loading point for barges transporting supplies downriver to northern outposts.

Physiography, Climate, and Land Use

Similar to the Peace River to the north, the Athabasca River basin flows through four major physiographic

provinces (Hunt 1974). Moving from southwest to northeast, these include the Rocky Mountains in Canada (RM), Great Plains (GP), Athabasca Plain (AT), and Bear–Slave–Churchill Uplands (BC) (see Fig. 18.17). Terrestrial ecoregions follow a similar trajectory and begin with the Alberta Mountain Forests ecoregion in the southwest portion of the basin (Ricketts et al. 1999). Moving from southwest to northeast, the drainage passes through the Alberta/British Columbia Foothills Forests, Canadian Aspen Forest and Parklands, Mid-continental Canadian Forests, Midwestern Canadian Shield Forests, and Northern Canadian Shield Taiga ecoregions. Similarly, soils are diverse and include brunisolic, gleysolic, luvisolic, and organic materials. Headwaters in the Rocky Mountains are dominated by mixed forests of lodgepole pine, trembling aspen, and white spruce, with balsam fir, balsam poplar, and paper birch characteristic of the region. The lower elevations of the basin form part of the continuous midboreal mixed coniferous and deciduous forest

that extends from northwestern Ontario to the foothills of the Rocky Mountains. Sites in this region that are cold and poorly drained are often covered with tamarack and black spruce. In general, conifers are more prevalent on the cooler and higher elevations of the foothills; aspen tends to be dominant in drier sites in the lower plains.

The Athabasca River basin has a relatively harsh climate, with short cool summers followed by cold winters. Temperature decreases from the southwestern to the northeastern portions of the basin, but precipitation is lowest in the southwest. Jasper, in the Rocky Mountains, has an average temperature of 3°C, with mean monthly temperatures ranging from -11°C to 15°C. Maximum readings of 22°C occur in July, whereas mean minimum temperatures of -16°C are expected in January. In contrast, Fort McMurray has a daily mean temperature of 0.2°C; the mean monthly temperature range spans 36°C (i.e., -20°C to 16°C; Fig. 18.18). Precipitation ranges from 39.4 cm/yr at Jasper to 46.5 cm/yr near Fort McMurray. Monthly precipitation at Fort MacMurray ranges from 1.6 cm in February to 7.9 cm in July (see Fig. 18.18). Approximately 70% of the moisture received within the basin falls as rain. A detailed analysis of the climate of the Athabasca basin can be found in Hudson (1997).

Although nearly 100,000 people reside in the basin, the population density is <1 person/km². Fort McMurray, with a population of 35,000 in 1996, is the largest city; other towns in the basin have 2000 to 10,000 residents. Land-use activities in the Athabasca River basin include commercial pulpwood and saw-log forestry, coal mining, oil and natural gas production, various agricultural activities, tourism, wildlife trapping, and hunting. Five pulp mills discharge to the river and major oil sands developments are ongoing near Fort McMurray. Land types within this subwatershed include forest (59.8%), taiga (17.4%), agriculture (9.8%), shrubland (6.0%), open land (4.3%), water (2.7%), and permanent ice and snow (0.1%) (<http://atlas.gc.ca/site/english/index.html> 2003).

River Geomorphology, Hydrology, and Chemistry

The Athabasca River descends more than 1000 m from Athabasca Falls on the upper main stem to its mouth at Lake Athabasca. River gradient exhibits a normal concave profile, with the greatest changes in average channel slope occurring in the mountainous

region of Jasper National Park. In this upper reach the gradient decreases from approximately 4 m/km near Athabasca Falls to 90 cm/km at the eastern boundary of the park (Fig. 18.6). Mean channel width is 100 m in this area and mean depth is about 1.5 m (Kellerhals et al. 1972). Middle reaches of the river near the town of Athabasca have a low slope (40 cm/km), large mean channel width (200 m), and a mean depth of 2.2 m (Kellerhals et al. 1972). The river below Fort McMurray is very wide (500 m) and deep (2.4 m), with minimal slope (<20 cm/km). Substrate in the river grades from largely cobble and gravel in Jasper National Park to sand below Fort McMurray, with local areas of gravel and limestone bedrock. Multiple channels dominate the upper and lower sections of the river; however, middle reaches of the river are rarely braided (R. L. and L. Environmental, Ltd. 1994a).

Mean monthly runoff for the Athabasca River basin ranges from 0.31 cm/mo in February to 2.67 cm/mo in July (see Fig. 18.18). Mean monthly runoff pattern is similar to precipitation, with highest levels in summer (July) and lowest in winter (February). From June to September evapotranspiration results in a greater difference between precipitation and runoff. Mean monthly discharge increases from 88 m³/s near Jasper to 433 m³/s at Athabasca and 783 m³/s at the river mouth (R. L. and L. Environmental, Ltd. 1994b). River discharge is dominated by mountain runoff in the spring such that average values for July exceed 1500 m³/s at the river mouth (see Fig. 18.18). The hydrograph descends the remainder of the year, except during periods of high rainfall. Minimum discharge values of about 200 m³/s occur in February and March prior to river-ice breakup.

The Athabasca is a hardwater river with ion concentrations dominated by bicarbonate and calcium (Anderson 1989), resulting in an average conductivity of 332 µS/cm. River discharge strongly influences the concentration of the major cations (calcium, magnesium, sodium, and potassium) and anions (bicarbonate, sulphate, and chloride). The carbonate ions provide good buffering capacity, with an average river alkalinity of 117 mg/L as CaCO₃. Seasonal changes in concentration are greater than spatial patterns within a season, as the highest values of most chemical constituents occur during minimum winter discharge and the lowest values occur in summer during annual mountain runoff (Anderson 1989). Relative to the more northerly Peace River, the Athabasca River has a higher and more variable concentration of dissolved substances (average TDS

187 mg/L) and a lower amount of particulate matter (Shaw et al. 1990). Dissolved oxygen under ice shows significant declines over an 800 km river distance from the most upstream pulp mill to the reaeration zone at Grand Rapids (upstream from Fort McMurray) (Chambers, Brown et al. 2000). Between 1990 and 1993, late winter values ranged from saturation in the headwaters (~12 mg/L) to approximately 8 mg/L upstream of the rapids. Average nutrient concentrations for the whole river are 0.54 mg/L for total nitrogen and 0.10 mg/L for total phosphorus. Analysis of long-term trends in total phosphorus and total nitrogen from 10 sites indicates that the concentrations of both nutrients increase along the length of the Athabasca River, with the lowest concentrations occurring in Jasper National Park (Chambers, Dale, and Scrimgeour 2000). Median total phosphorus was less than 0.01 mg/L at Jasper and increased to approximately 0.04 mg/L below Fort McMurray. Nutrient concentration is typically highest in winter and lowest during annual peak discharge in summer (Chambers 1996).

River Biodiversity and Ecology

The Athabasca, along with the Peace River basin, composes most of the Upper Mackenzie freshwater ecoregion (Abell et al. 2000). The biodiversity and ecology of the Athabasca is the best understood of any system in the Mackenzie River basin, largely as a result of the Northern River Basins Study (NRBS 1996, Culp et al. 2000b) and its successor, the Northern Ecosystems Research Initiative.

Algae and Cyanobacteria

Although algal biomass throughout the length of the river is typically low, biomass values >700 mg/m² chlorophyll *a* were recorded below point-source effluents such as pulp mills and municipal sewage. Algal standing crop as chlorophyll *a* in Jasper National Park, upstream of all major human impacts, was <20 mg/m² chlorophyll *a* and increased approximately sixteenfold immediately downstream of Jasper, the most upstream town along the river (Chambers, Dale, and Scrimgeour 2000). Information on algal community composition is limited to two surveys: a limited survey of epilithic algae near Hinton, Alberta, by Podemski (1999), and a study by McCart et al. (1977) near Fort McMurray that examined the seasonal patterns of algae colonizing glass

slides. Podemski found that autumnal periphyton communities on the upper Athabasca were dominated by diatom species, with more than 40 species recorded. The most common genera were *Achnanthes*, *Diatoma*, *Fragilaria*, *Cymbella*, and *Nitzschia*. On the lower Athabasca River the temporal study of McCart et al. recorded a rich algal flora, with 191 species from December through October. Standing stocks were dominated by cyanobacteria in the lower river (e.g., *Hapalosiphon*, *Lyngbya*, *Oscillatoria*, *Phormidium*), except during the summer, when diatoms were most abundant.

Plants

Macrophytes are rare in the main channel. Barton (1986) hypothesized this was because of high concentrations of suspended solids and unstable riverbed substrate. Riparian vegetation includes peat and brown mosses, reindeer lichens, sedges, willow, and Labrador tea. Tree species include white spruce, balsam poplar, tamarack, black spruce, aspen, and willow.

Invertebrates

Information on the upper Athabasca River (above the Grand Rapids) is limited to a few surveys (Ouellet and Cash 1996). Mean macroinvertebrate densities in the spring (20,000 to 50,000 individuals/m²) were typically lower than those observed in the fall (30,000 to 200,000 individuals/m²) (Anderson 1989). Similarly, more taxa were found in the fall (18 to 33) than in the spring (12 to 21) at the reference site. Actual species richness is much higher than these figures imply, because taxonomic identifications were made only to the lowest practical unit, which was genus for mayflies, stoneflies, and caddisflies. During both seasons macroinvertebrate assemblages consisted primarily of chironomid midges (Chironomini, Orthoclaadiinae, Tanypodinae), mayflies (*Ameletus*, *Baetis*, *Cinygmula*, *Heptagenia*, *Ephemerella*, *Rhithrogena*), stoneflies (*Alloperla*, *Capnia*, *Isoperla*, *Hesperoperla*, *Pteronarcella*, *Taenionema*), and caddisflies (*Brachycentrus*, *Glossosoma*, *Hydropsyche*).

Limited information is available on the macroinvertebrate communities of the lower Athabasca River (Barton 1986). Faunal composition on bedrock in this reach resembled that of stony tributary streams, but standing stocks were very low (about 2000 individuals/m²). Bedrock fauna included the mayfly *Ephemerella inermis* and four species of the stonefly

Isoperla. Barton (1980) reports that the benthic invertebrate fauna of unstable sand and gravel substrates consisted mostly of chironomid midges and oligochaete worms, with standing stocks of 10 to 9000 individuals/m². Dominant chironomids included *Polypedilum*, *Paracladopelma*, and *Cyphomella*. In addition, the dragonfly *Gomphus notatus* and the mayfly *Ametropus nevei* were often present in the sand and gravel substrates.

In contrast to most other smaller tributaries within the Mackenzie watershed, benthic invertebrate information has been collected on the Bigoray River, a tributary of the Pembina River, which flows into the upper Athabasca River (Mackay 1995). This slow-flowing brown-water stream is typical of muskeg areas in the region (Mackay 1995) and is dominated by chironomids (112 species), ostracods, and 66 species of beetles, mayflies, and caddisflies. (Boerger 1981, Clifford 1978). Standing crop densities range between 20,000 to 50,000 individuals/m², and average annual standing crop biomass in the river was estimated at 0.86 g DM/m² (Clifford 1978). Areas of fast-flowing habitat that occur at beaver dam outflows are thought to increase overall biodiversity in muskeg streams (Mackay 1995).

Vertebrates

The fish community of the Athabasca River contains 36 species distributed among 12 families (McCart 1986). Cyprinids, coregonids, and salmonids account for 22 of these species; five families have only one species. Postglacial colonization of the river originated mostly from source populations located in the Mississippi–Missouri and Columbia refugia. Recent surveys conducted for the Northern River Basins Study provide most of the limited information available on the Athabasca River fish community (R. L. and L. Environmental, Ltd. 1994a, 1994b). These surveys found that fish species richness was lowest in the upper Athabasca River and tributary streams and highest in the lower Athabasca. The major sport-fish species included mountain whitefish, walleye, goldeye, northern pike, burbot, and Arctic grayling. Bull trout, rainbow trout, and lake whitefish were rarely encountered. Mountain whitefish dominated the sport fishery in the upper and middle reaches of the river, whereas the lower river contained several codominant species, including goldeye, northern pike, and walleye. Longnose and white sucker were distributed throughout the main stem. Forage fishes, such as flathead chub, troutperch, and lake chub, were the most abundant species

in the main stem. Several species spawn in the main stem, including mountain whitefish, walleye, and goldeye; however, others use the tributaries for spawning, such as the bull trout. Finally, McCart (1986) indicates that runs of lake whitefish move from Lake Athabasca in summer to spawn in rapids of the Athabasca main stem; longnose suckers exhibit a similar spawning run in late winter and spring.

The majority of the Athabasca River basin is covered by mixed boreal forest, providing habitat for a large number of wildlife species. Amphibians in the watershed are represented by five species, including boreal chorus frog, western toad, wood frog, northern leopard frog, and long toed salamander. Reptiles are represented by one species, the wandering garter snake (www.biology.ualberta.ca/courses.hp/200301.hp/t-elegans.html 2000). Fifty-five species of mammals have been identified within the Athabasca River basin; those that can be found near the river include grizzly and black bear, mink, river otter, moose, muskrat, and beaver. The basin is also home to 222 bird species (http://scienceoutreach.ab.ca/resource_resources.htm#resources_inventories 2003). There are areas that support large numbers of waterfowl, including the Peace Athabasca Delta and the Pocahontas Marsh, which has nesting habitat for over 60 species (CHRB 2003). Birds that live along the river include sandpipers, plover, sandhill crane, bald eagle, osprey, American white pelican, cormorants, grebes, herons, loons, and geese (http://scienceoutreach.ab.ca/resource_resources.htm#resources_inventories 2003).

Ecosystem Processes

Over the river's length the accumulation of nutrients from multiple point and nonpoint sources increases algal biomass and bottom-up food web effects (Chambers 1996, Cash et al. 1996). In this ecosystem, nutrient enrichment appears to have more important ecological effects on the ecosystem than most contaminants. Nutrient enhancement is evident in periphyton biomass, with levels in the Athabasca River 2 to 50 times higher below effluent discharges, often at distances of >100 km downstream from the point source (Chambers, Dale, and Scrimgeour 2000). Nutrient limitation varied substantially along the river, primarily due to phosphorus concentration. However, periphyton growth in the middle and lower Athabasca River was also limited by nitrogen or by both nutrients, depending on the location (Scrimgeour and Chambers 2000). Effluent loadings from pulp mills or municipalities alleviated nutrient limi-

tation for a considerable distance below an effluent discharge. Abundance of total insects and dominant taxa was higher in areas of the river containing pulp mill effluent (Anderson 1989). Differences observed between assemblages upstream and downstream of impact sites were caused by changes in relative taxonomic abundance rather than the loss or gain of taxa (Cash et al. 1996, Culp, Podemski, and Cash 2000). This increased macroinvertebrate production is transferred to fishes downstream of the effluent, as these downstream populations exhibit increased body condition, gonad size, and egg mass compared to unexposed fishes (Gibbons et al. 1998).

Human Impacts and Special Features

The Athabasca River is the longest river in Alberta (1538 km), flowing from the glaciers of Jasper National Park to Lake Athabasca in Wood Buffalo National Park (www.chrs.ca 2003). Because of its natural beauty and significance and importance for river recreation, the section of the Athabasca River within Jasper National Park is designated as a Canadian Heritage River (www.chrs.ca 2003). Key features along the river include Athabasca Falls in Jasper National Park and the Grand Rapids in the lower Athabasca. The Grand Rapids re-aerates the river with dissolved oxygen in winter and is an important spawning area for fishes, such as lake whitefish and walleye (NRBS 1996). The watershed also includes the Columbia Ice Field, the largest ice field in the Rocky Mountains. The river is a popular canoeing and rafting destination.

Concern about water quality in the Athabasca River dates back to 1957, when the first pulp mill began operations on the upper river. By 1994 five pulp mills were operational, their combined input of total phosphorus (TP) and total nitrogen (TN) loads to the river totaling approximately 331 and 1033 kg/day, respectively (Chambers, Dale, and Scrimgeour 2000). Analysis of TP and TN concentrations measured monthly at 10 sites on the Athabasca River between 1980 and 1993 demonstrated that nutrient concentrations were lowest in Jasper National Park, upstream of any effluent loadings, and increased along the length of the river (Chambers, Dale, and Scrimgeour 2000).

A particularly impaired section of the river was the reach immediately downstream of Hinton, where high concentrations of contaminants and nutrients combined to raise concern for human and ecosystem health (Culp et al. 2000a). In the middle river reaches

(Whitecourt to Athabasca), the low concentrations of DO and moderate levels of nutrients and contaminants contributed to degraded water quality. The primary concern in the lower Athabasca River (below Fort McMurray) was the effect of contaminants (e.g., mercury in older predatory fishes exceeded Health Canada guidelines) (Cash et al. 2000). In addition to nutrient enhancement, effluent from pulp mills was responsible for declines in under-ice DO concentrations of 1 to 2 mg/L (Chambers et al. 1997, Chambers, Brown et al. 2000).

Recorded levels of chlorinated organic and metal contaminants in water or sediments are low and have not exceeded Canadian health and environmental guidelines (Wrona et al. 2000). Contaminant body burdens of caddisflies and mayflies occasionally exceeded the Canadian Water Quality Guideline for polychlorinated dibenzofurans (PCDFs) (Culp, Podemski, and Cash 2000). Low levels of contaminants were also found in fishes, although levels of dioxins, furans, PCBs, and mercury in biota occasionally exceeded Canadian guidelines (Cash et al. 2000). Stable isotope analyses indicated that a primary route of exposure to pulp mill contaminants was through the food chain (Cash et al. 2000). Pulp mill effluent appeared to be the source of these contaminants and also appeared to cause the endocrine disruption measured in spoonhead sculpin downstream of the first pulp mill effluent to the river. In addition, fishes captured immediately downstream of pulp mills exhibited an increase in external abnormalities, such as tumors, lesions, and skin discoloration (Cash et al. 2000).

ADDITIONAL RIVERS

The majority of the South Nahanni River basin is within the Mackenzie Mountains of the Northwest Territories (Fig. 18.19). The river originates in the ice fields of the Selwyn mountains, flows in a southeastern direction, and enters the Great Plains just before its confluence with the Liard River, 540 km downstream (www.chrs.ca 2003). Mean monthly discharge can range from 60 to 1300 m³/s, providing significant flow to the lower Liard River and ultimately to the main-stem Mackenzie (Fig. 18.20). The river passes through mountain valleys and has canyons with 500 to 1000 m high walls (Brunskill 1986). The river is located within the Nahanni National Park Reserve (an U.N. World Heritage Site) and is designated as a Canadian Heritage River (www.chrs.ca 2003). There are many significant

FIGURE 18.7 South Nahanni River at Last Chance Harbor above Virginia Falls (PHOTO BY D. BICKNELL).

natural features along the watershed, including Virginia Falls (almost twice the height of Niagara Falls), canyons, hot springs, and geological formations that escaped glaciation (Fig. 18.7) (www.chrs.ca 2003). This remote river can only be reached by plane or boat. There is no land development in the watershed; however, there have been mineral deposits discovered within the area. The South Nahanni is renowned for its adventure tourism, focused on river touring by canoe, kayak, or raft.

The Smoky River is located in the western central region of Alberta and has its headwaters in the Rocky Mountains (Fig. 18.21). The river flows in a northeasterly direction across the foothills of Alberta into the Great Plains, where 492 km downstream it

empties into the Peace River near the town of Peace River (Chambers, Dale et al. 2000). The Smoky River is not regulated and has two main tributaries, the Wapiti River and the Little Smoky River. Mean monthly discharge varies from a low of $43\text{ m}^3/\text{s}$ in February to a high of $1024\text{ m}^3/\text{s}$ in June during mountain snowpack melt (Fig. 18.22). The majority of the watershed is forested, with about 22% of the land area used for agriculture (<http://atlas.gc.ca/site/english/index.html> 2003). The headwaters of the Smoky River are located in Willmore Wilderness Park, just north of Jasper National Park. The terrain is mountainous, creating many diverse alpine and subalpine ecoregions, with white spruce, lodgepole pine, balsam fir, and aspen poplar. Kimiwan Lake,

FIGURE 18.8 Yellowknife River near outlet of Lower Carp Lake, Northwest Territories (PHOTO BY C. SPENCE).

located at the crossing of several flyways, is an area of great bird diversity. Grande Prairie (on the Wapiti River), with a population of 40,226, began as a Hudson's Bay post in 1881. Grande Cache (upper portion of the Smoky River), with a population of about 4000, was named for the large fur cache established by the Hudson's Bay Fur Trading Company in 1821 to store large shipments of fur from British Columbia.

The Hay River originates in the foothills of British Columbia's Rocky Mountains and flows in a northeasterly direction through the Great Plains of Alberta before draining into the southwest shore of Great Slave Lake (Fig. 18.23). Mean monthly discharge ranges from a low of only $3 \text{ m}^3/\text{s}$ in March during snow and ice storage in winter to $423 \text{ m}^3/\text{s}$ in May during snowmelt (Fig. 18.24). The Hay River drains an area that primarily consists of black spruce boreal muskeg/forest and wetlands, resulting in water that is humic and turbid in color (Fig. 18.1). Within the Hay River basin in northwestern Alberta is a remote lowland wetland complex known as the Zama and Hay Lakes area. This area is globally significant for its huge concentrations of geese and ducks (up to 1 million birds) during spring and fall migrations

(www.ibacanada.com 2003). Approximately 50 km from the mouth of the Hay River, the Hay River Gorge and the Twin Falls provide interesting scenery for tourists. The town of Hay River (population 3800), located near the mouth, was initiated in 1868 as a fur trading post by the Hudson's Bay Company. Today it is the northernmost railroad accessible area in the Northwest Territories and an important hub for barge travel along the Mackenzie River. Areas of the Hay River basin have had considerable oil and gas exploration.

The Yellowknife River basin is completely within the Northwest Territories and drains in a southwest-erly direction from Greenstocking Lake to Great Slave Lake, a distance of approximately 260 km (Fig. 18.8, Fig. 18.25). There are several significant lakes within the watershed, including Greenstocking, Reindeer, Drybones, Thistlethwaite, Duncan, and Gordon lakes. Mean monthly discharge ranges from a low of $21 \text{ m}^3/\text{s}$ in April to $72 \text{ m}^3/\text{s}$ in July (Fig. 18.26). The upper portion of the watershed is dominated by gently rolling hills and eskers of the barrenland, with black spruce as the dominant tree, followed by poplar and birch. Terrain near the mouth becomes more rocky, with taller wooded areas. The northern

end of the basin is part of the wintering grounds for the Bathurst caribou herd, and sections of the river are known for Arctic grayling. The name Yellowknife originated from the copper-wielding Chipewyan tribe, who resided near the present location of the city of Yellowknife (the only major community in the basin, with a population of 18,000) and the capital of the Northwest Territories. The city, founded in 1934, is known for its history of gold mining (www.assembly.gov.nt.ca/VisitorInfo/NWTMapandHistory/Yellowknife.html 2003). A dam is located on the lower portion of the river to provide hydroelectricity to the city.

The Peel River borders northeastern Yukon and northwestern Northwest Territories and straddles the Arctic Circle, flowing from south to north (Fig. 18.27). This is the most northerly tributary of the Mackenzie River, with headwaters initiating in the rugged Mackenzie Mountains, flowing into the Arctic Lowlands, and finally discharging into the Mackenzie River Delta, a total distance of 644 km. Mean monthly discharge ranges from only 60 m³/s in November to 143 m³/s in May (Fig. 18.28). In the upper headwaters, the valleys lie within the tundra region, with massive scree slopes devoid of vegetation and open stands of black and white spruce along the longer slopes. In the lower sections of the watershed, white spruce is dominant, with sections of black spruce and larch in poorly drained areas (www.chrs.ca 2003). There are several major tributaries of the Peel River, including the Hart, Bonnet Plume (a Canadian Heritage River), and Snake rivers, known for their ruggedness and beauty, providing many opportunities for adventure tourism (www.chrs.ca 2003). The Peel River watershed is mostly uninhabited, with Fort McPherson (near the confluence with the Mackenzie River) the largest community in the region (population 910), established in 1840 by the Hudson's Bay Company. The community is one of three located along the Dempster Highway, the most northerly public highway in Canada, linking Dawson City with Inuvik, a total distance of 736 km.

ACKNOWLEDGMENTS

Financial support for this research was provided by the National Water Research Institute (Environment Canada) and a Natural Sciences and Engineering Research Council Discovery Grant to J. M. Culp. Technical assistance and information collection during manuscript preparation was provided by C.

Casey, N. Glozier, D. Halliwell, H. Popoff and M. Meding. P. Harker (Natural Resources Canada) provided geographical support. Photographs were graciously supplied by D. Bicknell, T. Carter, C. Cushing and C. Spence. The manuscript benefited from constructive criticisms by A. Benke, C. Cushing and K. Roberts.

FIGURE 18.10 Mean monthly air temperature, precipitation, and runoff for the Mackenzie River basin.

MACKENZIE RIVER

Relief: 3620 m

Basin area: 1,787,000 km²

Mean discharge: 9020 m³/s

River order: 9

Mean annual precipitation: 25.8 cm

Mean air temperature: -9.5°C

Mean water temperature: 5.3°C

Physiographic provinces: Mackenzie Mountains (MM), Coast Mountains of British Columbia and Southeast Alaska (PM), Rocky Mountains in Canada (RM), Great Plains (GP), Athabasca Plains (AT), Bear–Slave–Churchill Uplands (BC), Arctic Lowlands (AL)

Biomes: Tundra, Boreal Forest, Temperate Mountain Forest

Freshwater ecoregions: Upper Mackenzie, Lower Mackenzie

Terrestrial ecoregions: 15 ecoregions (see text); main stem flows primarily through Northwest Territories Taiga, Muskwa/Slave Lake Forests

Number of fish species: 34 (main stem), 52 (basin)

Number of endangered species: none (main stem)

Major fishes: Arctic lamprey, goldeye, Arctic cisco, lake cisco, Arctic char, least cisco, lake whitefish, broad whitefish, mountain whitefish, pond smelt, rainbow smelt, lake chub, flathead chub, longnose dace, inconnu, Arctic grayling, lake trout, northern pike, longnose suckers, white sucker, troutperch, burbot, slimy sculpin, spoonhead sculpin, walleye

Major other aquatic vertebrates: wood frog, beluga whale (Mackenzie Delta), muskrat, moose, mink, beaver, river otter, snow goose, black brant, greater white-fronted goose, tundra swan, sandhill crane, glaucous gull, Arctic tern, canvasback duck

Major benthic invertebrates: true flies (Ceratopogonidae, Chironomidae, Simuliidae), mayflies (*Ametropus*, *Baetis*, *Ephemerella*, *Heptagenia*), stoneflies (*Isoperla*), caddisflies (*Brachycentrus*)

Nonnative species: none

Major riparian plants: horsetail, bulrush, cattail, Labrador tea, willow, sedges, balsam poplar, white spruce, black spruce, alder, birch, tamarack; reverse delta on Mackenzie supports grasses

Special features: largest river in Canada; Limestone Canyon of the Ramparts, Mackenzie Delta, Great Bear Lake, Great Slave Lake

Fragmentation: none on main stem

Water quality: pH = 7.9, conductivity = 269 μS/cm, alkalinity = 93 mg/L as CaCO₃, total N = 0.37 mg/L, total P = 0.13 mg/L

Land use (main stem): 36.5% taiga, 27.3% open land, 23.5% forest, 8.7% shrubland, 4.0% water

Population density: <1 person/km²

Major information sources: Barton 1986; Bodaly et al. 1989; Brunskill 1986; MRBC 1981a, 1981b; McCart 1986; Rosenberg and Barton 1986

FIGURE 18.9 Map of the Mackenzie River basin. Physiographic provinces are separated by yellow lines.

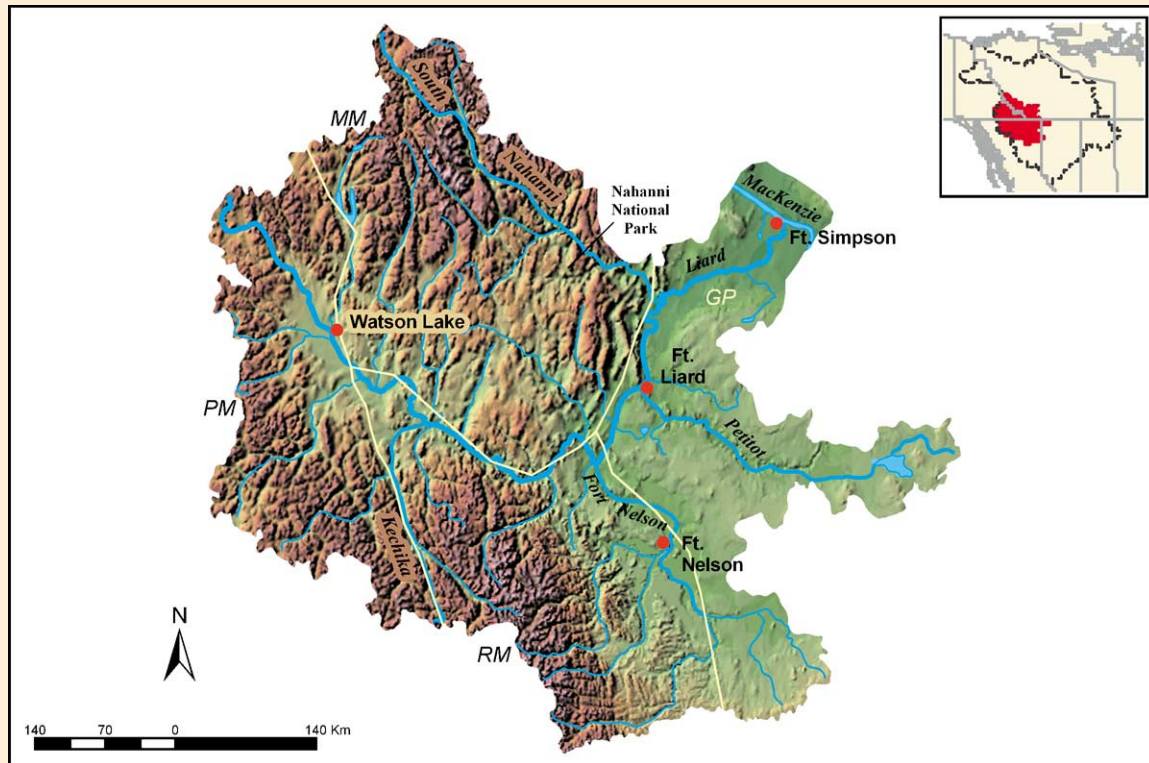

FIGURE 18.11 Map of the Liard River basin. Physiographic provinces are separated by yellow lines.

LIARD RIVER

Relief: 2573 m

Basin area: 277,000 km²

Mean discharge: 2446 m³/s

River order: 8

Mean annual precipitation: 36 cm

Mean air temperature: -3.7°C

Mean water temperature: 6.1°C

Physiographic provinces: Coast Mountains of British Columbia and Southeast Alaska (PM), Rocky Mountains in Canada (RM), Great Plains (GP), Mackenzie Mountains (MM)

Biomes: Boreal Forest, Temperate Mountain Forest

Freshwater ecoregion: Lower Mackenzie

Terrestrial ecoregions: Alberta/British Columbia Foothills Forests, Northern Cordillera Forests, Muskwa/Slave Lake Forests, Brooks/British Range Tundra, Arctic Coastal Tundra

Number of fish species: 34

Number of endangered species: 1 mollusk

Major fishes: chum salmon, Arctic cisco, mountain whitefish, lake whitefish, inconnu, bull trout, longnose sucker, white sucker, Arctic grayling, goldeye, northern pike, walleye, burbot, lake chub, flathead chub, northern squawfish, longnose dace, troutperch, slimy sculpin, spoonhead sculpin

Major other aquatic vertebrates: wood frog, moose, beaver, river otter, muskrat, mink, trumpeter swan (nesting population at Yohin Lake), common loon, red-necked grebe, common goldeneye, bald eagle

Major benthic invertebrates: true flies (Diametidae, Empididae, Orthocladinae, Simuliidae, Tanyderidae, Tipulidae), mayflies (Baetidae, Ephemerellidae, Heptageniidae), stoneflies (Capniidae, Chloroperlidae, Nemouridae, Perlidae), caddisflies (Brachycentridae, Limnephilidae, Rhyacophilidae)

Nonnative species: none

Major riparian plants: black spruce, white spruce, trembling aspen, balsam poplar, aspen, lodgepole pine, willow, sedges

Special features: Grand Canyon of the Liard, Liard Hot Springs, Hell Gate Rapids, Virginia Falls, Nahanni National Park

Fragmentation: none

Water quality: 1 color = turbid, pH = 8.0, conductivity 287 μS/cm, alkalinity = 125 mg/L as CaCO₃, total N = 0.43 mg/L, total P = 0.11 mg/L

Land use: 55.4% forest, 17.8% taiga, 13.8% open land, 11.5% shrubland, 1.4% water

Population density: <1 person/km²

Major information sources: Environment Canada 1999, 2002a, 2002b; MacDonald 1992; MRBC 1981a, 1981b; Rosenberg and Barton 1986; http://wlapwww.gov.bc.ca/bcparks/explore/parkpgs/liard_hs/nat_cul.htm 2004; www.statcan.ca

FIGURE 18.12 Mean monthly air temperature, precipitation, and runoff for the Liard River basin.

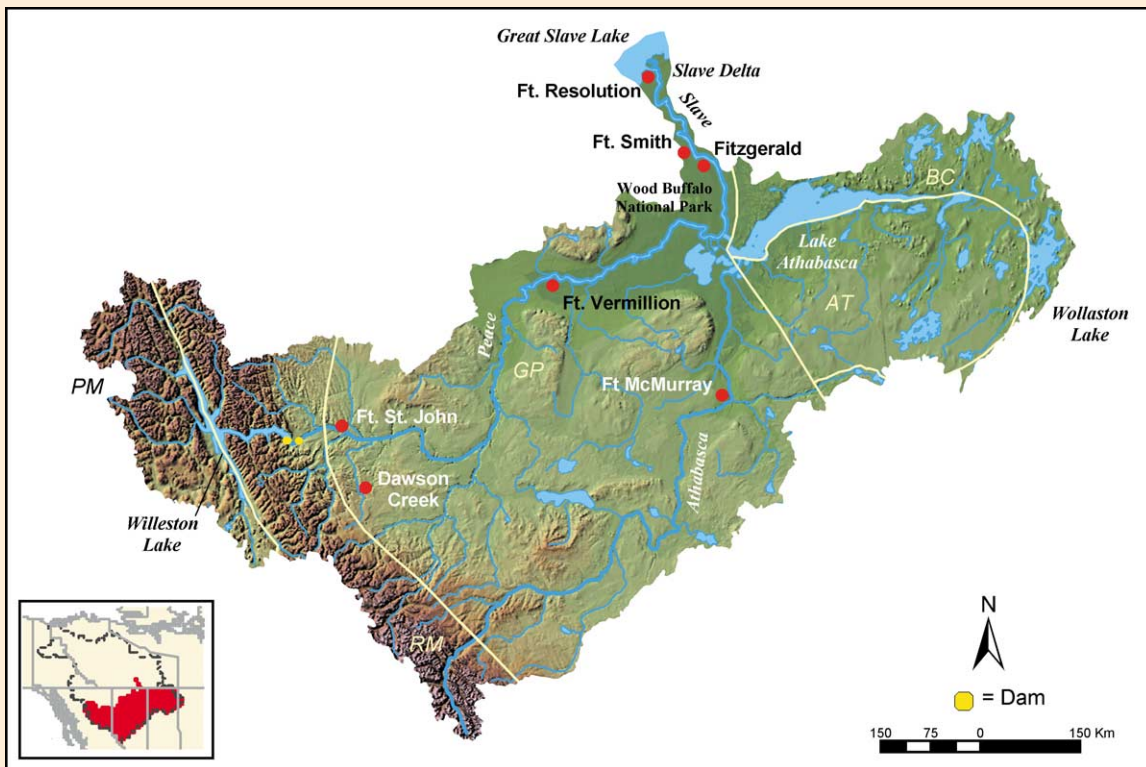

FIGURE 18.13 Map of the Slave River basin. Physiographic provinces are separated by yellow lines.

SLAVE RIVER

Relief: 3500 m

Basin area: 615,000 km²

Mean discharge: 3437 m³/s

River order: 8

Mean annual precipitation: 35.3 cm

Mean air temperature: -3.0°C

Mean water temperature: NA

Physiographic provinces: Coast Mountains of British Columbia and Southeast Alaska (PM), Rocky Mountains in Canada (RM), Great Plains (GP), Athabasca Plain (AT), Bear-Slave-Churchill Uplands (BC)

Biomes: Boreal Forest, Temperate Mountain Forest

Freshwater ecoregion: Upper Mackenzie

Terrestrial ecoregions: Northern Canadian Shield Taiga, Mid-continental Canadian Forests

Number of fish species: 28 (main stem), 45 (basin)

Number of endangered species: none

Major fishes: Arctic lamprey, goldeye, northern pike, Dolly Varden, lake cisco, lake trout, longnose sucker, white sucker, troutperch, lake whitefish, walleye, inconnu, flathead chub, spottail shiner, pearl dace, burbot, ninespine stickleback, slimy sculpin, yellow perch

Major other aquatic vertebrates: chorus frog, wood frog, northern leopard frog, beaver, muskrat, river otter, mink, whooping crane, white pelican, snow goose, Canada goose, common loon, red-necked grebe, common merganser, osprey, bald eagle

Major benthic invertebrates: chironomid midges (*Stictochironomus quagga*, *Procladius* sp., *Chironomus anthracinus*, *Polypedilum scalaenum*), oligochaete worms (*Limnodrilus hoffmeisteri*, *Chaetogaster diaphanous*), caddisflies, true bugs (*Corixidae*), beetles (*Dytiscidae*), mayflies, stoneflies

Nonnative species: NA

Major riparian plants: white spruce, black spruce, tamarack, balsam poplar, aspen, Labrador tea, reindeer lichens, peat mosses, sago weed, pickerelweed, river horsetail, sedges, cattails, reed grasses, rushes, burrweed, willow, alder

Special features: Wood Buffalo National Park (whooping crane breeding sites), Slave River Delta, Peace-Athabasca Delta

Fragmentation: submerged weir on the Riviere des Rochers at Little Rapids and Revillion Coupe; major dam on (Peace River)

Water quality: pH = 7.8, conductivity = 253 μS/cm, alkalinity = 82 mg/L as CaCO₃, total N = 0.40 mg/L, total P = 0.21 mg/L

Land use: 40.3% forest, 25.8% taiga, 20.9% shrubland, 9.9% water, 1.6% agriculture, 1.4% open land

Population density: <1 person/km²

Major information sources: Alberta Environment 1987, MacDonald 1994, MRBC 1981b, McCarthy, Robertson et al. 1997, McCarthy, Stephens et al. 1997, McCarthy, Williams et al. 1997, Prowse and Conly 1996, Rosenberg and Barton 1986, Tallman 1996

FIGURE 18.14 Mean monthly air temperature, precipitation, and runoff for the Slave River basin.

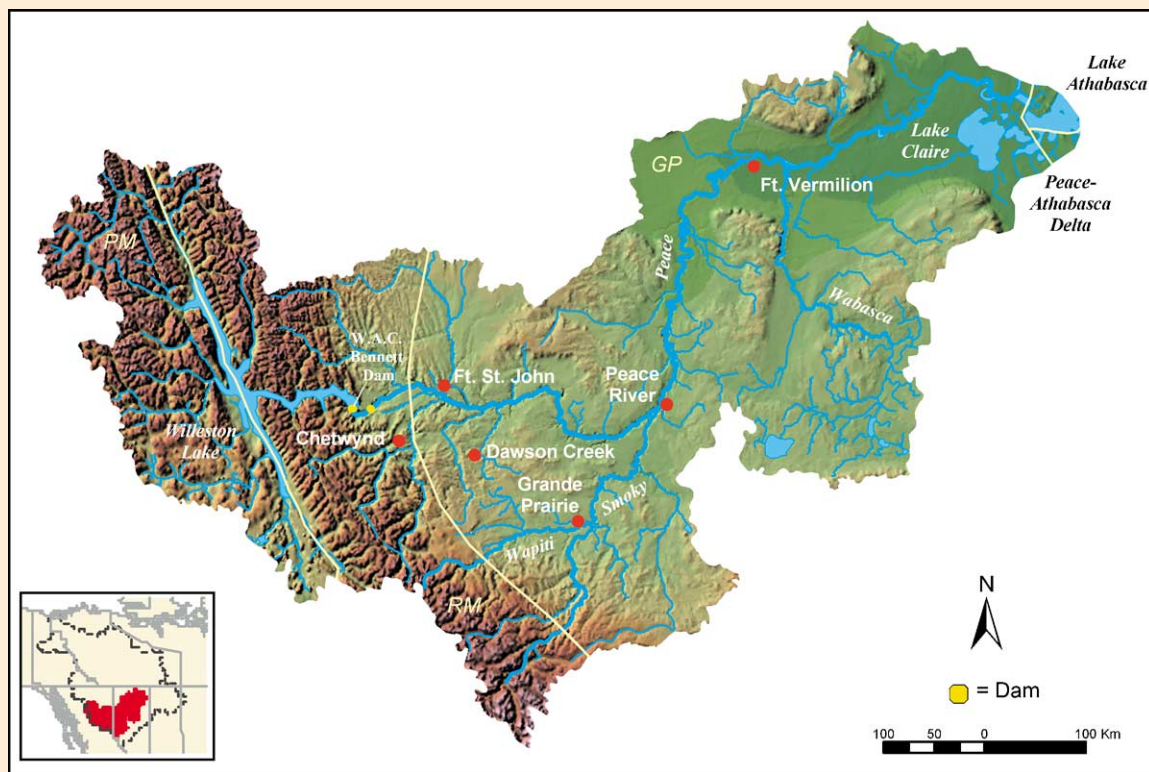

FIGURE 18.15 Map of the Peace River basin. Physiographic provinces are separated by yellow lines.

PEACE RIVER

Relief: 2130 m

Basin area: 293,000 km²

Mean discharge: 2118 m³/s

River order: 8

Mean annual precipitation: 31 cm

Mean air temperature: -0.9°C

Mean water temperature: NA

Physiographic provinces: Great Plains (GP), Rocky Mountains in Canada (RM), Coast Mountains of British Columbia and Southeast Alaska (PM)

Biomes: Boreal Forest, Temperate Mountain Forest

Freshwater ecoregion: Upper Mackenzie

Terrestrial ecoregions: Central British Columbia Mountain Forests, Alberta/British Columbia Foothills Forests, Canadian Aspen Forest and Parklands, Muskwa/Slave Lake Forests, Mid-continental Canadian Forests, Northern Cordillera Forests, Fraser Plateau and Basin Complex, Alberta Mountain Forests

Number of fish species: 31

Number of endangered species: none

Major fishes: goldeye, walleye, burbot, northern pike, rainbow trout, Dolly Varden, lake trout, mountain whitefish, lake whitefish, lake chub, flathead chub, northern squawfish, longnose dace, trout perch, prickly sculpin, spoonhead sculpin

Major other aquatic vertebrates: long toed salamander, spotted frog, wood frog, beaver, muskrat, river otter, mink, snow goose, Canada goose, trumpeter swan, common loon, red-necked grebe, common merganser, osprey, bald eagle

Major benthic invertebrates: chironomid midges (Orthocladiinae, Tanyptodinae, Tanytarsini), oligochaete worms (Enchytraeidae, Naididae), stoneflies (*Isoperla*, *Isogenoides*, Capniidae, Taeniopterygidae), mayflies (*Baetis*, *Ephemera*, *Heptagenia*, *Isonychia*, *Rhithrogena*)

Nonnative species: spottail shiner, fathead minnow, westslope cutthroat trout, brook trout

Major riparian plants: black spruce, trembling aspen, balsam poplar, willow, sedges, wheat grass, sedge, horsetail, Labrador tea

Special features: Vermilion Chutes, Boyer Rapids, Peace-Athabasca Delta

Fragmentation: W.A.C. Bennett Dam at Williston Lake on main stem

Water quality: pH = 7.9, conductivity = 257 μS/cm, alkalinity = 96 mg/L as CaCO₃, total N = 0.52 mg/L, total P = 0.16 mg/L

Land use: 57.4% forest, 16.2% agriculture, 12.5% taiga, 11.4% shrubland, 2.1% water, 0.5% open land

Population density: <1 person/km²

Major information sources: Boag 1993, Cash et al 2000, Culp et al. 2000a, Chambers, Brown et al. 2000, MRBC 1981b, Prowse and Conly 1996, Prowse and Conly 2000, Rosenberg and Barton 1986, Shaw et al. 1990, Wrona et al. 2000

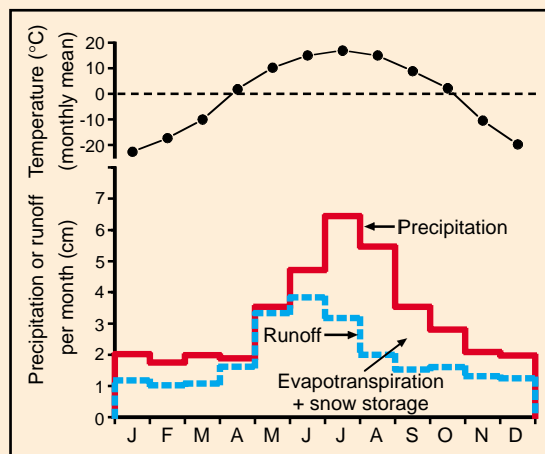

FIGURE 18.16 Mean monthly air temperature, precipitation, and runoff for the Peace River basin.

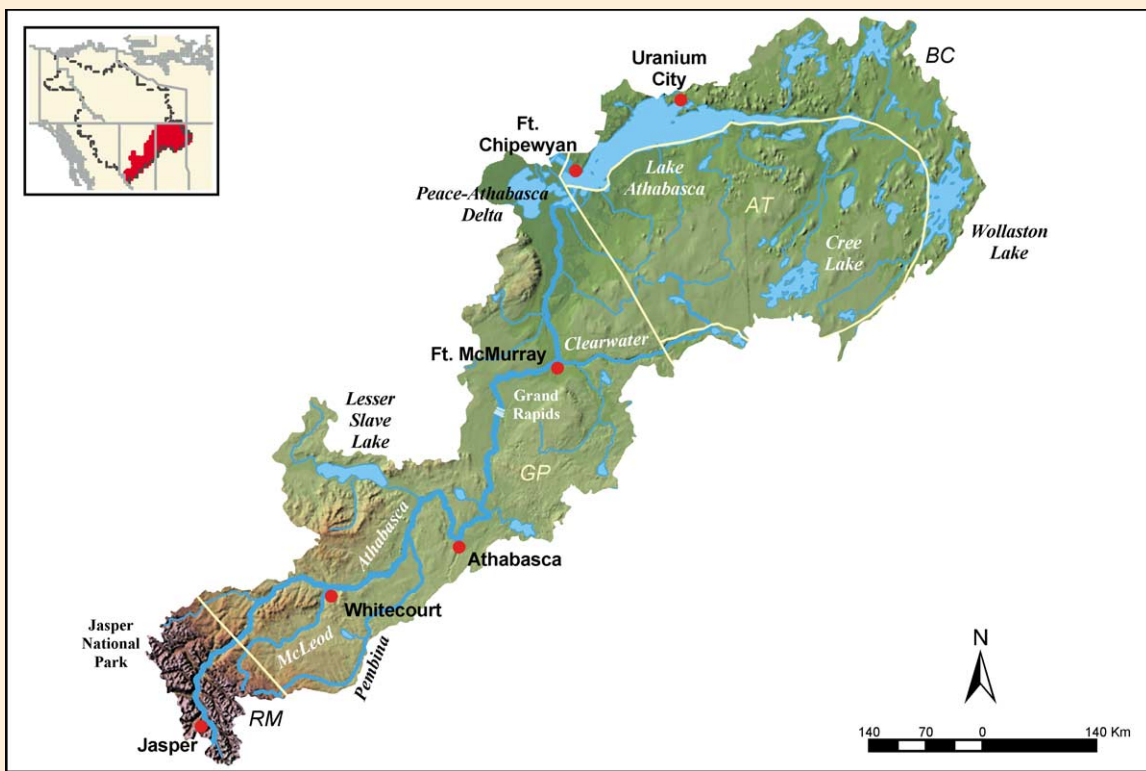

FIGURE 18.17 Map of the Athabasca River basin. Physiographic provinces are separated by yellow lines.

ATHABASCA RIVER

Relief: 3420 m

Basin area: 154,880 km²

Mean discharge: 783 m³/s

River order: 6

Mean annual precipitation: 46.5 cm

Mean air temperature: 0.2°C

Mean water temperature: 8.2°C

Physiographic provinces: Athabasca Plain (AT), Bear–Slave–Churchill Uplands (BC), Great Plains (GP), Rocky Mountains in Canada (RM)

Biomes: Boreal Forest, Temperate Mountain Forest

Freshwater ecoregion: Upper Mackenzie

Terrestrial ecoregions: Alberta/British Columbia Foothills Forests, Alberta Mountain Forests Canadian Aspen Forest and Parklands, Northern Canadian Shield Taiga, Mid-continental Canadian Forests, Midwestern Canadian Shield Forests

Number of fish species: 36

Number of endangered species: none

Major fishes: lake cisco, lake whitefish, round whitefish, mountain whitefish, rainbow trout, Dolly Varden, walleye, lake trout, goldeye, northern pike, burbot, Arctic grayling, longnose sucker, white sucker, flathead chub, longnose dace, troutperch, slimy sculpin, brook stickleback, lake chub

Major other aquatic vertebrates: boreal chorus frog, western toad, wood frog, northern leopard frog, long toed salamander, mink, river otter, moose, muskrat, beaver, greater yellowlegs (sandpiper), killdeer, sandhill crane, bald eagle, osprey, American white pelican, double-crested cormorant, red-necked grebe, great blue heron, common loon, Canada goose, tundra swan

Major benthic invertebrates: chironomid midges (*Chironomini*, *Orthoclaadiinae*, *Tanypodinae*), mayflies (*Ameletus*, *Baetis*, *Cinygmula*, *Heptagenia*, *Ephemerella*, *Rhithrogena*), stoneflies (*Alloperla*, *Capnia*, *Isoperla*, *Hesperoperla*, *Pteronarcella*, *Taenionema*), caddisflies (*Brachycentrus*, *Glossosoma*, *Hydropsyche*)

Nonnative species: brown trout, brook trout

Major riparian plants: white spruce, balsam poplar, tamarack, black spruce, aspen willow, water sedge, marsh reed grass, Labrador tea, strawberry-blite, Ross' sedge, reindeer lichen, peat moss, brown moss

Special features: Athabasca Falls, Grand Rapids, Peace–Athabasca Delta, Canadian Heritage River

Fragmentation: none

Water quality: TDS = 187 mg/L, conductivity = 332 μS/cm, pH = 7.8, alkalinity = 117 mg/L as CaCO₃, total N = 0.54 mg/L, total P = 0.10 mg/L

Land use: 59.8% forest, 17.4% taiga, 9.8% agriculture, 6.0% shrubland, 4.3% open land, 2.7% water

Population density: <1 person/km²

SOUTH NAHANNI RIVER

Relief: 2573 m

Basin area: 33,388 km²

Mean discharge: 404 m³/s

River order: 6

Mean annual precipitation: 36 cm

Mean air temperature: -3.7°C

Mean water temperature: NA

Physiographic provinces: Mackenzie Mountains (MM), Great Plains (GP)

Biome: Boreal Forest

Freshwater ecoregion: Lower Mackenzie

Terrestrial ecoregions: Northwest Territories Taiga, Northern Cordillera Forests, Ogilvie/Mackenzie Alpine Tundra

Number of fish species: 13

Number of endangered species: none

Major fishes: Arctic grayling, Dolly Varden, lake trout, northern pike, lake whitefish, longnose sucker, round whitefish, inconnu

Major other aquatic vertebrates: wood frog, muskrat, beaver, mink, river otter, moose, trumpeter swan, bald eagle, golden eagle, common loon, red-necked grebe

Major benthic invertebrates: NA

Nonnative species: NA

Major riparian plants: white spruce, poplar, black spruce, sedges, wild mint, goldenrod, yellow monkey flower

Special features: Virginia Falls, Rabbitkettle Hotsprings, Sandblowouts, Nahanni National Park, Canadian Heritage River

Fragmentation: none

Water quality: pH = 8.0, conductivity = 298 μS/cm, alkalinity = 105 mg/L as CaCO₃, total N = 0.45 mg/L, total P = 0.11 mg/L

Land use: 44.2% open land, 27.2% taiga, 19.1% forest, 8.4% shrubland, 1.1% water

Population density: <1 person/km²

SMOKY RIVER

Relief: 2605 m
Basin area: 49,584 km²
Mean discharge: 347 m³/s
River order: 7
Mean annual precipitation: 45 cm
Mean air temperature: 1.6°C
Mean water temperature: NA
Physiographic provinces: Rocky Mountains in Canada (RM), Great Plains (GP)
Biomes: Boreal Forest, Temperate Mountain Forest
Freshwater ecoregion: Upper Mackenzie
Terrestrial ecoregions: Alberta/British Columbia Foothills Forests, Alberta Mountain Forests, Canadian Aspen Forest and Parklands
Number of fish species: 14
Number of endangered species: none
Major fishes: longnose sucker, white sucker, walleye, northern pike, mountain whitefish, Arctic grayling, Dolly Varden, lake chub, longnose dace, reidside shiner, pearl dace, burbot, slimy sculpin, spoonhead sculpin
Major other aquatic vertebrates: wood frog, moose, beaver, muskrat, mink, river otter, American white pelican, great blue heron, trumpeter swan, tundra swan, snow goose, common loon, red-necked grebe, common goldeneye
Major benthic invertebrates: chironomid midges (*Chironomini*, *Orthocladinae*, *Tanytopodinae*), mayflies (*Baetis*, *Cinygmula*, *Drunella*, *Rhithrogena*), stoneflies (*Alloperla*, *Capnia*, *Isoperla*, *Hesperoperla*, *Pteronarcella*, *Taenionema*), caddisflies (*Brachycentrus*, *Glossosoma*, *Hydropsyche*)
Nonnative species: NA
Major riparian plants: trembling aspen, balsam poplar, black spruce, willow, sedges, wheat grass, sedge, Labrador tea, peat moss, brown moss
Special features: Willmore Wilderness Park, dinosaur tracks (Grande Cache area)
Fragmentation: none
Water quality: pH = 8.0, alkalinity = 132 mg/L as CaCO₃, total N = 0.46 mg/L, total P = 0.13 mg/L
Land use: 63.2% forest, 22.4% agriculture, 5.1% shrubland, 4.4% open land, 4.2% taiga, 0.5% water
Population density: <1 person/km²
Major information sources: Chambers, Brown et al. 2000; Chambers, Dale, and Scrimgeour 2000; Golder Associates 2000; MRBC 1981b; Rosenberg et al. 1986; www.statcan.ca/english/pgdb/geogra.htm 1996

FIGURE 18.22 Mean monthly air temperature, precipitation, and runoff for the Smoky River basin.

FIGURE 18.24 Mean monthly air temperature, precipitation, and runoff for the Hay River basin.

HAY RIVER

Relief: 1060 m

Basin area: 47,900 km²

Mean discharge: 113 m³/s

River order: 6

Mean annual precipitation: 34.2 cm

Mean air temperature: -3.4°C

Mean water temperature: 6.4°C

Physiographic province: Great Plains (GP)

Biome: Boreal Forest

Freshwater ecoregion: Lower Mackenzie

Terrestrial ecoregions: Alberta/British Columbia

Foothills Forests, Muskwa/Slave Lake Forests

Number of fish species: ~18

Number of endangered species: 0

Major fishes: lake chub, flathead chub, longnose dace, longnose sucker, white sucker, northern pike, lake whitefish, mountain whitefish, Arctic grayling, Arctic char, lake trout, walleye, burbot, brook stickleback, slimy sculpin, spoonhead sculpin

Major other aquatic vertebrates: wood frog, moose,

beaver, river otter, muskrat, mink, snow goose, Canada goose, osprey, bald eagle, Arctic tern, herring gull, northern pintail

Major benthic invertebrates: NA

Nonnative species: NA

Major riparian plants: balsam poplar, black spruce, white spruce, tamarack, dwarf birch, willows, sedges, Labrador tea, peat moss, brown moss

Special features: Zama and Hay Lakes Wetland area (IBA), Hay River Gorge, Twin Falls; Hay River (community) is northernmost railroad accessible area in Northwest Territories and important hub for barge travel along Mackenzie River

Fragmentation: none

Water quality: pH = 7.8, conductivity = 456 μS/cm, alkalinity = 151/L as mg CaCO₃, total N = 1.01 mg/L, total P = 0.09 mg/L

Land use: NA; for Great Slave subbasin, 35.2% taiga, 23.1% forest, 17.9% water, 17.3% open land, 6.2% shrubland, 0.4% agriculture

Population density: <1 person/km²

YELLOWKNIFE RIVER

Relief: 706 m

Basin area: 11,300 km²

Mean discharge: 39 m³/s

River order: 5 (approximated)

Mean annual precipitation: 26.7 cm

Mean air temperature: -5.1°C

Mean water temperature: NA

Physiographic provinces: Great Plains (GP),
Bear–Slave–Churchill Uplands (BC)

Biome: Boreal Forest

Freshwater ecoregion: Lower Mackenzie

Terrestrial ecoregion: Northern Canadian Shield Taiga

Number of fish species: NA

Number of endangered species: NA

Major fishes: northern pike, Arctic grayling, lake trout

Major other aquatic vertebrates: moose, beaver,
muskrat, river otter, bald eagle, red-breasted
merganser, common loon, northern pintail

Major benthic invertebrates: NA

Nonnative species: none

Major riparian plants: black spruce, birch, poplar,
willow, alder, Labrador tea, cranberry, bunchberry, bearberry

Special features: wilderness river draining northern region of Canadian Shield; small rivers connected by many lakes; wintering grounds for Bathurst caribou herd (north section of basin); gold mining

Fragmentation: one dam near mouth

Water quality: pH = 7.2, alkalinity = 16 mg/L as CaCO₃, total N = 0.22 mg/L, total P = 0.01 mg/L

Land use: NA; for Great Slave subbasin, 35.2% taiga, 23.1% forest, 17.9% water, 17.3% open land, 6.2% shrubland, 0.4% agriculture

Population density: <1 person/m²

PEEL RIVER

Relief: 2650 m

Basin area: 68,134 km²

Mean discharge: 103 m³/s

River order: 6

Mean annual precipitation: 25.8 cm

Mean air temperature: -9.5°C

Mean water temperature: NA

Physiographic provinces: Arctic Lowlands (AL), Mackenzie Mountains (MM)

Biomes: Tundra, Boreal Forest

Freshwater ecoregion: Lower Mackenzie

Terrestrial ecoregions: Interior Alaska/Yukon Lowland Taiga, Northwest Territories Taiga, Ogilvie/Mackenzie Alpine Tundra, Brooks/British Range Tundra

Number of fish species: 17

Number of endangered species: none

Major fishes: northern pike, mountain whitefish, round whitefish, Arctic grayling, Arctic char, Dolly Varden, longnose sucker, cyprinids, ciscos, sculpins

Major other aquatic vertebrates: moose, muskrat, beaver, river otter, mink, peregrine falcon, gyrfalcon, bald eagle, common loon, tundra swan, white-winged scoter

Major benthic invertebrates: NA

Nonnative species: NA

Major riparian plants: black spruce, white spruce, balsam poplar, larch, alder, willow

Special features: most northerly Mackenzie River tributary; several major tributaries known for their ruggedness and beauty, including Bonnet Plume (Canadian Heritage River), Hart, and Snake rivers; Mount MacDonald

Fragmentation: none

Water quality: pH = 7.9, conductivity = 314 μS/cm, alkalinity = 127 mg/L as CaCO₃, total N = 0.52 mg/L, total P = 0.17 mg/L

Land use: 43.7% open land, 29.1% shrubland, 18.8% taiga, 7.5% forest, 0.9% water

Population density: <1 person/km²

INTRODUCTION

Two great Canadian rivers, the Nelson and the Churchill, drain waters mainly from the interior of Canada, cut through the Canadian Shield of northern Manitoba, and empty into Hudson Bay (Newbury and Malaher 1972) (Fig. 19.2). The rivers flow through a “valley” in northern Manitoba that has been eroded by numerous glaciations along the boundary between two major geological zones, the Superior and Churchill provinces of the Canadian Shield (Newbury 1990b). This valley allows the western part of the Churchill, the Saskatchewan, the Red-Assiniboine, and the Winnipeg river systems to collect in Manitoba and flow through the Nelson and Churchill channels into Hudson Bay.

Waters of the Nelson system (latitude ~45.5°N to 57°N, longitude ~90°W to 117.5°W) begin their journey from the west on the eastern slopes of the Rocky Mountains and cross the three Canadian Prairie provinces (Alberta, Saskatchewan, and Manitoba) via the Saskatchewan River, which empties into the northern part of Lake Winnipeg. Waters from the east originate in northwestern Ontario and

flow via the Winnipeg River into the southern part of Lake Winnipeg. Waters flowing from the south drain parts of Minnesota and North Dakota via the Red River of the North and also empty into the southern part of Lake Winnipeg. The Assiniboine River flows from the Canadian west into the Red River. The Nelson River proper originates at the outflow of Lake Winnipeg and carries its continental collection of water to the sea. In total, the Nelson system covers >1,000,000 km² of the interior of North America, 892,300 km² in Canada and 180,000 km² in the United States (*National Atlas of Canada* 1985). The total distance from the mountain headwaters of the Bow River to Hudson Bay exceeds 3000 km (Lane and Sykes 1982).

The Churchill system (latitude 53°N to 59.5°N, longitude 94.5°W to 112.5°W) is much smaller than the Nelson (catchment area 281,300 km²; *National Atlas of Canada* 1985) and is contained entirely within Canada. The headwaters of the Churchill begin in Beaver Lake, northeast of Edmonton, Alberta, and, to the north, in the Wollaston Lake area of northeastern Saskatchewan. Churchill waters flow mainly through Saskatchewan and Manitoba. From

FIGURE 19.2 Rivers of the Nelson and Churchill basins covered in this chapter.

the Saskatchewan–Manitoba border the river flows northeastward through a complex chain of lakes, roughly paralleling the Nelson system to the south, and into Hudson Bay. The Churchill River is only briefly considered here because it was joined to the Nelson by a diversion in 1976.

The two river systems are separated by several hundred kilometers through most of their length, but Southern Indian Lake (Churchill catchment) and the Rat–Burntwood River (Nelson catchment) come close together in northern Manitoba. The possibility of diverting Churchill River flows into the Nelson catchment was first considered in the mid 1950s and became reality in the mid 1970s by connecting Southern Indian Lake with the Rat–Burntwood River (Hecky et al. 1984). Seventy-five percent of the

Churchill River flow was diverted into the lower Nelson River valley to augment flows for long-term hydropower development in the lower Nelson (Newbury et al. 1984), effectively joining the two rivers for their final run into Hudson Bay (Fig. 19.3, Fig. 19.4).

The Nelson and Churchill rivers have a 400 year history of European exploration and the opening of the interior of Canada to the fur trade. European explorers searching for the Northwest Passage to India had mapped the estuaries of the Seal, Churchill, Nelson, and Hayes rivers on Hudson Bay by the early 1600s (Newbury 1990b). Henry Hudson was abandoned somewhere on Hudson Bay by a mutinous crew in 1611 (Newbury 1990a). The following year Sir Thomas Button was sent to search for Hudson

FIGURE 19.3 Lower Churchill River between Southern Indian Lake and Hudson Bay before diversion into the Nelson River system (PHOTO BY A. P. WIENS).

and overwintered locked in the ice of Hudson Bay. Button built a land-based camp at the mouth of a large river, which he named “Nelson” after his sailing master, Frances Nelson of the HMS Resolution. By 1668 the French explorers Radisson and Grossilliers were trading furs at the mouth of the Nelson. The Hudson’s Bay Company (still today a major Canadian retailer) was formed in 1670 and established trading depots at the mouths of all the major rivers. The Churchill River was named after John Churchill, a governor of the Hudson’s Bay Company from the 1680s to the 1690s who would later become the Duke of Marlborough. In 1690, Henry Kelsey discovered that the river leading to the York Factory depot (the Hayes River) could be used to gain access to the interior of the continent. However, the actual route to the interior was unknown to Europeans until 1745, when David Thompson discovered the secret (see Newbury 1990b for the explanation). Passage from the docks of England through Hudson Bay to the western plains and mountains of North America was established, and York Factory became central to

this trading activity for the next 150 years. The “York Boat” route brought the first traders, and later settlers, to western Canada.

The Nelson River catchment is comprised of 11 major subcatchments (Lane and Sykes 1982). We will discuss four of the largest: (1) the Saskatchewan (334,100 km² in Canada and 1800 km² in the United States for a total 335,900 km²; *National Atlas of Canada* 1985), which drains the western part of the catchment; (2) the Red–Assiniboine (138,600 km² in Canada and 148,900 km² in the United States for a total of 287,500 km²; *National Atlas of Canada* 1985), which drains the western and southern parts of the catchment; (3) the Winnipeg (106,500 km² in Canada and 29,300 km² in the United States for a total of 135,800 km²; *National Atlas of Canada* 1985), which drains the eastern part of the catchment; and (4) the main-stem Nelson (89,000 km², all in Canada; Lane and Sykes 1982). One-page summaries of physical and biological information are provided for two additional rivers in the Nelson system: the Bow and Otter Tail.

FIGURE 19.4 Lower Churchill River between Southern Indian Lake and Hudson Bay after diversion (~75% of flow) into the Nelson River system (PHOTO BY A. P. WIENS).

Physiography and Climate

The Nelson catchment occupies six physiographic provinces (Hunt 1974): Rocky Mountains in Canada, Great Plains, Central Lowland, Bear–Slave–Churchill Uplands, Superior Upland, and Hudson Bay Lowland. In the Hunt (1974) classification, the Great Plains and Central Lowland provinces combine to form the Interior Plains division, and the Bear–Slave–Churchill Uplands, Superior Upland, and Hudson Bay Lowland combine to form the Canadian Shield division. The Rocky Mountains in Canada province, hereafter referred to as the Rocky Mountains province, is part of the Rocky Mountain System division. The Churchill catchment occupies four of these physiographic provinces (Great Plains, Central Lowland, Bear–Slave–Churchill Uplands, and Hudson Bay Lowland; Hunt 1974).

The Rocky Mountains province includes the eastern slopes of several mountain ranges along the British Columbia–Alberta border and consists of a series of parallel mountain ridges and valleys aligned

in a northwest–southeast direction (Lane and Sykes 1982). The mountain ranges (e.g., Rockies) rise >2000 m above the valley floors. The valleys have been shaped by glaciation and subsequent erosion. There is considerable precipitation in the mountains that drains eastward from this province. The soil on steep slopes is generally thin and coarse, allowing rapid infiltration and subsurface movement into streams.

The Interior Plains division (i.e., Central Lowland and Great Plains provinces; Hunt 1974) is a series of three steps, beginning with the Manitoba Plain in the east (Bear–Slave–Churchill Uplands westward to Manitoba Escarpment), extending in a second step to the Missouri Coteau, and then in a third step to the foothills (Lane and Sykes 1982). The Interior Plains in Manitoba and Saskatchewan are bordered on the north and east by the Bear–Slave–Churchill Uplands and Superior Upland (Canadian Shield division; Hunt 1974). The Interior Plains division has a general slope from southwest to northeast. Soils range from brown, dark brown, black, and dark grey soil groups in the southern areas to podzols in wetter

regions. Wetter regions contain widespread organic soils in muskeg. There are extensive permafrost areas in the north.

The Canadian Shield division (Hunt 1974) is a major physiographic feature of the Churchill catchment in the northern part of the prairie provinces (Bear–Slave–Churchill Uplands) and in the eastern part of the Nelson catchment in Manitoba and Ontario (Superior Upland). Glacial erosion has left extremely hard, erosion-resistant rock throughout the region (Lane and Sykes 1982). The Shield is characterized by numerous lakes and marshy depressions and has a poorly organized drainage system. The many lakes and marshes result in a large surface-water resource.

The mouths of the Churchill and Nelson rivers lie in the Hudson Bay Lowland province of the Canadian Shield division of Hunt (1974). In this area, flat muskeg plains are dotted with shallow lakes, often interrupted by raised gravel beaches (Lane and Sykes 1982).

The region occupied by the Nelson and Churchill catchments generally experiences long, cold winters (Lane and Sykes 1982). A winter ridge of high pressure typically develops between low-pressure areas over the Gulf of Alaska, extending to the region south of Hudson Bay in the east and bringing clear cold weather to western Canada. The coldest month is usually January (mean daily air temperature of $\sim -10^{\circ}\text{C}$ in the south to $\sim -27.5^{\circ}\text{C}$ in the north). Higher mean temperatures in the southwestern part of the Nelson catchment in Alberta are caused by foehn winds (“chinooks”). These warm, dry winds provide respite from the severe cold, but they also reduce snow cover, which reduces the amount of soil moisture and can reduce the amount of spring runoff. The warmest month of the year is usually July (mean daily air temperatures from $\sim 17.5^{\circ}\text{C}$ in the south to $\sim 15^{\circ}\text{C}$ in the northern part of the two catchments). The frost-free period varies from ~ 120 days in the south to ~ 60 to 70 days in the northern and western fringes of widespread agricultural activity.

The mean annual precipitation for the Nelson and Churchill catchments varies from ~ 40 cm in northern areas to ~ 60 cm in the Rocky Mountains province (Lane and Sykes 1982). However, a large, dry area (30 to 40 cm/yr) exists in southeastern Alberta and southwestern Saskatchewan. The relative dryness of western Canada east of the foothills is caused by the rain-shadow effect of the Rocky Mountains. However, most of the precipitation received in the western parts of the Interior Plains region still originates from moist Pacific air masses. Southern air masses more strongly

affect southern Manitoba. Another major source of precipitation in western Canada is convection storms on hot days in summer. These storm events are sometimes accompanied by hail, and the associated rainfall is usually intense but short.

Basin Landscape and Land Use

Both catchments occupy two major habitat types (Ricketts et al. 1999): Temperate Grasslands/Savanna/Shrub, which roughly corresponds to the Great Plains and Central Lowland, and Boreal Forest/Taiga, which roughly corresponds to the Bear–Slave–Churchill Uplands, Superior Upland, and the Hudson Bay Lowland. The Nelson catchment also occupies small parts of two other major habitat types: Temperate Coniferous Forests, which runs through the Rocky Mountains province, and Temperate Broadleaf and Mixed Forests in northwestern Minnesota and southwestern Ontario, through which part of the Winnipeg River subcatchment flows. Ricketts et al. (1999) further subdivide major habitat types into three ecoregions for the Churchill catchment and twelve ecoregions for the major subcatchments of the Nelson system.

Thirty-two percent of the Nelson catchment is forest (Revenga et al. 1998, www.waterandnature.org/eatlas/html/index.html 2004). Comparable data are not available for the Churchill catchment, although the proportion is almost certainly higher. The Boreal Forest/Taiga major habitat type extends in a broad band across the Nelson and Churchill catchments from Lake Winnipeg to north-central Alberta. The Temperate Coniferous Forests major habitat type is located along the extreme western edge of the Nelson catchment along the British Columbia–Alberta border. These forests support a number of commercial forestry operations (concentrated across the central part of Saskatchewan in the Churchill catchment and northeast and southeast of Lake Winnipeg in the Nelson catchment), provide important habitat for wildlife, and support considerable recreation activity (Lane and Sykes 1982). Forests in the foothills and mountains also influence the quality, quantity, and timing of water yields. The Canadian Aspen Forest and Parklands ecoregion (Temperate Grasslands/Savanna/Shrub major habitat type) to the south of the boreal forest is a mixture of woodland and grassland cover. The forests in this zone are generally too small to support forestry operations.

Forty-seven percent of the Nelson catchment is cropland (Revenga et al. 1998, Water and Nature Ini-

tiative 2004 <http://www.waterandnature.org/atlases/html/index.html>). Comparable data are not available for the Churchill catchment, although the proportion is almost certainly lower. Only rich soils in the parklands are cultivated, but the soils in the Temperate Grasslands/Savanna/Shrub south of the parklands are very widely used (Lane and Sykes 1982). These grasslands comprise the largest single expanse of agricultural land in Canada. Uncultivated land supports large herds of beef cattle, but most of the best land is tilled. Brown, dark brown, and black soils predominate. Solonchic soils are also present, but their cultivation is inhibited by salinity.

Nonrenewable resources include petroleum, especially in the Interior Plains division (under most of Alberta and smaller areas in Saskatchewan and Manitoba); coal, underlying some of the Rocky Mountains province and Interior Plains division; and potash, extending in a belt from the Alberta border through central Saskatchewan down to southwestern Manitoba (Lane and Sykes 1982). Most potash mines operate in Saskatchewan, where reserves are enormous. Metal mining is concentrated in the Canadian Shield division (Bear–Slave–Churchill Uplands) of northern Manitoba and northern Saskatchewan (Lane and Sykes 1982).

Water use in the Nelson and Churchill catchments can be categorized as either offstream use, which removes water from streams or lakes and returns the unused portion (e.g., irrigation, industrial, and municipal use), or instream use, which uses water directly in the stream or lake (e.g., fishing, recreation, hydropower production) (Lane and Sykes 1982). Instream water uses, dependent on reliable annual flows, are characteristic of northern parts of the study area. Offstream water uses, dependent on the total water available for use, are characteristic of southern parts of the study area. These two types of water use are discussed in more detail later in the chapter.

Subsistence hunting, fishing, and trapping, mainly by aboriginal people, are closely related to water quality and quantity (Lane and Sykes 1982). These activities are mainly pursued in more northern areas of the Nelson and Churchill catchments and often are in conflict with activities such as hydro development (e.g., Waldram 1988, Usher and Weinstein 1991). The proposed Wintego Dam on the Churchill River in northeastern Saskatchewan (Churchill River Study 1976) was successfully opposed by aboriginal peoples.

The wildlife of the Nelson and Churchill catchments, especially in the Interior Plains division, has been changed over the past 200 years by extensive hunting and trapping, and more recently by activities

such as agriculture, forestry, urban and industrial expansion, mining, dam construction, and road construction (Lane and Sykes 1982). Nevertheless, wildlife is still abundant in many areas. For example, deer, elk, moose, bighorn sheep, and mountain goat can be found in the mountains and foothills. Antelope, small fur-bearers, prairie dog, rabbit, hare, waterfowl, and other birds are common in the grasslands. Deer, elk, grouse, and waterfowl are part of the aspen parkland. Deer, elk, moose, bear, and a variety of small mammals and birds live in the boreal forest. Hunting and trapping for commercial and subsistence purposes are important throughout the two catchments.

Five major urban centers (populations from ~200,000 to ~1,000,000) are located in the southern parts of the Nelson catchment: Calgary, Edmonton, Winnipeg, Saskatoon, and Regina. Each of these cities, except for Regina, is located on a major river. Moreover, there has been a recent exodus from rural areas into the cities. Populations in the northern parts of the Nelson catchment and in the Churchill catchment are small and stable.

The Rivers

Both the Nelson and Churchill catchments are part of the Hudson Bay Complex of the Arctic–Atlantic Bioregion and occupy only two major habitat types: Temperate Headwaters and Lakes and Arctic Rivers and Lakes (Abell et al. 2000). The Nelson and Churchill catchments contain four freshwater ecoregions (Abell et al. 2000). The Churchill River mostly occupies the Lower Saskatchewan ecoregion. Of the major Nelson subcatchments discussed here, the Nelson River (main stem) occupies the Lower Saskatchewan ecoregion, the Saskatchewan River mostly occupies the Upper and Lower Saskatchewan ecoregions, and the Red–Assiniboine and Winnipeg rivers mostly occupy the English–Winnipeg Lakes ecoregion. In addition, the headwaters of the Saskatchewan River emanate from the Canadian Rockies ecoregion.

From a physiographic perspective the Interior Plains physiographic division includes the Saskatchewan River (which flows through the Rocky Mountains, Great Plains, and Central Lowland provinces) and Red–Assiniboine rivers (Central Lowland province). The Canadian Shield division includes the Churchill River (Great Plains, Central Lowland, Bear–Slave–Churchill Uplands, and Hudson Bay Lowland provinces), Nelson River (Bear–Slave–Churchill Uplands and Hudson Bay Lowland

provinces), and Winnipeg River (Central Lowland and Superior Upland provinces). The different physiographic regions heavily influence the hydrology, chemistry, and biology of the rivers we consider.

High precipitation and considerable relief in the Rocky Mountains province produce an annual yield of water to rivers in the foothills and the plains beyond. The Interior Plains division gets most of its streamflow from the mountains; water originating in the Interior Plains is limited because of low precipitation and high evapotranspiration (Lane and Sykes 1982). Soils in the Interior Plains have large moisture storage capacities, which can affect the timing of drainage to rivers following periods of rain. The Canadian Shield division has a high yield relative to precipitation, and the streams have a more seasonally balanced flow than those in the Rocky Mountains province because of the large natural storage capacity of lakes in the Canadian Shield.

Rivers of the Canadian Shield division, Interior Plains division, and Rocky Mountains province present three different hydrographic scenarios. Rivers in the Canadian Shield are regular in their flow characteristics, rivers of the Interior Plains tend to be erratic, and rivers of the Rocky Mountains are intermediate, although they resemble Canadian Shield rivers more than Interior Plains rivers.

Most mountain streams have good water quality, although streams draining glaciers can have high loads of suspended solids. Water quality of rivers arising on the Interior Plains is variable, but water is usually high in dissolved and suspended solids because of erosion. In the Canadian Shield division, low concentrations of dissolved and suspended solids usually result in good water quality, although high mineral and organic concentrations can occur. Dissolved and suspended solids concentrations are higher in the Hudson Bay Lowland province than in the Bear–Slave–Churchill Uplands and Superior Upland provinces because of more easily eroded surface material in the Hudson Bay Lowland.

Regional differences in water quality are also apparent, except for pH (7.5 to 8.5 throughout both catchments; Lane and Sykes 1982). Specific conductance is lowest in the Canadian Shield, followed by waters in the foothills east of the Rocky Mountains, and highest in the Interior Plains. Canadian Shield rivers flow over impermeable substrate, so their specific conductance tends to be low. Interior Plains rivers flow over highly erosive areas, so their specific conductances are higher. Rocky Mountain rivers can carry high suspended solids during high-flow periods,

and their specific conductances tend to be intermediate. Turbidity values follow a similar pattern. Canadian Shield waters tend to have low turbidity values, mountain streams have intermediate values, and Interior Plains streams can have the highest values because of erosion during periods of high flow. River regulation often lowers ranges of turbidity values.

Dissolved oxygen concentrations are usually high in Rocky Mountain and Canadian Shield streams during open water and under ice. Most Interior Plains rivers do not have oxygen problems in the open-water season (unless there are upstream sewage effluents), but a number of Interior Plains rivers have oxygen depressions under ice because of a lack of aeration caused by four to five months of ice cover.

Nitrogen and phosphorus concentrations are intrinsically low in rivers traversing the Rocky Mountains province and Canadian Shield division (i.e., the headwaters of the Bow, South Saskatchewan, and North Saskatchewan rivers, and the Churchill River) because of the largely granitic bedrock and shallow soils. However, concentrations increase as the rivers cross the Interior Plains division because of inputs of nutrients from naturally fertile soils as well as from anthropogenic sources (municipal, industrial, and agricultural activities).

Water use is extensive in the Nelson and Churchill catchments. Offstream uses include irrigation, municipal centers, industrial water needs, thermal power production, and water diversions (Lane and Sykes 1982). Irrigation is the largest consumer of water in the study area, and is done mostly in southern Alberta (Bow and Oldman rivers) but also in southern Saskatchewan (South Saskatchewan River) and southern Manitoba (Red–Assiniboine rivers). Significant expansion of irrigation is generally hampered by a lack of available water. Municipal centers return most of the water they use, but they require assured supplies. All the major cities have adequate supplies, although Winnipeg and Regina may need expansions to their supplies, which come from distant sources. In addition, Lethbridge and Medicine Hat, both Alberta cities located on rivers used extensively by upstream irrigation, depend on flows regulated to meet their needs. Industrial water needs are widespread through the study area. Most mining and forestry operations are located in remote areas, but small industries and petrochemical plants are usually located near large cities. Most water needs for industrial, petrochemical, and mining uses are being met, although disposal practices must be monitored to prevent pollution of surface and groundwater systems. Thermal power production is important in

Saskatchewan and Alberta, but not in Manitoba, where hydropower production predominates (Lane and Sykes 1982). Significant expansion of thermal power generating facilities in both Saskatchewan and Alberta may be hampered by inadequate water supplies, although water diversion may be feasible for some developments in Alberta. Minor and major water diversions can be found throughout the study area and serve three purposes: (1) reducing drought vulnerability, (2) flood control, and (3) enhancing or stabilizing flows for hydropower generation. A number of water diversions are still on the drawing board or have been delayed because of environmental concerns.

Instream uses include commercial fishing, water-based recreation, subsistence natural-resource harvesting activities, and hydropower development (Lane and Sykes 1982). Commercial fishing is either a stable or declining industry in most parts of the study area. Most commercial fishing is done in Saskatchewan and, especially, in the large lakes of Manitoba. There are fears that completion of the Garrison Diversion in North Dakota, which would mix Missouri River waters with those of the Hudson Bay drainage, could introduce fish diseases, fish parasites, and undesirable fish species to Lake Winnipeg (e.g., Loch et al. 1979). Water-based recreation is an important instream use throughout the study area. For example, the sport-fishing industry in Saskatchewan is worth many times more than commercial fishing. Resource development has opened previously inaccessible areas to recreational uses. However, there is competition with other uses. For example, water-quality and low-flow conditions are a concern to recreation in parts of the Saskatchewan River subcatchment. Other threats to recreational fishing include biocides, metals (e.g., mercury), and eutrophication. Waterfowl conservation and production also conflict with other land and water uses, such as the draining of wetlands and some tillage practices. The protection of wild rivers for esthetic and recreational purposes conflicts with regulation of rivers for hydroelectric purposes. This conflict is most often felt in high-use recreational areas of mountain rivers or in wild and scenic rivers like the formerly superb lower Churchill (Newbury and Malaher 1972). However, river regulation can benefit recreation on the Interior Plains rivers by providing more reliable flows. Hydropower has been extensively developed in the study area. Most of this development has been in Manitoba, followed by Alberta and Saskatchewan. The Nelson River dissipates ~5400 MW of hydraulic power in its fall from the

exit of Lake Winnipeg to Hudson Bay (Newbury et al. 1984), so development in Manitoba has focused on the lower Nelson. The three most recently constructed dams generate >3000 MW of power. The Winnipeg River is also highly regulated (560 MW). Hydropower developments in Alberta are centered on the Bow and North Saskatchewan rivers, and in Saskatchewan on the South Saskatchewan, Saskatchewan, and Churchill rivers.

Only seven species of fishes (northern pike, a subspecies of longnose dace, white sucker, troutperch, burbot, brook stickleback, and walleye) are broadly distributed throughout the Nelson and Churchill catchments, probably because of the glacial history of the area, the time since waters became available for colonization after the Wisconsinian glaciation (~12,000 to 15,000 years ago), and the physical and ecological characteristics of both the habitat and the fishes available to invade it (Crossman and McAllister 1986). Well-known species such as lake whitefish and lake trout are also broadly distributed, except for the extreme southwest or prairies. Crossman and McAllister (1986) recorded 39 nonnative species in the Hudson Bay drainage, including species native to some part of the drainage but introduced to other parts (e.g., brook trout in Alberta).

Rivers of the Nelson and Churchill catchments are not significantly biologically distinct (Abell et al. 2000). Total species richness is highest in the English–Winnipeg Lakes freshwater ecoregion (Red and Winnipeg river subcatchments) and lowest in the Lower Saskatchewan ecoregion (Nelson River subcatchment) (Abell et al. 2000). Endemic species only occur in the Canadian Rockies ecoregion. Fish species richness is highest in the English–Winnipeg Lakes ecoregion (79 species) but low in most of the rest of the area (Lower Saskatchewan, including the Hayes and Seal rivers, 38 species; Upper Saskatchewan, 41 species). Similar low species richness applies to crayfishes (1 species in each of the Lower and Upper Saskatchewan), unionid mussels (4 species in each of the Lower and Upper Saskatchewan), and herpetofauna (Lower Saskatchewan, 5 species; Upper Saskatchewan, 10 species). Very low percentages of fish or herpetofauna species in the ecoregions of the Nelson and Churchill catchments are imperiled. Taken together, biological distinctiveness is “continentally outstanding” for the English–Winnipeg Lakes, Lower Saskatchewan, and Canadian Rockies ecoregions and “nationally important” for the Upper Saskatchewan (Abell et al. 2000).

Ecoregions of the Nelson and Churchill catchments show a variety of “final conservation status”

FIGURE 19.5 Aerial view of the South Saskatchewan River as it passes through Saskatoon, Saskatchewan (PHOTO FROM TOURISM SASKATCHEWAN).

conditions (Abell et al. 2000). The Upper Saskatchewan ecoregion is “endangered.” This ecoregion contains rivers in the driest part of the Interior Plains division, in southern Alberta and southwestern Saskatchewan. The English–Winnipeg Lakes and Canadian Rockies ecoregions are “vulnerable,” and the Upper Saskatchewan ecoregion is “relatively stable” (Abell et al. 2000).

SASKATCHEWAN RIVER

Canada’s fourth-longest river, the Saskatchewan, is formed at the confluence of the North and South Saskatchewan rivers >1200km downstream of its glacial origins. This 8th order river is one of the most diverse rivers in North America. With its headwaters in the Rocky Mountains, the Saskatchewan River flows west to east across foothills, prairies, and boreal forest to Lake Winnipeg, via Cedar Lake (Fig. 19.11). The Saskatchewan River subcatchment has an area of ~335,900km² and drains part of Montana, Alberta, Saskatchewan, and Manitoba.

Saskatchewan is derived from the Cree word *Kisiskatchewan*, meaning “swift-flowing” or “rapid.” The river was an important transportation route for aboriginal peoples, and archaeologists have located >650 sites throughout the subcatchment showing

human presence as long ago as 10,500 years. The earliest European reference to this river is in 1750 on a map sent to France showing the discoveries of a family of explorers known as “La Verendryes” (Douglas 1925). This map labeled the river the Poskaiao; however, by 1790 maps prepared for the Hudson’s Bay Company used the present name, Saskatchewan River. It was an important route for exploration and commerce in the eighteenth century, carrying fur traders, missionaries, and settlers deep within the continent. River steamers once traveled its waters, but with the arrival of the railroad the Saskatchewan no longer had substantial navigational value.

Physiography, Climate, and Land Use

The Saskatchewan River is formed in the Great Plains (GP) and Central Lowland (CL) physiographic provinces of central Saskatchewan by the confluence of the North Saskatchewan and South Saskatchewan rivers before flowing eastward through Cedar Lake to Lake Winnipeg (see Fig. 19.11). However, the river originates in the glaciers, snowfields, and cold headwater streams of the Rocky Mountains in Canada (RM) province in Alberta before flowing across the plains. Primarily flowing eastward between latitudes 49°N to 53°N and longitudes 117°W to 100°W, the subcatchment encompasses seven terrestrial

ecoregions, including Alberta Mountain Forests, Alberta/British Columbia Foothills Forests, Canadian Aspen Forest and Parklands, Montana Valley and Foothill Grasslands, Northern Mixed Grasslands, Northwestern Mixed Grasslands, and Mid-continental Canadian Forests (Ricketts et al. 1999).

Landscapes at the western edge of the subcatchment are dominated by mountains formed from Cretaceous sediments, with brunosolic, podzolic, and luvisolic soils, and forests of lodgepole pine, Engelmann spruce, alpine fir, and trembling aspen. In contrast, the northern arc of the subcatchment consists of boreal forest, with luvisolic, chernozemic, gleyso-lic, and mesisolic soils, and white spruce, balsam fir, black spruce, willow, and aspen. To the south the prairie has mostly chernozemic soils on glacial moraine and gently undulating lacustrine deposits underlain by Cretaceous shales and Paleozoic limestone. This area is the northern extension of open grasslands in the Great Plains of North America, once dominated by fescue, blue grama, and wheatgrasses.

Mean annual air temperature varies considerably across the subcatchment and exhibits a strong continental climate pattern (Fig. 19.12). For example, in the south (e.g., Calgary, Medicine Hat) mean annual temperature generally ranges from 3°C to 5°C, daily mean January temperatures are near -10°C, and daily mean temperatures rise to 16°C in July. In the north (e.g., Edmonton, Saskatoon, Prince Albert) mean annual temperatures are 0.5°C to 2°C and monthly means range from -20°C to 19°C. Annual precipitation is low across the subcatchment, ranging from ~32 to nearly 50 cm. Peak precipitation occurs during summer (see Fig. 19.12). Approximately 30% to 50% of this moisture is from snowfall, with snow amounts highest in mountain headwaters and lowest in the southern prairies.

Today the relatively high natural fertility and good moisture-holding capacity of the chernozemic soils in most of the subcatchment east of the mountains makes these lands highly productive for agriculture (67% of the subcatchment is cropland; Revenga et al. 1998). The relatively flat topography common to much of the aspen parkland, and particularly the prairies to the south, is conducive to highly mechanized farming and has resulted in this semiarid region becoming the most human-altered landscape in Canada. About 3 million people live in the subcatchment (P. A. Chambers, unpublished data). Most of these people live in the three largest cities (www.statcan.ca/english/Pgdb/People,Population/demo05.htm 2001): Calgary (~972,000), Edmonton (~957,000), and Saskatoon

(~231,000). Other major urban areas in the subcatchment include Lethbridge, Red Deer, Medicine Hat, and Prince Albert. Although the subcatchment contains several highly urbanized areas, particularly in Alberta, overall population density is quite low (<9.6 people/km²; Statistics Canada 2003), with the highest densities occurring in the western portion.

River Geomorphology, Hydrology, and Chemistry

The North Saskatchewan River arises from the Saskatchewan Glacier in the Rocky Mountains (see Fig. 19.11). It exhibits a typical concave longitudinal profile, with average gradients from ~2 to 3 m/km in the mountains upstream of Rocky Mountain House to ~40 cm/km around Edmonton and <15 cm/km in Saskatchewan (Kellerhals et al. 1972). The North Saskatchewan River was originally one channel of a braided stream draining proglacial Lake Edmonton; remnants of the braided channel can still be seen in reaches upstream of Edmonton. The river channel is braided and sinuous near the glacial source and quickly changes to an entrenched and frequently confined channel in the foothills. Downstream of Edmonton the river consists of a single channel (100 to 200 m wide) that meanders through a valley that is now 2 to 4 km wide and bordered by cliffs 25 to 200 m high. Bed material in the North Saskatchewan River is predominantly gravel, becoming sandy over easily erodible shale near the Alberta-Saskatchewan border (Anderson et al. 1986).

The Bow River headwaters to the South Saskatchewan River mouth also exhibits a classic concave longitudinal profile, with average gradients from ~7 m/km in the mountains near Banff to <50 cm/km below Medicine Hat on the South Saskatchewan (Kellerhals et al. 1972). The system was a glacial spillway during the late Pleistocene and the present-day river meanders through this ancient channel. The river channel is wide and relatively shallow throughout its extent. For example, the Bow River at Calgary is ~100 m wide and 1 m deep, and the South Saskatchewan River near the Alberta border above its confluence with the Red Deer River has a mean width and depth of ~180 m and 2 m, respectively (Kellerhals et al. 1972). Well-developed riffle, run, and pool sequences are evident along the river, although riffle habitats are rare below Lake Diefenbaker (Fig. 19.5). Substrate in the upper portion of the South Saskatchewan system (e.g., Bow

River) is coarse and mostly composed of gravel, cobble, and boulders (Longmore and Stenton 1981); downstream the South Saskatchewan has a substrate of gravel, sand, and silt.

The Saskatchewan River is formed by the convergence of the North and South Saskatchewan rivers in east-central Saskatchewan. Although it historically occupied a single well-defined channel, an avulsion occurred in the 1870s just west of the Manitoba–Saskatchewan border and converted >500 km² of floodplain into a belt of anastomosing channels, wetlands, and small lakes (Smith et al. 1998). Approximately 90% to 95% of the flow is diverted through this network of channels and eventually enters Cumberland Lake, later rejoining the old channel of the Saskatchewan through three outlets from the lake (see Fig. 19.11). The area encompassing the active and abandoned channels of the Saskatchewan River, as well as an extensive wetland south of the old channel, is known as the Cumberland Marshes (sometimes called the “Saskatchewan Delta”), a ~8000 km² region comprising major waterfowl breeding grounds and muskrat trapping areas. Downstream of Cumberland Lake the river continues eastward and broadens into Cedar Lake. The Saskatchewan River continues as the outlet from Cedar Lake, from which, prior to regulation in 1965, it flowed ~40 km and dropped 36 m over a series of waterfalls into Lake Winnipeg.

Precipitation and runoff patterns appear closely related in the Saskatchewan River subcatchment (see Fig. 19.12), although individual river systems may be strongly influenced by snowmelt. Mean daily flows of the North Saskatchewan River near its mouth average 241 m³/s, with peak flows occurring in July during mountain snowpack melt and lowest flows in February (Environment Canada 2001). Most of the river is ice covered from early November to mid-April, except downstream of effluent discharges or hydroelectric dams. Regulation of the upper main stem in 1972 for hydroelectric power generation has increased mean monthly discharge in winter (November to March) by two to three times and reduced summer (June to September) discharge by 20% to 30% compared to preregulation values. Annual discharge of the Bow–South Saskatchewan system typically peaks in the spring as the mountain snowpack melts, but summer rains can occasionally produce flood peaks equal to or greater than this spring runoff (Culp and Davies 1982). Much of the system is ice covered in winter (December to March), except where ice is prevented from forming because of groundwater discharges in headwaters or downstream of large reservoirs (e.g., Gardiner Dam on the

South Saskatchewan). Preregulation discharge of the Saskatchewan River at the Pas, upstream of Cedar Lake, was 684 m³/s; postregulation discharge is 585 m³/s. Postregulation discharge at the river’s inflow to Lake Winnipeg is 567 m³/s (Environment Canada 2001). Regulation of the river for hydroelectric power generation raised water levels in Cedar Lake by 3.7 m, created a 3500 km² reservoir, and reversed the natural discharge pattern so that at the inflow to Lake Winnipeg highest flows now occur in winter (January to February) and lowest flows occur in spring (April to May), in contrast to the preregulation runoff (see Fig. 19.12).

Like all rivers traversing the prairies, the North Saskatchewan carries a heavy silt load (8480 metric tons annual mean for 1962 to 1978; Environment Canada 1992). Typical of many lakes and rivers in the prairies, the water is hard (125 to 160 mg/L as CaCO₃), with calcium and bicarbonate the dominant ions (Saskatchewan Environment 1984, Anderson et al. 1986, Shaw et al. 1994). Total solute concentration ranges from 200 to 300 mg/L, with dilute mountain runoff determining solute concentrations along the entire length of the main stem (Taylor and Hamilton 1993). The river is intrinsically nutrient poor (14 µg/L total phosphorus [TP], 3 µg/L total dissolved phosphorus, 127 µg/L total nitrogen [TN], and 91 µg/L nitrogen as NO₂ + NO₃ near the headwaters); however, concentrations increase twofold to tenfold downstream of Edmonton and remain elevated along the remainder of the river. Discharge of treated wastewater from the city of Edmonton is also responsible for increased concentrations of sodium, chloride, potassium, and fecal coliform bacteria (Shaw et al. 1994). Rivers in the South Saskatchewan system have hard water because the basin bedrock is a limestone–shale complex. For example, Culp et al. (1992) reported high long-term mean values of specific conductance (357 µS/cm), total alkalinity (127 mg/L as CaCO₃), total dissolved solids (TDS; 200 mg/L), and hardness (163 mg/L as CaCO₃) near the mouth of the Bow River. All of these variables, as well as total organic carbon (6 mg/L) and turbidity (8 JTU), gradually increase downstream (Culp et al. 1992). In addition, the key limiting nutrient, phosphorus, increases downstream along the river continuum, as exemplified by patterns in the Oldman and South Saskatchewan rivers (Culp and Davies 1982, Chambers and Prepas 1994, Carr and Chambers 1998). Water quality in the Saskatchewan River upstream of Cedar Lake is fair (50 µg/L TP, 0.537 µg/L TN, 47 mg/L TDS) and generally improves downstream of the dam (Manitoba Environment 1997).

River Biodiversity and Ecology

The Saskatchewan River subcatchment is included within the Canadian Rockies and Upper and Lower Saskatchewan freshwater ecoregions (Abell et al. 2000).

Algae and Cyanobacteria

When wastewater was subjected to secondary treatment (Carr and Chambers 1999), concentrations of both planktonic and epilithic algae in the North Saskatchewan River near Edmonton were uniformly low ($<1\text{ mg/m}^3$ and 8.7 mg/m^2 chlorophyll *a*, respectively) upstream of Edmonton but increased substantially downstream of the municipal sewage treatment plant (to $\sim 40\text{ mg/m}^3$ and 200 mg/m^2 chlorophyll *a*, respectively). Planktonic algae were the dominant primary producers in spring and summer when the water was turbid, whereas epilithic algae dominated in the fall. Information on algal taxonomic composition was not available at this site. The epilithic algal community of the Bow and Oldman rivers is dominated by diatoms and cyanobacteria, whereas filamentous green algae tend to dominate in the South Saskatchewan downstream of the Bow–Oldman confluence (Culp and Davies 1982, Charlton et al. 1986, Culp et al. 1992). Davies et al. (1977) recorded 192 algal species in the Oldman–South Saskatchewan system. Common diatom genera included *Achnanthes*, *Cymbella*, *Fragilaria*, *Gomphonema*, *Navicula*, and *Nitzschia*. Cyanobacteria were represented by many filamentous forms, such as *Anabaena*, *Oscillatoria*, and *Phormidium*, whereas filamentous green algae (i.e., *Cladophora glomerata*, *Oedogonium*) accounted for 80% to 90% of the biomass in the lower South Saskatchewan (Green and Davies 1980). Algal biomass increases downstream in the river as a result of increased availability of plant nutrients. Seasonal trends suggest that spates, particularly during spring runoff, reduce epilithic biomass to minimum values. Peak periphyton biomass occurs during summer months, with mean summer values ranging from $<10\text{ }\mu\text{g/cm}^2$ upstream of major centers (e.g., Calgary) to $>200\text{ }\mu\text{g/cm}^2$ downstream (Culp and Davies 1982, Charlton et al. 1986). Adoption of advanced phosphorus removal by Calgary in the early 1980s resulted in declines of epilithic algal abundance downstream of the city, where TDP $<10\text{ }\mu\text{g/L}$ (Sosiak 2002). Epilithic chlorophyll *a* concentrations ranged from 104 to 1223 mg/m^2 upstream of Saskatoon compared with 49 to 2074 mg/m^2 just downstream of the city's sewage disposal (tertiary treatment) (Constable 2001). Com-

paratively little is known about the biodiversity and ecology of algae in the main-stem Saskatchewan River because the low population density in the system and high discharge have averted many water-quality problems.

Plants

Moisture conditions in the higher-elevation portion of the North Saskatchewan River subcatchment are similar near the river and in the upland so that upland vegetation extends close to the river bank. White spruce or aspen forests are often found on fluvial fans and terraces. At lower elevations, particularly once the river passes Edmonton, the wide river valley and its steep cliffs are colonized by balsam poplar and trembling aspen, shrubs such as alder, Saskatoon berry, chokecherry, and prickly rose, and a mixture of grasses and forbs. For the South Saskatchewan River subcatchment (Oldman and South Saskatchewan rivers), similar moisture conditions near the river and in the upland in the higher-elevation portion mean that trees and shrubs typical of the upland forest also occur close to the river margin. As elevations decline through the foothills, white spruce or aspen forests often occur on fluvial fans and terraces. Trees and shrubs in the prairies of southern Alberta and Saskatchewan are typically only found in river valleys where there is enough moisture to support riparian woodlands. In these areas, cottonwood forests occur, although human impacts (e.g., crop and livestock production, settlement, river damming and diversion) have decreased the extent of these forests. Downstream of Saskatoon the prairies give way to a boreal transition zone, where riparian vegetation is dominated by willow, aspen, and shrubs (chokecherry, Saskatoon berry), with an understory of mixed grasses and forbs.

Aquatic macrophytes (particularly pondweeds) in the North Saskatchewan River are infrequent, vary considerably in density among years and, when present, are limited to narrow bands near the river banks. Macrophytes (e.g., pondweeds) in the South Saskatchewan River system show distinct longitudinal zonation, their biomasses generally increasing sharply downstream of major municipal sewage discharges (Culp et al. 1992, Chambers and Prepas 1994, Carr and Chambers 1998, Sosiak 2002). Downstream of Calgary, plant biomass declined following phosphorus and nitrogen removal from sewage. Plant diversity in the Cumberland Marshes of the main-stem Saskatchewan River is high, with >50 emergent and submergent species recorded. Fen

meadows dominated by sedges give way to cattail, bur-reed, bulrush, sweet-flag, and grant reed-grass along the margins of shallow lakes, protected bays of deeper lakes, and streams (Dirschl and Dabbs 1969, Dirschl 1972). Pondweeds, yellow pond-lily, spiked watermilfoil, hornwort, and bladderworts are abundant in the shallower lakes and along the shores of deeper lakes.

Invertebrates

Organic pollution, sedimentation, and epilithic algal growth have resulted in classic changes in the abundance and composition of benthic invertebrates in the North Saskatchewan River (Anderson et al. 1986, Shaw et al. 1994). Upstream of Edmonton the invertebrate assemblage shows little evidence of anthropogenic impacts and is characterized by a relatively low density and high diversity of organisms. Taxa of mayflies, stoneflies, and caddisflies are, together, as important numerically as chironomid midges, oligochaete worms, and nematodes. Within and immediately downstream of Edmonton total densities are higher, diversity is lower, and chironomids, oligochaetes, and nematodes comprise up to 98% of total numbers. Evidence of recovery is observed ~100 km downstream of Edmonton, but impacts persist for at least 300 km downstream. Further downstream the riverbed changes from gravel to one dominated by shifting sandbars. Benthic invertebrate abundance in these areas is low and dominated by chironomids and oligochaetes. The mayfly genus *Baetis* and the caddisfly genus *Hydropsyche* predominate where gravel patches occur (Fredeen 1983, Golder Associates 2000, J. J. Merkowsky, personal communication). The macroinvertebrate communities of the Oldman and South Saskatchewan rivers correspond broadly with the terrestrial zones of subalpine forest, fescue prairie, and mixed prairie, although zonation distinctness varies seasonally (Culp and Davies 1982). A similar pattern of zonation in stoneflies was also observed for the Bow River (Donald and Mutch 1980). In the summer and fall, upstream invertebrate communities are dominated by collector-scrappers (the mayflies *Cinygmula*, *Rhithrogena*, and *Ephemerella inermis* and the caddisfly *Glossosoma*). In contrast, invertebrates in downstream reaches of the South Saskatchewan are almost exclusively collector-gatherers (e.g., Orthoclaadiinae midges and the mayflies *Ephoron album* and *Ephemera simulans*) and filter-feeders (the caddisflies *Symphitopsyche* and *Cheumatopsyche* and the mayfly *Traverella albertana*). Shredders (e.g., the stoneflies *Zapada* and *Capnia*) increase in impor-

tance during late winter in the subalpine forest zone, and the fauna of the lower longitudinal zones is dominated by collector-gatherers (Orthoclaadiinae and Chironominae midges). These longitudinal differences in faunal composition appear to be related to downstream changes in food resources in all seasons and downstream increases in thermal degree days during the open-water period (Lehmkuhl 1972, Culp and Davies 1982). No information is available on benthic invertebrates in the main-stem Saskatchewan River.

Vertebrates

The North Saskatchewan River supports a diverse community of 36 fish species distributed throughout the system and following patterns similar to those observed in macroinvertebrate communities. Coldwater species, such as cutthroat trout, rainbow trout (nonnative), bull trout, brook trout (nonnative), brown trout (nonnative), mountain whitefish, longnose sucker, and longnose dace, dominate forested, mountainous reaches. As the river flows out of the mountains into the prairies the fish community includes warmwater species, such as northern pike, walleye, sauger, goldeye, yellow perch, quillback, and shorthead redhorse. The number of fish species in the Saskatchewan portion of the North Saskatchewan River doubled from 1957–1958 to 1985–1986, likely because of improved water quality, particularly dissolved oxygen concentrations (J. J. Merkowsky, personal communication). The relative number of goldeye and northern pike was also reported to have declined over the same period, whereas walleye and sauger populations increased because of greater abundance of spawning areas.

The pattern of fish distribution that Longmore and Stenton (1981) described for the South Saskatchewan system resembles trends observed for macroinvertebrate communities. Forested, upstream reaches are dominated by coldwater species, such as cutthroat trout, rainbow trout, bull trout, brook trout, brown trout, mountain whitefish, longnose sucker, and longnose dace. Warmwater reaches in the lower Bow, Oldman, Red Deer, and South Saskatchewan rivers are inhabited by a wide range of species, including northern pike, walleye, goldeye, yellow perch, quillback, and shorthead redhorse. The transitional zone between the foothills and prairies contains both cold- and warmwater species. In the headwaters, the nonnative rainbow trout has displaced the endemic cutthroat trout in much of the system (Longmore and Stenton 1981, Culp et al. 1992). Although angling is popular throughout the

system, the best known and most heavily angled section is the 50km reach below Calgary, where >52,000 angler-days were spent during 1985 in search of mountain whitefish, rainbow trout, and brown trout (Culp et al. 1992). The South Saskatchewan River also has an important recreational fishery for lake sturgeon.

Forty-eight species of fishes have been recorded from the Cumberland Marshes of the main-stem Saskatchewan River. The marshes are critical staging and breeding habitat for many migratory waterfowl, including large populations of ducks, geese, swans, shorebirds, grebes, and the endangered whooping crane.

Other aquatic vertebrates found in or near the rivers of the Saskatchewan subcatchment include frogs, salamanders, muskrat, beaver, river otter, mink, weasel, and water shrew.

Ecosystem Processes

Most of our knowledge of ecosystem processes comes from field studies and experiments conducted in the South Saskatchewan system. Using ^{14}C methods, Charlton et al. (1986) found that mean primary productivity of epilithic algae was $<40\text{ mg C m}^{-2}\text{ hr}^{-1}$ upstream of large sewage plant effluents during the ice-free period and increased by two to five times in enriched reaches downstream; algal biomass followed a similar pattern. Aquatic macrophytes also increased in abundance downstream of sewage discharges; however, in contrast with epilithic algae the riverbed sediments were the primary source of nutrients (Chambers et al. 1989, Carr and Chambers 1998). The magnitude of the enrichment response was affected by both current velocity and sediment composition (Chambers et al. 1991, Chambers and Prepas 1994).

Analysis of invertebrate functional-feeding group composition in this system suggests that coarse particulate organic matter is important as a food base in upstream mountain and foothill river reaches (Culp and Davies 1982). Downstream invertebrate communities appear to be based upon fine particulate organic matter and epilithic algal production. Furthermore, Culp and Davies (1982) speculated that downstream reaches of the main-stem rivers are strongly affected by enrichment and autotrophic processes in summer and are heterotrophic in winter. In addition, longitudinal thermal regime is an important factor affecting macroinvertebrate distribution, particularly through the transitional zone from mountains and foothills to prairies (Donald and Anderson 1977, Culp and Davies 1982).

Human Impacts and Special Features

Much of the area in the Rocky Mountains in which the Saskatchewan River originates is a World Heritage Site and is protected by national and provincial parks. The area is a striking mountain landscape of peaks, glaciers, lakes, waterfalls, canyons, and limestone caves. The headwaters of the Saskatchewan in Banff National Park are also designated a Canadian Heritage Rivers System to recognize their outstanding nature and to ensure future management to protect their heritage value. An upper reach of the South Saskatchewan River (Empress to Lancer Ferry) and Lake Diefenbaker (a reservoir on the South Saskatchewan) have been designated globally important bird areas by Bird Life International because of their concentrations of waterfowl, some of which are considered rare species. Tobin Lake (a reservoir) and the Cumberland Marshes on the Saskatchewan main stem are also designated globally important bird areas by Bird Life International because both areas are populated by globally significant numbers of waterfowl. For example, ~2500 tundra swans, 2.3% of the total eastern tundra swan population, congregate at Tobin Lake, and 72,000 nesting ring-necked ducks (~10% of the 1970s world nesting population) use the Cumberland Marshes (www.bsc-eoc.org/iba/canmap.cfm?lang=en 2001).

Three main human actions impact the Saskatchewan River system: dams and reservoirs, municipal sewage effluents, and agricultural activities. Dams and reservoirs are present on all of the major tributaries. They serve primarily to generate hydroelectricity, store water for use during drought, and alleviate flooding during peak flows (Environment Canada 1996). Regulation of the Saskatchewan River subcatchment began in the 1890s with the initiation of irrigation projects and works to divert and deliver water to land in southern Alberta. Some of the larger irrigation works presently operating have maximum annual diversions of ~ 150 to $800 \times 10^6\text{ m}^3$; reservoir storage capacities range from ~ 200 to $350 \times 10^6\text{ m}^3$. Collectively, a maximum of $3 \times 10^9\text{ m}^3$ is permitted for diversion to irrigation districts in the Bow and Oldman river systems, servicing $\sim 5000\text{ km}^2$ of irrigated land, rural households, and recreational needs. The startup of irrigation diversions in the late 1890s was followed by regulation for hydroelectric power generation, first in the upper reaches of the Bow River (1911 to 1955) and then in the upper North Saskatchewan River (1965 to 1972) and Saskatchewan River (1963 to 1985). There are now eleven hydroelectric generating stations, six storage

reservoirs (one on the main stem and five on tributaries), and one regulating reservoir (upper Bow River). The storage reservoirs are filled during spring and summer and then drawn down during fall and winter, storing a total of $\sim 700 \times 10^6 \text{ m}^3$. There are also two hydroelectric storage reservoirs located in the upper North Saskatchewan River system and another three reservoirs on the Saskatchewan River. Hydroelectric developments have significantly altered the hydrology of the Cumberland Marshes by reducing flood frequency. In recent years, developments and management activities by Ducks Unlimited have attempted to restore some of the hydrologic events that were lost as a result of altered flow regimes. In addition to dams and diversions constructed initially for irrigation or hydroelectric power generation, dam–reservoir systems on the Red Deer River, the Oldman River, and the South Saskatchewan River provide assured year-round water supply to downstream users and generate hydroelectric power, and one provides flood control (Red Deer River). The Gardiner Dam (Lake Diefenbaker) on the South Saskatchewan River has changed benthic invertebrate communities as a result of altered discharge patterns and reductions in water temperature as a result of the release of cold hypolimnetic water (Lehmkuhl 1972).

Municipal sewage discharges from major centers (i.e., Banff, Calgary, Edmonton, Medicine Hat, Red Deer, Prince Albert, Saskatoon) to rivers in the Saskatchewan River subcatchment have significant impacts on aquatic biota, largely because of effects from nutrient loading. For example, macrophyte growth in the Bow River downstream of Calgary and the South Saskatchewan River below Saskatoon is enhanced largely because of increased nutrient availability in sediments as a result of municipal wastewater discharge (Chambers et al. 1989, Chambers and Prepas 1994, Carr and Chambers 1998). Eutrophication effects are most thoroughly documented for the Bow River at Calgary and have been reviewed by Culp et al. (1992) and Sosiak (2002). The Alberta Department of Public Health noted severe impacts to the aquatic biota of the Bow River as early as 1944. Secondary sewage treatment at Calgary beginning in 1970 greatly reduced the oxygen depletion evident in the fall and winter during the late 1960s, but nutrient loadings continued to cause excessive growth of macrophytes (e.g., the sheathed pondweed) and epilithic algae (largely diatoms) from Calgary to the confluence with the Oldman River. Enrichment also decreased benthic invertebrate richness but increased densities. Al-

though higher invertebrate density appears to have increased rainbow trout growth, low dissolved oxygen levels in summer may have caused episodic fish mortality prior to 1982 (Longmore and Stenton 1981). Advanced phosphorus removal began in late 1982, followed by nitrogen removal (1987 to 1990). These upgrades initially had little effect on nuisance macrophyte growth, likely because the bottom sediments acted as a nutrient reserve for some time after reduction in open-water nutrients (Carr and Chambers 1998), but macrophyte biomass downstream of the sewage treatment plant has decreased approximately tenfold from peak values of 1000 to 2000 g/m² dry mass in the early 1980s (Sosiak 2002).

Agricultural operations have become increasingly specialized, so that most farms are now either high-density livestock operations or intensive cash-crop farms. This development has resulted in a geographic separation between intensive livestock operations and cash-crop farms and the overapplication of manure as a fertilizer in some locales. Studies by CAESA (1998) have shown that for 27 Alberta streams (most of which were located in the Bow, Oldman, and North Saskatchewan river systems) TN and TP concentrations often exceeded interim provincial water-quality guidelines (1 mg/L TN, 0.05 mg/L TP) for the protection of aquatic life in streams in high- and moderate-intensity agricultural areas. Fecal coliform concentrations nearly always exceeded human drinking-water-quality guidelines (0/100 mL); however, pesticides were rarely detected. In addition, parts of the Cumberland Marshes have been diverted and drained for agricultural uses.

The Saskatchewan River and its tributaries do not harbor many nonnative species because of the presence of large areas of relatively undisturbed mountain and boreal coniferous forests, a continental climate, a less diverse agricultural base than in central Canada and the United States, and fewer cities and towns in which to develop local centers for the establishment of nonnative species. However, purple loosestrife is found in some wetland areas along the Saskatchewan main stem.

RED RIVER OF THE NORTH–ASSINIBOINE RIVER

The Red River of the North (“Red River”) begins at the junction of the Otter Tail and Bois de Sioux rivers at Breckenridge, Minnesota, and Wahpeton, North Dakota, respectively (Fig. 19.13). The Bois de Sioux River is the southernmost tributary and originates

with Lake Traverse near the junction of the state boundaries of Minnesota and North and South Dakota. The Red River subcatchment, which is near the geographic center of North America, includes portions of those three U.S. states and the southern parts of the provinces of Manitoba and Saskatchewan in Canada. It truly is an international river, originating in the United States and flowing north into Canada, but with some tributaries running across the international boundary from within both Canada and the United States. Most of the Red River main stem lies in the United States, but the Assiniboine River, a large eastward-flowing tributary that joins the Red River in Winnipeg, Manitoba, has branches that extend west into central and southern Saskatchewan (Fig. 19.15). The Souris River, a long tributary of the Assiniboine River, originates in southern Saskatchewan, flows into North Dakota, and then flows back into Canada in Manitoba. Keeping the international flavor of the subcatchment, the Pembina River flows from southwestern Manitoba into North Dakota before meeting the Red River, and the Roseau River originates in northeastern Minnesota and joins the Red River in Manitoba. The headwaters of the Red River subcatchment are intertwined with headwaters of the Missouri, Mississippi, and Winnipeg rivers, and in wet years exchanges of water may occur among these systems because of the low relief of shared swampy regions.

The Red–Assiniboine River axis had great historic importance as a trade-route junction, first among First Nations and later among First Nations and the fur traders of the North West Company and the Hudson’s Bay Company. There has been a long period of contact in this area among the First Nations of the Cree in the north and northwest, the Assiniboine (a branch of the Lakota Sioux) in the southwest, the Ojibwa in the southeast, and the Saulteaux in the northeast (Taylor 2002). Representatives of all three First Nations continue to inhabit the subcatchment.

The first documented visits to the area by Europeans include that of La Verendrye in 1735, who noted that the river was called *Miskwagama Sipi* or “red water river” by local First Nations people. The North West Company referred to the Assiniboine River (named after the First Nation through whose territory it flowed) as the Upper Red River and the main-stem Red River as the Lower Red River. The Assiniboine River was originally called the Beaver River by the Assiniboines, but by about 1820 it became known by its present name. The Beaver River name remains as one of the headwater tributaries. By

1897 the Red River became known as the Red River of the North to distinguish it from several other Red Rivers in the United States (Manitoba Conservation 2000).

European settlement in the Red River subcatchment began in earnest with the arrival of settlers brought to the Red–Assiniboine junction by Lord Selkirk in 1811. All of the Red River subcatchment originally was British territory, but with the establishment of the border at the 49th Parallel in 1818 the upper part of the subcatchment became U.S. territory. Settlement of the subcatchment proceeded slowly for the first few decades of the 1800s but grew rapidly west and south with the coming of railroads from the east and south in the 1880s. American settlement of the upper part of the subcatchment began in the 1870s, somewhat later than in the Canadian portion. Until the early 1900s small river steamers were used during periods of high flow to aid commerce between Winnipeg and communities along both the Red and Assiniboine rivers.

Physiography, Climate, and Land Use

Virtually all of the present-day Red River subcatchment falls within the Central Lowland (CL) physiographic province, although some headwater tributary streams on the west side of the subcatchment originate on the margins of the Great Plains (GP) province (see Figs. 19.13 and 19.15). There are several important physiographic areas of the Central Lowland part of the Red River subcatchment that affect land use. The Red River main stem flows north along the center of former glacial Lake Agassiz, a gigantic post-Pleistocene glacial lake that deposited deep beds of lake-bottom sediments over the glacial tills of the Wisconsinan glaciation. The lake covered much of central southern Manitoba, eastern North Dakota, and northwestern Minnesota (Teller and Clayton 1983). Glacial Lake Agassiz and its deposits are an overriding feature of the Red River subcatchment, whether its former presence is reflected in the lake-bottom clay deposits, peripheral beach ridges, and associated remnant lagoons, or by outwash fans deposited into the lake by influent rivers. The Red River Valley Lake Plain dominates the main axis of the Red River valley, from the headwaters to Lake Winnipeg. The Pembina Escarpment forms the western margin of the valley and rises sharply from the plain to the Drift Prairie physiographic area. The east side of the valley is demarcated by the Lake Washed Till Plain and Moraine areas that formed at the margins of the ice sheet that once was the eastern

edge of Lake Agassiz (Stoner et al. 1993). Some of these deposits are extensive, particularly in the southeast, whereas others formed low hills above the surrounding plain. The Assiniboine River system lies mainly on the Drift Prairie, north and west of the Pembina Escarpment. The soils of the region vary. Those of the Red River Valley Lake Plain tend to be heavy and wet, whereas the sandy soils along the western and eastern edges tend to be poorly developed and wet. Upland soils in the western Drift Prairie frequently are rich and light and prone to wind erosion under dry conditions. Most of the subcatchment, aside from moraine areas, is well suited to agricultural exploitation.

The Red River subcatchment includes parts of six terrestrial ecoregions (Ricketts et al. 1999). The Northern Tall Grasslands ecoregion includes the north–south axis of the Red River main stem. The Canadian Aspen Forest and Parklands and Northern Mixed Grasslands ecoregions form the western edge of the subcatchment. A small component in the northern part of the Assiniboine River system falls into the Mid-continental Canadian Forests ecoregion. Finally, the southeastern side of the subcatchment is comprised of the Western Great Lakes Forests and Upper Midwest Forest/Savanna Transition Zone ecoregions (Ricketts et al. 1999). These latter two ecoregions encompass the headwaters of the Otter Tail River in the southeast corner of the Red River subcatchment.

The climate of the Red River subcatchment is continental, characterized by relatively short, hot summers (mean air temperature $\sim 20^{\circ}\text{C}$ in July) and long, cold winters (mean air temperature $\sim -18^{\circ}\text{C}$ in January) (see Figs. 19.14 and 19.16). Peak precipitation occurs in June and July (6 to 7 cm). The western part of the subcatchment is classified as dry subhumid, which grades to subhumid on the eastern side of the subcatchment. Weather primarily results from a predominantly western flow resulting from upper-level winds, such as the subpolar jet stream. Red River subcatchment weather changes rapidly, and temperatures may rise and fall significantly in a matter of hours because of a lack of intervening relief for more than 1000 km to the west. Precipitation arrives predominantly from the southwest, either as winter snowstorms or as thunderstorm fronts in summer. Mean annual precipitation ranges from ~ 43 cm in the western part of the subcatchment to ~ 66 cm in the east (Stoner et al. 1993).

The terrestrial ecoregions of Ricketts et al. (1999) comprise the Prairie and Boreal Plain ecozones of Environment Canada's 1996 State of the Environ-

ment Report (Environment Canada 1996), which estimated that $\sim 97\%$ of the Prairie ecozone and 16% of the Boreal Plain ecozone were in agricultural uses. About 70% of the Prairie ecozone was in annual cultivation, with the remainder in pasture. The agricultural portion of the Boreal Plain ecozone was mainly in pasture, with growing forestry use of the remaining 84%. In the U.S. portion of the Red River subcatchment, Stoner et al. (1993) reported that $\sim 74\%$ of the subcatchment was in agricultural use, of which 66% was in cropland and 8% was in pasture. The remaining 26% mainly consisted of forests (12%), water and wetlands (4%), urban use (3%), and other categories (7%). The distribution of land-use types and cropping practices are largely determined by the distribution of soil types and moisture (Stoner et al. 1993). The two largest cities in the subcatchment are Winnipeg (685,000) and Regina ($\sim 198,000$) (www.statcan.ca/english/Pgdb/People,Population/demo05.htm 2001).

River Geomorphology, Hydrology, and Chemistry

The Red River flows north from the junction of the Otter Tail and Bois de Sioux Rivers ~ 877 km to Lake Winnipeg. The Assiniboine River flows east 1266 km from Preeceville, Saskatchewan, to join the Red at Winnipeg. The subcatchment is very flat along the Red River Valley (south to north), with a total relief of 70 m and an average slope of 8 cm/km. The Assiniboine is also considered a low-slope river (west to east), with a total relief of 350 m and an average slope of 28 cm/km (Andres and Thompson 1995). The depths of Wisconsinan tills and Lake Agassiz sediments decline northward in the Red River Valley as Lake Winnipeg is approached, and underlying sedimentary Paleozoic carbonate-dominated limestone and dolomite bedrock outcrops appear in the river bed and along channel sides of the lower river. These rocks have been eroded away from west to east nearing Lake Winnipeg, and the overlying Canadian Shield is exposed in a southeast-trending line from near the mouth of the Winnipeg River to ~ 100 km east of Winnipeg. Northwest of the Red River Delta at Lake Winnipeg the Paleozoic rocks are covered by shallow glacial till and Lake Agassiz deposits with frequent outcrops, whereas northeast of the Red River mouth the Canadian Shield, incompletely covered with glacial and lake-bottom sediments, bounds the east side of Lake Winnipeg. River-channel sediments are largely determined by Wisconsinan

FIGURE 19.6 Red River of the North during the 1997 “Flood of the Century” at the town of Emerson, Manitoba (Manitoba–U.S. border). North is to the left. The international boundary is the thin diagonal line just to the south of Emerson. The town stands dry because of a ring dike. The river channel is defined by the tree line (PHOTO BY B. OSWALD, MANITOBA DEPARTMENT OF WATER STEWARDSHIP, WINNIPEG).

glaciation and glacial Lake Agassiz deposits (Elson 1967). As the river meanders across the floodplain the surficial Lake Agassiz sediments are eroded down to the deeper, glacially determined sediments. Another consequence of meandering is the regular distribution of snag habitats on outside bends and point-bar formations on inside bends, both of which provide fish species ample habitat for various life-history stages while supporting an array of habitats for aquatic invertebrates. Unlike many streams in the United States, there have been no major initiatives to remove snag habitats because of the relatively low use of the river by pleasure boaters and commercial shipping, even in the major urban centers. Most of the anthropogenic alterations of the subcatchment are in the form of flood-control and irrigation reservoirs in the tributaries, as well as rather extensive drainage networks in agricultural regions that facilitate rapid runoff during heavy rain events (Goldstein

1995). The low slope of the subcatchment generates the potential for large-scale flooding, as occurred in 1997 (Fig. 19.6).

The median annual hydrograph of the Red River at Lockport, just north of Winnipeg, has a peak discharge of $\sim 740 \text{ m}^3/\text{s}$ during mid-April; discharge then drops off rapidly through May and normally declines steadily until ice-up (Fig. 19.14). Discharge begins to increase again in late March prior to ice breakup in early to mid-April. Mean annual discharge at Lockport is $236 \text{ m}^3/\text{s}$, including the flow of the Assiniboine River. The median peak flow of $\sim 140 \text{ m}^3/\text{s}$ on the Assiniboine River at Headingley, just west of Winnipeg, occurs in May; discharge then declines steadily through summer until March of the following year (Fig. 19.16). Mean discharge of the Assiniboine, which represents 56% of the combined catchment area, is only $47 \text{ m}^3/\text{s}$ or $\sim 20\%$ of the total Red River flow. The flood-control reservoir at

Shellmouth Dam (Lake of the Prairies) on the Saskatchewan–Manitoba border normally is drawn down through the winter to make room for spring discharge, so Assiniboine River flows just downstream rise in November and frequently remain higher than summer discharges all winter. The flood-control dam at Portage la Prairie, ~100 km west of Winnipeg, shunts lower Assiniboine River flood peaks north into the south end of Lake Manitoba (out of the Assiniboine subcatchment) and maintains undersized peak discharges in the lower 160 km of the river.

Evapotranspiration tends to be high in the Red–Assiniboine catchment. Even though precipitation is highest in spring and summer, runoff during summer is very low (<0.3 cm/mo) apparently because of high evapotranspiration (see Fig. 19.14). The low combined runoff of the entire catchment is heavily influenced by the more arid Assiniboine subcatchment (see Fig. 19.16). Thus, it is clear that the spring peak in the hydrograph, when precipitation is relatively low, is caused primarily by the melting of the winter snowpack. Precipitation and river discharge follow long-term trends (~25 to 30 years) of dry and wet periods known as the prairie drought cycle, which has major influences on hydrology and land use in the whole subcatchment.

The Red River supplies an average 2,255,898 metric tons/yr of suspended sediments to Lake Winnipeg, an estimated 7.85 metric tons km⁻²yr⁻¹ from the subcatchment (Brunskill et al. 1980). As a result, the waters of the Red River subcatchment are generally turbid (Secchi visibility 0.35 m in the Red River). The transported sediment load is largely suspended silts plus an undocumented amount of bedload sand. The rates of transport for major dissolved elements (10³ mol km⁻²yr⁻¹) are Ca (40.1), Mg (28.6), Na (43.0), K (5.55), SO₄ (30.2), chloride (23.1), HCO₃ (103.8), and Si (5.15), with total N and P rates of 5.18 and 0.37 (Brunskill et al. 1980). Total dissolved solids in the Red River generally are <600 mg/L, with mean values varying from ~347 mg/L near the headwaters to ~406 mg/L at the international boundary (Stoner et al. 1993). Water quality of headwater streams varies greatly with discharge and generally is high in dissolved constituents during low flow, reflecting groundwater chemistry. Headwater streams on both sides of the Red River valley typically run fairly clear at low flow but become very turbid from sheet and bank erosion during spring runoff and spates at other times of the year.

Concentrations of dissolved major ions and other variables for the Red River at Emerson, Manitoba,

are available from the U.S. Geological Survey. Median values from multiple-year periods were specific conductance 690 µS/cm, pH 8.1, alkalinity 215 mg/L as CaCO₃, bicarbonate 255 mg HCO₃/L, Ca 64 mg/L, Mg 30 mg/L, NO₃-N 0.34 mg/L, Na 34 mg/L, chloride 35 mg/L, SO₄ 94 mg/L, Al 20 µg/L, As 3 µg/L, Pb <2 µg/L, and total dissolved solids 381 mg/L. Additional values from David Donald (personal communication) were total P 0.3 mg/L, and turbidity (JTU) 125.1. Water-quality variables (means or ranges) for the Assiniboine River at Headingley, Manitoba, just upstream of the confluence with the Red River were specific conductance 865 µS/cm, pH 8.2, bicarbonate 140 to 400 mg HCO₃/L, Ca 60 to 120 mg/L, Mg 20 to 55 mg/L, total N 1.52 mg/L, Total P 0.25 mg/L, Na 50 mg/L, chloride 26 mg/L, SO₄ 60 to 240 mg/L, K 5 to 10 mg/L, and total dissolved solids 552 mg/L (Gurney 1991).

Pesticides and herbicides are used regularly in croplands of the subcatchment on both sides of the international boundary. Data provided by the U.S. Geological Survey (Stoner and Lorenz 1996) indicate that pesticides occur in amounts <2% of the amounts applied and in concentrations generally far less than accepted drinking-water standards (Tornes and Brigham 1995). The amounts of agricultural herbicides applied annually are fairly constant, but higher concentrations of herbicides occur in groundwater in regions of high precipitation (Cowdery 1995).

River Biodiversity and Ecology

The whole of the Red River subcatchment falls within the English–Winnipeg Lakes freshwater ecosystem (Abell et al. 2000).

Plants

Instream macrophytes, such as bulrushes and cattails, are common only in backwater areas of the subcatchment. There are few submerged macrophytes in the main-stem larger rivers because of high turbidity, but headwater streams may have abundant submerged and emergent macrophytes.

The Red and Assiniboine rivers have narrow riparian zones comprising a gallery forest of sandbar willow associated with sand bars and point bars, peach-leaved willow, green ash, elm, cottonwood, Manitoba maple, and to a lesser extent basswood and bur oak. The riparian zone provides a thin barrier between the river channel and the floodplain, which is largely an agricultural landscape. In many

areas, riverbanks are in annual crops or pasture, with little or no shrubs or trees.

Invertebrates

The main stems of the Red and Assiniboine rivers have a very diverse benthic invertebrate fauna. Mussels (Unionidae) are represented by 12 species belonging to the genera *Fusconaia*, *Amblema*, *Quadrula*, *Lasmigona* (2 species), *Anodontoides*, *Pygandon*, *Strophitus*, *Ligumia*, *Lampsilis* (2 species), and *Potamilus* (Watson et al. 1998). Fingernail clams (Sphaeriidae) are also present. Inter-mediate-size faunas include the snails *Physa* sp. and *Helisoma* sp. and the northern crayfish. The mayflies include (but are not limited to) the following families (and common genera): Baetidae (*Baetis*), Heptageniidae (*Heptagenia*), Polymitarcyidae (*Ephoron*), Ephemeridae (*Hexagenia*, *Pentagenia*), Isonychiidae (*Isonychia*), Tricorythidae (*Tricorythodes*), and Siphonuridae. There are two abundant caddisfly families, Hydropsychidae (*Ceratopsyche*, *Hydropsyche*) and Brachycentridae (*Brachycentrus*). The stonefly families include Perlidae (*Acroneuria*) and Pteronarcyidae (*Pteronarcys*). Other aquatic insects include the dragonfly (*Gomphus*), elmid riffle beetles (*Narpus*), and the true fly families Tipulidae (*Tipula*), Ceratopogonidae (*Bezzia*), and Chironomidae (*Axarus*). The true bug families Belostomatidae and Corixidae also are well represented. Clam shrimps and round worms (Tylaenchidae) also are present. These groups represent primary to tertiary consumers and predators. Microbenthic invertebrates include primary consumer groups like water mites and crustaceans, fish lice (copepods, cyclopoid and calanoid), water fleas (cladocerans), and seed shrimps (ostracods).

Vertebrates

The Red and Assiniboine rivers have a very diverse fish community represented by 18 families and ~94 species. Eleven species are known from the Red River and its tributaries in the United States that are not known from the Red River north of the mouth of the Pembina River (Stewart et al. 2001). Several fish species are secondary consumers (some cyprinids, young-of-the-year fishes, quillback sucker, and bigmouth buffalo), whereas the grazers include catostomids (white sucker, silver redhorse, golden redhorse, shorthead redhorse), and cyprinids (common carp, silver chub, shiners, flathead chub). Top predators include walleye, northern pike, channel catfish, and burbot. Several nonnative fishes occur in the Red River subcatchment, including

common carp, white bass, black and white crappie, and smallmouth and largemouth bass.

Amphibian vertebrates include wood frog, western chorus frog, spring peeper, northern leopard frog, gray treefrog, American toad, and isolated populations of the rare spadefoot toad. There are several salamander species in the subcatchment, including tiger salamander, blue spotted salamander, and mud puppy. Reptilian vertebrates include common snapping turtles and western painted turtles. Aquatic mammalian vertebrates include muskrat and beaver. Aquatic summer migratory birds include great blue heron, belted kingfisher, American white pelican, double-crested cormorant, and many species of ducks (e.g., nesting wood duck) and geese.

Ecosystem Processes

Ecosystem processes in the Red-Assiniboine remain largely unexplored. Although much of the landscape of the Red River is in agricultural uses, a narrow riparian gallery forest remains throughout much of the subcatchment. The gallery forest provides a rich source of allochthonous carbon to stream ecosystems. Stream hydrology of the main rivers (Otter Tail, Red Lake, Souris, Roseau, Pembina, and Assiniboine) is much altered but the rivers still support robust flora and fauna. All trophic levels are supported in the main-stem rivers and major tributaries. The lack of information on lower taxa (invertebrates, algae, etc.) makes large-scale generalizations on stream ecology impossible (Goldstein 1995). However, there is a trend of increasing fish species richness with increasing drainage area and number of ecoregions (after Stoner et al. 1993) through which a stream flows (Goldstein 1995). For example, the high biodiversity seen in the Otter Tail River (see Additional Rivers section of this chapter) is attributable partly to the fact that it flows through four ecoregions on its way to its confluence with the Red River and partly to the high abundance of lakes and the amount of forest cover in the Otter Tail system.

An ecosystem-oriented study of the entire Red River subcatchment never has been attempted, although studies on the U.S. side have begun (Stoner et al. 1993, USGS 2001 <http://mn.usgs.gov/redn/cits.html>). Renard et al. (1986), Peterka and Koel (1996), and Koel (1997) have reported on the distributions of fish fauna and habitats in the Minnesota and North Dakota parts of the Red River. Comprehensive data do not exist for the Canadian portion of the subcatchment, including the Assiniboine and Souris rivers, although there are unpublished studies of the Red River near Winnipeg (e.g., Clarke et al. 1980,

City of Winnipeg 2000) and of the Assiniboine River. However, both Canadian and international compilations of existing biological data are lacking.

Monitoring of water quality and quantity has been done at border stations on all the rivers crossing the international boundary because of the Boundary Waters Treaty of 1909. This reporting has been greatly enhanced by the large flood on the Red River in 1997 (see Fig. 19.6), which stimulated renewed scientific cooperation between the U.S. and Canadian federal governments and their border states and provinces. International catchment groups have been formed and seamless GIS-based maps of the subcatchment have been developed and are accessible on the internet (e.g., www.rrbdin.org).

Human Impacts and Special Features

Channelization, ditching, and water-level control dams are the major alterations that affect all the rivers. The largest dams are Shellmouth Dam (built in 1969) on the upper Assiniboine, which created Lake of the Prairies; Portage la Prairie Dam and spillway (built in 1970); and Lockport Dam on the lower Red River (built in 1922), which enhances navigation between Winnipeg and Lake Winnipeg. The major hydrologic impact on the Red River main stem is the continued operation of the Lockport Dam, which maintains water levels within the city of Winnipeg ~2 m to 3 m above normal summer levels, mainly for recreational purposes.

Operation of the Shellmouth Dam on the Assiniboine River greatly affects the hydrograph of the river. Prior to the installation of dams the lowest flows typically occurred in midwinter; lowest flows now tend to be in late autumn, prior to releasing stored water from the reservoir to make room for spring inflows. The flow regime during winter frequently is manipulated to reflect the latest predictions for spring flooding. Winter flows can be quite stable for long periods under low snowfall conditions, but if a major snowstorm brings significant precipitation to the upper part of the subcatchment flows may increase by as much as four to six times over a period of a few weeks. The effects of these flow variations on biota are unknown and virtually unstudied.

Other major dams in the subcatchment include Rafferty (built in 1991) and Alameda (built in 1994) dams on the upper Souris River in Saskatchewan, built for flood control, irrigation, and recreation. Additional low-head weirs are located at major towns in the U.S. portion of the main stem, but several were modified in the late 1990s to improve

fish and small-boat passage (Luther Aadland, personal communication). There also are two low-head weirs on the Assiniboine River in Brandon ~200 km west of Winnipeg. In addition to these main-stem structures, there are reservoir control structures on the Red Lakes, Otter Tail, and Sheyenne rivers and at the outlet of Lake Traverse (Stoner et al. 1993; see Fig. 19.13) and many water-level control weirs on tributary streams throughout the subcatchment (<350 in the U.S. portion of the subcatchment).

Some of the existing dams and weirs are barriers to fish passage, particularly at low flows. Fish distributions show, for example, that the Portage la Prairie dam on the Assiniboine is a barrier to the ongoing postglacial range expansions of recently colonizing species, such as the golden redhorse and the bigmouth buffalo, even though the dam is opened each fall.

The Manitoba government has initiated a study of instream flow needs for fish and river processes (designed according to recommendations of the Instream Flow Council 2002, www.instreamflowcouncil.org), but the analyses are not yet available. The impetus for this study was increasing demands for irrigation water for potato agriculture. A parallel study on water-quality issues in the river also is underway.

WINNIPEG RIVER

The Winnipeg River (latitude 47.39°N to 51.99°N, longitude 89.90°W to 96.37°W) drains northwestern Ontario, southeastern Manitoba, and northern Minnesota, flowing northerly and westerly before entering Lake Winnipeg at Traverse Bay (Fig. 19.17). The river has a subcatchment area of 135,800 km² (Ontario and Manitoba, 106,500 km²; Minnesota, 29,300 km²; *National Atlas of Canada* 1985) in a region straddling the weathered granite of the Canadian Shield and the sedimentary deposits of glacial Lake Agassiz. The river is intersected by numerous lakes. The 260 km long main-stem Winnipeg River collects water from its two main tributaries, the 553 km long Rainy River, beginning at Rainy Lake, and the 615 km long English River, arising in the Firesteel River at Lake Selwyn near the western shore of Lake Superior. The subcatchment has five main systems: English River–Lac Seul (35,308 km² or 26%), English–Wabigoon (12,222 km² or 9%), Rainy River–Rainy Lake (35,308 km² or 26%), Rainy River–Lake of the Woods (28,518 km² or 21%), and the Winnipeg River main stem (24,444 km² or 18%). About 20% of the Rainy River system is within the

United States, 66% is in Ontario, and the balance is in Manitoba. The term “Winnipeg” is variously attributed to the Cree words *Win ni pak* or *Wi nipi* for muddy or turbid waters (a plausible source for the name of Lake Winnipeg, whose waters are quite murky) or similar words *winipi* or *winnepe* for unsettled, turbulent, or confused (a plausible source for the name of the Winnipeg River).

The geological and hydrological characteristics of the Winnipeg River system made it an historical corridor for exploration and transport of European trade and culture to the heart of Canada. Although evidence of human habitation extends back 8000 to 10,000 years to the end of the last glacial retreat, it was the Woodland Amerindians, emerging around 3000 years ago, who first used the birchbark canoe to discover the network of waterways that would prove indispensable to the fur trade within the last few centuries. Jacques de Noyon was the first European to see Rainy Lake, in 1679, and Pierre de la Verendrye, who came in search of the wealth of furs and the prestige of discovery of the Great Western Sea, was probably the first white man to explore the Winnipeg River, in 1733. Passage across the subcatchment was relatively easy because much of the river’s length consisted of large, often long and narrow lakes connected by sections of relatively slow-flowing river punctuated by waterfalls and rapids. By the mid 1800s these waterways were already targeted for the construction of control structures and locks to regulate water levels and facilitate transport of goods and settlers to the Red River region (Dawson 1859).

Lake Winnipeg and Lake of the Woods also played a role in the exploration and arrival of trade and European culture to the prairies. These two lakes provided a route either to the prairies and the Rocky Mountains or down the Nelson and Hayes rivers to York Factory on Hudson Bay.

Physiography, Climate, and Land Use

The Winnipeg River subcatchment drains the Superior Upland (SU) province of the Canadian Shield division and the Central Lowland (CL) province of the Interior Plains division to the south and west (Hunt 1974) (Fig. 19.17). The system encompasses two terrestrial ecoregions: the Western Great Lakes Forests to the southeast and the Midwestern Canadian Shield Forests to the northwest (Ricketts et al. 1999).

The subcatchment is underlain with crystalline, acidic, Archean bedrock of the Canadian Shield,

forming broadly sloping uplands and lowlands. Hummocky bedrock outcrops, covered with discontinuous acidic, sandy, granitic tills, are common in the northern half of the subcatchment, interspersed with undulating glaciolacustrine deposits. The Lake of the Woods area is interspersed with fluvio-glacial outwash deposits, bare rock outcrops, and lacustrine deposits, forming clay plains in lowlands. The southern portion of the subcatchment ranges from bedrock outcroppings to dystic brunisols on ridged to hummocky, discontinuous, sandy morainal deposits on uplands. Lowlands are covered by rock-bound lakes, fine carbonate-rich sediments, and deep organic deposits. Dystic brunisols are dominant throughout the region, with major areas of gray luvisolic, mesisolic, gleysolic, fibrisolic, and fibrosolic organic soils. Areas of wetland are extensive throughout the region (up to 25% in the Lac Seul area), particularly in the vicinity of Lake of the Woods and the Rainy River, with treed, bowl bogs, and peat-margin swamps the predominant forms.

Presettlement vegetation in the Winnipeg River subcatchment is best known from studies in the Rainy River system, where jack pine, white pine, red pine, and hardwood–conifer forests of balsam fir, white spruce, white birch, and trembling aspen characterized the Border Lakes and Little Fork–Vermillion Uplands area of northeastern Minnesota (Heinselman 1973). Red and white pines were less common in the northern English River system. Peatlands with black spruce–sphagnum bog, and northern white cedar and black ash swamps were common in the Agassiz Lowlands (www.pca.state.mn.us 2003). Peat deposition began ~7000 years ago in the western part of the subcatchment, where deposits are now thickest, and expanded westward (Glaser 1992). The stratigraphic record indicates that the peatlands supported forests in the past, peat is becoming the dominant vegetation (Heinselman 1973), and several changes in forest vegetation corresponding to climatic changes have occurred (Heinselman 1970).

The contemporary boreal forest in northwestern Ontario is replete with common flora, including 71 species of trees and shrubs, 11 graminoids, 40 herbs, 18 bryophytes and lichens, and 16 ferns (www.rom.on.ca 2004). Dominant trees include jack pine, black spruce, white birch, and trembling aspen. Warmer portions of the subcatchment support red and eastern white pine and red and sugar maple. Cooler, wetter sites support black spruce and tamarack. Most of the Border Lakes area remains forested, with stand composition and structure

similar to the original community. The Superior Upland in the southeastern portion of the Rainy River system is still predominantly forested. Many upland sites are occupied by aspen, either in relatively pure stands or mixed with balsam fir.

Climate in the basin is cold temperate Continental with modification in the vicinity of larger lakes (Brunskill and Schindler 1971). Temperatures vary slightly across the basin, with mean annual values from 0.5°C to 2°C, mean summer values from 14°C to 15.5°C, and mean winter values from -12.5°C to -14.5°C. The coldest month is usually January; the warmest month is usually July (Fig. 19.18). Annual precipitation is moderate, ranging from 50 to 70 cm, with most (80%) falling as rain. Highest precipitation is in June and July; lowest precipitation is in February (see Fig. 19.18).

The Winnipeg River subcatchment has low population density (0.6 people/km²), thousands of lakes, and an economy based on renewable energy, forestry, mining, and recreation, but remains relatively unimpacted. Forestry, trapping, hunting, and tourism are the dominant land uses, though a significant portion of the Rainy River system is used in mixed farming or grazing. Twelve percent of the subcatchment has park designation or protected status. In Ontario, 81 provincial parks covering 3.1 million ha and the Pukaskwa National Park (188,000 ha) have been established. Several of Minnesota's most famous walleye fisheries and trout streams, as well as the Voyageurs National Park and the Boundary Waters Canoe Area Wilderness, are found in this area. Populations are concentrated in a few small towns (Kenora, Dryden, Red Lake, Sioux Lookout, Atikokan, and International Falls) devoted to forestry processing and tourism. Significant cottage development is found on Lake of the Woods and along the Winnipeg River from Lake of the Woods to Lake Winnipeg, which seasonally increases population to >1 person/km². Overall, 30% of the subcatchment is devoted to forestry activities, <5% is in agriculture, and <1% is urban. The remainder of the subcatchment is natural.

River Geomorphology, Hydrology, and Chemistry

The Winnipeg River subcatchment can be divided into two broad areas of geology, hydrology, and water quality: the Superior Upland part of the Canadian Shield and the bed of former glacial Lake Agassiz, which lies in the Central Lowland. The English River and upper eastern reaches of the Rainy

River drain the Superior Upland, whereas the lower westerly run of the Rainy River and Lake of the Woods flow through, drain, and occupy the clay and silt deposits of glacial Lake Agassiz.

The English River drops a total of 79 m (33 cm/km), 24 m from its source to Lac Seul and a further 55 m from Lac Seul to its confluence with the Winnipeg River. This entire region is Canadian Shield, dotted with thousands of small lakes in granitic, relatively watertight basins that yield high runoff with little groundwater. Their collected waters ultimately spill through fractured or glaciated channels into Lake St. Joseph and Lac Seul, both of which are now used as reservoirs. The river channel therefore consists of several long reservoirs of low gradient connected by narrow channels of relatively steep gradient. Much of the length of the Rainy River is occupied by several long, low-gradient (3 cm/km) lake reservoirs, and the river drops only 18 m over its length. The upper, easterly reaches of the Rainy River system are, like the English River system, characterized by many small lakes in granite basins that spill through either fractured or glaciated channels. Waters from thousands of these small lakes eventually empty into Lake Namakan and Rainy Lake. Water yields are high, with little groundwater loss. The Winnipeg River connects Lake of the Woods to Lake Winnipeg. The river drops 105 m over its length in a series of waterfalls and rapids separated by long stretches of deep, turbulence-free waters (average gradient 40 cm/km), providing ideal conditions for both historical water transport and contemporary production of hydropower. Flows from the English River join the Winnipeg River at Tetu Lake, near Whitedog, just before the Manitoba border.

The Winnipeg River subcatchment has relatively high precipitation (62 cm/yr) and a relatively impermeable substrate, so subcatchment storage and water yields are high (20 cm/yr), providing for large and consistent river flows. The river has an average discharge of 850 m³/s as it enters Lake Winnipeg. Most of the river and reservoirs of the English River are ice covered from early December to mid-April, except for raceways at control structures. Control structures at the outlet of Lake St. Joseph and Lac Seul, operated by the Lake of the Woods Control Board, have produced hydroelectric power since 1929 and have inverted the normal discharge pattern to the river downstream of Lake St. Joseph and Lac Seul from a spring/summer to a fall/winter maximum flow. Lake Namakan and Rainy Lake of the Rainy River system are both regulated for hydroelectric production by the International Rainy Lake Board of Control of the

International Joint Commission. Most of the river and reservoirs of this system are ice covered from early December to mid-April, except for raceways at control structures.

Waters of the English River system are of low ionic strength (conductivity 70 $\mu\text{S}/\text{cm}$, calcium 5 mg/L, alkalinity 15 mg/L as CaCO_3), except for a few lakes that are intersected by calcareous glacial deposits (Fee et al. 1989). Waters in lakes and rivers of the system tend to be nutrient poor, with most of their total nitrogen (TN 325 $\mu\text{g}/\text{L}$) and total phosphorous (TP 10 $\mu\text{g}/\text{L}$) supplied from atmospheric deposition. On the other hand, coniferous forests and wetlands are a source of relatively high levels of dissolved organic carbon (DOC 500 $\mu\text{mol}/\text{L}$). With low population densities, the English River system remains relatively unaffected by domestic waste or nonpoint-source pollutants. Resource-based industrial activities (pulp and paper and mining) are point sources of specific contaminants. Chloralkali plants associated with the pulp and paper industry were a significant source of mercury delivered to the Wabigoon River and the lower reaches of the English River in the 1960s and 1970s. Rainy River headwaters again are typical of those found on the Superior Upland: characteristically of low ionic strength (conductivity 30 $\mu\text{S}/\text{cm}$, calcium 3 mg/L, alkalinity <10 mg/L as CaCO_3) and nutrient poor (TN 300 $\mu\text{g}/\text{L}$, TP 7 $\mu\text{g}/\text{L}$) (M. P. Stainton, unpublished data). Waters from this part of the Canadian Shield flow westward, accumulate in Rainy Lake, and spill over Koochiching Falls off the Shield onto the flat bed of glacial Lake Agassiz sediments. Below these falls, in the western half of the system, the Rainy River flows fairly straight, with little relief, through a narrow valley carved into the old bed of glacial Lake Agassiz. Waters from the Rapid, Big Fork, and Little Fork rivers, which drain large areas of bog, swamp-land, and glacial clay, join the Rainy River before it empties into Lake of the Woods. These westerly waters are higher in ionic strength (conductivity >100 $\mu\text{S}/\text{cm}$), alkalinity (50 mg/L as CaCO_3), suspended solids (5 mg/L), and nutrients (TN 650 $\mu\text{g}/\text{L}$, TP 31 $\mu\text{g}/\text{L}$; Anderson et al. 2000). Winnipeg River water tends to be relatively dilute (conductivity 100 $\mu\text{S}/\text{cm}$) and somewhat alkaline (45 mg/L as CaCO_3), with levels of TN (550 $\mu\text{g}/\text{L}$) and TP (31 $\mu\text{g}/\text{L}$) that seem to have increased over the past 30 years (Jones and Armstrong 2001).

River Biodiversity and Ecology

The Winnipeg River subcatchment belongs to the English–Winnipeg Lakes freshwater ecoregion,

which also includes the Red River subcatchment (Abell et al. 2000). Following retreat of the Laurentide ice sheet ~11,000 years ago, inundation of the region by proglacial Lake Agassiz initiated the gradual reestablishment of biological assemblages, particularly species originating from the southern Mississippi refugium (Bajkov 1930, Dadswell 1974, Patalas in press). Lake Agassiz eventually drained to the north, leaving a patchwork of isolated and interconnected lakes varying in size from a few hectares to several thousand km^2 , each with a similar complement of Agassiz fauna. Boreal lakes contain few species compared to temperate or tropical lakes, particularly those lakes in richer geological settings and unglaciated regions (Schindler 1990). Because of the paucity of species, boreal ecosystems have been largely ignored in studies of biodiversity, and knowledge of Winnipeg River biodiversity thus remains limited. In addition, few ecological studies of the rivers and streams in this sparsely populated region have been undertaken.

Algae and Cyanobacteria

Although substantial amounts of information are available for lake algae, and some lake algal species may survive in the potamon zone of streams, little is known of true stream phytoplankton or epilithon in the Winnipeg River subcatchment (D. Findlay and H. Kling, personal communication). The three major classes of algae of importance in streams and rivers of other regions (Cushing and Allan 2001)—diatoms (Bacillariophyceae), green algae (Chlorophyceae), and cyanobacteria (Cyanophyceae)—are likely typical of Winnipeg River subcatchment streams. Humic, tea-colored streams draining wetlands often have reduced amounts of algal material.

Plants

Stream plants are usually diverse within boreal forest areas but with less biomass than occurs in similar streams in open country (Haslam 1978). At least 38 plant varieties, including bulrushes, cattails, hornworts, reeds, watermilfoil, sedges, waterlilies, arrowheads, and wild rice, are common in wetlands and medium-size streams of the subcatchment (Eggers and Reed 1997, Newmaster et al. 1997). Beaver dams, common in the region, increase stream width and water depth and decrease flow, allowing plants such as lesser duckweed and waterlilies to grow. The full range of wetland conditions, including bogs, fens, swamps, marshes, and open-water wetlands, is described in the Northwestern Ontario

Wetland Ecosystem Classification (Harris et al. 1996).

Invertebrates

Wide-scale characterization of stream invertebrates in the Winnipeg River subcatchment has not been done, although limited studies of the impact of pulp mill effluents, logging, aerial spraying, or acidification on stream biota are available (e.g., Hall 1994). Larvae of black flies (Simuliidae), mosquitoes (Culicidae), horse and deer flies (Tabanidae), dragonflies (*Libellula*, *Aeshna*), caddisflies (*Hydropsyche*, *Cheumatopsyche*), mayflies (*Caenis*, *Hexagenia*), and sand flies (Ceratopogonidae), and various life stages of crustaceans (*Hyalella*, *Gammarus*, *Orconectes*, *Candona*, *Canthocamptus*) are common in streams and shallow ponds of the Experimental Lakes Area (ELA) of northwestern Ontario (e.g., Bilyj and Davies 1989). Mayflies, caddisflies, stoneflies, true bugs (hemipterans), and bivalve mollusks are also found in streams throughout the region. Crustacean plankton diversity and abundance in streams of the Winnipeg River subcatchment, as in most lotic environments, are low.

Vertebrates

Of the ~101 species of fishes in the Hudson Bay drainage, 69 species, representing 16 of the 19 families present, exist in the Winnipeg River subcatchment. This number is surpassed only by the Red River of the North, with 94 species. Most (58 of 69) species, including northern pike, walleye, sauger, yellow perch, lake whitefish, lake trout, brook trout, smallmouth bass, and white sucker, are dispersed throughout the subcatchment. A few species, such as longear sunfish and green sunfish, are found only in Quetico Park and the Lake of the Woods region (Meredith and Houston 1988a, 1988b). Anecdotal evidence suggests that fish populations are decreasing in both accessible and remote parts of the Winnipeg River subcatchment. For example, daily limits of lake trout in remote northwestern Ontario locations have decreased from 12 fishes to 1 to 2 during the past 30 years as access by aircraft and snow machine improved and pressure from ice fishing increased. Lake sturgeon, which were once used by aboriginal people as a staple food, are still found in the Maligne River, in Sturgeon and Russell lakes of Quetico Park, Ontario, and in the Winnipeg River (Rusak and Mosindy 1997), but many populations have now been extirpated.

Fur-bearing vertebrates, such as beaver, river otter, muskrat, and mink, are numerous enough to

sustain commercial trapping operations throughout the subcatchment. About 250 species of birds have been recorded in the Quetico, Atikokan, and ELA areas of the subcatchment (www.birdsontario.org 2004, www.queticofoundation.org 2004). Primary species found on or near lakes and rivers include common loon, common merganser, great blue heron, mallard, American black duck, and belted kingfisher.

Ecosystem Processes

The generally low nutrient levels, rocky substrates, and high flows characteristic of most streams in the subcatchment do not support high primary productivity. Smaller brooks are usually devoid of plants in either summer dry or summer flooding periods (Haslam 1978). Actively functioning phytoplankton are restricted to large, slow-flowing, deep-river segments (Cushing and Allan 2001), such as impounded main-stem Winnipeg River sections, where excessive algal growth stimulated by nutrient inputs from shoreline cottage developments has recently developed. Direct assessments of in situ productivity are not available for the English or Rainy rivers. However, a maximum estimate of chlorophyll *a* concentrations of epilithon and phytoplankton in Canadian Shield streams may be taken from transparent ELA lakes, where values range from 0.05 to 0.5 mg/m² (Watkins et al. 2001), and 1 to 5 µg/L, respectively (Armstrong and Schindler 1971). Increased algal productivity in lower reaches of the Winnipeg River has contributed to high abundances of zooplankton in the river's inflow to Lake Winnipeg during the past two decades (Patalas and Salki 1992, A. Salki, unpublished data). Wetlands are important sources of DOC, and their capacity to sequester sulfates and nitrates in acidic precipitation partially protects downstream waters.

Human Impacts and Special Features

The Winnipeg River subcatchment simultaneously contains some of the oldest exposed rock (>3.5 billion years) and some of the youngest sedimentary and glacial deposits (<10,000 years) on earth. Low human population densities and relatively restricted regional economic development have left much of the area essentially undisturbed since the last glacial retreat, ~9000 years ago. Ancient fur trade routes, aboriginal petroforms, stands of old-growth pine, pristine lakes, and abundant wildlife are still intact, all of which attract more boating and canoeing enthusiasts than any other wilderness area in North

America. In contrast, rivers of the Winnipeg–Rainy subcatchment are among the most highly regulated waterways (for hydropower production) on the continent.

Human activity has changed the Winnipeg River ecosystem, starting with the explorations of La Verendrye, who introduced the cultivation of maize, squash, and beans on islands in Lake of the Woods to aboriginal peoples (Combet 2001). The aquatic and terrestrial components of the Superior Upland and Central Lowland provinces are changing as a result of contemporary anthropogenic and natural stresses (Urquiza et al. 1998). Human settlement, hydroelectric dams, forestry, mining, agriculture, recreational activities, and climate change are leaving measurable imprints. Even the English and Rainy rivers, which begin their journeys in ancient, near-pristine wilderness, are affected by quality-altering nutrients and contaminants as they flow westward, en route to their Winnipeg River confluence, past pulp mills, hydro dams, small urban centers, and burgeoning cottage developments. Contaminant levels in fishes within some areas of the Winnipeg River subcatchment are high enough to warrant consumption advisories in both Ontario and Minnesota fishing guides.

Reservoirs

As early as the mid 1800s Queen Victoria dispatched S. J. Dawson to survey the best routes for water transport and sites for settlement between Lake Superior and the Red River settlement at Winnipeg. Among Dawson's recommendations were the construction of several dams and locks along the Rainy River to facilitate steamboat travel (Dawson 1859). The relatively high relief that made the English River system unattractive for early exploration and transport now provides for most of the hydropower generation. The Winnipeg River has been constrained by several large dams to control water levels and provide storage to generate power for two provinces and two pulp and paper companies. Today international regulatory boards oversee water-level and flow regulation, using 34 control structures that provide water for 11 power-generating facilities with a combined capacity of >900 MW. Ontario Hydro has constructed four generating stations on the English and Winnipeg rivers with a total generating capacity of 240 MW. Boise Cascade, a paper company, owns and operates a single generating station on the Rainy River at International Falls. Manitoba Hydro operates six generating stations on the Winnipeg River main stem with a total capacity of ~560 MW, includ-

ing two plants at Point de Bois and Slave Falls, recently acquired from the city of Winnipeg. Most of the structures that regulate level and flow on the Winnipeg River were put in place without environmental impact assessments, so little is known of habitat that has been disrupted or lost. There is, however, some evidence indicating an improvement in walleye and perch habitat in the reservoirs of the Winnipeg River, making these reservoirs highly attractive to sport fishers. Lake of the Woods has been managed as a reservoir since the 1920s with the construction of the Norman Dam at Kenora, Ontario, which raised the lake 3 m above historic levels.

Radionuclides

The Whiteshell Nuclear Research Establishment (WNRE) was established on the Winnipeg River at Pinawa, Manitoba, in 1963 by Atomic Energy of Canada Limited. ¹³⁷Cs discovered in Lake Winnipeg sediment cores was traceable to leakage during the 1970s from the nuclear reactor, now slated for decommissioning (Lockhart et al. 2000). Levels of ¹³⁷Cs in Winnipeg River walleye downstream of WNRE were two times higher than in upstream fish from 1992 to 1997 (Graham et al. 1998).

Forestry and Agriculture

Alterations of stream-water quantity, quality, and habitat have occurred with the intensification of logging and forestry in northwestern Ontario (Feller and Kimmins 1984, Paterson et al. 1998, Garcia and Carignan 1999, Carignan et al. 2000, Schindler 2001). Three pulp mills, nine lumber mills, and two panel-production facilities, using 12 local tree species, are located in the subcatchment. Clear-cutting has resulted in faster runoff, soil erosion, increased stream siltation, and amplified exposure to ultraviolet (UV) radiation from lost shading along waterways. The Pine Falls pulp mill on the Winnipeg River has had severe effects on the downstream benthic community (Gregory and Loch 1973). Mercury contamination from pulp and paper mills on the English–Wabigoon River system (Rudd et al. 1983, Salki et al. 1985, Parks et al. 1991) during the 1960s forced closure of fishing in 1970. Recent government regulations and technological improvements have minimized aquatic pollution from bark and fiber waste, mercury, and organochlorine compounds. In the Rainy River system in Minnesota, fishes are generally of good quality, although contaminants have been found in fishes from certain waters. Juvenile fishes downstream of pulp mill efflu-

ents accumulated polychlorinated biphenyls and chlorinated phenols (Merriman et al. 1991), and leeches and mussels (*Elliptio complanata*) contained chlorophenol congeners as far as 100 km downstream (Metcalf and Hayton 1989). Agriculture in the Winnipeg River region is generally inhibited because of limited soil over bedrock, lack of nutrients in the soil, or the predominance of wet peatlands. Hay is produced in the Minnesota counties of the Rainy River system, but during the past two decades the extent of pastureland and cultivated cropland has declined from 115,000 to 85,000 acres and from 170,000 to 90,000 acres, respectively (www.nass.usda.gov/census/census97/volume1/mn-23/toc297.htm 1997). The structure of animal agriculture has changed dramatically in parallel fashion over the last two decades. Small- and medium-size livestock operations have been replaced by large operations at a steady rate. The total number of livestock has remained relatively unchanged, but more livestock are kept in confinement. These changes in animal agriculture have resulted in increased problems associated with the use and disposal of animal waste. However, the USDA reported that loading of nitrogen and phosphorous to soils in the Minnesota Rainy River system is not in excess. Aquatic communities in the Baudette River and Williams Creek of the Rainy River system in the United States have been impaired by lowered oxygen levels related to low stream flows and possibly increased nutrient loadings (www.pca.state.mn.us 2003).

Fires and Climate Change

Forest fires have influenced the contemporary physical, chemical, and biological properties of streams and lakes in the Winnipeg River subcatchment. Following fire, increases in sulfate and nitrate and hydrological outputs from streams draining the burned areas persist from a few to several years, depending on fire severity and weather and climate (Bayley, Schindler, Beaty et al. 1992, Bayley, Schindler, Parker et al. 1992, Schindler et al. 1992, Schindler, Bayley et al. 1996). Recent evidence of climate change in the Winnipeg River subcatchment suggests that stream, lake, and terrestrial ecosystems will come under additional stress in the future (Schindler 2001). Relatively small changes (1.6°C) in mean annual air temperatures at the ELA between 1970 and 1990 have resulted in shorter ice-cover periods for lakes and streams, reduced flows in 1st order streams, and decreased transport of nutrients and DOC to streams and lakes. Decreases of 70% to

80% in DOC in many boreal Canadian Shield lakes and streams have resulted in increases of up to 900% in UV exposure in aquatic environments (Schindler, Curtis et al. 1996). This exposure may be especially important to the communities of lake-outflow streams in the boreal forest. Subtle environmental changes that induce behavioral and distributional responses of biota may ultimately impact lower trophic levels and dependent fish communities. Impoverishment of DOC contributes to deeper UV penetration and lessening of phosphorous inputs, which lead to lower productivity of aquatic ecosystems.

Nonnative Species

The close proximity of the Winnipeg River and the Lake Superior catchment headwaters is facilitating the dispersal of Great Lakes nonnative invertebrate and fish species into central Canada through lakes and rivers of the Winnipeg River subcatchment. The cladoceran *Eubosmina coregoni* and the rainbow smelt are two species that have recently been found in Lake of the Woods and Lake Winnipeg (Franzin et al. 1994, Salki 1996). There is increasing potential for further introductions to occur as the subcatchment is spanned from east to west by a major highway with rising traffic volumes. A second nonnative cladoceran, *Bythotrephes cederstroemi*, was recently found in Lake Saganaga in the Boundary Waters Canoe Area Wilderness along the Minnesota–Canada border (www.seagrant.mnu.edu 2004).

NELSON RIVER MAIN STEM

The main-stem Nelson River is the natural outflow of Lake Winnipeg, which is a 26,000 km² remnant of glacial Lake Agassiz (Newbury 1990a). Lake Winnipeg collects flows from the Saskatchewan, Red–Assiniboine, and Winnipeg river subcatchments. The river runs for 680 km before emptying into Hudson Bay. The upper Nelson (the first 350 km) flows through a complex series of lakes as a series of short cascades between bedrock-controlled lake basins down to Split Lake (Fig. 19.19). Two major dams are located on this stretch of the river. The Grass and Burntwood rivers join the Nelson from the west in the area of Split Lake. The Nelson then runs fairly straight from Split Lake to its mouth on Hudson Bay in a single channel over a series of steps that end with rapids. However, it is interrupted by three major dams before reaching Hudson Bay.

Stretches have steep banks that gradually decrease in slope as they approach the estuary of the river at Hudson Bay. The lower 150 km of river is part of the marine intrusion zone that has emerged above sea level since the last glaciation (7000 to 9000 years ago).

The Nelson River is of considerable historical importance in the development and settlement of the interior of Canada. Although European exploration began in the early seventeenth century, aboriginal peoples had already occupied the area for thousands of years, and had highly developed societies (www.mbchiefs.mb.ca/efa/history2.html). At least 39 different aboriginal groups have occupied the area of the lower Nelson and lower Churchill rivers since the glaciers retreated (G. Dickson, personal communication). North–south movements of various cultures were dynamic, often coinciding with climatic changes (e.g., cooling ~3500 years ago, warming ~3000 years ago). Early historical documents identify the Churchill River as the rough boundary between the Dene from the north and the Cree from the south, but this boundary fluctuated until ~1000 years ago. The Cree, and the Assiniboine from further south, acted as middlemen for the Hudson’s Bay Company, with the Cree becoming the home guard. In fact, the help of the First Nations was essential to the success of the European colonization.

Captain Thomas Button, an Englishman, landed near the mouth of the Nelson River in 1612, two years after Europeans had begun exploring Hudson Bay (http://trulycanadian.freesevers.com/manitoba_history.htm). Exploration of the region was begun in earnest in the late seventeenth century by the Hudson’s Bay Company, which established a post on the Nelson River in 1670 and on the neighboring Churchill River in 1688. A flourishing fur trade developed from these posts, although access to the interior of the continent was through the smaller, more navigable Hayes River, which runs parallel to the Nelson River.

The importance of the Nelson and Hayes rivers to the fur trade and access to the interior of Canada diminished over time as new modes of transportation developed and consumers’ interests changed. The key trading posts were abandoned by the early 1900s. The York Factory post on the Nelson–Hayes estuary is now a national historic monument, and the Hayes River is currently a candidate for Canadian Heritage River status. However, the Nelson River became interesting for another reason: its hydropower potential. The Nelson River today is sparsely populated by aboriginal communities on isolated lake segments

along the main channel. Its central importance to the southern population of Manitoba is its present and future hydropower generation capability.

Hydroelectric power development was the impetus for the physical, chemical, and biological characterization of the Nelson main stem. Unfortunately, the bulk of the information has been published in difficult-to-access technical reports of special study boards, the provincial and federal governments, consultants, and other sources. Few of the data appear in primary journal publications or books.

Physiography, Climate, and Land Use

The Nelson River flows in a northeasterly direction roughly along the boundary between the Bear–Slave–Churchill Uplands (BC) and Superior Upland (SU) provinces of the Canadian Shield division and, in its lower reaches, through the Hudson Bay Lowland (HB) (see Fig. 19.19). Most of the river flows through the Midwestern Canadian Shield Forests terrestrial ecoregion, and the lowest part flows through the Southern Hudson Bay Taiga ecoregion (Ricketts et al. 1999). The region has been heavily glaciated and is covered by thin (<2 m) glacial till overburden and poorly drained peat-based wetlands. Typical vegetation includes stunted subarctic black spruce, jack pine, aspen, and willows on south-facing banks. Moisture and soil conditions are the main determinants of species distributions, and forest communities can change rapidly over short distances (Province of Manitoba 1974). However, black spruce is the climax forest through much of the subcatchment. Fire and logging cause abrupt changes in the environment and have a significant effect on the vegetation of the area. For example, the pinkish hue of fireweed is characteristic of a burned-over landscape and is the first stage of vegetative succession. Jack pine usually colonizes burned-over areas and hardwood species follow logging. The area of the Nelson River upstream of Stephens Lake is characterized by rolling, undulating topography of low relief that forms part of the Bear–Slave–Churchill Uplands (Province of Manitoba 1974). The area downstream of Kettle Rapids has numerous broad depressions.

The dominant bedrock is granite, but gneissic rocks occur in wide belts. Volcanic and metamorphosed rocks have a local distribution. Glacial till, deposited by melting ice as ground moraine, forms a thin mantle, and is often composed of loamy sand and Precambrian rock fragments. Some locations are marked by a loamy clay of calcareous till that

resulted from a readvance of the glaciers over lacustrine sediments. Till is locally concentrated in stream-lined hills or drumlins, but the relief of the ground moraine is determined by bedrock. Esker deposits of sand and gravel were laid down by rivers flowing under glacial ice and now form meandering sandy ridges of considerable relief. Fine-textured lacustrine clay deposits from glacial Lake Agassiz cover a major portion of the subcatchment.

Permafrost is widespread in clays of the northern reaches of the subcatchment (downstream of Split Lake) and some poorly drained clays in the middle reaches (Playgreen Lake to Split Lake) but does not occur in the clays of southern reaches (outflow of Lake Winnipeg). Most mineral and organic soils in the north contain permafrost, whereas permafrost only occurs in organic soils in the south. Mineral soils are luvosolic, brunosolic, and gleysolic. Organic soils are accumulations of various kinds of peat that are saturated for most of the year.

The climate of the subcatchment is continental and characterized by short, cool summers and long, cold winters (Province of Manitoba 1974). Mean annual temperature is $<0^{\circ}\text{C}$. Mean monthly temperatures have the greatest range between January and July (-40°C) (Fig. 19.20). Mean daily air temperatures are highest in July and range from $\sim 17.5^{\circ}\text{C}$ in the southern part of the subcatchment to $\sim 12.5^{\circ}\text{C}$ at the mouth of the river (Lane and Sykes 1982). Mean daily temperatures are lowest in January and range from $\sim -22.5^{\circ}\text{C}$ in the southern part of the subcatchment to $\sim -27.5^{\circ}\text{C}$ in its lowest reaches. Mean monthly precipitation is highest in July and lowest in February (see Fig. 19.20). Annual precipitation is $\sim 50\text{ cm}$ (A. Warkentin, personal communication). About two-thirds of the annual precipitation falls from May to October. Usually $<2.5\text{ cm/mo}$ of precipitation falls during the winter months.

The Nelson main stem has a very low population density (likely $<0.5\text{ people/km}^2$ compared to 5 people/km^2 for the entire Nelson subcatchment; Revenga et al. 1998, www.waterandnature.org/eatlas/html/index.html 2004). The largest aggregation of population in the main-stem subcatchment is Thompson ($\sim 15,000$) on the Burntwood River. However, there is extensive industrial development in the subcatchment, including a large nickel mine at Thompson and three sizeable dams on the main stem. The aboriginal population is involved in natural-resource harvesting (hunting, fishing, and trapping) for domestic use and commercial markets (e.g., Usher and Weinstein 1991). Land-use proportions for the entire Nelson catchment are as follows: cropland 47%;

forest 32%; grassland, savanna and shrubland 6%, urban and industrial 7% (Revenga et al. 1998, www.waterandnature.org/eatlas/html/index.html 2004).

River Geomorphology, Hydrology, and Chemistry

The upper Nelson channel is irregular in form and winds through the rocks of the Canadian Shield division, which are overlain by a few meters of lacustrine deposits (Province of Manitoba 1974). The channel is primarily bounded by Precambrian bedrock, with a shallow, coarse till cover. The river runs primarily off the bedrock surface between rapids and has steep, rocky tributaries. Transported sediments are mainly colloidal clays originating upstream. Average slope from Lake Winnipeg to Split Lake (a 50 m drop concentrated in three major falls) is 13 cm/km . There are numerous lakes on the upper Nelson, including Playgreen, Cross, Sipiwesk, and Split. This portion of the channel has numerous sets of rapids (see Fig. 19.7). The lower Nelson lies in the Hudson Bay Lowland, where Paleozoic limestones overlain with deep marine sediments prevail. The channel is controlled by bedrock outcrops (Precambrian in the upper reaches, Silurian dolomites and limestones in the lower reaches). The riverbed becomes gravel/cobble/bedrock when it enters the Hudson Bay Lowland downstream of Kettle Rapids because it is recutting its channel in the infill valley that has emerged since glaciation. Tributaries in the lower part of the main stem are also gravel because of the infill, which accounts for their resident brook trout populations, which were exploited by natives. Average slope from Split Lake to the estuary (a 156 m drop with no major falls) is 57 cm/km , quite a bit steeper than the upper Nelson main stem and the reason the lower main stem was so attractive for hydropower production. The river transports cobbles, gravels, and sands as well as colloidal inputs from upstream. There are no major natural lakes on the Nelson below Split Lake, and the channel straightens out (Fig. 19.8).

Downstream of Split Lake the river has a series of rapids, which become long chutes over horizontally bedded limestone covering the Canadian Shield surface (Newbury 1990a). Shores and islands in reaches that end in steep rapids and chutes sometimes display well-developed trimlines caused by ice accumulation well above the maximum open-water stage. The trimline often does not extend to the upper end of ice-generating reaches because of the lack of ice accumulation before the winter ends, and trees

FIGURE 19.7 Upper Nelson River crossing the rugged Canadian Shield above the Hudson Bay Lowlands. Profile of the river is controlled by large bedrock outfalls from lakes, as shown here at Whitemud Falls, the outlet of Cross Lake. Hydro developments have replaced several of the outlet falls with dams (PHOTO BY R. NEWBURY).

extend down the valley walls to the maximum open-water levels.

Care must be taken in interpreting pre- and postregulation runoff for the Nelson main stem at Kelsey Dam above Split Lake (see Fig. 19.20). Runoff at Kelsey involves a lot of basin storage effects (lakes, reservoirs, river channels) and these effects can carry forward for months (A. Warkentin, personal communication). Although summer precipitation is greater than for other seasons, summer runoff tends to be relatively low compared to other seasons because of evapotranspiration.

Redevelopment records indicate that the mean annual natural discharge of the Nelson main stem at Hudson Bay was $2480\text{ m}^3/\text{s}$ (Newbury et al. 1984), but the hydrology of the Nelson main stem has been greatly altered by the post 1970s effects of Lake Winnipeg regulation and the added $850\text{ m}^3/\text{s}$ licensed diversion from the Churchill River. Peak flows in the Nelson have increased substantially, and seasonal discharge patterns have been altered. For example, with completion of the Lake Winnipeg storage dam

at Jenpeg and operation of the Churchill diversion, mean natural summer flows to Hudson Bay have increased from $2689.5\text{ m}^3/\text{s}$ to $3250.0\text{ m}^3/\text{s}$, whereas mean winter flows have increased from $1885.5\text{ m}^3/\text{s}$ to $2859.3\text{ m}^3/\text{s}$ in recent years (FEMP 1992c). The reversal of the seasonal pattern on the lower Nelson River is obscured by the addition of Churchill River flows, but the alteration has shifted 7% of the combined annual delivery from the open-water season to the ice-covered period from November to May.

Day-to-day operation of the hydropower plants in the lower Nelson produces dramatic fluctuations in discharge. For example, at Kettle Dam (Fig. 19.9), approximately midway between Split Lake and the Nelson River estuary, most of the day-to-night decreases in hourly mean discharge were $>2000\text{ m}^3/\text{s}$ in winter and often $\sim 3000\text{ m}^3/\text{s}$ in summer (FEMP 1992c). Baker (1989), working in the Nelson River estuary, commented on discharge fluctuations caused by the upstream hydro dams: "Discharge is controlled . . . according to southern power demand." Mean hourly summer discharge rates (1978 to 1988

FIGURE 19.8 The lower Nelson River channel, shown here in summer, lies in a deep valley that is incised into the flat Hudson Bay lowlands. The near vertical riverbanks are permanently frozen. The south-facing banks shown here have an active thawed zone only where seasonal surface water flows over the banks, forming a series of “flat-iron” crenulations that are typical of permafrost regions (PHOTO BY R. NEWBURY).

data) have ranged between 0 and 7200 m³/s (see also FEMP 1992b). Daily discharge rates varied between 340 and 6500 m³/s. Mean daily minimum and maximum discharge typically varied between 0.6 and 700 m³/s and 4.5 and 4950 m³/s, respectively. Mean discharge during weekdays normally exceeds mean discharge during weekends by several orders of magnitude. Discharge fluctuations are attenuated somewhat in the distance between the last dam on the river and the estuary (Baker 1989). The ecological effects of these dramatic fluctuations remain largely unstudied.

Efforts to determine changes in water chemistry as a result of Lake Winnipeg regulation and Churchill River diversion led to a gathering of scarce predevelopment data for the Nelson River subcatchment (e.g., Williamson and Ralley 1993). Data from the Burntwood River, a major tributary of the Nelson main stem at Thompson, are compared to three Nelson main-stem stations (Norway House, located on the East Channel of the Nelson River just below

its outflow from Lake Winnipeg; Sipiwesk Lake, still in the upper Nelson; and Split Lake, the repository of the Burntwood River in the lower Nelson). High values in the Burntwood River relative to the Nelson main stem for color (47 TCU versus 15 to 21 TCU), total suspended solids (14 mg/L versus 8 to 13 mg/L), turbidity (14 NTU versus 7 to 13 NTU), and total organic carbon (13 mg/L versus 9 to 11 mg/L) indicate a tributary that is stained by flowing through peatlands during part of its course and through erodible sediments in other parts. Lower relative values for total alkalinity (63 mg/L versus 98 to 103 mg/L as CaCO₃), conductivity (139 mg/L versus 298 to 311 mg/L), pH (7.70 versus 8.02 to 8.06), and hardness (68 mg/L versus 115 to 121 mg/L as CaCO₃) indicate more dilute waters than in the Nelson main stem. Low pH and alkalinity in the Burntwood River may be consistent with colored (humic) water. Total nitrogen (Kjeldahl) concentrations (0.81 mg/L versus 0.56 to 0.73 mg/L) and total phosphorus concentrations (29 µg/L versus 24 to 34 µg/L) were similar

FIGURE 19.9 The Kettle Rapids dam on the Lower Nelson River was the first of a series of dams that have flooded out the rapids and divided the deeply incised river channel into a series of flooded valley reservoirs. Ice damming and ice jams no longer occur (PHOTO BY R. NEWBURY).

between the Burntwood River and Nelson main-stem stations. Assessment of the changes in water quality caused by Lake Winnipeg regulation and Churchill River diversion is difficult because of a lack of adequate predevelopment data (FEMP 1992c, Williamson and Ralley 1993). However, a number of general observations have been made (FEMP 1992c): (1) natural river sites showed little change; (2) sites along the Churchill River diversion had higher postdevelopment turbidity levels, caused by bank and shoreline erosion; (3) sites along the Churchill River diversion showed significant changes, such as decreased hardness and alkalinity, which reflected differences in water quality between the diverted Churchill River water and water quality in the Rat and Burntwood rivers through which the diverted waters flow; (4) variables such as hardness and conductivity decreased at the outlet of Split Lake as a direct result of the diversion, although annual mean turbidity did not increase; (5) phosphorus increased at most sites immediately after Lake Winnipeg regulation and Churchill River diversion, probably because of increased erosion, and then tended to stabilize as a new balance was reached between discharge and shoreline erosion; and (6) many

discharge-correlated variables shifted from being negatively correlated prior to development to being positively correlated after development for some sites along the diversion route and at the outlet of Split Lake. These shifts were attributed to the increased importance of shoreline erosion.

River Biodiversity and Ecology

The entire Nelson main stem is within the Lower Saskatchewan freshwater ecoregion of Abell et al. (2000). As indicated, few data on biological characteristics for the Nelson main stem appear in primary journal publications; the bulk of information is located in difficult-to-access technical reports.

Algae and Cyanobacteria

Substantial information is available on phytoplankton in lakes and reservoirs of the Nelson main stem. However, information on algae in rivers is limited. For example, Pip (1992c) collected a filamentous alga, *Mougeotia*, in the lower Nelson River in a search for naturally occurring phenolic compounds. None were found in *Mougeotia*.

Plants

Pip and Stepaniuk (1992a) collected 28 taxa of macrophytes from a variety of habitats in the lower Nelson River. The most frequently collected taxa were sedges, narrowleaf bur-reed, water horsetail, and common mare's tail. Major riparian plants include black spruce, tamarack, willows, alders, swamp birch, paper birch, aspen, and white spruce.

Pip and Stepaniuk (1992b) reported that mean macrophyte species richness was lower in habitats downstream of hydroelectric dams on the lower Nelson River than in other stream habitats sampled. Pip (1992c) also surveyed naturally occurring phenolic compounds in 20 species of submerged, floating, and emergent macrophytes in the lower Nelson and its tributaries. Of nine phenolic compounds identified, p-hydroxybenzoic acid was commonest.

Invertebrates

Once again, substantial information is available on zooplankton and benthic invertebrates in lakes of the Nelson main-stem area. However, river information is limited. Baker (1989) conducted a baseline survey of the zoobenthos and zooplankton of the Nelson River estuary and divided the estuary into four distinct zones; the invertebrate fauna of the "riverine" (i.e., freshwater) zone is of most interest here. Chironomid midges, copepods, oligochaete worms, and snails were the most abundant taxa and had the highest species diversity. Baker did not identify the insects to lower taxonomic levels, but he provided genus- and species-level identifications for Hydrozoa (4 taxa), Ectoprocta (2 species), oligochaetes (14 taxa), crustaceans (mysids, 1 species; branchiopods, 2 genera; copepods, 10 taxa), snails (7 taxa), bivalves (2 species), and water mites (1 species). Few of the species of mollusks reported by Baker were found by Pip (1992a) in the lower Nelson or its tributaries. The snails *Gyraulus* sp., *Physa gyrina*, three-ridge valvata snail, and swamp lymnaea snail were the most frequently collected taxa (Pip 1992a). She also collected three bivalve species. Pip claimed that gastropod richness was adversely affected by hydroelectric dams on the lower Nelson.

Vertebrates

A number of lake-based fisheries surveys were done on the upper Nelson prior to Lake Winnipeg regulation and Churchill River diversion. However, Ayles (1974) surveyed the east channel of the Nelson River and reported 13 species of fishes (walleye, cisco, burbot, northern pike, yellow perch, trout perch,

longnose sucker, white sucker, shorthead redhorse, mooneye, mottled sculpin, slimy sculpin, spottail shiner). The species composition resembled that of Cross and Playgreen lakes but with less productivity because of the riverine habitat. No commercial fishing existed on the East Channel. MacDonnell and Bernhardt (1992) summarized fisheries studies on the lower Nelson River over the period from 1915 to 1992. Fisheries studies in the lower Nelson began in 1915 when N. A. Comeau led the Burleigh expedition to examine the fisheries resources of Hudson and James bays. However, there was little further interest in fisheries resources until hydroelectric development started (~1974). With completion of the Kettle Generating Station and ongoing construction of the Long Spruce Generating Station in 1974, concern over impacts to the environment, and more specifically to brook trout (considered a heritage species in Manitoba), led the Manitoba government to do a number of studies on brook trout (~1974 to 1981). Construction of the Limestone Generating Station in the 1980s and plans for the Conawapa Generating Station in the early 1990s (not built yet) led to more fisheries studies by the Manitoba government and the consulting industry as part of environmental impact assessments. Studies covered the Nelson main stem from Long Spruce Generating Station to the Nelson River estuary, tributary rivers to the Nelson, and headwater lakes of the tributaries. Forty fish species were recorded from the lower Nelson main stem and 32 species were collected from its tributaries. Considerable information on distribution, abundance, life history, general ecology, and effects of impacts is available for brook trout from the area (MacDonnell and Bernhardt 1992). Lesser information is available for lake sturgeon, lake cisco, lake whitefish, white sucker, longnose sucker, and northern pike. Distribution records, but very little life-history information, are available for the other fish species collected from the lower Nelson River (MacDonnell and Bernhardt 1992).

Beaver, muskrat, mink, and lynx occur through the area (Webb 1973, Webb and Foster 1974). Baker (1989) reported large numbers of beluga whale in the riverine and nearshore estuarine zones during his spring and summer surveys. The Nelson estuary harbors most of the western Hudson Bay beluga population and may represent the largest concentration of beluga in the world (Baker 1989). Bearded seal were also commonly observed, mostly in the autumn.

Ecosystem Processes

Biological studies of the Nelson River have not progressed much past the descriptive phase, although

FIGURE 19.10 Mid-January ice damming in Wapicho Rapids on the lower Nelson River before construction of hydropower dams. Ice dams were formed over rapids in a winter-long sequence that began at Hudson Bay in early November and proceeded up the river over 250 km, ending in late March. Hydro developments have stopped the upstream accumulation by dividing the river into a series of frozen reservoirs (PHOTO BY R. NEWBURY).

information is available on primary productivity in lakes. Limited data on the production of some species of fishes in the lower Nelson main stem are summarized in MacDonnell and Bernhardt (1992). For example, production of sculpins was estimated to be 0.4 to 3.4 kg ha⁻¹ yr⁻¹ in lower Nelson nursery streams, and production of yearling and older brook trout in two lower Nelson tributaries were 9.0 and 1.2 kg ha⁻¹ yr⁻¹, respectively (1980a as in MacDonnell and Bernhardt 1992).

Human Impacts and Special Features

The Nelson is the only northward-flowing subarctic river in North America that gathers most of its flow from a temperate southern basin. As a result, warmwater inflows cause ice to form over the whole winter season in the lower Nelson, starting in its estuary and gradually ascending the river as a series of accumulated covers between hanging ice dams in rapids sections (Fig. 19.10). Spring occurs before the

whole of the lower Nelson is ice covered, so there are sections at the head of the upper reaches that are never ice covered. This natural ice regime has been drastically altered by hydropower dams on the lower Nelson. Reservoirs that freeze over in early autumn now halt the upstream progression of the ice cover, and upper reaches are ice scoured for the first time. Bank erosion and channel braiding now occur in these formerly stable reaches. Formerly safe winter ice routes have become hazardous, leading to tragic drownings as the new ice regime becomes established.

In ice-accumulation reaches of the lower Nelson, islands have a “top hat” appearance (i.e., a central core of trees surrounded by a brim of grasses), and shorelines look “trimmed” because of the natural ice regime (Newbury 1990a). The Nelson main stem also has numerous pictographic sites scattered throughout the region.

The Nelson River is a good example of single-purpose development on a massive scale (Newbury 1981). Manitoba’s power planners have been aware since the early 1900s of the tremendous hydroelectric potential of the province’s northern rivers, especially the Nelson (Newbury et al. 1984, www.hydro.mb.ca/export_minnesota/history.html). The first generating station, Kelsey, was built in 1961 to provide power for the International Nickel Company’s (INCO) mining and smelting operation at Thompson, upstream on the Burntwood River. Federal–provincial studies were initiated in 1964 to examine the feasibility of developing further generating stations on the Nelson and Churchill rivers for markets in southern Canada and the northern United States. In 1966, nine sites on the Nelson were identified. Instead of building generating stations on the Churchill River, diversion of the Churchill River into the Nelson River was recommended to increase flows through the Nelson River dams. The dam at Kettle Rapids (1272 MW, see Fig. 19.9) was completed in 1974, and a transmission system was built on the west side of Lake Winnipeg to bring power to the south. Diversion of the Churchill into the Nelson was completed in 1976, followed by Lake Winnipeg regulation in 1977. Lake Winnipeg regulation involved installing a complex series of channels and dikes through the outlet lakes downstream of Lake Winnipeg and building the Jenpeg control dam just upstream of Cross Lake. Long Spruce Dam (980 MW) was completed in 1979 and Limestone Dam (~1300 MW) was completed in 1992. Because the Nelson–Churchill dams were primarily built for power exports, plans to build the Conawapa Dam

further downstream were shelved in 1991 as power demand slumped in the northern United States and Ontario. Although plans to build Conawapa have recently reemerged, a number of smaller power-generating sites have already been identified along the Rat–Burntwood river system, which receives water from the Churchill diversion, and one or more of these sites will likely be started within the next few years.

Diversion of the Churchill River into the Nelson system and the flooding of Southern Indian Lake was extremely contentious in Manitoba; a provincial government went down to defeat over the issue. The environmental and social impacts resulting from diversion activities were immediate and severe and still continue today. For a summary of these effects, see Bodaly et al. (1984), Hecky et al. (1984), Canada–Manitoba Agreement on the Study and Monitoring of Mercury in the Churchill River Diversion (1987), Waldram (1988), Usher and Weinstein (1991), FEMP (1992c), and Rosenberg et al. (1995). The debate over compensation for the permanent loss of resources to people living on the Nelson River, and on the advisability of developing export power, has deeply divided Manitoba aboriginal communities, politicians, academics, and resource professionals (see Tritschler Report 1979 in Waldram 1988).

Mercury contamination of fishes is a by-product of reservoir formation almost everywhere in the world (Rosenberg et al. 1995), and the Nelson River main stem is no exception (Canada–Manitoba Agreement on the Study and Monitoring of Mercury in the Churchill River Diversion 1987). Elevated mercury levels were first detected in fishes from the Churchill River diversion route in 1978 to 1979, just after diversion was completed. Levels in piscivorous fishes (walleye, northern pike) exceeded the Canadian marketing limit of 0.5 µg/g in almost all of the lakes along the diversion route after their impoundment. Mercury levels in nonpredatory fishes will remain elevated for 10 to 20 years after flooding, and longer (20 to 30 years) in piscivorous fishes.

Other metals have also been studied in the Nelson River system. Cadmium, copper, and lead concentrations have been analyzed from biota collected in a variety of stream habitats in the lower Nelson River: sediments, algae, and macrophytes (Pip and Stepaniuk 1992a, 1992b), gastropods (Pip 1992b), and fishes (Pip and Stepaniuk 1997). Concentrations of some metals were sometimes higher downstream of hydroelectric dams in some biota, but no clear overall trends were obvious.

The only other major industrial land use in the main-stem Nelson subcatchment is a large nickel mine at Thompson. The mine poses localized problems because of leaching from mine tailings and more widespread problems from high atmospheric emissions during periods of full production (Lane and Sykes 1982).

ADDITIONAL RIVERS

The Bow River is located in southern Alberta, Canada (Fig. 19.21). Its source is the Bow Glacier in Banff National Park, one of the most famous and visited nature reserves in the world and a U.N. World Heritage Site. From its source, the Bow River flows southeast into the aqua blue waters of Lake Louise before emerging from the mountains in the Bow River Pass and entering the aspen parklands of the foothills (Fig. 19.1). The river then traverses the city of Calgary, home to ~1,000,000 people, passing through wide green valleys lined with cottonwood and spruce. The river continues across the Great Plains, where it joins with Oldman River near the Alberta–Saskatchewan border to form the South Saskatchewan River. The Bow is a major tourist attraction near its montane headwaters, sustains a world-class fly fishery for brown and rainbow trout (introduced in the 1920s and 1930s) along an 80 km reach downstream of Calgary, and is a source of water for millions of ha of prairie farmland.

The Otter Tail River is one of two tributaries that, with their confluence, begin the Red River of the North (Fig. 19.23). The other tributary is the Bois de Sioux, draining Lake Traverse. The Otter Tail is unique among the Red River tributaries in that it has a high incidence of lakes in its drainage area and it traverses three ecoregions along its length. These two aspects contribute to its singular character: generally clear waters and an exceptionally diverse biota. Several fish species known from the Otter Tail, for example, occur nowhere else in the subcatchment. The Otter Tail historically was dominated by forest cover (50%), but present forest cover has been reduced to 20%. This value is still higher than most other rivers in the Red River subcatchment. The Otter Tail has also maintained about 13% wetland cover over time and contains 14% open waters in its many lakes. Only 43% of the subcatchment is agricultural land. The lakes, wetlands, and streams of the headwaters help to maintain relatively constant streamflow, contributing to the maintenance of biodiversity. The Otter Tail is one of Minnesota's prime

recreational areas, with abundant fishing, hiking, and camping opportunities. In addition, the Otter Tail has a long history of water-powered mills and hydroelectric generation with dams and is the only river in the Red River subcatchment to provide significant power generation.

ACKNOWLEDGMENTS

We thank the following people for their valuable inputs to various sections of this chapter: Saskatchewan River, C. Casey, M. Guy, and M. Meding; Red–Assiniboine River, J. Hatch, S. Nelson, K. Schmidt, and K. Stewart; Winnipeg River, B. Bilyj; Nelson River, R. Baker, G. Dickson, M. Lawrence, D. MacDonnell, E. Pip, R. Remnant, D. Riddle, A. Warkentin, and D. Williamson; and Otter Tail River, T. Waters. We also thank D. Williamson for reviewing the Nelson River section.

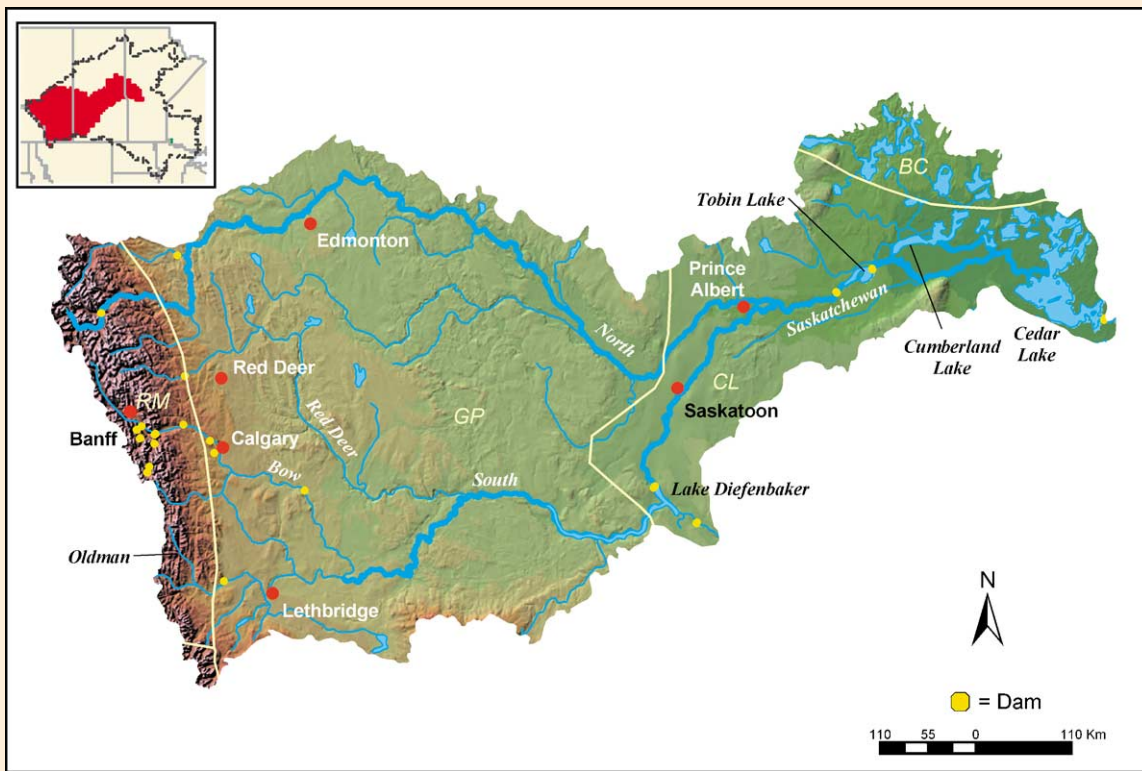

FIGURE 19.11 Map of the Saskatchewan River basin. Physiographic provinces are separated by yellow lines.

SASKATCHEWAN RIVER

Relief: 3307 m

Basin area: 335,900 km²

Mean discharge: 567 m³/s (postregulation)

River order: 8

Mean annual precipitation: 45.2 cm

Mean air temperature: -0.3°C

Mean water temperature: 9.7°C

Physiographic provinces: Rocky Mountains in Canada (RM), Great Plains (GP), Central Lowland (CL), Bear-Slave-Churchill Uplands (BC)

Biomes: Temperate Mountain Forest, Temperate Grasslands, Boreal Forest

Freshwater ecoregions: Canadian Rockies, Upper Saskatchewan, Lower Saskatchewan

Terrestrial ecoregions: 7 ecoregions (see text)

Number of fish species: ≥48

Number of endangered species: NA

Major fishes: cutthroat trout, rainbow trout, bull trout, brook trout, brown trout, mountain whitefish, longnose sucker, longnose dace, northern pike, walleye, goldeye, yellow perch, quillback, shorthead redhorse, lake sturgeon

Major other aquatic vertebrates: beaver, mink, white pelican, river otter, muskrat, tundra swan, ring-necked duck

Major benthic invertebrates: mayflies (*Baetisca*, *Baetis*, *Ephemera*, *Ephemerella*, *Ephoron*, *Heptagenia*, *Tricorythodes*), stoneflies (*Isoperla*, *Choroterpes*), caddisflies (*Brachycercus*, *Cheumatopsyche*, *Helicopsyche*, *Symphitopsyche*, *Traverella*), true flies (Chironominae, Tanypodinae, Orthocladiinae), crustaceans (*Orconectes*)

Nonnative species: brown trout, rainbow trout, brook trout, purple loosestrife, curly pondweed

Major riparian plants: red-osier dogwood, sandbar willows, poplar, water birch

Special features: originates in glaciers and snowfields of Rocky Mountains in Alberta, a World Heritage Site; headwaters of North Saskatchewan River in Banff National Park designated Canadian Heritage Rivers; designated globally important bird areas in portions of prairies and boreal forests

Fragmentation: dams throughout for hydropower and irrigation

Water quality: pH = 8.0, alkalinity = 131 mg/L as CaCO₃; relatively free of pollutants in mountains (NO₃-N = 0.075 mg/L, PO₄-P = 0.009 mg/L); higher nutrient concentrations below major cities and in agricultural areas

Land use: 67% cropland, 3% shrub, 7% grassland, 22% forest

Population density: 9.6 people/km²

Major information sources: Donald and Mutch 1980, Culp and Davies 1982, Charlton et al. 1986, Cross et al. 1986, Hamilton and North 1986, Sosiak 1990, Culp et al. 1992, Chambers and Prepas 1994, Carr and Chambers 1998, Environment Canada 2001, www.climate.weatheroffice.ec.gc.ca/climate_normals/index_e.html 2002

FIGURE 19.12 Mean monthly air temperature, precipitation, and runoff for the Saskatchewan River basin.

FIGURE 19.14 Mean monthly air temperature, precipitation, and runoff for the Red River of the North basin.

RED RIVER OF THE NORTH

Relief: 350 m (includes Assiniboine)

Basin area: 287,500 km² (including Assiniboine basin)
116,600 km² (upstream of Assiniboine confluence)

Mean discharge: 236 m³/s (includes Assiniboine)

River order: 8

Mean precipitation: 48.9 cm

Mean air temperature: 2.4°C

Mean water temperature: NA

Physiographic province: Central Lowland (CL)

Biome: Temperate Grasslands

Freshwater ecoregion: English–Winnipeg Lakes

Terrestrial ecoregions: Northern Tall Grasslands, Canadian Aspen Forest and Parklands, Northern Mixed Grasslands, Western Great Lakes Forests, Upper Midwest Forest/Savanna Transition Zone

Number of fish species: ~94

Number of endangered species: 14 fishes

Major fishes: channel catfish, black bullhead, walleye, sauger, freshwater drum, common carp, white sucker, shorthead redhorse, goldeye, mooneye, silver chub, emerald shiner, black crappie

Major other aquatic vertebrates: beaver, muskrat, western painted turtle, common snapping turtle, wood frog, chorus frog, spring peeper, northern leopard frog, gray treefrog, American toad, tiger salamander, blue spotted salamander, mud puppy

Major benthic invertebrates: mayflies (*Baetis*, *Heptagenia*, *Ephoron*, *Hexagenia*, *Pentagenia*, *Isonychia*, *Tricorythodes*), caddisflies (*Ceratopsyche*, *Hydropsyche*, *Brachycentrus*), stoneflies (*Acronuria*, *Pteronarcys*), true flies (*Tipula*, *Bezzia*, *Axarus*), bivalves (*Fusconaia*, *Amblema*, *Quadrula*, *Lasmigona*, *Anodontoides*, *Pyganodon*, *Strophitus*, *Ligumia*, *Lampsilis*, *Potamilus*)

Nonnative species: common carp, white bass, largemouth bass, smallmouth bass

Major riparian plants: cottonwood, green ash, peach-leaved willow, burr oak, basswood, elm

Special features: very low-gradient large river

Fragmentation: main stem largely continuous; all major tributaries dammed

Water quality: specific conductance = 690 μS/cm, pH = 8.1, alkalinity = 215 mg/L as CaCO₃, NO₃-N = 0.34 mg/L, total P = 0.3 mg/L, Na = 34 mg/L, total dissolved solids = 381 mg/L

Land use: U.S. portion, 74% agriculture (66% cropland, 8% pasture), 26% forest

Population density: 4.8 people/km² (United States); 59 people/km² (Canada)

Major information sources: Peterka 1978, 1992, Renard et al. 1986, Stoner et al. 1993, Goldstein 1995, Goldstein et al. 1996, Peterka and Koel 1996, Koel 1997

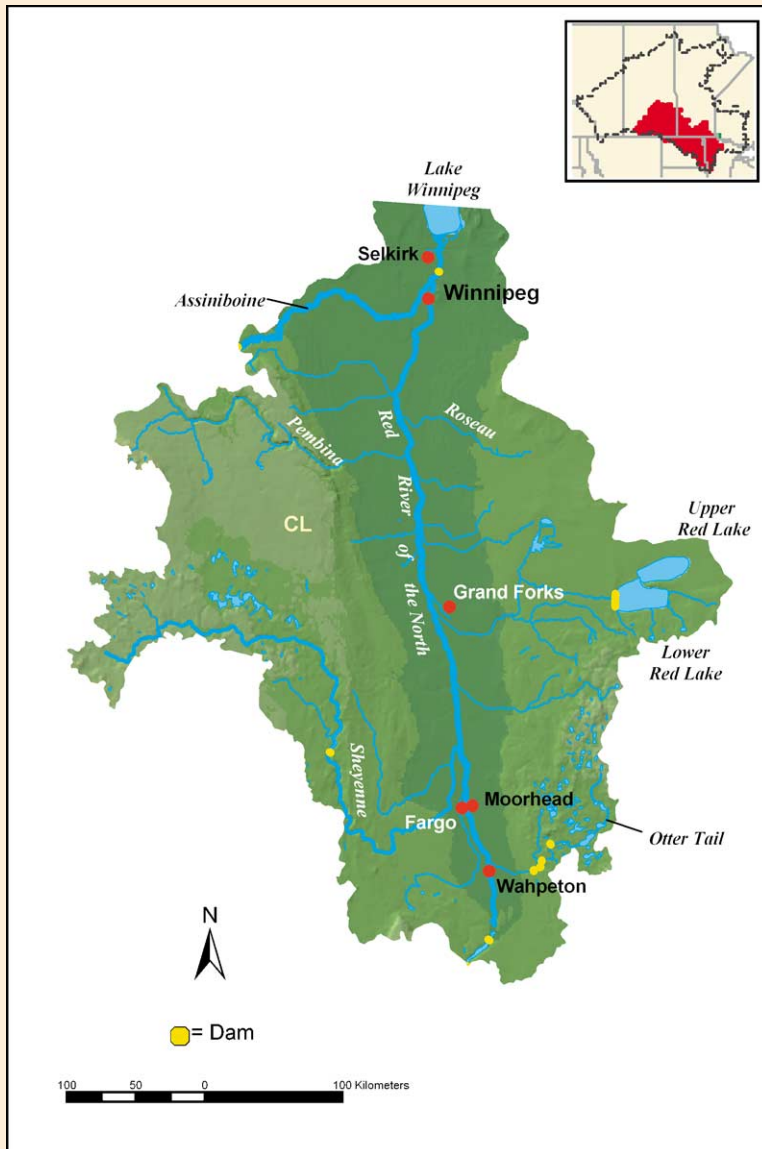

FIGURE 19.13 Map of the Red River of the North basin.

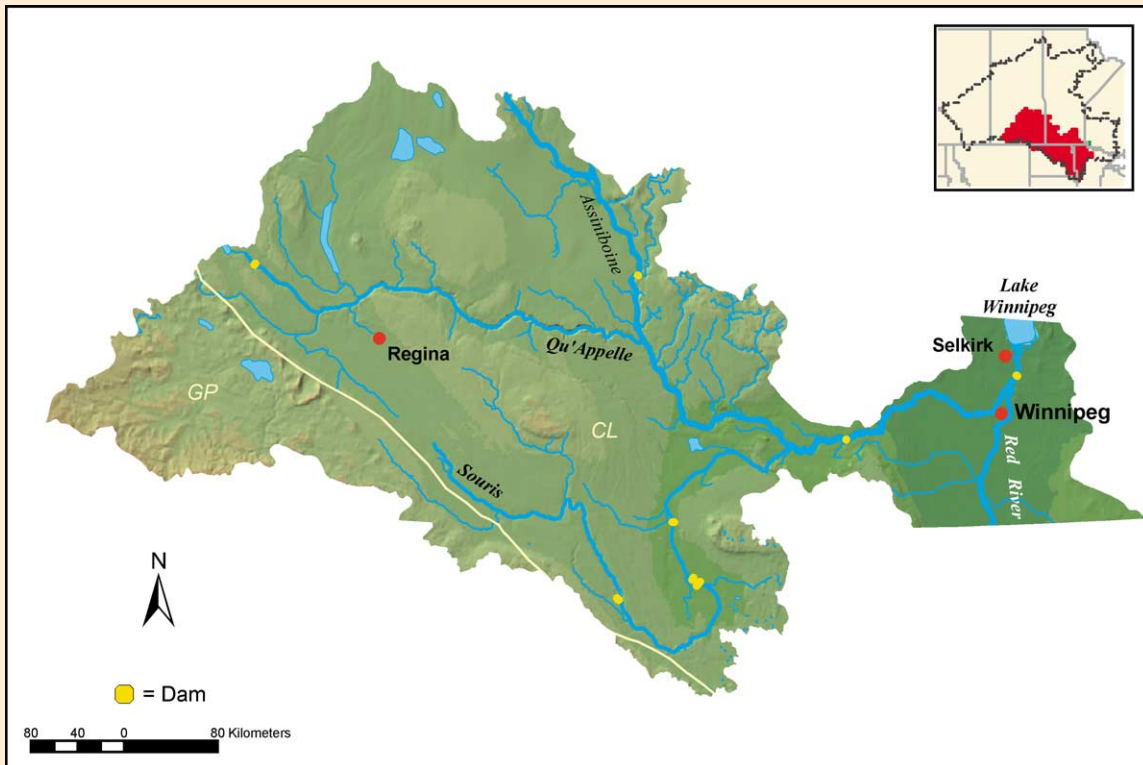

FIGURE 19.15 Map of the Assiniboine River basin. Physiographic provinces are separated by a yellow line.

ASSINIBOINE RIVER

Relief: 350 m

Basin area: 162,000 km²

Mean discharge: 47.4 m³/s

River order: ~7

Mean precipitation: 45.4 cm

Mean air temperature: 2.4°C

Mean water temperature: 9.0°C

Physiographic province: Central Lowland (CL), Great Plains (GP)

Biome: Temperate Grasslands

Freshwater ecoregion: English–Winnipeg Lakes

Terrestrial ecoregions: Mid-continental Canadian Forests, Northern Mixed Grasslands, Northern Tall Grasslands, Canadian Aspen Forests and Parklands

Number of fish species: 55

Number of endangered species: none

Major fishes: walleye, sauger, channel catfish, goldeye, mooneye, common carp, white sucker, silver redhorse, golden redhorse, shorthead redhorse, quillback

Major other aquatic vertebrates: beaver, muskrat, wood frog, western chorus frog, spring peeper, northern leopard frog, gray treefrog, American toad, snapping turtle

Major benthic invertebrates: bivalves (*Fusconaia*, *Amblema*, *Quadrula*, *Lasmigona*, *Anodontoides*, *Pyganodon*, *Strophitus*, *Ligumia*, *Lampsilis*, *Potamilus*, Sphaeriidae), snails (*Physa*, *Helisoma*), crustaceans (*Orconectes*), mayflies (*Baetis*, *Heptagenia*, *Ephoron*, *Hexagenia*, *Pentagenia*, *Isonychia*, *Tricorythodes*), caddisflies (*Ceratopsyche*, *Hydropsyche*, *Brachycentrus*), stoneflies (*Acro-neuria*, *Pteronarcys*), dragonflies (*Gomphus*), beetles (*Narpus*), true flies (*Tipula*, *Bezzia*)

Nonnative species: common carp, white bass

Major riparian plants: several grasses, red-osier dogwood, peach-leaved willow, American elm, cottonwood, green ash, basswood, cattail

Special features: very long, relatively intact prairie river

Fragmentation: several dams on tributaries; two dams on main stem

Water quality: specific conductance = 865 μS/cm, pH = 8.2, Ca = 60 to 120 mg/L, Mg = 20 to 55 mg/L, total N = 1.52 mg/L, total P = 0.25 mg/L, Na = 50 mg/L, chloride = 26 mg/L, total dissolved solids = 552 mg/L

Land use: ~70% to 80% agriculture (~70% cropland, 10% to 15% pasture), remainder forested uplands

Population density: 1 person/km² upstream of city of Winnipeg

Major information sources: Andres and Thompson 1995, McCulloch and Franzin 1996, Gurney 1991, www.climate.weatheroffice.ec.gc.ca/climate/climate_normals/index_e.cfm 2002

FIGURE 19.16 Mean monthly air temperature, precipitation, and runoff for the Assiniboine River basin.

FIGURE 19.18 Mean monthly air temperature, precipitation, and runoff for the Winnipeg River basin.

WINNIPEG RIVER

Relief: 195 m

Basin area: 135,800 km²

Mean discharge: 850 m³/s

River order: NA

Mean annual precipitation: 62 cm

Mean air temperature: 2.4°C

Mean water temperature: NA

Physiographic provinces: Central Lowland (CL), Superior Upland (SU)

Biome: Boreal Forest

Freshwater ecoregion: English–Winnipeg Lakes

Terrestrial ecoregions: Western Great Lakes Forests, Midwestern Canadian Shield Forests

Number of fish species: 69

Number of endangered species: 1 snail, 2 fishes, 1 snake

Major fishes: northern pike, walleye, sauger, yellow perch, lake whitefish, lake trout, muskellunge, brook trout, smallmouth bass, white sucker, rainbow smelt

Major other aquatic vertebrates: beaver, river otter, muskrat, mink, loon, Canada goose, mallard, wood duck, great blue heron, herring gull, painted turtle

Major benthic invertebrates: oligochaete worms (*Limnodrilus*, *Nais*), leeches (*Erpobdella*, *Helobdella*, *Placobdella*), crustaceans (*Hyaella*, *Gammarus*, *Orconectes*, *Candona*, *Canthocamptus*), odonates (*Aeshna*, *Enallagma*, *Libellula*), mayflies (*Caenis*, *Hexagenia*), caddisflies (*Hydropsyche*, *Cheumatopsyche*), true flies (*Chaoborus*, *Bezzia*, *Procladius*, *Cricotopus*, *Psectrocladius*), bivalves (*Pisidium*, *Musculium*), snails (*Gyraulus*, *Ammnicola*)

Nonnative species: rainbow smelt, *Eubosmina coregoni*, *Bythotrephes cederstroemi*

Major riparian plants: bunchberry, Canada mayflower, chokecherry, dogwood, fragrant bedstraw, green alder, highbush cranberry, lady fern, lowbush cranberry, mountain maple, northern bluebell, oak fern, pin cherry, pussy willow, rattlesnake plantain, slender wood grass, rose twisted stalk, sensitive fern, skunk currant, snowberry, starflower, white cedar

Special features: pristine wilderness except for dams; white-water rivers

Fragmentation: 33 major dams and control structures, many for hydropower

Water quality: no major pollutants but increased nutrients; total N = 0.30 to 1.00 mg/L, total P = 0.006 to 0.06 mg/L, alkalinity = 15 to 45 mg/L as CaCO₃

Land use: <5% agriculture, 30% forestry activities, <1% urban, remainder is natural

Population density: 0.6 people/km²

Major information sources: Heinselman 1970, 1973, www.rom.on.ca 2004, Schindler 1990, 2001, Scott and Crossman 1973, www.pca.state.mn.us 2003

FIGURE 19.17 Map of the Winnipeg River basin. Physiographic provinces are separated by a yellow line.

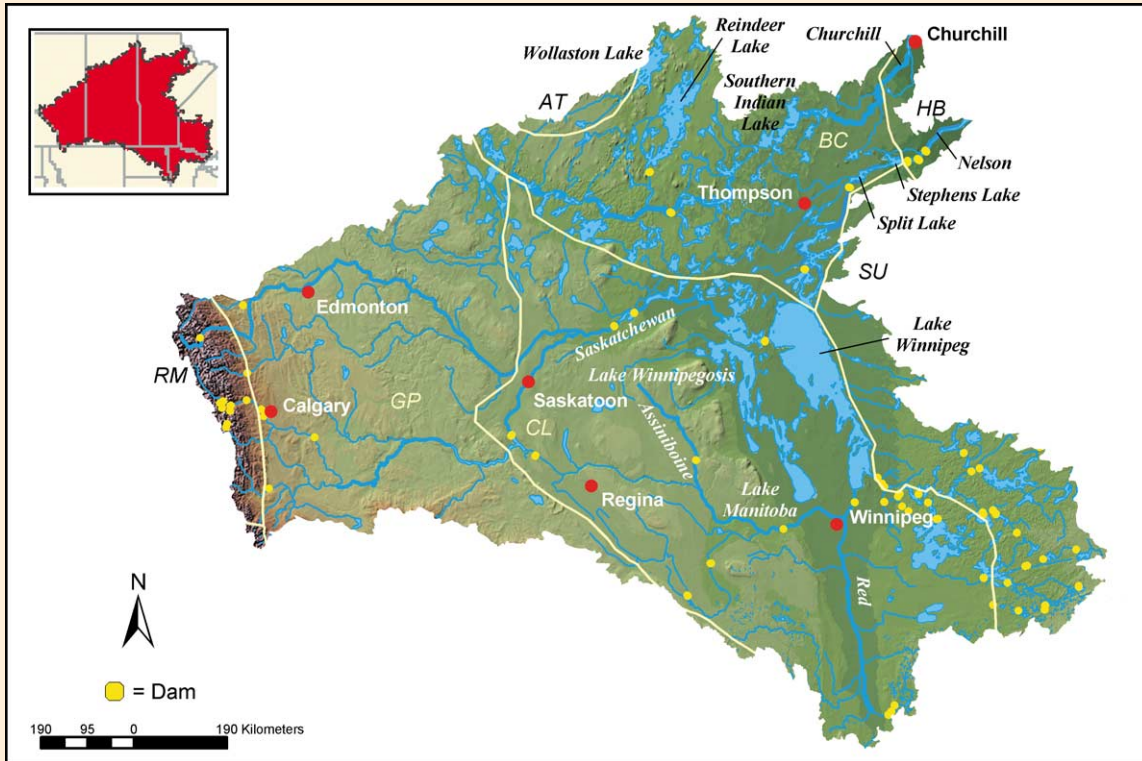

FIGURE 19.19 Map of the Nelson River basin. Physiographic provinces are separated by yellow lines.

NELSON RIVER

Relief: 218 m (main stem only) 3370 m (entire basin)

Basin area: 89,000 km² (main stem only) 1,093,442 km² (entire basin)

Mean discharge: 2480 m³/s

River order: 9

Mean annual precipitation: 52 cm

Mean air temperature: -3.4°C

Mean water temperature: NA

Physiographic provinces: Bear-Slave-Churchill Uplands (BC), Hudson Bay Lowland (HB) (main stem only); five other provinces for entire basin

Biome: Boreal Forest

Freshwater ecoregion: Lower Saskatchewan

Terrestrial ecoregions: Midwestern Canadian Shield Forests, Southern Hudson Bay Taiga (main stem only)

Number of fish species: 46 (main stem); >94 (entire basin)

Number of endangered species: NA

Major fishes: lake sturgeon, northern pike, brook trout, lake cisco, lake whitefish, longnose sucker, white sucker, burbot, walleye

Major other aquatic vertebrates: beaver, muskrat, mink, beluga whale, bearded seal

Major benthic invertebrates: chironomid midges, copepod crustaceans, oligochaete worms, snails (*three-ridge valvata*, swamp lymnaea, *Gyraulus*, *Physa gyrina*), bivalves

Nonnative species: NA (for main stem)

Major riparian plants: black spruce, tamarack, willow, alder, swamp birch, paper birch, trembling aspen, white spruce

Special features: on main stem, ice-caused "top hat" appearance of islands and "trimmed" shorelines in some reaches; pictographic sites throughout the region

Fragmentation: five hydropower dams on main stem; sites identified for future dams

Water quality: no major pollutants, some problems near population centers, sediment problems connected with Churchill River diversion; pH = ~8.0, alkalinity = ~100 mg/L as CaCO₃ (total), NO₃ + NO₂-N = ~15 mg/L, total N (Kjeldahl) = ~0.70 mg/L, total P = ~30 µg/L

Land use: main stem largely natural boreal forest, localized mining, hydropower, natural resource harvesting (aboriginal population); entire basin 34% forest, 51% cropland, 5% grassland, 2% shrub

Population density: ≤0.5 people/km² (main stem); 5 people/km² (entire basin)

Major information sources: FEMP 1992a, 1992b, 1992c, Newbury 1990a, Revenga et al. 1998

FIGURE 19.20 Mean monthly air temperature, precipitation, and runoff for the Nelson River basin.

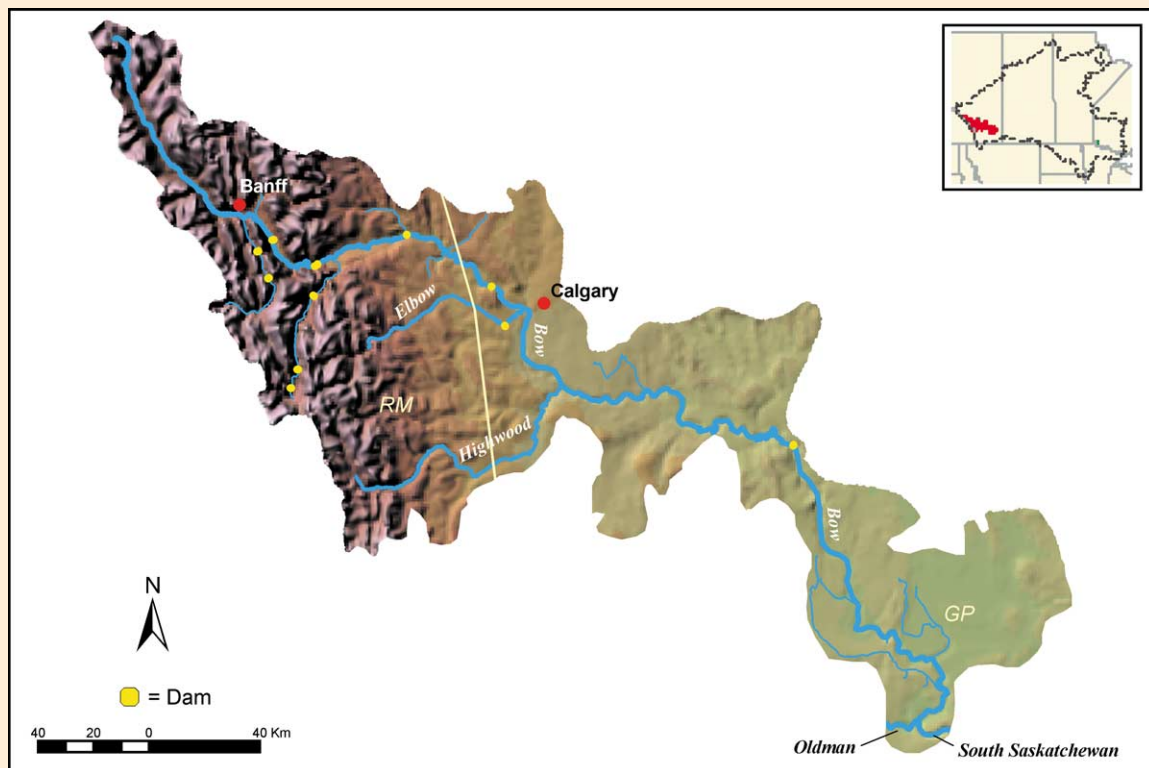

FIGURE 19.21 Map of the Bow River basin. Physiographic provinces are separated by a yellow line.

BOW RIVER

Relief: 2803 m

Basin area: 26,200 km²

Mean discharge: 91 m³/s

River order: 6

Mean annual precipitation: 40 cm

Mean air temperature: 3.9°C

Mean water temperature: 8.0°C

Physiographic provinces: Rocky Mountains in Canada (RM), Great Plains (GP)

Biomes: Temperate Mountain Forest, Temperate Grasslands

Freshwater ecoregions: Canadian Rockies, Upper Saskatchewan

Terrestrial ecoregions: Alberta Mountain Forests, Alberta/British Columbia Foothills Forests, Canadian Aspen Forest and Parklands, Montana Valley and Foothill Grasslands, Northern Mixed Grasslands, Northwestern Mixed Grasslands

Number of fish species: 29

Number of endangered species: NA

Major fishes: mountain whitefish, brook trout, brown trout, rainbow trout, bull trout, cutthroat trout, burbot, lake whitefish, northern pike, walleye, sauger, yellow perch, lake sturgeon, goldeye, mooneye, lake chub, emerald shiner, river shiner, spottail shiner, pearl dace, northern redbelly dace, quillback, longnose sucker, common white sucker, shorthead redhorse

Major other aquatic vertebrates: muskrat, beaver, mink, white pelican, Canada goose, bufflehead, common goldeneye, western grebe, gadwall, green-winged teal, horned grebe, lesser scaup, mallard, northern shoveler, pie-billed grebe, redhead

Major benthic invertebrates: mayflies (*Baetis*, *Cinygmula*, *Ephemerella*, *Epeorus*, *Heptagenia*, *Isonychia*, *Rhythrogena*), caddisflies (*Cheumatopsyche*, *Glossosoma*, *Rhyacophila*, *Symphitopsyche*), stoneflies (*Capnia*, *Isoperla*, *Taenionema*, *Zapada*), true flies (Chironominae, Orthocladiinae, *Pericoma*)

Nonnative species: brook trout, brown trout, rainbow trout

Major riparian plants: river alder, willow, poplar, water birch, red-osier dogwood, balsam poplar, sandbar willow

Special features: originates in glaciers and snowfields of Rocky Mountains in Alberta; World Heritage Site

Fragmentation: dams in mountains (for hydropower) and grasslands (for irrigation)

Water quality: pH = 8.1, alkalinity = 123 mg/L as CaCO₃; relatively free of pollutants in mountains (NO₃-N = 0.075 mg/L, soluble reactive phosphorus = 0.010 mg/L); nutrients higher below Calgary and in agricultural areas

Land use: 60% farmland (44% cropland), 2% urban, 38% forest

Population density: 42 people/km²

Major information sources: Donald and Mutch 1980, Culp and Davies 1982, Charlton et al. 1986, Cross et al. 1986, Hamilton and North 1986, Sosiak 1990, Culp et al. 1992, Environment Canada 2001, www.climate.weatheroffice.ec.gc.ca/climate_normals/index_e.html

FIGURE 19.22 Mean monthly air temperature, precipitation, and runoff for the Bow River basin.

FIGURE 19.24 Mean monthly air temperature, precipitation, and runoff for the Otter Tail River basin.

OTTER TAIL RIVER

Relief: 190 m

Basin area: 4507 km²

Mean discharge: 11.4 m³/s

River order: ~5

Mean precipitation: 67 cm

Mean air temperature: 5.4°C

Mean water temperature: 14°C

Physiographic province: Central Lowland (CL)

Biome: Temperate Grasslands

Freshwater ecoregion: English–Winnipeg Lakes

Terrestrial ecoregions: Upper Midwest Forest/Savanna Transition Zone, Western Great Lakes Forests, Northern Tall Grasslands

Number of fish species: 72

Number of endangered species: 1 lichen

Major fishes: golden redbhorse, northern hogsucker, shorthead redhorse, sand shiner, logperch, spotfin shiner, rock bass, black bullhead, yellow bullhead, brown bullhead, white sucker, pumpkinseed, largemouth bass, yellow perch, black crappie, walleye, common shiner, northern pike, channel catfish, smallmouth bass

Major other aquatic vertebrates: beaver, muskrat, snapping turtle, western painted turtle, mud puppy, tiger salamander, wood frog, western chorus frog, northern leopard frog, American toad, Great Plains toad, Canadian toad, Cope's gray treefrog, gray treefrog, mink frog, green frog

Major benthic invertebrates: mayflies (Heptageniidae, Oligoneuridae, Tricorythidae, Potamanthidae), stoneflies (Perlidae), caddisflies (Hydropsychidae, Leptoceridae)

Nonnative species: rainbow trout, brown trout, smallmouth bass

Major riparian plants: sugar maple, red oak, pin oak, tamarack, aspen, paper birch (east), basswood, bur oak, white oak (rare), American hazelnut, black willow, sandbar willow, peach-leaved willow, green ash, silver maple

Special features: high fish species richness for river size

Fragmentation: dams in upper and lower reaches

Water quality: pH = 8.2, specific conductance = 418 μS/cm, total P = 0.09 mg/L, total N = 0.22 mg/L, total dissolved solids = 252 mg/L

Land use: 43% cropland, 20% forest, 14% water, 13% wetland

Population density: low

RIVERS OF ARCTIC NORTH AMERICA

ALEXANDER M. MILNER MARK W. OSWOOD KELLY R. MUNKITTRICK

INTRODUCTION

NOATAK RIVER

KUPARUK RIVER

SAGAVANIRKTOK RIVER

MOOSE RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

This chapter covers rivers that lie within the Arctic region of North America, a vast area that encompasses northern regions of Alaska and Canada (Fig. 20.2). Some of the largest Arctic rivers (Mackenzie, Nelson–Churchill, and Yukon) are treated in other chapters. Although the Arctic is sometimes delineated by the Arctic Circle (66°32'N) (e.g., Rimmert 1980), which approximates the southern boundary of the midnight sun, this definition does not accurately reflect the characteristics of the region due to the overriding influence on climate of ocean currents and land mass topography (Barry et al. 1993). Consequently, the Arctic is frequently defined as regions north of the tree line, where mean July temperature does not exceed 10°C and at least one month is <0°C. These treeless areas or tundra cover an estimated 2.8×10^6 km² of Alaska and Canada (Bliss and Matveyeva 1992). There is a transitional zone (ecotone) between the treeless arctic tundra and the continuous closed-canopy woodlands of the boreal forest, including the subarctic, where white and black spruce dominate, and mean monthly air temperature does not exceed 10°C for more than four months of the year and at least one month is <0°C (Rimmert 1980). Thus, the coverage of the Arctic region in this

chapter (see Fig. 20.2) includes Hudson Bay in Canada, which extends as far south as 51°20', although the southerly part of the bay is more accurately considered the subarctic. The tree line also approximates the southern boundary of the zone of continuous permafrost, where the ground is permanently frozen and the surface (the active layer) thaws for only two to three months a year. As Hudson Bay is frozen for the greater part of the year, the Arctic front of cold air masses extends further south in Canada than in Alaska due to the presence of this inland sea. The treeless tundra extends to 58°40' south of Churchill.

Most archaeologists believe that the migration of humans into the New World occurred sometime between 15,000 and 50,000 years ago during the last Ice Age, when the Bering Land Bridge created a connection between Alaska and Siberia, termed Beringia (Langdon 1989). However these Paleo-Indians did not remain in Alaska but migrated southward to North, Central, and South America. When the Paleo-Eskimos (Old Eskimos) arrived across the Bering Straits from the Chukchi Peninsula of Siberia, they discovered the last major region on earth unoccupied by humans. The first discoveries of settlements date back 3000 to 4000 years, but they may have arrived earlier. By approximately 4000 years ago most areas

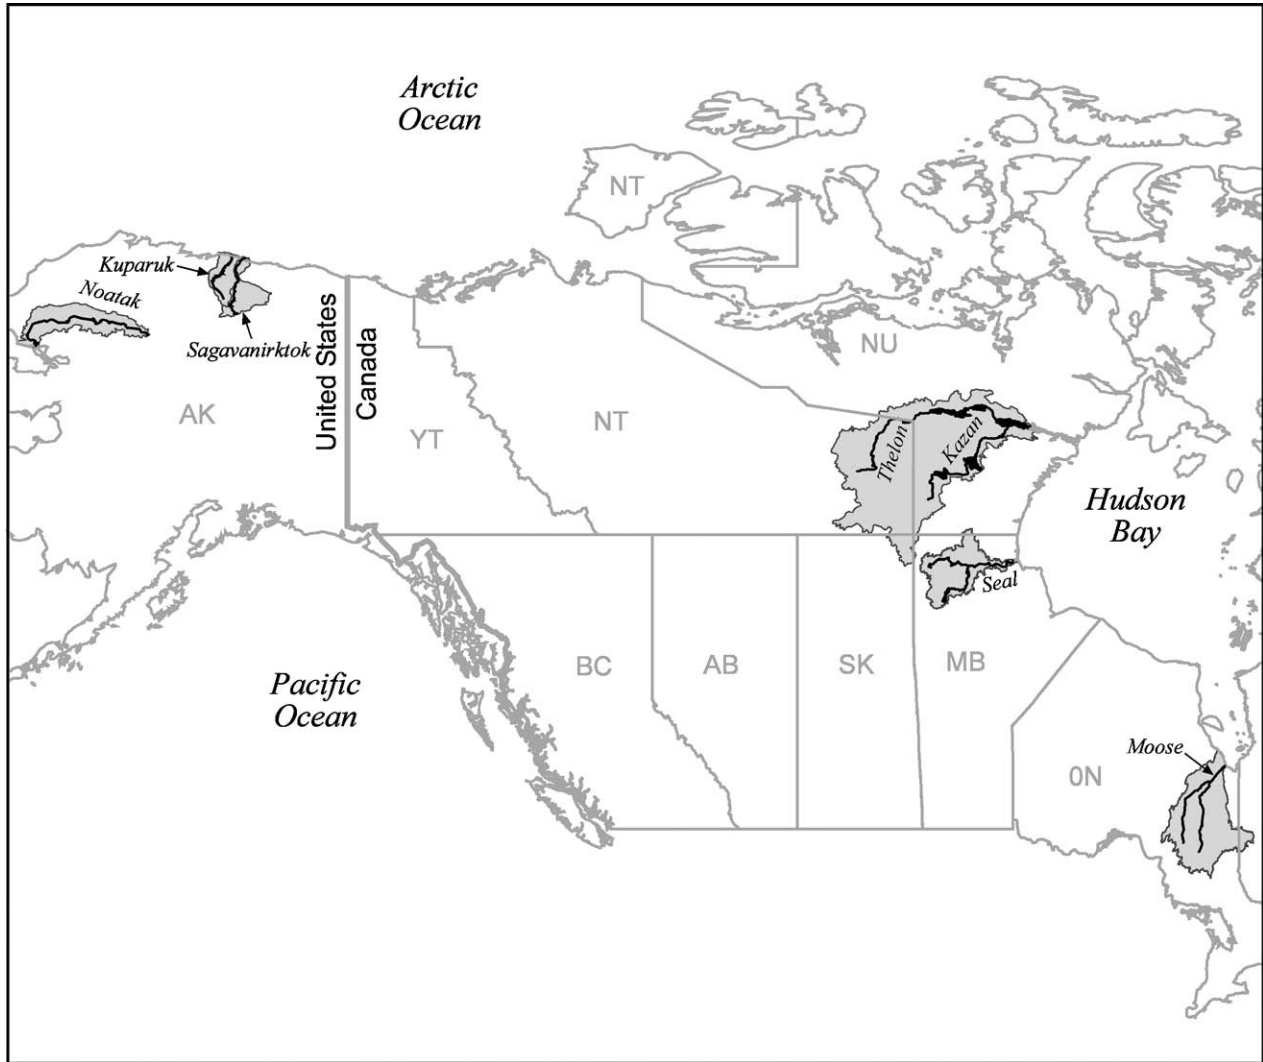

FIGURE 20.2 Rivers of Arctic North America covered in this chapter.

of Arctic Alaska, Canada, and Greenland were home to small and scattered bands of these Paleo-Eskimos (McGhee 1996). Although termed “Old Eskimos,” these groups had little connection to the Eskimo groups typical of the region today. Their way of life was very different, as they lived in very marginal conditions, particularly during the winter. The Northern Eskimos, the Inuit of Alaska and Canada, arrived more recently and descended from inhabitants originally in Alaska.

In this chapter, we will focus on four rivers (three from Alaska and one from Canada) within the Arctic region. These rivers represent a spectrum from pristine unimpaired waters (the Noatak and Kuparuk rivers) to those potentially influenced by oil development (the Sagavanirktok River) and finally to a large

river system flowing into Hudson Bay that has been influenced by hydroelectric dams and other basin development, including mining and forestry (the Moose River). Additional river catchments (Seal, Thelon/Kazan), described briefly, lie within Canada; each is designated as a Canadian Heritage River.

Physiography and Climate

The Noatak, Kuparuk, and Sagavanirktok rivers have their sources within the Brooks Range (BM) physiographic province in northern Alaska (Hunt 1974). Here the mountains are lower than the Alaska Range, with elevations to 3000 m. The Noatak catchment lies entirely within this province, flowing westward to its estuary at Kotzebue Sound of the Chukchi

Sea. Most reaches of the Kuparuk and Sagavanirktok rivers flow across the Arctic Slope (AS) province before entering the Beaufort Sea of the Arctic Ocean. The Sagavanirktok River essentially divides the Arctic Slope into two distinct areas: a broader western section and a narrower eastern section. The Arctic Slope is considered a continuation of the interior plains of North America, whereas the Brooks Range is an extension of the Rocky Mountains (Wahrhaftig 1965). South of the Arctic Lowlands but north of the enormous Nelson River basin are the Thelon/Kazan and Seal rivers, both of which flow into the western side of Hudson Bay. The Thelon/Kazan River drains both the Thelon Plains and Bear River Lowland (TB) and the Bear-Slave-Churchill Uplands (BC), and the Seal River drains entirely from the Bear-Slave-Churchill Uplands. Much further to the south and east is the Moose River. The Moose and its tributaries have their headwaters in the Superior Upland (SU) and then flow northward across the Hudson Bay Lowland (HB) before flowing into Hudson Bay.

During the Wisconsin glaciation, the last of the Pleistocene stages, which ended about 10,000 years ago, half of North America was covered by major ice sheets. These ice sheets were present in the Brooks Range and the Alaska Range, but much of the Arctic Slope remained ice free.

The Arctic climate is characterized by extremely low annual precipitation, typically <15 cm/yr, which falls mostly as snow, although higher levels are typically found in the mountain ranges and the Hudson Bay region (70 to 90 cm in the Moose River drainage). The low rates of precipitation are similar to deserts, explaining why the High Arctic (northern portion of the Canadian Arctic Islands) is sometimes classed as a polar desert, with sparse vegetation. Mean monthly temperatures in the Alaskan arctic range from -29°C in January to 10°C in July (University of Alaska 1989), whereas in the Moose River drainage of Canada the range is -19°C to 17.3°C (Environment Canada 1982a). Daylight is continuous in the summer, but in the winter the sun may not appear over the horizon for four months. Cold dominates the landscape and influences both physico-chemical and biotic processes in terrestrial and aquatic environments.

Basin Landscape and Land Use

Permafrost has a major influence on the landscape of the Arctic region and rivers flowing within it, resulting in dominance by thermokarst features. Per-

mafrost can be up to 600 m in thickness (Brown and Kreig 1983), with depths of thaw as little as 50 cm. Discontinuous permafrost is commonly associated with the boreal forest, particularly on south-facing slopes, where the depth of the seasonal thaw may exceed 2 m.

Regular freezing and thawing of permafrost within the active layer creates surficial thermokarst features, which may appear as characteristic polygons, circles, or stripes from the air. These features are termed “patterned ground.” Another common feature is pingos, which are large ice-cored mounds up to 600 m in diameter but typically less than 20 m high (Pissart 1988). Innumerable thaw lakes, characteristic of the landscape, are created where permafrost melts and the overlying soil collapses below the water table. Over 95% of the wet coastal tundra of the Arctic is made up of thaw lakes, which range in length from several hundred meters to several kilometers (Billings and Peterson 1980).

The three Alaskan rivers encompass three terrestrial ecoregions (Ricketts et al. 1999): the Brooks/British Range Tundra, the Arctic Foothills Tundra, and the Arctic Coastal Tundra (except the Noatak River). Subalpine vegetation of the Brooks/British Range is restricted to valleys and lower slopes and is composed mainly of stunted white spruce, willow, dwarf birch, and blueberry. At higher elevations alpine tundra is made up of lichens, mountain avens, sedge, and cotton grass (Ricketts et al. 1999). The Arctic Foothills Tundra forms a transition between the flat low-lying Arctic Coastal Tundra and the steeper terrain of the Brooks/British Range Tundra. The Arctic Foothills Tundra is better drained than the Arctic Coastal Tundra; the vegetation is dominated by sedges, cotton grass, and dwarf shrubs of birch, blueberry, crowberry, and Labrador tea. The Arctic Coastal Tundra has poor drainage, so sedges and grasses predominate on the wet soils. The cover of moss is nearly continuous, although better-drained sites may support dwarf shrub communities. Along the river corridors riparian dwarf birch and willow are characteristic but rarely exceed 1 m in height (Hershey et al. 1997). In Canada, the Thelon/Kazan basin lies partly within the Low Arctic Tundra terrestrial ecoregion. This ecoregion stretches across much of northern Canada, from (west to east) the Northwest Territories, through southern Nunavut, and edging into Quebec. Nearly the entire region is underlain by permafrost. Much of the vegetation in the rolling uplands and lowlands of the Low Arctic Tundra is shrubby tundra, with some areas having trees (including white spruce, black

spruce, and tamarack) and so transitional between treeless tundra to the north and taiga forest to the south. Further south, in central Canada along the western shore of Hudson Bay, is the Northern Canadian Shield Taiga ecoregion. The vegetation is transitional, with stunted black spruce and tamarack dominant. Much of the basins of the Thelon/Kazan and Seal rivers drain from this ecoregion. The Seal also traverses a short stretch through the Southern Hudson Bay Taiga ecoregion. Still further south and to the east, the Moose River drainage traverses, from its southern headwaters to its mouth at James Bay, three ecoregions: the Eastern Forest/Boreal Transition, the Central Canada Shield Forests, and the Southern Hudson Bay Taiga. The Moose River thus flows through a latitudinal and ecological transect, from forests of mixed deciduous and coniferous species and temperate climate in the south to stunted conifers and a subarctic climate in the north.

The inclement climate, with long, cold, and dark winters, limits human populations in Arctic Alaska and Canada. Barrow, the largest village in the Alaskan Arctic, has approximately 2400 residents as a mix of Eskimos and Caucasians. Barrow lies 16 km southwest of Point Barrow, the most northerly point in the United States (71°23'29"N). Point Barrow was named by Captain Beechey in 1826 for Sir John Barrow, then president of the Royal Geographical Society. Urban populations are higher in some of the more southerly parts of Arctic Canada. In the Moose River drainage, the largest towns are Kapuskasing, with over 12,000, and Timmons, exceeding 45,000.

Low population densities have limited urbanization effects on rivers of the Arctic region. However, the Arctic region is rich in natural resources, particularly oil and gas. Exploitation and export of oil on Alaska's North Slope is the main driver of the Alaskan economy, and is responsible for more than 80% of state income. Construction and operation of the Trans-Alaskan Pipeline, which connects the oil fields at Prudhoe Bay with the ice-free oil terminal in Valdez, runs along or crosses a number of rivers, particularly the Sagavanirktok River.

The Rivers

The river systems discussed in this chapter span a diagonal swath across the top of North America, from the Noatak River drainage in the northwest extreme of Alaska to the Moose River drainage discharging into the south of Hudson Bay at the southeast extreme (see Fig. 20.2). The Alaskan rivers have their origins in the Brooks Range and are fed princi-

pally by snowmelt, with some groundwater and glacial influence. Because of the low elevations in the Canadian Arctic, rivers are generally fed by lakes, of which there are many large ones, including Great Bear Lake and Great Slave Lake of the Mackenzie River system. As is typical for most of interior and northern Alaska, biological data for some of the drainages are largely derived from infrequent "expeditions" meant to provide surveys of major taxa and information on fish species of sport, subsistence, or commercial importance. Studies of ecological processes (e.g., biological production, carbon and nutrient budgets) require long-term frequent measurements. These studies have mostly been done in proximity to research stations (e.g., the Naval Arctic Research Laboratory in Barrow and the Toolik Lake Biological Station) or as "Big Science" (well-funded, multidisciplinary projects), such as the International Biological Program (IBP) and the Long Term Ecological Research (LTER) program (Hobbie 1997).

The freshwater ecoregions of the North American Arctic are primarily nested within two large complexes. The Noatak, Kuparuk, Sagavanirktok, Thelon/Kazan, and Seal systems are included in the Arctic complex. The Moose River is the only river in this chapter found in the Hudson Bay complex. The Noatak, Kuparuk, and Sagavanirktok of Alaska are found within the Yukon freshwater ecoregion even though they are not directly connected to the Yukon River to the south. The East Arctic ecoregion along the western shore of Hudson Bay includes the Thelon/Kazan and Seal rivers. Belonging to the Hudson Bay complex is the South Hudson ecoregion, which is found along the southern shore of Hudson Bay and includes the Moose River. The East Hudson ecoregion is along the east shore of the bay, but its rivers are not covered in this chapter.

The unifying theme of these river systems is not entirely an Arctic climate (as climates of these river systems range from Arctic to subarctic) but rather a general "northern syndrome." This northern syndrome derives from the ecological and historical consequences of cold: ice in rivers (surface ice and frazil ice), ice in the landscape (glaciers and permafrost), thermal limitations on carbon flow and growth rates, and the biogeographical consequences of Pleistocene ice sheets (Oswood 1997). At the maximum extent of glaciers during the Wisconsin period the Laurentide ice sheet (in the east) and the Cordilleran ice sheet (in the west) covered nearly all of present-day Canada and a strip across the northern United States (McPhail and Lindsey 1970, Pielou 1991). However, much of interior Alaska was unglaciated and con-

nected via the Bering Land Bridge to Asia, producing a glacial refugium (Beringia). Following the retreat of continental glaciers at the Pleistocene/Holocene transition (approximately 10,000 to 12,000 years ago) the fish fauna of northern river systems derived from three centers of dispersal: Beringia; a Pacific refuge (south of the continental glaciers and west of the Rocky Mountains); and a Mississippi/Missouri refuge (northern tributaries of the Gulf of Mexico drainage; west of the Appalachian mountains and east of the Rocky mountains) (McPhail and Lindsey 1970). Consequently, the fish fauna of Alaska is dominated by fishes derived from the Beringian refuge, including endemics (e.g., the Alaskan blackfish) (Pielou 1991, Power 1997) and fishes from the Pacific refuge, many moving northward along the Pacific coast via saltwater excursions (McPhail and Lindsey 1970, Oswood et al. 2000). Conversely, inland dispersal from the Mississippi/Missouri refuge dominated postglacial colonization of northern river systems in north-central North America (McPhail and Lindsey 1970).

Streams and rivers in Arctic Alaska and Canada display unique physicochemical characteristics, due in many respects to the influence of snow and ice. Hydrological regimes are characterized by very low or no winter flows from October through early May. Subsequently, high solar radiation creates rapid snowmelt, so that 80% to 90% of the annual flow in many Arctic streams occurs within a two-week period during June (Milner et al. 1997). Low discharges then occur until convective thunderstorms increase flows in late July and early August. Where glacial influence is present, flows are more sustained through the summer months. Due to the influence of continuous permafrost, meltwaters are unable to infiltrate deep into the soil, creating a major paradox of the Arctic: the wetness of the Arctic region, with countless ponds, lakes, and muskegs, even though rainfall is more characteristic of desert environments.

In glacier-fed rivers, major diurnal fluctuations in discharge occur as air temperatures vary widely over a 24 hr period during the summer months, influencing the extent of ice melt. Water quality (e.g., sediment load) in glacier-fed systems may also vary both seasonally and diurnally. Groundwater-dominated systems display greater stability in discharge, water temperature, and sediment load and may provide refugia to biota from the harsher habitats of snowmelt and glacier-fed systems, particularly during the winter. In nonglacially influenced rivers, water temperature may increase downstream as rivers approach their estuaries and the ocean.

Taxonomic richness and growth rates of consumers in rivers typically decrease with increasing latitude in the Arctic (Oswood et al. 1995). Low annual solar radiation and low air temperature result in extensive ice formation in river basins, which has a major influence on the overwintering survival of both macroinvertebrates and fishes, particularly during ice breakup (Scrimgeour et al. 1994, Prowse 1994). Mortality at this time of year can limit ecosystem productivity, but its effect is extremely variable from year to year depending upon the severity of the winter and the ice breakup. Overwintering influences can cause macroinvertebrate taxa to be present in a river one year but then absent the next (Milner et al. 2005). The annual thermal regime also determines taxa distributions, organism adaptations, and ecosystem productivity (Ward and Stanford 1982). Many taxa typical of more temperate waters have difficulty completing their life cycles in Arctic freshwaters and thus are absent or rare (Oswood 1997). Hence, water temperature acts as a limiting factor or reach-scale filter (Poff 1997) to taxa diversity such that Diptera (true flies) dominate the macroinvertebrate fauna in Arctic rivers (Oswood 1989).

Because shallow streams and rivers generally freeze to the substrate, resident and juvenile anadromous fishes migrate in the fall to ice-free refugia for overwintering. These refugia can be lakes, ponds, spring- or groundwater-fed streams, or deep wintering pools. When overwintering, fishes undergo behavioral and physiological changes to limit energy loss and territoriality is reduced (Reynolds 1997). Wintering pools are often used by several species and life stages of fishes and high densities can lead to mortality through oxygen depletion and accumulation of metabolic wastes (Schmidt et al. 1989). Overwintering mortality is probably the most limiting factor to fish production throughout the northern region. Amphidromous fishes (e.g., Arctic char, Arctic cisco, broad whitefish, and Dolly Varden) spawn and overwinter in rivers and streams and migrate to the lower reaches or deltas of larger rivers each summer (e.g., the Sagavanirktok and Colville rivers) (Reynolds 1997). The summer is a period of intense feeding, when most of the yearly growth occurs to survive the long winter (Fechhelm et al. 1995, Fechhelm et al. 1996).

Some Arctic rivers along the northern coastlines of North America, particularly the larger drainages, provide transport pathways from the terrestrial environment to the ocean and may carry pollutants from contaminated land to the continental shelves of the northern oceans (AMAP 1997). Pollutants are trans-

ported in the water, bound to sediment, or associated with river ice. Some contaminants settle in delta and estuarine areas, whereas others reach the marine environment. Many of these contaminants originate outside the Arctic region from industrialized nations in Europe and North America.

Streams and rivers of the Arctic are potentially more likely to be influenced by climate change than many other North American basins, as climate warming is predicted to be more amplified at higher latitudes (Melack et al. 1997). In a landscape dominated by permafrost influences, enhanced melting of permafrost and associated increases in the depth of the active layer would markedly influence hydrology and watershed biogeochemistry (Oswood et al. 1992). Tundra and boreal forest soils are major stores of carbon and increases in the depth of the active layer and soil warming may enhance carbon availability and increase levels of dissolved organic carbon transported to surface waters (Oswood et al. 1992). We have already discussed the harsh temperature regimes in Arctic rivers limiting the diversity of aquatic insects and fishes, but with an amelioration of water temperature regimes from global climate change a northward extension of certain taxa may occur, increasing their geographical distribution (Poff et al. 2001). Although macroinvertebrate diversity may thus increase in Arctic rivers, certain present-day taxa well adapted to the harsher environment may be eliminated with enhanced diversity, as they are typically poor competitors (i.e., fugitive species; see Flory and Milner 1999).

Unlike most of North America, hydroelectric power generation in northern Alaska has not had a significant influence on river basins, but in Canada, particularly on a number of the rivers flowing into Hudson Bay, dams have exerted a major influence on river hydrology. Nevertheless many free-flowing rivers remain and the Arctic region provides a unique collection of pristine rivers where longitudinal changes along the continuum can be studied without anthropogenic influence.

NOATAK RIVER

The Noatak River flows primarily in a westward direction in northwest Alaska and is the only major river lying almost entirely within the Brooks Range (Fig. 20.8). In contrast, other major arctic rivers of Alaska (e.g., the Kuparuk and Sagavanirktok) flow northward from the northern foothills of the Brooks Range, draining into the Arctic Ocean. The Brooks

Range is the northern extension of the Rocky Mountains, arcing east–west across northern Alaska from the Canadian border to within 100 km of the Chukchi Sea. The Brooks Range demarcates a major biogeographic divide: arctic tundra to the north and taiga forest to the south. Elevations are higher in the central and eastern mountains (up to 2400 m asl) and lower at the western end (up to 800 m asl). The Brooks Range is comprised of several major mountain groups. The Noatak River arises at Mount Igikpak in the Schwatka Mountains, then flows westward between the Baird Mountains and the De Long Mountains to the village of Noatak (Fig. 20.3). From the village of Noatak the river swings south to flow into the Kotzebue Sound of the Chukchi Sea, north of the town of Kotzebue (Williams 1958, Gallant et al. 1995).

The Noatak River valley is a historical and current home of the northern Eskimos—the Inupiat—one of five major groups of Alaska’s indigenous people (Langdon 1989). Archaeological work in northern Alaska suggests occupation as early as 11,700 years ago. Contact with European explorers began in the mid-1800s and gold-mining exploration produced the first maps of the area by the early 1900s (www.nps.gov/asko/akarc/index.htm 2004). The Inupiat people occupying the Noatak basin before contact with Western civilization belonged to the Noatagmiut (middle and upper Noatak) and Nau-paktomiut (lower Noatak) (Hall 1975, www.nps.gov/asko/akarc/index.htm 2004). The “miut” suffix means “people of” (Langdon 1989). Noatak was a fishing and hunting camp in the nineteenth century (Maniilaq Association 2001). A federally sponsored mission school begun in 1908 made Noatak a regional center for school, trade, and religion (www.nps.gov/asko/akarc/index.htm 2004), and a post office was established in 1940.

Physiography, Climate, and Land Use

The Noatak River basin lies entirely within the Brooks Range (BM) physiographic province (see Fig. 20.8; Hunt 1974) and the Brooks/British Range Tundra and Arctic Foothills Tundra terrestrial ecoregions (Ricketts et al. 1999). The entire basin is underlain by permafrost, with depths likely as great as 183 to 244 m (Childers and Kernodle 1981). Although the Arctic tree line is often used as an approximate boundary between the Arctic and subarctic biomes, the basin contains biotic elements of both the Arctic and subarctic (taiga) (Young 1974, Gallant et al. 1995). In the lower Noatak drainage, there are scattered groves of

FIGURE 20.3 Noatak River, Alaska (PHOTO BY A. MILNER).

white spruce, as well as balsam poplar groves throughout the drainage. However, most (95%) of the Noatak River valley supports tundra vegetation, with taiga vegetation less than 5% (Young 1974).

The climate of the Noatak drainage changes from its lower reaches near the Bering Sea coast, where climate is moderated by ocean influences, to its upper reaches in the Brooks Range Mountains, where a more rigorous continental climate prevails (Milner et al. 1997, Green 1999). Winter in northwestern Alaska and the Noatak drainage is long and cold; summer is short and often wet (Childers and Kernodle 1981). Weather records for Noatak village

are sparse; we use weather data from Kotzebue as a surrogate for the lower Noatak valley and from Kobuk as a surrogate for the upper Noatak valley. The average temperature in July (warmest month) is 12°C in Kotzebue (29°C record high) and 14°C in Kobuk (33°C record high), providing an estimated average of 13°C for the Noatak basin (Fig. 20.9). The average temperature in February (coldest month) is -20°C in Kotzebue (-47°C record low) and -23°C in Kobuk (-56°C record low), for an estimated average of -22°C in the Noatak basin. The cooler summer/warmer winter temperatures in coastal Kotzebue compared to inland Kobuk highlight the

transition from maritime influence to a cold continental climate inland from the coast. Most precipitation falls as rain in the summer, with rainfall peaking in August (see Fig. 20.9). Total precipitation averages 24.1 cm (126.5 cm of snow) in Kotzebue and 42.4 cm (137.2 cm of snow) in Kobuk. The Noatak River is north of the Arctic Circle and so is a “place of deep cold, the midnight sun, and the long polar night” (Young 1989).

Noatak village is the only current settlement in the Noatak valley. Thus, land use in the basin is essentially 100% natural tundra and taiga, and human population density is close to 0 people/km². Subsistence use of natural resources remains central to the people of Noatak, with harvest of chum salmon, whitefish, waterfowl, caribou, and moose (www.Alaska.com 2002). There is no road access to the Noatak River basin, but there are scheduled flights to Noatak village and bush plane access throughout the valley. Boats and ATVs (summer) and dog sleds and snow machines (winter) are used for local travel. For the Inupiat people of Northwest Alaska, it is “as if you’re viewing the aftermath of a violent collision between the past and the present”; the challenge is to “walk in two worlds with one spirit—to hunt caribou and then sit down at a computer, or sew mukluks and later balance a checkbook” (Jans 1993).

River Geomorphology, Hydrology, and Chemistry

The Noatak River basin occupies 32,626 km², with an elevation drop of approximately 1067 m from headwaters to the mouth (Childers and Kernodle 1981); Mount Igikpak is the highest elevation (2612 m asl) in the drainage. The elevational profile shows three distinct gradients: short steep reaches of the headwater branch and mountain tributaries, a modest gradient (approximately 76 cm/km) over most of the Noatak main stem, and a low-gradient segment (about 19 cm/km) in the estuarine lower reaches (Childers and Kernodle 1981). Young (1974)—working from Smith (1913) and Wahrhaftig (1965)—designates six major regions along the longitudinal profile of the Noatak drainage. These regions can be summarized as follows, from headwaters to the mouth:

- **Headwater Mountains:** Tributary streams, fed by snow and mountain glaciers, enter the main stem from U-shaped (glacially carved) valleys. The main stem meanders through a 3.2 km wide valley in glacial and fluvial sediments.

- **Aniuk Lowlands:** The Noatak meanders through gently sloping, rolling hills; in some locations the river is incised from 15 to 61 m in the glacial and fluvial sediments. Two large tributaries enter in this province: the Aniuk and Cutler rivers.

- **Cutler River Upland:** Pinched between the Baird Mountains and De Long Mountains, this region contains the upper reaches of the Cutler River. The Noatak River has cut a deep (183 to 244 m) canyon through quartzite, sandstones, limestones, and igneous intrusives; elsewhere, steep bluffs of gravel limit the floodplain.

- **Mission Lowland:** The Noatak turns south, flowing through a broad expanse of tundra, with numerous thaw lakes and pingos in the wet tundra of the floodplain. In the north and central portions of this province, the Noatak is a wide (3.2 km) braided river, coalescing into a single channel in the southern portion.

- **Igichuck Hills:** The Noatak cuts through limestone and calcareous schist, creating a canyon (Lower Noatak Canyon); floodplain development is minimal.

- **Coastal Lowland:** In this region of low relief, the Noatak flows in a single channel through alluvial, marine, and glacial sediments. As the river nears its mouth at Kotzebue Sound it branches into distributaries and forms a small delta.

Along the main stem, from near the headwaters (Ipnelivik River) to the confluence of the Eli River (near Noatak village), the river has a pool–riffle sequence with pool lengths ranging from 305 to >1524 m, pool widths from 61 to 213 m, and pool (maximum) depths from ~0.6 m to ~2.4 m. Bed materials along this sequence range from coarse gravel to large boulders (Childers and Kernodle 1981).

Permafrost is essentially continuous in the Noatak basin. Permafrost restricts infiltration of precipitation into deeper groundwater, producing “flashy” hydrographs in response to precipitation (Childers and Kernodle 1981, MacLean 1997, Milner et al. 1997). Streams begin to freeze in October, with streamflow from most streams ceasing by December; discharge measurements show no flow from the upper basin (upstream of Noatak Canyon) by late winter. Breakup of river ice occurs in May, with snowmelt producing high streamflow in June (Childers and Kernodle 1981). Some streams and river segments are frozen to the bottom but deeper sections may have water (with little or no current) beneath deep ice cover. Occasional springs, visible in winter as open water and massive icings, have perennial flow (Childers and Kernodle 1981). The winter

freezing in Alaskan Arctic running waters, with ice extending to the substrate or isolating shallow water beneath deep ice cover, forces migrations of fishes to suitable overwintering refugia (Craig 1989, Reynolds 1997) and limits the benthic macroinvertebrate fauna to taxa with behavioral (e.g., movement into deep streambed sediments) or physiological adaptations for avoiding or tolerating freezing (Oswood et al. 1991).

To our knowledge, there has only been one gaging station on the Noatak River (USGS 2003), located in the lower Noatak Canyon; winter data are sparse and unreliable (Childers and Kernodle 1981). Streamflow (see Fig. 20.9) is low in May (average flow 73 m³/s), peaks in June with snowmelt (average flow 1954 m³/s), and declines from July (820 m³/s) to August (756 m³/s) to September (493 m³/s). Freeze-up commences in October, producing much reduced flow (average 115 m³/s). Childers and Kernodle (1981) assessed streamflow and river conditions along a longitudinal profile of the Noatak River in 1978, once in late winter (April) and once in late summer (August). Winter streamflows were at or near zero in the upper basin and very low (<2.8 m³/s) in the lower basin. At low-flow conditions of late winter the lower Noatak River (near Noatak village) is tidally influenced, as indicated by high concentrations of sodium and chloride and high total dissolved solids. August streamflows along the Noatak River main stem ranged from approximately 28 m³/s in the upper basin to approximately 368 m³/s in the lower basin, near Noatak village.

Most surface waters in the Noatak basin are dominated by calcium bicarbonate, although magnesium is the dominant cation at some locations (Childers and Kernodle 1981). In late winter (April), water remaining beneath deep ice cover may have high concentrations of dissolved solids (Childers and Kernodle 1981). This cryoconcentration is due to exclusion of dissolved matter from the growing ice mass and hence concentration in the water remaining beneath the ice cover (Cheng et al. 1993). Similarly, dissolved oxygen concentrations were low in late winter at some sites in the Noatak drainage (Childers and Kernodle 1981) because of biotic respiration and isolation of water from atmospheric reaeration. High salinity, low oxygen concentrations, and ice encroachment beneath deep ice cover may make overwintering conditions inhospitable in Arctic running waters, forcing migrations of fishes to more suitable overwintering sites (Power et al. 1993, Reynolds 1997). In late summer (August), concentrations of dissolved oxygen were at or near satura-

tion throughout the basin, with water temperatures ranging from 10°C to 13°C. Along the main-stem sampling sites alkalinity ranged from 82 to 110 mg/L as CaCO₃ and pH from 7.8 to 8.2. The dominant cations were calcium (range 37 to 57 mg/L) and magnesium (range 8 to 16 mg/L); dissolved NO₂-N + NO₃-N ranged from 0.07 to 0.21 mg/L (Childers and Kernodle 1981).

River Biodiversity and Ecology

The Noatak River belongs in the Yukon ecoregion, the largest freshwater ecoregion in North America, incorporating most of Alaska and the Yukon Territory (Abell et al. 2000). In the remote and roadless regions of Alaska, biological data are often derived from expeditions and collecting trips. These expeditions generally provide qualitative data (e.g., taxa lists) from short-term visits (usually in summer). The isolation that makes the Noatak River such an outstanding biological reserve is mirrored in the lack of logistical support afforded by a research station or road access; the summaries here reflect the limitations of expeditionary biology.

Algae and Cyanobacteria

Data for running waters of the Noatak basin are sparse. Wiersma et al. (1986) collected epilithic periphyton samples from the Avan River, a tributary of the Noatak River. Cyanobacteria included *Coelospherium* and *Oscillatoria*. Chlorophyte algae included *Gleocystis*, *Mougeotia*, and the desmids *Cosmarium* and *Staurastrum*. Typical of northern Alaska, the taxonomic composition was dominated by diatoms: *Achnanthes*, *Amphora*, *Cymbella*, *Diatoma*, *Hannaea*, *Fragilaria*, *Melosira*, *Meridion*, *Synedra*, *Didymosphenia*, *Navicula*, *Pinnularia*, and *Nitzschia*.

Plants

Aquatic macrophytes appear to be sparse in the running waters of the Noatak Valley, confined to slow-moving streams in lowland areas. Young (1974) notes that aquatic vegetation is not well represented, even in small slow-moving streams, but that a few kinds, particularly northern bur-reed and Pallas' buttercup, are often abundant.

Invertebrates

Information on benthic macroinvertebrates is limited, but data (to order or family) are available from 13 lotic sites in August (Childers and Kernodle 1981). Nonbiting midges (Diptera: Chironomidae)

were found at every site and were a substantial portion of the fauna, averaging 33% of organisms collected (numerical abundance). Craneflies (Diptera: Tipulidae) were found at most sites but in low abundance. Black flies (Diptera: Simuliidae) were found at some sites, in low abundance. Mayflies followed a similar pattern, with the families Baetidae and Heptageniidae found at nearly every site, and mayflies often composed a considerable portion (25% to 50%) of the fauna. The Brachycentridae dominated the caddisfly fauna, but even brachycentrids were only found at low abundance at fewer than half of the collecting sites. Other caddisfly families (Leptoceridae, Hydropsychidae, Molannidae, Rhyacophilidae) were found sporadically at low abundances. Stoneflies (Chloroperlidae, Nemouridae, Perlodidae) likewise occurred sporadically, nearly always at low abundance. Among the noninsect macroinvertebrates, snails were found at only a few sites. However, water mites (Acarina) were ubiquitous and generally major elements of the fauna. The presence at many collecting sites of crustaceans and insects generally associated with lentic habitats—seed shrimps (Ostracoda), water fleas (Cladocera), diving beetles (Dytiscidae), water boatmen (Corixidae)—likely indicates drift from upstream ponds, lakes, or slow-moving streams. Taxa in life history stages (at late summer) not likely to be captured by dip net sampling of benthic substrates (eggs, recently hatched larvae, and terrestrial adults) will be missed or under-represented. Nonetheless, the general dominance of the benthic fauna by true flies (especially chironomid midges), dominance by mayflies of the families Baetidae and Heptageniidae, and sparse representation of caddisflies is consistent with northwestern Alaska in particular and Alaska in general (Oswood 1989).

Vertebrates

Information on fish fauna is also very limited, but there appear to be about 18 fish species in the running waters of the Noatak drainage (McPhail and Lindsey 1970, O'Brien and Huggins 1974, Morrow 1980, Cappiello 1995). The fish fauna of the Noatak River is dominated by the family Salmonidae, including whitefish, grayling, trout, and salmon. Apparently, all five species of Pacific salmon are present in the Noatak drainage: chinook, sockeye, coho, chum, and pink. Chum salmon are the only salmon taken in quantity from the rivers of northwestern Alaska (O'Brien and Huggins 1974). In 1982, a salmon hatchery (Sikusuliaq Springs) was constructed on the lower Noatak River, rearing chum salmon fry. Returning adults were taken in a commercial fishery in Kotzebue Sound and

for subsistence use by residents of Noatak village (Wilson and Kelly 1986). The hatchery has since closed. Arctic grayling are common throughout the drainage. Char (probably synonymous with northern Dolly Varden [Reynolds 1997]) support an important subsistence fishery, taken by seine, gill net, and hook and line from concentrations of fishes in overwintering areas (Cappiello 1995). Three (possibly five) whitefishes are found in running waters of the Noatak drainage: humpback whitefish, round whitefish, and least cisco. The Noatak drainage lies within the known ranges of two other whitefishes, broad whitefish and Bering cisco. Whitefishes are important in native subsistence fisheries on the Noatak River. A memorable essay describing subsistence gill-net fishing on the Kobuk River, just south of the Noatak River, can be found in Jans (1993).

Other families of fishes are apparently represented by one species each: northern pike, burbot (a freshwater member of the cods), Alaska blackfish (a Beringian relict), longnose sucker, slimy sculpin, and ninespine stickleback. The ecological limitations of high-latitude running waters—low food supply, severe hydrothermal regime (Oswood 1997), and barriers to dispersal—constitute a selective “filter” (Poff 1997), so that the fish fauna of Alaska in general and northern Alaska in particular is a highly selective subset of the North American fish fauna (Oswood et al. 2000). The fish fauna of the Noatak River is notably lacking fish families that are often dominant components of running waters in temperate regions (Cushing and Allan 2001): minnows (Cyprinidae); perches, walleye, and darters (Percidae); sunfishes and bass (Centrarchidae); and bullheads and catfishes (Ictaluridae).

Although the Noatak Valley is home to the full range of the Alaskan megafauna—grizzly bear, wolf, caribou, moose, wolverine—truly lotic vertebrates (other than fishes) appear to be very limited. Mammalian river specialists are limited to the river otter in the lower river. Manuwal (1974), in a short-term survey of the birds of the Noatak drainage, lists 18 species of birds with a habitat affinity for “fluvatile waters,” including loons, ducks, five species of shorebirds, and gulls. Of the potential avian “river specialists” in the Noatak drainage (Schroeder 1996), belted kingfishers are common and harlequin ducks (nesting alongside streams, consuming stream macroinvertebrates and fish eggs) are rare.

Ecosystem Processes

No ecosystem studies have been conducted on the Noatak River; however, processes are likely to

be similar to those described for the Kuparuk River.

Human Impacts and Special Features

The Noatak River arises in the Gates of the Arctic National Park and Preserve, then flows west through the Noatak National Preserve. All of the preserve (26,710 km²) is designated wilderness (except for about 2833 km² near the village of Noatak), one of the largest wilderness areas in the United States. From its headwaters to its confluence with the Kelly River, 531 km of the Noatak River are designated Wild and Scenic, the longest continuous river segment in the U.S. National Wild and Scenic system and the largest mountain-ringed river system in natural condition in the United States. The Noatak River is an “island out of time”—kudos to Horton (1996)—a river free flowing through a landscape nearly untouched by the industrial world and inhabited by people still largely living by subsistence take of animal resources.

KUPARUK RIVER

The Kuparuk River is another pristine Arctic river that affords several useful contrasts to the other Alaskan rivers (the Noatak and Sagavanirktok) considered in this chapter. Like the Sagavanirktok, the Kuparuk river flows north from the eastern Brooks Range, arising in the northern foothills, then traverses the low-gradient, poorly drained Arctic Coastal Plain, terminating in the Beaufort Sea of the Arctic Ocean (Fig. 20.10). In contrast, the Noatak River valley is almost contained within the mountains of the western Brooks Range, flowing west to the Chukchi Sea. The Kuparuk and Sagavanirktok river drainages share a harsh continental climate and tundra vegetation, whereas the gradient of marine-influenced and continental climate of the Noatak River permits an anomalous mix of taiga (forest) and tundra vegetation. The drainage area of the Kuparuk River is approximately 8100 km², with a basin length of nearly 250 km (McNamara et al. 1998). Maximum elevation in the upper Kuparuk drainage is 1464 m asl. The entire region is underlain by continuous permafrost and so surface waters are isolated from deep groundwater (McNamara et al. 1998).

Of the three Arctic Alaskan rivers considered in this chapter, the Kuparuk River has received far more intensive ecological study than either the Noatak or the Sagavanirktok rivers. However, these multidisci-

plinary and long-term studies have taken place in the headwaters and at a midcontinuum reach, rather than in the lower main stem of the river. We include brief discussions of this “stream” (as opposed to “river”) ecology because these studies provide insights into the ways that climate and physiography mold the biota and ecological processes of high-latitude running waters that are likely applicable across Arctic Alaska and along most of the river continuum.

Physiography, Climate, and Land Use

The Kuparuk River traverses two physiographic provinces (Hunt 1974), with headwaters in the Brooks Range (BM) and mouth in the Arctic Slope (AS) (see Fig. 20.10). Although the Kuparuk River lies entirely within the Yukon freshwater ecoregion of Abell et al. (2000), the Kuparuk drainage is north of the continental divide and so not within the drainage of the Yukon River. Near the headwaters the Kuparuk River traverses sediments eroded from the Brooks Range, with exposed sedimentary rocks (shale, sandstone, and gravel) of Cretaceous origin; nearer the coast there are younger (Tertiary) sediments (Connor and O’Haire 1988). The entire area is underlain by continuous permafrost (250 to 600 m depth), with summer thawing (active layer) typically from 25 to 40 cm but up to 100 cm deep (McNamara et al. 1998). Permafrost impedes drainage, so that in spite of low precipitation many areas of tundra are wet. The Kuparuk River crosses three terrestrial ecoregions on its path to the Beaufort Sea: Brooks/British Range Tundra, Arctic Foothills Tundra, and Arctic Coastal Tundra. This tundra landscape is dominated by herbaceous, tussock-forming vegetation, with dwarf shrubs along watercourses.

The Kuparuk River drainage lies entirely north of the Brooks Range and well above the Arctic Circle. The climate is therefore characterized by long, very cold winters and short cool summers. Average annual air temperature at the Imnavait Creek watershed in the headwaters of the Kuparuk is -7.4°C (Hinzman et al. 1996); near the mouth, on the Arctic Coastal Plain, the average annual air temperature is -12.1°C (www.wrcc.dri.edu). In the headwaters (Imnavait Creek), air temperatures (seven-day running averages) peak in late June/early July at about 15°C ; winter low air temperatures range from about -15°C to -25°C , with a record low (1985–1993) of about -45°C (Hinzman et al. 1996). Near the mouth (www.wrcc.dri.edu) average monthly air temperatures (Fig. 20.11) peak in July at about 8°C and are

lowest in February at about -29°C . Estimates of annual precipitation range from 35 cm in the headwaters (Hinzman et al. 1996), to 15 to 25 cm at mid-continuum (Selkregg 1977), to 9 cm near the mouth (www.wrcc.dri.edu). About two-thirds of the annual precipitation falls as rain in the summer (www.wrcc.dri.edu, Hinzman et al. 1996).

Although we have found no references to occupation of the Kuparuk River basin by indigenous peoples, the Kuparuk River is within the region of Alaska long home to the Inupiat Eskimos (Langdon 1989). There are no year-round communities in the Kuparuk River basin; the nearest habitations are the village of Nuiqsut at the mouth of the Colville River to the west of the mouth of the Kuparuk River and the oil-field developments of Prudhoe Bay and Deadhorse to the east of the Kuparuk River mouth. Thus, the basin is 100% Arctic tundra, with a human population density of zero. The remoteness of the Kuparuk River (no settlements and almost no road access) has thus far largely protected it from resource development, except for oil field developments near the mouth.

Geomorphology, Hydrology, and Chemistry

During Pleistocene glaciation the region north of the Alaska Range (including the present-day Kuparuk drainage) was ice free, except immediately north of the Brooks Range (Connor and O'Haire 1988, Gallant et al. 1995). Present-day glaciers in the Brooks Range contribute glacial meltwater to many north-flowing drainages (Oswood et al. 1992). Although adjacent watersheds have active glaciers, the Kuparuk River basin has no active glaciers, so the Kuparuk River is classified as a clear-water tundra stream in the Craig and McCart (1975) classification of Arctic Alaskan running waters. At least in the middle reaches (4th order river, near the Toolik Lake Research Station) the Kuparuk River meanders through tundra, with alternating pools and riffles and rocky substrates (Fig. 20.4).

The extreme seasonal eccentricity of climate is mirrored in the annual hydrological and thermal regimes. In the upper drainage basin, snowmelt (May to early June) is a dominant hydrological event, with spring floods flowing over anchor ice and frozen streambed sediments (Oswood et al. 1996, Hershey et al. 1997). Summer streamflows often approach zero because the catchment is sealed by permafrost and so there is no sustaining contribution from groundwater. Conversely, the underlying permafrost prevents percolation of precipitation into ground-

water, so that summer rainstorms produce rapid but transient rises in streamflow. Flow decreases dramatically in September, with drying of riffles and freezing of the stream to the substrate by October except in the deepest pools (Oswood et al. 1989, Oswood et al. 1996, Hershey et al. 1997). On the lower river, near the mouth, deep winter flows (from December through April) are very low, averaging less than $0.1\text{ m}^3/\text{s}$ (see Fig. 20.11). Discharge increases in May (average $45\text{ m}^3/\text{s}$) as air temperatures rise above freezing and runoff begins. Discharge spikes in June ($305\text{ m}^3/\text{s}$) as snowmelt runoff peaks. From July to September average (monthly) discharge ranges from $31\text{ m}^3/\text{s}$ to $43\text{ m}^3/\text{s}$, with flows sustained by rain (or occasional snow) throughout the basin. From October to November discharge decreases precipitously as declining precipitation turns from rain to snow and the active layer of the soil refreezes, suppressing water delivery from soil to streams (see Fig. 20.11).

As noted, estimates of annual precipitation show a gradient from 9 cm near the mouth, to ~ 18 cm at the middle of the river continuum, to 35 cm at a 1st order tributary. Monthly precipitation data shown in Figure 20.11 are from a climate station at the river mouth. Although the seasonal pattern of precipitation shown is likely representative of the Kuparuk River basin, the amounts of monthly precipitation are almost certainly substantial underestimates of the basinwide average. If the actual, basinwide annual precipitation is close to the midrange value of 18 cm, the monthly means shown in the figure would be approximately doubled, providing a more believable hydrological balance (annual precipitation about 18 cm versus runoff about 15 cm). This suggests that even after adjusting for basinwide annual precipitation annual runoff is still a very high percentage of precipitation ($>80\%$).

At Imnavait Creek (a headwater stream) summer water temperatures (monthly means) range from 6°C to 14°C , with extreme maximum values ranging from 19°C to 21°C (Irons and Oswood 1992). In the middle river continuum (Kuparuk River near Toolik Lake), summer water temperatures average 8°C to 10°C ; during low flows, water temperatures may reach 20°C (Hershey et al. 1997). In the lower river (near the mouth), summer water temperatures (sporadic determinations; mean monthly values over 16 years) warm to 4°C in June, peak at 12°C in July, decline slightly to 10°C in August, and fall rapidly in the short autumn to 2°C in September (<http://nwis.waterdata.usgs.gov/ak/nwis>). In winter (October to May), water temperatures beneath the ice cover are

FIGURE 20.4 Upper Kuparuk River, Alaska. Mountains of the Brooks Range can be seen in the distance. Vegetation along the bank is primarily willow shrubs (PHOTO BY S. PARKER).

approximately 0°C; in shallow waters, surface ice can reach the streambed, with temperatures at the substrate surface considerably below freezing (Irons and Oswald 1992).

Nutrient concentrations are low in the midcontinuum Kuparuk River; typical concentrations are phosphorus (SRP) 0.4 µg/L, NH₄-N 18.0 µg/L, and NO₃-N + NO₂-N 5.2 µg/L (Hershey et al. 1997). Calcium values appear to increase downstream, from 0.8 to 1.4 mg/L in a headwater stream (Everett et al. 1996), to 1.7 mg/L in a midcontinuum site (Hershey et al. 1997), to 25.6 mg/L at the mouth (<http://nwis.waterdata.usgs.gov/ak/nwis>). Values of pH range from 5.6 to 6.3 in a peat-dominated headwater stream (Everett et al. 1996), to 7.1 for the midcontinuum Kuparuk River (Hershey et al. 1997), to 7.3 near the river mouth (<http://nwis.waterdata.usgs.gov/ak/nwis>). Organic matter concentrations in stream waters of the Kuparuk drainage are dominated by leaching of dissolved organic matter from the peaty

tundra, with water flowing through the soil active layer (over permafrost) en route to the stream channel. Dissolved organic carbon concentrations (averaged over the open-water season) are about 10 mg C/L in a peat-bottomed headwater stream (Oswald et al. 1996), 6.4 mg C/L in a (rocky-bottomed) midcontinuum river (Peterson et al. 1986), and 9.3 mg C/L near the mouth (<http://nwis.waterdata.usgs.gov/ak/nwis>). Concentrations of particulate organic carbon are at least an order of magnitude lower than DOC concentrations.

River Biodiversity and Ecology

The Kuparuk River is located within the Yukon freshwater ecoregion (Abell et al. 2000). The “Big Science” projects in the headwaters of the Kuparuk River—the R4D project (Imnavait Creek) and especially the Tundra LTER studies (Kuparuk River near the Toolik Lake Biological Station)—have produced

a uniquely rich picture of running-water ecology in Arctic Alaska. Unless otherwise noted, information on the midcontinuum Kuparuk River is based on the summary by Hershey et al. (1997); biological information on Imnavait Creek, a headwaters stream, is from Bond (1988), Viavant (1989), and Oswood et al. (1996).

Algae and Cyanobacteria

Fifty-two genera of algae have been identified from Imnavait Creek. A red alga (*Batrachospermum*) is a major component of the algal community, likely dominating the algal biomass. There are 15 genera of cyanobacteria. The green algae show the highest generic diversity (23 genera), with desmids a common component of the green algae. Diatoms, represented by 9 genera, are infrequent. The algal community of Imnavait Creek seems consistent with other studies of peat-bottomed streams with acidic (pH 5 to 6), oligotrophic, and soft waters. The relative scarcity of diatoms is likely due to the very low concentrations of silica (<0.5 mg/L) in Imnavait Creek. In contrast, the epilithic algal community of the midcontinuum Kuparuk River is dominated by diatoms (187 species; 12 genera comprise up to 95% of individual cells); numerically dominant genera include *Achnanthes*, *Cymbella*, *Hannaea*, and *Diatoma*. Filamentous or macroalgae are found in patches and include the red algae *Lemmonia* and *Batrachospermum*, the cyanophyte *Calothrix*, and the green algae *Stigeoclonium*, *Mougeotia*, and *Spirogyra*.

Plants

In the pools of Imnavait Creek, deeper waters have a community of common mare's-tail and northern bur-reed, with shallow pond margins characterized by yellow marsh marigold, common mare's tail, northern bur-reed, and sphagnum mosses (Walker and Walker 1996). At the midcontinuum Kuparuk River site, Agassiz's schistidium moss occurs in low abundance; in an experimentally fertilized (phosphorus) reach, hygrophypnum moss proliferated (Lee and Hershey 2000). Riparian plants are primarily dwarf birches and willows.

Invertebrates

As is typical for Alaskan running waters (Oswood 1989), true flies (Diptera) dominate the macroinvertebrate fauna of both the midcontinuum Kuparuk River and headwater Imnavait Creek. However, geomorphological differences between the Kuparuk River (rocky-bottomed stream with substantial flow during the open-water season) and Imnavait Creek

(largely peat-bottomed stream with pondlike pools at low flows) are reflected in the invertebrate fauna. Black flies are the numerically dominant macroinvertebrates in the Kuparuk River, with *Prosimulium perspicuum* the most abundant consumer and largest contributor to secondary production. The fauna of Imnavait Creek is completely dominated (nearly 99% of numerical abundance) by chironomid midge larvae. Midges dominate the taxonomic richness of both streams (20 genera in Imnavait Creek; 25 genera in the Kuparuk River). *Orthocladius rivulorum* (midge) larvae are a major contributor to secondary production of benthos in the Kuparuk River. Mayflies (*Baetis*, *Cinygmula*, *Ephemerella*), stoneflies (*Alaskaperla*, *Nemoura*), and caddisflies (*Brachycentrus*, *Rhyacophila*) are represented by only two or three species in each order in the Kuparuk River. However, *Baetis* mayfly nymphs and *Brachycentrus* caddisfly larvae are the dominant components of benthic secondary production (along with the dipterans *Prosimulium* and *Orthocladius*).

Vertebrates

Moulton and George (2000) summarize fish species found in the lower Kuparuk River (near the mouth of the river in the oil field region). Five fish species are listed: broad whitefish, arctic grayling, burbot, slimy sculpin, and ninespine stickleback. In the upper basin, arctic grayling are reported in both the Kuparuk River and Imnavait Creek. Arctic grayling spawn in spring immediately after breakup and feed in summer in the warm waters of tundra streams. Because tundra streams typically freeze solid in winter, arctic grayling must migrate (often long distances) to overwintering sites in deep pools, lakes, river deltas, and springs (Reynolds 1997). Also observed in the upper Kuparuk basin are slimy sculpin and lake trout, the latter found within connecting headwater lakes (Alexander Huryn, personal communication). Pink salmon have been reported in the lower Kuparuk, but are likely strays from other natal rivers rather than evidence of a sustained run (Craig and Haldorson 1986). A few other fish species are possible (but unconfirmed) inhabitants of the Kuparuk River, occurring in adjacent rivers (the Colville and Saganirktok rivers; Moulton and George 2000) or within the general distributional range of the species in Alaska (McPhail and Lindsey 1970, Morrow 1980). These taxa include the arctic lamprey, several whitefishes (least cisco, arctic cisco, and round whitefish), northern pike, and longnose sucker.

This area of the Arctic Coastal Plain and the adjacent coast of the Beaufort Sea are home to

the “charismatic megafauna” for which Alaska is famous, including moose, muskox, and especially caribou. Large predators include grizzly bear, polar bear, arctic fox, and (rarely) wolf, but there are no aquatic or semiaquatic mammals (e.g., river otter) of which we are aware. During the brief summer, wetlands dominate the Arctic Coastal Plain, providing breeding habitat for 180 bird species (nearly all present only in the summer), with absolute numbers of birds on the North Slope approaching 10 million individuals (Gilders and Cronin 2000).

Ecosystem Processes

Organic carbon dynamics of the upper Kuparuk River (midcontinuum, 4th order site) are dominated by allochthonous inputs (Peterson et al. 1986, Hershey et al. 1997). However, inputs of leaf litter from riparian vegetation (dwarf birches and willows) are apparently negligible. Instead, allochthonous inputs derive from dissolved organic carbon leached from the tundra and from peat particles (200 to 300 g C m⁻² yr⁻¹) eroded from the stream banks. In contrast, autochthonous inputs—net primary production of periphyton—are only about 13 g C m⁻² yr⁻¹. Bioassay experiments have shown that phosphorus is the principle nutrient limiting biomass and production of periphyton. However, periphyton biomass is also limited by insect grazers. Secondary production of the major macroinvertebrate consumers ranges from 5.7 to 14.4 g dry mass m⁻² yr⁻¹, with production by black flies dominating. Arctic grayling adults (5 to 12 years old, 30 to 42 cm length, 300 to 500 g weight) move into the 4th order Kuparuk River site soon after ice-out for spawning. By early July young-of-the-year emerge from stream gravels and feed for the remainder of the summer (older juveniles appear to spend several years in tributary streams before moving to the river as adults). On average, adults gain 40 g weight over the summer feeding season but growth is highly variable from year to year, with little growth or even loss of weight in poor years (low summer water flow). Gut content analyses of the four major macroinvertebrate consumers indicate that the diets of a black fly (filter-feeder) and a brachycentrid caddisfly (filter-feeder and grazer) overlap, with fine particulate organic matter dominating and smaller quantities of diatoms and animal prey; brachycentrid larvae also consume filamentous algae, presumably via grazing. A tube-building midge larva consumes only diatoms, obtained by grazing the diatom “lawn” on its silk case. Baetid mayfly nymphs consume detrital FPOM and diatoms via epilithic grazing. A long list of other taxa of midge larvae are

presumably mostly collector-gatherers, but these small-bodied midge larvae contribute very little (<3%) to overall secondary production. Food items in grayling stomachs are mostly detritus (presumably of little nutritional value); baetid mayfly nymphs, brachycentrid caddisfly larvae, and terrestrial insects comprise most of the macroinvertebrates in grayling guts.

Human Impacts and Special Features

This pristine river, although relatively small, is probably the most extensively studied of all Arctic rivers in North America. Flowing from the northern foothills of the Brooks Range across the Arctic Slope (or Coastal Plain), its seasonal amplitude of physical conditions is among the most extreme on earth. The long and extremely cold winter forces migrations of most organisms and limits biological diversity, but the long days of the short summer generate a burst of productivity that sustains resident organisms and attracts one of the great avian migrations of North America. The Kuparuk River is free flowing over its entire length but runs parallel and countercurrent to crude oil flowing south in the Trans-Alaskan Pipeline. The attraction of ancient carbon in massive oil and gas reserves has drawn the only industrial incursion into this otherwise pristine landscape.

The lower reaches and mouth of the Kuparuk River traverse the Prudhoe Bay Oil Field, the largest oil and natural gas discovery in North America (Gilders and Cronin 2000). Confusingly, the more recently developed Kuparuk Oil Field is to the west of the Kuparuk drainage. Some concerns about the effects of oil field development on the Kuparuk River and its lower tributaries center on minimizing the risks (and scale) of contamination from crude oil, fuels, and materials associated with drilling, and from nutrient additions from sewage and domestic wastes. Because most species of riverine fishes migrate seasonally between freshwater and marine systems or between overwintering and summer spawning and feeding habitats, maintenance of migration corridors is essential. Early oil field and pipeline construction activities created some road crossings with culverts inadequate for passage of migrating arctic grayling, a problem solved by replacing inadequate culverts. Gravel is mined locally for construction of drilling pads and roads, providing a stable surface and thermal insulation (preventing melting of the underlying permafrost and subsequent soil subsidence). Some resulting gravel pits have been filled with water and connected to small streams

(spawning and summer feeding habitat), providing the deep water necessary for overwintering of grayling and thus developing new reproducing populations of arctic grayling (Moulton and George 2000). At present, only the lower reaches of the Kuparuk River (near the mouth) are potentially affected by industrial development; the upper Kuparuk drainage is unaffected by human activities except at infrequent river crossings by the Trans-Alaskan Pipeline and Dalton Highway. Therefore, the current and near-future impacts of resource development on the fisheries and aquatic ecosystems of the Kuparuk River seem manageable.

SAGAVANIRKTOK RIVER

The Sagavanirktok River (often termed simply the “Sag”) is the second-largest river, after the Colville, on the North Slope of Alaska. Many variations of the river’s name exist, and the Eskimo name, Sawanukto River, was used at one time, which meant “strong current” (Orth 1967). The river basin covers an area of 14,890 km² located in the central third of Alaska’s North Slope; the river originates in the Brooks Range (between the Endicott and the Philip Smith mountains) before flowing northward approximately 270 km to enter the Beaufort Sea (Hodel 1986) (Fig. 20.12). The Trans-Alaskan Pipeline and the haul road (now the Dalton Highway) to the North Slope oilfields closely parallel the river for a large portion of its length on the Arctic Slope (Coastal Plain). Consequently, the Sagavanirktok is the most easily accessible river on the Alaskan North Slope. The Sagavanirktok is fed by Galbraith Lake, via the Atigun River, and by a number of tributaries originating in small glaciers within the Brooks Range, rising to 2400 m asl. Close to its mouth between Foggy Island and Prudhoe Bay the river forms an extensive delta approximately 20 km wide, containing numerous channels (Fig. 20.1).

Following the Paleo-Eskimos, who lived in isolated groups throughout the region, the Inupiat Eskimos constituted the native community and comprised two groups in the Sagavanirktok River area: the Tareumuit of the coastal regions and the Nunamiut further inland. The total population of these groups of Inupiat Eskimos in Alaska at the time of European contact between 1850 and 1870 was estimated to be 3350 people (Langdon 1987). Contact was nearly 100 years later here than in coastal regions of Alaska due to its greater inaccessibility, and it was not until the Yankee whalers fol-

lowed the bowhead whale through the Bering Strait that extensive contact with Europeans was made.

Physiography, Climate, and Land Use

The basin geology is characterized by sedimentary rocks, with Paleozoic rocks dominating in the mountains and Mesozoic and Cenozoic rocks in the foothills. Three glacial deposits occur in the upper reaches of the basin (Schallock and Mueller 1981). The watershed encompasses two physiographic provinces (see Fig. 20.12): the Brooks Range (BM) and the Arctic Slope (AS). The river rises in the Brooks/British Range Tundra terrestrial ecoregion, where vegetation is restricted to valleys and lower slopes and is composed mainly of stunted white spruce, willow, and dwarf birch. Wet sites contain sedges and cottongrass, whereas drier sites support mountain avens and blueberry (Ricketts et al. 1999). The river then flows through the Arctic Foothills Tundra and the Arctic Coastal Tundra ecoregions, containing herbaceous plants and dwarf shrubs.

The climate in the lower basin is typical of the Arctic Slope, with cold long winters and low precipitation levels. From approximately mid-April to the end of August the sun remains above the horizon. Mean annual precipitation is from 10 to 15 cm across the Coastal Plain, peaking in August (almost 3 cm), but is ≤ 0.5 cm/mo from January through May (Fig. 20.13). The coastal precipitation totals, however, greatly underestimate precipitation for the entire basin, with annual totals of 50 to 100 cm in the Brooks Range. Nearly 50% of this precipitation occurs as snowfall from September to May (Hodel 1986). Mean monthly air temperature in winter varies from -26°C to -35°C near the coast to -30°C to -40°C along the mountains, and in summer ranges from a monthly mean of 5°C to 13°C near the coast to 10°C to 18°C inland (Scott 1978; see Fig. 20.13).

Most of the drainage is unpopulated Arctic tundra, but installations related to oil development are present. Sagwon, upstream of the confluence with the Ivishak River, was an exploration facility with a large airstrip but now is usually referred to as a reference for the USGS gaging site and is close to pump station 3 on the Trans-Alaskan Pipeline.

River Geomorphology, Hydrology, and Chemistry

Approximately 45 km from the mouth the river divides into an east and a west channel (see Fig. 20.12). Boothroyd and Timson (1983) have sug-

gested that the Sagavanirktok River is degradational (sediment eroding from streambed) for much of its length and aggradational (sediment deposited on the streambed) for 20 km toward the delta, but Hodel (1986) suggests the aggradational distance is longer. The west channel has a width up to 2.4 km and a gradient of 13 cm/km. Median grain size is 4.6 mm (Lunt et al. 2004). Significant suspended sediment loads are carried into the Beaufort Sea, estimated to reach 340 mg/L during the breakup flood in the west channel (Lunt et al. 2004).

Most of the readily accessible hydrologic information for the Sagavanirktok River derives from USGS gaging stations higher up the drainage. Although oil industry consultants monitor river flow close to the mouth, the deltaic nature of the river in these reaches makes total measurements difficult. Some preliminary data collected in 1981 and 1982 indicated in July and August the west channel carried between 68% to 70% of the flow, but at peak flow in June the channels carried similar flows (Ecological Research Associates 1982). The west channel has bankfull flows in the region of 600 m³/s.

The longest discharge record is for the period from 1983 to 1999 for the USGS station near Sagwon (close to pump station 3) at an elevation of 351 m asl and with a drainage area of 4800 km². This site does not include some of the tributaries (notably the Ivishak River), and the drainage area is only about one-third of the total drainage. Mean annual streamflow was 44 m³/s, with a maximum peak of 1200 m³/s in August 1992. Assuming the Sagwon gage to represent about one-third of the discharge, using relative basin size would give mean annual streamflow at the mouth of 132 m³/s. The river is frozen between September and May and thaws in late May to June. Peak flows at Sagwon were typically in June and early July, averaging 539 m³/s. Mean monthly flows at Sagwon ranged from 161 m³/s in June to 0.42 m³/s in March. Thus, runoff from June to August exceeded 6 cm/mo, declining to almost zero during winter (see Fig. 20.13). Interestingly, flow was zero in the river during March from 1983 to 1995 (except a negligible flow in 1986) but averaged 1.78 m³/s from 1996 to 1999. These data could possibly indicate climate change, but the length of record is relatively short and is restricted to one site. Such speculations, however, indicate the importance of time-series data to understand long-term changes, but unfortunately this gage was discontinued in September 2000. Annual runoff appears to be greater than precipitation (see Fig. 20.13) due to underestimation of precipitation for the basin as a whole.

Water chemistry in the Sagavanirktok River varies seasonally. One of the most interesting characteristics is the variation in dissolved oxygen, from a saturated 13.3 mg/L in August to a low of 1.1 mg/L in winter during April (Schallock and Mueller 1981). This oxygen depletion is more pronounced in the lower regions of the river due to low water flow and the limitation of atmospheric reaeration through ice cover. Water temperature in June varies from 3.9°C to 14°C, with typically higher water temperature reported in the foothills and decreasing toward the ocean. Schallock and Mueller (1981) attributed the decrease to the characteristic fog banks that cover the Arctic coast in the summer, reducing solar insolation even though there is 24 hr daylight. Temperatures of 0°C have been recorded in November in free-flowing water beneath ice cover. Conductivity varied from 140 to 310 µS/cm, with a mean of 203 µS/cm (1969 to 1975) for the gaging station near Sagwon. Highest turbidity values were recorded in June, reaching approximately 70 NTU, and decreased as the summer progressed, with most values in August <20 NTU. One of the major tributaries, the Ivishak River, typically has lower turbidity than the main channel of the Sagavanirktok River, upstream of the Ivishak River (Schallock and Mueller 1981). Total phosphorus values in 1969 averaged between 0.01 and 0.02 mg/L in the headwaters, increased to 0.05 mg/L near the mouth (Schallock and Mueller 1981), but were typically below detection (<0.01 mg/L) at the USGS gaging site at Sagwon. Nitrate-N typically ranged between 0.10 and 0.20 mg/L, indicating phosphorus is potentially the limiting nutrient (of N and P) to primary production. Silica is relatively high, reaching 12.5 mg/L, possibly accounting for the diverse and abundant diatom community.

River Biodiversity and Ecology

The Sagavanirktok River is located within the Yukon freshwater ecoregion (Abell et al. 2000), as are the Noatak and Kuparuk rivers. None of these rivers, however, has a direct connection with the Yukon River to the south. In contrast to the Kuparuk River to the west, biological and ecological information for the Sagavanirktok River is sparse.

Algae

An examination of diatoms collected at these sites produced a remarkable list of 261 species and species variations in 44 genera, as identified by Ruth Patrick at the Academy of Natural Sciences (Schallock and

Mueller 1981). Some of these species were locally abundant and widespread, indicating the wide diversity of diatoms at these high latitudes. The common genera were *Achnanthes*, *Cymbella*, *Eunotia*, *Fragilaria*, *Gomphonema*, *Navicula*, *Nitzschia*, and *Pinnularia*.

Invertebrates

The macroinvertebrate community is in marked contrast to the diatom diversity. Limited information is available on the benthic communities of the Sagavanirktok River, but it is clear that diversity is low. Most of the available data are from the study by Schallock and Mueller (1981), who sampled 13 sites on the main river in 1969 and 4 sites on three tributaries, the Atigin River, the Ribdon River, and the Ivishak River. Ephemeroptera, Plecoptera, Trichoptera, Diptera, and Annelida dominate the Sagavanirktok River community. The most widely distributed and abundant stoneflies were Capniidae (*Capnia*), Nemouridae (*Nemoura*), and Perlodidae (*Isogenus*). Stonefly abundance decreased downstream from the headwaters in the Brooks Range. Three genera of mayflies were dominant: *Baetis*, *Cinygmula*, and *Ameletus*. However, caddisflies were relatively poorly represented, with only three genera in two families (Brachycentridae and Limnephilidae) collected sporadically. Chironomidae (nonbiting midges) was typically the overall dominant family, particularly at sites near the river mouth, with sixteen genera documented. Orthocladiinae was the dominant subfamily, with nine genera identified, whereas only two Diamesinae genera were found. Although chironomid midges were abundant throughout the open-water season, black flies showed marked seasonal variations, sparse in June but widely distributed in August. Oligochaete worms were ubiquitous in the Sagavanirktok River, although abundance varied widely. Macroinvertebrate communities in the Sagavanirktok River tributaries and the Canning River showed similar patterns to the main river.

Vertebrates

Fish species known to occur within the Sagavanirktok River drainage include arctic char, arctic grayling, Dolly Varden, northern pike, broad whitefish, round whitefish, burbot, slimy sculpin, and nine-spine stickleback. Some of these species are both resident and diadromous. Indeed, the current understanding of Arctic diadromous fishes derives mainly from summer fish monitoring studies within the Sagavanirktok delta (Gallaway and Fechhelm 2000). Arctic cisco and threespine stickleback are found

principally within the estuary. Char and arctic grayling are important to the sports fishery.

Arctic char are also found in Galbraith Lake but are likely nonmigratory (McCart and Craig 1971). Although the lake is not land-locked, steep fast-flowing sections linking Galbraith Lake with the Sagavanirktok River are likely barriers to fish migration. A few pink and chum salmon have been reported in the drainage (Bill Wilson, personal communication).

The Sagavanirktok River is believed to support the largest Dolly Varden population on the North Slope (McCart et al. 1972). Dolly Varden typically arrive in the river mouth in June before migrating upstream to spawn in the foothill streams of the Brook Ranges in late July and August. Dolly Varden typically spawn every two to three years, with their juveniles remaining in their natal streams a similar period before their first seaward migration. Dolly Varden in this region typically overwinter in stream headwater areas near perennial springs during years in which they have been to sea (Gallaway and Fechhelm 2000). Typically the summer feeding of juvenile Dolly Varden is close to shore but long-distance movements have been reported, including documentation of traveling 1690 km to Russia (DeCiccio 1992). Fechhelm et al. (1997) found that Dolly Varden rearing juveniles grew slower in summer than juvenile whitefish and arctic cisco as a life history strategy to avoid similar habitats as the other species, thereby minimizing interspecific competition for food resources. The presence of perennial springs appears essential for Dolly Varden spawning in these arctic rivers (Fechhelm et al. 1997). The Sagavanirktok River is the only river between the Colville and the McKenzie that supports diadromous fishes apart from Dolly Varden; namely, arctic and least ciscos and broad whitefish. Arctic cisco typically leave the river by age three, possibly due to insufficient overwintering habitat for older fishes (Gallaway and Fechhelm 2000). Although broad whitefish occur in the Sagavanirktok River, the population is limited by the steeper channel gradient and the low number of accessible lakes (Moulton and George 2000). Broad whitefish also displayed wide population fluctuations over a nine-year period from 1990 to 1999 (Gallaway and Fechhelm 2000).

Lake trout are also found in Galbraith Lake. Arctic grayling are widespread throughout the drainage, although they migrate to specific areas for rearing and spawning (Moulton and George 2000). One of the features for resident fishes is the lack of flow in most of the river during late winter and con-

sequently the need to migrate to suitable overwintering habitat to survive. These habitats include deep river pools, springs, deltas, and lakes (Craig 1989, Reynolds 1997). One problem with deep river pools is the possibility of low dissolved oxygen levels, as this habitat is a closed system in winter with negligible water flow or atmospheric reaeration.

Caribou, grizzly bears, wolves, Dall sheep, snowshoe hare, arctic foxes, squirrels, and a number of rodents are found throughout the Coastal Plain of the Sagavanirktok drainage. Over 100 bird species have been recorded along this Coastal Plain, of which only six are resident year-round: rock and willow ptarmigan, snowy owl, common raven, gyrfalcon, and dipper (Lyons and Trawicki 1994). Tundra habitat within the river delta is an important nesting and staging area for shorebirds, swans, ducks, and geese (Sedinger 1997).

Human Impacts and Special Features

The Sagavanirktok River is characterized by being unregulated and flowing across the unique Arctic tundra. However, the most notable feature of the Sagavanirktok River is that it is the most anthropogenically influenced river on the Arctic North Slope. Geological investigations in the environs of the Sagavanirktok River played an important role in the discovery of oil in this region. It was in 1963 that geologists from the Richfield Oil Company (later to become Atlantic Richfield Company [ARCO], and now Conoco Phillips) located a sand outcrop soaked in oil on the banks of the Sagavanirktok River that indicated possible oil reserves in the region, and it was “Sag River well No. 1,” an exploratory well located near the mouth of the river, that eventually confirmed the considerable extent of the petroleum reservoir of the Prudhoe Bay fields (Roderick 1997).

Within the Sagavanirktok drainage developments have been linked principally to oil operations at Prudhoe Bay and the Trans-Alaskan Pipeline and Dalton Highway that runs along much of its length. The city of Deadhorse lies in close proximity to the west channel of the river delta, principally to facilitate the oil industry. One of the largest impacts has been the removal of gravel from the floodplain for road construction and oil pad building. Gravel extraction techniques have changed over time. Initially, gravel was removed by shallow scraping of riverine deposits but, due to environmental concerns, gravel extraction has shifted to deep mining, up to 20m below the surface from abandoned ox-bows or relic channels to reduce surface disturbance

(Hemming 1991). To rehabilitate gravel extraction sites within the delta, connection of both shallow and deep mined sites to the main channel has occurred and their subsequent fish use monitored. Hemming (1991) found grayling, round whitefish, and burbot used both types of extraction site, whereas ninespine stickleback and broad whitefish were found only in flooded shallow mined sites. Large numbers of broad whitefish in August indicate these sites act as important summer rearing habitat for this species. Passage facilities, like bridges or culverts, are now designed to provide both high- and low-flow access for fishes to feeding and overwintering habitats (Moulton and George 2000).

MOOSE RIVER

The Moose River basin, located in Northeastern Ontario, originates in the Superior Upland, flowing north through the Hudson Bay Lowland before emptying into James Bay near the town of Moosonee (Fig. 20.14). The drainage basin is >100,000 km², but the human population is <100,000, with more than 50% living in the upper (southern) reaches of the basin. The Moose River is a 7th order river but consists of five major river systems from west to east: the Missinaibi, Kapuskasing, Groundhog, Mattagami, and Abitibi (Brousseau and Goodchild 1989) (Table 20.1). The rivers are of similar size, and flow within the middle reaches is similar in gradient. All the river systems within the Moose River basin, with the exception of the Missinaibi, have undergone development to some extent, including hydroelectric dams and pulp and paper mills (Fig. 20.5). However, development is chiefly restricted to the Superior Upland region, principally since the early 1900s.

The native peoples (Cree) of the Moose River basin were nomadic and their presence dates to about

TABLE 20.1 Physical characteristics of Moose River tributaries.

River order	Length (km)	Basin size (km ²)	High flow (m ³ /s)	Average flow (m ³ /s)	
Missinaibi	6	430	22,530	1,740	105
Kapuskasing	5	324	8,633	963	77
Groundhog	5	363	12,518	1,844	144
Mattagami	6	491	41,672	1,230	113
Abitibi	5	285	33,987	3,210	384

7000 years ago. The Hudson's Bay Company outpost at the river mouth dates from 1673. Upper basin mining prospecting started in the early 1900s, with settlements after 1910. The national transcontinental railway construction in the area commenced in 1905 and the Kapuskasing pulp mill dates to around 1920. During World War I a large prisoner of war camp was sited near Kapuskasing, representing the first settlement in the midbasin. Further settlements occurred after the war, with people attracted to the area by land grants.

Physiography, Climate, and Land Use

The Moose River drainage basin spans two physiographic provinces with the Canadian (Precambrian) Shield physiographic division. The upper (southern) drainage is within the Superior Upland (SU) province, whereas the lower reaches cross the Hudson Bay Lowland (HB) province (see Fig. 20.14) (Hunt 1974). The Superior Upland is underlain by the Canadian Shield and covered by glacial, glaciofluvial, and glaciolacustrine deposits. An escarpment near 50°N

marks the beginning of the Hudson Bay Lowland, where sedimentary deposits of the Mesozoic and Paleozoic eras (limestone bedrock) lie beneath the northern part of the drainage basin (Brousseau and Goodchild 1989). The bedrock is covered with marine and glacial deposits, typically overlain by peat.

The drainage basin encompasses three terrestrial ecoregions: The headwaters lie in the Eastern Forest/Boreal Transition, the midreaches in the Central Canadian Shield Forests, and the lower reaches in Southern Hudson Bay Taiga (Ricketts et al. 1999). Mixed-species forests characterize the Eastern Forest/Boreal Transition, which includes white spruce, balsam fir, quaking aspen, paper birch, and yellow birch. Red, white, and jack pine favor the drier sites, and black spruce is found on wetter sites. Most of the land within these uplands is under timber-management plans. Black spruce dominates the Central Canadian Shield coniferous forests, but jack pine and some paper birch are also found due to the frequency of fire. The other species in the Eastern Forest/Boreal Transition are also present, particularly on south-facing slopes. Stunted black spruce and tamarack dominate the vegetation of the Southern Hudson Bay Taiga. Where uplifting of the land has occurred due to isostatic rebound, raised beaches are formed that support white spruce. Poorly drained areas are characterized by sedge and moss.

Mean annual temperature decreases in a south-north direction, with the mean annual temperature at Smoky Falls on the Mattagami River 1°C lower than at Timmins near the southern end of the basin. Seasonal variation in temperature of the central basin is wide, with a January mean of -19°C, approximately 36°C lower than the July mean of 17.3°C (Fig. 20.15). This wide variation is due to the continental climate of inland Canada but is less variable at the mouth due to the ameliorating effect of the inland sea of Hudson Bay. Mean annual precipitation is between 70 and 90 cm (Environment Canada 1982a, 1982b). Precipitation is highest during the summer, with peak rainfall in July and September (see Fig. 20.15). The majority of precipitation during the winter falls as snow, which contributes 30% to 40% of the annual precipitation.

The low population density in the basin (<1 person/km²), the concentration of developments in the middle reaches, and the absence of a road transportation network throughout much of the northern portion of the basin means that development is localized. About 94% of the basin is forested, 5% is agricultural, and 1% is urban and industrial. In many

parts of the basin it is still possible to have relatively pristine conditions. Past developments are primarily related to dams and reservoirs, the forest industry, and mining. Additional information on development within the Moose River basin can be found in reports associated with previous workshops related to cumulative effects within the Moose River basin (Greig et al. 1992; ESSA Technologies 1996a, 1996b).

River Geomorphology, Hydrology, and Chemistry

Within the Superior Upland there are hundreds of bedrock outcrops that create waterfalls and rapids, many of which are barriers to fish migration. In most areas these deposits are thin and heterogeneous, but in the southeastern portion of the watershed there is a large glaciolacustrine clay deposit. The river systems in the southeastern region (i.e., Abitibi and Frederickhouse rivers) flow through this clay belt and are characterized by high turbidity.

The escarpment at the beginning of the Hudson Bay Lowland is characterized by waterfalls on the Missinaibi (Thunderhouse Falls), Mattagami (Mattagami generating station complex), and Abitibi Rivers (Abitibi River Canyon). North of the escarpment the rivers have low gradients and consist of long, straight stretches with sand and gravel shoals and numerous riffle areas (Fig. 20.6). The peaking hydroelectric facilities result in a significant amount of available aquatic habitat being dewatered during peaking cycles.

Overall, river gradients in the upper basin are moderate, averaging 50 cm/km, before the streams descend over the edge of the Superior Upland. The change in elevation from the headwaters to James Bay is on the order of 325 m, and reaches of particularly high gradient occur on the Missinaibi and Mattagami rivers, where they descend from the Superior Upland (gradient 520 to 580 cm/km) to the lowlands. In several rivers the gradient has been altered due to hydroelectric facilities exploiting significant elevation drops (see Fig. 20.5).

The Moose River has an annual discharge of at least 1370 m³/s. For the four western tributaries, the discharge of the largest of the rivers (Groundhog River) is roughly twice that of the smallest (Kapusking River) (see Table 20.1). Seasonal discharge patterns and patterns of year-to-year variability in discharge are similar between the rivers (Fig. 20.7). The peak river discharge occurs in late April

FIGURE 20.6 The confluence of two tributaries of the Moose River, Ontario (PHOTO BY W. GIBBONS).

and May as the snowpack melts. However, there is considerable dampening of the extreme peak and low flows in those rivers with upstream storage reservoirs, such as the Mattagami River, that are not present in the unregulated Missinaibi River. Monthly runoff calculations also illustrate the strong snowmelt effect reaching 10 cm/mo in May (see Fig. 20.15). Seasonal changes in snow storage, evapotranspiration, and possibly lake storage account for the strong seasonal pattern of runoff in spite of the highest precipitation occurring after peak runoff (see Fig. 20.15).

Water chemistry is similar in all the main tributary rivers, with conductivity ranging from 126 to

179 $\mu\text{S}/\text{cm}$ and turbidity from 5 to 61 NTU (levels are typically higher downstream of the pulp mills). pH values range from 7.1 to 7.7, with relatively high levels of alkalinity (54 to 96 mg/L as CaCO_3) (Farwell 1999) and similar levels of dissolved oxygen among rivers. Seasonal fluctuations included lower values of alkalinity, dissolved inorganic carbon, and pH in the spring compared to the fall, whereas total suspended solids, particulate organic carbon, and nitrogen were higher in the spring (Farwell 1999). Water chemistry of the Kapuskasing and Mattagami rivers recently improved as the major pulp mills installed secondary waste treatment (Munkittrick et al. 2000). In a broader analysis of smaller tributaries in the basin,

FIGURE 20.7 Monthly discharge for the western tributaries of the Moose River basin.

Source: Munkittrick et al. (2000).

Kilgour et al. (2000) found pH levels between 6.3 and 8.1, conductivity between 7 and 312 $\mu\text{S}/\text{cm}$, alkalinity between 0.3 and 165 mg/L as CaCO_3 , and total phosphorus between 0.01 and 0.05 mg/L.

Water temperatures remain close to 0°C from November until late April in the main channel, rising rapidly to the low 20s for the summer period. Munkittrick et al. (2000) also found water temperature decreased as the main rivers flowed north. Comparisons of the rivers to the hydroelectric reservoirs demonstrated reservoirs were buffered from warmer and colder temperatures, as well as daily fluctuations.

River Biodiversity and Ecology

In contrast to the other rivers in this chapter, which are located within the Arctic complex of freshwater ecoregions, the Moose River is found within the South Hudson ecoregion of the Hudson Bay complex. The biology of the river is relatively well studied, at least for the invertebrates and fishes.

Plants

Aquatic vegetation consists of a narrow 1 m band along most of the rivers, due to the steep-sided channel morphology and the water's turbidity. Annual water-level fluctuations vary from 1 to 2 m, and significant areas of ice scour occur along river banks. Aquatic macrophytes are common in the shallow nearshore areas, and dominant plants are bulrush, eelgrass, watermilfoil, waterlily, common waterweed, sawtooth (*Najas*), crowfoot, hornwort, arrowhead, and pondweed.

Reservoirs above impoundments and shallow bays flooded by the dams on some of the tributaries have extensive beds of floating and submergent species, including yellow pond-lily, Richardson's pondweed, watermilfoil, and threadleaf crowfoot. Flooded areas also have numerous logs and stumps. Aquatic macrophytes are not obvious downstream of impoundments, where water-level fluctuations are large. Bands of woody shrubs (dogwood, alder, and willow), grasses and sedges, and emergent plants (rushes, horsetails, and arrowheads) colonize the riparian margin in upper portions of the basin.

Invertebrates

Macroinvertebrate diversity in the Moose River drainage is relatively well studied. Fiset (1995a) identified 288 macroinvertebrate taxa in a basinwide study, whereas Kilgour et al. (2000), collecting at 79 sites (1st to 6th order streams), identified 278 taxa, with chironomid midges the most dominant and diverse group (77 taxa; common subfamilies include Chironominae, Orthocladiinae, and Tanypodinae). Mayflies (19 taxa, especially the genera *Baetis*, *Caenis*, *Ephemerella*, *Hexagenia*, *Heptagenia*, and *Stenonema*), stoneflies (12 taxa, especially the families Perlodidae and Pteronarcyidae), and caddisflies (34 taxa, especially Hydropsychidae, Limnephilidae, and Polycentropodidae) were well represented, as were oligochaete worms (29 taxa, including *Nais*, *Arcteonais*), dragonflies (15 taxa, especially Aeshnidae, Corduliidae, Macromiidae, and Gomphidae), snails (15 taxa, especially Physidae and Planorbidae), beetles (13 taxa, especially in the families Dytiscidae, Elmidae, and Gyrinidae), and Tubificidae (including *Limnodrilus* and *Tubifex*). Only four species of bivalve mollusks were found (all Sphaeriidae), although Unionidae shells were also collected. Crustaceans include crayfishes in the genera *Cambarus* and *Orconectes* (Fiset 1995b). High-order sites (5th to 6th order) supported higher relative abundance of grazers and collector-gatherers. Low-order sites typically had higher relative abundance of deposit feeders, such as chironomid midges and worms.

Vertebrates

The fish community of the river basin is diverse for a northern river, with at least 14 families and 40 species occurring in the nontidal portion of the river. Typically these fishes are divided into large-bodied and small-bodied species (Fiset 1995a, Seyler 1994, Portt et al. 1999, Kilgour et al. 2000), with the families Acipenseridae, Coregonidae, Catostomidae, Centrarchidae, Cottidae, Cyprinidae, Ecoscidae,

Gadidae, Gasterosteidae, Hiodontidae, Ictaluridae, Percopsidae, Percidae, and Salmonidae represented. Percids (16 species) and cyprinids (12 species) are the dominant families. Many of the small-order streams are low gradient, with fish species such as pearl dace and stickleback (Kilgour et al. 2000). Higher-order stream sections tended to have species adapted to faster flows. Among the larger fish species the most abundant are lake sturgeon, northern pike, walleye, and white sucker. The most widely distributed small-bodied species are pearl dace, longnose dace, trout-perch, and spotfin shiner. No species in the Moose River basin are identified as endangered, rare, or threatened in Ontario.

Aquatic mammals or mammals often associated with the Moose River include muskrat, beaver, fisher, marten, mink, river otter, and moose, particularly throughout the upper and middle parts of the basin. There are reports of seal and beluga whale in the lower river in spring to feed on whitefish. The upper basin is on the North Atlantic flyway, and a wide variety of migratory waterfowl can be found, including Canada goose, lesser snow goose, white-fronted goose, Brant's goose, surf scoter, and many other sea ducks.

Human Impacts and Special Features

Although certain parts of the Moose River drainage have been significantly influenced by anthropogenic activities, particularly in the Central Canadian Shield Forests, overall the Missinaibi represents a large undeveloped river that has been designated a Heritage River and an Ontario Provincial Park. This tributary is protected from land-use activities within the park boundary that extends from 120 m to 200 m from the water's edge for much of the river's length. The dominant anthropogenic impacts within the Moose River basin are related to hydroelectric development, forestry, and mining activities, with dams having the greatest negative effects. Agricultural activity is minimal (other than silviculture) (ESSA 1998).

There are 20 hydroelectric generating facilities, with 10 operated by Ontario Hydro and 10 as non-utility generating facilities (NUGs). The existing hydroelectric facilities range from 0.15 to 285 MW in capacity (total 950 MW), and the NUGs vary from 0.5 to 50 MW in capacity (total 120 MW). The oldest facilities are on the Mattagami River (1911, 1912, 1923, and 1931), with most of the remaining facilities constructed in the 1960s. There are also 50 non-hydroelectric water-control structures within the system; 27 are flood-control or water-diversion facil-

ities and 23 are associated with work by Ducks Unlimited related to wetlands enhancement projects.

In the Moose River basin, sections of 23 forest-management units are harvested for timber. Previously, extensive log-driving operations existed on several rivers, but these ceased in the 1980s and 1990s. The major effluent discharges related to the forest industry are from three pulp mills within the basin. The pulp mills are distributed on the Kapuskasing River (380,000 tonne/yr thermo-mechanical pulp [TMP] mill located at Kapuskasing), the Mattagami River (170,000 tonne/yr bleached kraft mill located at Smooth Rock Falls), and the Abitibi River (310,000 tonne/yr mill, recently converted to a TMP process, located at Iroquois Falls). The mills underwent extensive renovations in the mid-1990s, including the installation of secondary waste treatment facilities. In addition to the three pulp mills, a variety of wood-processing facilities exist, including an oriented strand board mill in Timmins, sawmills in Hearst, Cochrane, Kirkland Lake, South Porcupine, and Timmins, and a plywood and veneer mill in Cochrane. No new development is predicted for the forest industries, other than modest increases in production associated with existing facilities (ESSA 1999).

During the 1990s there were nine operating mines, eight operating mills, and one refining facility associated with gold, copper, zinc, lead, silver, hemonite, and talc. There were also two sites associated with peat extraction. Most of the mines are near the headwaters of the Abitibi, Frederickhouse, and Mattagami rivers. There are also eight advanced mining exploration sites in the basin (seven gold, one nickel) and over 100 additional exploration activities during 1994 alone (reviewed in ESSA 1996b). Additional potential exists within the basin for mining of phosphates, aluminum, lignite, gypsum, diamonds, gold, copper, zinc, lead, silver, nickel, cadmium, indium, kaolin, and peat. Although there are currently no aggregate facilities, potential exists within the basin. There are also extensive peat deposits, estimated at >9 billion m³. Approximately 39% of the deposits are fuel grade and 24% have good horticultural potential (ESSA 1996a). Potential impacts associated with peat extraction include impacts on drainage and erosion.

ADDITIONAL RIVERS

The Seal River is the largest undammed river in northern Manitoba and flows in an easterly direction

before emptying into Hudson Bay (Fig. 20.16). Much of the basin is drained by the South Seal and North Seal rivers, which flow into Shethanei Lake (north-east of the larger Tadoule Lake on the South Seal). The main-stem Seal thus begins at Shethanei Lake, which is ringed by sand-crowned eskers, a distinguishing feature along much of the river. Much of the basin contains subarctic boreal forest of the Precambrian Shield, before giving way to Arctic tundra as it crosses into the Hudson Bay Lowland. Like the larger Thelon/Kazan basin to its north, the Seal is home to a diverse and abundant fauna. Particularly noteworthy are its harbor seals (which give the river its name), found 200 km upstream of Hudson Bay, and a large population of beluga whales, which feed and calve in its estuary. Although the basin is entirely undeveloped wilderness and there are no dams on the main stem or tributaries, only the main-stem Seal is in the Canadian Heritage River system. The Seal is popular for white-water river trips.

The Thelon River and its largest tributary, the Kazan River, flow in an easterly and northeasterly direction, respectively, in the Nunavut Territory before emptying into Baker Lake (Fig. 20.18). The outlet from Baker Lake then flows into Chesterfield inlet at the northwestern corner of Hudson Bay. The main rivers and their tributaries have no dams, but they often widen into lakes along their course, including Aberdeen, Dubawnt, Kasba, Yathkyed, and Baker lakes (see Fig. 20.18). The basin is a boreal Arctic wilderness that supports diverse and abundant wildlife; notably caribou, muskox, grizzly bear, lynx, wolf, wolverine, peregrine falcon, tundra swan, and Canada goose. The only major human presence in the Thelon/Kazan basin is about 1000 Caribou Inuit who live in the community of Bakers Lake, near the mouth. Both the Thelon and the Kazan are in the Canadian Heritage Rivers system. The rivers are very scenic, including white water and several falls, such as the 25 m Kazan Falls.

ACKNOWLEDGMENTS

We would like to thank Bill Wilson of LGL Research in Anchorage for discussions regarding the Sagavanirktok River and Dr. Ian Lunt for access to unpublished data. We are grateful to the meticulous editing of Art Benke, who improved the final manuscript.

FIGURE 20.8 Map of the Noatak River basin.

NOATAK RIVER

- Relief: 2612 m
- Basin area: 32,626 km²
- Mean discharge: 469 m³/s
- River order: NA
- Mean annual precipitation: 33 cm
- Mean air temperature: -5.8°C
- Mean water temperature: NA
- Physiographic province: Brooks Range (BM)
- Biomes: Tundra, Boreal Forest
- Freshwater ecoregion: Yukon
- Terrestrial ecoregions: Brooks/British Range Tundra, Arctic Foothills Tundra
- Number of fish species: 15 to 18
- Number of endangered species: none
- Major fishes: chum salmon, Arctic char, Arctic grayling, humpback whitefish, round whitefish, least cisco, ninespine stickleback, slimy sculpin
- Major other aquatic vertebrates: river otter, grizzly bear, loons, ducks, belted kingfisher
- Major benthic invertebrates: water mites (Acarina), mayflies (Baetidae, Heptageniidae), chironomid midges, stoneflies (Chloroperlidae)
- Nonnative species: none
- Major riparian plants: willows, cottongrass, sedges
- Special features: pristine Arctic tundra river within Gates of the Arctic National Park and Preserve and Noatak National Preserve; longest river segment in U.S. Wild and Scenic River system; little or no winter flow under deep ice cover; subsistence use of riverine resources by Inupiat Eskimos
- Fragmentation: none
- Water quality: no significant pollution sources; alkalinity = 82 to 110 mg/L as CaCO₃, NO₂-N + NO₃-N = 0.07 to 0.2 mg/L, pH = 7.8 to 8.2
- Land use: 100% tundra and boreal forest wilderness
- Population density: 0 people/km²
- Major information sources: Childers and Kernodle 1981, Young 1974

FIGURE 20.9 Mean monthly air temperature, precipitation, and runoff for the Noatak River basin.

FIGURE 20.11 Mean monthly air temperature, precipitation, and runoff for the Kuparuk River basin.

KUPARUK RIVER

Relief: 1464 m

Basin area: 8107 km²

Mean discharge: 40 m³/s

River order: 5

Mean annual precipitation: 22 cm

Mean air temperature: -9.8°C

Mean water temperature: 2.6°C

Physiographic provinces: Arctic Slope (AS), Brooks Range (BM)

Biome: Tundra

Freshwater ecoregion: Yukon

Terrestrial ecoregions: Arctic Coastal Tundra, Arctic Foothills Tundra, Brooks/British Range Tundra

Number of fish species: ≥6

Number of endangered species: none

Major fishes: Arctic grayling, broad whitefish, ninespine stickleback, slimy sculpin, burbot

Major other aquatic vertebrates: loons, swans, many duck species, including spectacled eider and king eider

Major benthic invertebrates: chironomid midges (*Orthocladus*), black flies (*Prosimulium*), mayflies (*Baetis*), caddisflies (*Brachycentrus*)

Nonnative species: none

Major riparian plants: dwarf willow, birch

Special features: pristine tundra river originating in the foothills of Brooks Range and traversing Arctic Coastal Plain to Beaufort Sea

Fragmentation: none

Water quality: no pollution, except potential from oil field near mouth; phosphorus (SRP) = 0.4 μg/L, NO₃-N + NO₂-N = 5.2 μg/L, pH = 5.6 to 7.3, DOC = 6 to 10 mg/L

Land use: almost 100% tundra wilderness

Population density: 0 people/km²

Major information sources: Hershey et al. 1997, Reynolds and Tenhunen 1996

FIGURE 20.10 Map of the Kuparuk River basin. Physiographic provinces are separated by a yellow line.

FIGURE 20.13 Mean monthly air temperature, precipitation, and runoff for the Sagavanirktok River basin.

SAGAVANIRKTOK RIVER

Relief: 2400 m

Basin area: 14,890 km²

Mean discharge: 132 m³/s

River order: 7

Mean annual precipitation: 10.8 cm (underestimate)

Mean air temperature: -7.7°C

Mean water temperature: NA

Physiographic provinces: Brooks Range (BM),
Arctic Slope (AS)

Biome: Tundra

Freshwater ecoregion: Yukon

Terrestrial ecoregions: Brooks/British Range Tundra,
Arctic Foothills Tundra, Arctic Coastal Tundra

Number of fish species: 10

Number of endangered species: none

Major fishes: Dolly Varden, Arctic grayling, Arctic cisco, broad whitefish, round whitefish, lake trout

Major other aquatic vertebrates: grizzly bear, spectacled eider, king eider, yellow-billed loon

Major benthic invertebrates: stoneflies (*Capnia*, *Nemoura*, *Isogenus*), mayflies (*Baetis*, *Cinygmula*, *Ameletus*), chironomid midges (Orthocladiinae), black flies

Nonnative species: none

Major riparian plants: dwarf willow, birch

Special features: one of major rivers on Alaskan Arctic Slope supporting large fish populations; unregulated; delta provides important bird and fish habitat; oil development, including Trans-Alaskan Pipeline, along most of river's length

Fragmentation: none

Water quality: no pollution, except potential near mouth from oil development; total P ≥ 0.05 mg/L, NO₃-N ≥ 0.2 mg/L

Land use: almost 100% tundra wilderness

Population density: 0 people/km²

Major information sources: Schallock and Mueller 1981, Hodel 1986, Gallaway and Fechhelm 2000

FIGURE 20.12 Map of the Sagavanirktok River basin. Physiographic provinces are separated by a yellow line.

FIGURE 20.15 Mean monthly air temperature, precipitation, and runoff for the Moose River basin.

MOOSE RIVER

Relief: 325 m

Basin area: 109,000 km²

Mean discharge: 1370 m³/s

River order: 7

Mean annual precipitation: 80 cm

Mean air temperature: 0.1°C

Mean water temperature: 7.0°C

Physiographic provinces: Superior Upland (SU),
Hudson Bay Lowland (HB)

Biome: Boreal Forest

Freshwater ecoregion: South Hudson

Terrestrial ecoregions: Eastern Forest/Boreal
Transition, Central Canadian Shield Forests,
Southern Hudson Bay Taiga

Number of fish species: 40

Number of endangered species: none

Major fishes: lake sturgeon, northern pike, walleye,
white sucker, troutperch, pearl dace, longnose
dace, spotfin shiner, emerald shiner

Major other aquatic vertebrates: muskrat, beaver,
fisher, marten, mink, river otter, moose, lesser snow goose

Major benthic invertebrates: snails (*Valvata*, *Ammicola*), mayflies (*Hexagenia*, *Baetis*, *Caenis*, *Ephemerella*, *Heptagenia*,
Stenonema), crustaceans (*Hyalella*, *Cambarus*, *Orconectes*), chironomid midges (*Chironomus*, *Paratanytarsus*, *Cladopelma*),
stoneflies (Perlodidae, Pteronarcyidae), dragonflies (Aeshnidae, Corduliidae, Macromiidae, Gomphidae), oligochaete worms
(*Dero*, *Pristina*)

Nonnative species: none

Major riparian plants: white birch, trembling aspen, white spruce, black spruce, jack pine, dogwood, alder, willow, grasses,
sedges, rushes, horsetails, arrowheads, pondweed, coontail

Special features: >200 waterfalls and the Missinaibi pristine Heritage River

Fragmentation: more than 40 dams and water-control structures throughout basin

Water quality: in undisturbed areas, pH = 7 to 7.8, conductivity = 100 to 200 μS/cm, alkalinity = 50 to 100 mg/L as CaCO₃,
turbidity = <20 NTU, total P = <0.020 mg/L

Land use: 94% forests, 1% developed, 5% open

Population density: <1 person/km²

Major information sources: Environment Canada 1982a, 1982b, Munkittrick et al. 2000, Brousseau and Goodchild 1989

FIGURE 20.16 Map of the Seal River basin.

SEAL RIVER

Relief: NA

Basin area: 48,100 km²

Mean discharge: 346 m³/s

River order: NA

Mean annual precipitation: 41 cm

Mean air temperature: -7.1°C

Mean water temperature: NA

Physiographic province: Bear–Slave–Churchill Uplands (BC)

Biomes: Boreal Forest, Tundra

Freshwater ecoregion: East Arctic

Terrestrial ecoregions: Northern Canadian Shield Taiga, Southern Hudson Bay Taiga

Number of fish species: ≤18

Number of endangered species: NA

Major fishes: lake trout, northern pike, Arctic grayling

Major other aquatic vertebrates: river otter, beaver, beluga whale, harbor seal

Major benthic invertebrates: NA

Nonnative species: none

Major riparian plants: willow, birch

Special features: Canadian Heritage River; one of Canada's wildest and most remote rivers; upper reaches characterized by magnificent sand-crowned eskers

Fragmentation: none; largest remaining undammed river in Manitoba

Water quality: no pollution

Land use: 100% undeveloped tundra and montane

Population density: 0 people/km²

Major information source: Environment Canada

FIGURE 20.17 Mean monthly air temperature, precipitation, and runoff for the Seal River basin.

THELON/KAZAN RIVER

Relief: 300 to 500m

Basin area: 239,332 km²

Mean discharge: 1380 m³/s

River order: NA

Mean annual precipitation: 17.2 cm

Mean air temperature: -8.7°C

Mean water temperature: NA

Physiographic provinces: Thelon Plains and Bear River Lowland (TB),
Bear-Slave-Churchill Uplands (BC)

Biomes: Tundra, Boreal Forest

Freshwater ecoregion: East Arctic

Terrestrial ecoregions: North Canadian Shield Taiga, Low Arctic

Tundra, Middle Arctic Tundra

Number of fish species: 13

Number of endangered species: none

Major fishes: lake trout, Arctic grayling, northern pike, Arctic char,
humpback whitefish, round whitefish, cisco, slimy sculpin,
spoonhead culpin, lake chub

Major other aquatic vertebrates: grizzly bear, bald eagle, tundra swan, Canada goose

Benthic invertebrates: NA

Nonnative species: none

Major riparian plants: willow shrub, bog birch, birch, spruce

Special features: Canadian Heritage River (both Thelon and Kazan); large remote wilderness river; Thelon Game Sanctuary;
Kazan Falls

Fragmentation: NA

Water quality: no pollution

Land use: 100% wilderness (11% wetlands, 6% forest, 21% grassland, 48% barren)

Population density: <1 person/km²

Major information sources: Revenga et al. 1998, Environment Canada

ATLANTIC COAST RIVERS OF CANADA

RICHARD A. CUNJAK ROBERT W. NEWBURY

INTRODUCTION

EXPLOITS RIVER

MIRAMICHI RIVER

ST. JOHN RIVER

MOISIE RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

The rivers of eastern Canada flow into the Atlantic Ocean from Newfoundland, Labrador, Nova Scotia, Prince Edward Island (PEI), New Brunswick, and parts of eastern Quebec. Geographically, the region is bounded by the Atlantic Ocean on the south and east, 70°W longitude on the west, and 55°N latitude in the north. The northern boundary generally follows a height of land between rivers flowing north to Ungava Bay or south into the Gulf of St. Lawrence (Fig. 21.2). To the north the rivers run through near-wilderness regions of the rocky Canadian Shield. To the south many of the rivers flow through the Atlantic lowlands in wide valleys formed by large glacial meltwater rivers. Towns, industries, and farmland now occupy the valley flats and shallow plains beside the smaller present-day rivers. To the west the interior drainage of eastern Canada (the Great Lakes and various downstream tributaries) flows into the Atlantic through the St. Lawrence River, the second-largest river (by discharge) in North America (see Chapter 22).

The rivers have been used by aboriginal peoples for over 9000 years: the Inuit along the coast of

Labrador, the Innu in central and southern Labrador, the Montagnais and Mi'kmaq of the Maritimes, and the now-extinct Beothuks of insular Newfoundland. The last Beothuk died in 1829 (www.tolatsga.org/Compacts.html 2002). These rivers have long served these peoples for movement between seasonal settlements and for accessing hunting and fishing areas. Travel to eastern Canada by Europeans includes some of the earliest explorers. Basques traveled regularly to southern Labrador between 1530 and 1600, primarily in search of whales and cod; Norwegian sailors are known to have reached northwestern Newfoundland before the tenth century. Colonization of eastern Canada, primarily by French and English explorers such as Jacques Cartier and John Cabot, began in the early sixteenth century, mainly along the coast of the Bay of Fundy and along the St. Lawrence River, the route to the interior of North America.

There are 37 seaboard rivers with drainage areas greater than 100 km² that lead directly into the Atlantic (National Atlas of Canada 1974). The major rivers north of the Gulf of St. Lawrence include the Manicouagan, Outardes, Moisie, and Churchill rivers in Labrador. On insular Newfoundland are the Humber, Exploits, and Gander rivers. In the Maritime Provinces the major rivers are the St. John,

← **FIGURE 21.1** Aerial view of the Southwest Miramichi River near Doaktown, New Brunswick. Note the wide glacial river valley and sand and gravel bed braided channel (PHOTO BY R. NEWBURY).

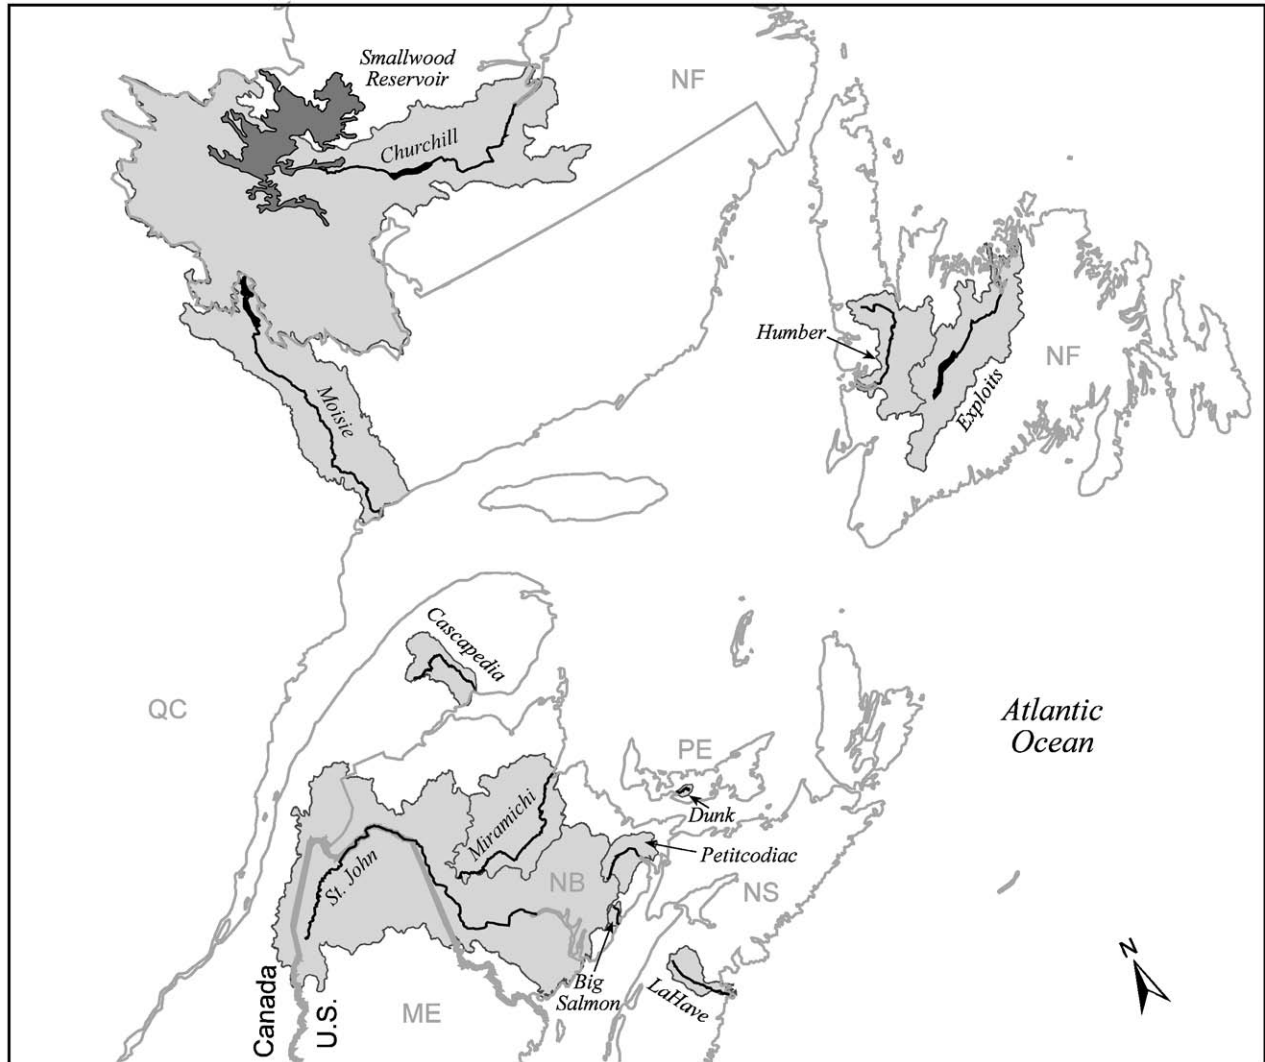

FIGURE 21.2 Atlantic Coast rivers of Canada covered in this chapter.

Restigouche, Miramichi, and Margaree rivers. In this chapter we will focus on four of these rivers: the Moisie, Exploits, St. John, and Miramichi. Together, they represent a range of human colonization and perturbation as well as wild beauty and impressive productivity. Abbreviated physical and biological descriptions are provided for the Churchill, Humber, and several smaller rivers (Cascapedia, Dunk, LaHave, Petitcodiac, and Big Salmon).

Physiography and Climate

The Atlantic Canada region includes four physiographic provinces. The northern portion of the region is located within the Labrador Highlands (LB)

province at the eastern extension of the Canadian Shield physiographic division. Here, the Torngat Mountains can be found, with peaks in excess of 1500m. The Laurentian Highlands (LU) province occupies the southwestern corner of the region, mainly represented by the lands of eastern Quebec. The coastal lowlands of the Gulf of St. Lawrence, including the Quebec north shore, Anticosti Island, and the west coast of insular Newfoundland, are located within the St. Lawrence Lowland (SL) province. Finally, the New England/Maritime (NE) province covers most of the rest of the region's land mass. The mountain ranges are old, weathered, and of moderate height. These include the northeastern extension of the Appalachian physiographic division (with Mount Carleton, at 820m asl, the highest point

of the mainland provinces) and the Long Range Mountains (800m asl) of western Newfoundland.

The drainage pattern is dominated by the Canadian Shield in the north and the extension of the Appalachian Mountains in the south. Drainage from the Shield, a raised arc of predominantly granitic pre-Cambrian rock that surrounds Hudson Bay, is inward to the Bay and outward into the St. Lawrence and Mackenzie river systems. In the east, the Shield drainage flows from southern Quebec and Labrador directly into the Gulf of St. Lawrence or the Atlantic. South of the Canadian Shield the Appalachian Mountain region extends for 4000 km from Alabama in the southwest to the New England/Maritime province, which includes New Brunswick, Nova Scotia, Prince Edward Island, and Newfoundland. The drainage basins are heavily glaciated and composed of a wide variety of granitic, metamorphic, and sedimentary rock. Surficial deposits vary from a thin till cover in Labrador and Newfoundland to thick riverine and tidal deposits in the southern river valleys. Sea and land elevations have changed dramatically in the last 100,000 years. The region was depressed by as much as 300 m under the weight of the Pleistocene ice sheets. About half of this depression has been recovered in the last 12,000 years. Consequently, the lower reaches of the larger rivers, such as the St. John and Miramichi, flow through broad flat valleys infilled with former marine and estuarine proglacial deposits.

The climate varies from subarctic to boreal in the north to wet maritime in the south. Cool summers and extremely cold winters are typical of the northern portion of the region, with the climate strongly influenced by proximity to the coast. Summers can be hot and humid in the interior of New Brunswick, where maximum air temperatures $>30^{\circ}\text{C}$ are common in July and August. By contrast, summer maxima of 20°C are rare along the Labrador coast. Mean annual air temperatures in the region range from -3°C in the north to 7°C in the south. Snow is the dominant form of precipitation in winter, except along the Bay of Fundy and southern Nova Scotia coasts, where $<25\%$ of the annual precipitation is from snow. By contrast, approximately 50% of annual precipitation falls as snow in Labrador. Churchill Falls (interior) has an annual accumulation of 480 cm of snow, making it one of the snowiest places in Canada. In northern portions of the region, the ground is snow covered for six to eight months of the year. The mean total annual precipitation varies from 80 cm in the north to 150 to 165 cm in the southeast (water equivalent).

Basin Landscape and Land Use

The Atlantic Canada region is distinctive for two features of its landscape: an extensive marine coastline and an extensive forest cover surrounding abundant inland waters. The land mass covers an area of 503,000 km², or about 5.5% of Canada's land mass. The major biome of the region is Boreal Forest, found throughout Labrador and the northern peninsula of insular Newfoundland and extending south into Nova Scotia, Prince Edward Island, and New Brunswick. A small portion of eastern New Brunswick and the western half of Nova Scotia along the Bay of Fundy is considered Temperate Deciduous Forest.

The major terrestrial ecoregions of the Canadian Atlantic river basins include portions of the Eastern Canadian Shield Taiga of Labrador, the Eastern Canadian Forests of eastern Quebec and Newfoundland, the New England/Acadian Forests of parts of New Brunswick and Nova Scotia, and the Gulf of St. Lawrence Lowland Forests of northern New Brunswick and Prince Edward Island (Ricketts et al. 1999). The Eastern Canadian Shield Taiga ecoregion primarily consists of stunted black spruce and tamarack. The Eastern Canadian Forests include black spruce, but also include balsam fir and white spruce resulting from the maritime influence. The New England/Acadian Forests is a transition zone between this spruce–fir forest and the deciduous forest to the south, thus including sugar maple, American beech, and yellow birch. The Gulf of St. Lawrence Lowland Forests ecoregion contains an even stronger mix of hardwoods, but also includes balsam fir, red spruce, and eastern white pine.

Population density is low (13.2 people/km²), with less than 2.3 million people living in the region (7.7% of the population of Canada). Large urban centers are scarce; instead, a pattern of isolated small towns follows the river valleys and coastlines. The economy of the region is based on the exploitation of natural resources, agriculture, and tourism. Commercial fisheries (including aquaculture) and forestry are the two major industries of the region, and recreational pursuits like fishing and hunting are practiced by a large number of residents of the region.

The commercial harvesting of trees for wood products in Atlantic Canada dates back to the 1700s, when lumber was exported to Britain, largely for use in shipbuilding. During the Napoleonic Wars (1800 to 1815) the strong demand for eastern white pine for masts and spars in the British navy fueled the forestry industry in Nova Scotia and New Brunswick

(Wright 1944). In 2000 the value of the forestry exports from Atlantic Canada was \$4.7 billion (Canadian), with approximately 35,000 jobs stemming directly from the industry. Agricultural land is extensive in Prince Edward Island, parts of Nova Scotia (Annapolis Valley), and New Brunswick (mainly within the St. John River basin); elsewhere, farming is restricted to the broader valley bottomlands.

The Rivers

One natural resource is common to all four of the focus rivers and to many of the rivers of the region: the Atlantic salmon, a symbol of economic value and environmental quality. The rivers and lakes of the region have supported recreational angling since the first colonists arrived. By the nineteenth century the rivers of New Brunswick were the most prized destination for Atlantic salmon angling among Europeans and Americans. The value of recreational fisheries in the region is less impressive than that of forestry but still significant. According to 1995 statistics direct expenditures made by anglers in the Atlantic provinces amounted to approximately \$100 million (Canadian), or 4% of the value of the recreational fishery for the entire country (EPAD 1997). Indeed, the state of each of the focus rivers today—what’s right and what’s wrong—can be assessed by understanding the state of Atlantic salmon in each of the rivers. Each of the four rivers represents a different situation in its relation to the salmon. The Miramichi River, a large unregulated river in New Brunswick, is considered the premier river for Atlantic salmon in North America and is reputed to produce more Atlantic salmon than any other river in the world, but stocks are in decline and deep concern exists for the future. The Moisie River is wild and relatively unexploited and has some of the oldest private fishing lodges of anywhere in North America; it represents the best-case scenario for a rather unique stock of large Atlantic salmon. The Exploits River is a success story for salmon enhancement, primarily because of fish stocking in reaches that were not utilized by salmon because of impassable upstream migration barriers. In the past decade 15,000 to 30,000 adult salmon have returned annually to spawn. Finally, the St. John River represents the worst case for wild Atlantic salmon survival in eastern Canada. It was once characterized as a salmon river rivaling the Miramichi in terms of fish production. Today the combination of hydroelectric dams, land-use activity that degrades habitats, pollution from

large urban centers and industries along the watercourse, and historic overexploitation have contributed to the situation where a small fraction of the historic runs of wild salmon now return to the system. Some unique stocks are now considered extinct. However, despite the gloomy scenario, the resilient nature of the river ecosystem and recent community-led proenvironment initiatives mean that such rivers can and should be viewed with hope, rather than despair, in terms of the potential for restoring ecological integrity to these once proud waterways.

In addition to the status of their salmon resources, the rivers in the region display a wide range of conditions and development. Some, like the Petitcodiac River, suffer from a causeway situated below head of tide that has changed sediment flow patterns and resulted in channels that are blocked and filled with agricultural runoff. The St. John River, an international river and the largest in the region, has suffered numerous similar insults by way of dams, urban pollution, and industrial discharges. By contrast, the Moisie, Humber, and Grand Cascapedia rivers are treasured for their pristine waters and the opportunity for realizing a wilderness experience. Some of the rivers are singularly developed for hydroelectric power, like the Churchill and Exploits rivers, whereas others, like the Dunk and LaHave rivers, provide multiple uses for agriculture, fisheries, and municipalities. The Dunk River, the smallest basin described here, is a low-gradient, short river dominated by groundwater discharge, which is characteristic of the island watercourses. A few are so scenically unique that they are found in and near National Parks, like the Big Salmon River along the Bay of Fundy and the Humber River in western Newfoundland.

Winter conditions greatly influence the hydrology, recreation, land use, and ecology of these rivers. Groundwater and the coastal maritime climate moderate the thermal and flow regimes and ice cover of the Dunk, Big Salmon, and LaHave rivers. The interior and northern rivers, like the Miramichi, Moisie, Grand Cascapedia, and Churchill, experience intact ice cover for six to eight months of the year, and most of the region’s rivers experience a strong spring snowmelt influence on the hydrograph. A large dam on the Churchill has totally eliminated the annual pattern of discharge downstream.

The Canadian Atlantic rivers cover three freshwater ecoregions as defined by Abell et al. (2000). The North Atlantic–Ungava ecoregion, located in Labrador, is considered nationally important in biological distinctiveness and includes the Churchill River in this chapter. The Lower St. Lawrence

ecoregion to the south is considered continentally outstanding and includes most other rivers in this chapter. As indicated, a major reason the ecoregion is considered outstanding is because of the runs of anadromous Atlantic salmon. The St. John and LaHave rivers are at the north edge of the North Atlantic ecoregion, which is considered nationally important and is also distinguished by runs of Atlantic salmon and shad.

EXPLOITS RIVER

As early as 1773 the Exploits River appeared on navigators' charts. A 6th order river, the Exploits is the largest in insular Newfoundland, flowing in a northeasterly direction for over 236 km into the Bay of Exploits on the northern edge of the island (Fig. 21.8). This 11,272 km² basin includes the second-largest lake in Newfoundland, Red Indian Lake (181 km²), the last outpost of the now extinct Beothuk nation. Like most insular Newfoundland river systems, there is extensive lacustrine habitat in the catchment, in this case representing approximately 99% of the total fish-rearing habitat. The reg-

ulated flow for hydroelectric production has altered the seasonal patterns of discharge and natural ice regime in the river (Fig. 21.3). Spectacular ice jams may now occur in midwinter, instantly flooding and freezing riverside towns like Badger.

Evidence of the aboriginal Beothuk people of insular Newfoundland dates back to AD 200. Originally a coastal people during summer, hostilities with British salmon fishers and trappers who settled seasonally along the coast in Notre Dame Bay (early eighteenth century) led to the Beothuks being driven further inland, particularly in the Exploits River valley around Red Indian Lake. There they experienced a steadily deteriorating life of subsistence, disease, starvation, and finally extinction. The first record of any permanent station by white settlers was in 1778 near the mouth of the Exploits River. The fur and salmon fishing industries were closely linked during the early settlement of the area. In summer they resided on the coast for easy access to the salmon rivers, but wintered inland in the more wooded, protected areas, hunting and fur trapping. By the nineteenth century the shores of Newfoundland, including the Bay of Exploits, were overtaken by year-round European fishers, fur trappers, and loggers. In the

FIGURE 21.3 The Exploits River and hydroelectric dam at Bishop's Falls, Newfoundland. A fishway is present on the far side of the river at the base of the waterfall (PHOTO BY C. BOURGEOIS).

Exploits River valley of the early twentieth century, the Anglo-Newfoundland Development Company—known by its apt acronym as the “A.N.D. Company”—controlled much of the region’s industrial and commercial sector. It founded the pulp and paper industry in Grand Falls on the lower Exploits and conducted the original exploration of the Buchans Mine just north of Red Indian Lake.

Physiography, Climate, and Land Use

The drainage basin lies in the New England/Maritime (NE) physiographic province on the northeastern edge of the Appalachian Provinces physiographic division (see Fig. 21.8). The headwaters lie in the Newfoundland Highlands, whereas the main channel flows through the Notre Dame region of the Newfoundland Central Lowlands (Stockwell 1963). The basin is underlain by volcanic and metamorphic rocks associated with slate, sandstone, and conglomerates. The rocks in the upper reaches of the basin, near Red Indian Lake, are principally Ordovician in origin and volcanic in structure; there are significant granitic formations in the area that probably give the river its characteristic water quality of low dissolved solids and low conductivity. The northeasterly trending geological structures gave rise to the parallel alignment of lakes and streams that are easily identifiable in the Exploits basin. Maximum relief is 490 m asl in the headwaters of the Lloyds River in the Annieopsquotch Mountains. Unlike the other focus rivers, the Exploits basin has an abundance of lacustrine habitat (approximately $337 \times 10^6 \text{ m}^2$; Bourgeois et al. 2001).

The Exploits basin is primarily within the Eastern Canadian Forests terrestrial ecoregion (Ricketts et al. 1999). Black spruce and balsam fir are the predominant tree species; the most common hardwood is white birch. Higher elevations are considered to be in the Newfoundland Highland Forests ecoregion, which also includes dwarf kahnia in addition to spruce–fir forest. Although most of the basin is forested, bog lands and rocky barrens also make up a significant portion of the area.

The average annual precipitation in the region is 99.1 cm (110 cm midbasin), evenly distributed throughout the year (Fig. 21.9). However, approximately half of the precipitation is stored as snowfall until the spring melt period. Mean monthly temperatures range from -9.3°C in February to 15.6°C in July (see Fig. 21.9). There are approximately 115 frost-free days.

Forestry is the main industry for this part of insular Newfoundland. A pulp and paper industry

has operated at Grand Falls since 1909. It discharges its effluent into the main stem of the Exploits River in the same general area where domestic sewage enters from the towns of Grand Falls and Windsor. In 1995, Grand Falls Pulp and Paper began aerating their effluent as part of a secondary waste treatment process; this has resulted in a reduction in suspended solids and BOD within the effluent (Bourgeois et al. 2000). Timber harvest for pulp wood is generally by clear-cutting, and has occurred over much of the Exploits basin. For example, forest harvesting operations in the area around Red Indian Lake date back to 1903 (Morry and Cole 1977). Log driving on the river and tributaries, often involving the erection and operation of small “splash-dams,” was discontinued in the mid-1960s (O’Connell et al. 1983), although log driving on the main stem continued to the late 1980s and early 1990s (C. Bourgeois, personal communication).

River Geomorphology, Hydrology, and Chemistry

Several times during the Pleistocene epoch ice sheets covered the island as they did continental North America. One of the last ice caps was centered near Grand Falls. As the glaciers moved seaward they scraped most of the soil from the land surface and left a cover of gravel, sand, and till strewn with glacial erratics (boulders). The glaciers were also largely responsible for the topography of the basin, where they scooped out the bedrock to form basins for lakes and ponds and planed the hills into asymmetrical forms featuring a gentle slope on one side and a steep drop on the other. The uneven distribution of the glacial drift resulted in poorly drained regions characterized by an abundance of bogs. Average gradient for the main channel from the headwaters to the head of tide is approximately 1.6 m/km.

Flow data are recorded at a gauging station on the main stem with an area of 8640 km^2 (about two-thirds of the total basin area). The average discharge at this station is $273 \text{ m}^3/\text{s}$, varying between a maximum daily flow of $2090 \text{ m}^3/\text{s}$ and a minimum of $36 \text{ m}^3/\text{s}$ in 29 years of record. Approximated mean discharge at the mouth is $356 \text{ m}^3/\text{s}$. Peak snowmelt flow occurs between April and June (see Fig. 21.9). A dam at the outlet of Red Indian Lake regulates the flow for hydroelectric production further downstream, so the seasonal pattern is not as strong as it otherwise would be.

Water-chemistry data collected from the lower reach (Grand Falls and Bishop's Falls) indicate that the Exploits River is similar to the Miramichi River (i.e., a soft-water stream that is typically low in productivity). Surveys carried out in Red Indian Lake in 1984 indicated an oligotrophic, coolwater lake (7°C to 11.5°C), with transparencies between 5.1 and 6.1 m (Hammar and Filipsson 1985). Limnological studies conducted by Morry and Cole (1977) also indicated low productivity in the lake; they suggested that this was partly due to unstable shoreline conditions resulting from severe fluctuations of water levels due to regulation at the outflow dam. Headwater tributaries are suggestive of even softer water, with average conductivities measured between 20 and 35 µS/cm (Randall et al. 1989). Typical pH measurements range between 5.8 and 6.8 but there is some indication that the waters of the Exploits may be more acidic at times, with pH values reaching 4.1 to 4.2 (Randall et al. 1989), probably during spring snowmelt conditions. Dissolved organic carbon has ranged from 9.7 to 10.5 mg/L, total N from 0.05 to 0.10 mg/L, and total P from 0.006 to 0.012 mg/L (Morry and Cole 1977, Randall et al. 1989).

River Biodiversity and Ecology

The Exploits River is found in the Lower St. Lawrence freshwater ecoregion (Abell et al. 2000). There have been surprisingly few studies of the biota of the system despite the hydroelectric development that has impacted the environment. In comparison with the other focus rivers, the Exploits River has a rather species-depauperate flora and fauna, a reflection of its island status and limited opportunity for colonization.

Algae

No information is available on the phytoplankton community or primary production in the Exploits River system. Morry and Cole (1977) characterized the community of phytoplankton in Red Indian Lake as depauperate, but provided no data.

Plants

Black spruce and balsam fir are the most common riparian trees in the basin and are the basis of the pulp and paper industry in the lower river valley; speckled alder is commonly found along the banks of tributaries. As is the case in much of Newfoundland, edible berries, such as blueberries, partridgeberries, and cloudberries, are abundant throughout the basin, including the riparian zone, except where there are

ponds and bogs. The berries provide food for numerous birds and mammals, including man. They were especially important to the Beothuk people, who historically used the berries for food as well as medicine (e.g., bunchberry). Pitcher plants are common in the acidic bogs that dot the floodplain. Aquatic macrophytes are rare in the Exploits River except for occasional mats of aquatic buttercup in the slow to moderately flowing shallows of small tributary streams, where they can be an important food source for moose.

Invertebrates

Morry and Cole (1977) provided the only data on zooplankton and macrobenthos in the Exploits River system, at Red Indian Lake; the following summary is based on their 109 plankton tows in 1974. Species diversity was low, as was the number of zooplankters and their small size, suggesting a low-productivity lake, as expected based on the water chemistry. Only 12 species of Entomostraca were identified. Of these, two cladocerans (*Bosmina longirostris* and *Holopedium gibbernum*), one calanoid copepod (*Diatomus minutus*), and one cyclopoid copepod (*Cyclops scutifer*) were the most commonly occurring species. All are characteristic species of low-productivity waters in eastern Canada.

The benthic community of Red Indian Lake was also sampled by Morry and Cole (1977). Less than 25% of the 109 grab samples yielded any macroinvertebrates. Five taxa were present; these included leaches (Hirudinea), sphaeriid clams, chironomid midges, and two families of aquatic worms (Oligochaeta). All the species are common to Newfoundland waters and are not associated with polluted conditions. Rather, the lack of species diversity and abundance reflect the unproductive state of the waters in the system, as was the case for zooplankton. No other information is available on the macrobenthos in the Exploits River system, although insects such as mayflies, stoneflies, caddisflies, and midges are present; biting flies such as black flies and mosquitoes are particularly abundant in the summer.

Vertebrates

In addition to Atlantic salmon (both the landlocked [ouananiche] and anadromous forms), four other fish species are present in the river proper: brook trout, Arctic char, American eel, and threespine stickleback. Anadromous rainbow smelt are known to occur as far upriver as Bishop's Falls.

The largest brook trout (approximately 50 cm long) captured by Hammar and Filipsson (1985)

during their fish surveys of Newfoundland lakes were from Star Lake in the upper Exploits River basin; the largest ouananiche captured, at 55.6 cm, was a specimen taken from Red Indian Lake. The sampling in this large lake also yielded Arctic char, the only species found at depths >20 m, although their results indicated a general low density of fish in Red Indian Lake. Char are rare downstream of the lake. Unfortunately, very little information exists on the status of trout and char elsewhere in the river system. Eels are most common in the lakes, being found upstream of Red Indian Lake; sticklebacks prefer slow-flowing shallow waters, often in littoral zones of ponds and lakes. All the fishes occurring in the Exploits River are indigenous to insular Newfoundland; no non-native species are known to occur.

Beaver, river otter, and muskrat are common in the Exploits River valley. They were trapped for their pelts in the early twentieth century, but this activity has largely ceased.

Ecosystem Processes

There are no known studies of ecosystem processes in the Exploits River. Given the predominance of lakes and the decomposition-resistant nature of riparian carbon sources (largely coniferous needles), it is suspected that autochthonous production may drive much of the energy cycling within the river. This is further supported by the high concentrations of filter-feeding macroinvertebrates often found at the outflows of riverine ponds and lakes (R. A. Cunjak, unpublished data).

There are no direct measurements of fish production in the lakes of the Exploits River. However, Randall et al. (1989) made estimates using values from other Newfoundland systems. Based on measurements from Western Arm Brook (northwest of the Exploits), where lacustrine habitat represents 98% of the rearing habitat (similar to the situation in the Exploits), 67% of smolts were produced in standing waters. Therefore, salmonid production in the lakes is significant, and the total production rate for the Exploits system was estimated to average 0.03 smolts/m², slightly less than the 0.04 smolts/m² estimated for the Miramichi River (Randall et al. 1989). The authors also noted that although fewer smolts are produced in the Exploits, production rate is similar to the Miramichi River because Exploits smolts are larger on average (54 g versus 25 g) and older (mean age of 3.4 versus 2.7 yr). Total fluvial production rate was estimated to be 3 to 5 g m⁻² yr⁻¹ (Randall et al. 1989). More recent data compiled by Bourgeois et al. (2000) indicate some significant

changes in smolt characteristics over the past decade. Between 1990 and 2000 smolts leaving the Exploits have been smaller (average weight 40.1 g), whereas age has remained similar (mean age 3.3 yr), suggesting that production rate may have decreased.

Human Impacts and Special Features

Much of the Exploits River lies within the central part of insular Newfoundland, where access is very limited. Hence, the river offers a true wilderness experience for those willing to venture into the remote parts of the upper reaches. In addition, Red Indian Lake offers an opportunity to view one of Newfoundland's largest natural lakes and the site where the Beothuks last lived.

The Exploits River provides a prime example of the potential success of a well-planned salmon enhancement program. Prior to 1957, <10% of the catchment area was available to diadromous fishes such as salmon due to a combination of natural and man-made barriers to fish passage. With a series of enhancement actions, including adult transfers (lower reaches), planting of swim-up fry (into the middle Exploits), and the transfer of adult salmon and fry stocking into tributaries flowing to Red Indian Lake, >90% of fish habitat within the catchment is presently available for anadromous salmon production (O'Connell and Bourgeois 1987). These actions have yielded impressive smolt–grilse return rates as high as 8% (Bourgeois et al. 1987). Since 1993 salmon production has been maintained entirely by a self-sustaining population. Part of the success can be attributed to measures outside the river system, such as the 1992 moratoria on commercial salmon fishing around insular Newfoundland, and on northern cod (thereby eliminating the by-catch of salmon in cod-fishing gear). For example, the number of returning adult salmon to Bishop's Falls averaged 8864 fish when there was a commercial fishery (1975 to 1991) compared with 20,647 after the moratorium (1992 to 2001; C. Bourgeois, personal communication). In addition, the hydroelectric industry has mitigated its environmental impacts by constructing fish-passage facilities at dams and, in 1996, by installing fish deflectors (louvers) to deter the entry of smolts and kelts into an artificial power canal associated with the dam at Grand Falls (Bourgeois et al. 2000).

Recreational fisheries target the three salmonid species in the river: Atlantic salmon, brook trout, and Arctic char. Most Atlantic salmon angling occurs in the lower reaches of the river, especially in the area

between Bishop's Falls and Grand Falls. Catch and effort have both increased since the mid 1970s, presumably because of the enhancement program. To allow for a recreational fishery while the Exploits stock is still developing, the federal government (DFO) has established a management target of 13,000 spawners, a target that was reached in all years but one since its establishment (Bourgeois et al. 2000).

Hydroelectric development has resulted in significant impacts to the Exploits River system (O'Connell et al. 1983). Beginning in 1909, two hydroelectric dams were constructed on the main stem of the river, near the head of tide, at Grand Falls (45MW capacity) and Bishop's Falls (see Fig. 21.8 and Fig. 21.3); both continue to operate today, and each site has some form of fish-passage facility. Historically, Bishop's Falls was not a barrier to fish migration, whereas Grand Falls was a complete barrier to upstream migration by diadromous fishes. Water-storage dams occur at the outlet of Red Indian Lake (constructed in 1909, and an impassable barrier), Long Lake, North Twin Lake, South Twin Lake, and Sandy Lake. Goodyear's Dam, 3km upstream of the Grand Falls dam, was built for log driving in 1975 (two fishways present). In addition to dams, in 1968, waters from a 1068km² subcatchment of the upper reaches of the Exploits River (Victoria River) were diverted south to another river system as part of the Bay d'Espoir power development (O'Connell et al. 1983). Recent concern has also been voiced over the potential impacts to fish passage at Grand Falls as a result of ongoing hydro development.

Morry and Cole (1977) suggested that the low productivity and paucity of char, trout, and ouaniche in Red Indian Lake were related to the severe water-level fluctuations, in excess of 9m, resulting in an unstable littoral environment. More recently (~1999) a hydroelectric development was completed at the outflow from Star Lake, a subbasin draining into Red Indian Lake. The dam was built with no fish-passage facility and the subsequent inundation flooded the main spawning tributaries for a trophy-size population of resident brook trout. The project generated much controversy and concern for the unique populations of Arctic char and brook trout that inhabit the subbasin (Gibson et al. 1999).

Forestry is the main industry for this part of Newfoundland. Timber harvest is generally by clear-cutting and has occurred over much of the basin, dating back to 1903 in the area around Red Indian Lake (Morry and Cole 1977). Log driving on the

main stem continued into the late 1980s and early 1990s (C. Bourgeois, personal communication). A pulp and paper industry has operated at Grand Falls since 1909. In 1995, the mill began aerating its effluent as part of a secondary waste treatment process; this has significantly reduced suspended solids and BOD (Bourgeois et al. 2000).

A base-metal mine (copper, zinc, lead) began operation in 1927 at Buchans. Prior to 1966, mine tailings were discharged directly into Buchans Brook and subsequently into Red Indian Lake; after 1966, tailings were diverted into a settling pond and the effluent treated (O'Connell et al. 1983). Today most of the mining activity in the catchment (including the Buchans mine) has ceased except for some base-metal exploration in the subbasin of Noel Paul's Brook (C. Bourgeois, personal communication).

Development is concentrated in the lower reaches of the river in communities ranging from Grand Falls/Winsor (population 17,500) to Millertown (population 750). Of the seven communities located in the drainage basin of the Exploits River, only one, Badger, treats its domestic waste prior to discharge into the river (O'Connell et al. 1983). The town of Grand Falls/Windsor recently constructed a sewage treatment plant and the town of Bishop's Falls is in the process of doing the same. No information was found detailing the possible environmental impacts of these discharges.

MIRAMICHI RIVER

The Miramichi River flows northeastward from central New Brunswick into the Gulf of St. Lawrence through the Barrier Islands at 47°N latitude (Fig. 21.10). It is the 2nd largest river system in the Maritime Provinces after the St. John River, draining an area of about 14,000km² and contributing about half of the freshwater inputs to the southern portion of the Gulf of St. Lawrence. The entire river is unregulated and unobstructed and has the largest production of Atlantic salmon and other diadromous fishes in North America. The valley is lightly populated with widely separated settlements (Fig. 21.1), often located at abandoned log dumping and removal sites that were used in the nineteenth and early twentieth centuries during riverwide log drives.

For at least 10,000 years before the coming of the Europeans the area was inhabited by Mi'kmaq Indians, who called the river the Lustagoocheehk ("little goodly river"). Basque and French fishermen came to fish in the Miramichi Bay each summer from

the early 1500s, but no attempt was made at settlement until French colonies were established in the seventeenth century.

Physiography, Climate, and Land Use

The Miramichi River basin lies wholly within the New England/Maritime (NE) physiographic province of the Appalachian Provinces division (see Fig. 21.10). Approximately half of the basin rises in the New England and New Brunswick Uplands. The lower river flows across the New Brunswick Lowlands. Three main tributaries, the Northwest, Little Southwest, and Southwest, rise in the predominantly granitic and volcanic highlands. In the lower reaches, the Southwest and Northwest Miramichi river branches combine to form the main channel at Beaubear's Island, several kilometers below the head of tide. The highland (western) region of the river basin is underlain by Ordovician, Silurian, and Devonian rocks, consisting primarily of granite, quartz, monzite, and granodiorite. The eastern portion of the Miramichi basin lies in the Maritime Plain, which is underlain with sandstones, conglomerates, and siltstones dating from the Pennsylvanian period and earlier (Chiasson 1995).

Although the basin is considered to be in the Boreal Forest biome, it is actually a transitional zone represented by portions of three terrestrial ecoregions: the Eastern Canadian Forests, New England/Acadian Forests, and Gulf of St. Lawrence Lowland Forests terrestrial ecoregions (Ricketts et al. 1999). The typical boreal species of balsam fir, white spruce, and black spruce are most common in the highlands and northern portions of the basin. Temperate deciduous species, such as maple, yellow birch, beech, and oak, are relatively abundant in the floodplains and ridges of the lower basin.

The climate is more continental than marine influenced due to the general movement of air masses from west to east. The mean annual air temperature is 4.3°C, with the highest mean monthly temperature of 18.8°C in July (Fig. 21.11). However, summer maximum temperatures in the interior typically reach 25°C to 30°C. Air temperatures cool rapidly in October and reach the freezing point by November. Mean temperatures from December through February are below -7°C, with the Miramichi River and estuary freezing over by mid-December on average. Spring breakup occurs between mid-March and late April (Fig. 21.4). The region has >120 frost-free days over the year. In an average year in the region, 113 cm of precipitation occurs on 160 days as rain

or snow. This is distributed relatively evenly throughout the year, with the highest amount, almost 12 cm, falling in December (see Fig. 21.11).

More than 90% of the basin is forested. Since 1779, when the first contract was granted to export square timber to Britain, the harvesting of the forests has taken place throughout the Miramichi basin. This activity increased during the Napoleonic Wars (1800 to 1815) with the demand for lumber, especially white pine, for use as masts and spars for the British navy. In 1825, the Great Miramichi Fire burned much of the forest; what survived was selectively harvested in the latter half of the nineteenth century to support a thriving shipbuilding and lumber-export industry. In the twentieth century, forestry in the Miramichi changed focus to support the pulp and paper industry. Technological advancements and market demand shifted the woodland operations from selective harvest to clear-cutting.

A pattern of isolated small towns follows the river valleys, with some local farming on the broader valley bottomlands. Forestry and tourism are the major sources of income in the region and support a workforce of approximately 60,000 people. Mining for precious metals and base metals like zinc, lead, copper, and cadmium was once a major industry, particularly in the headwaters of the Northwest Miramichi River, but this activity has been discontinued in the last decade due to poor markets and depleted resources. The largest settlement is the city of Miramichi (~25,000 people) located on the upper estuary on Miramichi Bay.

River Geomorphology, Hydrology, and Chemistry

The entire Miramichi basin was covered in ice during the last Wisconsin glaciation. Ice advances from the west and north reduced the headwater bedrock contours to rounded hills. At the beginning of the deglaciation period about two-thirds of the lowland portion of the basin was submerged in a shallow marine estuary. As glacial rebound occurred large meltwater rivers extended through the lowlands to the retreating shoreline, scouring broad meandering valleys. The present-day river occupies about one-quarter of the width of the meltwater valley bottom, leaving intervals of fertile bottomland utilized by small farms and towns along the river's course. The predominantly bedrock-controlled channel changes from boulder-filled reaches in the upper valley to broad reaches of coarse gravel in the middle and

FIGURE 21.4 The Southwest Miramichi River during late winter, looking downstream from Quarryville, New Brunswick, near the head of tide. Note the 3 m high ice walls and the large ice fragments (within and outside the channel) that were formed during a recent breakup in the river (PHOTO BY R. CUNJAK).

lower valley. The river gradient changes from 5 m/km to 1 m/km between the upper and lower reaches. The mean tidal amplitude of 1 m in the Miramichi estuary also affects the water levels in the last few km of the channel.

Estimated mean annual discharge for the Miramichi is 322 m³/s, based upon extrapolating from an upstream gaging station. The average annual runoff based on five streamflow gauging stations was estimated as 71.4 cm (Caissie and El-Jabi 1995). This represents a high percentage of the mean annual basin precipitation of 113 cm (63%). Although precipitation occurs fairly evenly throughout the year, the major portion of the runoff occurs as spring snowmelt events (see Fig. 21.11). Minimum flows in late August can threaten fish movement and survival.

Water-chemistry data collected from tributaries and main-stem sites in the Miramichi River catchment indicate a near-neutral, soft-water stream (mean conductivity range 28 to 55 μ S/cm) that is

typically low to moderate in productivity (see Randall et al. 1989, MREAC 1992, Komadina-Douthwright et al. 1999). Although the water in the Miramichi system is generally well buffered (mean pH 6.5 to 7.8), the melting snowpack during the spring thaw can occasionally result in localized, short-term acidic pulses. For example, the pH of water samples collected in the early spring of 1990 was occasionally <5.2 in the headwaters of the Southwest Miramichi River (MREAC 1992). Excessive loading of phosphorus or nitrogen is rare in this system, reflecting the relatively sparse population along the river's upper and middle reaches and the lack of agricultural or industrial inputs until one reaches the estuary (mean range of total N 0.06 to 0.19 mg/L, total P 0.006 to 0.016 mg/L). Below the head of tide, pulp and paper industries and urban discharges add significantly to the dissolved organic carbon, N, and P loadings. For example, average DOC values for samples collected from tributaries to Miramichi Bay are >25 mg/L (MREAC 1992).

River Biodiversity and Ecology

The Miramichi River is located within the Lower St. Lawrence freshwater ecoregion (Abell et al. 2000). Although it is one of the few unregulated rivers in this region, its biology and ecology have not been especially well studied, except for its well-known Atlantic salmon and brook trout populations.

Algae

No published information is available on the species distribution of freshwater algae of the Miramichi River. Diatom growth is pronounced on rock surfaces in the open main-stem reaches from midsummer to autumn. Filamentous algae such as *Cladophora* is locally abundant in slow-flowing reaches of the lower river, particularly in areas associated with nutrient enrichment, such as near human settlements.

Plants

A lush mixed forest occurs in the floodplain. Common tree species, such as white spruce, white pine, black spruce, yellow birch, and northern red oak, tend to grow well back from the water's edge along the principal branches of the river due to the annual scouring of ice each spring; fast-growing bushes, such as willows and sweet gale, abound in these locations. In the headwaters and tributaries, speckled alder is prolific. Macrophytes are scarce in the upper and midreaches of the river. Pondweed, cordgrass, and bur-reed are common in a wide variety of still and flowing waters, from full freshwater to the salt marshes of the estuary (where eelgrass or *Zostera* spp. are locally abundant). Aquatic mosses, particularly *Fontinalis* spp., cover the boulders and rubble in shaded headwater streams throughout the basin.

Invertebrates

A 1951 study (Bousfield 1955) found 24 zooplankton taxa in the lower Miramichi, ranging from freshwater species, such as the cladoceran *Bosmina longirostris*, to marine species, such as the copepods *Pseudocalanus elongatus* and *Tortanus discaudatus*. Locke and Courtenay (1995) carried out one of the few other studies of zooplankton (historic and recent) of the Miramichi River, also restricted to the lower river reaches and estuary, yielding 73 invertebrate taxa or more than three times the number found in 1951. Most common were copepods (e.g., *Eurytemora affinis*, *Acartia hudsonica*), the cladoceran *Bosmina* spp., barnacle nauplii, and the aquatic

stages of various insects (Plecoptera, Ephemeroptera, and Diptera). Much more information is needed on the ecology and distribution of phytoplankton and zooplankton in eastern Canadian rivers such as the Miramichi.

There has been little sampling of the benthic invertebrate fauna in the Miramichi River system. A few tributaries have been sampled but there is no published information on the benthic invertebrates of the main-stem branches: the Northwest, Southwest, and Little Southwest Miramichi rivers. From limited data it appears that the macrobenthic fauna is diverse and rich. In a 3rd order tributary of the Little Southwest Miramichi River (Catamaran Brook), Giberson and Garnett (1995) identified >95 genera of aquatic insects, with the greatest diversity found in the mayflies (25 genera) and caddisflies (19 genera); dipterans were the most common insects found in emergence traps, reaching a peak of approximately 3000/m² (mainly black flies) at one site in July. The most common genera included the mayflies *Baetis*, *Ephemerella*, and *Stenonema*; the stoneflies *Leuctra*, *Alloperla*, and *Pteronarcys*; the caddisflies *Hydropsyche*, *Dolophilodes*, *Glossosoma*, and *Pycnopsyche*; and the true flies *Prosimulium* and *Tipula*. Chironomid midges and elmids beetles were also abundant. Brachycentrid caddisflies are very common in boulder-rubble riffles in lower river reaches. As evidence of the poor state of knowledge of aquatic insects in Atlantic Canada, a study of the stoneflies in Catamaran Brook by Giberson and Garnett (1996) identified 31 species, of which 8 were new provincial records.

Few freshwater mollusks are known to occur, but no quantitative surveys have been carried out in the river, a reflection of the lack of targeted sampling for this environmentally sensitive group of organisms. Four species have been positively identified from the Miramichi River but more may exist (D. McAlpine and A. Martel, personal communication). These include the freshwater pearl mussel, the eastern lamp mussel, the eastern floater, and the eastern elliptio.

Vertebrates

The Miramichi River is world renowned for its sport fishing, primarily for anadromous Atlantic salmon and brook trout. Indeed, it is believed to produce more wild Atlantic salmon than any other river in North America (an estimated 200,000 adult salmon returned to the river to spawn in 1992). In addition to these salmonid species, the Miramichi River supports significant numbers of eight other diadromous fishes (sea lamprey, American eel,

alewife, blueback herring, American shad, rainbow smelt, Atlantic tomcod, and striped bass). The Atlantic sturgeon, also diadromous, is occasionally found in the lower reaches of the Miramichi River. Historically (about 2500 years ago) this species was the focus for the food fishery of the Mi'kmaq people in the Miramichi region (P. Allen, personal communication). Although fish production in the fluvial freshwater portion of the river is low, the fisheries yield is high because of the high biomass produced in the marine environment (Randall et al. 1989).

Two unique characteristics of this river system, its moderate gradient (~2m/km average slope) and the absence of barriers to fish passage (natural and man-made) on the three principal branches, make much of the system accessible to migrant species. Some, like the salmon, trout, lamprey, and eel, are capable of reaching the very headwaters in each of the three principal branches, whereas tomcod and striped bass rarely move above head of tide during their migrations.

After reaching a peak in abundance in 1992, Atlantic salmon returns to the Miramichi River have steadily declined over the past decade, presumably a consequence of poor marine survival. The decline in salmon returns has been realized despite increasing numbers of juvenile salmon in the river, the closure of commercial salmon fisheries since 1984, and a highly regulated recreational and aboriginal fishery (collectively accounting for <8% of potential egg deposition; DFO 2001a).

The Miramichi River has a diverse fish fauna for the maritime provinces. In addition to the 11 diadromous species, numerous freshwater and estuarine/marine fishes reside in the variety of habitats offered by this large river system. The brackish waters and rich food base of the Miramichi estuary make this an important rearing environment for >20 species whose larvae use this environment, including "true" estuarine fishes, like tomcod and sticklebacks, as well as marine species, such as flounder, herring, and capelin (Locke and Courtenay 1995). An extensive survey of the fish community in the Miramichi estuary was carried out by Hanson and Courtenay (1995), who found that the estuary serves as a temporally important habitat for >40 species of adult fishes. Some of these fishes use the area for brief periods en route upriver or to the sea (e.g., salmon), for spring/summer feeding (trout), or for overwintering (tomcod, smelt), whereas others used the estuary for their entire life (smooth flounder, mummichog). Recent radio-tracking data have shown that some postspawned Atlantic salmon move >50 km to over-

winter below head of tide, presumably because of the lack of ice-related disturbance relative to lotic reaches of the river (Cunjak et al. 1998, Komadina-Douthwright et al. 1997).

In the river proper, above the head of tide, the number of species in the fish community is less than in the estuary but still impressive. Randall et al. (1989) listed 21 species (representing nine families) that were found entirely in freshwater. (The only addition to this list is the recently introduced brown trout, which is found in a few isolated locations of the system.) The Cyprinidae, with nine species, form the largest group and are especially abundant in the lakes and warm, slow-flowing reaches of the main river channels. Based on electrofishing data from 27 sites sampled annually for 11 years, Randall et al. (1989) found that four species accounted for most of the fish community. These were, in order of abundance, Atlantic salmon, blacknose dace, slimy sculpin, and brook trout. Total biomass of these four dominant species was estimated to be approximately 2 g/m² (of which salmon contributed 50%), thereby indicating a production rate of 2 g m⁻² yr⁻¹ in fluvial habitat of the Miramichi River. In the 1st order headwater streams of the Miramichi, often above barriers to anadromous fishes, fish communities are less diverse; in these situations, brook trout and occasionally slimy sculpin are the only fishes present.

Nonnative fishes in the Miramichi system include white perch, brown trout, and chain pickerel. Their distribution is limited to small sections of the basin. There is much concern about the potential impacts on native Atlantic salmon and brook trout from further introductions, especially of piscivorous species (e.g., smallmouth bass).

Commercial fisheries are confined to the estuary (mainly Miramichi Bay) and the lower reaches of the river below the head of tide. Gaspereau (a term used to collectively refer to the freshwater clupeids, blueback herring and alewife) and smelt account for >90% of the total biomass of commercially exploitable diadromous fish passing through the estuary (Chaput 1995). Average landings of these species ranged between 1900 and 2900 tons in the last 10 years (Chaput 1995, DFO 2001b). Striped bass and shad, two species at the northern limit of their distribution, are exploited at low levels, and their populations have displayed significant declines in recent years.

Beaver, mink, and river otter are the most common aquatic mammals occurring in the Miramichi River. Common merganser and double-crested cormorant are abundant in the upper and

lower reaches of the river, respectively. Their piscivorous habits and large numbers have made them the target of angling groups, who blame them for a significant portion of the decline in salmonid abundance in the river, although direct evidence for the impact is lacking. Two-lined salamanders are commonly found in the headwater streams.

Ecosystem Processes

Large-scale or process-oriented research is rare in the Miramichi River system. One exception is the Catamaran Brook research project (Cunjak et al. 1990, Cunjak 1995), with its ecosystem approach to the study of population dynamics of the aquatic fauna. Invertebrate sampling in this 52 km² catchment have found a predominance of shredders in headwaters (1st and 2nd order streams) and increasing abundance of scrapers in the larger, open sections in the lower reaches of Catamaran Brook (Cunjak 1995). Doucett et al. (1996) provided supportive evidence of this trend using stable isotope analyses. They demonstrated that the food webs of headwater streams were largely dependent on allochthonous carbon compared with the larger 5th order river (Little Southwest Miramichi), where food webs are more dependent on autochthonously produced carbon (e.g., algal production). How such food webs and nutrient cycling may be impacted by large-scale human disturbances (e.g., the extensive forest harvest in the Miramichi headwaters) or point-source discharges, such as those concentrated in the estuary, require more attention. Certainly, the research on endocrine-disrupting chemicals (from forest spraying for pest control) and their potential impact on salmon survival (Fairchild et al. 1999) is suggestive of how complex such environmental assessment needs to be.

Human Impacts and Special Features

The Miramichi River, set in a broad glacial river valley, remains unregulated and unobstructed. The river produces more Atlantic salmon than any other river in North America, attracting fly fishers and river enthusiasts from around the globe. Historic fishing lodges, unique folklore, and a culture of acclaimed fishing guides and lumberjacks exists on this river, which is like no other in the Atlantic region.

Although many reaches of the river exist in near pristine condition, the basin has been subjected to several major environmental disasters, beginning with the 1825 forest fire that burned over 25% of

New Brunswick's forest and riverwide log drives in the main-stem channels (Kranck 1988). Widespread DDT spraying occurred in the 1950s as part of an annual spruce budworm control program, and heavy metal pollution was found in the Northwest Miramichi branch from poorly controlled mining activities between 1956 and 1971 (Zitko 1995).

The environmental impacts of forest harvest operations, together with log drives on large and small tributaries, were likely responsible for significant degradation of aquatic habitats but poorly documented and quantified (Cunjak 1995). Today forest managers are more considerate of environmental impacts and guidelines are more strictly enforced than in the past. Zitko (1995) summarized the three most important contemporary impacts on the flora and fauna of the Miramichi River as follows: (1) forest spraying activities to control insect pests, (2) base-metal mining activities and discharges, and (3) municipal and wood-processing discharges in the lower river and estuary.

Beginning in 1952, the Miramichi basin had the largest and longest-running spruce budworm control spray program in Canada. Early research on the effects of DDT on survival of Atlantic salmon (e.g., Elson 1974) led to banning the chemical in North America. Subsequent forest spraying (after 1963) with fenitrothion was less damaging to fish but caused increased rates of macroinvertebrate drift (Symons 1977). Some recent scientific research has linked forest spray chemicals (that resemble natural hormonal compounds) to disruption of physiological mechanisms in Atlantic salmon, which may partly explain population fluctuations (Fairchild et al. 1999). In the 1990s, virtually all spraying in Miramichi forests was with Bt, a biological control agent.

Effluents from a base-metal (copper and zinc) mine developed in the Northwest Miramichi in the 1950s resulted in mortality of resident fishes and downstream movement of large numbers of adult salmon (Elson et al. 1973), and reduction in aquatic insect abundance (Peterson 1978). Elevated concentrations of copper and zinc continue to affect the biota of this section of the Northwest Miramichi River.

The estuary is the site of greatest biological productivity and most human activity in the Miramichi basin (Chadwick 1995). The estuary receives large inputs of municipal discharges, wood-processing and wood-treatment waste from nearby industries, and heavy metals from mining discharges upriver.

Although some effluent concentrations have been reduced with new treatment facilities, stored contaminants, particularly in the sediments of the estuary, continue to be released during dredging operations and through the erosion of former dredge spoil areas (Buckley 1995, Zitko 1995, MREAC 1992).

In addition to these concerns, overexploitation of fisheries resources, such as salmon, shad, smelt, tomcod, and eels, is of concern to commercial and recreational fishers, government regulatory agencies, and citizens interested in the environmental health of this great river. Finally, conflicts over resource harvesting in the estuary, such as the Burnt Church confrontations between native and commercial lobster

fishermen, continue without a definitive resolution in sight.

ST. JOHN RIVER

The native people of the St. John River valley called it *Wolastoq*, the “Beautiful River” (Blair 2001). Its current name, the St. John River, is attributed to Samuel de Champlain, who arrived at the river mouth in 1604 on the feast day of St. John the Baptist. The 673 km long river, with a basin area of 55,110 km², is the longest in this region. It flows northeast through northern Maine (Fig. 21.5) and into Quebec before flowing southeast through New

FIGURE 21.5 St. John River headwaters, downstream from Moody Bridge in northern Maine, approximately 430 km from the river mouth. Note the lack of significant woody vegetation on the immediate riparian edge, a consequence of annual ice scouring (PHOTO BY M. GAUTREAU).

Brunswick and into the Bay of Fundy at 45°15'N latitude in the city of Saint John (Fig. 21.12). Indeed, between the Gulf of St. Lawrence and the Gulf of Mexico only the Susquehanna River is longer (Folster 2001). There are numerous important and substantive tributaries along the river's length. These include the Kennebecasis, Nashwaak, and Tobique rivers in New Brunswick, the Allagash and Aroostook rivers in Maine, and the Madawaska River in Quebec.

The St. John valley was first occupied by Maliseet and Mi'kmaq tribes, who raised agricultural crops on the rich valley bottomlands. French Acadians and then English Loyalists fleeing the American Revolution occupied the valley in the seventeenth and eighteenth centuries. Despite its size, its long history of navigation and colonization, its being the location of significant eighteenth-century British–American conflict (at one time home of Benedict Arnold), and its being the river on which the famous northwoods Chestnut canoe (MacGregor 1999) was perfected, the river is little known outside of New Brunswick and Maine.

Physiography, Climate, and Land Use

The St. John River basin lies in the New England/Maritime (NE) physiographic province (see Fig. 21.12). From headwaters in the Appalachian highlands to the estuary there is a vertical drop of 481 m as the river flows through three distinct physiographic zones. The upper basin flows from the river's source in Maine to Grand Falls in New Brunswick. Thirty-six percent of the basin arises in Maine in the forested hill and lake country of the "North Maine Woods." This section also includes the branch draining the Témiscouata–Madawaska River region of eastern Quebec (15% of the river basin). The upper St. John basin is sparsely populated and in relatively pristine condition. The central basin lies in the western sedimentary plain of the New Brunswick lowlands in a wide, smoothly glaciated meltwater valley (see Fig. 21.12). This reach is impounded by hydroelectric storage dams for much of its length. The lower basin from the Mactaquac Dam (west of Fredericton) to the ocean is tidal. This recently emerged coastal zone has little relief, collecting water to form three long bays, an inland delta, and several large shallow lakes. Two bedrock sills (Kennebecasis Bay, with an 11 m drop, and Reversing Falls, with a 5 m drop) limit the exchange of flows (and saline waters) between the deeper estuarine waters and the Bay of Fundy.

The St. John River basin primarily lies within the New England/Acadian Forests terrestrial ecoregion,

but also drains small portions of the Eastern Canadian Forests ecoregion and the Gulf of St. Lawrence Lowland Forests ecoregion near its mouth (Ricketts et al. 1999). Common upland vegetation includes black spruce, balsam fir, trembling aspen, and white birch. In the broad river valley, white spruce, white pine, red maple, yellow birch, beech, and red oak are common.

The climate is humid continental throughout most of the basin, with a mean annual air temperature decreasing from 5.5°C at Saint John in the estuary to 2.2°C in the northern headwaters. Mean monthly temperatures range from –9.6°C in January to 19.1°C in July (Fig. 21.13). Precipitation is evenly distributed throughout the year, varying from only 7.4 cm/mo to 11.4 cm/mo (see Fig. 21.13). Annual precipitation varies from 140 cm in the south to 90 cm in the northern headwaters, removed from maritime influence.

Settlements along the river were linked traditionally by river transportation, although this has now been interrupted by hydroelectric dams. Potatoes are the most important cash crop in the province, with approximately 22,000 ha in production, most of it in the St. John River valley principally between Grand Falls and Woodstock. Poultry and hog farms are concentrated in the upper and middle basins. Beef and dairy cattle farming are of similar importance, with dairy farms most common in the lower river valley around Sussex and the Kennebecasis subbasin. Grain crops, such as barley and oats, are of moderate importance and largely support the cattle industry. There is commercial farming of blueberries in the highlands and cranberries in the floodplains of the lower valley. Many small communities still rely on forestry, particularly in the upper basin (Maine). The most intensive harvesting for the pulp and paper industry is concentrated in the headwaters of the Tobique, upper St. John, and Nashwaak rivers. Wood-processing mills are located along the river, with the largest plants at Edmundston, Grand Falls, Nackawik, and Saint John.

River Geomorphology, Hydrology, and Chemistry

The entire St. John River basin was covered in ice during the last glaciation, reducing the headwater bedrock contours to rounded hills. The middle reach of the river follows a broad valley that was scoured by southerly trending glacial flows. As the ice melted the valley served as a major spillway from the inte-

rior. The preimpoundment river occupied a small channel within the valley. The present river widens to flood the whole valley bottom in hydroelectric reservoirs. Average main-channel gradients range from 1.3 m/km in the upper basin, to 0.5 m/km in the central basin, to 0.3 m/km in the lower basin.

Mean annual discharge for this large river is about 1110 m³/s. The average annual runoff varies from 90 cm in the south to 64 cm in the headwaters, reflecting the spatial distribution of rainfall. A larger portion of the precipitation runs off the rugged headwater region (71%) than in the lower basin (64%). Although the precipitation is evenly distributed throughout the year, much of it is stored in the northern snowpack. The largest runoff (>15 cm/mo) occurs when the snow melts in April and May (see Fig. 21.13). The highest stages of the river occur in ice-jam-prone reaches.

Water chemistry is very much influenced by the degree of land use and the influence of industrial and urban discharges along the river corridor. Based on recent sample collections in the main river from the headwaters (Maine) to Fredericton, the following results characterize water chemistry in the St. John River during the ice-free period (R. A. Curry, unpublished data): average pH 7.7 (range 7.3 to 8.1), alkalinity 51.2 mg/L as CaCO₃ (25 to 102), conductivity 154 μS/cm (83 to 275), total N 0.47 mg/L (<0.3 to 1.37), total P 0.115 mg/L (0.005 to 1.33), dissolved organic carbon 7.1 mg/L (3.2 to 14.0).

River Biodiversity and Ecology

The St. John is the northernmost river within the North Atlantic freshwater ecoregion (Abell et al. 2000). In describing the fish fauna of the St. John River we have divided the basin into three sections. The upper basin includes those waters above Grand Falls, a natural barrier to upstream passage by diadromous fishes. The central basin refers to that section of the St. John River between Grand Falls and the Mactaquac Dam (west of Fredericton, and essentially head of tide). The lower basin refers to the section of the St. John River between the Mactaquac Dam and Reversing Falls (in the town of Saint John, where water flows upstream during rising tides generated from the Bay of Fundy).

Algae and Cyanobacteria

The general pattern of phytoplankton species composition and abundance is one of general similarity along the length of the river and indicative of a moderate rate of productivity. Seasonal patterns in

the abundance of phytoplankton have been well documented since the 1960s. Winter (January to April) populations of dinoflagellates, greens, cyanobacteria, and diatoms tend to be very low (<100 cells/ml) for all phytoplankters combined (Watt 1973); this is followed by a rise in abundance in May, with peaks in July and August before declining in the autumn (October). These peaks are coincident with declining water levels in the river when physical conditions (discharge) are sufficient to permit time for growth prior to being flushed out of system. The late-summer decline in phytoplankton abundance seems to be related to zooplankton grazing, as the population trends roughly parallel those of the phytoplankters (SJRBB 1974). The relative abundance of chrysophytes (mainly ochromonads) during late winter in the impoundments of Woodstock and Beechwood (middle reach) may have been the result of heterotrophic activity in these deep, low-flow water bodies (Watt 1973).

The diatom *Melosira*, typically associated with eutrophic waters (Hutchinson 1967), was common at all main-stem (middle reach) stations in the St. John River but was rare in the upper basin and headwaters (Watt 1973). Instead, the phosphate-sensitive chrysophyte *Dinobryon serularia* was prominent only in the relatively unpolluted (phosphorous-limited?) headwaters (i.e., Tobique). Filamentous algae, such as *Cladophora* spp., can be locally abundant in the central and lower river basins during summer where point-source discharges of nutrients occur. Dense mats can become a nuisance, especially where low water levels are exacerbated by river-flow regulation in proximity to hydroelectric dams.

Plants

In the floodplains, speckled alder, balsam poplar, and willows are common riparian plants that grow in abundance. Ostrich ferns are especially common in the floodplains of the lower basin, where they are harvested every spring and sold as “fiddleheads.” The St. John River lousewort is a large but rare parasitic member of the snapdragon family that became the first plant in Maine to be listed as endangered. The only known place in the world that this plant grows is in the floodplain of a very small section of the northern St. John River in New Brunswick and Maine (Allagash subbasin).

Invertebrates

There is very limited information concerning the abundance and diversity of invertebrates in the St. John River. Zooplankton diversity is based on

sampling efforts in the impoundments coordinated by the St. John River Basin Board (SJRBB 1974). They noted that the zooplankton community was predominantly crustaceans (Copepoda and Cladocera). *Bosmina coregoni* and *Daphnia* spp. were the most common taxa. Monthly sampling in the early 1970s showed that densities were low in winter (primarily copepods), increased in May and June (mostly cladocerans), before declining in the autumn, a trend that generally matches the seasonal abundance of phytoplankton, presumably the main food source of zooplankton in the headponds.

In the upper basin, at First Green Lake, zooplankton abundance and density were the highest recorded in the study, similar to the situation for phytoplankton, suggesting that the Green River is a naturally productive subbasin of the St. John River system. Community composition in First Green Lake and Second Falls were similar to those in the impoundments, but the Glasier Lake species composition was different.

Limited sampling of the benthic invertebrate fauna has been carried out. In the early 1970s, a series of bottom "dredge" samples were taken from the six impoundments in the St. John River. Tubificid worms (oligochaetes) and chironomid midges were the most common benthic organisms collected in these samples and are generally indicative of polluted conditions. In the Grand Falls and Beechwood headponds, tubificids exceeded 100,000 worms/m², suggesting gross organic pollution (SJRBB 1974). The density of these benthic indicator species was much less in the upper part of the Mactaquac and Tobique impoundments.

Recent riverine samples from riffle habitats extending from the headwaters in Maine to Fredericton indicate that chironomid midges were abundant at all sites; black flies were common in summer. In the upper basin, heptageniid and baetid mayflies, chloroperlid stoneflies, and philopotamid and hydroptychid caddisflies were most commonly found. In the central basin, heptageniid and ephemereid mayflies, perlid stoneflies, and philopotamid and hydroptychid caddisflies were common (R. A. Curry, unpublished data).

No quantitative descriptions of the molluscan fauna yet exist for the St. John River, an unfortunate situation that typifies much of Atlantic Canada's freshwaters. Recent (unpublished) underwater surveys have noted a rich community of freshwater mussels in the lower reaches of the St. John River (below Mactaquac Dam), where seven to eight species have been confirmed (D. McAlpine and A.

Martel, personal communication). These species include those found in the Miramichi River (i.e., eastern pearl mussel, eastern floater, and eastern elliptio), as well as the yellow lamp mussel, the alewife floater, and the tidewater mucket. In Belle Isle Bay, large numbers of freshwater mussels, mainly eastern elliptio, were found in densities estimated to be 10 to 60 individuals/m² (A. Martel, personal communication). These organisms are recognized as sensitive, long-lived indicators of environmental health. Further, they are probably important agents of cycling nutrients (e.g., C and N) in the upper layers of river sediments, especially where they occur in such high densities.

Two species of freshwater mollusks are of special environmental concern. The alewife floater has a very restricted distribution in Canada but is widespread in the St. John River, and the yellow lamp mussel is significant because it is known from only two locations in Canada: Sydney River (Cape Breton, Nova Scotia) and the St. John River (D. McAlpine, personal communication). The latter has been designated an endangered species in the United States and is presently being considered for similar designation in Canada by the Committee on the Status for Endangered Wildlife in Canada (COSEWIC).

Vertebrates

The early data (1970s) compiled for the SJRBB were biased to samples collected in the impoundments and selected lakes (e.g., Glasier Lake), mainly by gill nets and seine nets. These data make for an interesting comparison with a recent report on the fish community of the St. John River by Curry et al. (2001), who sampled 11 riverine sites between Fredericton and northern Maine using seine nets and electrofishing in 2000. Relatively little published information is available from the tributaries along the river.

In the 1970s, a total of 28 fish species were identified in the upper basin, representing 11 families; 43 fish species were found in the central basin, due primarily to the occurrence of diadromous fishes such as striped bass, American eel, shad, and gaspereau (Meth 1973). Cyprinidae (11 species) were the most common family in both sections of the river. More recently, Curry et al. (2001) found 36 fish species in the upper and central basins of the St. John River, with common shiners and white suckers the most widely distributed fishes and lake trout, Arctic char, and round whitefish noticeably absent.

Freshwater fishes are typically found in the upper two-thirds of the lower basin, whereas salinities near

the river mouth are sufficient to allow at least periodic invasions by some marine species (Meth 1971). Various species, including commercially significant species, such as Atlantic salmon, American eel, alewife, and striped bass, use the estuary for some portion of their life as they stage in these environments during their spawning migrations. A fisheries survey in 1971 found 54 species of fishes in the lower basin, including obligate freshwater, marine, and diadromous species (Meth 1972).

Prior to 1890 and the construction of the Caribou Dam on the Aroostook River, virtually all of the river system downstream of Grand Falls, an area of 33,300 km², was accessible to diadromous fishes. Historically, the St. John River has been considered the third-largest producer of Atlantic salmon in New Brunswick, behind the Miramichi and Restigouche rivers (Washburn and Gillis Associates 1996). However, given the paucity of data prior to the building of the first dams and the large drainage basin, it is possible that the St. John River was once the greatest producer of diadromous fishes in eastern Canada.

In the St. John River, restrictions on recreational fishing for Atlantic salmon started in the late 1960s with a five-year ban initiated between 1973 and 1977, followed by annual extensions and quotas in the 1980s (L. Marshall, personal communication). A complete closure on salmon angling in the river has been in place since 1998 because the number of returning adult salmon has not reached conservation targets (DFO 2001a). In 2000, the number of returning wild multi-sea-winter (MSW) salmon to Mactaquac Dam was 277 fish, the lowest count in the 31-year record and in stark contrast to 6000 to 8000 MSW salmon between 1975 and 1980 (DFO 2001a).

Of special note is the unique “Serpentine stock” of Atlantic salmon that typically entered the rivers in late May and resided in freshwater for more than a year before spawning in headwater tributaries of the St. John River in the autumn of the year following river entry. Despite the numerous main-stem dams, a remnant of this stock still exists and deserves special protection to ensure its continued existence.

Numerous introductions have also occurred in the St. John River, most notably muskellunge (Stocek et al. 1999), chain pickerel, and rainbow trout. Smallmouth bass, another nonnative species, was introduced to New Brunswick waters, including the St. John system, in the late nineteenth century; they have now increased in distribution and represent a considerable sport fishery (especially in the impoundments), contributing approximately \$5 million annually to the New Brunswick economy.

In the 1970s, commercial fisheries for species such as gaspereau, American eel, and sturgeon were concentrated in the lower basin. The value of the gaspereau fishery (>\$250,000) was more than four times the combined value of all other species, with the majority of fish destined for use as pet food (Meth 1972). Today very limited commercial fisheries continue. For example, there is only one commercial license to fish Atlantic sturgeon in the St. John River.

Beaver, mink, and river otter are common aquatic mammals occurring in the tributaries of the St. John River; muskrat are common on the main river. Great blue heron, common merganser, and double-crested cormorant are the most abundant aquatic birds along the river in the ice-free season.

Ecosystem Processes

Studies of ecosystem processes in the St. John River are primarily limited to estimates of primary production. The fragmented nature of the river and the numerous impoundments must certainly influence the energy cycling within the river. Estimates of total primary productivity for the impoundments and main stem of the St. John River system in the spring to autumn of 1972 were 8.5 to 25.5 g C m⁻² d⁻¹, moderate to low rates that are not indicative of eutrophication (Watt 1973). Watt (1973) considered the impoundments to be severely heterotrophic where primary production contributed <1% of the total carbon balance above Beechwood and about 15% in the Mactaquac headpond. In the tidal waters downstream of Fredericton, primary production in the riverine sites was lower (48 to 99 mg C m⁻² d⁻¹) than for the bays, like Washademoak Lake and Kennebecasis Bay (124 to 276 mg C m⁻² d⁻¹). As was the case with the impoundments in the middle reach of the river, production in the lower river reaches was limited by the depth of the photic zone and occasionally by low phosphorous concentrations. Rates of primary production tend to be negligible beneath snow and ice cover between January and March.

Based on phytoplankton abundance estimated in the early 1970s by Watt (1973) and the classification of lakes by Vollenweider (1970), the St. John headwaters and upper basin are oligotrophic (<100 mg C/m³), changing to mesotrophic in the middle and lower reaches of the river (300 to 500 mg C/m³).

Human Impacts and Special Features

The St. John River, the longest river in Atlantic Canada, has a long and proud history of colonization, commercial development, forestry, agriculture,

fishing, and hunting. An international river, it runs through one state (Maine) and two provinces (Quebec and New Brunswick) before discharging into the Bay of Fundy, its high tides responsible for the famous Reversing Falls at the river's mouth in Saint John. Some of the most beautiful wild scenery in maritime Canada and New England still exists within the extensive river valley. The Allagash River in northern Maine is a protected National Wild and Scenic River.

Dams for hydroelectric power generation began in the St. John River in 1890 with the construction of the Caribou Dam on the Aroostook River (Carr 2001). Today there are 11 dams in the St. John River system, including 3 main-stem dams (Mactaquac, Beechwood, and Grand Falls) with valleywide impoundments in the middle basin above tidal waters (see Fig. 21.12). Fish passage is obstructed by the dams, although trapping and trucking of some fish species, primarily Atlantic salmon, from the Mactaquac Dam to the impoundments above Beechwood and Tobique takes place. The issue of reduced biodiversity of freshwater mussels (and their specific fish hosts) is another consequence of the numerous barriers, because dams preclude movement of many migratory species of fishes that served as hosts for glochidia larvae of mollusks.

Hydroelectric facilities continue to impose significant obstacles to upstream passage and no opportunity for safe downstream passage. Stressfully high summer water temperatures, especially in the impoundments, restrict growth for many species. Altered flow regimes may affect in-river movements (e.g., migrant smolts; Carr 2001), and the abundance of piscivorous species, many of them nonnative (e.g., smallmouth bass, chain pickerel, muskellunge), provides additional constraints to juvenile salmon production in the river. Finally, there is potential for "genetic swamping" by farmed salmon escapees from nearby aquaculture operations in the Bay of Fundy and Maine (DFO 1999).

There is much concern about the impact of introduced nonnative species (e.g., muskellunge; Stoeck et al. 1999). Their distribution continues to expand, as noted by the recent smallmouth bass record above Grand Falls (C. Collett, personal communication). There is also concern about possible invasion by zebra mussels from the St. Lawrence River system.

Organic loading from food and wood processing in the upper and middle basins of the river far exceeds the assimilative capacity of the river. Watt (1973) found that heavy organic carbon loading (from industrial effluents) created a zone of extreme

heterotrophy that extended from Edmundston to Beechwood in the summer. This condition is exacerbated in the slow-flowing, depositional impoundments, where less dissolved oxygen is available to meet the biological oxygen demand, resulting in low dissolved oxygen levels. In winter, with low temperatures and reduced aeration (under ice cover), the heterotrophic condition extended as far downriver as the Mactaquac Dam. In the lower river, Watt concluded from the phosphate data and estimates of primary productivity in 1972 that there was no immediate eutrophication threat to the estuary.

Contamination continues to affect the aquatic biota of the St. John River some 30 years after those initial surveys. Physiological impairment in white suckers and slimy sculpin has been found downstream of hydroelectric facilities and food-processing industries in the upper and middle basins (Munkittrick et al. 2000). Pulp mill effluents in the St. John River estuary still have sublethal (physiological) effects on estuarine fishes (e.g., mummichog) that may alter reproductive function (Dube 2000). Elevated polychlorinated biphenol (PCB) concentrations were found in five species of fishes sampled from the Aroostook River in 2001 (R. Parker, personal communication), and brook trout and Atlantic salmon egg survival seem to be negatively affected by intensive agriculture and flow regulation in small subbasins (Flanagan 2003, Munkittrick et al. 2000).

MOISIE RIVER

The Moisie River, with a basin area of 19,871 km², flows southward into the Gulf of St. Lawrence 25 km east of the town of Sept-Iles, Quebec (Fig. 21.14). The river flows for approximately 500 km, from an elevation of 533 m asl in the Laurentian Highlands in Labrador through a deep glaciated river valley to the St. Lawrence Lowlands into the Gulf of St. Lawrence (Fig. 21.6). Principal tributaries are the Nipissis, Caopacho, Pékans, and Ouapetec. The Moisie River is one of the largest rivers of the Quebec North Shore and has a worldwide reputation as a pristine wilderness river and a destination for Atlantic salmon angling and wilderness paddlers. It flows through steeply walled canyons rising 300 m above the river, and waterfalls, gorges, and big rapids attract outfitters and paddlers to what they refer to as "the Nahanni of the East" (see Chapter 18).

For at least 2000 years the river has been used by the Montagnais Indians as a traditional route into the interior of the Quebec woods (Laurentian Plateau)

for hunting and trapping. The Montagnais (“mountain people”), a name given the local Innu by French explorers, refer to the river as *Mis-te-shipu*, meaning “the great river” (Weeks 1971). The abundance of salmon made it a favored site for Indian settlements because salmon was a diet staple; a major Montagnais community (Malioténam) still exists near the mouth of the river. The explorer Jacques Cartier was the first known European to visit the lower river valley and bay, in 1535. The Jesuit missionaries who established themselves in the area by 1600 first used the name “Moisie,” from the French word *moisi*, meaning “damp” or “muddy.” Henry Youle Hind, a professor of chemistry and geology at the University of Toronto in the middle of the nineteenth century, was the first white man to explore the Moisie to its source. Weeks (1971) provides a detailed account of the history of the Moisie River and its inhabitants.

Physiography, Climate, and Land Use

The Moisie River basin is found primarily in the Laurentian Highlands (LU) physiographic province of the Canadian Shield physiographic division (see Fig. 21.14). The Precambrian Canadian Shield bedrock is widely exposed and thinly covered throughout most of the basin (Stockwell 1963). Metamorphic rocks dominate the basin, mainly in the form of granitic gneisses and migmatite. Sedimentary rocks in the Pékans River tributary near Mont Wright contain significant iron-ore deposits (Lalonde et al. 1990). The basin lies in the Eastern Canadian Forests and Eastern Canadian Shield Taiga terrestrial ecoregions, with upland forests typical of the Boreal Forest biome. The dominant upland species are white and black spruce, white birch, trembling aspen, and balsam fir.

The climate is subalpine, with a mean annual air temperature of only 1°C (Mackay 1995). The mean monthly temperature, as recorded at nearby Sept-Îles, Quebec, ranges from a high of about 15°C in July to a low of –15°C in January (Power 1981; Fig. 21.15). Mean annual precipitation from the northern to the southern portions of the basin ranges from 113.1 cm to 87.6 cm (Lalonde et al. 1990). Precipitation is fairly uniform throughout the year, ranging from about 7 cm/mo in February to 11 cm/mo in September (see Fig. 21.15). An extensive snowpack is common in the region, with average accumulation of 42.3 cm until spring snowmelt begins in May (Power 1981).

Forests continue to cover >90% of the Moisie River basin. In the latter half of the twentieth century, land use in the basin was limited to peat extraction in the lower basin and some mining activity, princi-

pally for iron ore, in the headwaters (Nipissis and Pékans subbasins). The level of mining activity is much reduced from what it was 30 years ago. Very limited trapping for fur-bearers is practiced in the Moisie catchment. Targeted species included (in order of importance) beaver, muskrat, mink, lynx, wolf, and fox (Bertrand 1978).

River Geomorphology, Hydrology, and Chemistry

The Moisie River is a 9th order river fed by numerous headwater lakes on the Labrador plateau. The Moisie River valley lies directly south of the center of outflow of the late Wisconsin Laurentide ice sheet. The heavily glaciated valley leads from the Labrador Plateau in the uplands through a steep-walled valley leading to the St. Lawrence River (see Fig. 21.6). In the lower river, the slope is 1.6 m/km and the bottom substrate is a mix of sand and cobble (Naiman et al. 1987). The relative lack of any abrupt changes in slope in the lower reaches of the Moisie means that early travelers to the region and diadromous fishes could ascend much of the length of the river. At the mouth there is a well-defined estuary, but given the relatively steep slope the maximum extent of the salt wedge is only 2 km upstream (Black et al. 1983).

The annual hydrograph is typically dominated by the spring discharge peak, with 50% of the annual discharge occurring in May and June following snowmelt (see Fig. 21.15). The maximum daily flood recorded is 3820 m³/s. The mean annual flow is 426 m³/s, with summer low flows of <300 m³/s. The lowest flows (<130 m³/s) actually occur from January through March, when most of the precipitation accumulates as snow. Atlantic storms occasionally stall in the St. Lawrence valley, dropping enormous amounts of rainfall and causing extensive flooding. For example, in the Saguenay River basin, a similar North Shore basin located to the west of the Moisie River, over 20 cm of rain fell in 36 hours in July 1996. Widespread flooding and several dam failures occurred in all of the nearby rivers.

Maximum water temperatures in the river rarely exceed 20°C and are often much less in the tributaries, reflecting the boreal climatic zone. Ice forms on the river in November, forming a complete cover by December that persists until April or May. Mean annual water temperature is 6°C, accumulating only about 2100 degree-days (Mackay 1995).

The Moisie River is a soft-water river (alkalinity range from 8 to 18 mg/L, conductivity 10 to 77 µS/cm)

FIGURE 21.6 Katchapahum Falls on the main branch of the Moisie River in Quebec (Rkm 175). Note the steep granite cliffs, coniferous forest, and tea-colored water typical of this boreal river (PHOTO BY K. SCHIEFER).

colored by humic acids, with a stable (neutral) pH (6.3 to 7.5) and low levels of dissolved organic carbon (2.9 to 23.3 mg/L) (Environment Canada 1982, Naiman 1982, Schiefer 1982). Total nitrogen and total phosphorous were measured in the early 1980s by Naiman (1982) and Hamilton (1983), who found mean values of 134 to 392 µg/L and 4 to 22 µg/L, respectively. Although the water-chemistry data are more than 20 years old, there is little reason to expect a different situation today, as catchment activities are essentially the same as they were in the early 1980s. A 1983 study of sedimentary diatoms in the headwater lakes of the Moisie and adjacent Matamek river systems found evidence of slightly acidic soft-water conditions; pH ranged from 4.6 to 5.8 and conductivity from 9 to 20 µS/cm (Hudon et al. 1986).

River Biodiversity and Ecology

The Moisie River is located within the Lower St. Lawrence freshwater ecoregion, as are all the rivers draining the Quebec North Shore. Given the remote and largely pristine nature of the basin, it is somewhat surprising that a fair amount of biological and ecological research has been conducted in the Moisie River. These studies have focused primarily on fisheries research on Atlantic salmon and studies of ecosystem processes, the latter combined with studies of the adjacent and much smaller Matamek River (e.g., Naiman et al. 1987, Mackay 1995).

Algae and Cyanobacteria

Hamilton (1983) sampled in both the Moisie and Matamek rivers to determine factors controlling periphyton productivity and biomass. In spring, riffle periphyton growth was positively correlated with the increase in light and water temperature, and there was some suggestion that insect grazing controlled periphyton biomass. In addition to documenting drift patterns by benthic periphyton species, such as *Tetraspora cylindrica*, *Eunotia pectinalis*, *Oscillatoria minima*, and *Synedra acus*, there was evidence of algal drift by less known planktonic species, such as *S. minutum* and *Kephyrion boreale*. Hudon et al. (1987) studied the physiology of the periphytic community in the Matamek River and found 64 species of diatoms belonging to 23 genera. Two filamentous taxa, *Tabellaria flocculosa* var. *flocculosa* and *Eunotia pectinalis* var. *pectinalis*, composed >70% of the total cell counts. In their 1983 sampling of the surficial sediments of 20 headwater lakes, Hudon et al. (1986) identified 158 species of diatoms representing 27 genera. Only six taxa (*Melosira distans*,

T. flocculosa, *T. fenestrata*, *E. pectinalis* var. *minor*, *E. pectinalis* var. *pectinalis*, and *Frustulia rhomboides*) were abundant in the sediments.

Plants

Dominant riparian plants include black spruce, white spruce, speckled alder, Labrador tea, and willows. Macrophytes (mainly pondweed) are relatively common in the lentic habitats in the lower reach of the Moisie River.

Invertebrates

Studies of invertebrates are limited in the Moisie, but Environment Canada (1982) collected invertebrate data from several sites associated with a study of environmental impacts of mining activities on a Moisie tributary (the Pékans). In general, it was found that the headwaters of the Pékans Rivers were rich in benthic fauna, with the number of benthic taxa similar between sites (30 to 37). In the vicinity of an iron-ore mining operation in the headwaters (Webb Creek), the fauna was less diverse and dominated by chironomid midges. The preponderance of oligochaete worms and the relative paucity of bivalve mollusks below the mining operation was indicative of pollution. A total of 10 bivalve species representing two genera, *Pisidium* and *Sphaerium*, were collected at 20 sampling sites in the river system (Environment Canada 1982). These were most abundant in the Pékans River rather than the main river.

For the insects, stoneflies were predominantly represented by *Paracapnia* and *Taeniopteryx* and several species of Leuctridae in the headwaters; in the Pékans River, *Paracapnia*, *Isoperla*, and species of Leuctridae and Perlidae were abundant (Environment Canada 1982). The most common mayfly genera were *Ephemerella*, *Leptophlebia*, and *Heptagenia* in the headwaters and in the Pékans River; *Ephemerella*, *Heptagenia*, and *Ameletus* (Siphonuridae) were common in the Moisie River. Caddisfly larvae were most abundant and diverse in the Pékans and Moisie rivers, with *Lepidostoma* and *Chimarra* common; *Hydropsyche* were common in all reaches. Chironomid midges were the most abundant and widespread dipteran larvae collected.

Vertebrates

The Moisie River is most famous for its stock of Atlantic salmon. An estimated 20,000 adult salmon enter the river each year to spawn, making it the largest salmon-producing river on the Quebec North Shore (Friends of the Moisie River 1989). It is the exceptionally large individual and average sizes of the

Moisie salmon that make them distinctive. Power (1981), in his description of salmon stocks of Quebec and Newfoundland–Labrador rivers, found that grilse (adult salmon spending one winter at sea) were relatively scarce in the Moisie, and two- and three-sea-winter salmon and repeat spawners averaged 74.6, 90.7, and 103.8 cm in length, respectively.

Scientific fisheries research in the Moisie River, primarily directed at salmon, has been conducted since the 1920s, when scale samples were collected for ageing (Schiefer 1982). The most extensive research on salmon biology in the river was carried out by Schiefer (1971, 1972, 1982) and Bielak (1984). Growth rates were higher for parr in upstream sections, presumably because of low densities and lack of intraspecific competition in years immediately following installation of the fishway at Katchapahum Falls. Smolts have a mean age of 3.7 years and a fork length of 12.0 cm, relatively small for most salmon stocks of the region (Power 1981).

In addition to Atlantic salmon and brook trout (resident, or landlocked, and sea-run forms), northern pike, longnose sucker, white sucker, burbot, American eel, sea lamprey, lake chub, lake whitefish, and round whitefish are present in the river system. A full biological account of these nonsalmonid species in the Moisie River system is lacking. More species are likely to occur in the river but we are unaware of an inventory of the fish fauna of the Moisie River. However, Power et al. (1973) provided a list of species found in the nearby Matamek River that is probably similar to the Moisie. In addition to those already listed, they found Arctic char (mostly in the larger lakes); threespine, fourspine, and nine-spine sticklebacks; and rainbow smelt in freshwater habitats. Alewife, tomcod, shorthorn sculpin, and winter flounder were captured in the estuary. No nonnative fish species are known to occur in the Moisie River. Among the nonfish vertebrates, beaver are particularly abundant in the tributary streams and headwaters of the Moisie River. Mink and river otter are also common.

Ecosystem Processes

There is no evidence of eutrophication in the Moisie. Productivity is low, but few data are available on primary or secondary production. Based on research carried out largely in the adjacent Matamek River basin and a single site in the lower Moisie River, most in situ organic matter was produced by periphyton (small-order streams) or by moss and macrophytes (high-order streams), or originated from material being transported downstream;

allochthonous input from riparian vegetation was minor (Naiman 1982, 1983; Naiman et al. 1987). Gross production ranged from 0.3 to 0.8 g O₂m⁻²d⁻¹ in small streams and from 0.8 to 1.08 g O₂m⁻²d⁻¹ in the larger river sites (Naiman 1983). Macrophytes in the lower reach of the Moisie River (mainly pondweed) contributed 3 to 30 g/m² but only for the summer period before plants senesced (Naiman 1983).

Regarding fish (salmon) production, the growing season seems to be a bit shorter in the Moisie than in the Miramichi but similar to the Exploits, with spring ice-out occurring in early May and summer water temperatures in the main river rarely exceeding 21°C. Therefore, fish production rates may be similar to those in Newfoundland rivers like the Exploits (e.g., Randall et al. 1989). Morin and Naiman (1990) estimated maximum fish biomass of <9 g/m² and production of approximately 10 g m⁻²yr⁻¹ in 4th order streams of the nearby Matamek River.

Large-scale or process-oriented research is largely lacking for the Moisie River system. Scientific research to date has focused largely on the biology and fisheries management of the Atlantic salmon (Schiefer 1971, 1972; Bielak 1984) and on the potential impacts of mining pollution (Schiefer 1982, Environment Canada 1982). The only exception is the thorough study of suspended sediment and organic carbon transport relative to the discharge regime in the Moisie River and four other nearby boreal streams of decreasing stream order (Naiman 1982, 1983; Naiman et al. 1987; see also review by Mackay 1995). That research showed that during the spring snowmelt freshet 71% to 92% of the annual sediment load is exported from the river but only about half of the annual load of dissolved and particulate organic carbon. There was a rapid loading of carbon between 1st and 2nd order streams, followed by biological and physical processing along the river continuum. At the mouth of the Moisie River organic carbon export was reduced to a rate comparable to the 1st order streams. Primary production increased in importance in a downstream direction, with production by macrophytes particularly significant in larger rivers. Many of the results were in accordance with the predictions of the River Continuum Concept (Vannote et al. 1980). Also, Naiman (1982) concluded that in such pristine boreal rivers instream processing and retention devices (e.g., beaver ponds and large woody debris) exert considerable control over the quantity of organic matter transported; river discharge, by contrast, was more important in deter-

mining sediment concentrations. Such ecosystem-scale studies are important for understanding how organic matter is processed spatially and temporally in boreal river systems.

Hudon et al. (1996) measured carbon transport in 47 Quebec rivers, including the Moisie. They found that carbon loads were strongly related to runoff values in all rivers but that the specific dissolved organic carbon load of tundra rivers was about half that of rivers flowing through forested basins to the Gulf of St. Lawrence (e.g., Moisie).

Human Impacts and Special Features

The Moisie River is famous for its exceptional scenery and wilderness setting, and for its stock of large Atlantic salmon. The river is also popular for outdoor enthusiasts, for camping, canoeing, and kayaking. The basin continues to be relatively inaccessible, as the only road system occurs at the mouth of the river; land travel upstream is possible only by a railway that is wholly owned by the iron-ore company operating in the basin. The rail route is along the main stem of the lower Moisie for approximately 40 km before heading up the Nipissis River subbasin.

Sport fishing, primarily for Atlantic salmon, has been occurring in the Moisie River for more than 150 years. Salmon abundance was the reason for fishing settlements and commercial exploitation by French colonists and the Hudson's Bay Company. Private salmon clubs like the Moisie Salmon Club (originally the Adams Camp) have been in operation since the 1850s (Weeks 1971), with exclusive fishing rights to all but the first 15 km above the river mouth. By the mid-1800s as many as 70 salmon nets (approximately 27 km in total length) were set in the lower river and bay, where salting and icing plants were built to process the fish. By the late 1800s sport-fishing interests converged on the Moisie River, largely as a result of depleted stocks and poor fishing in the rivers of New England and parts of the Maritimes. No commercial fisheries exist today in the Moisie River or estuary. Salmon (and brook trout) continue to be exploited by the Montagnais Indians, who harvest some fishes as part of a subsistence fishery in the lower river and estuary.

Salmon enhancement has taken place in the Moisie River. Two fishways have been constructed, one on the main stem at Rkm 175 (Katchapahum Falls) between 1965 and 1975 and the other on the Nipissis River tributary at Rkm 50 (McDonald Falls) in 1973 (Bertrand 1978). The number of adult

salmon enumerated passing upstream of the former barrier at Katchapahum between 1975 and 1981 ranged from 640 to 5800 fish (Schiefer 1981).

Various mining operations have caused the only significant pollution in the Moisie River. During the 1970s mining discharge and tailings pollution caused significant environmental impacts in the upper Pékans River, particularly in the Webb Creek drainage, where elevated levels of mercury, iron, nickel, and copper were measured in sediments (Environment Canada 1982) and the red iron-rich plume was detected 300 km downstream from the source (Schiefer 1981). Benthic diversity and abundance were affected in the tributaries, as was the abundance of salmonids; the Moisie River below the confluence with the Pékans appeared not to be affected by the mining discharge to the river (Environment Canada 1982). In 1996, a significant nickel discovery was made in the Nipissis River subbasin, a tributary to the Moisie. Hundreds of claims have been staked in the area, posing a new threat to the basin ecosystem if developments take place (Native Forest Network 1997).

Although no dams currently exist in the Moisie River, Hydro-Québec proposed a hydroelectric development scheme in the 1980s that would have diverted 74% of the flow of the Pékans River to an adjacent regulated river basin, the Ste. Marguerite River (Friends of the Moisie River 1989). The diversion would have resulted in an estimated reduction of 13% of the flow of the Moisie as measured at the river mouth. Due to a combination of public opposition, unfavorable economics, and the recommendations of an expert review panel, the project was never pursued. Hydro-Québec continued to pursue development in the basin. However, in early 2003, the Quebec government assured the future protection of the Moisie River by announcing the creation of an aquatic reserve (3897 km²) for the basin. The reserve status prohibits logging, mining, and hydro/oil development in a corridor between 6 and 30 km wide for approximately 320 km, thereby including the Pékans and Carheil subbasins.

ADDITIONAL RIVERS

The Big Salmon River is actually a very small river located in southern New Brunswick. It flows primarily in a southerly direction to empty into the Bay of Fundy (Fig. 21.16). This is a unique coastal basin with pristine old-growth forest still present in the deeply incised river valley (Fig. 21.7). Currently, there

FIGURE 21.7 Lower reach of the Big Salmon River (Rkm 2). Note boulder and rubble substrate and steep forested valley that characterizes much of the length of this river (PHOTO BY R. NEWBURY).

are only small water-level control dams at the outlets of several headwater lakes (e.g., Walton Lake; see Fig. 21.16). Historically, it was one of the most productive of the Inner Fundy (IF) salmon rivers, but today so few salmon return that the stock has been listed as “at risk” (endangered). To protect this unique genetic stock of IF salmon from extinction, a gene-banking program was initiated in 1998.

The Dunk River is a very small southwest-flowing river located on the small island province of Prince Edward Island (Fig. 21.18). The Dunk is a low-gradient river with high in-stream productivity that flows into a shallow nutrient-rich estuary. It has a stable thermal regime from numerous groundwater sources. The Dunk has been very popular for sport fishing, especially for sea-run trout, but PEI rivers like

the Dunk have experienced massive fish kills in recent years, presumably from pesticides entering water-courses during summer rainstorms. It has five small irrigation dams that reflect the importance of agricultural activity in most PEI river valleys, mainly potato farming.

The LaHave River flows in a southeasterly direction, primarily through a forested region in the southeastern portion of Nova Scotia (Fig. 21.20). The LaHave is fed by more than 113 lakes in the basin and has been severely impacted by acid rain deposition, reducing pH to <4.8 in some tributaries during spring snowmelt (Fig. 21.21). This has resulted in poor survival of many aquatic species. Enhancement of Atlantic salmon was initiated in 1970 with construction of a fishway at Morgan Falls (Rkm 25) on

the main stem of the LaHave and subsequent stocking in upper reaches.

The Grand Cascapedia River is a southeasterly flowing river on the Gaspé Peninsula of Quebec that empties into Chaleur Bay of the Gulf of St. Lawrence (Fig. 21.22). The basin is mostly forested, with a population density of <1 person/km². There is a particularly strong spring snowmelt in this river, occurring in May (Fig. 21.23). The river is very popular for anglers and is unique for having the highest percentage of large Atlantic salmon (maiden three-seawinter) of any North American river. A successful alliance of native (with Mi'kmaq) and nonnative partners for river management has seen salmon returns increase tenfold in the past three decades.

The Petitcodiac River flows northeast in the southeastern corner of New Brunswick before emptying into Shepody Bay in the uppermost portion of the Bay of Fundy (Fig. 21.24). Forestry and agriculture predominate in the upper basin, and much of the lower basin is urbanized near the city of Moncton (up to 69 people/km²). The Petitcodiac had a historic tidal bore twice a day, as tides from the Bay of Fundy pushed upriver beyond Moncton, but the size of the bore was much reduced after construction of a causeway in the estuary in 1968. The causeway also caused infilling with sediments and blocked migratory movements of diadromous fishes.

The Humber River is located on insular Newfoundland, just to the west of the Exploits River basin, and flows in the opposite direction, emptying into the Gulf of St. Lawrence (Fig. 21.26). The basin includes Grand Lake, the largest lake in Newfoundland, which is also used for hydropower. The seasonal hydrograph for the Humber is unusually flat (Fig. 21.27), apparently the result of flow releases from Grand Lake. The Humber is popular for sport fishing for Atlantic salmon and brook trout. The headwaters are nearly pristine, part of which are in Gros Morne National Park. Domestic sewage from Deer Lake and other towns causes pollution problems in the lower river. The basin is mostly forested, and trees are harvested throughout the basin, mainly for the pulp and paper mill in Cornerbrook.

The Churchill River (unlike the river of the same name that runs across Central Canada into Hudson Bay, see Chapter 19) flows east across Labrador (Newfoundland) to empty into Lake Melville and eventually the Labrador Sea (Fig. 21.28). The Churchill is the second-largest river in North America that eventually empties into the Atlantic Ocean (by way of the Labrador Sea, and not counting the Koksoak River, Quebec, which flows north

into Ungava Bay). This large river drains the Labrador Highlands and Laurentian Highlands physiographic provinces of the Boreal Forest biome. It was mostly undeveloped boreal forest until the Churchill Falls Hydro-Electric project, which created the huge Smallwood Reservoir (see Fig. 21.28) was completed in 1974. This controversial project flooded 6700 km², including Innu hunting lands and burial sites. Much of the power generated by the project is sold by Hydro-Québec to the United States. The governments of Newfoundland and Quebec are currently developing plans for two more power stations on the Churchill River. Without regulation by the Churchill Falls dam, this northern river experienced “spring snowmelt” from May through July (Fig. 21.29). With regulation, however, the spring snowmelt has been totally eliminated, and a uniform seasonal hydrograph has been created.

ACKNOWLEDGMENTS

The authors wish to thank A. Fraser, S. McWilliam, K. Long, M. Gauthier, E. Arseneau, F. Cowie, R. A. Curry, N. Duke, J. O'Keefe, B. Dempson, J. Ritter, J. Deschenes, C. Hudon, R. MacFarlane, K. Teather, D. Guignon, M. Gauthier, D. Caissie, A. Martel, D. MacAlpine, R. Parker, D. Giberson, and C. Collett for contributing data and carrying out research for this chapter, and H. Collins, R. Jones, L. Marshall, M. O'Connell, C. Bourgeois, A. Bielak, and K. Schiefer for kindly reviewing earlier drafts of the manuscript. Funding was provided by the Canada Research Chairs program.

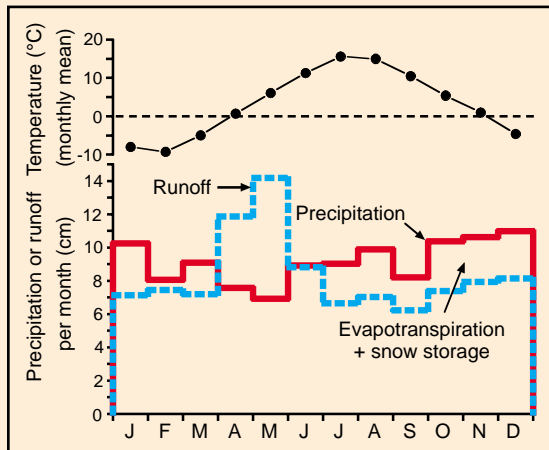

FIGURE 21.9 Mean monthly air temperature, precipitation, and runoff for the Exploits River basin.

EXPLOITS RIVER

Relief: 490 m

Basin area: 11,272 km²

Mean discharge: 270 m³/s

River order: 6

Mean annual precipitation: 99.1 cm

Mean air temperature: 4.4°C

Mean water temperature: NA

Physiographic province: New England/Maritime (NE)

Biome: Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregion: Eastern Canadian Forests

Number of fish species: 6

Number of endangered species: none

Major fishes: Atlantic salmon, brook trout, threespine stickleback, rainbow smelt, American eel, Arctic char

Major other aquatic vertebrates: beaver, river otter, mink

Major benthic invertebrates: in Red Indian Lake, leeches (Hirudinea), sphaeriid clams, chironomid midges, aquatic worms (Oligochaeta); no data on river invertebrates

Nonnative species: NA

Major riparian plants: black spruce, balsam fir, speckled alder, bog laurel, Labrador tea

Special features: large island river with second largest lake in Newfoundland (Red Indian Lake); historic meeting place of Europeans and last of Beothuk peoples at Red Indian Lake; major midwinter ice jams below storage dams caused instant and catastrophic flooding in riverside towns.

Fragmentation: nine hydroelectric and water-storage dams in basin, some with no fish-passage facilities (e.g., Star Lake); water diversion from Victoria River to adjacent river basin

Water quality: very good in upper and middle reaches, but deteriorates in lower reaches; pH = 5.8 to 6.8, dissolved organic carbon = 10 mg/L, total nitrogen = 0.05 to 0.10 mg/L, total phosphorus = 0.006 to 0.012 mg/L

Land use: forestry, base-metal mining (historic) in Buchans area

Population density: 5 people/km²

Major information sources: www.msc-smc.ec.gc.ca/climate/climate_normals/html/ 2004, www.nationalgeographic.com/wildworld/terrestrial 2001, Morry and Cole 1977, Gibson et al. 1999, www.gov.nf.ca/env/Env/waterres/Surfacewater/WQI/Exploits-WQI-study.pdf 2004, <http://atlas.gc.ca/site/english/index.html>, Scott and Crossman 1964

FIGURE 21.8 Map of the Exploits River basin.

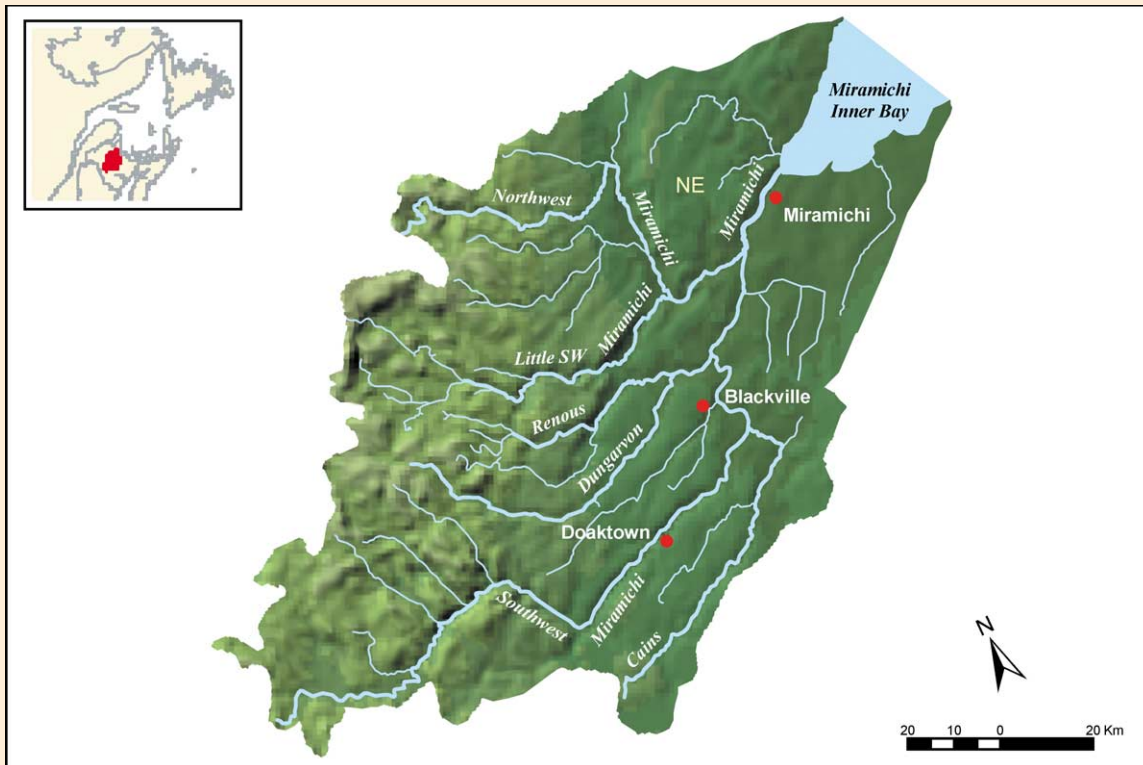

FIGURE 21.10 Map of the Miramichi River basin.

MIRAMICHI RIVER

Relief: 764 m

Basin area: 14,000 km²

Mean discharge: 322 m³/s

River order: 8

Mean annual precipitation: 111.5 cm

Mean air temperature: 4.7°C

Mean water temperature: NA

Physiographic province: New England/Maritime (NE)

Biome: Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregions: New England/Acadian Forests, Gulf of St. Lawrence Lowland Forests, Eastern Canadian Forests

Number of fish species: 21 freshwater, 8 diadromous

Number of endangered species: none

Major fishes: Atlantic salmon, brook trout, sea lamprey, American eel, alewife, American shad, rainbow smelt, striped bass, Atlantic sturgeon, slimy sculpin, blacknose dace, common shiner, lake chub, white sucker, sea lamprey

Major other aquatic vertebrates: beaver, river otter, mink, northern two-lined salamander, double-crested cormorant

Major benthic invertebrates: mayflies (*Baetis*, *Ephemerella*, *Stenonema*), stoneflies (*Leuctra*, *Alloperla*, *Pteronarcys*), caddisflies (*Hydropsyche*, *Dolophilodes*, *Glossosoma*, *Pycnopsyche*, brachycentrids), true flies (*Prosimulium*, *Tipula*, chironomid midges), elmids beetles, pearl mussels

Nonnative species: white perch, brown trout, chain pickerel

Major riparian plants: white spruce, white pine, black spruce, yellow birch, northern red oak, sweet gale, speckled alder

Special features: several principal branches and tributaries set in broad glacial river valley; produces more Atlantic salmon than any other river in North America; very popular for anglers and canoeists

Fragmentation: none

Water quality: headwaters and midreaches excellent; pH = 6.5 to 7.8, conductivity = 28 to 55 μS/cm; estuary with urban and industrial discharges; evidence of chemical pollutants in sediments from historic spills

Land use: forests, agriculture on valley bottomlands, historic base-metal mining, localized gravel extraction in lower river valley

Population density: 4 people/km²

Major information sources: www.msc-smc.ec.gc.ca/climate/climate_normals_2004, www.nationalgeographic.com/wildworld/terrestrial.html 2001, <http://atlas.gc.ca/english/site/english/index.html>, MREAC 1992, Chadwick 1995

FIGURE 21.11 Mean monthly air temperature, precipitation, and runoff for the Miramichi River basin.

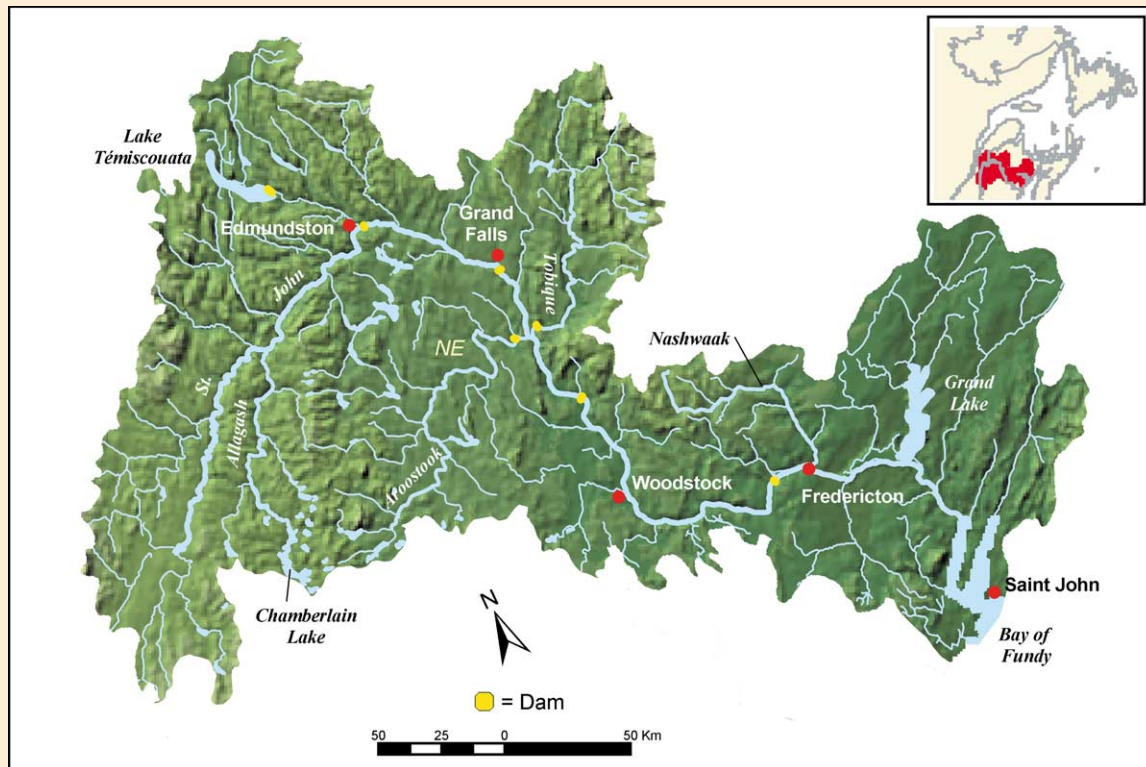

FIGURE 21.12 Map of the St. John River basin.

ST. JOHN RIVER

Relief: 820 m
 Basin area: 55,110 km²
 Mean discharge: 1110 m³/s
 River order: 7
 Mean annual precipitation: 114.3 cm
 Mean air temperature: 5.3°C
 Mean water temperature: NA
 Physiographic province: New England/Maritime (NE)
 Biome: Temperate Deciduous Forest
 Freshwater ecoregion: North Atlantic
 Terrestrial ecoregion: New England/Acadian Forests
 Number of fish species: 36
 Number of endangered species: 1 mussel, 1 plant, 1 fish (special concern)

Major fishes: common shiner, blacknose dace, brown bullhead, slimy sculpin, white sucker, Atlantic salmon, brook trout, striped bass, American eel, alewife, Atlantic sturgeon, shortnose sturgeon, sea lamprey, yellow perch

Major other aquatic vertebrates: muskrat, beaver, common merganser, double-crested cormorant

Major benthic invertebrates: true flies (chironomid midges, black flies), mayflies (Baetidae, Heptageniidae, Ephemerellidae), stoneflies (Chloroperlidae, Perlidae), caddisflies (Philopotamidae, Hydropsychidae), mollusks (eastern elliptio)

Nonnative species: muskellunge, chain pickerel, brown trout, rainbow trout, smallmouth bass

Major riparian plants: white spruce, white pine, balsam poplar, willows, white birch, northern red oak, speckled alder

Special features: longest river in eastern Canada; international border; “Reversing Falls” near mouth due to large tidal amplitude from Bay of Fundy; extensive marshes in lower river; >100 km under tidal influence

Fragmentation: 11 hydroelectric dams from headwaters to mouth

Water quality: effluents from pulp and paper mills, food processing plants, sewage treatment facilities; pesticide residues in sediments of intensive agriculture areas; mean alkalinity = 51.2 mg/L as CaCO₃, conductivity = 154 μS/cm, pH = 7.7, total nitrogen = 0.47 mg/L

Land use: agriculture (potatoes, beef, and dairy; cranberry farms in lower valley), forests (some harvesting)

Population density: 8 people/km²

Major information sources: www.msc-smc.ec.gc.ca/climate/climate_normals 2004, www.nationalgeographic.com/wildworld/terrestrial.html 2001, <http://atlas.gc.ca/site/english/index.html>, Meth 1972, Watt 1973, Washburn and Gillis Associates 1996, Curry et al. 2001

Figure 21.13 Mean monthly air temperature, precipitation, and runoff for the St. John River basin.

FIGURE 21.15 Mean monthly air temperature, precipitation, and runoff for the Moisie River basin.

MOISIE RIVER

Relief: 1011 m

Basin area: 19,871 km²

Mean discharge: 426 m³/s

River order: 9

Mean annual precipitation: 115.6 cm

Mean air temperature: 1.0°C

Mean water temperature: 6.0°C

Physiographic province: Laurentian Highlands (LU)

Biome: Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregion: Eastern Canadian Forests

Number of fish species: ≥13

Number of endangered species: none

Major fishes: Atlantic salmon, brook trout, northern pike, white sucker, American eel, lake chub, lake whitefish, threespine stickleback, longnose sucker, burbot, sea lamprey

Major other aquatic vertebrates: beaver, mink, muskrat

Major benthic invertebrates: mollusks (*Pisidium*, *Sphaerium*), stoneflies (*Paracapnia*, *Isoperla*, Leuctridae, Perlidae), mayflies (*Ephemera*, *Heptagenia*, *Ameletus*), caddisflies (*Lepidostoma*, *Chimarra*, *Hydropsyche*), chironomid midges

Nonnative species: none

Major riparian plants: black spruce, white spruce, balsam fir, white birch, speckled alder, trembling aspen, Labrador tea

Special features: exceptional scenery and wilderness setting; stock of large Atlantic salmon; traditional route to Quebec interior for trapping and hunting for Montagnais Indians; recent designation as aquatic reserve to ensure protection from development

Fragmentation: no dams, although past interest in development of hydroelectric dams and diversions

Water quality: generally excellent; historic mining discharges (1970s) in headwaters (Pékans) caused elevated base-metal concentrations in sediments; pH = 6.3 to 7.5, alkalinity = 8 to 18 mg/L as CaCO₃, dissolved organic carbon = 2.9 to 23.3 mg/L

Land use: >95% forest; some iron mining in headwaters

Population density: <1 person/km²

Major information sources: www.msc-smc.ec.gc.ca/climate/climate_normals_2004, www.nationalgeographic.com/wildworld/terrestrial.html 2001, <http://atlas.gc.ca/site/english/index.html>, Mackay 1995, Weeks 1971, Naiman et al. 1987, Naiman 1982, 1983

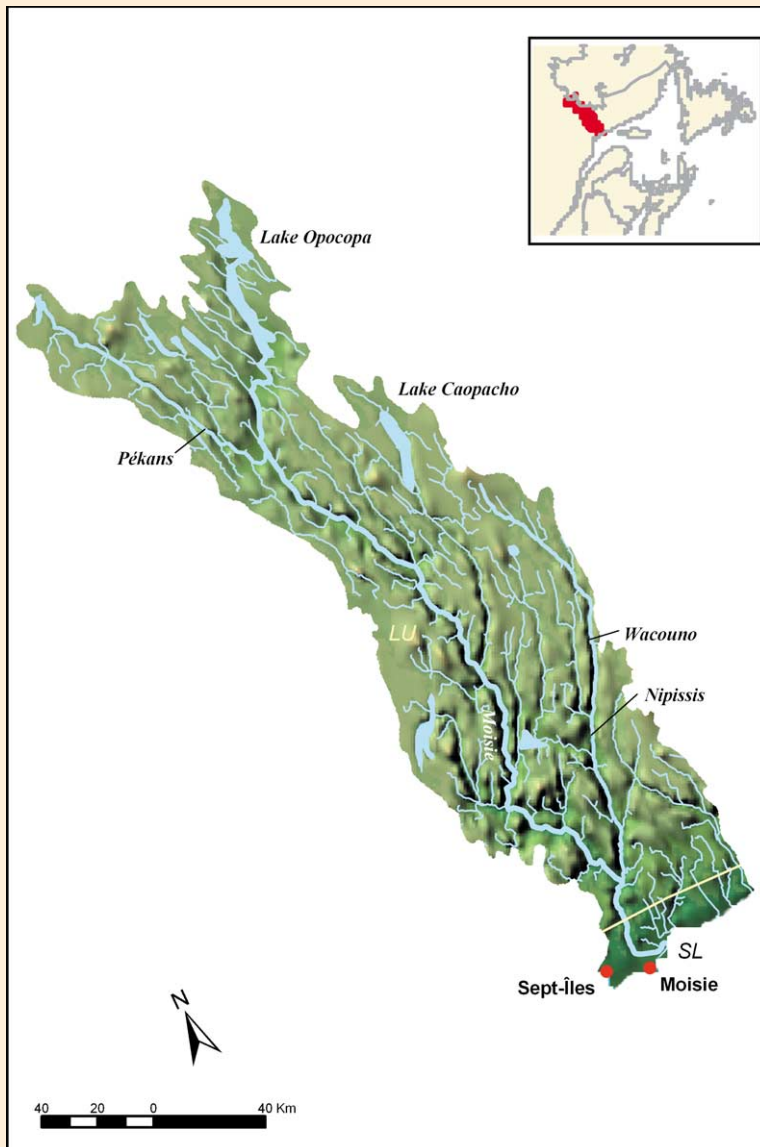

FIGURE 21.14 Map of the Moisie River basin.

FIGURE 21.17 Mean monthly air temperature, precipitation, and runoff for the Big Salmon River basin.

BIG SALMON RIVER

Relief: 410 m

Basin area: 332 km²

Mean discharge: 11.8 m³/s

River order: 5

Mean annual precipitation: 146 cm

Mean air temperature: 5.3°C

Mean water temperature: NA

Physiographic province: New England/Maritime (NE)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: North Atlantic

Terrestrial ecoregion: New England/Acadian Forests

Number of fish species: 7

Number of endangered species: 1 fish

Major fishes: Atlantic salmon, brook trout, American eel, blacknose dace

Major other aquatic vertebrates: mink, beaver

Major benthic invertebrates: mayflies (Ephemeroptera), Baetidae, stoneflies (Leuctridae), true flies (chironomid midges, black flies)

Nonnative species: rainbow trout, Arctic char (Walton Lake)

Major riparian plants: red spruce, white pine, speckled alder, white birch

Special features: unique wilderness coastal basin of Bay of Fundy with pristine, old-growth forest in deeply incised river valley; historically one of the most productive Inner Fundy salmon rivers, but today few salmon return

Fragmentation: dam near head of tide on main branch removed in 1963; currently small water-level control dams at outlets of several headwater lakes (e.g., Walton Lake)

Water quality: soft-water stream of exceptional quality and clarity; mean pH = 6.3 (range = 4.9 to 8.3), mean conductivity 20.5 to 43.2 μS/cm, mean total hardness 4.5 to 11.8 mg/L as CaCO₃

Land use: forest harvest in middle and upper reaches (on plateau); largely pristine, intact forest cover in lower valley; tourist center at river mouth; historic shipbuilding and logging settlement at river mouth (now abandoned)

Population density: <2 people/km²

Major information sources: Jessop 1986, R.A. Curry unpublished data, www.nationalgeographic.com/wildworld/terrestrial.html 2001, <http://atlas.gc.ca/site/english/index.html>, www.mscsmc.ec.gc.ca/climate/climate_normals 2004, www.cosewic.gc.ca/eng/sct0/index_e.cfm

FIGURE 21.16 Map of the Big Salmon River basin.

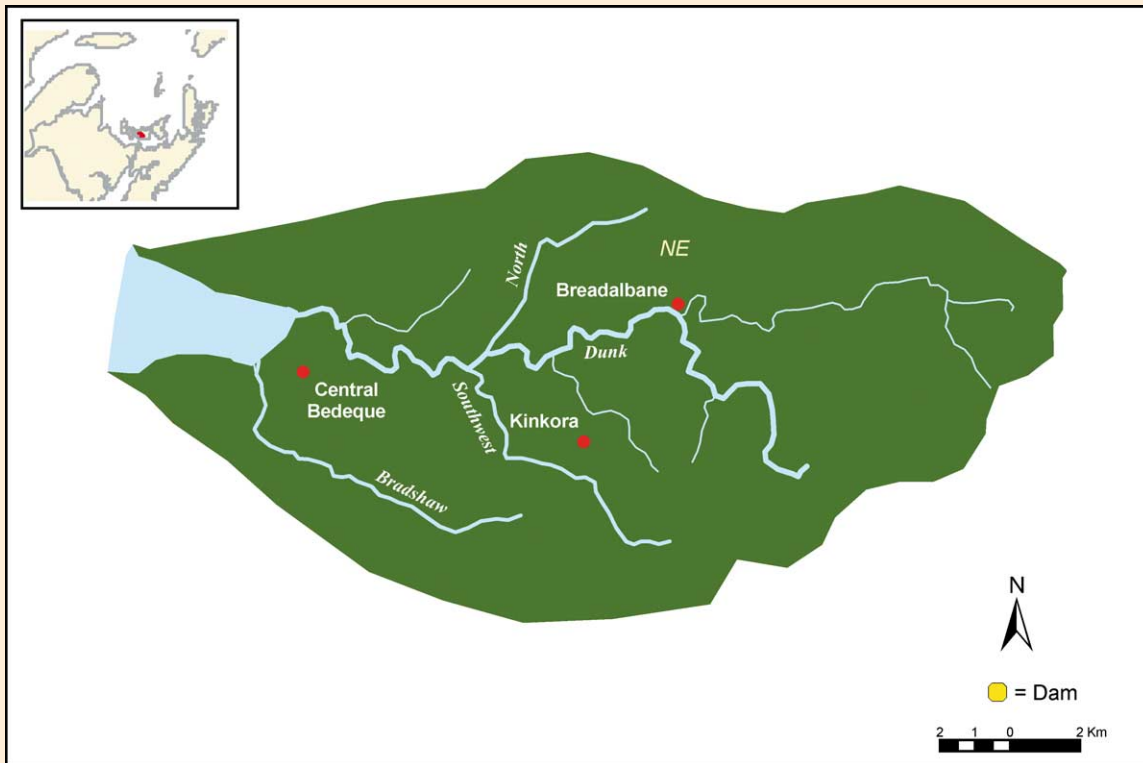

FIGURE 21.18 Map of the Dunk River basin.

DUNK RIVER

Relief: 110 m

Basin area: 217 km²

Mean discharge: 4.9 m³/s

River order: 4

Mean annual precipitation: 106 cm

Mean air temperature: 5.5°C

Mean water temperature: NA

Physiographic province: New England/Maritime (NE)

Biome: Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregion: Gulf of St. Lawrence Lowland Forests

Number of fish species: 8

Number of endangered species: none

Major fishes: brook trout (resident and anadromous forms), Atlantic salmon, American eel, rainbow smelt, alewife

Major other aquatic vertebrates: beaver

Major benthic invertebrates: stoneflies (Perlidae), mayflies (*Baetis*, *Ephemerella*, Heptageniidae), caddisflies (Limnephilidae, Lepidostomatidae, *Rhyacophila*), true flies (Simuliidae, chironomid midges), Elmidae, oligochaetes

Nonnative species: rainbow trout

Major riparian plants: white spruce, red maple, white birch, yellow birch, white pine, speckled alder

Special features: short, low-gradient river with high in-stream productivity on small provincial island; shallow, nutrient-rich estuary and stable thermal regime from groundwater discharge; popular river for sport fishing, especially sea-run trout; unique in that anadromous fishes can access the source pools in headwaters

Fragmentation: five impoundments (locally called ponds)

Water quality: heavy sediment loads (mean soil loss in area estimated at 10 t ha⁻¹ yr⁻¹), fertilizer, and pesticide runoff; the latter appears to be responsible for massive fish kills; pH = ~7.8, conductivity = ~210 μS/cm, turbidity = 9.7 to 700 JTU, mean total nitrogen = 3 mg/L, fecal coliforms (MPN) = 139/100 ml

Land use: intensive farming (mainly potatoes) throughout basin; limited forest harvest in headwaters.

Population density: 10 to 24.9 persons/km²

Major information sources: Martin 1981, Washburn and Gillis Associates 1992, Cairns 2002, Johnston 1980,

LAHAVE RIVER

- Relief: 195 m
- Basin area: 1668 km²
- Mean discharge: 45.9 m³/s
- River order: 5
- Mean annual precipitation: 147.3 cm
- Mean air temperature: 6.7°C
- Mean water temperature: NA
- Physiographic province: New England/Maritime (NE)
- Biome: Temperate Deciduous Forest
- Freshwater ecoregion: North Atlantic
- Terrestrial ecoregion: New England/Acadian Forests
- Number of fish species: 7
- Number of endangered species: none
- Major fishes: Atlantic salmon, brook trout, alewife, American shad
- Major other aquatic vertebrates: beaver, mink
- Major benthic invertebrates: NA
- Nonnative species: none
- Major riparian plants: pin cherry, white spruce, black spruce, red maple, speckled alder, white birch
- Special features: river system with >113 lakes; enhancement of Atlantic salmon initiated in 1970 with construction of fishway at Morgan Falls (km 25) on main branch and subsequent annual stocking in upper reaches
- Fragmentation: partial barriers at mouth of Sixty Brook and three natural obstructions on North River, many man-made obstructions removed in last 50 years and fishways constructed
- Water quality: severely impacted by acid rain, reducing pH to <4.8 in some tributaries during spring snowmelt; transportation artery for oil tankers, heavy-metal pollution in Bridgewater area (estuary); very good quality of upper river but highly colored soft water; pH = 5.8, conductivity = 33.3 μS/cm, total hardness = 5 to 8 mg/L as CaCO₃
- Land use: forested, with agricultural lands along river valley and shores of tidal zone
- Population density: <10 persons/km²
- Major information sources: Gray et al. 1989, Gray 1986, Caissie 2000a, Amiro and Jansen 2000, www.nationalgeographic.com/wildworld/terrestrial.html 2001, <http://atlas.gc.ca/site/english/index.html>, www.msc-smc.ec.gc.ca/climate/climate_normals 2004, www.cosewic.gc.ca/eng/scto/index_e.cfm

FIGURE 21.21 Mean monthly air temperature, precipitation, and runoff for the LaHave River basin.

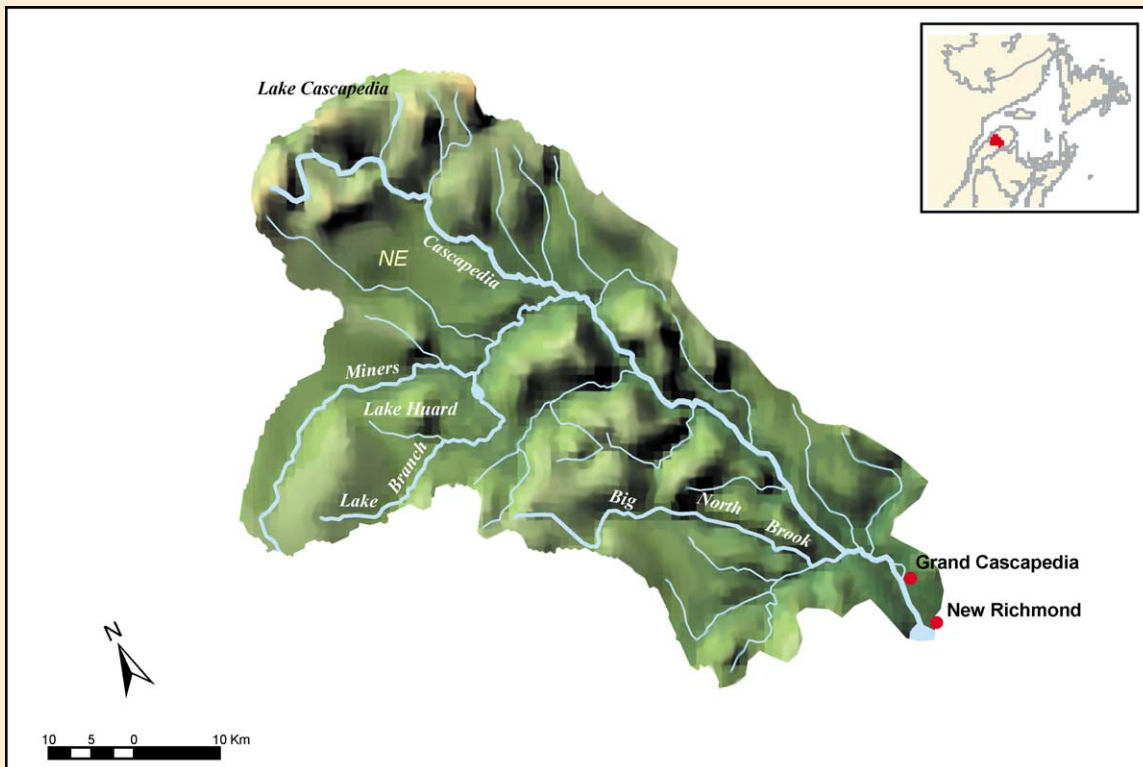

FIGURE 21.22 Map of the Grand Cascapedia River basin.

GRAND CASCAPEDIA RIVER

Relief: 490 m

Basin area: 1480 km²

Mean discharge: 36.1 m³/s

River order: 6

Mean annual precipitation: 101.9 cm

Mean air temperature: 3.7°C

Mean water temperature: NA

Physiographic province: New England/Maritime (NE)

Biome: Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregion: Eastern Canadian Forests

Number of fish species: 11

Number of endangered species: Simuliidae, Hydropsychidae

Major fishes: Atlantic salmon, brook trout, white sucker, lake chub, slimy sculpin, common shiner, northern redbelly dace

Major other aquatic vertebrates: mink, beaver

Major benthic invertebrates: NA

Nonnative species: rainbow trout

Major riparian plants: black spruce, white pine, white birch, speckled alder

Special features: popular for anglers; unique for having highest percentage of large Atlantic salmon (maiden three-sea-winter) of all North American rivers; native/nonnative alliance has seen salmon returns increased tenfold in past 30 years

Fragmentation: no major dams

Water quality: sedimentation and turbidity from poor logging practices (roads) has affected Lake Branch; lower river and estuary repeatedly dredged and receive municipal effluents and waste from pulp and paper mill; Salmon Branch has best water quality but under threat of forestry impacts

Land use: forestry

Population density: <1 person/km²

Major information sources: Cox 1899, Dube et al. 1999, <http://atlas.gc.ca/site/english/index.html>, www.nationalgeographic.com/wildworld/terrestrial.html 2001, www.msc-smc.ec.gc.ca/climate/climate_normals 2004, http://magazine.andubon.org/features0111/on_the_brink.html

PETITCODIAC RIVER

Relief: 415 m
 Basin area: 1360 km²
 Mean discharge: 27.3 m³/s
 River order: 6
 Mean annual precipitation: 103 cm
 Mean air temperature: 5.5°C
 Mean water temperature: NA
 Physiographic province: New England/Maritime (NE)
 Biome: Temperate Deciduous Forest
 Freshwater ecoregion: North Atlantic
 Terrestrial ecoregion: New England/Acadian Forests
 Number of fish species: 8
 Number of endangered species: 1 fish, 1 mussel (extirpated in 1968)
 Major fishes: alewife, American eel, brook trout, rainbow smelt, white sucker

Major other aquatic vertebrates: beaver, muskrat

Major benthic invertebrates: stoneflies (*Leuctra*), mayflies (*Baetis*, *Paraleptophlebia*), caddisflies (*Hydropsyche*, *Brachycentrus*), true flies (*Simulium*, *Tanyptodinae*), Hydracarina

Nonnative species: brown bullhead, chain pickerel, smallmouth bass

Major riparian plants: willows, white spruce, white pine, speckled alder

Special features: historic tidal bore is formed twice a day as tides from Bay of Fundy push upriver beyond Moncton

Fragmentation: causeway in estuary (at Moncton) causes infilling with sediments (headpond) and blocks migratory movements of diadromous fishes; dam on Turtle Creek for municipal water supply; three abandoned dams in tributaries impede fish passage

Water quality: strong tides carry huge volumes of suspended sediment upstream twice a day; highest natural concentration of suspended sediments in North America (nickname “Chocolate River”); former Moncton landfill on riverbank suspected of leaching toxic chemicals; pH 6.4 to 7.5, conductivity 30 to 100 μs/cm

Land use: lower section urbanized; forestry and agriculture in upper basin (60% of drainage area)

Population density: 10 to 69.9 people/km²

Major information sources: Caissie 2000b, Locke and Bernier 2000, www.cosewic.gc.ca/eng/sct0/index_e.cfm, www.nationalgeographic.com/wildworld/terrestrial.html 2001, www.msc-smc.ec.gc.ca/climate/climate_normals 2004, <http://atlas.gc.ca/site/english/index.html>, www.petitcodiac.org/riverkeeper 2004

HUMBER RIVER

Relief: 700 m

Basin area: 7860 km²

Mean discharge: 246 m³/s

River order: 7

Mean annual precipitation: 118.6 cm

Mean air temperature: 5.2°C

Mean water temperature: NA

Physiographic province: New England/Maritime (NE)

Biome: Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregions: Newfoundland Highland Forests, Eastern Canadian Forests

Number of fish species: 7

Number of endangered species: none

Major fishes: Atlantic salmon, brook trout, rainbow smelt, American eel, Arctic char, threespine stickleback

Major other aquatic vertebrates: mink, river otter, beaver

Major benthic invertebrates: numerous species of stoneflies, mayflies, caddisflies, black flies

Nonnative species: rainbow trout

Major riparian plants: black spruce, white birch, speckled alder, juniper, sweet gale, bog laurel

Special features: popular sport-fishing river for Atlantic salmon and brook trout; Grand Lake is largest lake in Newfoundland; landlocked populations of Atlantic salmon (ouananiche) and Arctic char upstream of impassable falls; parts of headwaters in Gros Morne National Park and provincial park

Fragmentation: natural obstruction at Main Falls (6.4 m), 113 km from river mouth; North Brook has natural obstruction 14.8 km from mouth; Grand Lake used for hydro-power; several hydro storage dams in Grand Lake subbasin

Water quality: headwaters nearly pristine; domestic sewage from Deer Lake, Corner Brook, and other towns; pulp and paper effluent from Corner Brook

Land use: limited agriculture near Deer Lake; forest (harvest common throughout basin)

Population density: <10 people/km²

CHURCHILL RIVER

- Relief: 549 m
- Basin area: 93,415 km²
- Mean discharge: 1861 m³/s
- River order: 6
- Mean annual precipitation: 94.5 cm
- Mean air temperature: -3.5°C
- Mean water temperature: NA
- Physiographic provinces: Labrador Highlands (LB), Laurentian Highlands (LU)
- Biome: Boreal Forest
- Freshwater ecoregion: North Atlantic-Ungava
- Terrestrial ecoregions: Eastern Canadian Shield Taiga, Eastern Canadian Forests
- Number of fish species: 20
- Number of endangered species: none
- Major fishes: northern pike, lake whitefish, white sucker, brook trout, lake trout, Atlantic salmon (landlocked salmon only above Muskrat Falls), Arctic char, lake chub, threespine stickleback, mottled sculpin, slimy sculpin
- Major other aquatic vertebrates: muskrat, beaver, mink
- Major benthic invertebrates: NA
- Nonnative species: none
- Major riparian plants: black spruce, white birch, larch, Labrador tea
- Special features: second-largest river (by discharge) in Atlantic drainage; Muskrat Falls, an 8 m waterfall 40 km from mouth, is complete barrier to upstream migration; original Innu name “Mishtashipu” means “big river”
- Fragmentation: Churchill Falls Dam, huge hydroelectric project (5400 MW), a major energy provider for northeastern United States; many dams and dykes for hydroelectric project act as unnatural barriers to fish migration
- Water quality: generally very good throughout system
- Land use: primarily forest; extensive area (6700 km²) flooded by Smallwood Reservoir upstream of Churchill Falls dam
- Population density: <1 person/km²
- Major information sources: Anderson 1985, <http://atlas.gc.ca/site/english/index.html>, National Geographic 2001 <http://www.nationalgeographic.com/wildworld/terrestrial.html>, Environment Canada 2004 http://www.msc-smc.ec.gc.ca/climate/climate_normals, <http://www.ccge.org/ccge/english/resources/ivers>

INTRODUCTION

ST. LAWRENCE RIVER MAIN STEM

OTTAWA RIVER

SAGUENAY RIVER

ST. JOSEPH RIVER

ADDITIONAL RIVERS

ACKNOWLEDGMENTS

LITERATURE CITED

INTRODUCTION

The second-largest river network in North America in annual discharge is the international St. Lawrence River–Great Lakes system. The importance of this river–lake system in times of increasing global shortage of fresh water is hard to overestimate because its basin holds about 23,000 km³ of water (roughly 18% of the world's freshwater; Fuller et al. 1995). The river's catchment stretches from ~40°N to 50°N latitude and ~65°W to 93°W longitude (Fig. 22.2). Rivers flowing northward from there mostly enter the Labrador Sea or Hudson Bay, whereas immediately southward they pass either into the Atlantic Ocean via mid-Atlantic or northeast coastal rivers or into the Gulf of Mexico via the Mississippi River system. The St. Lawrence River–Great Lakes system forms part of the boundary between Canada and the United States, and in some places it physically divides or links various Indian nations, including the Mohawks in northern New York and southern Canada.

The ~1.6 million km² watershed that constitutes the St. Lawrence River–Great Lakes system is divided into three subbasins, with ~47.8% draining into the Great Lakes, 35.7% into the St. Lawrence River main stem, and 16.5% into the estuarine Gulf of St. Lawrence (St. Lawrence Centre 1996). Water in this

system can travel at least 3260 km from western Lake Superior to the Cabot Strait in the estuarine Gulf of St. Lawrence. Along this lentic–lotic–estuarine pathway to the sea the river system draws sustenance from nine states (Minnesota, Wisconsin, Illinois, Indiana, Michigan, Ohio, Pennsylvania, Vermont, and New York) and at least two provinces (mostly Ontario and Quebec).

For perhaps 8500 to 9000 years the St. Lawrence River–Great Lakes system has played an important role in the lives of many nations of Native Americans, with Abnake, Algonquin, Huron, Iroquois, Montagnais, Potawatomi, and other groups thriving in this area. Although it is clearly impossible to obtain an accurate human census in this river–lake system prior to the immigration of Europeans, one estimate places the sixteenth-century population of Native Americans around the Great Lakes alone at 60,000 to 117,000 people. The earliest surviving record of the basin's exploration by Europeans dates to 1535, during a period of exploration for the fabled Northwest Passage from the Atlantic to the Pacific. In that year, the French explorer Jacques Cartier happened upon this great river and named it in honor of the coincident feast day of Saint Lawrence. In 1615, the French Explorer Samuel de Champlain or his scout Étienne Brulé were the first recorded Europeans to explore the

FIGURE 22.2 Rivers of the St. Lawrence River basin covered in this chapter.

Great Lakes portion of this river–lake system. The first permanent European settlement in the St. Lawrence River valley was established by Samuel de Champlain in the first decade of the seventeenth century near the present-day city of Quebec. The river changed hands in 1763 following Britain’s victory in the so-called French and Indian War. The movement of mostly Euro-Americans westward into the basin was linked in the early years to the fur trade, with only isolated trading posts and forts impinging on the watershed and aquatic habitats. Environmental effects on the basin were minor until immigrants severely disturbed the watershed and streams by extensively tilling the soil, felling timber, and overharvesting populations of fishes and aquatic mammals.

Although a disproportionate amount of scientific knowledge exists about lacustrine portions of this enormous lake–river system (i.e., on the five major Great Lakes), this chapter focuses on characteristics of the main-stem St. Lawrence River and three of its major tributaries: the Ottawa, Saguenay, and St. Joseph rivers (see Fig. 22.2). Although the St. Lawrence River–Great Lakes system includes many additional tributaries worthy of discussion, abbreviated descriptions of physical and biological information are provided for six representative rivers. These are generally smaller tributaries that flow either into the Great Lakes (AuSable, Black, Maumee, and Ontonagon rivers) or the main stem (Richelieu and Saint-Maurice rivers).

Physiography and Climate

The physiographic nature of the St. Lawrence River–Great Lakes system reflects the action of numerous glacial advances and retreats over tens of thousands of years. Three major physiographic divisions and eight physiographic provinces provide water for this system (Hunt 1974): the Canadian Shield (Superior Upland, Laurentian Highlands, and Labrador Highlands provinces), Appalachian Highlands (New England/Maritime, Adirondack, St. Lawrence Lowlands, and Appalachian Plateaus provinces), and Interior Plains (Central Lowland province). The Great Lakes watershed, which is quite small compared to the volume of water retained by the lakes, is influenced primarily by the Superior Upland and Central Lowland provinces and to a lesser extent by the Appalachian Plateaus, Adirondack, and Laurentian Highlands provinces. Tributaries directly entering the freshwater and estuarine portions of the St. Lawrence River are derived mostly from the St. Lawrence Lowlands and Laurentian Highlands provinces, with additional flow from the Adirondack, New England/Maritime, and Labrador Highlands provinces.

The St. Lawrence River–Great Lakes system stretches climatically from the continental weather zone at its western edge to the oceanic zone in its eastern edge. The Great Lakes and Atlantic Ocean greatly affect precipitation patterns and dampen temperature fluctuations within this broad geographic area. This temperate region is characterized by mild, humid summers and cold snowy winters. Within the St. Lawrence–Great Lakes basin the annual precipitation (56 to 111 cm) varies considerably with a site's location upwind or downwind of a major lake, but half the precipitation entering the Great Lakes is lost to the atmosphere via transpiration and evaporation before it enters the St. Lawrence River. Summer temperatures of tributaries emptying into the Great Lakes are influenced by both cool dry air masses from the Canadian Northwest and warm moister air moving northward from the Gulf of Mexico. Around the main stem and tributaries of the St. Lawrence River these two air masses interact in the summer, with moist air flowing from the northwest Atlantic. Winter temperatures are more strongly influenced over the lakes by Arctic winds but near the sea coast by ocean winds as well. Snow averages 208 cm per year (0 to 54.6 cm/month) in the basin; this generally starts in late October, reaches a maximum in

December and January, and tapers off in April. Snowfall is greatest in the lee of each of the Great Lakes.

Basin Landscape and Land Use

The two principal terrestrial biomes within the St. Lawrence River–Great Lakes system are the Temperate Deciduous Forest and the Boreal Forest, although grassland and savannah transition areas appear around major sections of Lake Michigan. Moving more-or-less westerly from the seacoast, nine terrestrial ecoregions are present in this basin: Eastern Canadian Forests, New England/Acadian Forests, Eastern Forest/Boreal Transition, Eastern Great Lakes Lowland Forests, Southern Great Lakes Forests, Western Great Lakes Forests, Central Canadian Shield Forests, Central Forest/Grassland Transition Zone, and Upper Midwest Forest/Savannah Transition Zone (Ricketts et al. 1999).

From a topographic perspective, the St. Lawrence River–Great Lakes system is relatively flat in the western half but rises to nearly 2000 m in the more mountainous eastern half of the basin. The latter includes northern portions of the Adirondack and Appalachian Mountains located southeast of the St. Lawrence River in New York and Quebec, as well as scattered mountainous areas northwest of the river in Quebec.

Nearly 60 million people live in the St. Lawrence River–Great Lakes system, with most individuals clustered within 100 km of the waterfront. The average population density in the basin is about 54 people/km², with a high of 97 people/km² in the Lake Ontario subbasin. Sixty cities in this watershed have populations of at least 100,000 people. Human densities fall off considerably in the northern Great Lakes regions and within the watershed for the main stem of the St. Lawrence River (except for cities such as Montreal, Ottawa, and Quebec).

In terms of land use and land cover, the southern portion of the Great Lakes basin is highly urbanized and industrialized, especially around Lakes Michigan, Erie, and Ontario. In contrast, northern areas of the Great Lakes and most of the watershed of the St. Lawrence River are much less developed except within ~100 km of the river. For the St. Lawrence River–Great Lakes system as a whole, the watershed is 55% forested, 20% cropland (with little or no irrigation), 22% urban, and 3% other types of land cover (Revenga et al. 1998).

The Rivers

The St. Lawrence River–Great Lakes system is nestled within the St. Lawrence Complex of the Arctic–Atlantic Bioregion, which contains five freshwater ecoregions (Abell et al. 2000). Moving westerly from the seacoast, these are the Lower St. Lawrence, Ontario, Erie, Michigan–Huron, and Superior freshwater ecoregions. The Lower St. Lawrence, which includes the main-stem river and all its tributaries below Lake Ontario, is considered continentally outstanding in terms of biological distinctiveness (Abell et al. 2000). Besides the St. Lawrence main stem, other rivers of the lower St. Lawrence ecoregion described in this chapter are the Ottawa, Saint-Maurice, Richelieu, and Saguenay. The continentally outstanding biodiversity of this river is significantly influenced by the ocean and Great Lakes as well as by the river’s position on major migratory pathways for shorebirds, waterfowl, and raptors. Aside from climatic influences, the nearby Atlantic Ocean also contributes migratory marine fishes and mammals to the river, the latter especially in the lower, and to some extent upper, estuaries.

This chapter includes at least one river within each of the freshwater ecoregions that drain into the Great Lakes (see Fig. 22.2). The Ontario ecoregion is considered nationally important in biological distinctiveness (Abell et al. 2000) and includes the Black River, which drains into the eastern end of Lake Ontario from the Adirondack Mountains. The Erie ecoregion is also listed as nationally important and includes the Maumee River, which drains from northeastern Indiana and northwestern Ohio and flows into the western end of Lake Erie. The Michigan–Huron ecoregion is regarded as continentally outstanding and includes the AuSable River, which flows into Lake Huron from the west, and the St. Joseph River, which flows into southern Lake Michigan. Finally, the Superior ecoregion is listed as continentally outstanding and is represented by the Ontonagon River, which flows into Lake Superior from the upper Michigan peninsula. In addition, seven internationally designated RAMSAR wetland sites occur within the St. Lawrence–Great Lakes system.

Most of the tributary rivers of the St. Lawrence basin are small to medium size (mean discharge $<200\text{ m}^3$), particularly those that flow into the Great Lakes from the Central Lowland and the Superior Upland physiographic provinces. Flowing into the St. Lawrence main stem, however, are some large rivers (mean discharge $>500\text{ m}^3/\text{s}$), particularly the

Saguenay, Ottawa, and Saint-Maurice, which drain the Canadian Shield (see Fig. 22.2). These large rivers, as well as many smaller tributaries entering the St. Lawrence below Lake Ontario, contribute more than half the freshwater flow into the Gulf of St. Lawrence, even though they drain less than half the total basin area.

The human impacts on rivers within the St. Lawrence basin are great. Within this area are 11 large dams built for navigation, hydroelectric production, and/or flood control. Hundreds of small dams are scattered throughout the watershed, especially on Adirondack rivers, such as the Raquette River of northern New York. Pollution impacts are serious in agricultural areas of the Great Lakes freshwater ecoregions, and below cities, particularly the large cities on the St. Lawrence main stem. Recently, humans have affected the St. Lawrence and some of its tributaries through the pernicious effects of acid rain. Most rivers in the northern St. Lawrence basin originate or flow through Precambrian Shield geologic formations, which have poor buffering capacity because of generally low alkalinity and conductivity. Sensitive rivers of the St. Lawrence basin that have been studied include the Saguenay, Ottawa, and St. Maurice, and ecotoxicological effects of progressive acidification on salmon populations are well characterized in these rivers.

ST. LAWRENCE RIVER MAIN STEM

The St. Lawrence River is arguably among the world’s most unique rivers, in part because about half its discharge originates from the huge Laurentian Great Lakes and their many tributaries. This river is also known as Rivière Saint-Laurent among the Francophones of Quebec and as Kaniatarowanenneh (approximately translated as “the big waterway”) in the Iroquois language. It ranks among the top 16 rivers of the world in annual discharge and has the second-highest flow in North America (if the Saguenay is included). Hydrological contributions of the voluminous Great Lakes produce a river characterized by clearer water and a more stable stage level than any other large river in North America (Fig. 22.3). Indeed, the St. Lawrence transports the smallest amount of suspended sediment of the world’s major rivers (Gleick 1993), a characteristic that undoubtedly affects primary productivity and food web relationships. The main portion of the river is listed here as 8th order, but this technically increases to 9th order at its confluence with the Saguenay River

FIGURE 22.3 St. Lawrence River at Thousand Islands Bridge near Ivy Lea, Ontario (PHOTO BY J. M. FARRELL, THOUSANDS ISLANDS BIOLOGICAL STATION).

at the downstream terminus of the upper estuary. However, this size designation has little utility in comparing rivers because the presence of the Great Lakes makes this river vastly larger than any other 8th or 9th order river in North America.

The main stem flows 965 km along a northeasterly path from the outlet of Lake Ontario to the mouth of the Saguenay River, which is the approximate downstream terminus of the upper estuary (Fig. 22.8). Along this pathway the river is bounded solely by Quebec, Ontario, and New York (in order of shoreline length). Another >300 km of the St. Lawrence River system constitutes the lower estuary, a section not covered in this chapter.

Although archaeological evidence indicates that Native Americans have lived in the St. Lawrence River basin for thousands of years, the earliest surviving archaeological record of construction of a longhouse dates to 1100, with maize agriculture entering this area in perhaps the fourteenth century. Many First Nations were present in this area, but the two dominant groups were tribes of the Algonquin Nation and the Confederation of the Haudenosaunee, a group now more commonly known as the Iroquois. The Haudenosaunee Confederation was established at least as early as 1570 and certainly prior to any significant contact with Europeans. By 1660 there were perhaps 25,000

Haudenosaunee living in the watershed of the main stem of the St. Lawrence River and many more elsewhere. This widely influential confederation was formed originally by five nations (Cayuga, Mohawk, Oneida, Onondaga, and Seneca) and expanded to six in 1722 with the addition of the Tuscaroras. The St. Lawrence River was vital to the culture, transportation, and livelihood of most Native Americans living near its waters, but Native Americans are thought to have had little impact on the aquatic ecosystem.

Physiography, Climate, and Land Use

The shoreline along the river's nearly 1000 km main stem and the basin's contributions to water chemistry are influenced by two major physiographic divisions: the Precambrian Shield and the Appalachian Highlands, although the river as a whole is affected by three major physiographic divisions and eight physiographic provinces because it draws water from watersheds around the Great Lakes. The huge Precambrian (or Canadian) Shield is located mostly west and north of the river, whereas the Appalachian Highlands division is present east and south of the river (see Fig. 22.8). The freshwater, nontidal main stem of the St. Lawrence is nestled primarily in the small physiographic province of the St. Lawrence Lowlands (SL) (Appalachian Highlands) and secondarily in the Laurentian Highlands (LU) (Precambrian Shield) and New England/Maritime (NE) province (Appalachian Highlands), but the river receives lesser flow through the Adirondack (AD) (Appalachian Highlands) and Labrador Highlands (LB) provinces (Precambrian Shield) (Hunt 1974). The geology of the Precambrian Shield is dominated by silicate rocks and includes metasediments (e.g., quartzite, crystalline limestone), metavolcanics, igneous rocks (e.g., granite), orthogneiss, and pegmatite. Found in the St. Lawrence Lowlands are formations of early Paleozoic rock (Cambrian and Ordovician) lying on Precambrian bedrock, with a thick horizontal deposit of sandstone, limestone, dolomite, and shale. The remaining provinces in the Appalachian Highlands are composed of sedimentary and volcanic (igneous) rock that underwent complex metamorphic deformation during the Paleozoic era. In summary, the upper catchment is dominated by silicate rocks of the Precambrian Shield, whereas downstream portions of the basin contribute large amounts of carbonates from the Paleozoic lowlands (Yang et al. 1996). Bedrock outcrops in the landscape surrounding the St. Lawrence River blend with flat plains, some rolling hills, and the ancient Adirondack Mountains southeast of the river.

Temperatures and precipitation in the valley of the St. Lawrence River are more stable than for rivers situated farther inland because of the influences of the Great Lakes and ocean. Moreover, precipitation is spread relatively evenly throughout the year (Fig. 22.9). Montreal averages 94.2 cm of precipitation per year (snow converted to rain equivalence) and has a monthly range of 6.6 cm in February to 9.1 cm in August. The historical average temperature is 6.2°C to 6.8°C, with mean monthly temperature ranging from -10°C in January to 21°C in July (see Fig. 22.9). As a result of the seasonal temperature pattern, the river is at least partially ice covered for most of the winter, especially in the fluvial lake regions. In Massena, New York (near the end of the international portion of the river), the main channel is covered with ice by late December to late January, snowfall averages 178 cm/yr, and the crop-growing season is about 139 days.

The St. Lawrence River occurs predominately in two terrestrial ecoregions. These consist of the Eastern Great Lakes Lowland Forests, through which the river cuts, and the Eastern Forest/Boreal Transition, from which the largest tributaries primarily originate. The freshwater portion of the river is also marginally affected by two other terrestrial ecoregions: the New England/Acadian Forests and the Eastern Canadian Forests. Forest communities are quite variable in the river's watershed (Ricketts et al. 1999) because this area is a geographical and ecological transition area between boreal coniferous forests and more temperate broadleaf deciduous zones.

A major portion of the Eastern Great Lakes Lowland Forests is dominated by eastern hemlock and pine, with a few species of deciduous trees: yellow birch, sugar maple, red maple, red oak, and American beech. The remainder of the ecoregion is a mosaic of deciduous stands in favorable habitats, with good soils contrasting with coniferous assemblages in less-favorable habitats with poorer soils. Drier sites feature red oak, red pine, white pine, and eastern white cedar. Some of these cedars have been aged at 700 to 800 years, making them among the oldest trees in eastern North America. Moist habitats contain red maple, elm, cottonwood, and various ashes. Wetland plant communities are abundant in the many poorly drained depressions, and small, occasionally deep lakes are present.

The Eastern Forest/Boreal Transition ecoregion is a mixed-wood forest dominated by white spruce, balsam fir, paper birch, and yellow birch (Ricketts et al. 1999). Pines are more common in drier north-

western areas. Common in southern Algonquin areas are stands of sugar maple, yellow birch, eastern hemlock, eastern white pine, and some beech. Poorly drained regions frequently have tamarack and eastern white cedar in particular.

Plant communities within the Great Lakes Lowland Forest ecoregion are highly fragmented, as no intact blocks >250 km² exist, and <5% of the total ecoregion is considered intact. In the surrounding Eastern Forest/Boreal Transition ecoregion, however, intact habitats remain in ~10% of the ecoregion, especially in Adirondack Park south of the river in New York.

Today millions of people in Canada and the United States live near the banks of the St. Lawrence River and benefit from its economic, municipal, and cultural attributes. For example, the 3.4 million people residing in Montreal and surrounding suburbs represent ~50% of the entire population of Quebec (www12.statcan.ca/english/census01/home/index.cfm 2001). Other large Canadian cities are Ottawa and Quebec City, at 1.06 and 0.68 million, respectively. No cities with populations of 100,000 or more occur in the United States along the river's main stem. As one moves downstream from Lake Ontario, population densities decline, especially in the United States. Agriculture becomes relatively more important in land cover, but high-density pockets of human population still exist.

Farming in the St. Lawrence Valley is still widespread in Canada but continues to decline in the United States as many dairy farmers move south, allowing former farmland to undergo reforestation. This trend has resulted in an increase in the percentage of forested lands in New York State over the last half century from ~37% to 60% (Alerich and Drake 1993). Likewise, Quebec experienced a 41% decline in the surface area devoted to agriculture from 1961 to 1991, but agriculture activities intensified on the remaining land. Beaver populations have rebounded from almost total extirpation, though trapping continues at a lower pace.

River Geomorphology, Hydrology, and Chemistry

The main stem of the St. Lawrence begins at the outlet of Lake Ontario and flows through four sections before reaching the Gulf of St. Lawrence (St. Lawrence Centre 1996): fluvial section, fluvial estuary, upper estuary (including the Saguenay River), and lower estuary (not discussed in this chapter). From Lake Ontario to the end of the lower

estuary the river drops about 184 m, for an average of ~14 cm/km. The maximum topographic relief in the basin of the St. Lawrence main stem is 1270 m, but this occurs near the downstream end of the upper estuary. Many shoreline areas of the main stem feature large boulders, but the channel is composed primarily of sand and gravel except where the natural falls formerly occurred.

The 655 km long fluvial section, which extends from Lake Ontario through the international portion of the river to Cornwall-Massena in Quebec, includes uppermost braided regions, constricted channels, rapids (now mostly bypassed with navigation locks), modest floodplain areas, and four natural fluvial lakes, often widened and deepened by hydroelectric dams. Many of the latter are in the upper river in a popular tourist area called the "Thousand Island" region (see Fig. 22.3). A shipping channel with a minimum depth of 8.2 m is maintained throughout this section of the river. This channel is deeper than the 3 m minimum navigation depth maintained for many other navigable rivers in the United States because oceangoing ships rather than just barges traverse the St. Lawrence Seaway. In the fluvial section, the river varies from 1 to 2 km wide in constricted reaches to an average of 12 km wide in some fluvial lakes.

The 160 km long fluvial estuary extends from the downstream terminus of Lac Saint-Pierre to the eastern tip of the Île d'Orléans (~45 km downstream of Quebec City). Tidal forces increase gradually through this section, but the water remains fresh until the Île d'Orléans, where salinities rise to 2 PSU. The 150 km upper estuary, which runs from the eastern tip of the Île d'Orléans to the mouth of the Saguenay River, is the principal transition area between the freshwater and saltwater environments. Salinities range across this section from 2 PSU at the upstream end to 30 PSU at the confluence of the St. Lawrence and Saguenay rivers. Tidal forces are strong here (mean tidal range 4.1 m at Quebec City) and the river is wide (mean 17 km) and up to 100 m deep in places.

In contrast to the pool and riffle-run sequence in many rivers of North America, the natural fluvial lakes of the St. Lawrence River (i.e., Lake St. Lawrence and Lacs Saint-François, Saint-Louis, and Saint-Pierre) are relatively shallow (80% of the area <6 m) in comparison to the generally deeper, main riverine channels (often 10 to 12 m deep). These wide, shallow pools were present prior to construction of the hydroelectric and diversion dams, but the dams have modified the size and depth of these more lacustrine portions of the river. Because of their shallow nature, fluvial lakes support broad expanses

of submerged vascular macrophytes and abundant populations of fishes, benthic invertebrates, and plankton. Fluvial lakes of the St. Lawrence should not be confused with typical lentic systems, as the water residence times in portions of fluvial lakes can be quite short (e.g., ~1.5 days in the main channel of Lac Saint-Pierre versus 2 to 3 weeks in north and south littoral areas; Jean Morin, personal communication).

Annual discharge of the St. Lawrence averages 12,101 m³/s at Quebec City (1962 to 1988) but this rises to 16,800 m³/s downstream of the confluence with the Saguenay River. The outflow of Lake Ontario averages 7,410 m³/s. Consequently, the Great Lakes contribute ~61% of the water reaching Quebec City and just under half the freshwater entering the Gulf of St. Lawrence. Most tributary inputs occur downstream of the international portion of the river. For example, at Massena, New York, and Cornwall, Ontario, which are very near the downstream end of the international section of the river, 99% of the discharge originates from Lake Ontario.

The longest-term discharge record for the St. Lawrence is at Massena–Cornwall, where peak discharge occurs from April through June in response to snowmelt, and minimum flows are in January. However, because this fluvial section of the river is so strongly influenced by discharge from Lake Ontario, it fluctuates to a very minor degree compared to other large rivers in North America. Indeed, the average maximum daily discharge from 1900 to 1989 was 11,337 m³/s at Cornwall, less than three times the minimum daily flow of 4170 m³/s over the same period. In a normal year, the minimum flow is only 19.5% less than the maximum flow in the fluvial section of the river, and the difference between average flow and peak flow is only 6.4%. This low variability is due mostly to the stabilizing influence of the high water volume held by the Great Lakes, where estimated water residence times for the five major lakes vary from 2.6 to 117 years. Runoff is relatively low and, like precipitation, is consistent among months (2.12 to 2.65 cm/mo) compared to many other rivers throughout North America (see Fig. 22.9). Farther downstream the river is more affected by seasonal flows and thus monthly variability increases. Indeed, at Quebec City, near the end of the fluvial estuary, the maximum monthly flow over the period from 1962 to 1988 (Bourgault and Koutitonsky 1999) was 62.2% higher than the minimum flow and 40.7% higher than the mean flow.

Because of the disparate nature of the sources of its water, the St. Lawrence is more poorly mixed from

bank to bank than one would expect from a large river. Consequently, clear water from the Great Lakes tends to occupy the central portion of the river channel, whereas the more sediment-laden water from tributaries in Canada and the United States hugs their respective shorelines for up to 100 km. Variability in depth, current velocity, flow patterns, and water origin also influence the size of bottom sediments, causing the bottom to vary within short distances from boulders to gravel, sand, or clay.

Water chemistry in the St. Lawrence is strongly controlled by the geology of the drainage basin for each tributary, with the Great Lakes exerting the strongest influence on the river as a whole. As one moves downstream tributaries have an increasing effect on water chemistry in the main stem, and the chemical character of the water fluctuates more seasonally. Tributaries draining the Precambrian Shield are relatively pristine because of their location in areas of low concentrations of humans, industrial activity, and agriculture. They are notably low in total dissolved solids, bicarbonates, sulfates, calcium, magnesium, nitrates, and strontium but are high in silicon and total iron (Yang et al. 1996). Tributaries draining Paleozoic lowlands, with their limestone, dolostones, and evaporites, are characterized by opposite chemical attributes. They are typically in areas of high human impact. Near the terminus of the international portion of the river, historical mean water quality values are as follows: dissolved O₂ 8.6 mg/L, alkalinity 90 mg/L as CaCO₃, hardness 130 mg/L as CaCO₃, pH 7.5 to 8.5, total dissolved solids 153 to 210 mg/L, conductivity 272 μS/cm, total suspended solids <5 mg/L, turbidity <52 NTU, and Secchi disk transparency 7.6 to 10.7 m (New York Power Authority 1996).

Nutrient and bacterial pollution in the St. Lawrence have been decreasing since the mid-1980s (New York Power Authority 1996). Mean nutrient concentrations now are as follows: NH₄⁺-N 0.01 to 0.04 mg/L, total Kjeldahl N 0.18 mg/L, and PO₄-P 0.010 mg/L. Fecal and total coliform values were <4/100 mL and 388/100 mL of water, respectively, all much better than the New York Department of Environmental Conservation water-quality standards (200/100 mL and 2400/100 mL, respectively). Phosphorus appears to limit primary productivity in the St. Lawrence River.

River Biodiversity and Ecology

The Lower St. Lawrence freshwater ecoregion, which includes the main stem of the St. Lawrence River, is

listed as continentally outstanding (Abell et al. 2000) because of its biological distinctiveness; Lac Saint-Pierre is a RAMSAR World Heritage Site based on its extreme diversity of wetland plants and habitat for fishes and waterfowl. Despite the outstanding nature of the St. Lawrence River fauna and flora, however, published studies on the ecology of the freshwater main stem seem relatively rare compared to the literature on other very large rivers like the Mississippi, and most of that is by Canadian scientists. Indeed, the St. Lawrence is not even mentioned in the index of Ruth Patrick's (1996) book on rivers of the eastern United States. Although the gray literature is abundant overall because of the activities of Environment Canada (especially in Quebec), both refereed and gray literature are minuscule in the United States. From the mostly Canadian literature (especially the excellent report by the St. Lawrence Centre [1996]), however, we can piece together a view of the ecology of the St. Lawrence River.

Algae and Cyanobacteria

The nature of phytoplankton assemblages in the St. Lawrence varies with season, tributary input, and position relative to fluvial lakes and other riverine habitats (e.g., Basu et al. 2000a, 2000b). Seasonal environmental changes appear more important to controlling phytoplankton community composition than changes in river conditions related to tributary inputs. Diatoms in particular, but also Cryptophyceae, are abundant year-round, with Chlorophyceae becoming important in the summer (Hudon et al. 1996). Several authors have noted a progressive downstream decrease in the total biomass and average individual size of phytoplankton along with changes in species composition that are related to distances from Lake Ontario. However, this trend can be reversed by tributaries and the presence of fluvial lakes. For example, phytoplankton assemblages below major tributaries, such as the Ottawa River, are often taxonomically richer and have a different relative species composition than those downstream of Lake Ontario, and individuals are likewise characterized by greater biomass, cell volume, and chlorophyll *a* content. Below fluvial lakes, resuspended periphyton adds to the phytoplankton assemblage.

Studies of benthic microalgae have concentrated on the fluvial section of the river and have shown that species composition and biomass vary over much smaller spatial scales than has been noted for planktonic microalgae, thus contributing to a relatively homogenous community throughout broad areas of

the fluvial section (St. Lawrence Centre 1996). Periphyton biomass sampled on glass slides were higher in the St. Lawrence in clear "green" waters derived mostly from the Great Lakes than in the more turbid "brown" water entering from tributaries like the Ottawa River (Ahmad et al. 1974). In the summer, aborescent Chlorophyceae (*Cladophora* sp.) are dominant at many sites, and this filamentous alga is often colonized by diatoms (e.g., *Rhoicosphenia curvata*) and Cyanophyceae (e.g., *Lyngbya* sp.). Ice scouring in winter and the senescence of vascular plants (as substrates for epiphytic algae) contribute to strong seasonal fluctuations in abundance and species composition of benthic microalgae.

Plants

Species composition and abundance of aquatic vascular plants varies greatly with river section, and freshwater wetlands as a whole are high in species endemism. Within the 240 km fluvial section of the river downstream from Cornwall, Ontario, are about 30,260 ha of macrophyte beds and 12,600 ha of marshes (from Table 2.4 in St. Lawrence Centre 1996; after Gratton and Dubreuil 1990). The fluvial estuary and upper estuary contain no significant populations of submerged macrophytes but have about 5500 and 2130 ha of marshes, respectively. The dominant plants are submerged vascular macrophytes, American bulrushes, and saltmarsh cordgrass (mostly smooth cordgrass) in the fluvial section, fluvial estuary, and upper estuary, respectively. About 98% of the aquatic macrophytes in the fluvial section are submerged species, and most of the remainder have floating leaves and occur in slower waters. The dominant submerged plant is the American wild celery, which averages about 100 to 220 g/m² in some fluvial lakes and wetlands. Some protected habitats in the freshwater sections of the river contain abundant populations of pondweeds (clasping leaf pondweed), duckweeds (star duckweed), hornleaf riverweed, and bur-reed (branching bur-reed); mostly sedges (hairy sedge); or a combination of pond-lily, bulrushes (slender bulrush), reed manna grass, and greater yellow-cress interspersed with diamond willow and silver maple trees.

Growth of aquatic vascular plants varies considerably with river levels and season. For example, the production of plants in the fluvial Lac Saint-Pierre more than doubled in years with low summer river levels compared to years of high river stages (Hudon 1997). Moreover, ice scouring and cold temperatures significantly restrict growing seasons. Light penetration, wind-wave energy, current velocity, and physi-

cal substrate characteristics seem to control species composition and biomass (Morin et al. 2000). Water-level stabilization from damming has both favored the growth of submerged plants over emergents and roughly doubled their biomass.

Aquatic plants typically enter the riverine food web via detritivores. In the St. Lawrence River, however, muskrats and greater snow geese prey heavily on aquatic macrophytes and American bulrushes, respectively (Giroux and Bédard 1987).

Invertebrates

Benthic invertebrate assemblages within the river vary greatly with depth, substrate size, and organic content (see Table 2.14 in St. Lawrence Centre 1996, data from Ferraris 1984; see also Lemarche et al. 1982, Ricciardi et al. 1997). The latter two are influenced, in turn, by current velocity and the presence of aquatic plants. Assemblages are also affected by the source and nature of the water, such as clear Lake Ontario-derived water versus turbid tributary-derived water. As is the case for many aquatic organisms, densities and diversities of invertebrate benthos tend to increase in slackwater sites (bays, secondary and side channels, protected shorelines, etc.) and in channel macrophyte beds as long as the surface sediments are not anoxic. Rocks in stronger currents are inhabited by mayflies, chironomid midges (especially Orthocladiinae), stoneflies (*Pteronarcys*), sponges, and filter-feeding caddisflies (*Hydropsyche*). In weaker currents, rocks are colonized by amphipod crustaceans (*Gammarus*), snails (*Amnicola*), and oligochaetes. Chironomid midges (e.g., *Dicrotendipes*, *Procladius*) and oligochaete worms dominate assemblages on sediments of clay and sand, whereas some combination of snails (*Bithynia*, *Valvata*), bivalve mollusks (*Elliptio*, *Pisidium*), oligochaetes (*Pelosclex*), nematodes, and amphipods inhabit sand and gravel substrates. In aquatic vegetation within slackwater sites and fluvial lakes, one often finds snails feeding on periphyton or detritus (*Bithynia*, *Probithynella*, *Gyraulus*) and numerous bivalve mollusks (*Elliptio*, *Lampsilis*), isopod crustaceans (*Caecidotea*), amphipod crustaceans (*Hyalella*), oligochaetes, dipteran larvae, odonates (e.g., *Enallagma*), and caddisflies (*Brachycentrus*). Crayfishes (*Orconectes*, *Cambarus*) also occur in plant beds, and they are ecologically and commercially important. Recent commercial catches of 4 to 8 metric tons/yr of crayfish have been made in Lac Saint-Pierre, and the potential catch is estimated at 50 tons/yr (St. Lawrence Centre 1996). Large emergence events of mayflies (*Hexagenia*) are also known for

this river, and the alderfly *Sialis* also occurs, at least in protected vegetated areas.

The St. Lawrence maintains a zooplankton community that is sustained far upstream by recruits from Lake Ontario and downstream presumably by reproduction occurring in lateral slackwater areas and in fluvial lakes of the main channel. Zooplankton biomass decreased from 40 µg/L dry mass to 16 µg/L within 90 km downstream of the outlet of Lake Ontario (Basu et al. 2000b) and continued to decline to ~10 µg/L dry mass at Montreal. Densities rise within macrophyte beds of the fluvial lakes (Basu et al. 2000a). Reproduction is minimal within the main channel but strong in slackwater areas (J. H. Thorp, unpublished data).

Zooplankton communities in the freshwater fluvial section are dominated numerically by rotifers, followed by cyclopoid copepods and small cladocera (Mills and Forney 1982, Basu and Pick 1996, Thorp and Casper 2002). Some common rotifers are *Polyarthra* (usually the overwhelming dominant), *Keratella*, *Ploesoma* (a predator), and *Synchaeta*. Fifty or so kilometers below Lake Ontario, cladocera in the river are generally small species and are dominated numerically by *Bosmina* (*Sinobosmina*) species, with smaller numbers of *Polyphemus pediculus* (a predator) and *Sida crystallina*. Chydorids, daphnids, *Polyphemus*, and other large species are more prevalent below the outlet of Lake Ontario and appear downstream in some slackwater sites. Common predaceous cyclopoid copepods are *Diacyclops thomasi* (the most abundant), *Mesocyclops edax*, and *Tropocyclops prasinus mexicanus*. *Eurytemora affinis*, an estuarine species that has recently begun colonizing large rivers, is the most common calanoid species, but *Leptodiptomus minutus* occurs in some samples. Harpacticoid copepods are common in vegetated slackwater areas near the bottom. Some crustacean zooplankton migrate vertically, both within slackwater sites and in the main channel (J. H. Thorp and A. F. Casper, unpublished data).

Vertebrates

There are 87 freshwater and 18 migrating (diadromous) species of fishes in the St. Lawrence River (Ducharme et al. 1992), with most of the freshwater species occurring in the fluvial section. Species endemism is low, and only the pygmy smelt and the copper redhorse (considered threatened by the Canadian government) are endemic to the freshwater ecoregion. Although many fish species frequent the main channel, the warmer, more productive slackwater habitats and fluvial lakes are more commonly used by

the river's ichthyofauna, including larval fishes (e.g., Werner 1977). This river is especially noteworthy as the home of the healthiest surviving stocks of Atlantic salmon in the world (albeit with declining numbers) and for supporting populations of lake and Atlantic sturgeon. Lake sturgeon can grow to a length of at least 2.4 m and live as long as 150 years (Smith 1985). Atlantic sturgeon grow even larger, with records of specimens reaching 4.3 m and 360 kg. Adult Atlantic sturgeon live in saltwater but migrate upriver several hundred kilometers to spawn and spend their first four years. Some other common species in the freshwater fluvial section of the river are smallmouth bass, largemouth bass, rock bass, brown bullhead, pumpkinseed, walleye, brook stickleback, northern pike, burbot, muskellunge, white sucker, longnose sucker, shorthead redhorse, silver redhorse, yellow perch, spottail shiner, brown trout, central mudminnow, brook char, American eel, alewife, and rainbow smelt (St. Lawrence Centre 1996).

Commercial and subsistence fisheries have declined on the river for a variety of reasons, but sport fishing still thrives. The most common commercial catches are lake sturgeon, American eel, brown bullhead, yellow perch, and sunfishes (St. Lawrence Centre 1996). Sport fishing concentrates on yellow perch, northern pike, walleye, and various bass species, with yellow perch accounting for 65% of all sporting catches in Quebec. Populations of the commercially important American eel are declining rapidly. Between 1985 and 1990 there was a ~99% drop in the number of juveniles entering Lake Ontario after passage upriver following their birth in the Sargasso Sea. Causes of this decline are probably linked to some combination of mortality from river contaminants, overharvesting of adults, loss of shallow-water habitats, and transiting the hydroelectric dams while migrating out to sea and back upriver. This is a serious situation for this East Coast species because an estimated 19% of the freshwater distribution range of the species involves the St. Lawrence River. Global factors may also be responsible, as a similar population decline has also been noted for the European eel, which also spawns in the Sargasso Sea.

Rainbow trout, common carp (which is ubiquitous along sheltered shorelines), and white perch are some of the nonnative species introduced to this river. Rainbow trout are becoming a serious competitor with Atlantic salmon. Bow fishing for carp is common, and fishing with rod and reel (often expensive rigs) is gaining in popularity with tourists from Europe.

About 115 species of waterfowl, shore birds, and raptors frequent aquatic habitats of the St. Lawrence

River's main stem, with about 38 species found in the freshwater fluvial section (St. Lawrence Centre 1996). Notable species in this area are geese (snow goose, common brant, Canada goose), dabbling ducks (American black duck, mallard, northern pintail, northern shoveler, gadwall, American wigeon, wood duck, green-winged teal, blue-winged teal), diving ducks (scaup, bufflehead, goldeneye, merganser), and sea ducks (eider, oldsquaw, scoter). Also commonly seen are great blue heron, ring-billed gull, belted kingfisher, osprey, and bald eagle. There are approximately 36 active heronries in the St. Lawrence system and around 8000 or more birds in the population by the end of summer (DesGranges and Desrosiers 1995). The largest known heron colony in the world (1000 birds) was reported from the fluvial Lac Saint-Pierre. Bird populations in the St. Lawrence River continue to recover following reductions in persistent organic contaminants, habitat protection, and creation of island bird sanctuaries. Recovery of greater snow goose and common eider in particular have been linked to these efforts.

Herpetofauna are not as characteristic of the St. Lawrence River as they are in more southerly rivers in North America. Northern leopard frogs and mudpuppies are common in wetlands associated with fluvial sections of the river, and some species occasionally appear in rocky areas of the main channel. The most frequently sighted reptiles are painted and snapping turtles. Amphibians and reptile species associated with the St. Lawrence River and given priority protection status in Quebec are pickerel frogs, northern chorus frogs, brown snakes, northern water snake, map turtle, Blanding's turtle, and spiny soft-shell turtle (the last considered threatened in both Ontario and Quebec).

Distributions of the mostly herbivorous muskrat and the carnivorous American mink and river otter extend throughout the St. Lawrence River in alluvial wetlands and along the river banks. Muskrats in particular are quite common, and they are frequently harvested for their pelts (~27,000 were taken in the 1988–1989 season; St. Lawrence Centre 1996). Beaver can also be seen in the St. Lawrence, but their primary association derives from their residence in the river's alluvial wetlands and tributaries.

A total of about 21 species of cetaceans and pin-nipeds are considered residents of or occasional visitors to the St. Lawrence from the upper estuary to the lower Gulf, but perhaps the most unusual and photogenic species to inhabit the St. Lawrence River is the rare white beluga whale. This small whale currently inhabits saline portions of the upper estuary, although

it formerly moved up into lower freshwater habitats and was sighted regularly at Quebec City until the 1930s. Following a ban on hunting of this whale in 1979 the population appears to have stabilized at around 500, but it is still classified as an endangered species (Kingsley 1994). Another cetacean, the long-finned pilot whale, also inhabits the upper estuary of the St. Lawrence, occasionally appearing upstream of the confluence with the Saguenay River.

Approximately 20 species of animals in or along the St. Lawrence main stem are categorized as vulnerable, threatened, or endangered by federal, state, or provincial governments; another dozen are considered at risk. No fish species is threatened or endangered according to the U.S. federal list for New York State, but four species are on the state list: lake sturgeon (threatened), pugnose shiner (endangered), mooneye (threatened), and blackchin shiner (species of special concern). Additional species that are considered at risk are Atlantic sturgeon, American eel, American shad, northern pike, Atlantic tomcod, rainbow smelt, striped bass, anadromous brook char, and Atlantic salmon. Blanding's turtle is on the federal threatened list, along with several species of birds frequenting the shores of the St. Lawrence River, and the eastern spiny softshell turtle is threatened in Quebec.

Ecosystem Processes

The St. Lawrence is an oligotrophic river, with chlorophyll *a* rapidly declining in the main channel below Lake Ontario to $\sim 1 \mu\text{g/L}$ and not rising to 2 to $5 \mu\text{g/L}$ until the confluence with the Ottawa River at Montreal (Basu et al. 2000b). Aside from direct effects of advective processes, low levels of primary productivity probably reflect low total phosphorus ($\sim 10 \mu\text{g/L}$) in the upper river. However, as turbidity increases and total phosphorus levels rise to 20 to $40 \mu\text{g/L}$ below the confluence with the Ottawa River, light may be an important limiting factor. In general, however, light is probably less limiting to phytoplankton production in the St. Lawrence than in most large rivers, because this northern river is relatively sediment free compared to other large rivers of the world (Gleick 1993).

The potential role of riverine "storage zones" in nutrient spiraling and plankton productivity has recently been recognized for several American and European rivers. Compared to channel sites, slackwater habitats have faster population growth rates for phytoplankton (Reynolds and Descy 1996) and zooplankton, as demonstrated for the St. Lawrence and tributaries (Basu and Pick 1996, Basu et al. 2000b).

Food web relationships within the St. Lawrence are poorly known in general (Thorp and Casper 2002). Main-channel habitats may be controlled by advective forces, but there is some evidence that biotic interactions are important in slackwater sites (Thorp and Casper 2002, 2003). Using stable isotope data, Barth et al. (1998) concluded that in the upper St. Lawrence most suspended particulate organic carbon POC was derived from phytoplankton; this is an important food source for many zooplankton.

The zooplankton community of the St. Lawrence River is controlled by a poorly understood mixture of abiotic and biotic factors varying seasonally and among habitats (Thorp and Casper 2002). Abiotic factors regulating the potamoplankton include those influencing food abundance (e.g., intensity of photosynthetically active radiation), access to energy (e.g., hydrological mixing), mechanics of feeding (e.g., suspended sediments), downstream transport versus temporary retention (water velocity, channel configuration, impoundments, etc.), direct mortality (physical abrasion and attenuation of ultraviolet radiation), and thermal conditions. Biotic factors include competition for food, parasitism, disease, and planktivory, both by benthic and pelagic invertebrates and by most larval, some juvenile, and a few adult fishes. In an in situ experiment in the St. Lawrence on mussel predation (Thorp and Casper 2002), densities of the most abundant rotifer, *Polyyarthra*, declined dramatically in enclosures with dreissenid mussels compared to controls and enclosures with unionid mussels. Rotifer densities in unionid enclosures were not different from controls. Effects on rotifers were probably from predation, as chlorophyll *a* did not vary among treatments. Densities of the dominant calanoid copepod, *Eurytemora affinis*, increased in the presence of dreissenids, probably as an indirect food web response. In another in situ experiment on effects of yellow perch predation on zooplankton of the St. Lawrence River, cladocera were the principal prey of smaller perch, followed by copepods, ostracods, and very few rotifers; larger juvenile perch fed almost exclusively on copepods and ostracods (Thorp and Casper 2003). Fish were associated directly with significant declines in densities of copepods and indirectly with increases in rotifers and cladocera.

Human Impacts and Special Features

As population densities in the St. Lawrence Valley and tributary basins rose over the last four centuries

of colonization by non-Native Americans, the impacts of humans gradually increased and changed in nature. The simple removal of mammal pelts gave way to deforestation linked to rural agriculture. Pollution from urbanization and industrialization increased, and river flow was regulated nearly half a century ago to improve shipping and produce electricity. The international St. Lawrence Seaway became an important commercial link between the Great Lakes and the Atlantic Ocean, with 37 million metric tons of cargo passing the Lake Ontario–Montreal section in 1997 alone. This population density and commercial activity have come with an ecological price tag, however, both because of the construction and operation of several major hydroelectric dams, navigation locks, and diversion dams and because of pollution from industrial, municipal, and agricultural sources.

Although environmental laws now exert a stronger control over point-source and nonpoint-source pollution, regulation of the river channel continues unabated and with little significant attention to environmental consequences. Four hydroelectric dams are present on the river's main stem, and numerous channel-control structures redirect flow. Small dams on the St. Lawrence's tributaries are also quite common. In addition to these hydroelectric dams, seven navigation locks enable passage of ships through the 68 m elevational drop from Lake Ontario to the fluvial Lac Saint-Pierre, and a minimum flow channel of 8.2 m is maintained for passage of deep-draft, seagoing commercial ships. The binational International Joint Commission (IJC) was established by the Boundary Waters Treaty of 1909 for the purpose of regulating aquatic-impact structures within the Great Lakes and the St. Lawrence River and for regulating the level and flow of these boundary waters. As a result of this regulation, the annual stage variation at the mouth of Lac Saint-François has been reduced from 60 to 15 cm (St. Lawrence Centre 1996).

Major regulation of the river began in 1958 with the commissioning of the Moses-Saunders hydroelectric dam, spanning the river between Massena, New York, and Cornwall, Ontario. This project includes four dams (three of which redirect water flow) and over 17 km of dikes, which help impound the natural fluvial Lake St. Lawrence. Electricity is generated on the U.S. side of the dam by the New York Power Authority and on the Canadian side by Ontario Hydro. Together the 32 hydroelectric turbine/generator units have a capacity of 1.8 million kW. Another three hydroelectric dams are present

near Montreal. The St. Lawrence is rated as strongly fragmented because only 25% to 49% of the main-channel segments lack dams and both large and many small tributaries are impounded (Dynesius and Nilsson 1994).

Commercial traffic on the river is vital to the economy of Canada and the United States. An average of more than 10,000 trips per year are made by commercial vessels, and in 1997 alone, for example, 37 million metric tons of cargo passed through the Lake Ontario–Montreal section. An increasing number of passenger ships (including pleasure ships from Europe) traverse the St. Lawrence Seaway, and recreational boating continues to grow.

The effects of regulation of the river for power generation and navigation are poorly known because of inadequate ecosystem studies and the absence of sufficient preregulation environmental data. In the case of the Beauharnois Dam near Montreal, for example, 84% of the river's flow was diverted to pass through the dam, resulting in major hydrodynamic alterations of two nearby fluvial lakes and the river's bed with unknown biotic consequences. Nonetheless, it is clear that most river dams substantially alter the nature of a lotic ecosystem, making it more lentic and interfering with the movement of fishes and other fauna. For example, the population size of the catadromous American eel has declined precipitously in the St. Lawrence, and some environmentalists consider the major cause to be the difficulty these fishes have in passing the four hydroelectric dams to reach their oceanic breeding grounds. Several species of anadromous fishes are also hurt by the presence of dams on the main stem and tributaries. Whether the environmental price of power dams and commercial shipping is justified by their economic benefits is a political and social question outside the realm of this chapter.

Commercial fishing was a major operation in the freshwater portion of the St. Lawrence River in the 1800s, and it continues today at a lower pace. Atlantic salmon became virtually extinct by the late 1800s because of overharvesting, the presence of numerous dams on tributaries, and pollution associated with human impacts on the watershed. The large commercial sturgeon fishery also collapsed by the late 1890s from overharvesting. In 1992, 687 metric tons of multiple species of fishes were harvested in Quebec within the fluvial section of the river and another 278 tons were reported caught in the fluvial estuary (Johnson 1991, St. Lawrence Centre 1996). A much higher take is known for the saline portions of the river and the Gulf of St. Lawrence. The approximate percentages of the catch during 1992 within the

fluvial Lac Saint-Pierre were 38.9% brown bullhead, 33.9% yellow perch, 11.3% lake sturgeon, 7.5% American eel, 4.1% sunfishes, and 4.3% all other species combined. Populations of bullhead and perch seem stable, but those of eel and sturgeon appear to be declining.

Most humans along the St. Lawrence live near the fluvial section of the river, especially near Montreal, where over 3 million people reside (almost 50% of Quebec's population). Two other significant urban areas are Trois-Rivières in the fluvial section and Quebec City in the fluvial estuary. Consequently, it is in those areas and downstream where most pollution occurs. Perspectives on over two decades of water quality are reviewed in Désilets and Langlois (1989). The river above Massena–Cornwall is in very good shape from a pollution perspective, and it continues to improve. Concentrations of most pollutants of potential concern are generally below levels set by New York State's Department of Environmental Conservation. Downriver, however, the situation is bleaker, and the river immediately below Massena–Cornwall was declared an EPA Area of Concern. Current or historical inputs of metals and organic compounds (PCBs, PAHs, dioxin, and various pesticides such as mirex and DDT) from point (e.g., aluminum plants and pulp and paper mills) and nonpoint sources pose significant health problems to humans and the environment. In the 1960s and 1970s, the St. Lawrence was one of the more polluted large rivers in the world, but it has now become one of the cleanest following the cleanup begun in the late 1980s.

Biotic pollution of another form has also influenced the St. Lawrence River. From the mid or late 1980s through the early 1990s, two species of bivalve mollusks, quagga and zebra mussels, spread throughout the freshwater portion of the river, reducing phytoplankton productivity and extirpating populations of native unionid mussels. These nonnative species are thought to have entered the greater St. Lawrence River ecosystem in the ballast water of ships arriving from southeastern Europe. The St. Lawrence Seaway has also been the pathway for many nonnative species to enter the Great Lakes and from there the Mississippi River drainage.

Despite imposition of dams on the main channel and many tributaries, the St. Lawrence continues to be an unusual and good-quality river. In terms of biological distinctiveness, its fauna is rated continentally outstanding (Abell et al. 2000), and Lac Saint-Pierre is a RAMSAR World Heritage Site. Aside from its uniqueness in terms of lake origin and overall size,

the St. Lawrence is less turbid than all other larger rivers of the world. On the other hand, without the navigable access to the Atlantic Ocean provided by this river, development of large cities and a strong economy along the river and around the Great Lakes would have been severely impeded over the last 200 years.

OTTAWA RIVER

The Ottawa River, or Kichesippi (meaning “Great River” in the language of the Algonquin Nation), originates in Lake Temiskaming (or Lac Temiscamingue) and flows 1271 km across the Precambrian Shield to its confluence with the St. Lawrence River near the Montreal archipelago (Fig. 22.10). The Ottawa is the largest tributary in the freshwater fluvial St. Lawrence River–Great Lakes system, with a basin of 146,334 km². It is roughly 65% in Quebec and 35% in Ontario, and the river forms the border between these two provinces for most of its length. Although much of the river flows through a naturally constricted channel, there are several complexes of islands and bays, such as the Petrie Island Preserve in the lower river. These environmentally sensitive areas provide a diverse and highly productive habitat for fish, invertebrate, and macrophyte assemblages.

Compared to southern tributaries of the St. Lawrence River, the Ottawa River is softer and lower in alkalinity but higher in nutrients and organic carbon. This reflects the primary origin of this northern tributary in the crystalline Precambrian Shield as well as the intensive agricultural activity in its lower basin. At its confluence with the St. Lawrence River, the more turbid waters of this northern tributary are often referred to as “brown waters” in comparison to the “green waters” derived from the Great Lakes. Despite the natural tendency of the St. Lawrence River to mix with waters of the Ottawa River, relatively distinct bodies of green and brown water can be detected at least 100 km below their confluence.

The primary Native Americans inhabiting the Ottawa River valley immediately prior to European contact were the Algonquins, who called themselves the Anishinabeg, meaning “human beings.” Evidence exists of a copper-using people here 5000 years ago, but they are not thought to have been connected to the Algonquins of the historic period. The Algonquins were mostly a seasonally nomadic, hunter-gatherer nation, in part because they lived in a climatic zone that was generally unfavorable for agricultural development. Although the prehistory of the

Ottawa Valley is largely unknown, the first recorded meeting between Europeans (led by Samuel de Champlain) and the widespread Algonquin Nation occurred along the Rivière Saguenay at Tadoussac, Quebec, in the summer of 1603. The fur trade flourished thereafter; indeed, the Algonquian word *atawe*, meaning “to trade,” became the European name for this river. Ancestors of a separate nation, the Ottawa Indians from the shores of Lake Huron, occasionally traveled down the Ottawa River through Algonquin lands to trade with the French, leading to some confusion in modern times about which tribes lived in the Ottawa River valley. Algonquins continued to live on the Ottawa and its tributaries in the twentieth century, with bands at Temiskaming, Mattawa, and on the Rivière Coulogne (www.civilization.ca/cmc/archeo/oracles/outaouai/30.htm).

Physiography, Climate, and Land Use

The basin, which is located along the southern edge of the Precambrian Shield–Frontenac axis, contains three physiographic provinces (see Fig. 22.10): the St. Lawrence Lowland (SL), Laurentian Highlands (LU), and Superior Upland (SU). Lowlands of the Ottawa River basin, once the floor of the ancient Champlain Sea, are bounded by two mountainous regions: the Laurentians to the west and the Algonquin dome to the east. At 968 m asl, Mount Tremblant, located just north of Montreal in the Laurentian complex, is the highest named peak in the basin and a popular skiing area. The underlying geology is dominated by a base of crystalline and crystallophyllian Precambrian rock in the north (99%) and Ordovician sedimentary rock in the south (98%). Surface soils reflect a gradation between distinctive soils in the upper and lower basin. The upper basin is characterized by well-drained organic mesisols and podzols interspersed with silt and sand deposits from the prehistoric Champlain Sea. In contrast, the lower basin features well-drained podzols interspersed with poorly drained melanic brunisols near the confluence with the St. Lawrence in the Montreal archipelago.

The climate in the Ottawa River valley is best described as humid continental. Mean annual daily temperatures are $\sim 6^{\circ}\text{C}$, and the basin averages 160 to 210 growing days with temperatures of at least 5°C (Watson and MacIver 1995). Mean monthly temperatures range from -11°C in January to 21°C in July (Fig. 22.11). Annual precipitation averages 100.2 cm and is evenly distributed throughout the year (see Fig. 22.11), with rarely more than 25% falling as winter snow.

The Ottawa River basin is in the Temperate Deciduous Forest and Boreal Forest biomes, and it includes two terrestrial ecoregions: the Eastern Forest/Boreal Transition, occupying the greater part of the basin, and the Eastern Great Lakes Lowland Forests closer to the confluence with the St. Lawrence River. A white pine–aspen mix typifies northern forests, whereas more southerly regions contain mixed hardwoods (>30 species, especially sugar maple and American beech) along with white pine and hemlock. Annual productivity of these second- and third-growth stands range from ~ 200 to $500\text{ g C m}^{-2}\text{ yr}^{-1}$ (Perera et al. 2000).

Most of the Ottawa River basin is forested (86%), with the remaining land cover consisting of surface waters ($\sim 10\%$), urban areas (2%), and agriculture (2%). Most agricultural activities are clustered in the lower portion of the basin. The largest city in this watershed is Ottawa, the nation’s capital, with 1.06 million people (Canadian Census 2001).

River Geomorphology, Hydrology, and Chemistry

From its origin at Lake Temiskaming, the Ottawa River flows mostly through a naturally constricted channel interrupted in some parts by wider, shallow floodplains and island mosaics. Along this pathway the main channel slopes about 36 cm/km, whereas the maximum topographic relief in the basin is 911 m. In the upper and middle sections of the river, the constricted channel flows between artificial reservoirs. The lower section of the Ottawa River is also mainly constricted but includes some floodplain regions and areas replete with islands, especially in the section extending from its confluence with the Gatineau River downstream to the confluence with the St. Lawrence River.

The Ottawa River is the largest tributary of the fluvial section of the St. Lawrence River, with an annual discharge of $1948\text{ m}^3/\text{s}$. Among its 12 major tributaries are 3 with drainage basins $>5000\text{ km}^2$ in Quebec: the Gatineau, Coulonge, and du Lièvre, with annual discharges of 126, 97, and $75\text{ m}^3/\text{s}$, respectively. Although precipitation is fairly even throughout the year (range 7.2 to $9.8\text{ cm}/\text{mo}$), spring snowmelt results in runoff peaks in April and May at three to four times ($>6\text{ cm}/\text{mo}$) the minimal runoff of late summer (see Fig. 22.11).

Geologic formations of the Precambrian Shield strongly influence the chemistry of this river. Mean conductivity ($80\text{ }\mu\text{S}/\text{cm}$), alkalinity ($19.2\text{ mg}/\text{L}$ as

CaCO₃), hardness (29.2 mg/L as CaCO₃), suspended solids (6 mg/L), turbidity (4 NTU), and dissolved organic nitrogen (0.18 mg/L) are all low compared to waters of the Great Lakes and southern tributaries of the St. Lawrence. Conversely, levels of total organic phosphorus (0.053 mg/L) and organic carbon (5.6 mg/L) are higher than those other waters. Suspended detritus concentrations increase downstream, peaking in the faster-moving middle reaches. Concentrations then drop along with current velocities as the river approaches the major hydroelectric facilities at Carillon near the confluence with the St. Lawrence. Transit time from upper tributaries to Carillon is ~14 days. No consistent longitudinal patterns are evident in the mean annual levels (1979 to 1994) of NH₄-N (0.045 mg/L), NO₃-N + NO₂-N (0.17 mg/L), total nitrogen (0.41 mg/L), total phosphorus (0.029 mg/L), and chlorophyll *a* (1.9 µg/L). However, conductivity, temperature, alkalinity, total phosphorus, suspended solids, and chlorophyll *a* increase as one moves downstream, particularly below the Ottawa–Hull region, where three large tributaries join the Ottawa (Hydro-Québec 1994, Ministère de l'Environnement et de la Faune du Québec 1996).

River Biodiversity and Ecology

The Ottawa River basin occurs in the Lower St. Lawrence freshwater ecoregion and contains a diverse flora and fauna associated with the river. However, a number of taxa are threatened, including species of fishes (American eel, American brook lamprey, silvery minnow, lake sturgeon, and river herring), birds (least bittern and logger-head shrike), amphibians (boreal false-cricket treefrog), reptiles (eastern spiny softshell turtle), and even some insects, such as various dragonflies (*Gomphus ventricosus*, *Ophiogomphus anomalus*, and *Stylurus notatus*).

Algae and Cyanobacteria

A well-developed, diatom-dominated phytoplankton-periphyton community exists in the Ottawa River. *Melosira varians* dominates an assemblage that includes at least 150 pelagic and 42 epibenthic species (De Seve and Goldstein 1981, Vis et al. 1998). Densities of periphyton are greater in the Ottawa River than in the St. Lawrence (1762 versus 691 cells/mm² benthic surface area). Similarly, the density of phytoplankton was also greater in the lower Ottawa than the nearby fluvial Lac Saint-Louis (>50,000 versus 25,000 cells/L; Alaerts-Smeesters and Magnin 1974).

Plants

Throughout most of its length the Ottawa River is fringed with emergent and submerged macrophyte beds. Silver maple and green ash are the principal riparian canopy trees. They are usually found with alder, frost grape, and willow as understory species. The herbaceous layer of the riparian forest along the lower Ottawa includes reed canary grass, ground nut, and the invasive purple loosestrife (Fairchild 1983, Hydro-Québec 1994). Bands of emergent sedge wetlands composed of wild rice, bur-reed, and arrowhead are common along the banks. The 43 species of emergent riverine plants are divided into groups found in the upper marsh (e.g., northern bugleweed, fox sedge, silverweed), intermediate areas (e.g., marsh speedwell, Calamus root, bulrushes), the lower marsh (e.g., Small's spikerush, bur-reed, knot-sheath sedge), and those distributed across the spectrum (e.g., bladder sedge, creeping Jenny loosestrife, red top). Shipley (1987) determined that water level significantly influenced the species composition of these emergent macrophyte assemblages. Submerged macrophyte beds are most common in depositional zones of the lower section of the Ottawa. They are largely dominated by American waterweed, wild celery, and watermilfoil. Interspersed with these dominants are coontail, waterlily, and four species of pondweed (big-leaf, ribbon-leaf, Richardson's, and spiral).

Invertebrates

Littoral benthic habitats in the Ottawa River are heterogeneous patchworks of mud, silt, and sand interspersed with gravel bars and submerged macrophyte beds, the latter supporting the greatest invertebrate diversity. As in most large rivers, overall benthic invertebrate diversity tends to correlate with increasing habitat heterogeneity, whereas total density and biomass are closely related to substrate type and current velocity. Some large-river taxa, like mussels, are apparently also limited by food availability and ionic content of the water. The abundance of benthic invertebrates and phytoplankton in the Ottawa increases progressively from the upper reaches near Lake Temiskaming to its confluence with the St. Lawrence (Ontario Water Resources Commission 1972).

In the lower reaches, more than 150 species of invertebrates can be found in vegetated and erosional zones <2 m deep at densities of up to 2000 animals/m². Noninsect taxa comprise much of this riverine benthic assemblage. Main-channel zones are characterized by a combination of small finger-

nail clams, oligochaete worms, and large unionid mussels. Overall, the oligochaete assemblage is dominated by *Stylaria* spp., *Uncinaiis uncinata*, *Peloscoclex* sp., *Limnodrilus* sp., and *Spirosperma ferox*, and diversity, density, and biomass tend to increase with depth (Mackie 1971). Bivalve biomass is dominated by unionid mussels (eastern elliptio, spike mussel, and eastern lamp mussel), whereas fingernail clams are the most numerous. The latter consist principally of *Sphaerium* (7 species) and *Pisidium* (6 species) at 171 clams/m². There are 12 species of snails in the Montreal archipelago, the most abundant being faucet snails at 2311 snails/m², followed by mud Amnicolas, St. Lawrence pond snails, Chinese mystery snails, gyro snails, *Physella* spp., three-ridge valvata snails, and ancyliid snails (sometimes called freshwater limpets) (Magnin 1970; Ontario Water Resources Commission 1972; Hamill 1975, 1979; Clair 1976; Mackie 1971). Amphipods (*Gammarus fasciatus*, *G. pseudolimaeus*, *Crangonyx pseudogracilis*, *Hyaella azteca*) are more abundant (2073 amphipods/m²) than the common isopods *Asellus communis* and *Caecidotea* sp. (953 isopods/m²). Both amphipods and isopods are more abundant in slackwaters than the main channel of the river. Four species of crayfishes have been reported.

Benthic insects comprise the remainder of the assemblage; their abundance and diversity are generally greatest in the shallow, highly heterogeneous littoral habitats containing macrophytes and cobble. Common insect taxa include dragonflies and damselflies (e.g., *Enallagma*), stoneflies (*Isoperla*), alderflies (*Sialis*), beetles (*Berosus*, *Dubiraphia*, *Haliplus*, *Microcyloepus*), black flies, 19 genera of chironomid midges, 35 species of caddisflies, and 22 species of mayflies. The chironomid assemblage includes *Procladius*, *Zavrelimyia*, *Tanypus*, *Brillia*, *Cricotopus*, *Chironomus*, *Cryptochironomus*, *Dicrotendipes*, *Einfeldia*, *Demicryptochironomus*, *Polypedilum Paracladopelma*, and *Pseudochironomus* (Magnin 1970, Fairchild 1983). Among the caddisflies, the predators *Polycentropus* and *Oecetis* were the overall dominants, but there were habitat-specific exceptions. The herbivorous caddisfly *Hydroptila* dominated weed beds, whereas the filterer *Brachycentrus* was the principal deep-water taxon. The relative abundance of each of these species was drastically lower in the faster waters of a nearby fluvial lake (Lac Saint-Louis), where *Molanna*, a smaller collector-gatherer, was dominant. Subdominant caddisfly genera include *Agraylea*, *Ceraclea*, *Cyrnellus*, *Macrostemum*, *Mystacides*, *Triaenodes*, *Hydropsyche*, *Cheumatopsyche*, *Nectopsyche*, and *Neureclipsis* (Fairchild

1983). The mayflies included *Ephemerella* spp., *Hexagenia rigida*, *H. limbata*, *Caenis simulans*, and *Stenonema bipunctatum*.

The zooplankton assemblage of the Ottawa River is particularly well-described. Forty-five species from 27 genera of cladocera are known from the lower river (Croskery 1974). *Bosmina longirostris* is an early-season dominant across all habitats, with peak abundance in June and July. Three species of *Daphnia* are subdominants that peak from late July through September. In addition to cladocera, both calanoid (*Eurytemora affinis*, *Episcura lacustris*, and four species of *Diaptomus*) and cyclopoid copepods (*Cyclops vernalis*, *Diacyclops thomasi*, *Mesocyclops edax*, *Tropocyclops parsinus mexicanus*) are common. Copepod densities are seasonally opposite of cladocera, peaking in early May, then dropping and not rising again until September. This crustacean assemblage is in turn preyed on by *Chaoborus*, *Leptodora kindtii*, and *Hydra littoralis*. As with the benthic invertebrates, pelagic abundance is inversely related to current velocity. Indicator taxa were *D. retrocurva*, *D. parvula*, and *Ceriodaphnia* spp. for low-flow conditions and *L. kindtii*, *Sida crystallina*, *Eurycerus lamellatus*, and *Camptocercus rectirostris* in moderate currents. No taxa were consistently associated with the main channel. Other widely distributed cladocera include *Diaphanosoma*, *Simocephalus*, *Eubosmina*, *Latona parviremis*, *Latonopsis occidentalis*, *Pleuroxus uncinatus*, and four species of *Chydorus*.

Vertebrates

Three major habitat assemblages of fishes exist in the lower Ottawa: (1) bays with abundant macrophyte beds, (2) the shoreline and littoral slackwaters between bays and the main channel, and (3) the channel itself. In bays, the principal species are yellow perch, brown bullhead, pumpkinseed, emerald shiner, walleye, and sauger. In main-channel habitats are channel catfish, walleye, sauger, silver redhorse, white sucker, northern pike, and mooneye. In the fluvial Lac Duchênes region, brown bullhead, emerald shiner, and yellow perch are very abundant, but carp, black crappie, and central mudminnow join the group. In addition, two regionally rare large-river species are present: lake sturgeon and river redhorse (Hydro-Québec 1994).

Density and diversity of fishes are greater in the slackwater littoral zone than in any other river habitat. More than 80% of all fish species occur here, and it is very productive habitat (e.g., black crappie occur at >80 individuals/ha or 18.4 kg/ha). Slack-

water habitats range from extensive littoral macrophyte beds, sandy substrates, shoals, and sparse macrophyte beds in fluvial Lac Duchênes to narrow littoral zones with steep shores, silty substrate, and numerous submerged logs and stumps around the main channel islands of the lower Ottawa, where channel depths vary from 6 to 26 m and current velocities are 0.33 to 1.03 m/s. In slackwaters, the main secondary consumers range from insectivorous pumpkinseed to piscivorous walleye and sauger.

Seasonal changes in diet and growth rates closely follow the availability of prey items. Apex predators, such as sauger, walleye, and burbot, forage extensively on small, seasonally abundant fishes, such as silvery minnows and Iowa and Johnny darters. Walleye and sauger use slackwater zones to feed mainly on emerald shiner and small yellow perch. Intermediate predators like yellow perch, black crappie, brown bullhead, and pumpkinseed prey on amphipods, chironomids, copepods, cladocera, fish fry, and phantom midges common to the area. In addition to invertebrates, production of at least one riverine species, the brown bullhead, is supported by filamentous algae (*Spirogyra* and *Anabaena*) (Gunn et al. 1977). Fish growth in the Ottawa River reaches a maximum during the summer and in slackwater habitats (Rodgers and Qadri 1982, Osterberg 1978).

The island complexes and floodplain regions of the river are particularly favorable for birds and some herpetofauna. Two rare birds in this region, the least bittern and the sedge wren, are both periodically found in the cattail marshes adjacent to the Ottawa. Four species of herpetofauna reach the northern range limits in the Ottawa River valley and are occasionally found nearshore or in the riparian zone: spiny softshell turtle, northern water snake, common snapping turtle, and western chorus frog.

Ecosystem Processes

Productivity for most benthic invertebrates in the Ottawa peaks in mid- to late summer. Production rates for the mussels *Elliptio* and *Lampsilis* are consistently lower in the Ottawa River than in the nearby St. Lawrence (~30%), perhaps due to lower ionic content and calcium levels in the Ottawa River (Magnin and Stanczkowska 1971). Despite their small size, sphaeriids are abundant and productive ($0.409 \text{ g m}^{-2} \text{ yr}^{-1}$ dry mass) across all habitats, with *Pisidium casertanum* (92 clams/m² and $0.26 \text{ g m}^{-2} \text{ yr}^{-1}$) and *Musculium securis* (0.04 to $0.3 \text{ g m}^{-2} \text{ yr}^{-1}$) dominating. As an example of the generally greater production in slackwater compared to main-channel habitats, *P. casertanum* was over twice as productive

in slackwater areas (0.39 to $0.83 \text{ g m}^{-2} \text{ yr}^{-1}$ versus 0.04 to $0.19 \text{ g m}^{-2} \text{ yr}^{-1}$). These differences are linked primarily with current and secondarily with sediment grain size. Production of benthic crustaceans is directly correlated with abundance of macrophytes (typically common waterweed, bur-reed, and wild celery), ranging from 0.67 to $1.49 \text{ g m}^{-2} \text{ yr}^{-1}$ (Hamill 1975).

Diet studies reinforce the idea that the slackwater zones are key links between primary and secondary production in the Ottawa. *Lymnaea catascopium* and *Viviparus malleatus* ingested large amounts of detritus (~53%); however, the common, lipid-rich diatoms *Navicula*, *Fragilaria*, *Gomphonema*, *Rhoicosphenia*, and *Cocconeis* were also major items in their diets (~26%). This supports the observation that gastropods are most abundant and diverse in shallow waters due to food availability. Annual production appears to be very plastic and depends on seasonal and spatial differences in food conditions and water chemistry. *Lymnaea catascopium* produces one generation per year in the brown (soft) waters of the Ottawa compared to two in the green (hard) waters of the adjacent St. Lawrence, despite the greater food base in the Ottawa. Moreover, the distribution and abundance of gravid female isopods (*Asellus communis*) are spatially associated with abundance of diatoms. The maximum reproduction of *L. catascopium* coincides with periods of peak primary production (Magnin and Leconte 1971, Stanczkowska et al. 1972, Mackie et al. 1976, Qadri et al. 1977, Rodgers and Qadri 1982, Pinel-Alloul and Magnin 1979a, 1979b).

Production of chironomids in slackwaters (2.4 to $7.6 \text{ g m}^{-2} \text{ yr}^{-1}$) is greater than in deeper channel sites ($0.7 \text{ g m}^{-2} \text{ yr}^{-1}$), whereas island shores are not a very productive habitat, as evidenced by the midge *Polypedilum* (peak $0.2 \text{ g m}^{-2} \text{ yr}^{-1}$ between September and April, with four cohorts a year; Clair 1976).

Human Impacts and Special Features

In spite of many dams, the Ottawa basin is largely undeveloped with most of the area forested or covered by bodies of water. Particularly noteworthy is the Petrie Island Preserve, a complex of islands and bays in the lower river below the Ottawa–Hull metropolitan area. This patchwork of habitats extends from the confluence of the Gatineau and Ottawa rivers to the latter's confluence with the St. Lawrence at Lac des Deux-Montagnes upstream of the Montreal archipelago. This stretch of small islands in the main channel is similar to both the Thousand Islands region of the upper St. Lawrence and the braided channel at the head of Lac Saint-Pierre in that it creates a mosaic of

slackwaters and flooded forest habitats in close proximity to the highly advective main channel. The major difference between the Thousand Islands and the Petrie Islands area is that the latter is occasionally submerged during peak spring discharge period. The Petrie Island Preserve includes heterogeneous aquatic habitats that support very diverse fish, invertebrate, and macrophyte assemblages.

The Ottawa River is now generally considered to be in good condition following extensive environmental controls in the last 20 years. Prior to the early 1980s, the lower and middle reaches of the Ottawa River, with over 100 municipalities and 2000 farms in the drainage basin, had problems with elevated fecal coliform counts and nutrient inputs, especially downstream of metropolitan Ottawa–Hull and Montreal. Since then, more secondary treatment systems have come on-line and stricter regulations and installation of industrial wastewater treatment systems around the city of Gatineau have reduced inputs of copper, lead, and aluminum and cut emissions of persistent organics, such as PCBs. However, the greatest human impacts on the Ottawa River are probably its dams. Using criteria of Dynesius and Nilsson (1994), the river would be considered strongly fragmented because of the seven major dams on the main stem and over 300 impoundments on tributaries.

SAGUENAY RIVER

The second-largest tributary of the St. Lawrence River and the last river to enter the main stem at the downstream terminus of the upper estuary is the Saguenay River (Fig. 22.12). Flowing through a deep, rocky fjord, the Saguenay contributes over 1500 m³/s of freshwater to the St. Lawrence at a point where the larger river has a mean salinity of ~30‰ (Fig. 22.1). This freshwater is drawn from an 85,500 km² watershed that consists mostly of boreal forests, all within the province of Quebec. Before entering the Saguenay, however, most of the basin's tributaries first drain into Lac Saint-Jean, which in turn provides about 75% of flow at the mouth.

Native Americans of the Algonquin Nation were the primary inhabitants of this watershed prior to the exploration of the Saguenay River in 1535 by the Frenchman Jacques Cartier. In fact, the river's name is Algonquian and probably means "water flows out," possibly referring to the river's outlet from the large Lac Saint-Jean. Soon after Cartier explored the Saguenay a flood of European settlers arrived eager to exploit the vast tracks of virgin timber. Harvesting and processing this timber for lumber and paper

products, along with mining and smelting of metals, have produced the major negative impacts on the river and its watershed. Agriculture and urbanization have had relatively moderate impacts because agriculture is limited by a short growing season (133 days at Chicoutimi, Quebec) and the urban population density is very low. Today the Saguenay region is the most thoroughly French-speaking region of Quebec and has become the political stronghold of the drive for secession of Quebec from the rest of Canada through support for the Parti Québécois.

Physiography, Climate, and Land Use

The Saguenay River basin is located within both the Laurentian Highlands (LU) and the Labrador Highlands (LB) physiographic provinces of the Precambrian Shield physiographic division (see Fig. 22.12). The geology of these provinces is dominated by silicate rocks and includes igneous and metamorphic (gneiss and granite) bedrock.

The local climate is cool and moist throughout much of the year. Precipitation, which averages 96.5 cm/yr, does not vary substantially among months (monthly range 7.1 to 9.6 cm; Fig. 22.13). The mean air temperature is 3.0°C, with a monthly range of –13°C in January to 17°C in July. Gardeners can count on frost from as early as late September to mid-May (at Chicoutimi). Given the cold winter air temperatures, surface water temperatures range from a low of near 0°C in December through April to a high of 17°C to 19°C in July through August. The surface of the river is frozen through much of the winter.

Balsam fir and paper birch are the dominant trees within this Boreal Forest biome and Eastern Canadian Forest terrestrial ecoregion. These forests are primarily second growth or later because of extensive timber harvesting during the nineteenth and twentieth centuries. The basin is sparsely inhabited (2.5 people/km²) except for the urban-industrial centers of La Baie, Chicoutimi, Jonquiere, and Alma, located along the main stem of the Saguenay River below Lac Saint-Jean. There is some local agriculture, but it is restricted to the sedimentary soils immediately adjacent to this large lake. Consequently, the watershed is 90% forested, and most of the remaining basin area is composed of surface waters.

River Geomorphology, Hydrology, and Chemistry

The headwaters of the Saguenay River are often considered to be the relatively pristine Lac Saint-Jean, the

fifth-largest lake in Quebec at 1053 km². About ~25% of the lake is ≤3 m deep, and the maximum depth is 63 m. Consequently, the high lotic inputs from 21 tributaries combined with a relatively shallow lake basin produce a water-renewal time of only ~2 to 3 months (Côté et al. 2002). This reduces the lentic signature of the lake's outflow to the main stem of the Saguenay. Lac Saint-Jean receives water from a heavily forested and mountainous basin of ~68,000 km². About 75% of the outflow of the lake comes from three principal rivers in this basin: the Péribonka, Ashuapmushuan, and Mistassini. From this lake, the main stem of the Saguenay River flows eastward through a heavily forested watershed of over 17,000 km² into the brackish St. Lawrence River. At least 20 small tributaries feed into the main stem of the Saguenay River from this subbasin.

The main stem of the Saguenay River is ~165 km long, ~0.6 km wide, and has a fairly steep slope (60 cm/km) as it flows through a deeply incised channel. The main stem can be divided into three sections based on depth and hydrodynamic characteristics. Two medium-size tributaries flow into the moderately deep 40 km long upper reach. The ~25 km long middle reach, with its seven tributaries, is the most urban and industrialized portion of the Saguenay. This segment is turbulent, turbid, and less than half as deep (<10 m) as the upper section. Rocky escarpments are common along the shore. In its last 100 km, the Saguenay River flows through the largest fjord in the northwest Atlantic (see Fig. 22.1) and then enters the St. Lawrence River at Tadoussac, Quebec, which is the border between the upper and lower estuaries. Along this 100 km path the river passes through cliffs towering 450 m above its deep (≤250 m) estuarine channel. Salinities in this lower river segment range from slightly brackish (5 PSU) in the top 5 m of the water column to 25 PSU below the thermohalocline. The Saguenay has a tidal amplitude >4 m at its confluence with the St. Lawrence River.

At its mouth the Saguenay contributes on average 1535 m³/s of freshwater discharge to the St. Lawrence, and roughly 75% of this water flows from Lac Saint-Jean. Currents in the Saguenay can reach 2 m/s during spring freshets, in part because of the steep riverbed and in spite of the main-stem dams. Runoff from the basin is concentrated in May and June (mean 9.35 cm/mo for those months) due to spring snowmelt, when it is more than twice as high as the average for the other ten months (see Fig. 22.13). This occurs in spite of the fact that

precipitation is relatively uniform among months and peaks in July, when runoff is considerably lower (5.7 cm/mo).

The water chemistry of the Saguenay varies depending on a site's location with reference to tributaries, Lac Saint-Jean, and various municipal and industrial effluents. The main stem has an almost neutral pH (6.9), which varies only slightly among its tributaries (6.8 to 7.4). The range of conductivities among sites (20 to 120 μS/cm) is greater than for pH, and averages 34.9 μS/cm in the main stem. The mean concentrations of other basic water-quality parameters are alkalinity 7.3 mg/L as CaCO₃, dissolved O₂ 11.3 mg/L, and dissolved organic carbon 6.2 mg/L. Nutrients and primary production vary considerably among sites and seasons, especially with reference to point-source inputs. Mean concentrations for the main stem are chlorophyll *a* 0.95 μg/L, NH₄-N 0.02 mg/L, NO₂-N + NO₃-N 0.10 mg/L, and PO₄-P 0.01 mg/L (Mousseau and Armellin 1995).

River Biodiversity and Ecology

The Saguenay River is located within the Lower St. Lawrence freshwater ecoregion, where it supports flora and fauna similar to those in other nearby tributaries of the St. Lawrence River. However, the strong salinity barrier to freshwater immigration that is present in both the lower Saguenay and the St. Lawrence River upstream of their confluence makes the freshwater communities of the Saguenay more insular and less subject to invasion by nonnative freshwater species.

Discussions of the river's flora and fauna and the functioning of this ecosystem are difficult because aquatic ecologists have rarely studied the ecology of this relatively isolated, cold-water river. In contrast, research linking industrial contamination with human health, recreational fisheries, and the marine park are more common.

Algae and Cyanobacteria

One can infer from the short length (165 km) of the Saguenay River below Lac Saint-Jean and the downstream presence of brackish habitats within the fjord that riverine microalgal communities are dominated by species commonly found in the lake. However, the relative effects of any lentic signature on the Saguenay should be tempered by the lake's short water-renewal time and inflow from >40 tributaries above and below the lake. During the summer in Lac Saint-Jean, the assemblage of phytoplankton

species $>20\mu\text{m}$ is heavily dominated by the diatoms *Asterionella formosa* and *Tabellaria* (*T. fenestra* and *T. flocculosa*), and *Melosira islandica* (Thompson and Côté 1985, Côté et al. 2002). Given that diatoms tend to be relatively more important in rivers than lakes, these genera are also likely to be dominant within the main stem of the Saguenay. Indeed, the three most common species of phytoplankton in the river's brackish fjord are *A. formosa*, *M. ambigua*, *M. islandica*, and *T. fenestrata*. Total summer chlorophyll *a* concentrations and rate of primary production during 1979–1980 ranged from 4 to 79 $\mu\text{g/L}$ and 1 to 88 $\text{mg C m}^{-3}\text{h}^{-1}$, respectively (Côté 1983). Periphyton in this section of the river includes the cyanophyte *Lyngbya nordgardii* and the diatoms *Nitzschia holsatica*, *Synedra berolineusis*, *Melosira varians*, and *Oscillatoria* sp. (Mousseau and Armellin 1995).

Plants

Aquatic plants in the Saguenay are mostly restricted to the fjord. Littoral plant assemblages in the upper 65 km of the main stem are mostly limited to sparse patches of American bulrush. The paucity of plants results both from log bashing during commercial log driving in the river and from negative effects of alternating floods and dry-downs caused by operation of power generators. Most aquatic vegetation occurs in freshwater sections of the fjord, where the emergent herbaceous assemblage is dominated by bulrush and, to a lesser extent, arrowhead, sedge, spike rush, buttercup, and silverweed (Mousseau and Armellin 1995). The lower, more brackish section of the fjord is bordered on both shores by cordgrass marshes.

Invertebrates

Studies of benthic invertebrates of the Saguenay River are sorely lacking. In the upper Saguenay River, caddisflies, chironomid midges, and aquatic earthworms are the principal invertebrate taxa. Densities are highly variable, ranging from 200 to >2000 animals/ m^2 in habitats where oligochaete worms are a major component. In general, insects and isopods are numerically most abundant, followed by oligochaetes, bivalves, and gastropods (Mousseau and Armellin 1995).

Zooplankton in the Saguenay reflect in part the composition of the rotifer and microcrustacean community in Lac Saint-Jean but presumably with a slight shift to smaller species as one moves

downstream. The community appears to be dominated by a few species, such as the rotifer *Polyarthra vulgaris* and the protozoan *Codonella cratera* (Côté et al. 2002). The former is also the dominant rotifer in the St. Lawrence River.

Vertebrates

From a fisheries perspective, the Saguenay can be divided into three zones: Lac Saint-Jean and its tributaries, freshwater portions of the main stem, and brackish sections of the fjord. In Lac Saint-Jean and its tributaries, species like northern pike, walleye, yellow perch, landlocked Atlantic salmon, and white sucker predominate. In the freshwater Saguenay, the assemblage is similar, with the addition of anadromous Atlantic salmon, American eel, brook (speckled) trout, and black (lake) sturgeon. Six species of migratory fishes are known from the Saguenay: rainbow smelt, Atlantic tomcod, Atlantic salmon, and threespine, brook, and ninespine sticklebacks (Mousseau and Armellin 1995).

Historical records from the commercial fishing industry indicate an overall decline in several species since the early to mid-1900s. A combination of chemical pollution, habitat degradation, commercial exploitation, and introduced species is probably responsible. Much of this loss in biodiversity has apparently been caused by acid rain and bioaccumulation of metals and organic chemicals from industrial effluents. Acid runoff from both rainfall and spring snowmelt is a regional problem with special implications for the Saguenay (Brouard et al. 1982). As continuing atmospheric inputs of acid lower the pH of these streams, aluminum, copper, iron, and manganese are liberated from the shield bedrock. Adult salmon, like most fishes, are not particularly susceptible to low pH per se, but chronic exposure can reduce reproductive capacity, depress immunological responses, and promote tumors. In contrast, eggs, smolt, and fry of salmon are especially sensitive to acid precipitation. Current models for these rivers suggest that acidification is ongoing (average pH of rain ~ 4.3 , with high levels of both nitrates and sulfates) and coincident with elevated levels of metals (Van Coillie et al. 1982). Loss of reproductive habitat since the 1930s as a result of construction and maintenance of the locks, dams, and shipping channel has caused further population declines of resident and anadromous fishes. The catadromous American eel is an example of a species hit particularly hard by damming of their migratory pathways in the Saguenay and throughout the St. Lawrence–Great Lakes

system. The dams have blocked or killed (by hydroelectric turbines) juveniles migrating upstream through the Gulf of St. Lawrence as well as sexually mature adults migrating downstream.

The low density of humans in the Saguenay River basin has allowed retention of relatively healthy populations of beaver, river otter, muskrat, and mink in the Saguenay's freshwater tributaries. Long-finned pilot whales and beautiful white beluga whales frequent the Saguenay fjord. Their populations dropped to dangerous levels in response to pollution and severe overharvesting, but this decline appears to have been halted by implementation of more rational environmental policies of provincial and federal governments.

At the confluence of the Saguenay and St. Lawrence Rivers is Batture aux Alouettes, which has been identified as a continentally and globally significant site because of its diverse waterfowl and large numbers of migratory shorebirds and raptors. Many migratory shorebirds have been recorded here in spectacularly high numbers, including red knots (1% of the North American population recorded in a single day), sanderlings (1% of the global population spotted in one day), and purple sandpipers. Diving ducks are seasonally common, including oldsquaw, common eider, and common goldeneye. Also observed here frequently are Barrow's goldeneye (a national species of concern) and harlequin duck (a Canadian endangered species). Finally, the site is considered globally significant because of fall flights of migratory raptors, including merlin, peregrine falcon, osprey, and northern goshawk.

Although a few nonnative species have been intentionally introduced (e.g., rainbow trout), the native fauna of the Saguenay is relatively unchallenged by them. Only four fishes (American eel, American shad, Atlantic tomcod, and Atlantic sturgeon) and two aquatic-related birds (great blue heron and black-crowned night heron) are included on the provincial list of endangered species in the freshwater portion of the river.

Ecosystem Processes

Because of its high discharge the river substantially influences primary productivity downriver in the brackish estuarine habitats. Although the highly stratified fjord has consistently low primary productivity due to the strong mixing action of the tides and the high flushing rate from Saguenay River discharges, transport of allochthonous carbon through the fjord and estuary has been linked to increased algal and vertebrate production in the gulf. Seasonal

dynamics are characterized by little or no spring–summer phytoplankton bloom. When annual blooms in the middle and lower Saguenay begin, they are usually closely correlated with low summer discharge and improved photic conditions. These changes shift limitations of primary production from light to nutrients. The Saguenay fjord is strongly stratified both thermally and by salinity. The top 5 m are fresh or brackish, and this thin and unstable photic zone strongly limits primary production in the fjord. Phytoplankton production is low ($25 \text{ mg C m}^{-3} \text{ hr}^{-1}$) and highly variable on a tidal regime; coefficients of variation range from 55% to 127% as a result of advective processes (Côté and Lacroix 1979a, 1979b). Consequently, historical carbon exports from the freshwater Saguenay to the estuarine food web have been mainly recalcitrant organic matter. Much of the river's suspended load is derived from weathering of local bedrock and soils, more than 90% of which accumulates in sediments of the fjord and gulf (Louchouart et al. 1999). Since the advent of timber and paper industries, allochthonous lignin from timber paper wastes is the main form of carbon export; half of this material is quickly assimilated into marine carbon cycles (Louchouart et al. 1999, Louchouart and Lucotte 1998). Rich krill populations result when these exports are combined with intrusions of cold nutrient-rich upwellings in the gulf.

Human Impacts and Special Features

The Saguenay River system has several unique features, beginning with the main stem flowing out of a large lake (Lac Saint-Jean) that is fed by numerous rivers draining boreal forest. Furthermore, the large lower Saguenay flows through a spectacular fjord with towering cliffs before joining the St. Lawrence River at Batture aux Alouettes, a continentally and globally significant site for migratory birds. Among the unusual biological features of the river system are some benthic invertebrates in the fjord that are arctic relicts, two genetically distinct races of Atlantic salmon, and congregations of long-finned pilot whales and white beluga whales. Given that the human population density is so low in this basin, one might expect a relatively pristine river. Unfortunately, this is not the case, as human activities have resulted in negative impacts on the river for almost 100 years.

Although some agricultural activities occur in the Saguenay River basin, timber harvesting and paper manufacturing plants dominated the local economy

until the mid-1900s, when aluminum mining and smelting and chlor-alkali refining began growth spurts. As a result, human impacts on the river have been severe and include watershed disturbance (timber harvesting, mining, and some agriculture), point- and nonpoint-source pollution, and channel regulation for hydroelectric production and navigation beginning in the late 1930s. At present there are three hydroelectric/navigation dam complexes on the main stem and more than 300 small to medium-size dams on the >40 tributaries above and below Lac Saint-Jean.

Much of the industrial pollution can be traced as far back as 1910 and has often been associated with early techniques in paper manufacturing. Persistent bioaccumulating chemicals, such as mercury, PCBs, and PAHs, represent the most severe threat to nature and humans in and around the Saguenay River. Improvements in manufacturing technology since the worst contamination of the 1950s to late 1970s, however, have led to a steady rise in water quality. Of the freshwater sport fishes in the river, only walleye continue to have mercury body burdens exceeding recommended consumption guidelines for humans.

In contrast to many rivers, eutrophication has never been a widespread problem in the Saguenay because of its fast flushing rates. Moreover, a low human population density (>2.5 people/km²), the small number of livestock farms (~2000) relative to the size of this large basin, and secondary wastewater treatment facilities serving more than half the municipal population in the basin have contributed to low eutrophication rates. The major nutrient-related problems still existing are primarily bacterial and are related to the small percentage of the population not serviced by secondary wastewater treatment plants.

With the recent decline in the natural resource extraction economies and the creation of parks and nature preserves (the Saguenay–St. Lawrence Marine Park and the Laurentides and Saguenay National Park), recreation and tourism have become focal points for regional economic development. This shift to a tourist-based economy has helped reverse some of the negative impacts from resource extraction and manufacturing. However, other threats to the river and its tributaries exist. These include the recently proposed diversion of a significant percentage of the Manouane River's discharge (a tributary of the Peribonca River, the Saguenay's largest tributary) into the Pipmuacan Reservoir on the Betsiamites River for hydropower.

ST. JOSEPH RIVER

The St. Joseph River basin occupies portions of southwestern Michigan and north-central Indiana, with about 60% of its 12,150 km² basin residing in Michigan and 40% in Indiana (Fig. 22.14). The St. Joseph River is a major tributary of southern Lake Michigan, and with an average discharge of nearly 100 m³/s it is one of the larger watersheds draining into any of the Great Lakes. The river arises near the town of Hillsdale in south-central Michigan and flows in a southwesterly direction as far as South Bend, Indiana (Fig. 22.4), bending southward into Indiana (hence the city's name) and then abruptly northward before returning to Michigan and emptying into Lake Michigan at the city of St. Joseph. Only about 20% of the ~100 km long main stem is in Indiana, a state that includes a northeastern tributary of the Maumee River that is also called the St. Joseph River. The St. Joseph River of interest here has a diverse fauna that includes nearly 100 native fish species and 23 species of mussels and clams.

The St. Joseph River has considerable historical significance (Wesley and Duffy 1999). Native Americans of the Miami, Iroquois, and Potawatomi tribes were the main inhabitants of the river basin prior to European settlement. The Miami tribe of the Algonquin Nation settled the basin around 1000 to 1200 years ago and called the river *Sauk-Wauk-Sil-Bauk*, meaning "mystery river." The Algonquin clearly harvested the abundant fishes of the St. Joseph River using traps and weirs, as shown in bones from archaeological digs. In the 1600s, the Iroquois drove most the Miami Indians from the river basin because of competition in the fur trade. Potawatomi Indians occupied the basin until the mid-1800s, when Europeans began to settle heavily in the area and clear the land for cultivation.

The French explorer LaSalle is generally credited with being the first European to float the St. Joseph River when he worked his way upstream in 1679 from Lake Michigan to what is now South Bend. From there, LaSalle portaged to the Kankakee River to begin his journey to the Mississippi River. However, another Frenchman, Medard Chauart des Groseilliers, may have canoed the river as early as 1654. Control of the river alternated between the French, British, and Indians until the Revolutionary War forged its eventual status as an American river. A French Catholic colony was established on the banks of the St. Joseph River at South Bend in the mid-1800s for the purpose of establishing the

FIGURE 22.4 St. Joseph River near South Bend, Indiana (PHOTO BY G. LAMBERTI).

University of Notre Dame. The river was valued early for its fisheries and as a navigational corridor, but its principal uses now are for hydropower, water supply, waste disposal, and recreation.

Physiography, Climate, and Land Use

The St. Joseph basin, with its generally flat, glacially molded topography, is within the Central Lowland (CL) physiographic province of the Interior Plains

(see Fig. 22.14). During the Pleistocene epoch numerous glacial lobes entered the river basin from Lakes Michigan and Erie. The advancing glaciers scoured and flattened the land surface into till plains, whereas the retreating glaciers deposited scoured materials as moraines. Well over 200 natural lakes of various sizes are found in the basin because of its glacial history, which resulted in burial of ice blocks, damming of stream channels by moraines, and irregular deposits of glacial drift that trapped water.

The geology of this basin is complex and largely reflects its glaciated history. The basin's deep basement rock consists of Precambrian igneous materials, such as granite and basalt. More shallow bedrock consists mostly of layered Paleozoic materials, including limestone, sandstone, siltstone, and shale, which were deposited by ancient inland seas. The bedrock is covered by a layer of glacial drift material, often >100m deep. The overlying drift material is heterogeneous, ranging from sands to boulders, but mostly consists of sands and gravels. In many depressional areas, organic muds and peats have accumulated. Gravel intermixed with clay and loam tills are characteristic of the common outwash plains of the basin. Soils of the basin generally fall into one of three classes (State of Indiana 1987): (1) sandy or loamy soils developed on outwash and alluvium, (2) silt or clay developed on till, or (3) muck soils developed in depressional wetland areas.

The climate of the St. Joseph River basin is classified as temperate continental and is characterized by warm to hot summers, cold winters, and reasonably even year-round precipitation (4.8 to 10.4cm/mo; Fig. 22.15). Mean monthly temperatures range from -4.8°C in January to 25°C in July, with an annual average of 9.7°C . Summer precipitation often occurs from thunderstorms and winter precipitation occurs as snow, which can be heavy in some years. For example, annual snowfall in South Bend averages 180cm. Local precipitation amounts exceeding 5cm in a day are not unusual and can result in flash flooding in tributaries of the St. Joseph River. Humidity is moderate to high, especially in the summer, when southern air masses penetrate beyond the Ohio River valley. The climate of the western portion of the basin is influenced by Lake Michigan, which produces lake-effect snow and rain but moderates the air temperature close to the lake such that a fruit-growing district, including vineyards, is possible.

From a floristic perspective, the basin is classified as a Temperate Deciduous Forest biome within the Southern Great Lakes Forest terrestrial ecoregion, although much of the landscape has been dramatically altered by humans. Row-crop agriculture is the primary land use in the basin and now occupies about 60% of the total land cover. Forests cover another 20% of the watershed, and urban/residential land use accounts for about 8% of the remaining 20%. Common forest trees are ash, elm, cottonwood, maple, oak, and poplar.

River Geomorphology, Hydrology, and Chemistry

The generally flat topography of the glaciated landscape within the St. Joseph River basin results in a small elevational change from river source to mouth (total 200m, or about 20cm/km in the main stem). The highest gradients ($\leq 8\text{m/km}$) occur in the headwaters, but even these steep slopes do not match some historical gradients on the main stem that now have been inundated by impoundments, thereby also eliminating and fragmenting aquatic habitats.

The headwaters of the St. Joseph River have a narrow stream channel that is straight to meandering and has a cross-section typical of lower-gradient streams. The channel widens in the middle section with increased flow and an unconfined valley, but narrows again in the lower reaches, where it is restricted by a narrow glacial valley. Near its mouth at Lake Michigan the stream channel widens again as it flows over lake deposits. Substrate throughout the basin is generally small particles of silt, sand, and gravel, but some cobble is found in the lower section, where glacial tills predominate. The abundance of woody debris varies considerably in the tributaries related to the degree of human clearing of riparian vegetation and dredging of channels. Woody debris is relatively common along channel margins of the main-stem river, but large debris dams have been removed to accommodate navigation and recreation. Most of this clearing was accomplished by the mid-1800s, when the river was already being used as a "superhighway" to transport logs and grains by steamship and keelboat. At that time, several dams also were built on tributaries to the St. Joseph River to supply power for sawmills and grain mills.

The permeable glacial deposits of the St. Joseph basin result in fairly stable streamflows throughout the basin (mean annual discharge $96.3\text{m}^3/\text{s}$) because most precipitation readily infiltrates the surficial geology and enters stream channels via groundwater (see Fig. 22.15). Exceptions occur in highly urbanized areas and intense agriculture areas because of reduced soil permeability and active drainage. Although precipitation is highest in summer, maximum runoff ($>4\text{cm/mo}$) occurs in March and April as a result of spring snowmelt (see Fig. 22.15). Runoff declines to its low of about 1.6cm/mo during August and September, apparently as a result of increased summer evapotranspiration.

Water chemistry is highly influenced by the geology of the basin, which includes extensive

limestone deposits, and therefore the water naturally carries high loads of dissolved salts (State of Indiana 1987). For example, conductivity is typically 200 to 600 $\mu\text{S}/\text{cm}$ and total alkalinity is 200 to 400 mg/L as CaCO_3 . This high alkalinity effectively buffers against pH change, which ranges from 6.0 to 8.9 in the basin but is generally 7.5 to 8.0. Dissolved oxygen is quite variable, ranging from 1.2 to 10.9 mg/L in the main channel during the summer. The lower values occur in main-stem impoundments, whereas typical concentrations in the free-flowing portions of the river are 8 to 10 mg/L. Nutrient concentrations are relatively high throughout the basin because of extensive agricultural activities. Soluble reactive phosphorus typically varies from 0.02 to 0.10 mg P/L and $\text{NO}_3\text{-N}$ ranges from 0.7 to 2.9 mg/L. However, spot measurements of nitrate in some tributaries have approached or exceeded 10 mg/L, which is the USEPA drinking water standard.

River Biodiversity and Ecology

Located within the Michigan–Huron freshwater ecoregion, the St. Joseph River and its tributaries have a relatively rich fauna and flora of aquatic species. Unfortunately, the pressures of human exploitation of the watershed have eliminated some species and continue to threaten others. Federally or state endangered fauna include river otter, fishes (greater redhorse, creek chubsucker), turtles (spotted, Blanding's, alligator snapping), snakes (eastern massasauga, copperbelly water snake), and caddisflies (*Setodes oligius*). Threatened species consist of fishes (lake sturgeon, river redhorse) and marbled salamander. Species of special concern include fishes (starhead topminnow, black buffalo, spotted gar), eastern box turtle, frogs (Blanchard's cricket, northern leopard), blue-spotted salamander, snails (pointed campeloma, swamp lymnaea), and Douglas stenelmis riffle beetle. Approximately 105 riparian plant species are endangered, threatened, or of special concern.

Aquatic macrophytes and algae have been poorly studied within the St. Joseph basin in comparison to invertebrates and fishes, and will therefore not be discussed in great detail beyond noting that wild celery and various species of pondweed are common types of aquatic macrophytes in streams of this basin. On an ecological note of interest, Horvath and Lamberti (1997) reported that wild celery was a vector for dispersal of zebra mussels into lake-outflow streams in the St. Joseph River drainage. Broken pieces of this plant from lakes served as "lifeboats" for attached

zebra mussels, which could then drift many hundreds of meters in outflowing streams. Many tributary streams to the St. Joseph River exhibit interesting seasonal patterns of algal growth related to canopy cover and other factors. Shading by dense riparian canopy results in low standing crops of algae in summer, but dense algal blooms (especially *Cladophora* sp.) often completely cover the streambed by late winter or early spring in response to higher light after fall leaf abscission and perhaps elevated nutrients from the spring thaw (Lamberti and Berg 1995).

Invertebrates

The St. Joseph River has a rich array of invertebrate life, including 23 recorded species of native mussels and clams. Mussels have persisted in the river despite considerable commercial clamming pressure on some species in the early 1900s to provide shells for the button industry. It is now unlawful to harvest native mussels in Michigan without a scientific collector's permit. More recent threats to sensitive mussel species include chemical pollution and dams that halt the migration of host fishes that disperse the larval glochidia. The river basin also contains at least two species of nonnative clams: the zebra mussel and the Asiatic clam. Asiatic clams are found in sandy reaches of many streams in the basin. The spread of zebra mussels in the basin has been particularly well documented because of their recent invasion (1991). Horvath et al. (1996) correctly predicted with a "source-sink model" that lakes would have large self-sustaining populations, but streams would rely for recruitment on upstream reservoirs to sustain small populations (Horvath and Lamberti 1999). Where zebra mussels are abundant, native bivalve mollusks have largely been extirpated, because zebra mussels thoroughly encrust shells and hinder feeding and respiration.

Benthic invertebrates have been studied in only a few locations throughout the basin, and a complete species list for the basin is lacking. Some examples of important macroinvertebrates in the basin are oligochaete worms, bivalve mollusks (Corbiculidae, Dreissenidae, Sphaeriidae, Unionidae), snails (Bithyniidae, Hydrobiidae, Physidae, Pleuroceridae, Planorbidae), isopod crustaceans (*Caecidotea*), amphipod crustaceans (*Gammarus*), crayfish (*Orconectes*), beetles (*Dubiraphia*, *Macronychus*, *Optioservus*, *Stenelmis*), true flies (*Antocha*, biting midges, black flies, *Chelifera*, chironomid midges, *Hemerodromia*, *Hexatoma*, *Tipula*), mayflies

(*Baetis*, *Caenis*, *Ephemera*, *Hexagenia*, *Isonychia*, *Serratella*, *Stenacron*, *Stenonema*, *Tricorythodes*), alderflies (*Sialis*), damselflies (*Enallagma*), stoneflies (*Amphinemura*, *Paracapnia*, *Taeniopteryx*), and caddisflies (*Cheumatopsyche*, *Glossosoma*, *Hydropsyche*, *Hydroptila*, *Lepidostoma*, *Micrasema*, *Mystacides*, *Nectopsyche*, *Oecetis*).

Although information for the whole basin is sparse, concentrated invertebrate studies have been conducted in Juday Creek (South Bend, Indiana), a tributary of the St. Joseph that flows through the campus of the University of Notre Dame. This stream is of further interest because it contains naturally reproducing populations of trout related to high inputs of cool groundwater. R. A. Hellenthal and his students have studied benthic macroinvertebrates in the stream since the early 1980s (Schwenneker 1985, Berg 1989, Kohlhepp 1991, Latimore 2000), and Lamberti and Berg (1995) summarized some of these studies for the period from 1981 to 1992. Juday Creek is a 3rd order, cool-water stream whose basin experienced substantial land-use changes over that period, as woodland and some agriculture were converted to urban areas. By 1992 the watershed was dominated by agriculture (45%) and urbanization (31%), whereas only 7% of the basin remained as original woodland or prairie. A total of 119 taxa of invertebrates have been recorded from Juday Creek, and total richness did not change appreciably in the stream over the study period.

Vertebrates

Historically, the St. Joseph River contained a rich native assemblage of fishes. Wesley and Duffy (1999) document 97 native fish species in the St. Joseph River basin, although this list contains limited information about fish communities before the 1880s and prior to European settlement. Fish bones found in archaeological digs indicate that Potawatomi Indians harvested lake sturgeon, bowfin, northern pike, river herring, channel catfish, crappie, walleye, and freshwater drum from the river. Many additional species have been recorded in the last century, including brook trout, smallmouth bass, bluegill, white sucker, hornyhead chub, creek chub, yellow perch, logperch, pirate perch, blacknose dace, blackside darter, rainbow darter, bluntnose minnow, common shiner, common stoneroller, central mudminnow, northern hogsucker, mottled sculpin, channel catfish, and northern madtom. Many of these native species are now restricted to small portions of the basin by cumulative habitat change, nonnavigable dams, or

other sources of fragmentation. Approximately 17 species of nonnative fishes occur in the basin, many of which are salmonids.

Lake sturgeon historically migrated in large numbers from Lake Michigan into the river to spawn all the way to its headwaters. Many were huge (≤ 130 kg and 3.5 m long) and heavily sought after by anglers in the late 1800s. A strong commercial market existed for sturgeon meat, and eggs were sold to Russia as caviar. Construction of dams in the lower river, beginning in the late 1800s, gradually eliminated sturgeon runs because they could not navigate fish ladders designed for salmonids. Spawning is now limited to the short, undammed lower river reaches.

Fishery management in Indiana and Michigan has concentrated on game fishes and stocking programs. Pacific salmon garner most attention, and steelhead, coho salmon, and chinook salmon are reared for release into the river. These fishes migrate as smolts to Lake Michigan and return on spawning runs two to five years later. Stocking efforts have created a major sport fishery in the lower portions of the river. Rainbow trout are also planted in both Michigan and Indiana as mostly a put-and-take fishery, and brown trout have been sporadically stocked in the past. Concerns exist about effects of these nonnative salmonids on native fishes, especially brook trout, which are now uncommon in the basin. Fishery managers have given more attention recently to warm-water fishes, such as walleye, northern pike, channel catfish, and smallmouth bass.

Although fishes represent the greatest diversity of vertebrates in the St. Joseph River, there are healthy populations of mammals, reptiles, amphibians, and birds. Aquatic mammals in this basin are dominated by muskrat but also include beaver, mink, and a small population of river otter. Fur-bearing mammals have declined in the last two centuries, but they played an important role in the early history of colonization by non-Native Americans and competition among Indian tribes within this basin. Amphibians and reptiles are represented by 32 known species in the basin.

Ecosystem Processes

As in many large rivers, the main stem of the St. Joseph River has been understudied in terms of ecosystem processes, such as primary and secondary production, decomposition, metabolism, and nutrient cycling. One study of note by Biddanda and Cotner (2002) demonstrated that the St. Joseph River, combined with three other rivers flowing into

southern Lake Michigan, annually supplied about 5% of the carbon demand of planktonic bacteria and about 10% of the phosphorus needed by planktonic algae. Considering that these four rivers in aggregate only contribute about 1% of the volume of southern Lake Michigan on an annual basis, the river inputs are clearly important to lake productivity. On average, the St. Joseph River carried about 5 mg/L of dissolved organic carbon (mostly high quality) and 18 µg/L of total dissolved phosphorus into Lake Michigan.

In the early 1980s, secondary production of all nonchironomid benthos in Juday Creek near the University of Notre Dame campus was about 2.8 g m⁻²yr⁻¹ dry mass, but this declined 75% to about 0.7 g m⁻²yr⁻¹ by the early 1990s, apparently due to excess siltation of the stream (summarized by Lamberti and Berg 1995). Kohlhepp (1991) reported similar secondary production (to the early 1980s level) in Brandywine Creek, a Michigan tributary of the St. Joseph River that had much less sedimentation than Juday Creek. In contrast, secondary production of collector-gatherers increased by almost 300% over that period in Juday Creek, and collector-gatherer invertebrates contributed the bulk of the secondary production in both these streams. Interestingly, Berg and Hellenthal (1991) later found in Juday Creek that chironomid midges, which are often ignored in production studies, contributed much more production, about 29.7 g m⁻²yr⁻¹, than all other benthic invertebrates combined. They termed this omission in most production estimates “the standard error of the midge.” On a seasonal basis, midges dominated production in the autumn, winter, and spring (when benthic algae also were most abundant), whereas nonchironomid taxa dominated production in summer. Overall results suggest that Juday Creek historically supported a productive macroinvertebrate fauna that has gradually declined with deleterious change in land use within the watershed, a trend perhaps symptomatic of the entire basin.

The morphology and hydrology of many streams of the St. Joseph River watershed, especially the main stem, have been greatly altered by human activities. In a few remnant reaches of certain tributaries, however, reasonably natural conditions persist, including substantial amounts of large woody debris (LWD) in the channel. Ehrman and Lamberti (1992) studied LWD in Juday Creek and its influence on the retention of coarse particulate organic matter (leaves and sticks). A wooded reach of Juday Creek averaged 63 pieces of LWD and 16.3 m³ LWD volume per

100 m of stream length, levels reasonably comparable to streams in old-growth forests of the Pacific Northwest (Harmon et al. 1986). Retention of CPOM was quite high in these reaches, with 68% of released leaves and 75% of sticks retained in 100 m of channel. Therefore, it is reasonable to infer that, at least historically, these streams were highly efficient at trapping and processing organic matter delivered by the riparian zone. In the past 100 years, however, much of this retentive capacity has been lost because of channel alteration.

Human Impacts and Special Features

The St. Joseph River is one of the larger watersheds draining into any of the Great Lakes and is of historical significance in the lives of Native Americans and settlers from other continents. Its diverse fauna includes nearly 100 native fish species and 23 species of mussels and clams, but the diversity and distribution of biota have been greatly influenced by watershed changes such as dam construction, channel modification, point-source pollution, non-point-source pollution, agricultural and urban land use, and introductions of nonnative species.

Point sources of pollution include 221 industrial discharges to surface waters in the basin, which are permitted to contain certain limits of parameters of concern (e.g., dissolved oxygen, metals, nutrients, organic compounds, temperature). Combined sewer overflows plague most cities and result in periodic overflows of raw sewage into rivers during heavy rain events; such outflows have sporadic but acute effects on aquatic biota.

Extensive agricultural activities and concentrated urbanization in the basin have resulted in diffuse inputs of nutrients, contaminants, and fine sediment to the river. These generally nonpoint-source inputs are probably the most important current source of water-quality impairment. Intensive agriculture of mostly row crops has required clearing of forests, draining of wetlands, and channelization of streams. Tilling of agricultural fields for drainage has altered streamflow and temperature regimes, whereas riparian clearing has resulted in bank erosion and sedimentation of many small tributaries in the basin (Wesley and Duffy 1999). Urbanization has increased direct runoff of precipitation and inputs of sediments, contaminants, and other pollutants to streams (e.g., Lamberti and Berg 1995). Wetlands have been greatly reduced in the watershed and therefore their

water-filtration capacity is now limited. In many cases, agriculture has extended the stream network with the construction of ditches that drain agricultural fields and therefore carry agricultural runoff. Fine sediments and elevated nutrient levels appear to be chronic problems in the basin (Lamberti and Berg 1995, Wesley and Duffy 1999). The net cumulative effect of these practices has been reduced water quality in the larger tributaries and main stem of the St. Joseph River and chronic sedimentation problems.

Fragmentation of streams within the basin by habitat change and impoundments has had particularly severe impacts on biota. The basin contains 17 dams on the main stem and 173 on tributaries (Wesley and Duffy 1999). Dams have been classified as being for recreation (105 dams), hydroelectric power generation, irrigation, municipal water supply, or other functions. Only five dams on the lower main stem contain fish-passage structures (primarily for introduced salmonids), and these allow fishes to migrate only as far as the salmon and trout hatchery at Mishawaka, Indiana. At this point an impassable dam blocks migratory fishes from reaching the remaining 200 km of main stem and tributaries. Dams also create intermittent lentic environments where water-quality problems, such as reduced dissolved oxygen levels, often occur seasonally.

In recent years the St. Joseph River Basin Commission has focused on improving the condition of the river through proper planning and pollution reduction, and they have been helped at the local level by grassroots organizations. The latter include the Friends of the St. Joseph River Association and Friends of Juday Creek, which have often focused on habitat improvement through stream restoration. In Juday Creek, two channelized reaches were rerouted into remnant woodland, and the creek also received gravel, cobble, and large woody debris additions to enhance habitat for brown and rainbow (steelhead) trout. The restoration increased pool habitat, woody debris, flow microhabitats, and substrate diversity in the new reaches, which led initially to rapid colonization and use of the restored reaches by aquatic biota (Latimore 2000, Moerke 2000). Although length-frequency distributions of salmonids broadened and spawning activity initially increased in the restored reaches compared to channelized reaches (Moerke and Lamberti 2003), salmonid young-of-year recruitment declined over time, suggesting increased egg mortality. Through time, fine sediment deposition in restored reaches appeared to have

negated the positive effects of the habitat enhancements for fishes and macroinvertebrates (Latimore 2000). Long-term success of stream restorations in the St. Joseph River basin, as well as for most Midwestern streams, may depend on parallel attention to overall watershed conditions to control sources of degradation.

ADDITIONAL RIVERS

Flowing into Lake Superior along its south shore within the Superior freshwater ecoregion is the relatively pristine 4th order Ontonagon River (Fig. 22.16). Its 3569 km² watershed in the upper peninsula of Michigan is unusual for many Great Lakes tributaries in being heavily forested (>80%) and containing a National Wild and Scenic River designation. Impressive waterfalls flowing over basalt outcrops interblend with many beautiful lakes, ephemeral streams, and main-channel habitats in the Sylvania Wilderness of the Ontonagon River basin. About 50 species of fishes and many more invertebrates thrive within the Ontonagon River.

Lake Huron receives water from Michigan's 5240 km² eastward-flowing AuSable River basin, one-third of which is in the Huron National Forest (Fig. 22.18). The 4th order AuSable River, like the Ontonagon, is heavily forested and included within the Western Great Lakes Forests terrestrial ecoregion, but it is in the Michigan–Huron freshwater ecoregion. Nearly 40 km of the river has been designated as a National Wild and Scenic River and 560 km of the river's main stem and tributaries are included under the State Natural Rivers program. Its waters are teeming with nearly 100 species of fishes, abundant fur-bearing mammals (including river otter), and many species of other vertebrates, invertebrates, algae, and aquatic plants. Over 60 dams from 1 to 10 m high have been built on the AuSable River, with 6 hydroelectric dams on the lower river (Fig. 22.5).

Emptying into the southwestern basin of Lake Erie is the 7th order Maumee River, which draws water from a basin of 16,458 km² in the Erie freshwater ecoregion (Fig. 22.20). This is a river of contrasts in many ways. Clear waters of state-designated scenic river sections within some Ohio and Indiana tributaries of the Maumee support a rich fauna of fishes and invertebrates, but reaches of the lower main stem near Toledo, Ohio, were identified as an EPA Area of Concern because of high concentrations of mercury and PCBs. The diversity of fishes

FIGURE 22.5 AuSable River near mouth, Michigan (PHOTO BY TIM PALMER).

(>60 species) is lower than in the AuSable, but the Maumee attracts many fishermen because it has the largest population of migrating walleyes east of the Mississippi River. Much of the original land cover of forests in this Southern Great Lakes Forests terrestrial ecoregion have given way to agriculture (54% to 88% of the watershed) and urbanization, which have negatively affected the river ecosystem. As a result of the actions of concerned citizens and government agencies, however, the waters of the Maumee are gradually improving.

Arising from the southwestern slopes of the Adirondack Mountains of New York, the 5th order Black River flows through a 5057km² basin before entering northeastern Lake Ontario (Fig. 22.22). Much of the upper watershed is heavily forested (75% of the entire basin is temperate deciduous forest) and quite steep in comparison to both the lower portion of its basin and the watersheds of most other Great Lakes tributaries. The upper basin is replete with many clear, cold mountain lakes that

feed the Black River within the Ontario freshwater ecoregion. Several small dams are found on the main stem and its tributaries. Small quaint towns, such as Old Forge, New York, draw many tourists eager to canoe and hike in the surrounding sugar maple and beech forests that occur within the wild natural areas in the Eastern Great Lakes Forest terrestrial ecoregion. Although its watershed is only one-third the size of the Maumee River basin, the Black River contains nearly as many fish species (52), though far fewer than are present in the AuSable River, which has a comparable basin size to the Black River but half its annual discharge.

Many tributaries flow into the main stem of the St. Lawrence River, but one of the most unusual is the Rivière Richelieu. Its basin is included with the New England/Acadian Forest terrestrial ecoregion and the Lower St. Lawrence freshwater ecoregion. Over 80% of this large watershed (23,772km²) is spread through northeastern New York and northwestern Vermont, where many tributaries feed the

FIGURE 22.6 Rivière Richelieu at Saint-Jean-sur-Richelieu, Quebec (PHOTO BY G. WINKLER).

large natural Lake Champlain (called the 6th Great Lake by some enthusiastic proponents) (Fig. 22.24). Although the Richelieu is listed here as a 7th order river, this has little utility for comparative purposes because few other 7th order rivers have a watershed that includes such a large lake. Although the broad Lac Saint-Jean is a major feature of the upper Saguenay River watershed, this shallow lake does not exert the same influence on the outflowing river as the deep Lake Champlain. From this lake, the Rivière Richelieu flows north over Fryer Rapids, through Quebec, and into the St. Lawrence slightly downstream and across the river from Montreal (Fig. 22.6). Because much of the land use below Lake Champlain is heavily urban and agriculture, the water quality of this river has suffered.

The 43,427 km² watershed of the 7th order Rivière Saint-Maurice in Quebec is squeezed between the watersheds of two larger rivers, the Ottawa and Saguenay (Fig. 22.26, Fig. 22.7). Like those rivers, the Saint-Maurice partially drains a physiographic

province in the Precambrian Shield, which affects the nature of its water (making it softer) and makes the watershed more susceptible to acid precipitation. A substantial portion of this watershed is included within several Canadian national (La Mauricie National Park) and provincial faunal reserves and parks. Although only a little over 30 species of fishes are recorded for this river, this figure may be an underestimate reflecting insufficient study. Seven dams are present on the main stem of this river.

ACKNOWLEDGMENTS

We appreciate the information supplied by J. David Allan, Doug Carlson, Michael Eberle, Tim Mihuc, and Rodney Renkenberger on tributaries of the Great Lakes and the St. Lawrence River. This chapter benefited greatly from information contained in the excellent Canadian government publication on the St. Lawrence River by the St. Lawrence Centre (1996).

FIGURE 22.9 Mean monthly air temperature, precipitation, and runoff for the St. Lawrence River main stem.

ST. LAWRENCE RIVER MAIN STEM

Relief: 1945 m

Basin area: 574,000 km² (main stem)

Mean discharge: 12,600 m³/s (excluding Saguenay)

River order: 8 without Saguenay (9 with Saguenay)

Mean annual precipitation: 94.2 cm

Mean air temperature: 6.7°C

Mean water temperature: 9.7°C

Physiographic provinces: 4 ecoregions (see text)

Biomes: Temperate Deciduous Forest, Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregions: Eastern Great Lakes Lowland Forests, Eastern Forest/Boreal Transition, New England/Acadian Forests, and Eastern Canadian Forests

Number of fish species: 87 freshwater and 18 diadromous species

Number of endangered species: ~20 animals and plants vulnerable, threatened, or endangered at federal, state, or provincial levels, 12 other at risk

Major fishes: lamprey, lake sturgeon, Atlantic sturgeon, gar, bowfin, American eel, alewife, gizzard shad, creek chub, fallfish, yellow perch, walleye, white sucker, silver redhorse, channel catfish, tadpole madtom, muskellunge, central mudminnow, rainbow smelt, brown trout, troutperch, banded killifish, burbot, brook silverside, mottled sculpin, sand darter, drum

Major other aquatic vertebrates: muskrat, river otter, beaver, mink, beluga whale, long-finned pilot whale, Canada goose, mallard duck, wood duck, blue-winged teal, gadwall, American wigeon, great blue heron, ring-billed gull, belted kingfisher, cormorant, tern, bald eagle, osprey, northern water snake, painted turtle, snapping turtle

Major benthic invertebrates: sponges (*Eumapius*), flatworms (*Dugesia*), bryozoans (*Plumatella*), oligochaetes (*Chaetogaster*), mollusks (*Elliptio*, *Lampsilis*, *Birgella*, *Gyraulus*), crustaceans (*Gammarus*, *Orconectes*), mayflies (*Stenonema*, *Hexagenia*), caddisflies (*Nectopsyche*), stoneflies (*Pteronarcys*), chironomid midges

Nonnative species: common carp, rainbow trout, white perch, *Bithynia tentaculata* and *Viviparus georgianus* (snails), *Pisidium amnicum* and *Sphaerium* (finger nail clams), zebra mussel, quagga mussel, *Echinogammarus ischnus* (amphipod), purple loosestrife

Major riparian plants: silver maple, red maple, black ash, green ash, black willow, American basswood, cattails, sedges, rushes, bulrushes, reed canary grass

Special features: lower river continentally outstanding; RAMSAR World Heritage Site (Lac Saint-Pierre); globally distinct site (Batture aux Alouettes) for migratory birds at confluence with Saguenay River; least turbid of world's 15 largest rivers

Fragmentation: four hydroelectric dams and seven navigation locks on main stem; many dams on tributaries

Water quality: upper river rated second-highest category by New York State; EPA Area of Concern (below Cornwall, Ontario) from PCBs and mercury; pH = 7.5 to 8.5, alkalinity = 90 mg/L as CaCO₃, turbidity = 2 NTU, O₂ = >8.6 mg/L, NH₄-N = 0.01 to 0.04 mg/L, PO₄-P = 0.01 mg/L

Land use: 55% forest, 20% agriculture, 22% urban, 3% other for entire St. Lawrence–Great Lakes system; percentage urban considerably lower for main-stem watershed

Population density: 10.5 people/km² (St. Lawrence subbasin) to 54 people/km² (St. Lawrence River–Great Lakes basin)

Major information sources: Painchaud 1997, St. Lawrence Centre 1996

FIGURE 22.8 Map of the St. Lawrence River main stem. Physiographic provinces are separated by yellow lines.

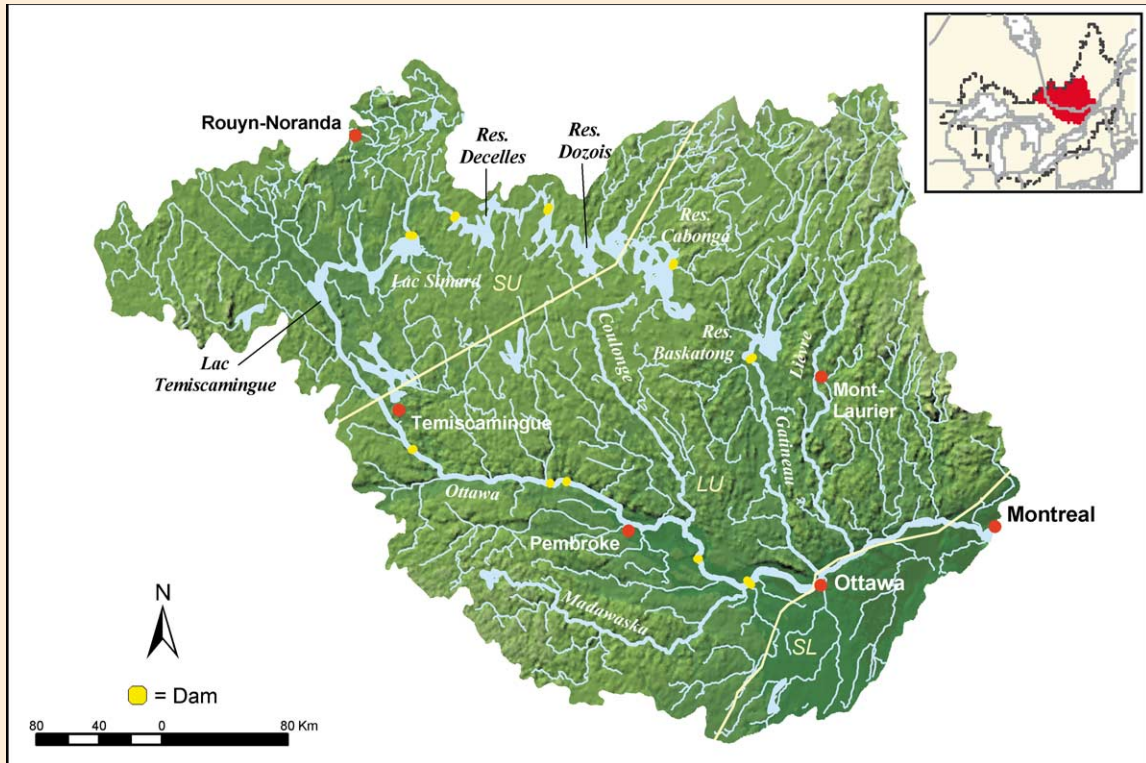

FIGURE 22.10 Map of the Ottawa River basin. Physiographic provinces are separated by yellow lines.

OTTAWA RIVER

Relief: 911 m
Basin area: 146,334 km²
Mean discharge: 1948 m³/s
River order: 8
Mean annual precipitation: 100.2 cm
Mean air temperature: 6.0°C
Mean water temperature: 9.6°C
Physiographic provinces: St. Lawrence Lowlands (SL), Laurentian Highlands (LU), Superior Upland (SU)
Biomes: Temperate Deciduous Forest, Boreal Forest
Freshwater ecoregion: Lower St. Lawrence
Terrestrial ecoregions: Eastern Forest/Boreal Transition, Eastern Great Lakes Lowland Forests
Number of fish species: 53
Endangered species: (threatened) 5 fishes, 2 birds, 1 amphibian, 1 reptile, 3 dragonflies
Major fishes: sturgeon, walleye, sauger, muskellunge, northern pike, yellow perch, crappie, lake whitefish, lake cisco, largemouth bass, smallmouth bass, channel catfish, brown bullhead, copper redhorse, suckers, cyprinids, mooneye
Major other aquatic vertebrates: muskrat, river otter, beaver, mink
Major benthic invertebrates: bivalves (*Elliptio*, fingernail clams), snails (*Bithynia*), oligochaete worms (*Stylaria*), crustaceans (*Gammarus*, *Caecidotea*, *Asellus*), 19 midge genera (*Polypedilum*), 22 mayflies (*Hexagenia*, *Stenonema*), damselflies (*Enallagma*), stoneflies (*Isoperla*), alderflies (*Sialis*), beetles (*Berosus*), 35 caddisflies (*Polycentropus*, *Brachycentrus*)
Nonnative species: brown trout, rainbow trout, zebra mussel, quagga mussel, purple loosestrife
Major riparian plants: wild rice, bur-reed, arrowhead, northern bugleweed, fox sedge, silverweed, marsh speedwell, calamus root, bulrushes, Small's spikerush, knotsheath sedge, red top, reed canary grass, silver maple, green ash, alder, willow
Special features: eight provincial faunal reserves; island-wetland complex (Petri Islands Preserve) near confluence with St. Lawrence
Fragmentation: 7 dams on main stem; >300 dams on tributaries
Water quality: good overall; pollutants from industry in Temiscamingue region and from sewage/industry near Ottawa-Hull; NH₄-N = 0.045 mg/L, NO₃-N + NO₂-N = 0.17 mg/L, total nitrogen = 0.41 mg/L, total phosphorus = 0.029 mg/L
Land use: 86% forest, 10% surface waters, 2% urban, and 2% agriculture
Population density: 2.4 people/km²
Major information source: Ministère de l'Environnement et de la Faune du Québec 1996

FIGURE 22.11 Mean monthly air temperature, precipitation, and runoff for the Ottawa River basin.

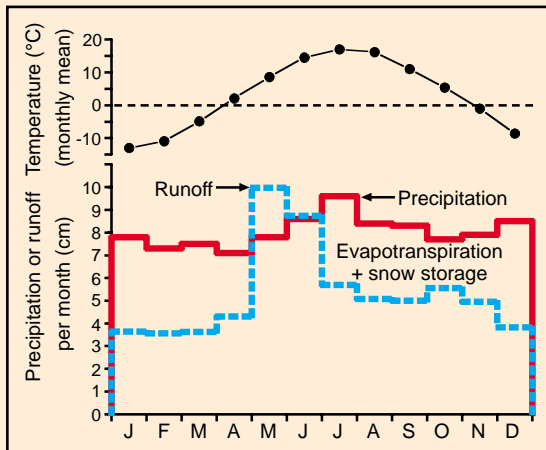

FIGURE 22.13 Mean monthly air temperature, precipitation, and runoff for the Saguenay River basin.

SAGUENAY RIVER

Relief: 1130 m

Basin area: 85,500 km²

Mean discharge: 1535 m³/s

River order: 8

Mean annual precipitation: 96.5 cm

Mean air temperature: 3.0°C

Mean water temperature: NA

Physiographic provinces: Laurentian Highlands (LU), Labrador Highlands (LB)

Biome: Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregion: Eastern Canadian Forest

Number of fish species: 76 in river and fjord

Number of endangered species: 4 fishes, 2 birds

Major fishes: Atlantic salmon, fallfish, brown bullhead, lake whitefish, brook trout, perch, burbot, rainbow smelt, lake (black) sturgeon, American eel, emerald shiner, sauger, white sucker, longnose sucker, northern pike

Major other aquatic vertebrates: beaver, river otter, muskrat, mink, long-finned pilot whale, beluga whale, great blue heron, black-crowned night heron; many bird species in fjord, including red knot, sanderling, purple sandpiper, peregrine falcon, osprey

Major benthic invertebrates: in sandy-muddy habitats insects, oligochaetes, bivalve mollusks, gastropods, and isopods are all common, but oligochaetes dominate in gravelly areas

Nonnative species: rainbow trout, purple loosestrife and >20 other plants in riparian zone

Major riparian plants: sparse vegetation in upper third due to dams and log driving; middle third dominated by American bulrush but with ≥250 species; lower third with sparse patches of American bulrush and, where salinity intrudes, saltwater cord grass

Special features: large Lac Saint-Jean in headwaters; last 100 km flows through largest fjord in northwest Atlantic; continentally and globally distinct site (Batture aux Alouettes) for migratory birds at confluence with St. Lawrence

Fragmentation: 3 hydroelectric/navigation dams on main stem and >300 small and medium-size dams in watershed

Water quality: good in upper river; poorer in lower river from nonpoint sources, aluminum processing, pulp/paper production; conductivity = 20 to 120 mS/cm, pH = 6.8 to 7.4, alkalinity = 7.3 mg/L as CaCO₃, dissolved O₂ = 5.7 to 7.8 mg/L, NH₄-N = 0.02 mg/L, NO₂-N + NO₃-N = 0.2 to 6.4 mg/L, PO₄-P = 0.01 mg/L, chlorophyll *a* = 0.9 to 8.3 mg/L

Land use: 90% forest, 8% surface waters, 1% agriculture, and <1% urban

Population density: 2.5 people/km²

Major information sources: Fortin and Peltier 1995, Mousseau and Armellin 1995

FIGURE 22.12 Map of the Saguenay River basin. Physiographic provinces are separated by yellow lines.

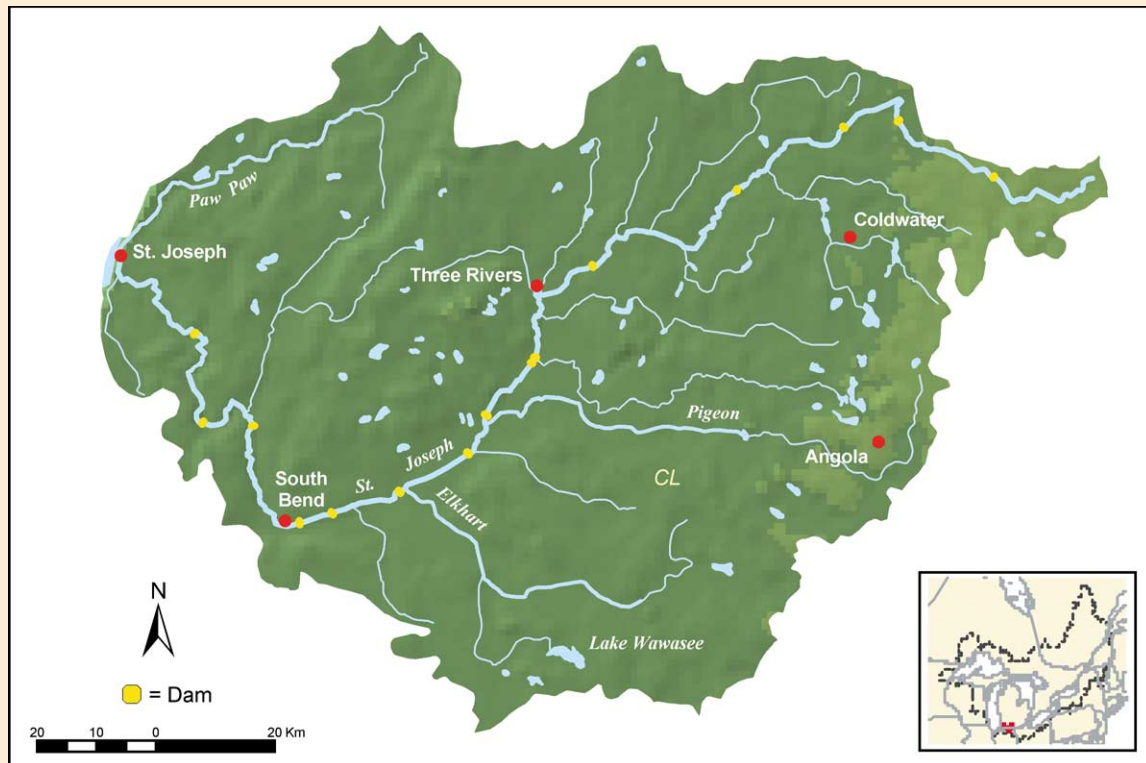

FIGURE 22.14 Map of the St. Joseph River basin.

ST. JOSEPH RIVER

Relief: 200 m
 Basin area: 12,150 km²
 Mean discharge: 96.3 m³/s
 River order: 5
 Mean annual precipitation: 99.4 cm
 Mean air temperature: 9.7°C
 Mean water temperature: 12.0°C
 Physiographic province: Central Lowland (CL)
 Biome: Temperate Deciduous Forest
 Freshwater ecoregion: Michigan-Huron
 Terrestrial ecoregion: Southern Great Lakes Forests
 Number of fish species: 114

Number of endangered species: (endangered, threatened, special concern) 1 mammal, 7 fishes, 6 reptiles, 4 amphibians, 2 insects, 2 snails, ~105 riparian plant species

Major fishes: brook trout, smallmouth bass, bluegill, walleye, white sucker, hornyhead chub, creek chub, yellow perch, logperch, pirate perch, blacknose dace, blackside darter, rainbow darter, bluntnose minnow, common shiner, common stoneroller, central mudminnow, northern hogsucker, mottled sculpin, channel catfish, northern madtom

Major other aquatic vertebrates: beaver, river otter, muskrat, mink

Major benthic invertebrates: crustaceans (*Caecidotea*, *Gammarus*, *Orconectes*), mollusks, (fingernail clams, faucet snails), beetles (*Dubiraphia*, *Macronychus*), mayflies (*Baetis*, *Hexagenia*), alderflies (*Sialis*), damselflies (*Enallagma*), stoneflies (*Amphinemura*, *Paracapnia*, *Taeniopteryx*), caddisflies (*Cheumatopsyche*, *Glossosoma*)

Nonnative species: brown trout, rainbow trout, chinook salmon, coho salmon, sea lamprey, common carp, goldfish, zebra mussel, Asiatic clam, purple loosestrife, Eurasian watermilfoil

Major riparian plants: ash, elm, cottonwood, maple, oak, poplar, wild celery, pondweed

Fragmentation: 17 dams on main stem, 190 dams in basin

Water quality: marginal water quality; pH = 6.0 to 8.9, alkalinity = 200 to 400 mg/L as CaCO₃, NO₃-N = 0.7 to 2.9 mg/L, PO₄-P = 0.02 to 0.10 mg/L

Land use: 58% agriculture, 20% forest, 8% urban, 7% open, 5% wetlands, and 2% water

Population density: 69 people/km²

Major information sources: Horvath et al. 1999, Lamberti and Berg 1995, Lee et al. 1980, Page and Burr 1991, Perry et al. 1997, Wesley and Duffy 1999, www.census.gov, www.usgs.gov, www.ummz.lsa.umich.edu

FIGURE 22.15 Mean monthly air temperature, precipitation, and runoff for the St. Joseph River basin.

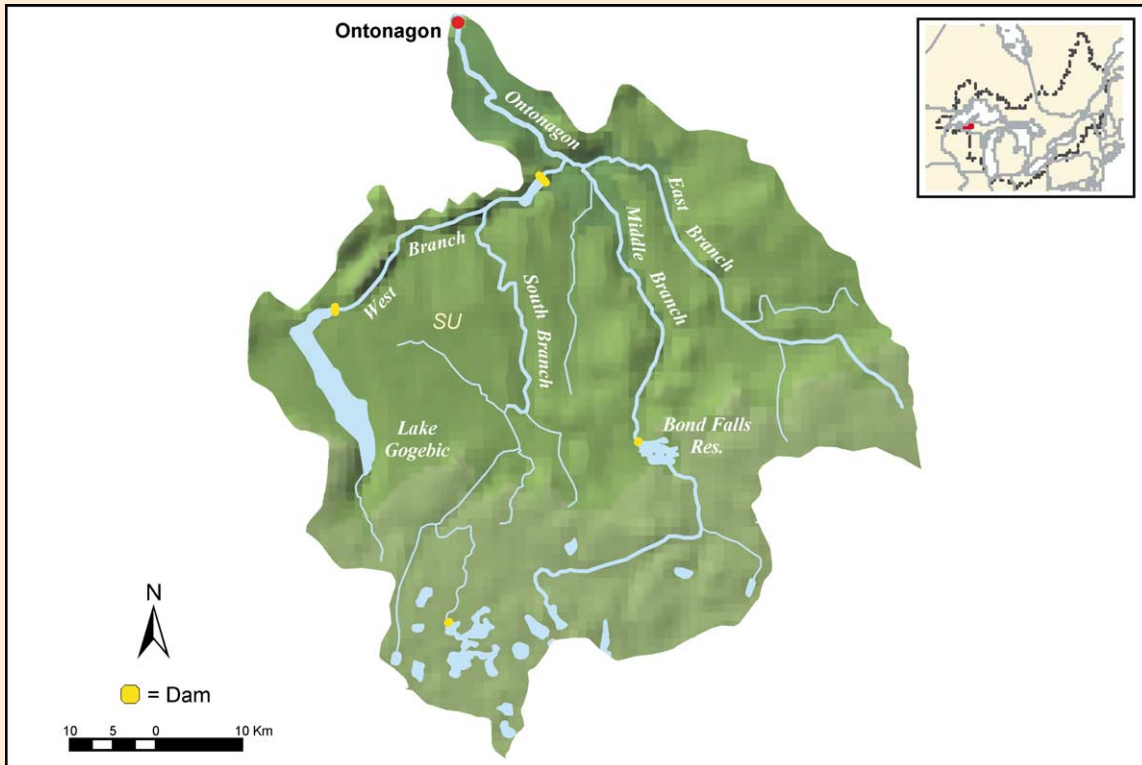

FIGURE 22.16 Map of the Ontonagon River basin.

ONTONAGON RIVER

Relief: 325 m

Basin area: 3569 km²

Mean discharge: 39.9 m³/s

River order: 4

Mean annual precipitation: 87.1 cm

Mean air temperature: 4.1°C

Mean water temperature: 8.3°C

Physiographic province: Superior Upland (SU)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Superior

Terrestrial ecoregion: Western Great Lakes Forests

Number of fish species: 50

Number of endangered species: (threatened or special concern)

1 turtle, ~6 riparian plants

Major fishes: native brook trout, yellow perch, walleye, northern pike, smallmouth bass, rock bass, bluegill, pumpkinseed, black crappie, common shiner, hornyhead chub, blacknose shiner, creek chub, slimy sculpin

Major other aquatic vertebrates: muskrat, beaver, river otter, mink

Major benthic invertebrates: crustaceans (*Gammarus*, *Orconectes*), beetles (*Haliplus*, *Stenelmis*), true flies (*Antocha*, *Simulium*), mayflies (*Acentrella*, *Baetis*, *Stenacron*), hellgrammites (*Nigronia*), dragonflies (*Ophiogomphus*), stoneflies (*Acroneuria*), caddisflies (*Brachycentrus*, *Cheumatopsyche*, *Glossosoma*)

Nonnative species: Eurasian ruffe, brown trout, rainbow trout, chinook salmon, coho salmon, rusty crayfish

Major riparian plants: cedar, spruce, hemlock, willow, alder

Special features: National Wild and Scenic River (several branches); Sylvania Wilderness with many high-quality lakes and ephemeral streams; impressive waterfalls on basalt outcrops

Fragmentation: four major dams direct flow to 12 MW hydroelectric facility at Victoria Lake; numerous low-head dams in basin

Water quality: generally good; improved since major logging in 1800s; most streams are lake fed and reflect lake water quality; pH = 6.7 to 8.4, alkalinity = 42 to 64 mg/L as CaCO₃, NO₃-N = 0.01 to 0.21 mg/L, PO₄-P = <0.01 to 0.05 mg/L

Land use: >80% forested (Ottawa National Forest), <20% urban and aquatic

Population density: 2.6 people/km²

Major information sources: Charlebois and Lamberti 1996, Lee et al. 1980, Maloney and Lamberti 1995, Page and Burr 1991, Stelzer and Lamberti 1997

FIGURE 22.17 Mean monthly air temperature, precipitation, and runoff for the Ontonagon River basin.

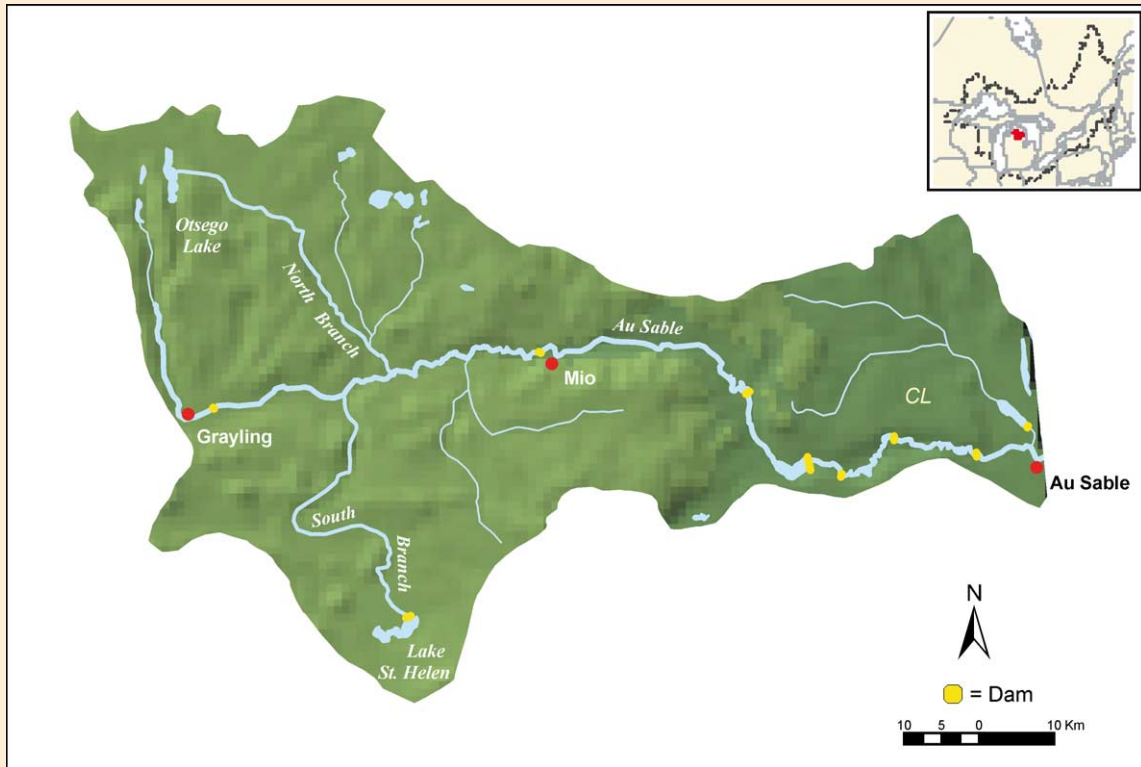

FIGURE 22.18 Map of the AuSable River basin.

AUSABLE RIVER

Relief: 250 m

Basin area: 5240 km²

Mean discharge: 42.1 m³/s

River order: 4

Mean annual precipitation: 83.3 cm

Mean air temperature: 5.5°C

Mean water temperature: 11.5°C

Physiographic province: Central Lowland (CL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Michigan-Huron

Terrestrial ecoregion: Western Great Lakes Forests

Number of fish species: 93

Number of endangered species: (endangered, threatened, or special concern) 4 fishes, 3 reptiles, ~5 riparian plants

Major fishes: brook trout, brown trout, rainbow trout, sculpins, shiners, white sucker, other suckers, several dace, Johnny darter

Major other aquatic vertebrates: muskrat, beaver, river otter, mink

Major benthic invertebrates: crustaceans (*Gammarus*, *Caecidotea*), beetles (*Dytiscus*, *Halipilus*), dipterans (*Antocha*, *Tipula*), mayflies (*Baetis*, *Ephemerella*, *Hexagenia*, *Rhithrogena*, *Stenonema*), hellgrammites (*Nigronia*), odonates (*Calopteryx*), stoneflies (*Paragnetina*), caddisflies (*Brachycentrus*, *Helicopsyche*, *Hydropsyche*, *Rhyacophila*)

Nonnative species: ≥7 fishes, including brown trout, rainbow trout, sea lamprey

Major riparian plants: alder, ash, cedar, fir, red maple, poplar, spruce, tamarack, willow

Special features: 37 km of main stem designated National Wild and Scenic River; 560 km (157 km of main stem) in State Natural Rivers Program; about one-third of watershed in Huron National Forest

Fragmentation: 67 dams along main stem and tributaries, ranging from <1 to >10 m in height

Water quality: good due to substantial groundwater input; point sources mostly septic systems; pH = 7.4 to 8.2, alkalinity = 121 to 156 mg/L as CaCO₃, NO₃-N = <0.01 to 0.36 mg/L, PO₄-P = <0.01 to 0.05 mg/L

Land use: <50% forested, >50% agricultural or urban; watershed completely logged ~1900

Population density: 17.6 people/km²

Major information sources: Cushing and Allan 2001, Hendrickson 1994, Lee et al. 1990, Page and Burr 1991, Richards 1976, Zorn and Sendek 2001

FIGURE 22.19 Mean monthly air temperature, precipitation, and runoff for the AuSable River basin.

FIGURE 22.20 Map of the Maumee River basin.

MAUMEE RIVER

Relief: 73 m

Basin area: 16,458 km²

Mean discharge: 150 m³/s

River order: 7

Mean annual precipitation: 84 cm

Mean air temperature: 9.0°C

Mean water temperature: 12.7°C

Physiographic province: Central Lowland (CL)

Biome: Temperate Deciduous Forest

Freshwater ecoregion: Erie

Terrestrial ecoregion: Southern Great Lakes Forests

Number of fish species: >60

Number of endangered species: (listed or candidates) 4 mussels,
2 reptiles

Major fishes: topminnow, chubs, spotfin shiner, bluntnose minnow, hognose sucker, redhorse sucker, blacknose dace, mudminnow, variegated darter, green sunfish, smallmouth bass, yellow bullhead, channel catfish, madtoms, walleye, crappie, gizzard shad, longnose gar, white perch, logperch, drum

Major other aquatic vertebrates: muskrat, beaver

Major benthic invertebrates: mussels (deertoe, mapleleaf), big water crayfish, White River crayfish, beetles (*Stenelmis*), true flies (*Rheotanytarsus*, *Simulium*), mayflies (*Baetis*), moths (*Petrophila*), caddisflies (*Cheumatopsyche*)

Nonnative species: 11 fishes (goldfish, carp, sea lamprey, white perch, round goby), rusty crayfish, quagga mussel, zebra mussel, purple loosestrife

Major riparian plants: sycamores, black locust, beech, sugar maple

Special features: largest drainage area of any Great Lakes river; largest population of migrating walleye east of Mississippi River; 112 km as Ohio state scenic river; Lower Cedar Creek (Indiana) listed as outstanding segment

Fragmentation: two dams on main stem and three relatively large dams on tributaries

Water quality: lower segment EPA Area of Concern; PCBs and mercury limit fish consumption; turbidity = 54.3 NTU, pH = 7.9, hardness = 267.9 mg/L as CaCO₃, NH₄-N = 0.09 mg/L, NO₂-N = 0.04 mg/L, NO₃-N = 5.5 mg/L, PO₄-P = 0.05 mg/L

Land use: Lucas County (near mouth) 54% agriculture, 21% forest, 18% urban, 4% wetland; remainder of basin 79% to 88% agriculture, 6% to 10% forest and wetlands, 6% to 11% urban

Population density: 21.2 people/km²

Major information sources: Bensch 1993, State of Indiana 1996

FIGURE 22.21 Mean monthly air temperature, precipitation, and runoff for the Maumee River basin.

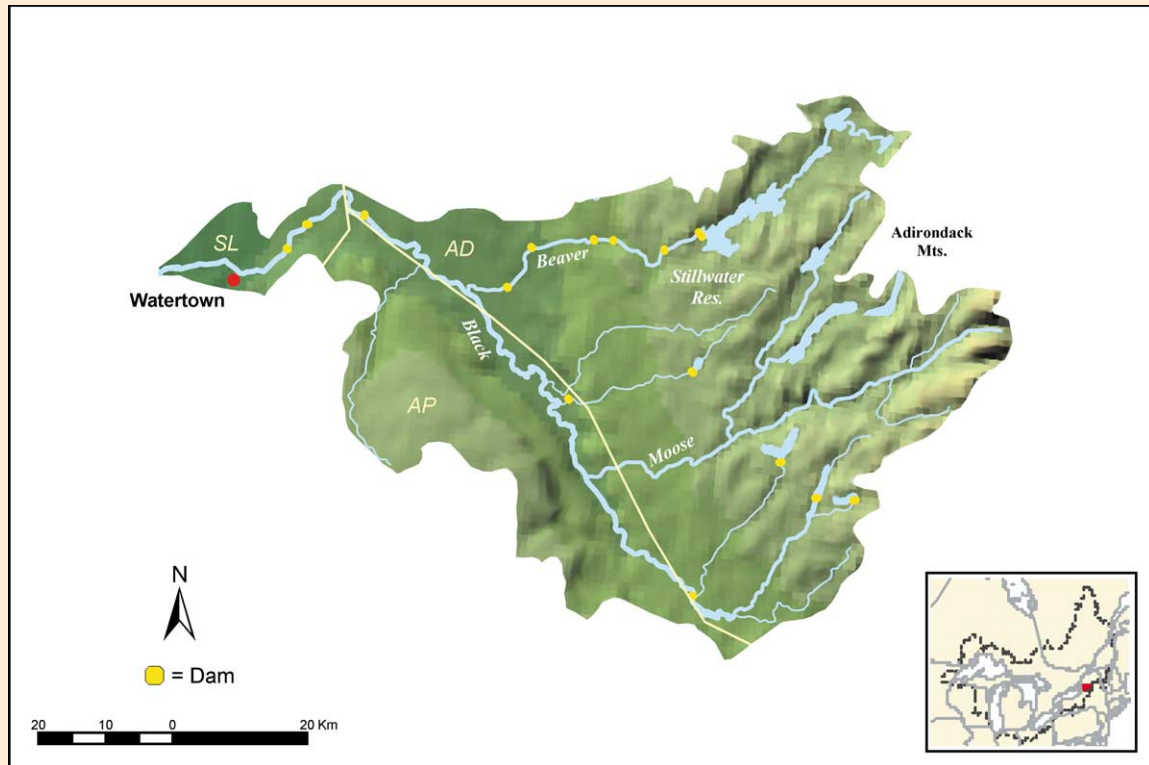

FIGURE 22.22 Map of the Black River basin. Physiographic provinces are separated by a yellow line.

BLACK RIVER

Relief: 510 m
Basin area: 5057 km²
Mean discharge: 118 m³/s
River order: 5
Mean annual precipitation: 97 cm
Mean air temperature: 6.8°C
Mean water temperature: 10.0°C
Physiographic provinces: Appalachian Plateaus (AP), Adirondack (AD)
Biome: Temperate Deciduous Forest
Freshwater ecoregion: Ontario
Terrestrial ecoregion: Eastern Great Lakes Lowland Forests
Number of fish species: ≥52
Number of endangered species: no federal; New York State (threatened and endangered) 2 fishes, 3 birds, 1 turtle, 1 mayfly, 1 dragonfly
Major fishes: rock bass, smallmouth bass, brown bullhead, fantailed darter, tessellated darter, fallfish, northern pike, margined madtom, cutlips minnow, central mudminnow, yellow perch, chain pickerel, pumpkinseed, common shiner, golden shiner, northern hog-nosed sucker, white sucker, brown trout, brook trout, walleye
Major other aquatic vertebrates: muskrat, beaver
Major benthic invertebrates: mussels (*Elliptio*, *Anodonta*, *Alasidonta*, *Lasmigona*, *Strophitus*, *Musculium*, *Pisidium*, *Sphaerium*), snails (*Amnicola*, *Bithynia*, *Valvata*, *Viviparus*, *Campeloma*, *Lymnaea*, *Ferrissia*, *Physella*, *Heliosoma*, *Gyraulus*), caddisflies (*Hydropsyche*, *Neureclipsis*), mayflies (*Baetis*, *Stenonema*), true flies (*Simulium*)
Nonnative species: purple loosestrife, faucet snail, sea lamprey
Major riparian plants: sugar maple and beech, with interspersed elms and birches
Special features: one of few rivers entering Great Lakes that originates in mountains (Adirondacks); consequently, it has a steep slope (2.3 m/km) for a short river
Fragmentation: 23 small hydroelectric dams on main stem and tributaries
Water quality: good, but vulnerable to degradation; turbidity = 2.46 NTU, dissolved O₂ = 11.19 mg/L, pH = 7.6, hardness = 38.8 mg/L as CaCO₃, NO₂-N + NO₃-N = 0.45 mg/L, NH₄-N = 0.05 mg/L, PO₄-P = 0.01 mg/L
Land use: 75% forested, 25% agriculture and urban
Population density: 16.8 people/km²

FIGURE 22.23 Mean monthly air temperature, precipitation, and runoff for the Black River basin.

FIGURE 22.25 Mean monthly air temperature, precipitation, and runoff for the Richelieu River basin.

RIVIÈRE RICHELIEU

Relief: 1614 m

Basin area: 23,772 km²

Mean discharge: 341 m³/s

River order: 7

Mean annual precipitation: 115.2 cm

Mean air temperature: 4.1°C

Mean water temperature: NA

Physiographic provinces: St. Lawrence Lowlands (SL), Adirondack (AD), New England (NE), Valley and Ridge (VR)

Biomes: Temperate Deciduous Forest, Boreal Forest

Freshwater ecoregion: Lower St. Lawrence

Terrestrial ecoregions: New England/Acadian Forests, Eastern Great Lakes Lowland Forests, Eastern Forest/Boreal Transition

Number of fish species: 48

Number of endangered species: 0

Major fishes: black fin shiner, largemouth bass, bowfin, banded killifish, emerald shiner, spottail shiner, river redhorse, mimic shiner, American eel, fathead minnow, fallfish, greater redhorse, yellow perch, rock bass, pumpkinseed, blunt nose minnow, brown bullhead, black crappie, white sucker

Major other aquatic vertebrates: muskrat, beaver

Major benthic invertebrates: crustaceans (*Caecidotea*), chironomid midges, caddisflies (Hydropsychidae, Hydroptilidae, Leptoceridae, Limnephilidae, Polycentropidae), mayflies (Baetidae, Caenidae), beetles (Elmidae, Hydrophilidae), damselflies (Coenagrionidae)

Nonnative species: sea lamprey, quagga mussel, zebra mussel, Asiatic clam, water chestnut

Major riparian plants: primarily beech and maple, with spruce and fir at higher elevations

Special features: outlet for Lake Champlain; river falls ~20 m at Fryer Rapids near Chambly, Quebec

Fragmentation: dam and reservoir below Fryer Rapids

Water quality: pollutants from >400 industries and >2700 farms; alkalinity = 52.4 mg/L as CaCO₃, hardness 67.3 mg/L as CaCO₃, conductivity = 184 μS/cm, pH = 7.7, turbidity = 10.4 NTU, dissolved O₂ = 10.65 mg/L, total nitrogen = 0.68 mg/L, total phosphorus = 0.06 mg/L

Land use: 49% forest, 43% agriculture, 7% other uses

Population density: 21 people/km²

Major information source: Environment et Faune Quebec 1998

FIGURE 22.24 Map of the Richelieu River basin. Physiographic provinces are separated by yellow lines.

FIGURE 22.26 Map of the Saint-Maurice River basin. Physiographic provinces are separated by yellow lines.

RIVIÈRE SAINT-MAURICE

- Relief: 548 m
- Basin area: 43,427 km²
- Mean discharge: 670 m³/s
- River order: 7
- Mean annual precipitation: 93 cm
- Mean air temperature: 9.7°C
- Mean water temperature: 10.0°C
- Physiographic provinces: Laurentian Highlands (LU), St. Lawrence Lowland (SL)
- Biome: Boreal Forest
- Freshwater ecoregion: Lower St. Lawrence
- Terrestrial ecoregions: Eastern Forest/Boreal Transition, Eastern Great Lakes Lowland Forests
- Number of fish species: ≥30
- Endangered species: 4 fishes, 1 turtle
- Major fishes: northern pike, lake trout, lake whitefish, fallfish, pearl dace, creek chub, fathead minnow, longnose dace, shiners, brown bullhead, troutperch, rock bass, pumpkinseed, smallmouth bass, yellow perch, walleye, logperch, white sucker, longnose sucker, brook trout
- Major other aquatic vertebrates: muskrat, mink, beaver, common loon, bufflehead, black scoter
- Major benthic invertebrates: NA
- Nonnative species: brook trout, pearl dace, purple loosestrife
- Special features: La Mauricie National Park; Mastigouche and several other provincial faunal reserves/parks in the basin
- Fragmentation: seven main-stem dams
- Water quality: good overall; municipal effluents at Shawinigan and Trois-Rivières; pH = 6.6, conductivity = 29.2 mS/cm, alkalinity = 4.0 mg/L as CaCO₃, O₂ = 11.0 mg/L, NH₄-N = 0.03 mg/L, NO₂-N + NO₃-N = 0.07 mg/L, PO₄-P = 0.012 mg/L, total P = 0.031 mg/L
- Land use: 85% forest, 10% surface waters, 0.2% agriculture
- Population density: 2.3 people/km²

INTRODUCTION

Mexico, with an area of 1.97 million km², has approximately 150 large rivers and appears to have an abundance of water resources. However, the distribution of water resources is far from homogeneous, with northern Mexico extremely dry and southern Mexico among the wettest areas of North America. Located between 15°N and 33°N latitudes, Mexico is the warmest part of North America (Fig. 23.2) but has tremendous variety in climate topography. The combination of its mountainous topography producing strong orographic influences on precipitation and the fact that it straddles the temperate-tropical divide produces a diversity of runoff patterns and river environments.

With 105 million people (www.prb.org), or an average population density of 53 people/km², tremendous pressure is placed on Mexico's rivers for

hydropower, irrigation, waste disposal, and domestic and industrial consumption. This is especially true in the central portion of the country, where nearly 25% of the total population lives in approximately 1% of the country's total surface area in the states of Mexico and Distrito Federal (www.citypopulation.de/Mexico.html). With a population growth rate of about 2.1% per year (www.prb.org 2004), pressure to use water from Mexico's rivers is rapidly increasing. Unfortunately, the fact that the hydrology, geomorphology, biodiversity, and ecology of Mexico's rivers are poorly studied is a serious shortcoming to understanding the environmental impacts of current and future water developments.

The history of human impacts on Mexico's rivers includes many groups of prehistoric inhabitants. Various accounts suggest the earliest inhabitants probably arrived more than 20,000 years ago and several major Mesoamerican culture regions developed large populations with sophisticated and complex cultures. Following the Olmec civilization that developed along the southeastern Mexican Gulf Coastal Plain around 4000 years ago, other major culture regions (Maya, Toltec, Huastec, and Aztec) developed within Mexico during the Classic period

◀ **FIGURE 23.1** Río Candelaria at bend in river, with surrounding floodplain and karstic hills in state of Campeche. Further investigations of basin management, pre-Hispanic floodplain manipulation, and canalization are discussed in Siemens and Soler-Graham (2003) (PHOTO BY A. H. SIEMENS).

(150 to 650 A.D.) (Coe and Koontz 2002). These complex civilizations were heavily dependent on Mexico's rivers and water resources until the Spanish conquest. It is now well accepted that some prehistoric societies had impacts on watershed processes of various basins. For example, O'Hara et al. (1993) found that in the Mexican Volcanic Belt, conversion of upland forests to traditional slash and burn agricultural land use by prehistoric civilizations resulted in accelerated soil erosion and associated sedimentation, with consequential impacts to downstream aquatic environments, and that the sediment continues to be stored within the basin. Beach (1998) found that slash and burn agriculture and resultant soil erosion in the Maya heartland (Yucatán) produced

distinctive soil horizons. Along the Mexican Gulf Coastal Plain, prehistoric Maya and Toltec practiced floodplain irrigation and wetland manipulation for intensifying agricultural production (Siemens 1980, 1983; Sluyter 1994; Whitmore and Turner 2002). The Olmec were primarily located within the states of Veracruz and Tabasco, from the Tuxla Mountains to the mouths of the Usumacinta, Grijalva, Coatzacoalcos, and Papaloapan rivers, and developed the first conduit drainage system in the Americas. Far to the north, other complex cultures developed, albeit to a somewhat lesser extent and in somewhat later periods. Doolittle (1985, 1988a, 1998b, 2000) provides information on the early development of agriculture, irrigation, and related erosion and other

hydrologic control systems in northwestern Mexico (Sonora and Chihuahua) in areas where the Papago, Pima, Yaqui, and Tarahumara (Rarámuri) peoples, among others, still reside.

The Mayan civilization flourished from about 600 to 900 A.D., reaching a population of approximately 5 million around 700. They inhabited the Yucatán peninsula as well as the states of Chiapas and Tabasco. Covering most of the Usumacinta River basin, the Maya used the river and its tributaries extensively for travel and trade. To the north, the Huasteca region, located along the east-central Gulf Coastal Plain states of Veracruz, Tamaulipas, and San Luis Potosí, is the northernmost major culture region in Mesoamerica, reaching its apex in the Post-Classic period, around 1000. West of the Mayan region, the Aztecs dominated Central Mexico from about 900 to 1521, from the state of Veracruz on the Gulf of Mexico to the west coast states of Guerrero and Oaxaca. The Aztec population had reached an estimated 25 million when conquered by the Spaniard Hernán Cortés in 1521. Cortés's conquest resulted in Spanish rule for about 300 years until Mexican independence was declared in 1810. Thus, like many other regions of North America, prehistoric humans throughout Mexico depended on rivers for travel and food, but the complex societies and higher densities within Mexico likely impacted watershed processes and riverine resources more than in the United States and Canada (O'Hara et al. 1993, Doolittle 2000, Whitmore and Turner 2002).

In this chapter the physical and biological features of five major Mexican rivers are described in detail (see Fig. 23.2). The Río Pánuco drains arid and high-rainfall mountainous areas in east-central Mexico before flowing into the Gulf of Mexico. The combined Usumacinta–Grijalva rivers drain lush tropical rain forest before flowing together into the southern Gulf of Mexico. The Río Candelaria drains the western karstic Yucatán Peninsula. The Yaqui of northwestern Mexico is a desert river draining into the Gulf of California. The Río Conchos is an important tributary of the Río Bravo del Norte (known in the United States as the Río Grande, covered in Chapter 5). Five additional rivers described in one-page summaries include the Chihuahuan Desert's Río Salado, another tributary of the Río Bravo del Norte; the Río Tamesí, which joins the Río Pánuco near its mouth; the Río Fuerte, which flows through some of the continent's largest canyons in the Sierra Madre Occidental to the Gulf of California south of the Yaqui and Mayo rivers; the Ayuquila–Armería river system, which empties into the Pacific Ocean; and the

Río Lacanjá, a small mountainous tributary of the Usumacinta.

Physiography and Climate

Exclusive of Baja California, which has no major rivers and is not further considered, Mexico's physiography, and thus its rivers, is dominated by its mountain ranges. Most rivers drain eastward to the Gulf of Mexico (Atlantic) and Caribbean or westward to the Pacific (including the Gulf of California). Two major mountain systems, the Sierra Madre Oriental and Sierra Madre Occidental, serve as the major drainage divides for the Pacific and Atlantic. However, between them lies the extensive Mexican Altiplano (or Mesa del Norte), which in some instances is characterized by having large areas with rivers draining to closed basins that prehistorically sometimes held large inland lakes, such as the Lagunas Palomas and Mayrán (Smith and Miller 1986), which undoubtedly had some degree of past interconnections. The Mexican Altiplano is bounded to the south by the Trans-Mexican Volcanic Belt, and further south is the Sierra Madre del Sur.

The physiography of Mexico's Pacific slope includes the Buried Ranges province in northwestern Mexico (Arbingast et al. 1975). This arid and hilly region, which includes part of the Sonoran Desert to the north, slopes gradually to the sea as it parallels the mountainous Sierra Madre Occidental province along a northwest–southeast shoreline. Inland, the Sierra Madre Occidental is the major physiographic province of Mexico, at 1200 km long, 200 km wide, and averaging 2000 m asl. It includes some of the world's largest canyons, such as the “Grand Canyon of Mexico” or Barranca del Cobre (Copper Canyon) of the Río Fuerte basin. These mountains parallel and form the western edge of the Basin and Range province that extends from the southwestern United States into north central Mexico and includes the Chihuahuan Desert and Desert Grasslands (northern portion of the Altiplano). Southward, across the Tropic of Cancer in the southern portion of the Altiplano, the Basin and Range rises and the Sierra Madre Occidental declines to form the northern and western edges of a vast tropical–subtropical plateau that makes up the forests and steppes of the Central Mesa province (also called the Central Plateau) and is the southern portion of the Altiplano. Further south, the Central Mesa ends at the Trans-Mexican Volcanic Belt (also called the Neovolcanic Plateau province), a chain of west-to-east-trending volcanic mountains 900 km long but only 100 km wide. These

mountains have numerous active volcanoes, including Mount Orizaba (5747 m asl), the third-highest peak in North America. Significantly, much of the drainage within this extensive volcanic system is interior draining, feeding many large freshwater lakes. Although the rivers, such as the Río Lerma, draining the Mexico City metropolitan area and flowing into these lakes are not further considered, it should be noted that these lakes are distinctive within North America and include many endemic, and often now endangered, aquatic species. To the south of the Volcanic Belt lies the Sierra Madre del Sur province, which extends to Mexico's southern border.

The physiography and drainage patterns of Mexico's Atlantic slope are controlled by three mountain systems: the Sierra Madre Oriental, the Trans-Mexican Volcanic belt, and the Sierra de San Cristobal. The largest, the Sierra Madre Oriental, is a major physiographic province aligned north-south along Mexico's Gulf Coast. These mountains consist predominately of folded Cretaceous limestone, with several ridges exceeding 3500 m asl. Between the Sierra Madre Oriental and the Gulf of Mexico lies the Mexican Gulf Coastal Plain province, a continuation of the U.S. Coastal Plain with seaward-dipping Tertiary and Quaternary strata of marine and fluvial origin (Grubb and Carillo 1988) that extends to the Yucatán peninsula. Compared to the U.S. Coastal Plain, Mexico's Coastal Plain has greater relief because of the structural control imposed by the adjacent mountain systems, and it is much narrower, being widest (150 km) near the Río Bravo (Río Grande) valley and narrowing to the south to pinch out in central Veracruz as the Volcanic Belt intersects the southern edge of the Sierra Madre Oriental (de Cserna 1989). Isolated outcrops of Tertiary and Quaternary volcanics disrupt Coastal Plain drainage patterns and localized topography in southern Tamaulipas and northern Veracruz. Just north of Ciudad Veracruz a small but topographically significant volcanic range, Sierra Punta del Morro, appears to have been a biogeographical barrier to temperate and tropical fauna (Contreras-Balderas et al. 1996, Hulsey et al. 2004) as it extends to the Gulf of Mexico. South of it the Gulf Coastal Plain broadens as it arcs around southern Veracruz and Tabasco, fronting the Bahía de Campeche (part of the Gulf of Mexico). Here the Gulf Coastal Plain borders the enormous carbonate platform of the Yucatán Peninsula. In comparison to the mountainous and Gulf Coastal Plain environments of most of the rest of the country, this region represents a significant change in geomorphology and hydrology. The Yucatán is a

classic example of a karstic landscape, with low relief characterized by predominantly subsurface drainage that has produced numerous caves, cenotes, springs, and solution depressions, and thus few large surface rivers. To the west and south the Yucatán Peninsula borders the Sierra de San Cristobal, a small mountain system of folded Cretaceous limestone (West and Augelli 1989) that is part of a larger system (Chiapas-Guatemala Highlands province) that extends into Guatemala and Belize, but which is distinct from the granitic Sierra de Chiapas of southern Mexico.

Approximately half of Mexico is south of the Tropic of Cancer (23.5°N) and within a tropical climatic regime. The significance of this is that the hydrological mechanisms of Mexico are distinct from those found in the temperate and northern latitudes of North America, and in particular are associated with the strengthening of easterly trade winds in summer months rather than westerly migrating midlatitude cyclones during winter months. Located at the interface between the midlatitudes and the tropics, the climate of Mexico becomes increasingly warm and humid toward the south. Mean annual temperatures exceed 20°C in low elevations of both the east and west coasts, and in the far south, mean annual lowland temperatures exceed 25°C. Temperatures are considerably cooler in mountainous areas, with mean annual values of 10°C to 15°C in the Sierra Madre Occidental and the Volcanic Belt. Seasonal differences in temperature are greater in the north and at high elevations; for example, January mean daily temperatures in the northern montane Sonoran and Chihuahuan deserts are about 5°C, whereas mean daily summer temperatures exceed 30°C. In southern Chiapas, however, mean January temperatures are about 25°C, with mean summer temperatures only a few degrees higher.

Precipitation is highly seasonal throughout Mexico, occurring mainly from summer through early fall with the strengthening of easterly trade winds associated with a northerly shift in the Intertropical Convergence Zone (ITCZ), and the occurrence of tropical cyclones between August and October (Metcalf 1987). Mountain systems exert a significant orographic influence on precipitation, focusing Gulf moisture along the eastern mountain flanks and Coastal Plain and resulting in a steep west-east, low-high precipitation gradient. Mean annual precipitation increases toward the south. The driest regions are in the northern interior, where mean annual precipitation is less than 50 cm in the Sonoran and Chihuahua deserts. East of the

Chihuahuan Desert near the coast, the lower Río Bravo receives 80 cm, and the greatest rainfall exceeds 300 cm in portions of southeastern Veracruz (INEGI 1981c). Midlatitude cyclones (*nortes*) represent only a minor source of precipitation during winter months, occasionally penetrating as far south as Tabasco and Yucatán (West et al. 1969, Metcalfe 1987). Galindo (1995) suggests that ENSO (El Niño) has an influence on seasonal precipitation patterns in eastern Mexico. Specifically, the warm phase of ENSO is associated with increased winter precipitation along eastern Mexico due to a strengthened meridional circulation that results in a higher frequency of midlatitude cyclones penetrating into Mexico (Diaz and Kiladis 1992). In contrast, La Niña years appear related to an increase in summer precipitation because of a higher frequency of tropical cyclones (Jauregui 1995). Thus, La Niña has more significant effects on streamflow and sediment transport than El Niño (Hudson 2003b).

Basin Landscape and Land Use

The variability of the Mexican climate allows this part of North America to support diverse vegetation, including desert, tropical, subtropical, temperate, and montane communities. More than 40 terrestrial ecoregions are recognized based on the recent analysis by the Comisión Nacional para el Conocimiento y Uso de la Biodiversidad (CONABIO) (Ricketts et al. 1999, National Geographic, www.nationalgeographic.com/wildworld/terrestrial.html). Among the largest ecoregions are the Sonoran Desert (northwest) and Chihuahuan Desert (north-central), both characterized by creosote bush, tarbush, mesquites, acacias, yuccas, and diverse cacti. Surrounded by these deserts to the east and west, the diverse Sierra Madre Occidental Pine–Oak Forest ecoregion includes 27 species of conifers and 21 species of oaks. Pine–oak forest ecoregions also characterize other mountainous areas, which roughly correspond to physiographic provinces, such as the Sierra Madre Oriental, Trans-Mexican Volcanic Belt, and Sierra Madre del Sur. In the northeast, along the lower Río Bravo del Norte, is the Tamaulipan mezquital ecoregion, with acacia, desert hackberry, javelina bush, cenizo, common bee-brush or white brush, Texas prickly pear, and tasajillo or desert Christmas cactus. South of the Tamaulipan mezquital is the Veracruz Moist Forests, the northernmost “tropical rain forests,” characterized by many broad-leaved species and extremely high diversity of terrestrial plants and animals. Further south and east are

the Petén–Veracruz Moist Forests, a lowland tropical forest dominated by Mayan breadnut, sapodilla, rosadillo, and gumbo limbo. Various types of dry forest ecoregions are found primarily in western Mexico. In the middle of the continent are arid high plateaus, such as the Meseta Central Mattoral and the Central Mexican Mattoral.

According to a 1993 analysis, land use in Mexico is 12% arable land, 1% permanent crops, 39% permanent pasture, 26% forest, and 22% other (probably mostly arid lands) (www.new-agri.co.uk/02-3/country.html). The major agricultural products are corn, wheat, soybeans, rice, beans, cotton, coffee, fruit, tomatoes, beef, poultry, dairy products, and wood products. Approximately half of the forested area is the coniferous and broad-leaved forests of the more mountainous areas that account for 90% of Mexico’s forest production (www.worldforestry.org/wfi/WF-mexic.htm). The other half of Mexico’s forests is the tropical and subtropical forests of southern Mexico that account for only 10% of forest production.

The Rivers

Abell et al. (2000) defined 25 highly diverse freshwater ecoregions on the basis of the distribution and characteristics of Mexican river basins. The rivers selected for discussion in this chapter cover only a fraction of these ecoregions but were selected to illustrate the diversity of the country’s rivers for which there is a reasonable amount of information. Although the majority of Mexico’s 150 rivers drain into the Pacific Ocean, the majority of the streamflow is discharged from the Gulf Coastal Plain river systems, and the latter receive more attention in this chapter.

The rivers described for northern Mexico (Yaqui, Fuerte, Conchos, and Salado) are arid systems. The Conchos and Salado rivers are both tributaries of the Río Bravo del Norte (Río Grande). The Conchos (Río Conchos ecoregion), the primary drainage of the north-central state of Chihuahua, has historically provided the majority of the flow in the Río Bravo del Norte after most of the latter’s water is extracted for agriculture and domestic uses in New Mexico. The Salado (Río Salado ecoregion) drains eastward across the states of Coahuila, Nuevo León, and Tamaulipas before emptying into Falcon Reservoir on the Río Bravo del Norte, northeast of the large industrial city of Monterrey. The Yaqui (Sonoran ecoregion) and Fuerte (Sinaloan Coastal ecoregion) rivers both drain into the Gulf of California (Pacific

drainage) after arising in the mountains of the Sierra Madre Occidental and flowing through the Sonoran Desert. The Yaqui drains the states of Sonora and Chihuahua, as well as the extreme southeast corner of Arizona, and the Fuerte drains a large part of Chihuahua and small areas of both Durango and Sonora, with its lower reaches passing through Sinaloa. Further south, the Armería–Ayuquila river system (Manantlán–Ameca ecoregion) flows directly to the Pacific Ocean from the states of Jalisco and Colima, south of the large city of Guadalajara.

Most rivers draining into the Gulf of Mexico are from more mesic basins, with five of these, the Grijalva, Usumacinta, Pánuco, Papaloapán, and Coatzacoalcos, accounting for over 50% of Mexico's average annual flow discharged into ocean basins. Here we describe the Usumacinta–Grijalva and Pánuco in some detail. The Río Pánuco is the only major Mexican river located outside of southeastern Mexico. It and its lowermost tributary, the Tamesí, drain the Tamaulipas–Veracruz ecoregion and join near the port city of Tampico. Their headwaters begin in the arid Mexican Altiplano and the mesic Sierra Madre Oriental and flow across the Coastal Plain, draining parts of the states of Tamaulipas, San Luis Potosí, Hidalgo, Querétaro, Mexico, Guanajuato, and Veracruz. The largest river system of Mexico, the Usumacinta–Grijalva (Grijalva–Usumacinta ecoregion), drains into the southern Gulf of Mexico near Villahermosa, Tabasco, from tropical rain forests of Chiapas and Tabasco, although headwaters of both rivers are in Guatemala. The much smaller Candelaria (also Grijalva–Usumacinta ecoregion) to its northeast is one of the larger rivers draining the highly karstic Yucatán Peninsula.

In general, Mexico's major rivers are highly exploited. Northern and central Mexico, which have over 45% of the land area and roughly 60% of Mexico's population, have fewer than 10% of the country's water resources (<http://worldfacts.us/Mexico-geography.htm>). Since arid and semiarid regions are highly sensitive to hydrological change, it is not surprising that easily exploitable water sources have already been developed (Tortajada and Biswas 1997) and rivers in these more northerly regions have become highly degraded. Many dams have been built, primarily for crop irrigation in otherwise desert environments (Contreras-Balderas and Lozano 1994). Water management that favors irrigation, such as in the Ríos Conchos, Yaqui, and Fuerte, often results in a complete elimination of flow, ignoring aquatic biological and ecological concerns. Water pollution from discharge of domestic wastes, high

salinity, and nutrients from irrigation returns, mining, and industrial wastes is widespread throughout Mexico. Such problems are particularly acute in the Pánuco and Conchos, as well as many other rivers not described in this book, such as the Lerma, San Juan, and Balsas. The most pristine waters, containing the greatest biodiversity and the most natural ecosystem functioning, are usually found in the more mountainous regions and in the tropical rain forest of southern Mexico. Even the tropical rain forest rivers are facing extensive exploitation, with plans for multiple hydropower dams that would flood large natural ecosystems as well as important archaeological sites. In particular, biosphere reserve sites in the Usumacinta basin are in considerable peril, both from impoundment and forest exploitation. Thus, although many of Mexico's rivers are already under considerable stress, the situation appears to be getting substantially worse, with an increasing population and associated land-use change and generally limited resources available for conservation of natural resources.

Although Mexico's rivers are under great stress and are poorly studied, the evidence suggests they contain unique collections of aquatic communities (Minckley et al. 1986, Smith and Miller 1986, Miller and Smith 1986, Obregón-Barboza et al. 1994, Abell et al. 2000, Arriaga-Cabrera et al. 2000). The fishes are probably the best known group, and it is clear that there are many species in Mexico found nowhere else in North America. Nelson et al. (2004) list 1277 North American freshwater fishes, with 521 occurring in Mexico (348 endemic), whereas 912 are found in the United States (544 endemic) and 212 in Canada (8 endemic). Mexican endemics thus comprise nearly 28% of the North American fish fauna, and its fauna is more highly endemic (67%) than are those of either the United States (60%) or Canada (4%) (Miller et al. in press, www.mongabay.com/fish/data/Mexico.htm). If these numbers are scaled to account for the differences in area among these countries, the number of Mexican fish species per km² is found to exceed that of the United States by a factor of 2.7 and that of Canada by a factor of 12.4. Numbers of endemic species per unit area in Mexico exceed that of the United States by a factor of 3 and that of Canada by a factor of 220. Such statements about the diversity and uniqueness of Mexico's fish fauna may also be true of its significantly less studied freshwater invertebrates. For example, among the aquatic insects, odonates (dragonflies and damselflies) show similar diversity patterns, with 326 species recorded from the United States, 160 from

Canada (Bick and Mauffray 2004, www.afn.org/~iori), and 342 from Mexico (Paulson and Gonzalez Soriano 2004, www.afn.org/~iori); the hellgrammite genus *Corydalus* has only two species found north of Mexico, but five within Mexico (Contreras-Ramos 1998).

RÍO PÁNUCO

The Pánuco is the second largest (98,227 km²) of the Mexican watersheds draining to the Gulf of Mexico (Hudson 2000). Three major subbasins supply the majority of the system's runoff and sediment: the Moctezuma, Tamuín, and Tamesí (Fig. 23.11). Because the Río Tamesí (19,127 km²) joins the Pánuco near its mouth, it is a distinct system and is considered separately. The Pánuco basin, without the Tamesí subbasin, drains 79,100 km². The Río Pánuco is formed by the confluence of the Ríos Tamuín (33,260 km²) and Moctezuma (42,726 km²) after they cross the Sierra Madre Oriental. The Río Pánuco then meanders 185 km before being joined by the southeasterly flowing Río Tamesí (see Fig. 23.23) at Tampico, Tamaulipas, several kilometers before discharging into the Gulf of Mexico. The small Río Topila (3114 km²) flows north within the Coastal Plain, joining the Río Pánuco 25 km upstream of Tampico.

The major prehistoric culture region associated with the Pánuco system is the Huasteca, located in east-central Mexico along the Gulf Coastal Plain and eastern ranges of the Sierra Madre Oriental (Hudson 2004). Hunters and gatherers occupied the region since at least the mid-Holocene, but there is no evidence that these primitive peoples significantly disturbed the Pánuco system. The Teenek are the major Indian group associated with the Huasteca, but that group is not considered to be homogeneous. The Teenek migrated north along the Coastal Plain before the Maya civilization reached its zenith. Indeed, although the Teenek speak a primitive Mayan language, their material culture is distinct (Ekholm 1944). Although the Huastec civilization did not construct extensive irrigation projects, they settled along the floodplains of the Gulf Coastal Plain to take advantage of the resources, such as shellfish, and to develop extensive floodplain agriculture. Thus, the Huastec would have greatly modified the riparian environments of the lower Pánuco system; however, rather than constructing large population centers, such as the Aztec in the Mexican Altiplano, the Huastec settled in small dispersed villages with the

Pánuco valley serving as the major axis within the Huastec culture region (Hudson 2004). The Huastecans were in decline by the time of Spanish arrival, and were quickly subjugated by the conquistadors, with many fleeing to the adjacent Sierra Madre Orientals, where subsistence agriculture continues to be practiced. The Spanish also contributed to extensive land-use change within the lower Pánuco system, which they found particularly useful for cattle and horse raising, and this area became the focal point of cattle raising in the Americas.

Physiography, Climate, and Land Use

The Pánuco basin drains four major physiographic provinces: the Central Mesa (CM), the north-south Sierra Madre Oriental (SO), the east-west Trans-Mexican Neovolcanic Belt (or Neovolcanic Plateau, NP), and the Mexican Gulf Coastal Plain (CP) (see Fig. 23.11). The regional physiography of the basin has a strong influence on local climate within the basin, especially spatial variability in precipitation.

The basin's precipitation exhibits a steep west-east gradient, becoming increasingly humid toward the Gulf of Mexico (INEGI 1984a, 1984b). Major mechanisms responsible for generating precipitation include trade winds and tropical cyclones during summer months and early fall. Midlatitude cyclones (*nortes*) deliver brief episodes of rainfall during winter months, but collectively are not as significant as summer precipitation mechanisms. Indeed, precipitation for this portion of Mexico averages >12 cm/mo from June through October (Fig. 23.12). Likewise, temperature is highly variable, depending on altitude, but an approximate monthly range for the entire basin is only from about 15°C in January to 24°C in June.

The eastern Central Mesa (or Central Plateau) is semiarid to arid, with average annual precipitation ranging from 30 to 40 cm and occurring mainly from May through October (INEGI 1984a, 1984b). Temperatures on the plateau are mild, but killing frosts are not uncommon during the winter along higher ridges and slopes when *nortes* sweep southward from the United States (West and Augelli 1989). The elevation of the Central Mesa increases south toward Mexico City and the increase in volcanics creates a rugged landscape with greater relief than seen in the northern Altiplano. Near Guanajuato elevations reach 3000 m asl. The major terrestrial ecoregions in this area are the Mexican Central Mattoral and the Meseta Central Mattoral (Ricketts et al. 1999). Vegetation varies within this region; it is largely

limited by the lack of precipitation and consists mainly of desert scrublands, cacti, and short grasslands, with low forests of pine and oak in higher elevations (INEGI 1984c).

The central portion of the Pánuco basin drains the mountains of the Sierra Madre Oriental physiographic province. Within its folded western escarpments, headwater tributaries converge to form the Río Tampaón (draining from the west) and the Río Moctezuma (draining from the southwest), resulting in deeply incised valleys. The mountains here are mainly comprised of Cretaceous limestone, folded into a series of parallel ridges and valleys. In addition to having the greatest relief, this mountainous portion of the basin has the greatest climatic diversity. Average annual precipitation increases from 35 cm in the western mountains to 240 cm along the easternmost escarpments of the Sierra Madre Oriental (INEGI 1981b). Temperatures are moderate at higher altitudes, although light snows are common during winter months along higher ridges, which may exceed 3500 m asl. Desert scrub predominates along the western ranges of the Sierra Madre Oriental. Toward the interior of the mountains to the east and at higher elevations a high diversity of pines and oaks are present within the Sierra Madre Oriental Pine–Oak Forests terrestrial ecoregion (Ricketts et al. 1999, INEGI 1984c), although there may be dramatic differences in vegetation along a single ridge because of east- and west-facing slopes. With increasing precipitation to the east one finds the Veracruz Moist Forests ecoregion, the northern extent of tropical broadleaf evergreen forests (West and Augelli 1989). Traditional farming practices occur throughout the mountains, even on steep slopes, whereas mechanized agriculture and ranching are practiced in the larger river valleys of the Coastal Plain.

The Veracruz Moist Forests ecoregion continues across the Sierra del Abra, the easternmost ridge of the Sierra Madre Orientals, into the Mexican Gulf Coastal Plain physiographic province. The Coastal Plain extends another 90 km to the Gulf Coast at Tampico. Due to significant structural controls imposed by the adjacent Sierra Madre Orientals, the Mexican Gulf Coastal Plain is more complex than the U.S. Gulf Coastal Plain. A south-plunging anticline results in the Río Tamesí and Río Topila being diverted toward the east (Trager 1926, Muir 1936) to eventually join the Río Pánuco just upstream of Tampico. Most of the Tertiary deposits consist of weakly consolidated shale, with thin beds of friable sandstone that are highly erodible and contribute to a more diverse Gulf Coastal Plain landscape than is

seen in the U.S. Gulf Coastal Plain. Just south of Tampico, Tertiary deposits extend to the coast and reach a height of 90 m (INEGI 1984d, 1984e).

Land use and land cover exhibit considerable spatial variability across the Pánuco basin due to the west–east precipitation gradient and the regional environmental history. There is very little large-scale agriculture practiced within the arid western portions of the Sierra Madre Oriental and Altiplano, where small-scale subsistence agriculture confined to the river valleys predominates. One exception is the large-scale citrus production around the city of Río Verde in the central Sierra Madre Oriental. Toward the eastern and increasingly humid ranges of the Sierra Madre Oriental, extensive slash and burn (swidden) agriculture is practiced in river valleys and on toe and steep mountain slopes. Common crops include corn, beans, bananas, coffee, and citrus (Alcorn 1981). Although the forest has the appearance of being natural, in many instances it is secondary or tertiary growth and is heavily managed. In addition to corn and beans grown on small plots, some coffee and citrus are grown within the understory of the forest canopy. The natural vegetation of the Gulf Coastal Plain originally included thornbrush savanna on terraces and lush tropical forests within the river valleys; however, satellite imagery reveals very little forest remaining in the Gulf Coastal Plain (Crews-Meyer et al. 2004). Most of the Gulf Coastal Plain is now used for cattle ranching and farming, a land-use legacy that began in the early 1500s and continues today. Within the river valleys of the western portions of the Coastal Plain, sugar cane and citrus (mixed with some banana and papaya) are the major agricultural products, and this agriculture spread down valley during the twentieth century to displace some former cattle ranching. In part, displacement of ranching in favor of farming within these valleys is due to the Mexican government and the World Bank initiating an enormous irrigation project, designed as one of the largest irrigation systems in Latin America. Due to poor planning, however, the project is largely inoperable and was never completed (Aguilar-Robledo 1999, Hudson et al. in press).

River Geomorphology, Hydrology, and Chemistry

The Pánuco drainage system undergoes tremendous changes in river morphology and hydrology from its headwaters to the coast (Fig. 23.3). From the Central Mesa through the mountains the tributary rivers have

FIGURE 23.3 Lower Río Pánuco at average flow, 40 km upstream of Tampico. Note the small boat for scale (PHOTO BY P. H. HUDSON).

wide and shallow channels adjusted for the transportation of bed load. Within the mountains, rivers have narrow valleys and channels tend to braid with laterally active channel margins. The floodplain consists of narrow ribbons of deposits comprised of coarse sediments, and lack the complexity found in the lower portions of the basin. Because of the high-energy setting within the mountains, floodplain deposits are likely rapidly reworked during extended periods of episodic flooding.

Larger rivers within the Central Mesa have flashy discharge regimes characterized by great differences in base flow and storm flow. Smaller streams are intermittent or ephemeral, transporting water seasonally or only after precipitation events. The Río Tula, the main river in the upper Moctezuma basin, flows north from the edge of Mexico City (see Fig. 23.11). The Río Santa Maria and Río Verde are the major headwater streams for the Río Tampoán (Tamuín) basin and form to the east of the capital

city of San Luis Potosí. Here the river drains mainly Tertiary and Quaternary lacustrine and alluvial deposits of the Central Mesa about 2000 m asl, with isolated Tertiary volcanics having peaks of about 2500 m asl.

Within the mountains, river gradients are highly variable but can exceed 5 m/km in some locations. Spectacular waterfalls occur where tributaries join incised valleys. For example, the Cascada de Tamul is a 102 m waterfall at the confluence of the Ríos Gallinas and Santa Maria, forming the Río Tampoán. The Tampoán and Moctezuma, the two largest tributaries of the Pánuco, exit the Sierra Madre Orientals as formidable rivers. Along the eastern Sierra Madre Oriental, before the Tampoán exits the mountains, it encounters numerous karstic features, including sinkholes, natural bridges, and waterfalls. Surface drainage is often disrupted by solution cavities, manifested in dry valleys and disappearing streams. This water eventually returns as enormous springs along

FIGURE 23.4 Lower Río Tropaón at low stage. The Río Valles enters from the right. Further downstream the Tropaón becomes the Tamuin, and after joining the Moctezuma it becomes the Pánuco. Note the small boat for scale (PHOTO BY P. H. HUDSON).

the lower flanks of the eastern Sierra Madre Oriental. For example, the Río Coy forms from one of the largest springs in the world (Fish 1977) and joins the Río Tropaón upstream of Ciudad Tamuin to become the Río Tamuin (Fig. 23.4).

There are fewer karstic features within the lower Moctezuma basin. Tertiary shale units in the Gulf Coastal Plain produce much larger sediment loads. The Río Tempoal, receiving runoff and sediment from this lithology, enters the Moctezuma in the Coastal Plain at El Higo, resulting in an immediate increase in the sediment load of the Moctezuma and producing café-colored waters that contrast sharply with the clearer spring-fed streamflow of the Tamuin. The Moctezuma transports an annual sediment load of 4623×10^3 tons, whereas the Tamuin transports 2030×10^3 tons annually. Much of the suspended

sediment is transported in early summer and is exhausted before the arrival of larger flood events in September (Hudson 2003a). The two rivers meander through wide alluvial valleys before joining to form the Río Pánuco in the western Gulf Coastal Plain, 185 km upstream of the Gulf of Mexico. Valley gradients are predictably low, decreasing from the western edge of the Gulf Coastal Plain to the Gulf of Mexico. Between Tamazunchale and El Higo, for example, the Río Moctezuma has a gradient of 1.2 m/km, whereas downstream of Ciudad Pánuco the gradient is 0.04 m/km. This extremely low gradient of the lower Pánuco valley enables saltwater to intrude as far upstream as Ciudad Pánuco during low flows and results in a daily tidal exchange between the large lagoons downstream of Ciudad Pánuco (Hudson 2002).

Upon entering the Gulf Coastal Plain, the Moctezuma and Tamuin valleys widen considerably, and the rivers develop meanders. Holocene floodplain deposits increase in complexity and include deposits representative of lateral and vertical floodplain construction, such as point bar, natural levee, backswamp, crevasse splay, and infilled paleochannels. In several reaches the river is in contact with Tertiary outcrop, the contrasting resistance of which disrupts the planform geometry from a symmetrical meandering pattern (Hudson and Heitmuller 2003). The sinuosity (ratio of channel length to valley length) of the Río Pánuco averages 1.85 over its 185 km channel but shows considerable variability where the river is reworking more resistant Tertiary deposits (Hudson 2002). The lower 30 km of the Río Pánuco is incised into Holocene deltaic deposits with sinuosity of 1.15, essentially a straight channel. The fine-grained clayey bank sediments are sufficiently cohesive to resist erosion, and the lack of sandy bed material does not permit point bar construction. Moreover, at the lower limits of the delta, shortly before discharging into the Gulf of Mexico, the Río Pánuco is incised into a ridge of Tertiary sandstone that prevents lateral channel migration (INEGI 1984e).

Lakes and wetlands are largely absent in the mountains and Central Mesa but become more common in the lower reaches of the basin, where they are related to floodplain geomorphology (Hudson 2002). Abandoned channel courses and meander neck cutoffs serve as oxbow lakes and arcuate swamps, depending on the degree of infilling. Such lakes and wetlands are common in the lower Moctezuma and Tamuin valleys and upper Pánuco valleys. Backswamps, evidence of long-term floodplain stability, are common where valley width is sufficient. In the lower Pánuco and lower Tamesí valleys, large lakes and wetlands form between meander belts and resistant Tertiary deposits that serve as topographic drainage barriers. Although these features were naturally created, the river water is used by the city of Tampico and so is heavily regulated by a system of weirs and control structures. The lagoons and wetlands in the lower Tamesí are tidal and important to the regional fishery, and provide vital habitat for an array of North American migratory waterfowl.

Average discharge of the Río Pánuco at Pánuco, upstream of the Tamesí and Topila, is 473 m³/s, and the annual discharge regime strongly reflects the regional precipitation pattern for eastern Mexico (Hudson 2000). Discharge and runoff are uniformly low from December through early May but increase rapidly with the onset of summer trade winds in late

May (see Fig. 23.12). Peak discharge events usually occur in September, often associated with an increase in tropical cyclone activity (Hudson and Colditz 2003).

In spite of the strong seasonal pattern of runoff, only the largest floods generated by tropical cyclones inundate the entire valley. Mechanisms for inundating the floodplain include a rise in the water table of the alluvial aquifer; conduits, such as crevasse channels and paleochannels connected to the active channel; and local precipitation (Hudson and Colditz 2003). The timing of flood events is similar for the Río Tamuin and Río Moctezuma, although the more humid Moctezuma basin supplies the majority of flow. In addition, the hydrograph for the Tamuin is less flashy than the Moctezuma, probably because more of its discharge derives from groundwater and spring-fed sources (Hudson 2003b). In comparison to the Usumacinta–Grijalva system to the south, the Pánuco is not as flood prone because the floodplain is approximately 10 m above average stage. For example, at Ciudad Pánuco, ~30 km west of Tampico, the floodplain is elevated above the water surface by 12 m where the valley crosses the axis of an anticline. Indeed, the abundance of prehistoric sherds along the channel banks attests to this site long being considered less likely to flood (Ekholm 1944, Hudson 2004).

Although information on water chemistry of the Pánuco system is not easily accessible, it is clear that the river and its tributaries are seriously threatened by pollution from agrochemicals, municipal discharge, and salinization (Abell et al. 2000).

River Biodiversity and Ecology

The Río Pánuco is the major river within the Tamaulipas–Veracruz freshwater ecoregion (Abell et al. 2000), where CONABIO has identified several priority sites for conservation. Although information is available on fishes of the river, other aspects of biodiversity and ecology are less well known.

Plants

Information on aquatic plants and major riparian vegetation is not easily accessible for the Pánuco system. However, nonnative hydrilla is found in some of the oxbows and sloughs of the major valleys in the Gulf Coastal Plain.

Invertebrates

Information on invertebrates also is sparse, although some information is available on mollusks,

crustaceans, and hellgrammites. Crustaceans found in the Pánuco system include the freshwater shrimp *Palaemonetes mexicanus*, as well as the cave-dwelling shrimps *Troglomexicanus perezfantaie*, *T. huastecae*, and *T. tamaulipenses*. The crayfishes include *Procambarus (Ortmannicus) ortmanii*, *Procambarus (Ortmannicus) acutus cuevachicae*, and *Procambarus (Scapullicambarus) strenghi*, and mollusks include *Hydrobia tampicoensis*, *Littoridina crosseana*, and *Lithasiopsis hinkleyi* (A. Contreras-Ramos, personal communication). Among the aquatic insects are the hellgrammites *Chloronia mexicana* and *Corydalus magnus* (Contreras-Ramos 1998). Abell et al. (2000) state that the Tamaulipas–Veracruz freshwater ecoregion (of which the Pánuco is a major part) has 17 endemic species of crayfish, although the specific species are not mentioned.

Vertebrates

The Río Pánuco (not including the Río Tamesí) harbors at least 80 described native fish species, with more than one-third of them endemic (Miller and Smith 1986, Rauchenberger et al. 1990). Much of the basin is remote and underexplored by ichthyologists, and many more species (notably cichlids, catfishes, and goodeids) surely will be discovered and described in the near future. The much smaller and more thoroughly sampled Río Tamesí has at least 93 fish species. Notable Pánuco endemics among the cichlids include the Media Luna cichlid, blackcheek cichlid, chairrel cichlid, and slender cichlid. There are also several endemic goodeids, including bluetail splitfin, dusky goodea, relict splitfin, and jeweled splitfin, all but the last endemic. Among pupfishes, the endemic, endangered, monotypic genus *Cualac* is noteworthy. Swordtails (genus *Xiphophorus* of the family Poeciliidae) include many endemic species and are popular in the aquarium trade and important as research organisms (Ryan and Rosenthal 2001). They are diverse and well studied in this basin, including sheepshead swordtail, short-sword platyfish, delicate swordtail, highland swordtail, Moctezuma swordtail, barred swordtail, mountain swordtail, Pánuco swordtail, pygmy swordtail, and variable platyfish (Rauchenberger et al. 1990). The minnow family, nearing its southern distributional limit, also is represented by numerous endemics, especially in the genus *Dionda* (Pánuco minnow, bicolor minnow, chubsucker minnow, lantern minnow, flatjaw minnow, blackstripe minnow), which includes several sympatric species pairs

(Mayden et al. 1992). An extremely rare and endangered blind cave catfish, the phantom blindcat, recently discovered in the Río Guayalejo in southernmost Tamaulipas (Walsh and Gilbert 1995, Hendrickson et al. 2001) presents an interesting evolutionary enigma (Willcox et al. 2004). Many caves of this region harbor the blind form of Mexican tetra, which may well be one of the most studied nongame fishes of North America (e.g., Mitchell et al. 1977, Langecker et al. 1995, Borowsky 1996, Jeffrey 2001, Dowling et al. 2002). Several more fascinating cave fishes are likely to be discovered in this large karstic river basin. Larger fishes include the endemic large native fleshylip buffalo and the endemic Río Verde catfish.

Abell et al. (2000) mention that nonnative tilapias (*Oreochromis* spp.) are a problem in this basin, having irreversible negative impacts on the native fauna as seen throughout much of Mexico, and we concur (D. A. Hendrickson, personal observations). Fish culturists have, unfortunately, also introduced herbivorous cyprinids (grass and silver carps), channel and blue catfish, largemouth bass, and other centrarchids, to mention only some nonnatives (García de León et al. in press). These will undoubtedly impact native faunas via hybridization (catfishes especially) and competition or habitat alteration.

A high diversity of other aquatic vertebrates is present in the Pánuco basin, but there are no basinwide compilations of aquatic herpetofauna, birds, or mammals. Abell et al. (2000), however, state that the Tamaulipas–Veracruz freshwater ecoregion contains at least 16 endemic species of aquatic herpetofauna.

Ecosystem Processes

Although there have been no ecosystem studies done in the Río Pánuco, this system offers an interesting contrast with the River Continuum Concept (Vannote et al. 1980). Instead of headwater streams beginning in high-altitude forests, they begin in the arid Central Mesa, then flow through pine–oak mountain forests and finally through tropical rain forests at lower elevations. The upper arid streams, both spring fed and not, appear to be supported by autochthonous production (with several herbivorous fishes, such as *Dionda* species, and abundant grazing snails in some streams). There is, however, likely to be a major shift to increasing allochthonous inputs as the major tributaries flow first through the mountains and then into the Gulf Coastal Plain as turbidities increase.

Human Impacts and Special Features

Before colonization by major civilizations, the Río Pánuco system must have exhibited some of the greatest physical and ecological diversity of the region. Draining from arid plateaus in its headwaters, its tributaries cut through the rugged pine–oak forests of the Sierra Madre Oriental, entered the Veracruz Moist Forests in the eastern ranges, and then spilled into the low-gradient tropical forests of the Coastal Plain. Among the scenic features are spectacular waterfalls, natural bridges, tremendous sinkholes, enormous springs, and some of the world's most extensive and deep cave systems, dropping from high pine and cloud forests precipitously to foothills. The transition in physical features along this river continuum was undoubtedly reflected in major transitions of its biological communities. Although many of the river's scenic physical features still exist, it is likely that remnants of its natural aquatic communities will be found primarily in tributaries that have been spared the exploitation and pollution found throughout much of the system.

Because of the physical diversity and history of land use, the Pánuco system has been impacted by humans in many ways. It is difficult to establish causal relationships on the current status of the system. However, it is worthwhile to provide a brief characterization of these different activities.

Upper arid portions of the basin are impacted by the legacy of mining. In smaller valleys, check dams (*trincheras*) are emplaced. These small structures result in infilling of sediment and increase the arable land area. Perhaps the most significant human impacts in the upper reaches involve pollution. Although Mexico City is not within the Pánuco basin, a network of canals delivers raw sewage from that metropolitan area to the Río Tula, a tributary of the Río Moctezuma. An even greater threat to the system, however, may be that headwaters of the basin drain the mining district of Mexico. Old colonial cities such as San Luis Potosí, San Miguel de Allende, Guanajuato, and Queretero were established centuries ago by Spain and extensive silver, copper, heavy-metal, and semiprecious stone mining operations remain. Unfortunately, mismanagement of these operations has resulted in extensive environmental damage that is contaminating many of the regional drainage systems, and these contaminants are likely adsorbed to fluvial sediments transported by the Pánuco system. Another form of mining, groundwater pumping for agriculture, is having profound

negative impacts on some important endemic fish habitats of the arid altiplano that are drained by this river system.

Although dams are not as extensive as in some other river basins of Mexico, they interact negatively with other human impacts, and future dams are in the planning or construction phases. In the mountainous middle reaches there is a large dam on the Río Moctezuma, upstream of the major inputs of streamflow and sediment on the arid western side of the Sierra Madre Oriental. A new hydroelectric dam is under construction in the lower Río Tamuin (at Ciudad Tamuin), approximately 75 km upstream of the confluence with the Moctezuma. How this will influence river morphology and ecology remains to be seen, although at a minimum it will contribute to the hydrologic fragmentation and reduce downstream sediment loads. In the lower reaches of the basin there are few engineering modifications influencing the drainage basin hydrology, although artificial flood-control levees were constructed along selected reaches of the lower Pánuco after the devastating flood of 1955. Here the river is a freely meandering channel, as there have been no artificial cutoffs or bank protection works constructed to reduce lateral migration. Although the prehistoric legacy did not leave a conspicuous imprint, agriculture during the twentieth century extensively altered composition of the riparian corridor. Because of the significant fluctuation in the water table of the alluvial aquifer, most agriculture requires irrigation. In some instances the oxbow lakes are used for irrigation, but primarily the water is locally pumped directly from the channel. Chemical fertilizers and pesticides used for sugarcane farming throughout the lower Pánuco basin are of concern and have resulted in extensive pollution of the lower Tampaón (Tamuin) system, particularly downstream of Valles. More significant impacts, however, are likely to occur due to contamination of river sediments associated with the extensive petroleum activities along the lower river. Petroleum was discovered in the lower Pánuco basin in 1904, and this is the oldest region of petroleum development in Mexico.

RÍOS USUMACINTA–GRIJALVA

Draining 112,550 km² of southern Mexico, the Usumacinta–Grijalva drainage system is the largest in Mexico. The basin has two distinct regions, the mountainous uplands and the Coastal Plain in

FIGURE 23.5 Upper portion of Río Usumacinta (Río Lacantún) (PHOTO BY H. BAHENA).

Tabasco, both receiving ample amounts of rainfall (Fig. 23.13). The main rivers within this system are the Usumacinta and Grijalva, both with headwaters in Guatemala (35% of entire basin) but with 45% of their basin in Chiapas, Mexico's southernmost state. The Usumacinta drains western Chiapas, serves as the international border between Mexico and Guatemala, and is joined by the San Pedro downstream of Tenosique (Fig. 23.5). The Grijalva begins as the Río San Miguel in Guatemala becomes the Grijalva in Mexico and is joined by several large tributaries, including the Río Suchiapa, which drains the Sierra Madre de Chiapas of western Chiapas. As

it flows toward the Coastal Plain the Grijalva also receives drainage from the eastern margins of the states of Oaxaca and Veracruz. The Grijalva and Usumacinta join, but only partially, near Frontera, Tabasco, about 15 km above their mouth in the Gulf of Mexico (Rodiles-Hernández 2004).

The basin has a rich legacy of prehistoric human history, and prior to the Spanish arrival supported a dense population. Uplands in Chiapas were probably densely populated by the Maya during that culture's Classic period from 150 to 650 A.D. (West et al. 1969), and the area underwent land-use change as a consequence of slash and burn agriculture. The lower

reaches of the basin were colonized by several different Indian groups and served as an important trading link between the Aztec to the west and the Maya in the Yucatán. Indeed, lowland Tabasco long formed the western edge of Mayan civilization during the Classic period, and the eastern fringe of the Olmec heartland, the most ancient of the great Mexican culture groups (Coe and Koontz 2002). Most prehistoric settlement in lower portions of the basin occurred along broad natural levees of mainstem channels and distributaries, with higher grounds of the levees providing safety from frequent lowlands flooding. Prehistoric peoples residing in lowlands practiced slash and burn agriculture of maize, beans, squash, and various types of tubers. The wet climate enabled cacao cultivation and that product was used extensively throughout the region for trading (West et al. 1969). Although there are few reliable population estimates from the time of Spanish conquest, archaeological evidence suggests that indigenous populations had already declined but were decimated by the Spanish after contact and did not recover until the mid-nineteenth century (West et al. 1969).

Physiography, Climate, and Land Use

Three physiographic provinces are represented in the Usumacinta–Grijalva basin (see Fig. 23.13). The largest is the Chiapas–Guatemala Highlands (CG), with its mountainous uplands, primarily in Chiapas. The other major province is the Mexican Gulf Coastal Plain (CP) to the north, mostly in Tabasco. A small part of the basin (upper Río San Pedro drainage) is in the Yucatán (YU) province to the east.

Fundamental differences in lithology of the headwaters of the Usumacinta and Grijalva result in differences in surface erosion and drainage patterns. The Usumacinta drains the extensive folded block of Cretaceous limestone of the Sierra de San Cristobal, which approaches 3000 m asl. This range is part of a more extensive mountain system that reaches 3500 m asl in northern Guatemala, where it is known as the Sierra Alto Cuchumatanes (West and Augelli 1989). The folded terrain of the upper Usumacinta produces a trellis drainage pattern. As is common in limestone regions with abundant precipitation, there is considerable subsurface dissolution that creates numerous karst landforms, particularly in the eastern portions of the basin. Common topographic features include cenotes (sinkholes), disappearing streams, and major spring systems. In contrast to the limestone of the Sierra de San Cristobal, the upper Grijalva basin drains the granitic Sierra Madre de

Chiapas, part of a much larger mountain system that extends throughout Central America. Along its eastern fringes the lithology includes deeply weathered Tertiary shale and sandstone that produce much higher rates of surface erosion than are seen in the Usumacinta system.

In contrast to the Pánuco system, which has its headwaters in the arid and semiarid Central Mesa, the upper reaches of the Usumacinta–Grijalva system receive abundant precipitation (West et al. 1969). Annual precipitation ranges from more than 400 cm along the eastern side of the Sierra de San Cristobal to 80 cm in the Sierra Madre de Chiapas highlands of the western Grijalva basin (INEGI 1981c). Most of the basin is influenced by a tropical monsoon precipitation regime set up by seasonal northeasterly trade winds and tropical cyclones that persist from early summer through early fall, although less seasonality characterizes the swampy lowlands near Villahermosa, Tabasco. The highlands also are tropical, but drier in winter and less humid. Temperatures are hot in the lowlands but decrease with altitude. At lower elevations average daily high temperatures range from 29.4°C to 32.2°C. At 2000 m asl temperatures are moderate for most of the year, with average daily highs from 23.9°C to 26.7°C, but killing frosts occur several times per year (West and Augelli 1989). There can be wide variation in temperature between mountains and lowlands, but mean monthly temperatures from four climate stations throughout the basin (Villahermosa, Ville Flores, Pichucalco, Huehuetenango) give an annual mean temperature of 23°C. When viewed on a basinwide scale, mean monthly temperatures fall to only about 20°C in January and are consistently about 25°C from April through August (Fig. 23.14). On the other hand, mean monthly precipitation for the basin is strongly seasonal, being less than 8 cm/mo from February through April but exceeding 20 cm/mo from June through October (see Fig. 23.14). Annual precipitation for the entire basin is estimated to be 199 cm based on the four climate stations.

Much of the basin was originally covered in tropical rain forest, part of a larger zone of tropical broadleaf evergreen forest that extends from the southeastern portions of the Moctezuma (Pánuco) basin throughout eastern Central America to represent Mexico's most extensive forests. Large portions of this forest have been removed for coffee plantations and cattle ranching, whereas smaller plots are used for slash and burn (swidden) agriculture. What may appear to be pristine forest is now more likely secondary or tertiary growth (West and Augelli

1989). In the cooler environment above 3000 m asl, large tracts of evergreen coniferous trees are common, as well as deciduous broadleaf vegetation more commonly associated with higher latitudes. The upper Grijalva basin drains the Chiapas Depression Dry Forests terrestrial ecoregion, consisting largely of pine–oak forests (Ricketts et al. 1999, www.nationalgeographic.com/wildworld/terrestrial.html). A larger high-elevation ecoregion to the north, west, and east of the dry forests is the Central American Pine–Oak Forests, including a high diversity of endemic plant species. To the north of these pine–oak forests is the Chiapas Montane Forests ecoregion, a relatively narrow strip of extremely high precipitation on the steep northeastern slopes of the Chiapas highlands.

The Tabascan lowlands include lush tropical rain forests and extensive wetlands, but much of the tropical rain forest in the Usumacinta–Grijalva basin is part of the larger Petén–Veracruz Moist Forests ecoregion, which extends to the Pánuco basin to the northwest. Wetlands of this basin include saltwater and freshwater marshes, many within the Pantanos de Centla ecoregion, a seasonally flooded moist forest with associated bogs and swamps. Closer to the mouths of both rivers is the Usumacinta Mangroves ecoregion, a complex system of marshes and bogs, considered to be one of the most important wetlands in Mexico, with mangroves that reach 30 m in height.

Revenga et al. (1998) reported that land cover in the Usumacinta portion of the two-river drainage is 59% forest, 30% cropland, 7% grassland, and 3% developed, with a mean population density of 25 people/km². These same authors also reported a 37% loss of original forest. Historically, cattle ranching and tropical agriculture (cacao, bananas, sugar cane, henequen) were the most important industries in the lowlands of both rivers, but they are now second to the petroleum industry, the major economic force within Tabasco. As with the lowlands, subsistence agriculture is still practiced by small communities in the mountainous portion of the basin, although coffee production is also important.

River Geomorphology, Hydrology, and Chemistry

The Usumacinta and Grijalva rivers are Mexico's longest rivers, with a combined total of 1521 km of main-stream channel in Mexico (www.cna.gob.mx 2004). Although the Río Usumacinta remains unpounded, the Río Grijalva has two large dams (Presa

Nezahualcóyotl or Malpaso and Presa de la Angostura or Belisario Domínguez) constructed in the 1960s and 1970s, and so now serves as a major source for hydroelectric power generation (see Fig. 23.13). Both rivers flow through spectacular gorges in the upper reaches of the basin but become increasingly sinuous as the valleys widen in the Coastal Plain. Coastal Plain geology is characterized by a sequence of seaward-dipping Pleistocene terraces and, closer to the coast, Holocene deltaic deposits that overlap Pleistocene terraces. It is here that the rivers form a complex system of interconnected channels (West et al. 1969), with multiple channel bifurcations that result in no single channel carrying the entire discharge of the basin. As several channels may transport streamflow only during flood events, the result is a mosaic of wetlands interconnected by arcuate swamps and sloughs. Saltwater intrusion during the dry season creates favorable habitat for extensive mangrove swamps. Other types of wetlands include freshwater backswamps, estuarine, and abandoned channels and sloughs.

In the Tabascan lowlands, geomorphology and flood regime of the rivers are intricately related. Floods are of long duration, with the Grijalva the most prone to flooding. Flooding is important because it transports sediment overbank, forming broad flanking natural levees that are an essential component of the landscape. Coarse sediments (silty sand) and higher slope of the natural levees permits rapid drainage. For this reason natural levees do not remain inundated long after peak flood events, and they have therefore been favored sites for human settlement over the past few millennia and continue to be important for agriculture. Levees, however, also increase the severity and duration of flood events by preventing floodwaters from draining back into the river, and because of the extensive size of the delta plain, flooding can occur from local precipitation collecting in the basins.

Before joining upstream of Frontera, both the Grijalva and Usumacinta have split much of their flows into distributaries. The Grijalva, also known as the Río Mezcalapa in the lower mountains, splits into several channels after it enters the Coastal Plain. One of the channels is the Río Samaria, which becomes the Río Cañas before flowing into an extensive marsh and wetland system, never reentering the main-stem channel. Another distributary, the Río Carrizal, transports approximately one-third of the Mezcalapa discharge and subsequently becomes the Grijalva upstream of Villahermosa (West et al. 1969). To make the system even more complicated, two smaller

basins, the Chilapa (7000 km²) and Sierra (5180 km²) systems, flow into the Grijalva shortly before it joins the Usumacinta (West et al. 1969). Similarly, the Usumacinta has at least two major distributaries (Río Palizada, Río San Pedro) that split from the main channel before it joins the Grijalva. Thus, although the Usumacinta and Grijalva rivers partially join to form a single channel near the coast, much of the discharge from these two basins never flows within a single channel, finding multiple pathways to the Gulf of Mexico.

The discharge and runoff of the entire Usumacinta–Grijalva system is thus complicated and somewhat difficult to quantify. Daily discharge of the Río Usumacinta before it splits into distributaries was measured at the Boca del Cerro gauging station (near Tenosique) from 1949 to 1983 (UNESCO website by I. A. Shiklomanov, <http://webworld.unesco.org/water/ihp/db/shiklomanov/index.shtml>), and average discharge over that period was estimated to be 1857 m³/s. In contrast to the long-term record of the Usumacinta, only a single estimate of 821 m³/s is available from 1960 for the Grijalva (Río Mezcalapa) before it branches into distributaries within the Coastal Plain (West et al. 1969). Thus, an approximate total for the combined drainage is 2678 m³/s, even though the partially combined rivers never carry nearly this much water in a single channel on average. A long-term estimate (most years from 1947 to 1981) of 532 m³/s exists for the Río Samaria, a distributary of the Mezcalapa that never joins the Usumacinta. Thus, only about one-third of the Grijalva discharge (Río Carrizal) joins with only a portion of the Usumacinta discharge north of Villahermosa before they form a single channel to the Gulf of Mexico.

Estimates of monthly runoff are presented only for the single site on the Usumacinta at Boca del Cerro (UNESCO, <http://webworld.unesco.org/water/ihp/db/shiklomanov/index.shtml>), which represents approximately 43% of the entire two-river basin (see Fig. 23.14). For this portion of the basin, annual runoff is extremely high at 123 cm, and monthly runoff exceeds 10 cm/mo from July through December (see Fig. 23.14). Although Fig. 23.14 suggests that runoff is 62% of precipitation (estimated from four weather stations as 199 cm), this percentage is unrealistically high. Runoff for the entire Usumacinta–Grijalva basin is only about 74 cm because the Grijalva basin has less precipitation and contributes much less discharge than the Usumacinta. Thus, discharge to the Gulf of Mexico is roughly 38% of precipitation, rather than 62%. This is still a relatively

high-percentage runoff for a basin with high temperatures and high evapotranspiration.

The Río Grijalva has a much larger sediment load than the Usumacinta due to high uplands erosion rates. The Río Usumacinta transports an annual load of 6257×10^3 tons of sediment, whereas the Río Grijalva transported $24,134 \times 10^3$ tons annually (before the dams and reservoirs were constructed; West et al. 1969).

Little information was found on water chemistry for the Grijalva–Usumacinta or its tributaries. Water quality is assumed to be good in the upstream reaches where there is little development and extensive vegetation, but it likely deteriorates with industrial development in the lower reaches.

River Biodiversity and Ecology

According to Abell et al. (2000), the Usumacinta–Grijalva basin is located within the Grijalva–Usumacinta freshwater ecoregion, which also encompasses the southern portion of the Yucatán Peninsula (including the Río Candelaria). The region is poorly studied in terms of its biodiversity and ecology, although some information exists on its fishes and aquatic insects.

Plants

Riparian trees and brush of wetland forests include *Andira galeottiana*, *Pachira acuatica*, *Bravaisia integririma*, *Bravaisia tubiflora*, bloodwoodtree, gregorywood, *Paquira aquatica*, willow, and mimosa. Important plants of the mangrove flooded zones are button mangrove, black mangrove, white mangrove, and American (or red) mangrove (Breedlove 1981, Ocaña and Lot 1996). Emergent aquatic plants include bent alligator-flag, common cattail, southern cattail, and common reed, and American eelgrass is an important submerged species (Lot and Novelo 1988). Floating aquatic plants form dense covers in places: water snowflake in clear waters, whereas dotleaf waterlily and nonnative water hyacinth are common in stagnant water and disturbed areas of the lower parts of the basin.

Invertebrates

Information on the invertebrates of this system is sparse. Among mollusks there are applesnail (Mexican), minute hydrobe, *Aroapyrgus clenchi*, *A. passionensis*, *Cochliopina infundibulum*, *Pachychilus chrysalis*, and *P. pilsbryi* (A. Contreras-Ramos, personal communication).

Reports on aquatic insects are also rare, but Bueno-Soria et al. (in press) describe the fauna in major tributaries of the lower Grijalva system and at other sites within this region. Taxa reported here are all from the Grijalva system: the Río Carrizal, Río Samaria, and Río Mezcalapa–Grijalva. Although these lists probably only include a fraction of the taxa in this region, they give some idea of the diversity of insect communities in these rivers. The fauna includes six families of mayflies, five families of odonates (dragonflies and damselflies), twelve families of aquatic bugs, nine families of aquatic beetles, and five families of aquatic flies, but only three families of caddisflies. The hellgrammite *Corydalus luteus* is also present in the Grijalva–Usumacinta basin (A. Contreras-Ramos, personal communication).

Among the mayflies from Bueno-Soria et al. (in press) were Baetidae (*Baetis*, *Camelobaetidius*), Ephemeridae (*Hexagenia*), Heptageniidae (*Heptagenia*, *Stenonema*), Leptophlebiidae (*Leptophlebia*, *Traverella*), Polymitarcyidae (*Campsurus*), and Tricorythidae (*Leptohyphes*, *Tricorythodes*). Odonates included Gomphidae (*Archaeogomphus*, *Phyllocyca*, *Progomphus*), Libellulidae (*Libellula*, *Miathyrria marcella*, *Pachydiplax*, *Tauriphila*), Protoneuridae (*Protoneura*, *Neoneura*), Calopterygidae (*Hetaerina*), and Coenagrionidae (*Argia*, *Argiallagma* [= *Nehalennia*], *Heteragrion*, *Zonagrion*). The bugs included Belostomatidae (*Belostoma*), Corixidae (*Tenagobia*), Gelastocoridae (*Nertha*), Gerridae (*Rheumatobates*, *Trepobates*), Hydrometridae (*Hydrometra*), Pleidae (*Paraplea*), Veliidae (*Microvelia*, *Platyvelia*, *Rhagovelia*), Macroveliidae (*Macrovelia*), Mesovelidae (*Mesovelia*), Gerridae (*Metrobates*, *Neogerris*), Naucoridae (*Ambrysus*, *Pelocoris*), Nepidae (*Ranatra*), and Notonectidae (*Martarega*). Caddisflies included only Hydropsychidae (*Smicridea*), Hydroptilidae (*Neotrichia*, *Ochrotrichia*), and Leptoceridae (*Nectopsyche*), but the hydropsychids were found at most sites. Bueno-Soria et al. found more genera of aquatic beetles than any other order, including Hydrophilidae (*Anacaena*, *Berosus*), Dytiscidae (*Brachyvatus*, *Laccophilus*, *Pachydrus*, *Thermonectus*), Hydrophilidae (*Derallus*, *Enochrus*, *Helochares optiata*, *Paracymus*, *Tropisternus ovalis*), Haliplidae (*Peltodytes*), Hydraenidae, Gyridae (*Gyretes boucardi*), Hydrochidae (*Hydrochus*), Limnichidae, Noteridae (*Hydrocanthus*, *Suphisellus*), and Scirtidae (*Ora*). Chironomidae were the most widely distributed dipterans, but they were not identified beyond family by Bueno-Soria et al. (in press). In addition to the taxa collected in the river segments mentioned already,

Bueno-Soria et al. also provide more extensive lists of the aquatic insects of Tabasco.

Vertebrates

Miller (1986) mentions a total of 115 fish species known from the Grijalva–Usumacinta system in Mexico (Minckley et al. 2005), but a recent compilation for the entire state of Chiapas documents the presence of 111 species. These are from at least 52 genera in 29 families, with 76 (74%) species native freshwater (primary and secondary), 18 (17%) marine, and the remainder marine forms now isolated in freshwater. Four families contain 58% (68) of the species: 33 cichlids (30%), 22 poeciliids (16%), 9 characids (8%) and 4 profundulids (3.6%) (Rodiles-Hernández 2004). These same families provide most of the large number of endemic species (60 to 70). Noteworthy species are from the Characidae (longjaw tetra), Profundulidae (headwater killifish), Poeciliidae (widemouth gambusia, Chiapas swordtail, sulphur molly, upper Grijalva livebearer), and Cichlidae (white cichlid, Angostura cichlid, Montechristo cichlid, Usumacinta cichlid, freckled cichlid, Teapa cichlid). Among the euryhaline species are threadfin shad, longfin gizzard shad, Maya sea catfish, freshwater toadfish, Gulf silverside, Maya needlefish, Mexican halfbeak, Mexican mojarra, and freshwater drum. In addition, there are 11 endangered species: Pénjamo tetra, Lacandon sea catfish, pale catfish, Olmec blind catfish, Chiapas killifish, Palenque priapella, Yucatán molly, Chiapas cichlid, tailbar cichlid, Petén cichlid, and Chiapa de Corzo cichlid.

Nonnative species from four families have been introduced primarily for aquaculture: Cyprinidae (common carp and grass carp), Salmonidae (rainbow trout), Centrarchidae (largemouth bass), and Cichlidae (blue tilapia, redbelly tilapia, Nile tilapia, Mozambique tilapia, and jaguar guapote) (Rodiles-Hernández 2004). Some species are fished commercially, such as tropical gar, common snook, blue catfish, white mullet, giant cichlid, and tilapias.

Though the diverse fish fauna of the Usumacinta–Grijalva has been relatively well studied, recent discovery in the Río Lacantún (upper Usumacinta) of a new species in an entirely new catfish family illustrates how little we know of this portion of North America (Rodiles-Hernández et al. 2000, Rodiles-Hernández et al. 2004). This large species (up to 500 mm standard length) is relatively common, with its description based on over 30 specimens, some of which were obtained from local residents who

include it in their diets. Its evolutionary origins remain enigmatic, with extensive and detailed analyses of morphology and DNA sequence data failing to reveal any obvious relationships to any of the world's other catfish families. Obviously, if something so unusual, so large, and so obvious can remain unknown to science for so long in this remote basin, many more discoveries can be anticipated.

Amphibians and reptiles associated with riparian habitats of the Usumacinta–Grijalva system include river crocodile, swamp crocodile, common snapping turtle, tortugas blanca, and tortugas casquito. According to Abell et al. (2000), there are 82 species of native aquatic herpetofauna in the Grijalva–Usumacinta freshwater ecoregion of which 12 are endemic. Mammals include neotropical river otter, West Indian manatee, water opossum, tepezcuintle, greater bulldog bat, and Baird's tapir (March et al. 1996, Rodiles-Hernández et al. 2002).

Ecosystem Processes

There are no known studies of ecosystem processes in the Usumacinta–Grijalva system. Although much of the region is forested, ecosystem processes are likely to be quite variable, particularly between the high-gradient uplands and the influence of flooding in the low-gradient Tabascan lowlands.

Human Impacts and Special Features

The Usumacinta–Grijalva system is not only Mexico's largest river system but probably retains more invaluable natural features than any other large system, as well as having great archeological value as the center of the ancient Mayan culture. It contains part of the largest remaining tropical rain forest north of the Amazon and, in recognition of its importance, several parks and biological reserves have been established in the basin, including the Pantanos de Centla Biosphere Reserve (a RAMSAR wetland), Laguna del Tigre National Park in Guatemala (also a RAMSAR wetland), Selva Maya (Maya Forest), Montes Azules Biosphere Reserve, Lacantun Biosphere Reserve, and Maya Biosphere Reserve in the Petén of Guatemala (the region's largest "protected area").

Although the Usumacinta and Grijalva rivers include some of the most remote areas of Mexico, the drainage systems are impacted by anthropogenic activities. Deforestation is occurring in upper portions of the drainage basin, resulting in loss of

Chiapas's once extensive tropical forests. The Usumacinta continues to be a free-flowing river, but the Grijalva has two large hydroelectric dams that dampen the streamflow regime and remove large amounts of sediment from the system. Unfortunately there have not been any detailed studies to examine the influence of these activities on the lower reaches of the watershed, particularly the hydrology and riparian ecology. Studies on this subject in other regions typically report a loss of plant and aquatic diversity associated with a change in the flood regime and modification to the stream channel morphology. In the lower reaches of the basin, where the Usumacinta and Grijalva interconnect through multiple bifurcating distributaries, the extensive wetland complex is being impacted by engineering activities. Several larger channels have been straightened to reduce flooding, and dikes have been constructed along the channel banks to maintain a navigable depth for transport of raw materials and agricultural products. However, the petroleum industry has probably created the most substantial damage in the lowlands. Oil pipelines and canals have drained many wetlands, and dredge spoil has created topographic barriers that alter wetland hydrology. In many cases the reduction of water and sediment to floodplain and deltaic wetlands results in dramatic changes to the ecology and hydrology of these sensitive ecosystems.

A major concern for the undammed Usumacinta River is that construction of a series of dams on the main stem appears imminent. Since at least 1987 construction of a large dam at Boca del Cerro, about 9 km south of Tenosique, has been publicly discussed. In 1987 and 1992, proposals to build a dam at Boca del Cerro met with stiff opposition and were cancelled. In 2002, however, evidence surfaced that a new plan was being developed by Mexico's Federal Commission of Electricity (CFE) for a hydroelectric dam at this site. It appears an agreement was reached between the Mexican and Guatemalan governments that calls for a dam at Boca del Cerro and a series of five upstream dams; however, little information has been released. This plan is on the watch lists of many environmental and archeological organizations, and major international protests are anticipated. Such a dam or series of dams on the Usumacinta would have enormous ecological, archaeological, and sociological impacts, potentially flooding thousands of square kilometers of tropical rain forest rich in unexplored biodiversity, as well as ancient Mayan ruins and artifacts. Upstream and downstream impacts on riparian ecology could be enormous.

RÍO CANDELARIA (YUCATÁN)

The Río Candelaria drains 10,755 km² of the western Yucatán (Gunn et al. 1995) and is one of the few significant rivers within the Yucatán Peninsula, an enormous karstic region of southeastern Mexico (Fig. 23.15). The river flows over 250 km through dense jungle and wetlands to the coastal zone, where it empties into the Laguna de Terminos, a large brackish lagoon in western Campeche (see Fig. 23.1). Most of the basin is in Mexico, although 50 km of channel extends into the Petén of northern Guatemala to account for 1158 km² in that country (Gunn et al. 1995). The Candelaria is a large river for the Yucatán and should be considered atypical of that region; most of the Yucatán lacks significant rivers, as its hydrology is controlled primarily by interior-draining cenotes aligned along large faults (INEGI 1981a).

The ancient Maya occupied the Yucatán landscape from 3000 to 1100 years ago, and at the height of their civilization had a large population within the Candelaria region. Ancient Mayan ruins located throughout the region have become popular destinations for international tourists. Although the Maya located throughout the Candelaria basin, the major ancient Mayan population centers were located in the upper basin, in the Petén of Guatemala and at Calakmul within the Maya Biosphere Reserve. Because the basin drains the old Mayan heartland, it is not surprising that surficial landscape processes have been anthropogenically modified for several thousand years (Pope and Dahlin 1989, Beach 1998). Landscape modification to exploit water resources was necessary because the permeable and fractured limestone results in the water table being as much as 100 m beneath the surface (Lesser and Weidie 1988).

The large Mayan population was decreasing by the post-Classic period (900 to 1500 A.D.), before the Spanish conquest. The Spanish did not conquer the Yucatán until a couple of decades after conquering the Aztecs in central Mexico, and the population quickly plummeted, but by the mid-nineteenth century was recovering. Because of the absence of significant mineral wealth, this region remained relatively undeveloped until the twentieth century, and in comparison to central Mexico remains largely indigenous. There was even a movement for independence after Mexico became independent from Spain. The Yucatán did not have extensive agriculture; however, henequen, a fibrous product from the agave plant used for manufacturing rope, has long been produced. Although its impact on hydrology would be difficult to speculate, the conversion of dense forest to henequen represents

a significant land-use change for portions of lowland Yucatán, principally in the northwestern Yucatán state of Campeche.

Physiography, Climate, and Land Use

The Río Candelaria flows through two major physiographic provinces, the Yucatán (YU) and the Mexican Gulf Coastal Plain (CP) (Grubb and Carillo 1988) (see Fig. 23.15). More specifically the upper portion of the Candelaria basin is within the Southern Hilly Karst Plain of the Yucatán, where most of the surface drainage of the Yucatán is found (Lesser and Weidie 1988).

Few rivers drain the Yucatán because, as is common in karst settings, high infiltration and features such as swallets and cenotes prevent development of large surface drainage systems. Smaller rivers are often not connected to a surface drainage network, but instead are often diverted into solution depressions. In these settings the concept of a surface drainage divide may be inadequate because of the numerous subsurface passages that transport water across surface drainage boundaries. The northern Yucatán has a large concentration of cenotes, but almost no surface water features (Lesser and Weidie 1988). In comparison, the Candelaria region is referred to as the “Lake District” by Gunn et al. (1995) and has a higher degree of surface drainage features, such as poljes, large solution depressions that form lakes or wetlands. In this portion of the Yucatán small river channels connect these features and comprise the Candelaria drainage network.

Three rivers, the Caribe, Esperanza, and upper Candelaria, comprise the Candelaria headwaters, all funneling water from irregular networks of interconnected wetlands and small rivers toward the northwest, where they converge to form the main channel of the Candelaria on the Coastal Plain. These headwaters all drain the swampy and marshy Southern Hilly Karst Plain physiographic region. The Río Caribe begins in the east, near the border between the states of Campeche and Quintana Roo, west of the Maya Biosphere Reserve. Like the rest of this headwater region, the lithology here consists of horizontal bedded Eocene and Miocene carbonate deposits, including limestone, dolomitic limestone, and dolomite (Lesser and Weidie 1988). Here the El Tigre River flows through a poorly drained landscape with extensive wetlands. East of the swampy lowlands that make up the poorly defined drainage divide are the headwaters for the Río Hondo, the largest Mexican river draining into the Caribbean

that serves as the international border with Belize. The Xpujil Hills, with a maximum elevation of 375 m asl, appear to represent the drainage divide. In general these conical karst hills are ~100 m above the swampy plain (INEGI 1998b, 1998c) and are a testament to the intensive chemical weathering that has shaped this landscape. The Río Esperanza drains the southeastern portion of the basin, extending to near the Guatemala–Mexico border (INEGI 1998b, 1998c). Finally, the uppermost reaches of the Río Candelaria extend into the Petén of Guatemala, where the drainage divide between it and Río San Pedro (which ultimately flows into the Río Usumacinta) lies in a swampy wetland and is difficult to delineate. These three major headwater rivers of the Candelaria flow northwesterly, converging near the boundary between the Southern Hilly Karst Plain and Mexican Gulf Coastal Plain, which consists of Quaternary sediments of fluvial and marine origin. From here the river flows generally north, although several resistant outcrops disrupt this pattern in the vicinity of the small town of Candelaria.

The major soil type in the Southern Hilly Karst Plain portions of the basin is rendzina (INEGI 1998a), thin clayey soils rich in organics (humus) and calcium carbonate, reflecting the limestone parent material. Caliche horizons are common and are an indication that the intensive chemical weathering that occurs during the rainy season is followed by rapid evaporation in the dry season. Like the uplands, soils within the Gulf Coastal Plain are very clayey, but these vertisols and gleysols are much deeper. Slickensides, shiny pressure surfaces on soil peds, are an indication of substantial subsurface soil churning. Slickensides are common in Coastal Plain soils and also in the deeper upland soils at the base of hills or solution cavities (INEGI 1998a, Beach 1998).

The climatic regime for the Candelaria watershed is tropical monsoon, with distinctive wet and dry seasons (West and Augelli 1989). Average annual precipitation from 1951 to 1980 was 150 cm at the village of Candelaria, and this does not likely vary too much throughout the basin because of the absence of significant topography (INEGI 1981a). The majority of precipitation falls between June and October with the onset of summer trade winds and tropical cyclones (Fig. 23.16). Average temperature over the same 29-year period was 24.6°C (Gunn et al. 1995), and monthly mean temperatures range from 21°C in December to 28°C in May.

The Río Candelaria primarily drains from two terrestrial ecoregions in its upper reaches: the Yucatán Moist Forests and the Petén–Veracruz Moist

Forests (Ricketts et al. 1999). Here the climate supports growth of a dense tropical broadleaf rainforest, part of a much larger forest that extends into Belize and Guatemala and throughout southeastern Mexico. Wetland vegetation in the uplands occurs within solution depressions, varying broadly in composition between perennially and seasonally inundated basins. As the river approaches the coast it then passes through the Pantanos de Centla and Usumacinta Mangroves ecoregions. The Pantanos de Centla is seasonally flooded moist forest with associated wetlands. In the lower reaches these freshwater wetlands merge with saltwater wetlands along the coast that are dominated by mangroves.

Land use in the upper portions of the basin is limited to small-scale traditional farming, with maize most important. Logging and ranching are more important in the lower reaches of the basin, creating a mosaic of land-cover types as viewed from satellite imagery. There is little industrial development in this region.

River Geomorphology, Hydrology, and Chemistry

The channel morphology of the Río Candelaria basin reflects regional hydraulic and sedimentary controls. The course of these rivers is controlled by bedrock fractures and solution cavities. Because of an absence of sand, the bank material is comprised of resistant cohesive clayey sediments that result in a narrow and deep channel. The Río Caribe, for example, has an average depth of 3.8 m along its lower 40 km. Combined with the low energy, this setting does not permit the development of a meandering pattern. The river becomes much larger in the Coastal Plain, where it receives drainage from the Ríos Caribe and Esperanza (INEGI 1998b, 1998c). River depths in the lower Río Candelaria vary from 7.2 to 11.3 m (Gunn et al. 1995).

Karst river floodplains differ from rivers transporting clastic sediments. Because of greater channel stability, a less variable flow regime, and smaller sediment loads, these rivers tend to develop thick backswamp deposits but have smaller natural levees (Pope and Dahlin 1989). After the headwaters form the main channel, the river flows as a single channel for 90 km within a defined alluvial valley. Several kilometers downstream of the small town of Candelaria the river becomes an anastomosing channel, flowing within a network of channels for 35 km (INEGI 1998b, 1998c). This probably reflects an increase in valley width coincident with a reduction in valley

gradient (e.g., Nanson and Croke 1992). A transition from anastomosing to meandering occurs toward the coast, and the river flows as a sinuous channel for 25 km until it reaches brackish coastal wetlands and discharges into the Laguna de Terminos. Before entering the Laguna de Terminos, the Candelaria and Río Mamantel, a smaller river to the north, enter into the much smaller but well-defined Laguna Panlau.

The monthly streamflow pattern for the Río Candelaria reflects the seasonal precipitation regime but also regional hydrogeologic controls. Although most tropical wet and dry rivers encounter great variability in streamflow, the Río Candelaria's discharge regime is dampened by the substantial amount of base flow supplied by groundwater, and by reduction in runoff due to the wetlands in the uplands (Gunn et al. 1995). Average daily discharge over the 29-year period, from 1958 to 1990, was 46.2 m³/s. The highest (105.5 m³/s) and lowest (18.5 m³/s) average daily discharges occur in October and April, respectively. Extremes ranged from a low of 8.7 m³/s in April 1975 to 309.2 m³/s in October 1963 (Gunn et al. 1995). Large events are generally associated with intense rainfall events from tropical cyclones. In spite of the high precipitation for the basin, runoff is much lower than that calculated for the Usumacinta–Grijalva just to its southwest (compare Figs. 23.14 and 23.16). The highest monthly discharge of the Candelaria in October results in a runoff of only 2.8 cm/mo compared to a runoff of 20 cm/mo in the Usumacinta. Such large differences appear to be due to groundwater losses in the Candelaria that eventually return much of its water to the sea through submarine springs.

Surface-water features within the Candelaria basin are distinct from the Pánuco and the Usumacinta–Grijalva systems. In contrast to these two large systems, the majority of wetlands in the Candelaria occur in the upper reaches of the watershed within the swampy karstic plain that Pope and Dahlin (1989) refer to as the Yucatán Lake District. These features are poljes, which are large, irregular-shaped karstic solution depressions that lack the cylindrical morphology of cenotes. They are classified as either perennial or seasonal wetlands and further classified as forest, thicket, or herbaceous, which in part depends on the amount of sediment filling them. Collectively these features disrupt traditional surface flow paths and dampen the streamflow regime of the Río Candelaria; however, individually they may undergo great seasonal variation in hydrology. Wetlands below ~100 m asl tend to be perennial because they are close to the regional water table, and

those above ~100 m are typically seasonal, representing perched aquifers supplied by local precipitation and runoff. Evaporation, seepage, and channel outflow remove water from these systems, and there is tremendous variability in their ability to hold water. An important characteristic of these features is the degree to which they have been infilled by surficial sediments. Where infilled with clay, these features may hold water for much of the year, and if supplied by a channel may even flood adjacent areas during the rainy season. The rapid change in water results in considerable shrinking and swelling of wetland soils. The clay expands during the rainy season and contracts and cracks during the dry season, thus limiting vegetation to those plants that can adapt to such a harsh environment.

Although water-chemistry data specific to the Río Candelaria were unavailable (Arriaga-Cabrera et al. 2000), the karstic geology of the region should result in high values for alkalinity/hardness and pH values greater than 7.

River Biodiversity and Ecology

The Río Candelaria is classified by Abell et al. (2000) in the Grijalva–Usumacinta freshwater ecoregion rather than the Yucatán ecoregion. They point out that the freshwater biota is largely unexplored in the Yucatán, and this is certainly true for the Río Candelaria.

Plants

Wetlands in the lower alluvial valley are located mainly in backswamp environments. The composition of vegetation on natural levees is similar to upland forests because the coarser sediments and slight elevation of these deposits provide better drainage. Toward the coast, freshwater marsh merges with brackish swamps, much of which are predominantly mangrove, but support a variety of salt-tolerant species (Pope and Dahlin 1989).

Invertebrates

Information on invertebrates in the Candelaria is sparse, although the narrowmouth hydrobe (a snail), the hellgrammite *Corydalis bidenticulatus*, the stonefly *Anacroneuria*, and the true bug *Abedus* have been found (A. Contreras-Ramos, personal communication).

Vertebrates

Ayala-Perez et al. (1998) provide the only published summary of the fish fauna of the Río

Candelaria, but their work was based entirely on trawling samples in the shallow (3 m) 14 km² terminal estuary (1 to 22 ppt salinity) of this system, Laguna Panlau, which is fed by both the Río Candelaria and the Río Mamantél. The economically important fish faunas of many similar saline lagoons associated with the Laguna Terminos are relatively well studied, and their study was typical of that larger community. All 50 species were from 24 primary marine families, with the exception of two cichlids (Mayan cichlid and one unidentified species) and the threadfin shad. Dark sea catfish, bay anchovy, rhombic mojarra, checkered puffer, silver perch, ground croaker, sand seatrout, and spotted seatrout were the dominant species. We found no published reports on the fish fauna of the upstream freshwater system; however, a search of museum collections produced a list from a single collection (University of Michigan) from a tributary of the Río Candelaria at a highway bridge 40 km southeast of Candelaria in 1982. Not surprisingly, the fauna of this system is closely related to that of the Río Grijalva. Only one of the 17 species collected is not also recorded from the Grijalva and only one of the species collected here was also taken in the estuary by Ayala-Perez et al. (1998). Nine species of cichlids dominated the 1982 collection, comprising numerically about 75% of the 222 specimens: firemouth cichlid, blackgullet cichlid, yellow cichlid, yellowjacket, Mayan cichlid, yellow-belly cichlid, Montechristo cichlid, redhead cichlid, and giant cichlid. Cyprinodontiformes included stippled gambusia, Champoton gambusia, shortfin molly, picotee livebearer, and pike killifish. The two characids were banded tetra and Maya tetra, and a single catfish specimen was pale catfish.

Ecosystem Processes

As pointed out by Arriaga-Cabrera et al. (2000), very little or almost nothing is known about most aspects of this river system. No ecosystem studies have been done on the Candelaria but it would appear to present an interesting contrast in its hydrological and organic matter budget to most rivers.

Human Impacts and Special Features

Occupation of the Candelaria basin by the ancient Maya resulted in significant anthropogenic landscape disturbance much earlier than in most other regions of Mexico. Until the last few decades, however, this area had received relatively little human disturbance for several hundred years. Thus, much of the basin retains features of a relatively natural landscape.

Although it is part of the vast karstic Yucatán, which loses most of its water to groundwater seepage, the Candelaria is unique in retaining sufficient surface-water flow to represent one of the largest Yucatán rivers. Although its biodiversity and ecological characteristics are poorly known, this unusual hydrological system, with anastomosing channels and wetlands in its headwaters, its meandering channel in the Coastal Plain, and its coastal mangroves, is an unusual river ecosystem.

The Maya modified their landscape in two major ways: forest clearing associated with slash and burn agriculture and manipulation of the surface hydrology for agriculture, which included canals and terraces. The immediate impact of Mayan land-use practices was to increase soil erosion and lake-wetland sedimentation. This occurred on even moderate slopes, and several scholars have identified a distinctive layer of fine sediment associated with wetland infilling called the “Maya clay” (Beach 1998). Detailed soils and paleoecological analysis has identified a human imprint on the soils, including an increase in the amount of ash and pollen types that differ from natural pollen assemblages. Large-scale irrigation systems were constructed for agriculture. Even in the humid Yucatán, high infiltration associated with limestone greatly limits the availability of surface water. Within the lower reaches of the Candelaria, large canals were constructed perpendicular to the main river channel and were often connected to uplands or to a matrix of smaller canals within backswamps (Fig. 23.1). Canals were also built within perennial wetlands, although there is debate as to whether seasonal wetlands were utilized for agriculture. Pope and Dahlin (1989) argue that the rapid fluctuation of these perched aquifers greatly limited their usage for agriculture. Ayala-Pérez et al. (1998) mention that the Maya built an elevated road across the shallow estuary they studied that is still exposed during the lowest water levels.

After the collapse of the Mayan empire around 1100 years ago the landscape went fallow and forests returned. There is considerable debate regarding the degree to which this landscape is “natural.” It is now widely recognized that the Maya cleared enormous tracts of forest during their 3000-year occupation of this landscape and much of the existing forest does not predate the Maya collapse. Until the late 1960s there was little development in this region other than traditional slash and burn agriculture and nondestructive extractive forestry. Since then, renewed deforestation has occurred as a result of large-scale logging operations and rapid population growth. In the uplands,

FIGURE 23.6 Upper Río Yaqui (PHOTO BY W. E. DOOLITTLE).

forest clearing has mainly been for small-scale slash and burn (swidden) agriculture. Although traditional in form, the pace of milpa clearing is more rapid than in prehistoric times, which may result in this being much more disruptive in comparison to prehistoric swidden practice. Coupled with this has been forest clearing for ranching, particularly in the Coastal Plain, which can be seen as permanent forest removal. Although it is difficult to quantify, Gunn et al. (1995) speculate that these actions are likely increasing runoff and storm flow through the main channel of the Candelaria. However, the coastal area is now within the Lagunas Terminos Protected Area. There is very little industry or commercial activities in the lower reaches of the river. The only significant urban area on the river is the city of Candelaria, located 57 km above the river mouth.

RÍO YAQUI

The Río Yaqui is a relatively large 6th order river basin in northwestern Mexico that drains an area

(73,000 km²) between 34°N and 32°N latitude in the Mexican states of Sonora and Chihuahua and the extreme southeastern corner of Arizona (Figs. 23.6 and 23.17). Based on literature and extensive field-work during the late 1970s, Hendrickson et al. (1981) provide a useful general overview of physical aspects of the basin and an account of its biota, with primary focus on its fishes. That account, as much as possible, will be updated and expanded upon here.

The main stems of two major subbasins, the southern Papigochic–Sirupa–Aros and the northern Bavispe, drain first generally north to northwest in upper reaches of the Sierra Madre Occidental in western Chihuahua. The Bavispe makes a broad turn just south of the international border, adding the San Bernardino system flowing from Arizona to flow south to southwest. The Papigochic–Sirupa–Aros system makes several similar nearly 180-degree turns as it wanders through valleys and intervening deep canyons to eventually join the Bavispe and form the main-stream Río Yaqui. Although the higher elevations and intermediate canyon reaches have high gradients, downstream the low-gradient reaches

meander through a desertic forest to cross the Coastal Plain of Sonora to the Los Algodones Estuary about 24 km southwest of Ciudad Obregón.

Human impacts on the Río Yaqui date to pre-Columbian times, when the basin was occupied by the prehistoric Cahita peoples, believed to have given rise to present indigenous groups of the region, such as the Rarámuri (Tarahumara), Yaqui, Mayo, and Pima. Apache bands later roamed higher elevations of the basin, and Pueblo cultures were also present, mostly in Chihuahua. European influence began with the establishment of Spanish missions in lower elevations beginning in the early sixteenth and seventeenth centuries, with relatively little incursion into the Indian-occupied areas upstream but strong influence on the tribes of the more accessible lower reaches of the drainage.

Physiography, Climate, and Land Use

Most of the upper Yaqui basin lies in the Sierra Madre Occidental (SC) physiographic province, where it flows through rocky, complex, and often deep scenic canyons (see Fig. 23.17). A small part of the upper basin in Arizona lies in the Basin and Range (BR) province and a small part of the Buried Ranges (BU) province. As the river drains from the mountains it flows across lower elevations of the Buried Ranges province along the coast of the Gulf of California.

The Papigochic and Bavispe drainages in the eastern portion of the basin originate on the high rolling plains to the east of the crest of the Sierra Madre, and at least parts of these systems were captured from former drainages into closed basins to the east by headwater erosion of west-draining streams (Hendrickson et al. 1981, Minckley et al. 1986). These systems then drop, sometimes quite precipitously, from conifer-dominated forests and high-elevation grasslands (especially in the far southeastern reaches of the basin) to descend through the highly diverse Sierra Madre Occidental Pine–Oak Forests terrestrial ecoregion (Ricketts et al. 1999, www.nationalgeographic.com/wildworld/terrestrial.html). The northernmost portion of the drainage, including in southeastern Arizona, drains from the arid Chihuahuan Desert ecoregion, typified by creosote bush, yucca, and various cactus species, as well as grasslands. The lower Yaqui flows primarily through the Sonoran–Sinaloan Transition Subtropical Dry Forests ecoregion, a transition between the Sonoran Desert to the northwest and the Sinaloan Dry Forests to the southeast. Thus, it includes a mix

of desert vegetation, such as various cacti, and seasonally deciduous trees of the Sinaloan Forest. The very lowest portion of the Yaqui basin north of the westward-trending river (see Fig. 23.17) is part of the Sonoran Desert ecoregion.

The climate of the Yaqui basin ranges from temperate in the mountains to very dry in the desert (INEGI 2000a, 2000b). Mean monthly air temperatures and precipitation were estimated from seven weather stations throughout the basin. Monthly temperatures ranged from 11°C in January to 26°C in July (Fig. 23.18), with an annual mean of 18.4°C. Daily nighttime temperatures, however, commonly fall well below 0°C in winter at high elevations, and daytime temperatures in low and middle elevations commonly exceed 40°C in summer. Throughout the basin most of the precipitation falls (as rain) in July and August (over 11 cm/mo), comprising about half the annual amount of 48 cm (see Fig. 23.18). Precipitation is highest in the higher eastern mountains, where substantial accumulations of snow are common, and least in the lower mountains and foothills of the western side of the basin.

Human population density in the basin averages only 7 people/km², with Ciudad Obregón, Sonora, the largest city at about 345,222 people (INEGI 2000a, 2000b). In spite of this low density, agriculture and logging are pervasive. Currently, agriculture is fairly diverse but only occupies 3% of the basin, with the largest and most productive portion on the lowermost Coastal Plain. Wheat, soybeans, cotton, garbanzo, corn, cattle, poultry, pork, and even shrimp farms are found, and apples and other orchard crops are important in the upper Papigochic. Forestlands represent 75% of the basin, and intensive logging of pine forests is obvious over much of the Sierra Madre in both Sonora and Chihuahua. Recent years have seen the logging industry starting to exploit the diverse oak forests of middle elevations. Some of the few inaccessible and sometimes small but significant headwaters areas that remain in a more or less natural state are being considered for designation as natural protected areas.

River Geomorphology, Hydrology, and Chemistry

The river can be separated into four subbasins with somewhat varied physical, hydrological, and flow characteristics (INEGI 2000a, 2000b). In the southeast, the Papigochic, Sirupa, and Aros rivers drain parts of both Sonora and Chihuahua, whereas to the north the Bavispe system drains large areas of the

same two states and a small part of Arizona. The third-largest subbasin, the lower Río Yaqui, harbors the system's reservoirs and most of its irrigated agriculture. The small Moctezuma–Nacozari subbasin lies on the west margin of the basin.

The name Río Yaqui is first applied starting at about 600 m asl for the reach extending downstream from the confluence of the Aros and Bavispe rivers. Here the natural uncontrolled discharge of the Aros merges with the regulated flows of the Bavispe to form a river with a mean width of 60 m. The Río Yaqui here is characterized by a well-developed channel with alternating riffles, runs, and pools, with a diversity of depth and velocity regimes, thus providing a wide variety of habitats for riverine biota. Substrates range from boulders, cobble, and well-sorted gravels with little embedding in higher reaches to high concentrations of fine benthic organic sediments with woody debris, sand, and finer particles.

The discharge of the Yaqui is now regulated by three large reservoirs: La Angostura (Lázaro Cárdenas), Plutarco Elías Calles (El Novillo), and Alvaro Obregón (El Oviachic). Two of these, Plutarco Elías Calles and Alvaro Obregón, are on the main-stream Yaqui, and La Angostura is farther upstream on the Bavispe (see Fig. 23.17). The habitat produced by these dams is intermediate between a free-flowing river and a more typical deep and established lake. At least below La Angostura, discharge occasionally is dropped to zero for days at a time. Sediments in the reservoirs are primarily the soils of the ancient canyons and bedrock and boulders that are overlain or embedded with sand and silt.

Mean annual discharge from 1976 through 1979 was 78.5 m³/s, although much of this flow is now diverted before reaching the Gulf of California. Monthly discharge and runoff are now relatively evenly distributed throughout the year by the dams (see Fig. 23.18). Highest flows occur in July and August, when precipitation exceeds 10 cm/mo.

The lower section of the lower basin includes that portion of river from just below El Oviachic Reservoir to the river's mouth, a distance of about 100 km. Concrete channels divert most of the flow here and become the most characteristic habitat, and only a small portion of the river remains to flow through the natural channel. The natural habitats here are now low velocity with an abundance of organic matter, as the remaining flows and irrigation returns course through meanders within a narrow zone of the broad natural channel through the Coastal Plain. Controlled releases resulting in removal of peak flood discharges through this reach have allowed

encroachment of riparian vegetation that constrains the now small river to a narrow channel through dense vegetation. Tides are present only in the Algodones estuary, the natural mouth of the main course of the Río Yaqui, though a significant portion of the river's discharge now finds its way to sea via other, man-made routes.

Except for localized point industrial and logging contamination and somewhat more diffuse agricultural runoff, water quality is generally good along most of the upper and middle river. Numerous small sawmills in the Sierra Madre continue to discharge sawdust to stream channels, sometimes causing extensive impacts, and roads associated with logging, as well as general logging practices, have sometimes greatly increased erosion. Intensive agriculture in the upper Papigochic drainage has obvious impacts on streams of that area. Nonetheless, somewhat lower on these rivers, reservoirs support fisheries, mostly of nonnative species, that are exploited both by local residents and foreign and domestic sport fishermen.

River Biodiversity and Ecology

The Río Yaqui is located within the Sonoran freshwater ecoregion (Abell et al. 2000), which includes rivers to the west and south of it that also drain through the Sonora Desert into the Gulf of California: the Río Concepción, Río Sonora, and Río Mayo.

Algae and Cyanobacteria

Little information exists on the periphyton in the river and its wetlands, although species richness likely is quite high given the variety of habitats.

Plants

Aquatic macrophytes occur throughout the river system, but only 11 species have been collected from the river and its floodplain, with pondweed, buttercup, and *Nasturtium* the most common. Hendrickson et al. (1981) mention specific occurrences of, but did not collect, voucher specimens.

Wetlands in the lower basin are characterized by a variety of emergent and floating-leaved species, depending primarily on salinity. Typical species in freshwater areas include cattail and a few small ciénegas (desert marshlands), especially in the desert grassland areas of southern Arizona and nearby northeastern Sonora and northwestern Chihuahua (Hendrickson and Minckley 1985), where some have been given government protection (e.g., USFWS 1994). Halophytes occur in the extensive estuarine

marshes and also in patches in otherwise freshwater areas where salt springs emerge. Black mangrove, white mangrove, and red mangrove dominate in salt marshes; iodinebush, saltbrush, seepweed, and Florida mayten dominate in inland areas with increased salinity. Water hyacinth (nonnative) has been recorded, but unlike what has happened in some basins further south, this problematic weed has not yet established extensively (Arriaga-Cabrera et al. 2000).

Riparian corridors in headwaters and middle elevations consist primarily of Arizona sycamore, Arizona alder, willows (Goodding, Bonpland), green ash, and Fremont cottonwood. Expansive mesquite forests occupy most terraces along larger middle- to lower-elevation rivers through the Sonoran Desert, with Fremont cottonwood, willows, common reed, salt-cedar (nonnative), and hackberry associations along the river's bank (Minckley and Brown 1994).

Invertebrates

Information on invertebrate communities in the Yaqui is sparse, but at least collections of some taxa have been made (A. Contreras-Ramos, personal communication). Among the aquatic insects collected in the system are hellgrammites (*Corydalus bidenticulatus* and *Corydalus texanus*), mayflies (*Siphonurus occidentalis*, *Nixe salvini*, *Acentrella insignificans*), and stoneflies (*Capnia decepta*, *Mesocapnia frisoni*, and *Anacronuria wipikupa*) (Bauman and Kondratieff 1996, Contreras-Ramos 1998, A. Contreras-Ramos, personal communication). The snail *Fossaria (Bakerilymnaea) bulimoides* has also been found, and isolated populations of the large riverine bivalve *Anodonta* sp. occur in at least the Río Sirupa in canyon reaches in Chihuahua (D. A. Hendrickson, unpublished data). Estuarine crustaceans include Cauque River prawn, blue shrimp, and white shrimp.

Vertebrates

The fish assemblage of the Yaqui is diverse, particularly because its habitats range from 2500 m asl to sea level. A few sources suggest there are at least 107 fish species, including native fishes and marine species sometimes found in freshwater or in the mouth of the river (Hendrickson et al. 1981, Minckley et al. 1986, Campoy-Favela et al. 1989, Calderón-Aguilera and Campoy-Favela 1993, Castro-Aguirre et al. 1999). There are at least seven species of Cyprinidae (chubs, shiners, and minnows), four species of Catostomidae (suckers), and two species of Poeciliidae (topmin-

nnows). Endemic species are few, but include Yaqui chub (DeMarais 1991, DeMarais and Minckley 1993), Leopold sucker (Siebert and Minckley 1986), and probably Yaqui trout (undescribed, but see Hendrickson et al. 2002, Behnke and Tomelleri 2002), and Yaqui topminnow (Quattro et al. 1996). Most of the Cyprinidae and many medium-size species (Catostomidae and others) prey on aquatic and terrestrial insects. Bottom-feeding fishes include Yaqui sucker and Leopold sucker, as well as the primarily algal-grazing Río Grande sucker and Mexican stoneroller. Only the native roundtail chub and Yaqui catfish, in adult form, feed almost exclusively on fishes. Topminnows are the most abundant surface feeders from the basin in middle to low elevations, preying on aquatic algae and small insects. An interesting all-female form of topminnow (headwater live-bearer) (Vrijenhoek 1993, Quattro et al. 1992) occurs in middle to lower elevations of the basin, representing the northernmost of a complex of many independently evolved asexual (clonal) lineages that exist as sexual parasites of sexual forms that gave rise to them via hybridization.

Euryhaline species are an important component of the lower basin (56 species) and comprise about of half the Yaqui fish fauna. The most common and abundant are striped mullet, machete, striped mojarra, and Heller's anchovy. Among the natives with conservation interest is Pacific gizzard shad, for which the lack of information impedes an appropriate conservation plan (Varela-Romero 1989).

The Río Yaqui has at least 17 nonnative fishes that have been introduced over the past century (Hendrickson et al. 1981, Hendrickson 1983, Campoy-Favela et al. 1989, Varela-Romero 1989). Among the most abundant are channel catfish, river carpsucker, largemouth bass, common carp, Mozambique tilapia, rainbow trout, and green sunfish. Western mosquitofish is an important nonnative that threatens the ecologically similar native topminnow. Nonnative piscivores feed primarily on smaller forage fishes, such as native cyprinids, catostomids, and poeciliids. Concern exists about the highly piscivorous flathead catfish, which has been reported in the Yaqui (Leibfried 1991), but no vouchers or subsequent specimens have been recorded. Blue catfish have long been established in the Bavispe and surely impact native faunas there. Success of these nonnatives appears directly related to the existence of reservoirs, which create less diverse habitats and function as centers for their dispersal. Largemouth bass and channel catfish now occur far above reservoirs in both the Bavispe and Papigochic-Aros-Sirupa sub-

basins. Genetic interactions with introduced species also endanger native stocks. Pure stocks of Yaqui catfish are essentially nonexistent because of hybridization with channel catfish.

A number of Río Yaqui fishes are considered endangered or threatened by the Mexican federal government (SEMARNAT 2002, Varela-Romero 1995). Yaqui chub is the only species considered endangered, whereas longfin dace, ornate minnow, Yaqui shiner, Cahita sucker, Río Grande sucker, and Yaqui topminnow are considered threatened and Yaqui sucker, Leopold sucker, and Yaqui catfish are categorized as under special protection. Yaqui topminnow is formally a subspecies of Gila topminnow, but some populations in the Yaqui appear to be sufficiently different to be elevated to the species level (Quattro et al. 1996). Recovery efforts for endangered Yaqui fishes are coordinated with efforts in the U.S. portion of the basin, centered at the Dexter National Fish Hatchery, New Mexico (Johnson and Jensen 1991). The final destiny of these native fishes is the San Bernardino National Wildlife Refuge (SBNWR), Arizona, and potentially one day former native habitats in Mexico (USFWS 1994).

Amphibians and reptiles directly associated with the Yaqui also are diverse. Fourteen species of frogs and toads, one salamander, five snakes, and three turtles are found either in the river main stream or the floodplain much of the year (SIUE 1992, Flores-Villela 1993, Stebbins 1985). Among the more representative amphibians are Tarahumara salamander, Tarahumara frog, and Chiricahua leopard frog, all provided legal protection by the Mexican government. The introduced American bullfrog is found in natural habitats of the northernmost Bavispe and in the lower basin, and culture of the species for commercial purposes has begun. Unfortunately, it has been amply demonstrated to have severe impacts on native amphibians and snakes, particularly those of the genus *Thamnophis*, which are diverse (six species) and common in the Yaqui. Sonoran mud turtle, common slider, and Western box turtle are all common. A major mammal associated with the Río Yaqui is the neotropical river otter, which is occasionally observed in the channelized portion of the river between the major dams (Gallo-Reynoso 1997) and also far above the reservoirs.

Ecosystem Processes

No broad-scale studies are available on ecosystem processes, though much effort has focused on sustainability of agriculture systems in the lowermost river (<http://yaquivalley.stanford.edu>).

Human Impacts and Special Features

The Río Yaqui is one of most important rivers of northwestern Mexico, not only because of its interesting biodiversity (Arriaga-Cabrera et al. 2000) but also because of the economic importance of the agriculture its water supports. It is, however, heavily impacted by humans. Natural discharge and inundation patterns occur only in the headwaters, upstream from its three large main-stem dams. Nonetheless, despite more than a century of exploitation and extensive, highly modified landscapes (Forbes and Hass 2000), many of the river's tributaries and their riparian zones have remained relatively intact throughout substantial portions of the basin.

Impacts are greatest in the lower basin, which continues to absorb a rapid increase in population and has been highly developed for intensive irrigated agriculture, as have the coastal plains of rivers further south in Sinaloa, such as the Ríos Mayo, Fuerte, and Sinaloa. As with those areas, human communities on the lower Río Yaqui floodplain are now experiencing problems with high pesticide levels (e.g., Arreola-Lizárraga 1995, Guillette et al. 1998) and water-supply limitations following recent record droughts. Water has recently had to be pumped over reservoir spillways to distribution canals that supply apparently unsustainable levels of agriculture, and local economies are crashing (Dean 2004).

Aquaculture is now rapidly developing in the region as a possible alternative. Despite questions regarding its sustainability, the intertidal areas of the upper estuary are being converted to extensive shrimp farms in response to government and private incentives. These activities stand to increase problems related to nonnative species brought in with aquaculture development. Still, despite its complex problems related to extensive agricultural and forestry development, the Río Yaqui basin retains long reaches of free-flowing natural desert mountain rivers, and its biota is at least more intact than those of similar desert rivers further north, such as the Gila of Arizona and New Mexico. This basin should therefore remain a high priority for management and conservation (Arriaga-Cabrera et al. 2000).

RÍO CONCHOS

The Conchos basin begins high in the Sierra Madre Occidental of northwestern Mexico along the North American continental divide. Most of the basin lies

FIGURE 23.7 Upper incised Río Conchos (PHOTO BY W. E. DOOLITTLE).

within the state of Chihuahua, but the system also drains a portion of northern Durango (Fig. 23.7, 23.19). From the pine-forested semiarid flanks of the rugged Sierra Tarahumara, a range within the Sierra Madre Occidental, the primary tributaries of the Conchos basin (Ríos Chuviscar, San Pedro, Toronto, Parral, and Florido) flow northeasterly before converging in the arid Chihuahuan Desert. Below the confluence with the Río Chuviscar the Río Conchos

flows northerly to the Río Bravo del Norte (Río Grande), joining that river at Ojinaga, Chihuahua, across from Presidio, Texas. The drainage area of the Río Conchos is estimated at 68,386 km², which accounts for 14% of the Río Bravo's drainage; however, because the Río Bravo now has very little flow upstream of this confluence, the Conchos contributes a large proportion to total discharge below the confluence. It is thus mostly the Conchos that

provides the essential discharge through Big Bend National Park, and downstream of the park the water is heavily used for floodplain irrigation and municipal purposes by the growing populations along the Texas–Mexico border. Indeed, there is considerable debate surrounding the issue of water resources along the Río Grande, and the contribution of the Conchos basin has become a controversial topic between Mexico and the United States. A recent comprehensive overview of the Conchos basin (Kelly 2001) summarizes the water plan developed by Mexico’s National Water Commission (Comisión Nacional del Agua, or CNA) in 1997.

Northern Mexico contained significant numbers of indigenous peoples. However, unlike Mesoamerican Mexico south of the Tropic of Cancer, with perhaps some exceptions (e.g., Hard and Roney 1998, Schaafsma and Riley 1999, Whalen and Minnis 2001) and at a somewhat smaller scale, it did not contain large culture regions (Coe and Koontz 2002). In addition, indigenous peoples within the area did not have irrigation projects on the scale of those of more southern populations. The Sierra Tarahumara are home to the Rarámuri, one of the largest indigenous groups in Mexico. After the conquest of Mexico the Rarámuri people migrated to this portion of Mexico to escape enslavement in Spanish silver mines. The Rarámuri, also known as the Tarahumara, did modify hydrological and sedimentological processes in a couple of ways. On hill slopes they constructed terraces to reduce runoff and soil erosion and to allow for more intensive agriculture. Along smaller streams, *trincheras* (wooden and stone structures oriented across stream channels) were constructed to reduce runoff and promote accumulation of fertile sediments for agricultural purposes (Doolittle 1985, 2000). The Tarahumara peoples have been isolated for much of history, and it is not until recently that they started to be significantly impacted by modern society. The principal disturbance to the Tarahumara people today involves logging of the extensive pine forests of the Sierra Madre Occidental.

Physiography, Climate, and Land Use

The Conchos basin drains the Sierra Madre Occidental (SC) and Basin and Range (BR) physiographic provinces (see Fig. 23.19). Its headwaters are primarily within the Sierra Madre Occidental, Mexico’s most extensive mountain system. The mountains are aligned north–south and extend from the U.S. border

to central Mexico. Comprised primarily of Tertiary volcanic rocks, andesite, and rhyolite, some mountains within the Conchos basin contain several ridges at least 3500 m asl, such as the headwaters of the Río Florido, a tributary draining the Sierra Tarahumara in northern Durango. Runoff from some of these peaks also enters Pacific drainages, such as the Ríos Mayo, Fuerte, Sinaloa, and Culiacán, with which the Conchos headwaters closely interdigitate. The volcanic rocks overlay older Cretaceous sedimentary rocks of marine origin that contain extensive ore deposits from igneous intrusions. These are frequently exposed where rivers have incised deep canyons, and have long been exploited for mining.

The lower portions of the basin, greater than half the total, drain the southern extension of the Basin and Range province (Hunt 1974). The major tributaries exit the mountains and form the Río Conchos within the western fringe of the Basin and Range. Chihuahua’s Basin and Range topography is characterized by small northwest-trending mountains, although the ridge and valley topography is not as symmetrical as that found in the United States. This series of fault block ridges primarily consists of uplifted Tertiary igneous or Mesozoic sedimentary rocks, the elevations of which are generally around 1750 m asl, although several ridges within the lower portions of the basin exceed 2000 m asl. (INEGI 1998e). The low-lying portions include large elongated valleys infilled with Quaternary alluvial deposits. Along the flanks of the ridges the valleys have extensive *bajadas* (coalescing alluvial fans). The Basin and Range also includes (outside of, but adjoining, the Conchos basin) large internally draining playas infilled with Quaternary lacustrine deposits. These internally draining basins are fed by ephemeral streams that have undergone repeated shifts in channel patterns, complicating delineation of these drainage systems.

The terrestrial ecoregions of the basin correspond closely with the physiographic provinces (INEGI 1981d, Ricketts et al. 1999). The Sierra Madre Occidental Pine–Oak Forests ecoregion within the Sierra Madre Occidental province contains a high diversity of both pine and oak species. The Chihuahuan Desert ecoregion of the Conchos basin is largely within the Basin and Range province. This dry desert ecoregion has only xeric plants, such as creosote bush, tarbush, viscid acacia, yucca, and cacti.

The dominant precipitation mechanism within the Conchos basin is the North American monsoon, or Mexican monsoon (Douglas et al. 1993), characterized by an abrupt increase in precipitation over the

basin's headwaters with more than 50% falling from mid-June to mid-September. This occurs as the subtropical high pressure cell migrates north, diverting warm moist air from the Pacific over southwestern North America. Rather than producing large frontal storms, the moist air interacts with the region's topography to create orographic rainfall with convective thunderstorms. Individual rainfall events thus tend to be of short duration but intense. Less important precipitation mechanisms include easterly migrating tropical cyclones from the Pacific and less frequently occurring westerly migrating tropical cyclones from the Gulf of Mexico. However, this mechanism is also likely influenced by synoptic scale circulation, particularly the position of the jet stream and the ridge of high pressure. The upper elevations of the headwaters (generally 2000 m asl) also experience light snowfall during winter months.

Although the basin has a generally warm and dry climate, there is substantial spatial variation in temperature and precipitation. Annual precipitation at some points in the Sierra Madre Occidental can exceed 100 cm but is as low as 20 cm in some parts of the Chihuahuan Desert. Temperature varies greatly with altitude and season, with summer daytime temperatures in the desert often exceeding 40°C and winter temperatures in the mountains falling below -10°C. Mean monthly precipitation and temperature for the basin as a whole was estimated using data from weather stations at Chihuahua (at the edge of mountains and desert) and Guanacevi (in the mountains of the Río Florido basin at 2200 m asl). Precipitation is highly seasonal, being less than 1 cm/mo from February through April and increasing to more than 10 cm/mo in July and August (Fig. 23.20). Mean monthly temperatures for the basin are close to 10°C in midwinter but rise to 23°C in June. Mean annual precipitation was estimated as 48 cm (also see www.sequia.edu.mx) and mean annual temperature was 18°C.

The economy, and thus land use, in the basin are primarily agriculture, mining, and forestry. The large amount of agriculture is made possible by large irrigation districts in the lower basin in the areas of Hidalgo de Parral, Camargo-Jiménez, Delicias, and the lower Conchos. Irrigation has made a variety of crops possible, including maize, winter wheat, alfalfa, cotton, and pecans (Kelly 2001). The population in the basin was estimated at 1.32 million in 2000 (about 17 individuals/km²) and is projected to increase to 1.77 million in 2020 (Kelly 2001). The bulk of this population is concentrated in the largest cities, such as Chihuahua (677,852), Hidalgo

de Parral (103,185), Delicias (99,137), Camargo (39,189), and Jiménez (32,966).

River Geomorphology, Hydrology, and Chemistry

The geomorphology of the Conchos system reflects significant spatial variability, which would be expected of an arid basin having close to 3000 m of relief. The upper headwaters in the Sierra Taramuhara are deeply incised within the volcanic strata (see Fig. 23.7). Here the valleys are narrow, and the rivers are primarily bedrock controlled. However, in the larger valleys in the mountains the floodplains widen and the channel is primarily alluvial. In these segments the water may be diverted for agricultural irrigation, such as in the Río Balleza and the upper Río Conchos (INEGI 1998d). The river valley near Delicias, where the Río San Pedro exits the mountains, is heavily utilized for grazing and extensive agriculture. Here the valley is 2.5 km wide with an extensive system of irrigation canals, such as Canal Principal Numero Cinco, which flows from the Francisco I. Madero reservoir (INEGI 1976a, 1976b). Overgrazing and associated runoff is becoming a significant issue with respect to water quality in these areas, and recharge of the alluvial aquifer is being affected, with consequences for sustaining biologically critical low flows. The downstream reaches of the Conchos are significantly influenced by structural controls as the river flows through the Basin and Range province. Here the river channel alternates between meandering and braided patterns. In some reaches the floodplain averages 2 km wide, whereas in other reaches it is incised into the uplifted ridges of the Basin and Range province and lacks an alluvial channel (INEGI 1976a, 1976b, 1976c, 1978). Just upstream of the river mouth, at Ojinago, the valley widens to 3 km and the meandering pattern increases in sinuosity. A low-flow structure creates a small reservoir, which is primarily used for diverting water into an irrigation system (INEGI 1998a).

A 49-year discharge record (1955 to 2003) is available for the Río Conchos from the International Boundary and Water Commission (www.ibwc.state.gov). Mean annual discharge from 1955 to 1994 was 20.5 m³/s, varying from 7.5 to 37.1 m³/s (Fig. 23.8). From 1995 to 2003, however, discharge dropped to an average of only 3.8 m³/s, or only 19% of the long-term mean. Although it is commonly cited that the Río Conchos provides much of the flow of the Río Bravo del Norte (Río Grande) above the U.S. Big

FIGURE 23.8 Long-term mean annual discharge (m^3/s) on the Río Conchos at Ojinaga, Chihuahua, Mexico.

Bend National Park, flows since 1995 have dramatically reduced this contribution. Part of this flow reduction has apparently been due to a drought in the region that has reduced runoff; however, the decrease also appears due to increased diversions for agricultural irrigation from dams along the Conchos.

Water in the Río Conchos is highly regulated by a series of dams. Of the seven major reservoirs in the system, La Boquilla (also called Lago Toronto), located on the main stem of the Conchos near Camargo, is the largest (see Fig. 23.19). Other major reservoirs are the San Gabriel on the Río Florido, the F. Madero on the San Pedro, and the Luis L. León on the lower Conchos. All of the major reservoirs are used for irrigation supply, and La Boquilla is used for hydropower. The León Reservoir is of particular significance because it is the last to discharge water (or not) before the Conchos enters the Río Bravo. Not only have the mean discharge levels at the mouth of the Conchos been greatly reduced since 1995, but for extended periods water releases have been reduced to zero by dams at several points along the lower river (see 2003 reports of the Center for Space Research at the University of Texas at Austin, www.csr.utexas.edu). For example, the León Reservoir has withheld water for several months at a time, and the only flow into the Río Bravos has been from precipitation downstream of the dam.

Because the major dams on the Conchos were built before even the earliest available discharge records (1955), it is difficult to know to what extent

they have influenced the natural pattern of flow, but comparison of mean monthly precipitation to mean monthly runoff provides some insight. The long-term average runoff, even from 1955 to 1994, was low, as would be expected in an arid landscape (see Fig. 23.20). Note that runoff in Figure 23.20 is multiplied by 10 to facilitate visualization of the monthly pattern. Total annual runoff from 1955 to 1994 was only 0.8 cm, or about 2% of total precipitation. Of particular interest is that the mean runoff pattern during this time is considerably flatter than might be expected in a region with highly seasonal precipitation (see Fig. 23.20). This suggests strong regulation over this 40-year period. From 1995 to 2003, however, there is not only strong regulation, but annual runoff has greatly decreased (0.16 cm or 0.3% of precipitation). This reduction is particularly obvious during the dry winter months; mean discharge and runoff from 1995 to 2003 decreased to less than 10% of prior runoff.

Although water-chemistry and water-quality information have not been readily available for the Conchos, a one-time study by Gutiérrez and Borrego (1999) provides some valuable information. Various water-quality variables were measured at 105 sampling locations, primarily in the lower river in the vicinity of Camargo, Delicias, and upstream of Ojinaga. The natural chemistry of the lower river is affected by its limestone geology, with a pH exceeding 8 and a Ca concentration greater than 100 mg/L. However, the river is so strongly polluted that it is

difficult to know the baseline chemistry for most other variables. Kelly (2001) points out that there are only five water-quality monitoring stations within the basin but indicates that the most serious problem is fecal coliform contamination, primarily from Jiménez and Camargo. She also mentions that the Río Florido is contaminated with high levels of oil and grease from a chemical plant in Camargo. Because much of the river's water is used for irrigation, particularly in the Delicias area, agricultural return flows are highly contaminated with high nutrients and increased salinity. Gutiérrez and Borrego (1999) provided more specific data and indicated a great increase in total dissolved solids from 60 mg/L in the headwaters to >700 mg/L in the lower river. They showed that waters returning to the river from irrigation returns can be almost 2000 mg/L. Nutrients in the lower river were very high, with mean values of NO₃-N ranging from 2.3 to 4.6 mg/L in three different river segments. Phosphates ranged from 0.15 to 0.53 mg/L. Upstream of the irrigation districts Na usually was measured at less than 20 mg/L, whereas in the irrigated area near Delicias Na approached 300 mg/L at several sampling sites.

River Biodiversity and Ecology

The Río Conchos has its own freshwater ecoregion of the same name as part of the Río Grande complex of ecoregions (Abell et al. 2000). The river is of particular interest biologically because of substantial endemism in its fishes and herpetofauna.

Invertebrates

Information on invertebrates of the Río Conchos is sparse. One would expect the fauna of the lower Conchos to be similar to that of the Río Bravo del Norte (Río Grande), but information for the Río Grande is also limited (see Chapter 5).

Vertebrates

It is surprising that a basin as important as the Conchos is so poorly collected for fishes. As pointed out by Hendrickson et al. (2002), "The basin remains almost completely uncollected above 1700 m elevation," yet a huge area of the basin drains surfaces above that elevation to more than 3000 m asl, and lower reaches of the basin clearly still require much more extensive faunal inventories than have been realized to date. In spite of the paucity of collections, several recently published accounts of the river's fish

fauna are available, although none provide a comprehensive, detailed overview, and there is considerable disagreement about even basic information. Miller (1978) provides the first account known to us that attempted to comprehensively inventory the basin's fauna, listing 31 species. That work was updated in Smith and Miller (1986), which lists 35 species, with 7 endemic and 1 nonnative. Abell et al. (2000), in their continental-scale biodiversity analyses, stated there were 47 native fish species of which 12 were endemic. However, because they included neither a complete species list nor provided specific citations from which their data were compiled, it is impossible to determine the validity of their numbers. Arriaga-Cabrera et al. (2000) listed over 40 species for the upper Río Conchos and Río Florido, but sources for the lists are not cited and the lists contain many errors. Edwards et al. (2002a, 2002b) reported a total of 44 species from their own collections in the 1990s, but their relatively extensive collections were limited to lower and middle elevations and are not comprehensive for the entire drainage.

For purposes of this chapter, therefore, a list of species was compiled by combining data from Smith and Miller (1986), Edwards et al. (2002a, 2002b), Lozano-Vilano (2002), and records from an assortment of available ichthyology collection databases (including UMMZ, TNHC, CAS, FLMNH, INHS, ASU, and FMNH, museum codes as in Leviton et al. 1985, Leviton and Gibbs 1988). Based on that compilation and analysis, 53 fishes are recognized with apparently valid occurrence records in the basin. Of those, 38 are native (or very probably so; some doubt remains regarding a few because early collection records are inadequate to exclude the possibility that they were present before introductions started), 7 are considered endemic, and 8 are clearly introduced.

Documented Conchos basin endemics are Conchos shiner, bigscale pupfish, bighead pupfish, Salvador's pupfish, Conchos darter, yellowfin gambusia, and crescent gambusia. Species clearly introduced include goldfish, common carp, warmouth, inland silverside, white bass, rainbow trout, and perhaps plains killifish, though the latter's occurrence in rivers further south and ability to disperse through highly saline environments may cast some doubt on this conclusion.

In addition to the endemics, the remaining native fauna not surprisingly shares many species with the Río Bravo, a river that has also seen major changes in its fish fauna due to human impacts (Contreras-Balderas et al. 2003). A few marine derivatives at least formerly ascended the Río Bravo to occupy the

Conchos, including American eel and freshwater drum. Tropical freshwater components include Mexican tetra and Río Grande (or Texas) cichlid. A diversity of small minnows abound, including Mexican stoneroller, ornate minnow, red shiner, roundnose minnow, and several other shiners, including Texas shiner, Tamaulipas shiner, Chihuahua shiner, and Río Grande shiner, and longnose dace, as well as at least one species of the western genus *Gila* (*Gila pulchra* or a close relative of it). Catfishes are relatively diverse, including, in the genus *Ictalurus*, headwater, blue, and channel catfishes and an undescribed form. No trout are included as native, though Hendrickson et al. (2002) point out several lines of evidence that indicate that a still undocumented trout may live in remote high elevations of this basin. Conchos pupfish and blotched gambusia are fairly wide-ranging cyprinodontiforms. Ranges of both extend into Texas, but the latter has not been collected in that state for about a decade at least (Hubbs et al. 1991). Suckers include Yaqui sucker and Río Grande sucker, as well as Mexican redhorse. Only one gar, longnose gar, is known. Although some debate may exist regarding whether they are native or not, we consider green sunfish, bluegill, longear sunfish, and largemouth bass as native until such a hypothesis can be rejected with more conclusive data; all are native to nearby streams in both Texas and/or to the east and south in Mexico. Early collections were inadequate to rule out their presence long before introductions started.

Miller (1961, 1978), Contreras-Balderas (1978), and Contreras-Balderas et al. (2003) have all discussed the dramatic aquatic faunal changes taking place in northern Mexico, including the Conchos basin. By the time of their publications in 1978, Miller and Contreras-Balderas were separately able to provide specific examples of dramatic changes during the first three-quarters of the twentieth century in three rivers of the Conchos basin at major population centers (Chihuahua, Camargo, and Jimenez). By that time the faunas at these sites had been reduced to anywhere from 5% to 66% of their former diversity.

Abell et al. (2000) estimated that there are 46 native species of aquatic herpetofauna in the Conchos, of which 12 are endemic, but provided no information on the actual species.

Ecosystem Processes

No ecosystem studies have been done on the Río Conchos. It is difficult to speculate what preimpact processes might have been like in this system, other

than being similar to that found in other desert systems studied in Arizona, New Mexico, and Texas. At present, however, any ecosystem processes have been radically altered with the heavy pollution loads, dams, and dewatering of entire river sections for months at a time.

Human Impacts and Special Features

The Conchos basin overall is heavily impacted by humans, but as is the case in many places, fish faunas and other components of aquatic communities remain most intact in headwater areas, above the majority of such impacts. These less-impacted areas are in mountainous portions of the Conchos basin, which have extensive tracts of forest. Chihuahua has more forests than any other state in Mexico, and these are primarily the pine-oak forests of the Sierra Tarahumara. These forests are essential to both the terrestrial and aquatic ecology of the region and serve as a key migratory route for North American birds. Some tributaries of the Balleza drainage, in particular, despite extensive logging activities that characterize all parts of the basin at higher elevations, appear to still harbor relatively intact high- and middle-elevation aquatic communities in some areas. Lower reaches, especially below major agricultural and/or urban areas and below reservoirs, as mentioned earlier, retain relatively little of their native diversity as a result of contamination, dewatering, and otherwise altered natural regimes. The basin, however, still retains much of its overall scenic beauty. Certainly its lower canyon, just upstream of its mouth at Ojinaga, is spectacular. The Tarahumara highlands are also a tourist attraction often visited by those en route to, or coming from, the Río Fuerte's Barranca de Cobre.

There are several major ways in which the Conchos basin has been negatively impacted by humans, including logging, dams, surface and aquifer withdrawals, irrigated agriculture, overgrazing, and pollution from various sources (Kelly 2001). The major impact in the headwaters is logging, which is primarily located within the mountainous headwaters of the basin. Recent decades have witnessed a dramatic increase in logging within this region, particularly by large international logging companies (Guerrero et al. 2001), and these semiarid mountainous regions are particularly sensitive to deforestation, which frequently results in soil erosion that has downstream consequences. Moreover, the increased runoff means that less water is available to infiltrate into the soil, and consequently ground-

water recharge that supplies streams with base flow between rainfall events is reduced. A reduction in base flow has consequences for aquatic species, and in 14 locations in Chihuahua between 1901 and 1975 it is estimated that over 41% of the fish species disappeared.

As indicated earlier, the combination of dams, water withdrawals, and pollution from municipalities, agriculture, and industry has had a profound effect on the Río Conchos, particularly in the lower main stem. The dominant water use (93%) is for irrigation, with domestic withdrawals accounting for 6.4% (Kelly 2001). Contaminants are often very high and flows have sometimes been reduced to zero for extended periods, all of which is devastating to aquatic life. Here, as in many arid streams that have been dammed, there have not only been significant reductions in total flow and flow variability but a narrowing of the stream channel as vegetation, particularly nonnative salt-cedar, has encroached upon the river banks. Much of the natural grasslands have been transformed by either irrigated crops or overgrazing and the introduction of nonnative species of grass (Guerrero et al. 2001).

Water management of the Río Conchos basin has been a major point of contention between Mexico and the United States. According to the 1944 U.S.–Mexico Water Treaty, Mexico is supposed to provide a certain minimum amount of water to the United States (Kelly 2001, Center for Space Research 2003). Until the early 1990s Mexico met its treaty obligations; however, since 1992 it has failed to do so, arguing that obligations cannot be met due to persistent and extraordinary drought (Center for Space Research 2003). Simultaneously, the amount of water used for irrigation has increased. Recent heavy rainfall in 2004, however, has filled Conchos reservoirs, and Mexico has agreed to release water to the Río Grande.

ADDITIONAL RIVERS

The Río Fuerte flows in a generally southwesterly direction within the southern portion of the state of Chihuahua to cross the coastal state of Sinaloa (Fig. 23.21). Its major tributaries (Urique, San Miguel, Verde) arise in the high elevations of the Sierra Madre Occidental of Chihuahua and Durango. Of particular interest are portions of middle reaches of the basin in scenic Barranca del Cobre (Copper Canyon) Park, home to many Tarahumara (see section on the Río Conchos). Coming out of these canyons, the main-

stem river flows primarily across the Piedmont hills and deltas of the Buried Ranges physiographic province to empty into the Gulf of California, but its flow is highly regulated by dams (e.g., Miguel Hidalgo) at the lower elevations. This is a relatively arid landscape, particularly in the lower elevations near the coast, which have been converted to irrigated agricultural areas. The reservoirs have been stocked with many species of nonnative game fishes.

The Río Tamesí flows in a southeasterly direction within the northeastern state of Tamaulipas, draining an area of 19,127 km² (see Fig. 23.23). It joins the larger Río Pánuco near Tampico, 10 km upstream of the Gulf of Mexico. The basin's population is rather diffuse and generally low, although Ciudad Victoria (population about 260,000) is located just outside the northeastern boundary. The Tamesí headwaters arise high in the semiarid ranges of the northern Sierra Madre Oriental, west of Ciudad Victoria, and in the Sierra Tamaulipas, a small mountain range located between the Gulf of Mexico and the Sierra Madre Oriental. Lithology of the headwater areas consists predominantly of Cretaceous limestone and is considered to be heavily karstic. Much of the streamflow for the Tamesí originates as springs at the base of the mountains and enters the middle Tamesí within the Coastal Plain. Forty kilometers from its confluence with the Río Pánuco, the Río Tamesí crosses the Tamaulipas Arch, a south-plunging anticline and an extension of the Sierra Tamaulipas. The valley has an appreciably low gradient downstream of the arch, 0.49 m/km, with an extensive system of floodplain lakes. These lakes are utilized for drinking water by Tampico but, like the lagoons and lakes in the lower Pánuco, represent an important ecological component of the Coastal Plain (Fig. 23.9).

The Río Salado flows in a generally easterly direction through the northeastern states of Coahuila and Nuevo León before emptying into Falcon Reservoir on the Río Bravo del Norte in Tamaulipas (Fig. 23.25). The basin drains an arid region, spanning from the headwaters of Río Sabinas, a major tributary that begins high in the northern Sierra Madre Oriental, and flows into the Coastal Plain. A large dam (V. Carranza) just below the confluence of these rivers results in a high degree of regulation. Water from the reservoir irrigates extensive agricultural areas, particularly for cotton. Much of the main stem does not flow for extended periods. However, because of the continued international concern with irrigation and the declining condition of the Río Bravo/Grande, the Río Salado is an important tributary. Average daily discharge near its mouth in Falcon

FIGURE 23.9 Wetlands and lagoons of the lower Río Tamesí at Tampico (PHOTO BY P. H. HUDSON).

Reservoir (near Las Tortilleras, Tamaulipas) from September 1953 to June 2004 was $10.1 \text{ m}^3/\text{s}$ (www.ibwc.state.gov/wad/histflo1.htm). The Salado watershed is increasingly threatened because of a growing population and associated land-use change in northern Mexico, which places greater stress on water supplies such as springs and streams. For example, Contreras-Balderas and Lozano (1994) note that in arid Southwestern Nuevo León reduced spring flow has eliminated several endemic species of crayfish and snails.

The Río Armería flows in a southerly direction in west-central Mexico, beginning in the state of Jalisco and passing through the small state of Colima before entering the Pacific Ocean (Fig. 23.27). The Pacific coast of Mexico is along an active plate margin and therefore has a narrow Coastal Plain. The Río Armería drains both the Neovolcanic Plateau and

Sierra Madre del Sur, changing its name from Río Ayuquila to Río Armería as it approaches the coast. A 71 km section of river comprises the northeastern boundary of Sierra de Manantlán Biosphere Reserve and this basin also receives runoff from the 4240 m asl volcano in the Volcán Nevado de Colima National Park. Although 60% of the basin is in forests, its population density is relatively high at 56 people/ km^2 . Much of the river water is diverted for irrigation in a series of agricultural valleys, with 30% of the basin devoted to agriculture (largely sugarcane).

The Río Lacanjá is a small tributary of the Río Usumacinta located in southern Mexico in the Chiapas–Guatemala Highlands physiographic province (Fig. 23.29). This basin has very high annual precipitation ($>200 \text{ cm}$) and lies within the Petén–Veracruz Moist Forests terrestrial ecoregion. The river is the boundary between two of the most

FIGURE 23.10 Río Lacanjá, a tributary of the Río Usumacinta (PHOTO BY H. BAHENA).

important biosphere reserves in Mexico, Montes Azules and Lacantún, and 80% of the basin is within reserves. The river remains in a relatively natural condition, with fast-flowing runs, a waterfall with numerous runs and rapids, floodplain clearwater lakes, a floodplain backwater, and a riparian wetland (Fig. 23.10).

ACKNOWLEDGMENTS

We acknowledge and thank Norman Mercado-Silva (University of Wisconsin and Universidad de Guadalajara, Mexico), John Lyons (State of Wisconsin Department of Natural Resources), and Luis Manuel Martínez-Rivera and

Luis Ignacio Íñiguez-Dávalos (Universidad de Guadalajara, Mexico) for contributing much of the information for the one-page summary of the Armería–Ayuquila River. We also greatly appreciate the information on aquatic invertebrates provided by Atilano Contreras-Ramos for several of the rivers. Joachin Bueno-Soria provided an unpublished manuscript on the invertebrates of the Grijalva system. José Campoy-Favela helped with the Río Yaqui account. We are most grateful for the contribution of photos by A. H. Siemens and W. E. Doolittle.

FIGURE 23.12 Mean monthly air temperature, precipitation, and runoff for the Río Pánuco basin.

RÍO PÁNUCO

Relief: 3800 m

Basin area: 98,227 km² (with Tamesí) 79,100 km² (without Tamesí)

Mean discharge: 537.4 m³/s (with Tamesí)
472.8 m³/s (without Tamesí)

River order: NA

Mean annual precipitation: 96 cm

Mean air temperature: 20°C

Mean water temperature: NA

Physiographic provinces: Neovolcanic Plateau (NP), Sierra Madre Oriental (SO), Mexican Gulf Coastal Plain (CP), Central Mesa (CM)

Biomes: Tropical Savanna, Mexican Montane Forest, Desert

Freshwater ecoregion: Tamaulipas–Veracruz

Terrestrial ecoregions: 6 ecoregions (see text)

Number of fish species: >88 (>80 native) (not including Río Tamesí)

Number of endangered species: 7 fishes

Major fishes: Media Luna cichlid, blackcheek cichlid,

Chairel cichlid, slender cichlid, bluetail splitfin, dusky goodea, relict splitfin, jeweled splitfin, Media

Luna pupfish, sheepshead swordtail, short-sword platyfish, delicate swordtail, highland swordtail, Moctezuma swordtail,

Pánuco swordtail, variable platyfish, spottail chub, Pánuco minnow, bicolor minnow, chubsucker minnow, flatjaw minnow,

Río Verde catfish, phantom blindcat, fleshylip buffalo, Mexican tetra

Major other aquatic vertebrates: NA

Major benthic invertebrates: mollusks (*Hydrobia tampicoensis*, *Littoridina crosseana*, *Lithasiopsis hinkleyi*), crustaceans (*Palaemonetes mexicanus*, *Procambarus* [Ortmannicus] *ortmanii*, *P.* [Ortmannicus] *acutus cuevachicae*, *P.* [Scapullicambarus] *strengbi*, *Troglomexicanus perezfantaetae*, *T. huastecae*, *T. tamaulipenses*), hellgrammites (*Chloronia mexicana*, *Corydalus magnus*)

Nonnative species: tilapias, grass carp, silver carp, channel catfish, blue catfish, largemouth bass, water hyacinth

Major riparian plants: NA, but see Río Tamesí

Special features: Cascada Tamul, 102 m high waterfall (at confluence of Río Gallinas and Río Santa María); natural springs; caves and sinkholes are common, some perhaps among world's deepest, many with abundant aquatic habitat; some of highest areas harbor cloud forest (El Cielo Biosphere Reserve)

Fragmentation: dams on Río Moctezuma, Río Tula, Río Topila; dam under construction on lower Río Tamuin

Water quality: highly variable, but poor in many places

Land use: sugarcane farming, citrus, and cattle ranching in Coastal Plain; traditional slash and burn, citrus, and coffee in mountains; petroleum extraction in lower basin

Population density: low

Major information sources: Contreras-Ramos 1998, www.weatherbase.com, <http://webworld.unesco.org/water/ihp/db/shiklomanov/index.shtml>, Hudson 2003a, Hudson 2003b, Hudson and Heitmuller 2003, Hudson and Colditz 2003, Hudson et al. in press

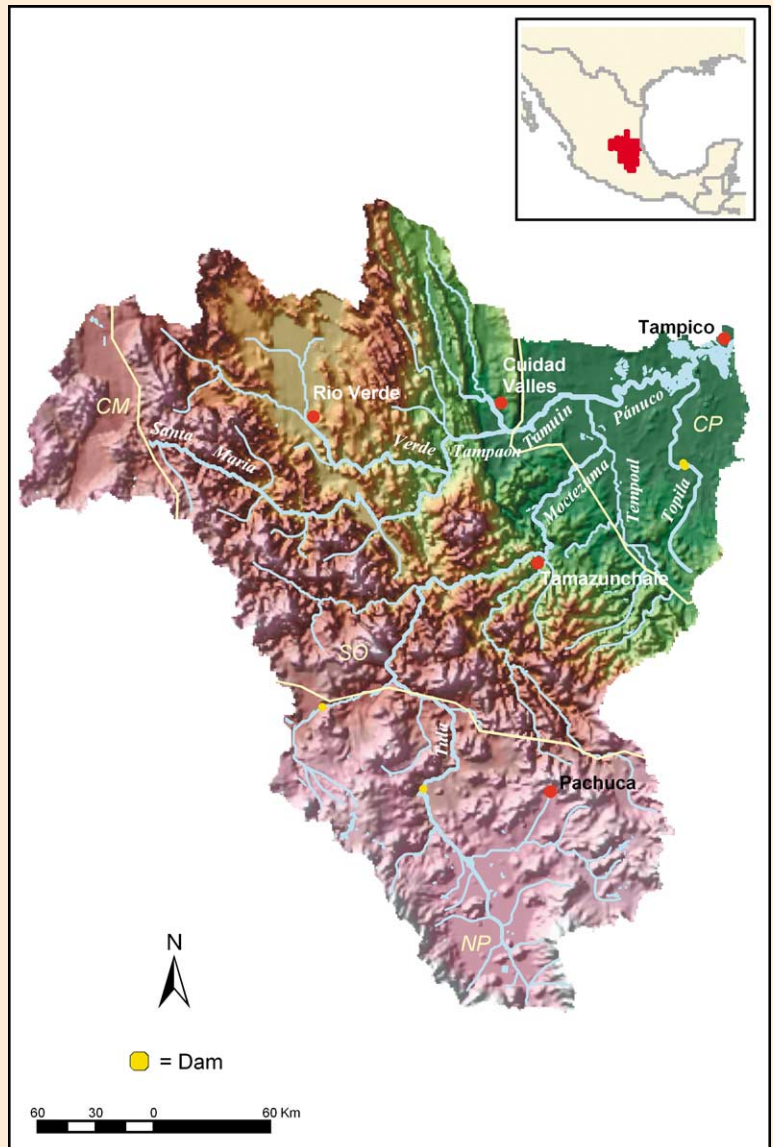

FIGURE 23.11 Map of the Río Pánuco basin. Physiographic provinces are separated by yellow lines.

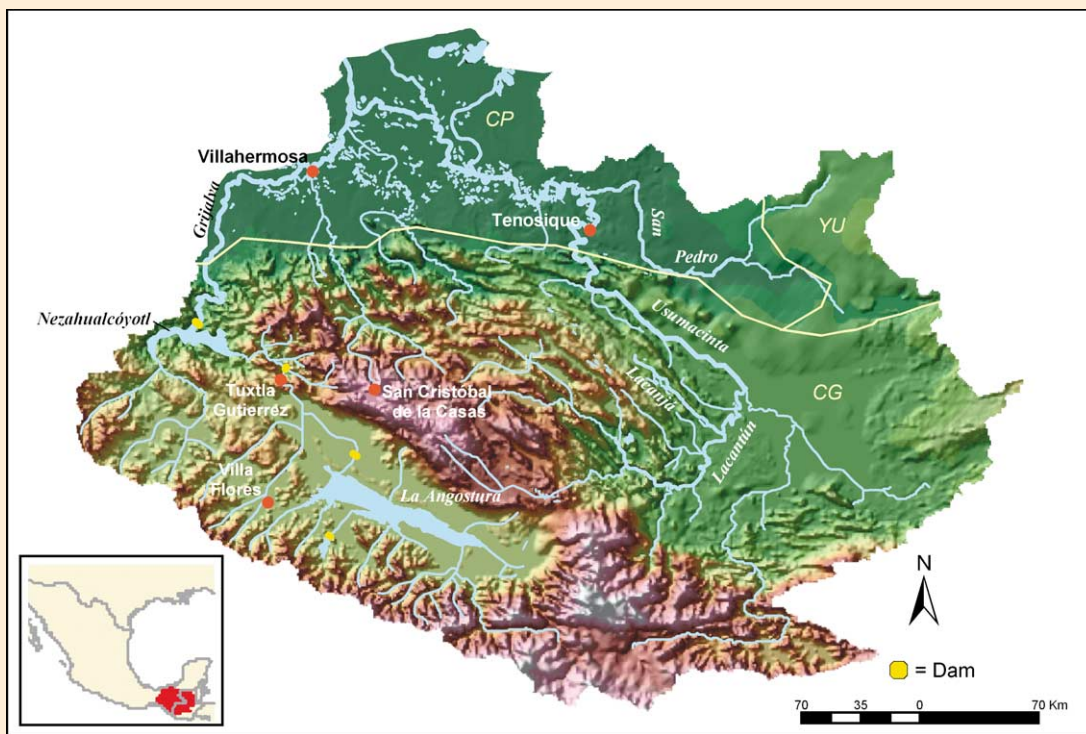

FIGURE 23.13 Map of the Ríos Usumacinta–Grijalva basin. Physiographic provinces are separated by yellow lines.

RÍOS USUMACINTA–GRIJALVA

Relief: 3800 m
Basin area: 112,550 km²
Mean discharge: 2678 m³/s
River order: NA
Mean annual precipitation: 199 cm
Mean air temperature: 23°C
Mean water temperature: NA
Physiographic provinces: Chiapas–Guatemala Highlands (CG), Mexican Gulf Coastal Plain (CP), Yucatan (YU)
Biomes: Tropical Rain Forest, Tropical Savanna
Freshwater ecoregion: Grijalva–Usumacinta
Terrestrial ecoregions: Peten–Veracruz Moist Forests, Chiapas Depression Dry Forests, Pantanos de Centla, Central American Pine–Oak Forests, Chiapas Montane Forests, Usumacinta Mangroves
Number of fish species: >112 (103 native)
Number of endangered species: 11 fishes
Major fishes: Pénjamo tetra, headwater killifish, Chiapas killifish, widemouth gambusia, Chiapas swordtail, sulphur molly, upper Grijalva livebearer, white cichlid, Angostura cichlid, tailbar cichlid, Petén cichlid, Montecristo cichlid, Usumacinta cichlid, Chiapa de Corzo cichlid, freckled cichlid, Teapa cichlid, longfin gizzard shad, Lacandon sea catfish, Maya sea catfish, Maya needlefish, Mexican halfbeak, Mexican mojarra
Major other aquatic invertebrates: river crocodile, swamp crocodile, common snapping turtle, tortugas blanca, tortugas casquito, neotropical river otter, West Indian manatee, water opossum, tepezcuintle
Major benthic invertebrates: mollusks (*Pomacea*, *Aroapyrgus*, *Cochliopina*, *Hydrobia*, *Pachychilus*), hellgrammites (*Corydalus luteus*), caddisflies (*Smicridea*, *Nectopsyche*, *Neotrichia*), mayflies (*Camelobaetidius*, *Leptophlebia*, *Traverella*, *Campsurus*), odonates (*Archaeogomphus*, *Phyllocycla*, *Protoneura*, *Neoneura*, *Heteragrion*), beetles (*Anacaena*, *Brachyvatus*, *Laccophilus*)
Nonnative species: common carp, grass carp, rainbow trout, largemouth bass, blue tilapia, redbelly tilapia, Nile tilapia, Mozambique tilapia, jaguar guapote, water hyacinth
Major riparian plants: *Andira galeottiana*, *Pachira acuatica*, *Bravaisia integerrima*, bloodwoodtree, gregorywood, *Paquiria aquatica*, willow, button mangrove, black mangrove, white mangrove, American mangrove, cattails, common reed
Special features: Pantanos de Centla Biosphere Reserve; Laguna del Tigre National Park in Guatemala; Selva Maya, possibly largest remaining tropical forest in North/Central America; center of ancient Mayan culture; Montes Azules Biosphere Reserve; Lacantún Biosphere Reserve
Fragmentation: several large dams on Río Grijalva; new dams proposed on Usumacinta
Water quality: NA
Land use: 59% forest, 31% cropland, 8% grassland/savanna/shrubland, 3% urban
Population density: 28 people/km²
Major information sources: Revenga et al. 1998, A. Contreras-Ramos, personal communication, www.weatherbase.com, Rodiles-Hernández 2004, Bueno-Soria et al. in press, March et al. 1996, <http://webworld.unesco.org/water/ihp/db/shiklomanov/index.shtml>

FIGURE 23.14 Mean monthly air temperature, precipitation, and runoff for the Ríos Usumacinta–Grijalva basin.

FIGURE 23.16 Mean monthly air temperature, precipitation, and runoff for the Río Candelaria basin.

RÍO CANDELARIA (YUCATÁN)

Relief: 375 m

Basin area: 10,755 km²

Mean discharge: 46 m³/s

River order: NA

Mean annual precipitation: 150 cm

Mean air temperature: 24.6°C

Mean water temperature: NA

Physiographic provinces: Yucatan (YU), Mexican Gulf Coastal Plain (CP)

Biomes: Tropical Rain Forest, Tropical Savanna

Freshwater ecoregion: Grijalva–Usumacinta

Terrestrial ecoregions: Yucatan Moist Forests, Usumacinta Mangroves, Peten–Veracruz Moist Forests, Pantanos de Centla

Number of fish species: >65 (>17 freshwater, 48 estuarine)

Number of endangered species: none

Major fishes: firemouth cichlid, blackgullet cichlid, yellow cichlid, yellowjacket, Mayan cichlid, yellowbelly cichlid, Montecristo cichlid, redhead cichlid, giant cichlid, stippled gambusia, Champoton gambusia, shortfin molly, picotee livebearer, pike killifish, banded tetra, Maya tetra, pale catfish, threadfin shad, bay anchovy, silver perch

Major other aquatic vertebrates: swamp crocodile, neotropical river otter

Major benthic invertebrates: mollusks (narrowmouth hydrobe), hellgrammites (*Corydalus bidenticulatus*), stoneflies (*Anacroneturia*), true bugs (*Abedus*)

Nonnative species: none documented

Major riparian plants: cattails, breadnut tree, bay palmetto, gumbo limbo, gregorywood, mangroves

Special features: one of the few rivers flowing through the highly karstic region of the Yucatan Peninsula; large water losses to groundwater; where ancient Mayan civilization developed

Fragmentation: no dams or reservoirs; prehistoric canal systems

Water quality: NA, but perceived to be good

Land use: slash and burn in uplands; cattle ranching in coastal plain

Population density: low, but has increased rapidly since 1960s

Major information sources: www.weatherbase.com, Gunn et al. 1995, Ayala-Perez et al. 1998

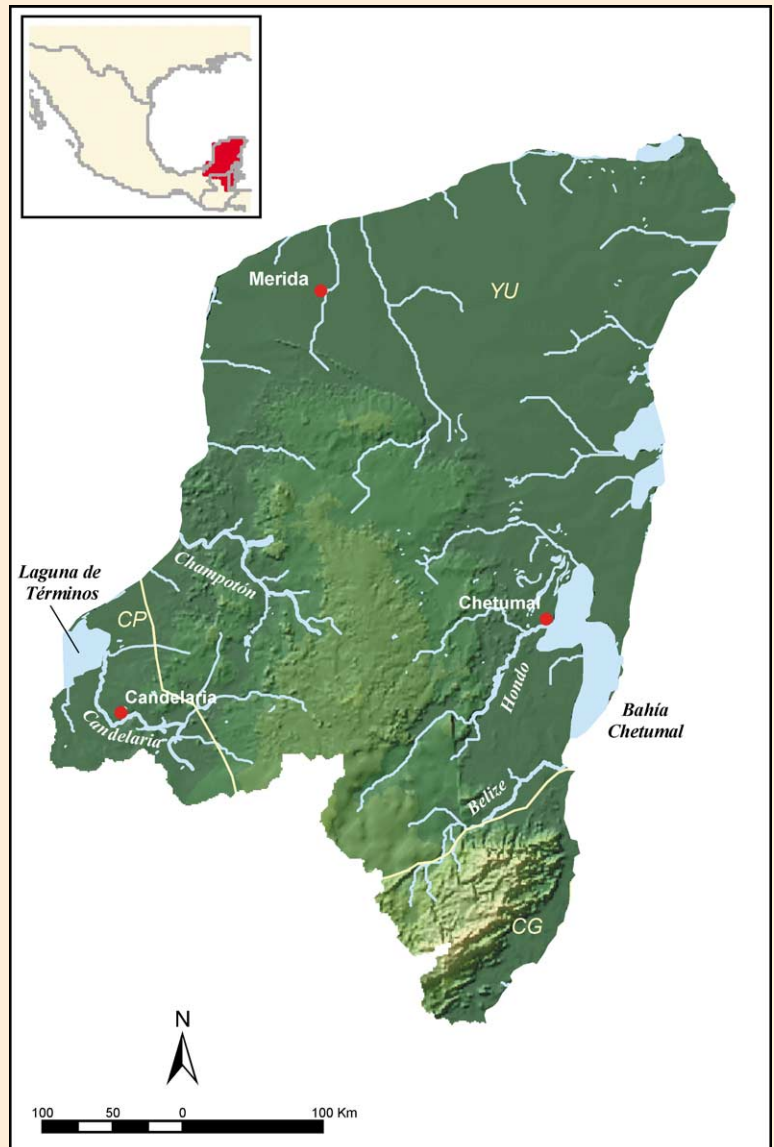

FIGURE 23.15 Map of the Río Candelaria basin. Physiographic provinces are separated by yellow lines.

FIGURE 23.18 Mean monthly air temperature, precipitation, and runoff for the Río Yaqui basin.

RÍO YAQUI

Relief: 2520 m

Basin area: 73,000 km²

Mean discharge: 78.5 m³/s

River order: 6

Mean annual precipitation: 48 cm

Mean air temperature: 18.4°C

Mean water temperature: 18.0°C

Physiographic provinces: Sierra Madre Occidental (SO), Basin and Range (BR), Buried Ranges (BU)

Biomes: Mexican Montane Forest, Desert

Freshwater ecoregion: Sonoran

Terrestrial ecoregions: Sonoran–Sinaloan Transitional Subtropical Dry Forests, Sierra Madre Occidental Pine–Oak Forests, Sonoran Desert, Chihuahuan Desert, Sinaloan Dry Forests

Number of fish species: 107

Number of endangered species: 7 fishes (threatened)

Major fishes: Yaqui trout, Yaqui sucker, Yaqui chub, roundtail chub, Mexican stoneroller, longfin dace, Yaqui catfish, Yaqui topminnow, Leopold sucker, Cahita sucker, Pacific gizzard shad, striped mullet, striped mojarra, machete, Heller's anchovy

Major other aquatic vertebrates: water snakes (*Thamnophis* spp.), Sonora mud turtle, Tarahumara frog, Tarahumara salamander, Chiricahua leopard frog, neotropical river otter

Major benthic invertebrates: crustaceans (Cauque River prawn, blue shrimp, white shrimp), mollusks (*Fossaria* [*Bakerilymnaea*] *bulimoides*), hellgrammites (*Corydalus bidenticulatus*, *Corydalus texanus*), mayflies (*Siphonurus*, *Nixe*, *Acentrella*), stoneflies (*Capnia decepta*, *Mesocapnia frisoni*, *Anacroneturia wipikupa*)

Nonnative species: channel catfish, blue catfish, black bullhead, largemouth bass, rainbow trout, common carp, river carpsucker, green sunfish, bluegill, western mosquitofish, American bullfrog

Major riparian plants: Arizona sycamore, Arizona alder, Goodding willow, Bonpland willow, green ash, Fremont cottonwood, common reed, Chinese saltcedar, velvet mesquite

Special features: basin shared between Arizona and México (Sonora and Chihuahua); spectacular canyons (barrancas); high fish diversity for arid system, but low endemism; protected areas are Tutuaca, Papigochic, and Sierra de Ajos Bavispe

Fragmentation: three major dams on main stem; flow regulation over 50% of the basin

Water quality: NA

Land use: 62% forest, 2% cropland, 33% grassland/savanna/shrubland, 3% urban

Population density: 7 people/km²

Major information sources: Arriaga-Cabrera et al. 2000, Hendrickson et al. 1981, Baumann and Kondratieff 1996, Watersheds of the World CD 2003, A. Contreras-Ramos, personal communication, <http://webworld.unesco.org/water/ihp/db/shiklomanov/index.shtml>

FIGURE 23.20 Mean monthly air temperature, precipitation, and runoff for the Río Conchos basin.

RÍO CONCHOS

Relief: 2700 m

Basin area: 68,386 km²

Mean discharge: 20.5 m³/s

River order: NA

Mean annual precipitation: 48 cm

Mean air temperature: 18°C

Mean water temperature: NA

Physiographic provinces: Sierra Madre Occidental (SC), Basin and Range (BR)

Biomes: Mexican Montane Forest, Desert

Freshwater ecoregion: Río Conchos

Terrestrial ecoregions: Sierra Madre Occidental Pine–Oak Forests, Chihuahuan Desert

Number of fish species: 53 (>38 native)

Number of endangered species: 5 fishes

Major fishes: Conchos shiner, bigscale pupfish, bighead pupfish, Salvador's pupfish, Conchos darter, yellowfin gambusia, crescent gambusia, longnose gar, largemouth bass, Mexican tetra, Río Grande cichlid, Mexican stoneroller, ornate minnow, red shiner, roundnose minnow, Tamaulipas shiner, longnose dace, Conchos chub, headwater catfish, blue catfish, channel catfish

Major other aquatic vertebrates: water snakes (*Thamnophis* spp.)

Major benthic invertebrates: virile crayfish, others NA

Nonnative species: goldfish, common carp, warmouth, inland silverside, white bass, rainbow trout

Major riparian plants: NA

Special features: major inflow for the Río Bravo del Norte upstream of Big Bend National Park; considerable endemism of fish species and herpetofauna; specialized fauna in spring and cave habitats

Fragmentation: several dams, Presa Boquilla is largest; flow is reduced to zero for months at a time

Water quality: pH = 7.7 to 8.4, total dissolved solids = 156 to 722 mg/L, NO₃-N = 2.3 to 3.8 mg/L, PO₄-P = 0.15 to 0.53 mg/L, Na = 23 to 168 mg/L, Ca = 8 to 190 mg/L; degraded in some areas by sewage, nutrients, pesticides, industrial wastes

Land use: NA

Population density: >16 people/km²

Major information sources: Kelly 2001, Abell et al. 2000, Arriaga-Cabrera et al. 2000, Gutiérrez and Borrego 1999, www.ibwc.state.gov, SEMARNAT 2002, Edwards et al. 2002a, 2002b

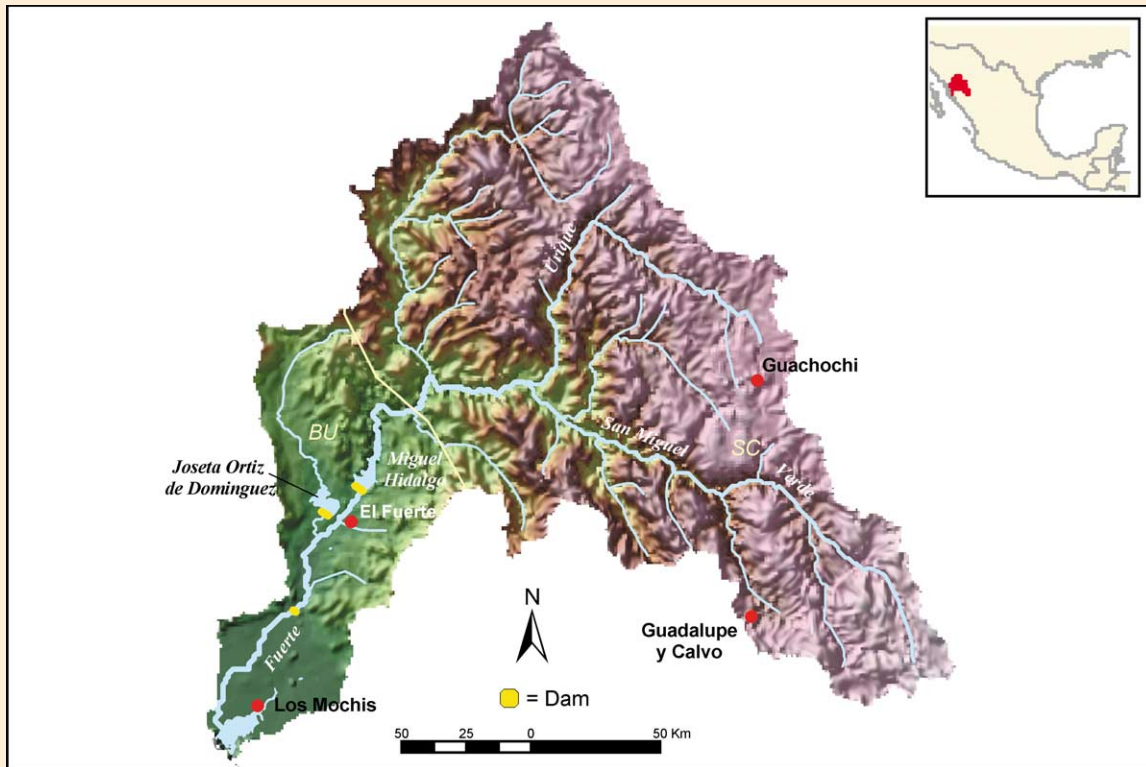

FIGURE 23.21 Map of the Río Fuerte basin. Physiographic provinces are separated by yellow line.

RÍO FUERTE

Relief: 3300 m

Basin area: 34,247 km²

Mean discharge: 31 m³/s

River order: NA

Mean annual precipitation: 78 cm

Mean air temperature: 24°C

Mean water temperature: NA

Physiographic provinces: Buried Ranges (BU), Sierra Madre Occidental (SC)

Biomes: Desert, Mexican Montane Forest

Freshwater ecoregion: Sinaloan Coastal

Terrestrial ecoregions: Sinaloan Dry Forests, Sonoran–Sinaloan Transition Subtropical Dry Forests, Sierra Madre Occidental Pine–Oak Forests

Number of fish species: 51

Number of endangered species: 6 fishes (threatened), 3 fishes (special protection)

Major fishes: Mexican stoneroller, ornate shiner, Mexican golden trout, diverse unisexual clones of topminnow, roundtail chub, Yaqui sucker, Yaqui catfish, mountain clingfish

Major other aquatic vertebrates: neotropical river otter

Major benthic invertebrates: crustaceans (*Macrobrachium*), others NA

Nonnative species: largemouth bass (important reservoir sport fishery), bluegill, green sunfish, rainbow trout, channel catfish, blue catfish, common carp, tilapia

Major riparian plants: none

Special features: major tributaries descend through Barranca del Cobre (Copper Canyon) Park; remote historic settlements; indigenous cultures (Rarámuri or Tarahumara) occupy much of the basin

Fragmentation: large dams in lower river

Water quality: NA

Land use: logging in higher-elevation pine forests; nonmechanized, dry agriculture (corn, beans, grazing) practiced by Rarámuri throughout headwaters and some canyon bottoms; extensive irrigated mechanized agriculture in Coastal Plain

Population density: NA

Major information sources: Arriaga-Cabrera 2000, www.weatherbase.com, <http://webworld.unesco.org/water/ihp/db/shiklomanov/index.shtml>, Hendrickson et al. 2002, SEMARNAT 2002, Hendrickson and Varela 2002, Vrijenhoek 1984

RÍO TAMESÍ

Relief: 3353 m

Basin area: 19,127 km²

Mean discharge: 64.6 m³/s

River order: NA

Mean annual precipitation: 105 cm

Mean air temperature: 24°C

Mean water temperature: NA

Physiographic provinces: Sierra Madre Oriental (SO), Mexican Gulf Coastal Plain (CP)

Biomes: Desert/Semidesert, Tropical Savanna

Freshwater ecoregion: Tamaulipas–Veracruz

Terrestrial ecoregions: Sierra Madre Oriental Oak-Pine Forests, Veracruz Moist Forests, Alvarado Mangroves

Number of fish species: 93

Number of endangered species: 4 fishes

Major fishes: sailfin molly, Amazon molly, shortfin molly, Mexican tetra, alligator gar, variable platyfish, smallmouth buffalo, channel catfish, rainwater killifish, Río Grande cichlid, sheepshead minnow, striped mullet, hardhead catfish, phantom blindcat, chair cichlid, slender cichlid, blackcheek cichlid, lantern minnow, Gulf gambusia, golden gambusia, spinycheek sleeper

Major other aquatic vertebrates: NA

Major benthic invertebrates: mollusks (*Lithasiopsis crassa*, *Pachychilus corpulentus*, *Pachychilus vallesensis*), crustaceans (*Palaemonetes hobbsi*, *P. kadiakensis*, *P. mexicanus*, *Procambarus [Ortmannicus] acutus cuevachicae*, *Procambarus [Ortmannicus] acutus*), hellgrammites (*Chloronia mexicana*, *Corydalus luteus*), beetles (*Tropisternus*), caddisflies (*Leptonema*), mayflies (*Baetis*), caddisflies (*Nectopsyche*)

Nonnative species: common water hyacinth, hydrilla, cinnamon river shrimp, grass carp, silver carp, largemouth bass, blue tilapia

Major riparian plants: breadnut tree, gumbo limbo, cattails, mangroves

Special features: headwaters include large El Cielo Biosphere Preserve (near Ciudad Victoria); large springs at edge of karstic Sierra Guatemala feed river via caves originating at high elevations in same range with numerous aquatic cave organisms; extensive freshwater lagoon on lower 40 km of river valley

Fragmentation: main-stem dam east of Mante; several small dams

Water quality: poor in several areas

Land use: sugarcane and citrus farming and cattle ranching in Coastal Plain; traditional slash and burn in mountains; petroleum extraction in lower basin

Population density: NA

Major information sources: Arriaga-Cabrera et al. 2000, Contreras-Ramos 1998, www.weatherbase.com, Garcia de León et al. in press, Hendrickson and Krejca 2000, Hudson 2002

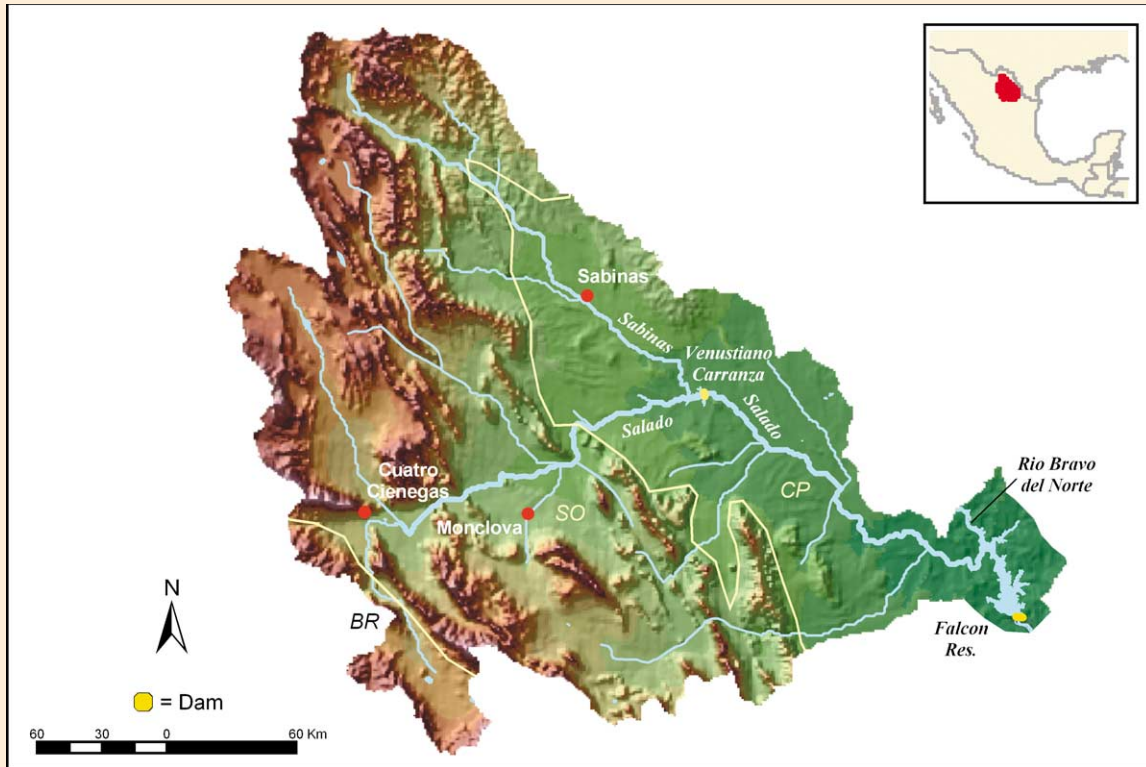

FIGURE 23.25 Map of the Río Salado basin. Physiographic provinces are separated by yellow lines.

RÍO SALADO

Relief: 2560 m
Basin area: 60,000 km²
Mean discharge: 10 m³/s
River order: NA
Mean annual precipitation: 31 cm
Mean air temperature: 21°C
Mean water temperature: NA
Physiographic provinces: Coastal Plain (CP), Sierra Madre Oriental (SO)
Biome: Desert
Freshwater ecoregion: Río Salado
Terrestrial ecoregions: Tamaulipan Mezquital, Sierra Madre Oriental Pine–Oak Forests, Chihuahuan Desert, Tamaulipan Matorral
Number of fish species: 52 (including Cuatro Ciénegas)
Number of endangered species: none
Major fishes: Salado shiner, tufa darter, Salado darter, Cuatro Ciénegas gambusia, robust gambusia, marbled swordtail, Cuatro Ciénegas platyfish, bolson pupfish, Cuatro Ciénegas pupfish, Mexican red shiner, Mexican tetra, largemouth bass, longear sunfish, Cuatro Ciénegas cichlid, Río Grande cichlid, roundnose minnow, Tamaulipas shiner, Devils River minnow, blue catfish, headwater catfish, channel catfish, flathead catfish, gray redhorse
Major other aquatic vertebrates: Cuatro Ciénegas box turtle, Cuatro Ciénegas red-eared slider, Cuatro Ciénegas softshell, diamondback water snake
Major benthic invertebrates: crustaceans (red swamp crayfish, *Hyallolella*, *Paleomonetes suttkusi*), mollusks (redrim melania)
Nonnative species: warmouth, blue tilapia, spotted jewelfish, common carp, threadfin shad, red swamp crayfish, Asiatic clam, water hyacinth
Major riparian plants: mesquite, cottonwood, willows, common reed, giant reed, saltcedar, athel
Special features: major headwaters in Cuatro Ciénegas Protected Area for Fauna and Flora, a small desert valley with hundreds of large geothermal springs feeding marshes and rivers that harbor a diverse and highly endemic fauna and flora
Fragmentation: one major dam (V. Carranza) on main stem; most of main stem usually dry
Water quality: pollution from agriculture and industry; point and nonpoint sources
Land use: NA
Population density: NA
Major information sources: www.weatherbase.com, Abell et al. 2000, Arriaga-Cabrera 2000, Hendrickson et al. in press, www.ibwc.state.gov, Guerra 1952, Minckley 1969

FIGURE 23.28 Mean monthly air temperature, precipitation, and runoff for the Río Armería-Ayuquila basin.

RÍO ARMERÍA-AYUQUILA

Relief: 4240 m

Basin area: 9803 km²

Mean discharge: 30.4 m³/s

River order: 6

Mean annual precipitation: 104 cm

Mean air temperature: 22.1°C

Mean water temperature: 21.8°C

Physiographic provinces: Neovolcanic Plateau (NP), Sierra Madre del Sur (SD)

Biomes: Desert, Mexican Montane Forest

Freshwater ecoregion: Manantlán-Ameca

Terrestrial ecoregion: Trans-Mexican Volcanic Belt, Oak-Pine Forests, Jalisco Dry Forests

Number of fish species: 38 (32 native), 3 extirpated

Number of endangered species: 3 fishes, 1 mammal

Major fishes: banded tetra, riffle chub, Mexican redhorse, Lerma catfish, bandfin splitfin, goldbreast splitfin, Pacific molly, Lerma livebearer, golden livebearer, Michoacán livebearer, redbreast cichlid, mountain mullet, mountain clingfish, Pacific sleeper, finescale sleeper, multispotted goby

Major other aquatic vertebrates: giant toad

Major benthic invertebrates: crustaceans (*Macrobrachium occidentale*, *M. americanum*, *Pseudohelphusa dilatata*, *Atya ortomannoides*, *A. margaritacea*), stoneflies (*Anacroneuria*), mayflies (*Baetis*, *Baetodes*, *Callibaetis*, *Farrodes*, *Thraulodes*, *Leptohyphes*), caddisflies (*Ceratopsyche*, *Cheumatopsyche*, *Leptonema*, *Smicridea*), mollusks (*Littoridina orcutti*), hellgrammites (*Corydalus bidenticulatus*)

Nonnative species: common carp, green swordtail, bluegill, largemouth bass, blue tilapia, redbreast tilapia

Major riparian plants: Humboldt's willow, West Indian marsh grass, common water hyacinth, fragrant flatsedge

Special features: one of the 15 largest rivers of the Mexican Pacific Slope; 71 km section of river comprises northeastern boundary of Sierra de Manantlán Biosphere Reserve; drains 4240 m volcano (Nevado de Colima; designated National Park)

Fragmentation: 40 dams in system with a total capacity of 731 million m³; series of agricultural valleys where flow is diverted for irrigation

Water quality: relatively good in isolated sections; highly impacted by organic pollutants near cities and agricultural valleys; dissolved oxygen = 1.0 to 4.3 mg/L, pH = 7.4, alkalinity = 123 mg/L as CaCO₃, NO₃-N = 1.91 mg/L, PO₄-P = 0.79 mg/L

Land use: 30% agriculture, 60% forestry, 10% urban

Population density: 55.9 people/km²

Major information sources: Martínez et al. 1999, Lyons, Navarro et al. 1995, Lyons, González et al. 1998, CNA 2001, DRSBM-IMECBIO 2000, Contreras-Ramos 1998, Santana-Michel et al. 2000, <http://webworld.unesco.org/water/ihp/db/shiklomanov/index.shtml>, www.weatherbase.com, additional data provided by Norman Mercado-Silva, John Lyons, Luis Manuel Martínez-Rivera, and Luis Ignacio Íñiguez-Dávalos

RÍO LACANJÁ

Relief: 350 m

Basin area: 800 km²

Mean discharge: NA

River order: 3

Mean annual precipitation: 223 cm

Mean air temperature: 25°C

Mean water temperature: 27°C

Physiographic province: Chiapas–Guatemala Highlands (CG)

Biome: Tropical Rain Forest

Freshwater ecoregion: Grijalva–Usumacinta

Terrestrial ecoregion: Peten–Veracruz Moist Forests

Number of fish species: 44

Number of endangered species: 2 fishes, 2 reptiles, 2 mammals

Major fishes: Usumacinta cichlid, white cichlid, Petén cichlid, arroyo cichlid, freckled cichlid, bluemouth cichlid, pantano cichlid, Palenque cichlid, undescribed catfish, Lacandon sea catfish, Maya sea catfish, Mexican freshwater toadfish, white mullet, Mexican mojarra, giant cichlid, tropical gar, macabi tetra

Major other aquatic vertebrates: river crocodile, neotropical river otter

Major benthic invertebrates: crustaceans (*Potamocarcinum chajulensis*, *Odontohelphusa palenquensis*, *O. lacandona*), hellgrammites (*Platyneuromus honduranus*)

Nonnative species: grass carp, several species of tilapia

Major riparian plants: willow, cottonwood, sycamore, cypress, *Pachira acuatica*, *Bravaisia integerrima*, southern cattail, common reed, *Thalassia*, *Guadua spinosa*, waterlily

Special features: fast-flowing runs, waterfalls with numerous runs and rapids, floodplain clear-water lakes, floodplain backwater, riparian wetland; boundary between two of most important biosphere reserves in México, Montes Azules and Lacantún

Fragmentation: no dams; natural fragmentation by waterfall of 15 m

Water quality: relatively free of pollutants; pH = 7.4, conductivity = 668 μ S/cm; TDS = 335.5 mg/L, dissolved oxygen = 7.18 mg/L, transparency = 3.3 m

Land use: 15% agriculture, 5% rural community, 80% ecological reserves

Population density: <1 person/km²

OVERVIEW AND PROSPECTS

J. DAVID ALLAN ARTHUR C. BENKE

INTRODUCTION
THE VARIETY OF RIVERS
FEW RIVERS ARE PRISTINE

NORTH AMERICA'S RIVERS IN THE
TWENTY-FIRST CENTURY
LITERATURE CITED

INTRODUCTION

This concluding chapter provides an overview of information in the previous chapters and addresses some of the major challenges facing rivers in the twenty-first century. It is clear from previous chapters that the rivers of North America exhibit an almost bewildering variety of natural features and degrees of human impact. Our initial purpose, therefore, is to convey a sense of their variety and status. They differ greatly in their natural features, depending on physical, climatic, and biological factors. Few rivers can be called pristine, and the extent and type of human influence adds additional layers of complexity and variation according to how humans have used these rivers for water supply, power, navigation, waste disposal, and other purposes. Thus, the observed variability among rivers is ultimately a combination of natural variation and changes brought about by human activities. Both of these types of variation differ greatly across the continent, and this is reflected throughout the chapters.

A second purpose of this chapter is to examine the major challenges today and into the future facing North America's rivers. How will the diverse pressures from human society further alter North America's rivers? What might we anticipate about the future challenges that rivers will experience? What are the opportunities to make the twenty-first century

a time of repair and restoration of the rivers of North America?

THE VARIETY OF RIVERS

The twenty-two chapters describing individual river basins or geographical regions are rich with detailed information about their regions and include one-page summaries for 218 rivers, representing most of the largest rivers on the continent. Although the majority of rivers are relatively large within their respective regions, river size exhibits wide variation across and within chapters. In addition, river basins vary greatly in their mean temperatures and precipitation, the fractions of precipitation that flow into rivers, the diversity of landscape types drained by rivers, and their natural biological diversity.

Variation in Physical Characteristics

The major rivers of North America, the focus of this book, typically are large rivers, whether assessed by river order, drainage area, or discharge. Of the five to twelve rivers described for each basin or region, some individual rivers are substantially smaller, of order as low as 3 (e.g., the Virgin and Bill Williams in the Colorado basin) or 4 (the Octonagon and AuSable of the St. Lawrence basin); their inclusion

reflects their occurrence in very arid regions or their regional significance. In contrast, the lower main stems of the largest rivers are of order 9 (Mackenzie, Ohio, Missouri, St. Lawrence, Yukon, Nelson) or 10 (Mississippi). In rare instances, rivers of substantially smaller basin size (the Moisie in Atlantic Canada) have been considered as order 9. In spite of this wide range, the median value for river order in this book is generally 6 or 7, which usually represents a medium to large river.

Another way of looking at the variety of river sizes is that whereas the median drainage area of individual basins is approximately 25,000 km², basin areas range from as small as 217 km² (the Dunk River on Prince Edward Island) to 3,270,000 km² (the entire Mississippi basin, about 42% of the land area of the 48 coterminous states). A drainage area over 100,000 km² provides an arbitrary criterion for “very large”; after excluding the lower main stems of the largest river systems, some 33 individual rivers meet this criterion. However, because many basins >100,000 km² are in arid regions, they do not necessarily have the highest discharges.

Because of their spatial extent, most river systems encompass considerable physical heterogeneity, and this is especially true of the largest river basins. The number of physiographic provinces through which rivers run influences potential diversity in geology, gradient, channel morphology, and habitat types. The number of ecoregions not only reflects this geological diversity, but climate and vegetation as well. Thus, plant communities in particular should influence the amount and type of organic matter inputs from a basin’s smallest tributaries to its main stem (Vannote et al. 1980, Webster and Meyer 1997), and climate influences precipitation and the fraction that becomes runoff.

A typical river drains two ecoregions and two physiographic provinces (median values¹), but the largest river basins encompass much more heterogeneity. For example, the St. Lawrence drains eight physiographic provinces and nine ecoregions; these numbers are four and seven for the Saskatchewan, seven and thirteen for the Missouri, and six and eight for the Ohio. In some cases, relatively small basins can have high heterogeneity (e.g., five ecoregions and five physiographic provinces for the Potomac). Basin

relief (from highest peak to river mouth) also varies within and among rivers. The median value for basin relief for individual rivers is approximately 1300 m, but vertical relief in some “flatland” rivers is minimal. For example, basin relief is <120 m for the Maumee River of Ohio, the Illinois and Minnesota rivers of the Upper Mississippi, and the St. Johns and Satilla rivers of the southeastern Coastal Plain. In contrast, median vertical relief for Pacific Coast rivers of Canada and Alaska is 2628 m, despite a relatively modest average basin area of about 46,000 km², and median relief for Mexican rivers is 3000 m, with an average basin area of about 49,000 km². Given such wide variation in river basin relief, the variety of habitats and ecological conditions within a river can be expected to vary accordingly.

The rivers of North America differ greatly in discharge and runoff. Of the 218 rivers described, two-thirds have a mean annual discharge exceeding 100 m³/s, 15% exceed 1000 m³/s, and two exceed 10,000 m³/s. Mean annual discharge in m³/s is an indication of how much water is exported by a river basin. It is higher for rivers with large drainage areas and wet climates (Table 24.1). The lower Mississippi (which receives inflows from the Upper Mississippi, the Missouri, and especially the Ohio) ranks 9th in the world (Leopold 1994). A number of northern river systems, including the St. Lawrence, Mackenzie, Columbia, Yukon, and Fraser, discharge very large quantities of water. River basins in arid climates have markedly lower mean annual discharges. In arid regions, the majority of rivers have discharges below 100 m³/s. For an individual example, consider the Brazos River on the Gulf Coast of the southwestern United States and the Tennessee River in the Ohio basin. Both have slightly over 100,000 km² in drainage area, but annual discharge of the Tennessee is ten times higher than the more arid Brazos.

Discharge (Q) is influenced by basin area, precipitation (PPT), and the amount of PPT that becomes evapotranspiration (ET), as can be observed by comparing rivers and regions (see Table 24.1). Table 24.1 includes the largest river for each region or basin (left side), as well as the median values for the remaining rivers (right side). Annual runoff (RO, cm/yr) is another way to represent water yield (1 cm/yr = 100 m³ ha⁻¹ yr⁻¹) or the amount of water that annually runs off a unit area of basin. We estimated annual runoff directly from monthly runoff data provided by chapter authors (see figures in one-page summaries of each chapter). Median annual runoff for rivers of each region is shown in Table 24.1. It reveals the low water yields of such arid-land basins

¹Most values reported are medians rather than averages because of occasional extreme values, and the subset of rivers included within a basin is not truly a random sample. Hence, all comparisons reported here should be interpreted as broadly indicative, but values given are approximate.

TABLE 24.1 Some vital statistics of the rivers of North America based on data presented in the 22 chapter summaries. The name, basin area, and discharge are given for the largest single river of each basin or region, which is the main stem when all rivers drain into a single basin. Median values are given for major attributes of the rivers of each region, but main-stem rivers were excluded so that median values are not influenced by the much higher main-stem values.

Major Basin or Region	Largest River			Median Values for Rivers of Region					
	Name	Discharge (m ³ /s)	Basin area (km ²)	Discharge (m ³ /s)	Basin area (km ²)	Basin relief (m)	Median annual runoff (cm)	Runoff/precip (%)	No. of rivers
Lower Mississippi	Lower Mississippi	18,400	3,270,000	98	7,773	452	44	35	9
St. Lawrence	St. Lawrence	12,600	1,600,000	150	16,458	510	42	40	9
Mackenzie	Mackenzie	9,020	1,743,058	404	68,134	2,605	18	45	9
Ohio	Ohio	8,733	529,000	420	30,300	690	54	45	11

as the Missouri (6 cm/yr), the Colorado (4 cm/yr), the Great Basin (7 cm/yr), the Gulf Coast of the southwestern United States (4 cm/yr), and the Nelson–Churchill (7 cm/yr). Runoff values also identify rivers with high yields, typically draining areas of high precipitation and low evapotranspiration. The highest runoff regions are the Pacific Coast rivers of Canada and Alaska (90 cm/yr), and the Atlantic Coast rivers of Canada (73 cm/yr). At least one river of Mexico (Usumacinta–Grijalva), however, has an annual runoff of at least 70 cm/yr in spite of high evapo-

transpiration, having the highest annual precipitation of any basin in North America. Several rivers of the Pacific United States have high runoff, including the Rogue and Eel, but the median for rivers of that region is lower due to the inclusion of some very arid river basins in southern California.

Another advantage of converting discharge to runoff is that it can be compared directly to precipitation (both expressed as cm/yr) to provide a rough estimate of evapotranspiration, assuming no losses or gains to groundwater or interbasin transfers. For all

rivers in this volume, the median annual precipitation and runoff were 84 and 31 cm, respectively, indicating that roughly 37% of precipitation becomes runoff, and the remainder is lost to evapotranspiration (or possibly groundwater). Our estimate of median precipitation is higher than values of 67 cm (Hornberger et al. 1998) and 76 cm (Shiklomanov 1993) reported for the continent as a whole (see Chapter 1). This might suggest that the river data from this book are biased toward regions where rivers are concentrated (i.e., in higher-precipitation areas). On the other hand, the median runoff of 31 cm is similar to reported continent-wide values of 29 cm (Hornberger et al. 1998) and 34 cm (Shiklomanov 1993).

Table 24.1 gives median estimates for the individual (excluding main stem) rivers of runoff as a percentage of precipitation, where low values usually indicate high ET. The percentage of precipitation that becomes runoff varies greatly among rivers and regions and is strongly dependent on both precipitation and temperature. Not surprisingly, northern rivers with their cold climates and low plant production have very high RO/PPT ratios, approaching 100% (values for Pacific Canada likely are inflated because precipitation data are available mainly for the lower basins whereas runoff reflects higher precipitation in the upper basins). In comparison, median annual precipitation for the rivers of Mexico included in this volume is approximately 100 cm, and runoff only 10 cm, indicating that many of these low-latitude basins are relatively wet but experience high evapotranspiration (although at least one, the Candelaria, loses much of its water through groundwater seepage to the sea).

The effect of temperature on percentage runoff is particularly clear from examination of rivers draining into the Atlantic Ocean, where mean annual precipitation for 32 river basins (Chapters 2, 3, and 21) falls within the relatively narrow range of 92 to 147 cm. In these eastern rivers, mean air temperature explains 72% of the variation in percentage runoff (Fig. 24.1). In the southeast, where mean air temperatures range from 15°C to 20°C, percentage runoff is near 30%. But in eastern Canada, where mean air temperatures are <6°C, percentage runoff is typically >60%. The influence of low precipitation on percentage runoff in regions of relatively high temperature can be illustrated for the Gulf Coast rivers of the southwestern United States. The westernmost Pecos and Rio Grande have <30 cm precipitation and ≤1% runoff, whereas the easternmost rivers (Sabine and Neches) have >125 cm of precipitation and 16%

FIGURE 24.1 Annual runoff as a percentage of precipitation versus mean annual air temperature for rivers draining into the Atlantic Ocean (from Chapters 2, 3, and 21). $R^2 = 0.72$. This graph excludes the St. Lawrence River, which drains a much larger area, including the Great Lakes and their tributaries.

to 20% runoff. Of course, these estimates can be strongly influenced by human withdrawals, which also reduce runoff, and it is often impossible to separate this from natural evapotranspiration losses.

In addition to the annual water balance described here, seasonal patterns of PPT versus ET and the extent of intra- and interannual variability in both are primary determinants of a river's flow regime (Poff et al. 1997; Chapter 1). Mean and seasonal temperatures also are important, as they affect how much precipitation falls as snow and may be stored until spring thaws result in a rise in runoff. The extent of agriculture, types of crops, and reliance on irrigation drawn from surface waters (deep groundwater would not be part of the normal water budget) will further affect flows, principally during the growing season, and human withdrawals for other purposes, including municipal use, may have noticeable impacts.

In Chapter 1, several examples were given to illustrate the major factors affecting seasonal patterns of PPT and RO (see Fig. 1.4). Similar graphs of monthly PPT and RO presented throughout this book (with ET inferred from the difference) provide multiple examples that clearly distinguish the seasonal flow signatures of different regions. For example, seasonal runoff patterns of the southeastern Atlantic and Eastern Gulf drainages appear largely influenced by seasonal patterns of evapotranspiration. The northeastern Atlantic United States, the upper Mississippi, and the Ohio basin also are influenced by seasonal patterns of evapotranspiration, but in addition, they are affected to varying degrees by spring snowmelt, depending on their latitudes and monthly air tem-

peratures. On the other hand, runoff patterns of northern rivers and those draining large western mountains are dominated by spring snowmelt. Along the Pacific Coast of the coterminous United States, however, the pattern of runoff is most obviously influenced by the distinct winter precipitation. In contrast, the runoff in most rivers of Mexico follows the strong pattern of summer precipitation.

Variation in Biological and Ecological Characteristics

The foregoing comparisons emphasize the variety of rivers in physical terms and landscape context, but what about biological and ecological variation among rivers? Chapter accounts amply document substantial diversity in the number of fish species among rivers and regions. Rivers of the Ohio basin have a reported median number of 120 fish species per individual river basin. Similarly, the median number of fish species in the southeastern Atlantic, the Gulf Coast of the southeastern United States, the upper Mississippi, and the lower Mississippi all exceed 100 per river. The Tennessee River and Mobile River each have a staggering >225 fish species. These Midwestern and southern basins support far more fish species per river basin than rivers of the west or far north. For example, the median number of native fish species reported by individual river basin was 23 for rivers of the Columbia basin, 18 for rivers of the Pacific United States, and 10 for rivers of the Colorado basin (although the entire basin of the Columbia and Colorado includes considerably more native fishes than the median for individual rivers). The Nelson–Churchill system of southern and central Canada supports a median of 62 fish species (the extensive lake habitat of the Nelson–Churchill likely contributes to this species count), and the rivers of the Yukon basin support 27 species. Physiographic and habitat variation, glacial history, and dispersal opportunities are some of the factors that underlie this enormous zoogeographic variation (Hocutt and Wiley 1986). In general, the number of fish species increases with area of drainage basin, is markedly higher in the east than the west, and is reduced in far northern rivers relative to the eastern United States. Mexican rivers have somewhat fewer species per river than the eastern United States, but they are not as well sampled. The fraction of endemic species is very high in Mexican rivers, however, and when scaled to account for differences in area by country rather than river basin, the

number of Mexican fish species per km² exceeds both the United States and Canada (Chapter 23).

Biogeographic information for other taxa is scant. There was insufficient information available on a river-specific basis to describe patterns for any taxa other than fish. Molluscan diversity (approximately >300 species in North America; Master et al. 1998, Abell et al. 2000) is well known to be highest in the southeastern United States, which is globally rich in freshwater mollusks, less diverse in the west, and depauperate in the far north. This statement also applies to decapod crustaceans (nearly 300 species in North America). However, much more work is needed before species diversity trends can be identified for the abundant aquatic insects of rivers, which, based on a few well-studied systems, likely include several hundred species per river. Many studies of aquatic insects use genus-level taxonomy, species distributions are largely unknown, and large rivers are understudied. Certain genera, including *Baetis* and *Stenonema* (mayflies), *Hydropsyche* (caddisflies), *Simulium* (black flies), and *Polypedilum* (nonbiting midges) are widely reported in rivers throughout this book, indicating that species in these genera (and others) may often be important components of the majority of river communities.

Few rivers of order 6 and higher have received intensive investigation of ecosystem processes, and even description of the biota often is restricted largely to surveys of fishes, owing to the tendency of running-water ecologists to focus on smaller streams that are easier to study. In addition, our interpretation of current knowledge is complicated by the variable extent of anthropogenic disturbance. Relative to their presettlement state, many rivers have elevated turbidity and nutrients, reduced connectivity both laterally and longitudinally, and altered water budgets and water-residence times, and receive a complex brew of industrial, agricultural, and pharmaceutical chemicals.

Based on studies of ecosystem metabolism from a modest number of North American rivers, low ratios of gross primary production to respiration (P/R) appear to be common in large rivers. Among the best examples of low P/R ratios are careful studies in the Hudson, Ogeechee, and Ohio rivers (Chapters 2, 3, and 9, respectively). Of these three, the Ogeechee is arguably the least altered because it is unregulated by dams along its entire length and has a large intact floodplain. Given the tea-colored waters and extensive floodplain of this low-gradient blackwater river, which receives much allochthonous organic matter from the floodplain swamp and has relatively low

primary production in the water column, the observed dominance of heterotrophic processes is expected. The carbon budget of the Hudson (Table 2.1), although also providing strong evidence of heterotrophy, nonetheless suggests a substantial role for autochthonous production, which perhaps was even greater prior to a number of human impacts.

Primary production within large rivers is expected to be limited by some combination of environmental factors, including light, nutrients, and downstream export of algal cells (Allan 1995). Light limitation is frequently reported. In the lower Missouri River (Chapter 10), reported photic depths averaged 0.78 m and mixed depth/photoc depth ratios averaged 10.2. Because river water columns are well mixed and most of the water column experiences light levels too low to support algal growth, light limitation can be significant. Summer primary production by river phytoplankton for the middle and lower Ohio river sections also showed evidence of light limitation, although in this system large impoundments have notable effects by lengthening water residence time, and so phytoplankton production in river sections slowed by impoundments likely is higher than would otherwise be expected. The well-studied Hudson River (Chapter 2) illustrates several ways in which human actions may influence observed primary production. High turbidity due to silt resulting from intensive land use and reduced water residence times during summer due to human alteration of hydrology both reduce algal production. The introduced zebra mussel has had profound impacts, including through its suspension-feeding, and likely has contributed to a reduction in phytoplankton and an increase in macrophytes.

Although nutrients may seldom be limiting in the rivers just mentioned, northern rivers frequently have low background nutrient levels and therefore respond strongly to nutrient enrichment. The Wapiti River (Chapter 18), a tributary of the Smokey and Peace rivers, has low background nutrients but receives high point-source inputs of N and P from a pulp mill and a municipality. Periphyton biomass below inputs increased more than tenfold, resulting in higher macroinvertebrate densities and increased fish condition in a bottom-up trophic cascade.

Despite the dominance of ecosystem metabolism by heterotrophy, presumably reflecting the extent of inputs of allochthonous carbon, autochthonous primary production can be important to large-river food webs (Chapter 1; Thorpe and DeLong 2002). Some studies suggest that high system respiration likely is due to the metabolism of allochthonous

carbon by microbes, and little of this carbon is thought to reach the metazoan food chain. Stable isotope and other evidence indicates that most metazoan production is derived from autochthonous production, often phytoplankton. Thus, the river is heterotrophic overall, with a P/R ratio well below 1, but the metazoan food webs may be primarily autotrophic. Reports for the Ohio River, where much of the work leading to this hypothesis was done, and for the Hudson River provide supporting evidence.

Snags and large wood play an important role in the ecology of large rivers, creating stable substrate for producers and invertebrates and cover for fishes (Benke et al. 1985). Snags and backwater areas support the most diverse and productive assemblages of invertebrates, as the fine substrate of main channels commonly is too unstable for invertebrates. Very high secondary production of invertebrates occurs on snags, and, exported as drift, contributes to fish biomass and production. Many large rivers had an abundance of snags in their presettlement condition, as exemplified by descriptions of the Cape Fear River in the early 1700s (Chapter 3). Clearing of snags, which was common in the 1800s and early 1900s, improved river navigation and provided access for steamboats but likely had substantial effects on ecosystem processes. Blockage of the main channel of the Red River in Louisiana with driftwood was so extensive that a major effort by the U.S. government, beginning in the 1870s, was undertaken to open the river to boat traffic (Chapter 7). Detailed studies of snag habitat in the Satilla and Ogeechee rivers (Chapter 3) reveal what has been minimized or lost in many other rivers. The main channel of the unchannelized Missouri River provides another example, where woody habitats were shown to contribute over two-thirds of total insect production compared with mud and sand substrates and backwaters (Chapter 10).

In summary, ecosystem processes have been studied for only a modest number of North American rivers, which strongly argues for the importance of further study. The lack of information on ecosystem-level processes for many of the large rivers of North America represents not only a significant frontier for further investigations but also a serious shortage of knowledge on which to base management decisions. Because these large rivers differ in their natural settings and extent of anthropogenic disturbance, the comparisons and generalizations offered here should be viewed with considerable caution, and much remains to be learned.

FEW RIVERS ARE PRISTINE

Many rivers of North America have been affected by human actions since at least European settlement and some were influenced much earlier, as described for ancient cultures in Mexico (Chapter 23). Over time the variety and magnitude of impacts has grown dramatically, although we should recognize that there have also been successes in river management. At the beginning of the twenty-first century we cannot accurately describe the condition of North America's rivers, because presently we lack effective systems of national assessment and large rivers are understudied. We do know that many of our rivers suffer from pollution, habitat degradation, fragmentation by dams, colonization by nonnative species, and more, and that climate change, water withdrawals, the continued spread of nonnative species, and the ongoing expansion of human activities will pose greater threats in the future.

Chemical contamination and water quality in rivers continue to be of major importance, reflecting the public's legitimate concern for drinking water and public health, as well as the ecological consequences of polluted waters. Although the past 30 or more years of regulatory activities focused on improvements in water quality have achieved notable successes, many rivers struggle to overcome a legacy of severe pollution, particularly from industrial pollution on the lower portions of rivers. This has been especially true in high-population areas of the Atlantic Coast rivers of the northeastern United States (Chapter 2). Water quality of rivers such as the Delaware, Hudson, and Connecticut have improved, but these rivers and others still have sediments heavily contaminated with heavy metals, PCBs, and other chemicals.

The Delaware River in the vicinity of Philadelphia reminds us that water-quality deterioration has a long history (Chapter 2). Significant pollution was reported as early as 1799; low values of dissolved oxygen, presumably due to the decomposition of organic waste, were reported in 1915; and dock workers along the river during World War II reportedly were nauseated by the stench. In the era after World War II, new, potentially highly harmful chemicals were added to the brew being discharged into rivers. The Connecticut River contains a substantial burden of contaminants, including trace metals (chromium, copper, lead, mercury, nickel, and zinc) and organic compounds (chlordane, DDT, polychlorinated biphenyls, and various polycyclic aromatic hydrocarbons). Fish and shellfish advisories have

been issued in Massachusetts and Connecticut because of high levels of polychlorinated biphenyls. PCB contamination in the middle Hudson likewise is responsible for restrictions on commercial and sport fisheries and an ongoing battle over the methods and financial responsibilities for their removal (Chapter 2).

Other rivers have been greatly affected by the timber industry due to pulp mill wastes and associated factors. The Saguenay, a very large tributary of the St. Lawrence (Chapter 21), has seen considerable pollution from the timber industry and industrial pollution associated with paper manufacturing (mercury, PCBs, and PAHs) despite its relative remoteness, low population density, and sparse agricultural activity in its watershed.

Consolidated animal feeding operations on an unprecedented scale add a new dimension to chemical contamination of large rivers. The numerous industrial hog and poultry operations located in and near the floodplain of the Cape Fear River (Chapter 3), a region prone to hurricanes and extreme flooding, illustrate the risk that river ecosystems will receive high volumes of organic wastes.

Nutrient enrichment is widespread in most major river systems that drain landscapes of significant human population and disturbed land use. Heavily agricultural rivers such as the Platte (>90% agriculture, Chapter 10), the Great Miami (80% agriculture, Chapter 9), and the Minnesota (>95% agriculture, Chapter 8) typically have high concentrations of nutrients (phosphates and nitrates) and pesticides. For example, the Minnesota River, as well as other rivers of the Upper Mississippi basin, typically has concentrations of $\text{NO}_3\text{-N}$ and $\text{PO}_3\text{-P}$ approaching or exceeding 3 mg/L and 0.1 mg/L, respectively, each of which is substantially higher than natural background levels (Chapter 1). Although the impact of elevated nitrogen levels on primary production and the resultant hypoxia within the Gulf of Mexico is now well established (Chapter 6), the potential effect of nutrient enrichment on large-river food webs is not well studied and may be masked by other factors, including turbidity and altered water residence times. However, in some northern rivers that have experienced little disturbance and have very low nutrient concentrations the effects of elevated nutrients can be very pronounced, as in the case of the Wapiti River.

Dams and impoundments, levees, and channelization have altered the physical dimensions and dynamics of many kilometers of large rivers. Even before the twentieth-century era of large-scale river

FIGURE 24.2 The percentage of river systems within a region (based on 5 to 12 rivers, median of 10) that were recorded as strongly fragmented, with multiple or large dams along their main stems (black bar); moderately fragmented (gray bar); or essentially unfragmented (unshaded bar).

engineering, North America's major rivers were altered for transport. An extensive canal system was dug in the seventeenth century to provide access and transport of goods into the Delaware valley (Chapter 2). Broad floodplains of backwaters and wetlands were transformed by the simultaneous activities of narrowing and deepening the main channel, snag removal, and drainage of adjacent bottomlands for farming. The considerable loss of channel complexity and lateral connectivity in the upper freshwater tidal Hudson, where deepening of the channel and filling of wetlands and backwaters resulted in a narrow and simplified river system, is illustrated in Figure 2.11. In the mid 1800s, less than half a century after Lewis and Clark ascended the Missouri, similar channel modification processes began, followed in the early 1900s by the construction of a system of wooden pile dikes to create a single, self-scouring navigation channel. Then came flood-control levees by the mid-twentieth century, and a series of major dams. As Chapter 10 reports, flooding historically was essential in maintaining the natural character of the river–floodplain complex. Subsequent to this chain of channel-modifying events the channelized section of the Missouri River underwent major geomorphic changes, including an 8% reduction in channel length, a 50% reduction in channel water surface area, a 98% reduction in

island area, and an 89% reduction in the number of islands (see Fig. 10.2).

Using information on size, number, and distribution of dams in main-stem rivers we have attempted to place rivers into one of three categories: rivers with few or no dams along main stems or on tributaries; rivers moderately fragmented, with at least one sizable main-stem dam; and rivers strongly fragmented, with multiple or large dams along the main stem. Figure 24.2 shows the percentage of river systems within a basin or region that were recorded in each category. Over half of the river basins or regions of North America and 10 of 13 basins or regions primarily located in the United States had at least 50% of their main rivers scored as strongly fragmented. Of the eight primarily Canadian basins and regions, the Nelson–Churchill and the St. Lawrence are highly impacted by dams, as are rivers of the Atlantic Canada region. The remaining Canadian basins and regions experience low dam fragmentation overall, although this conceals some specific rivers highly influenced by dams, including the Peace River in the Mackenzie basin and the Nechako River in the Fraser basin. Although the most fragmented Mexican rivers are found in the arid north, less fragmented rivers in the tropical south, particularly the large and free-flowing Usumacinta, are endangered due to proposed hydropower projects.

FIGURE 24.3 Median values of human population density (people/km²) for regions and river basins. In some instances within-basin variation varied widely; for instance, the Fraser basin has a density of 11.7/km² for the Fraser itself, compared to <1/km² in most of its tributary river basins. Densities for individual Atlantic Coast rivers of Canada show a similarly wide range of values.

The extent of dams in North America has been well-documented by previous publications (Dynesius and Nilsson 1994, Graf 1999), and there is a large literature on their consequences (Ward and Stanford 1979, Hart and Poff 2002, Stanley and Doyle 2003). The imposition of lentic conditions can eliminate benthic species, including many freshwater mussels, and generally promotes a shift to plankton-based food webs. With nine main-stem reservoirs, very little of the Tennessee River main stem remains free flowing (Chapter 9), the density and diversity of the main-stem mussel populations have declined dramatically, and gizzard shad and threadfin shad, which are dependent on the abundant plankton in the system, have become the principle forage fishes. The influence of dams on any given river can vary greatly, but alterations to the river’s natural flow regime are widespread. In some cases, regulation by a dam largely flattens the monthly hydrograph (e.g., Churchill Falls dam on the Churchill River, Labrador; Hoover Dam on the Colorado River). In many other cases, hydropower facilities cause enormous hourly and daily fluctuations in discharge and water height that are hidden by plots of mean monthly discharge or runoff values. Perhaps the most extreme example is on the Nelson River (Chapter 19), where dams can cause hourly summer discharge to range between 0 and 7200m³/s. In other cases, dams and diversions can reduce downstream flows to

zero for very long periods (e.g., Rio Grande, Chapter 5; Gila River, Chapter 11; Rio Conchos, Chapter 23). By reducing the magnitude and frequency of flood events, a large reservoir on the Peace River, a major tributary of the Slave River, is causing the Slave River delta to shrink (Chapter 18). Loss of wetland habitat in the Slave River Delta and in many such wetlands throughout North America has devastating impacts on birds and other wildlife.

Human population density can be a useful proxy measure of human impacts, including nutrient loading (Cole et al. 1993). It may also serve as a very rough proxy for land-use change and urbanization, although the current phenomena of urban sprawl and depopulation of agricultural areas complicate this relationship significantly (Meyer and Turner 1994). Although human density estimates reported in this book may be approximate, they nonetheless reflect very substantial regional differences. River basins in the Atlantic states of the northeastern United States support much higher population densities than any others in North America (Fig. 24.3). Within the coterminous 48 states the Missouri and Colorado basins and river basins of the southern plains are least densely settled. The St. Lawrence and Nelson–Churchill basins support human populations comparable to less dense U.S. basins, whereas more northern river basins have comparatively very low populations.

The extent of urban and agricultural land within river basins provides another indication of human impact. It is difficult to assess the influence of between-basin differences in the extent of urban land, because urban land use commonly is a low percentage of total area yet exerts a disproportionately large influence both proximately and over distance (Paul and Meyer 2001). The river basins with the greatest percentage of urban land include Atlantic Coast rivers of the northeastern United States, Gulf Coast rivers of the southwestern United States, the St. Lawrence, and the Colorado. Agricultural land use varied considerably among basins, from near zero in some Canadian basins to 66% of the Upper Mississippi basin. Six major river basin of the United States had over 40% of their areas in agriculture: the Lower Mississippi, Upper Mississippi, Southern Plains, Ohio, Missouri, and Colorado.

The combined data on dams, population, and land use argue that all river basins of the coterminous United States experience considerable human disturbance. However, all or nearly all of these basins contain tributaries and river segments of very high quality that are suitable for designation under federal and state river protection programs. Indeed, these data, and the insightful analyses of individual chapters, clearly demonstrate the urgency and importance of protecting least-disturbed river segments whenever possible. Major river basins of the far north include many that appear little changed according to the measures reported here (which do not, however, include mineral extraction, timber harvest, or road and recreational development, which are significant threats to boreal regions; Schindler 1998), offering the potential for protection of even larger and more intact watersheds and river systems.

Nonnative species pose another, less-visible threat to river ecosystems, and in a number of instances the native fauna is largely displaced, at least in terms of biomass, energy flow, and community structure. This is especially so in western rivers, where the number of nonnative species can equal or exceed the total species richness of native fishes (Fig. 24.4). Commonly in such situations, native species persist at reduced abundances and in isolated locales, and often warrant endangered species status. From the viewpoint of species richness, the fish assemblage may appear little changed in the number of native species but be greatly augmented with nonnative species. From the perspective of the biological community, however, biomass and energy flow may be totally dominated by the nonnative component (e.g., a survey of the Colorado River in Canyonlands

FIGURE 24.4 Native fish species and total fish species in three river basins or regions of the western United States (from Chapters 11, 12 and 13). Note that the limited native fish fauna has been substantially augmented by nonnative species.

National Park, Utah, by Valdez and Williams [1986], reported 83% percent of individuals to be nonnative), and so ecologically the system is even more altered than might be inferred from consideration of a species list.

Based on information presented in river summaries, the median number of native fish species for the 11 river basins of the Colorado system exclusive of the main stem is 10 (Chapter 11), and a median of 4 species are listed as endangered. Today the

median number of all fish species for these 11 basins is 29, and so the addition of nonnatives has roughly tripled the species count, whereas much of the native fauna is in need of protected status. The 10 river basins of the Pacific Coast rivers of the United States contain 18 native species and a total of 39 fish species (median values). Within the Columbia system, based on eight rivers (excluding the main stem), chapter data indicate a median number of 23 native fishes and a total of 38 species.

The influence of nonnative fishes may be less dramatic elsewhere compared to the western United States, perhaps because high native species richness of some regions has helped to limit invasions and perhaps in far north river systems because fewer nonnative species are preadapted to these environments, and there have been fewer invasion opportunities. Nonetheless, the influence of nonnative fishes has been profound in many other rivers. For example, in several rivers of the northeastern (Chapter 2; Connecticut, Hudson, Delaware, and Susquehanna rivers) and southeastern United States (Chapter 3; James River), approximately one-third of all species are nonnatives, raising the total number of species to >100 in many cases. Nonnatives sometimes dominate fish collections in these rivers (e.g., Chapter 3; Cape Fear River, North Carolina), with unknown impacts on ecosystem function.

Finally, a changing climate driven by greenhouse gasses is likely to have profound impacts on freshwater ecosystems, altering hydrologic cycles, flow regimes, and riparian vegetation and likely facilitating range expansions and the proliferation of nonnative species. These climate-related effects are as yet poorly understood and so pose one of the most important emerging threats to rivers in coming decades.

NORTH AMERICA'S RIVERS IN THE TWENTY-FIRST CENTURY

During the twenty-first century the rivers of North America will experience growing human pressures. Water use will increase due to the growth of affluence and population, and in many areas surface-water supplies are nearly fully appropriated (NRC 2001). Reliance on groundwater will increase, with uncertain but serious consequences for river flows (Postel and Richter 2003). Some areas of the western United States are expected to exhaust their groundwater sources during this century. Surely some will call for transbasin water diversions on a scale

presently unknown in North America, potentially altering river flows and facilitating the spread of nonnative species. Conflicts between human and environmental needs for water are certain to increase. Meanwhile, all of the known threats remain, although some, such as point-source pollution, are diminished in many areas, whereas climate change adds a new challenge, likely to interact with other threats in complex ways. Opportunities exist to halt the decline in the condition of the rivers of North America and even to improve their status. However, those undertakings call for better knowledge to guide management and restoration and a stronger resolve that consumption of water resources cannot be dictated by uncontrolled growth.

Climate Change

Rivers and other freshwater ecosystems will be affected by projected climate change in multiple direct and indirect ways, of which only the most straightforward can be identified with high confidence (Firth and Fisher 1992, Meyer et al. 1999, Allan et al. 2005). A warmer climate will result in greater evaporation from water surfaces and greater transpiration by plants. However, whether rainfall will increase or decrease in a particular region is uncertain, and it also is difficult to predict whether the change in PPT or ET will be greater. Thus, increased precipitation might be accompanied by even greater evapotranspiration, leading to reduced runoff. General circulation models (GCMs) are not yet able to reliably predict how precipitation and water supplies will change at the local or regional levels (NAST 2000), and there is still a great deal of uncertainty in climate-change forecasts (Forest et al. 2002, Elzen and Schaeffer 2002). For example, Frederick and Gleick (1999) examined runoff for 18 water-resource regions of the United States using two contrasting GCMs and found that predictions often were in disagreement. The two models predicted the same direction of change in runoff in only 9 of the 18 regions, and where the direction was similar often the magnitude was not. Perhaps the greatest single challenge in evaluating aquatic ecosystem response to future climate change is the considerable uncertainty regarding the local and regional responses of the hydrologic cycle.

Despite this uncertainty, the potential for climate change to alter total runoff and the seasonality of flow regimes is considerable. Some seasonal shifts are certain to take place, because warming winter temperatures will cause some areas to experience more

winter rain and episodes of rain on snow, transforming predictable spring melt runoff into highly variable winter runoff. Rivers of the far north may be most vulnerable because they will experience disproportionately greater warming, along with associated dislocations of the hydrologic cycle (Poff et al. 2001); for example, the Mackenzie basin may warm by as much as 5°C by the middle of the century (Chapter 18).

In addition to affecting the hydrologic cycle, warmer temperatures are expected to result in higher ecosystem metabolism and productivity. The biota of rivers are dominated by cold-blooded organisms, and these ectotherms generally increase their metabolism with each degree increase in temperature until very near their upper temperature tolerances. Rates generally increase by a factor of 2 to 4 with each 10°C increase in water temperature, up to about 30°C (Regier et al. 1990). In a review of over 1000 estimates of macroinvertebrate production, Benke (1993) estimated a 3% to 30% increase in biomass turnover rates for each 1°C increase in temperature. Thus, although there may be complex and unpredictable changes in species composition, an overall increase in system productivity is a potential response to climate warming.

Poleward range shifts by those taxa able to disperse are highly probable under warmer climate scenarios. Sweeney et al. (1992) estimated that a 4°C warming would result in a 640 km northward latitudinal shift in thermal regimes for macroinvertebrates, and several authors have estimated comparable distances for the range displacement of particular species of fishes. The opportunity to disperse, and the presence of corridors versus barriers, can be highly variable among river basins, however. For example, fishes in the southern Great Plains and the desert Southwest cannot move northward because those streams and rivers tend to run west and east. Because summer water temperatures now approach the upper limit for a number of fish species, just a few degrees of warming poses serious risk of extinction for native fishes in these regions (Chapter 7; Covich et al. 1997, Matthews and Zimmerman 1990). Fishes of the far north may be especially vulnerable, as warming will favor species that presently are only marginally successful. Arctic coregonids (broad whitefish, least cisco, Arctic cisco) may be particularly at risk. Temperature also sets the northern range limit for harmful nonnative species such as the zebra mussel (Strayer 1991), and so a northward range expansion seems highly probable. Given the well-established negative impacts of nonnative species on freshwater

ecosystems (Allan and Flecker 1993), native biodiversity may be adversely affected by such range shifts.

Rivers draining forested landscapes and with forested riparian and headwater zones derive much of their energy as organic matter inputs from the terrestrial environment (Chapter 1). Climate change is likely to bring about shifts in terrestrial vegetation and changes in leaf chemistry and affect the processing of detritus and functioning of the microbial-shredder food web linkage in complex ways. Altered carbon/nitrogen ratios of the leaves likely will reduce palatability, temperature changes will affect leaf-processing rates, and floods may export leaf matter before it can be processed (Rier and Tuchman 2002, Allan et al. 2005). These interactions are complex and potentially offsetting, making the overall impact of climate on this important energy supply difficult to predict.

Other Threats

Although the potential impact of a changing climate deservedly is the focus of much current concern, more familiar threats may prove to be of equal or greater importance. Pollution from point and non-point sources continues, and legacies of past contamination are numerous. Rivers continue to be fragmented by dams, which modify flow, alter water budgets, disrupt migrating species, and interfere with ecosystem connectivity and function. Levees and other flood-control measures remain largely in place. The spread of nonnative species is virtually a certainty. Although heartening examples of improvements can be found and some of the most harmful pollution practices have largely been halted, many rivers experience a mix of stressors that include legacy effects, long-standing threats, and newly emerging challenges.

Water withdrawals and transfers comprise another potential threat to rivers but are associated with so much uncertainty they are difficult to assess. Due to the combined influence of population and economic growth, freshwater demand is expected to grow significantly during the twenty-first century (NRC 2001). On the other hand, past projections of demand have invariably proven to be overestimates due to unanticipated advances in efficiency. Nonetheless, because surface waters are largely appropriated in many regions, it seems highly likely that groundwater withdrawals will increase, with uncertain effects on hydrologic budgets and river ecosystems. Some areas of the Great Plains and the southwestern United States that now rely heavily on nonrenewable

groundwater will almost assuredly desire to import water via canals and interbasin transfers.

Examples of existing out-of-basin transfers are described in several chapters. The Sacramento River in northern California (Chapter 12) has approximately 50% of its flow diverted via the California Aqueduct and Delta–Mendota Canal to meet urban and agricultural water demands in the southern part of the state. The Colorado River experiences transfers from its headwaters via the Colorado–Big Thompson project to provide water to Denver and other cities of the Mississippi drainage, whereas a diversion from the Lower Colorado below Lake Havasu to Phoenix and California sends almost 40% of the virgin river flow out of basin (Chapter 11). Water is siphoned off from three reservoirs in the Delaware River headwaters as part of the water supply of New York City and discharged into the Hudson estuary (Chapter 2). A massive diversion of water occurs from the Churchill River in northern Manitoba in order to increase hydroelectric generating capacity through dams in the nearby Nelson River. Some 75% (or $>700\text{ m}^3/\text{s}$) of the flow of the Churchill River was diverted into the Nelson system during the 1970s, causing severe ecological and social impacts on both the lower Churchill and the lower Nelson, where hydroelectric releases also have extreme daily fluctuations (Chapter 19). Large diversions are a common practice in Canada, where Dynesius and Nilsson (1994) report total out-of-basin transfers of $4400\text{ m}^3/\text{s}$. Based on various news media accounts, interbasin water transfers have been considered from the Great Lakes to surrounding areas, between the Upper Missouri and southern tributaries of the Hudson Bay drainage via the proposed Garrison River diversion, and from the Pacific Northwest to California. Although no transfer of such magnitude has yet taken place, pressure may intensify as water shortages become more severe.

Restoration

We should aspire to make the twenty-first century a period of restoration and repair of damaged ecosystems, including rivers, for many reasons. First, we are increasingly aware of the extent of environmental degradation and have the capacity to make improvements. Second, society increasingly values biological diversity, the variability of nature, and the psychological and social benefits we derive from natural surroundings. Third, all of us benefit from a number of ecosystem goods and services, including clean water, recreation, and harvestable fishes. Healthy rivers are

of direct value. Sometimes restoration will be costly, such as in the greater Florida Everglades ecosystem, where large sums were spent to channelize the Kissimmee River and even larger sums are currently being spent to restore it. This is a call to learn from past mistakes. In other instances restoration will be cost effective, as with the purchase of riparian land to preserve water quality in the Catskill and Delaware watersheds supplying water to New York City (www.nyc.gov/html/dep/html/fadplan.html 2002), a far cheaper solution than the alternative, building treatment plants to remove excess sediments. This is a call to recognize the efficiency of sound environmental policy.

Restoration has been defined as “returning a system to a close approximation of its condition prior to disturbance, with both the structure and function of the system recreated” (NRC 1992). However, it may not be possible to know the predisturbance condition, and it may not be practical to achieve it. Various authors and scientific working groups have wrestled with the definition of restoration and the setting of goals and targets (Bradshaw 1988, Lake 2001, www.ser.org/content/ecological_restoration_primer.asp 2004). In our opinion, although we should make every effort to be aware of the historical state of the system, restoring systems to presettlement condition will very rarely be practical. In practice, restoration today seems to encompass everything we might do to repair or improve an ecosystem. Using reference sites and historical information when available, and incorporating an understanding of the dynamic processes that govern rivers and their biota are key ingredients of thoughtful restoration practice. Recognizing the importance of stakeholders, it may be sensible to consider a range of options, with public input determining the desired outcome (Hobbs and Harris 2001).

A great deal of river restoration presently takes place under the auspices of federal, state, and local governments, as well as by private citizens. Unfortunately, we do not have very good information concerning the extent and types of restoration practices or their effectiveness, and little or no accountability for the large sums being spent (Bernhardt et al. 2003). In fairness, river restoration is a relatively new area, and recent program initiatives such as CALFED (a partnership of California and federal governments, which is investing substantially in San Francisco Bay–area restoration) are requiring external scientific review, explicit hypotheses, and other key elements that should help to ensure sound science and the application of adaptive management.

The type of river restoration depends greatly on location, prioritization of threats, and how the river is valued. In addition, there may be several ways to address a particular problem. For example, in agricultural regions and wherever bank erosion is serious, maintenance of a vegetated buffer zone along river margins, which may be accompanied by planting trees, is common practice. Gabions (wire baskets of rocks) and rip-rap (individual large stones or concrete blocks, even old automobiles, referred to as “Detroit rip-rap”) are less attractive means to stabilize banks. In some cases, recognizing that river channels naturally migrate, it may be appropriate to do nothing at all. Clearly, identifying the problem, understanding the fundamental processes at work, and clarifying the desired outcome are all important in arriving at the optimal solution (Palmer et al. 2005).

Flow restoration is increasingly becoming an objective of water managers, particularly those responsible for dam releases and water withdrawals. How much water a river needs is being reevaluated in light of the scientific consensus that rivers (and most ecosystems) are naturally variable and depend upon that natural variability for full geomorphic, hydrologic, and ecological function (Richter et al. 1997, Poff et al. 1997). River channels are shaped largely by the interplay among slope, sediment supply, and water supply and maintained mainly by bankfull flood events; if human actions change one of these variables, adjustments will occur in one of the others. For example, regulation of the Colorado River below Glen Canyon Dam after 1963 restricted the supply of sediments, and in response the river cut downward, lowering its slope. How much water is needed for fish populations may be difficult to determine, or perhaps society has not yet agreed to include a margin of error in its estimates. For example, in an extreme conflict between human use (for agriculture) and ecosystem use (for fishes), water-supply managers for the Klamath lake and river system experienced massive protests from farmers whose crops were threatened, and then only months later oversaw the largest die-off of Pacific salmon yet recorded, in a case marked by conflicting reports of investigating committees (Service 2003). This may indicate a need for more and better science to guide decisions and more documentation of successes and failures in order to build the case-based knowledge necessary for management of conflicts with such potentially high costs on both sides (Poff et al. 2003).

Few examples of river restoration are reported in the chapters of this book, and this likely can be taken

as rough evidence that few well-documented cases can be found. This may reflect the fact that river restoration is a new agenda. In addition, restoration of large rivers is expensive and often encounters real conflicts of interest and financial constraints. In several instances, including the Columbia, Missouri, and Willamette, recovery and restoration plans date from 2000 or later and are not yet implemented. Recovery plans for anadromous fishes, including salmon and shad, typically are based on hatcheries and fish passage around dams and occasionally on dam breaching, and are perhaps most frequently cited. Examples include largely successful efforts to restore shad to the Connecticut River and largely unsuccessful efforts to restore salmon runs on the Columbia River.

Flow restoration through modifications of dam operations is at least not uncommon as a restoration tactic, although costs of lost hydropower and other commercial benefits pose a constant challenge to such efforts. In some instances, including sections of the Missouri, the Flaming Gorge Dam on the Green River of the Colorado drainage, and the Yakima River, which enters the only free-flowing section of the Columbia and is where most natural salmon reproduction occurs, biological opinion is clear, but action has yet to be taken.

Recovery proposals recommended by the National Research Council show that current science can guide actions to improve ecological services, as well as societal benefits, through a combination of acquiring floodplain lands, increasing main-channel habitat complexity, and modifying reservoir water management to restore more natural river flows (National Research Council 2002) (Chapter 10). However, it is unfortunately worth noting that efforts to resolve environmental and human uses of the Missouri River have been in political and legal gridlock for years and continue to be in controversy as of this writing.

If there is a lesson to be drawn from these few restoration examples from large rivers, it may be that the effort is at an early stage, and the extent of societal valuation of river ecosystems for their natural values and their ecosystem services remains to be determined.

In conclusion, whether North America’s rivers will be in better condition at the end of the twenty-first century than at the beginning is uncertain. But they can be. Many rivers have improved due to a reduction of careless resource extraction followed by sufficient time for some natural recuperation. Additional improvement has resulted from reductions in

point-source pollution and other targeted actions, including habitat improvement, dam removals, and active river restoration. Moreover, rivers have significant restorative capacity: The flow of water and movement of sediments can cleanse pollutants, and periodic floods can restore dynamism to river channels and allow natural processes to dominate. Some recovery has occurred passively and some due to sound management.

But there is discouraging news as well. At present, some good restoration plans are struggling to be implemented due to conflicting pressures and financial constraints. Water demand will increase with the growth of population and affluence, climate warming and the spread of nonnative species may pose even greater threats over the present century, and all of the familiar threats associated with human activities remain with us. We find ourselves between, on the one hand, improved knowledge, stakeholder support, and the capacity to manage and restore, and on the other hand, an array of familiar and unfamiliar threats. Although improvements in the science and practice of river restoration clearly have much to contribute, they matter little unless major strides are made to grow awareness, political will, and the policies and institutions necessary to advocate sound river management.

In this light, the growing influence of citizen groups and nongovernmental organizations concerned with river health is of great importance. By joining the dialogue on the future of our rivers and contributing scientific expertise where it is appropriate, whether through giving public lectures, serving on panels, sharing scientific knowledge with river advocates, or in any other way, scientists as individuals can help to see that knowledge is used. It will be rare (and probably should be) for decisions affecting river health to be made by a few specialists. In the long run, involvement of all sectors of society likely holds the greatest promise for the future condition of the river ecosystems so ably discussed in this volume.

APPENDIX

COMMON AND SCIENTIFIC NAMES FOR PLANTS, VERTEBRATES, AND SELECTED INVERTEBRATES

This appendix, which is provided to enable readers to locate scientific names from the common names provided in the text, was assembled from various sources. Initially, authors of the various chapters were asked to submit a list of common and scientific names for species mentioned in their chapters. Because there were differences among the lists provided by the authors, as might be expected given the constant revision of taxonomy, we have modified the final list to provide consistency. We have primarily used the U.S. Department of Agricul-

ture's taxonomic Web site (www.itis.usda.gov) as a basis to resolve most differences; however, it is possible that some "invalid" common names still appear in the text. Some authors found that the ITIS list was not totally up-to-date, and other sources have sometimes been used. This is particularly true for fish common names, which have sometimes been updated based on Nelson et al. (2004). Many fishes from Mexico are not found in the ITIS, and Nelson et al. (2004) was used almost exclusively for those species.

PLANTS

Common names		Scientific names	Common names		Scientific names	
acacia	cat-claw	<i>Acacia greggei</i>	athel		<i>Tamarix aphylla</i>	
alder	Arizona	<i>Alnus</i>	aven	mountain	<i>Dryas</i>	
	brook-side (or hazel)	<i>Alnus oblongifolia</i>			<i>drummondii</i>	
	green	<i>Alnus serrulata</i>	baccharis		<i>Baccharis</i> spp.	
	mountain	<i>Alnus crispa</i>		Emory	<i>Baccharis emoryi</i>	
	red	<i>Alnus incana</i>	barley	foxtail	<i>Hordeum</i>	
	seaside	<i>Alnus rubra</i>			<i>jubatum</i>	
	Sitka	<i>Alnus maritima</i>	basswood	American	<i>Tilia americana</i>	
		<i>Alnus viridis</i> ssp. <i>sinuata</i>	bearberry		<i>Arctostaphylus</i>	
	speckled	<i>Alnus rugosa</i>			<i>uva-ursi</i>	
	thin-leaf	<i>Alnus tenuifolia</i>	bedstraw	fragrant	<i>Galium triflorum</i>	
	white	<i>Alnus rhombifolia</i>	beechnut	American	<i>Fagus grandifolia</i>	
		<i>Thalia geniculata</i>	blue		<i>Carpinus</i>	
	alligator-flag	bent	<i>Alternanthera</i>			<i>caroliniana</i>
alligatorweed		<i>philoxeroides</i>	beggar's tick		<i>Bidens</i> spp.	
all-scale		<i>Atriplex</i>	berry	Saskatoon	<i>Amelanchier</i>	
		<i>polycarpa</i>			<i>alnifolia</i>	
ammania	purple	<i>Ammannia</i>	bindweed	hedge false	<i>Calystegia sepium</i>	
		<i>coccinea</i>	birch		<i>Betula</i> spp.	
anacua		<i>Ehretia anacua</i>		gray	<i>Betula populifolia</i>	
		<i>Epigaea repens</i>		dwarf	<i>Betula nana</i>	
arbutus		<i>Peltandra</i>		paper, white	<i>Betula papyrifera</i>	
	arrow-arum	<i>virginica</i>		river	<i>Betula nigra</i>	
arrowhead		<i>Sagittaria</i> spp.		swamp	<i>Betula</i>	
	awl-leaf	<i>Sagittaria</i>			<i>glandulosum</i>	
		<i>subulata</i>		sweet	<i>Betula lenta</i>	
	broadleaf	<i>Sagittaria latifolia</i>		yellow	<i>Betula</i>	
		<i>v. latifolia</i>	bitterbrush	antelope	<i>alleganiensis</i>	
	grassy	<i>Sagittaria</i>	blackberry		<i>Purshia tridentata</i>	
		<i>graminea</i>	blackbrush		<i>Rubus</i> spp.	
	sessile fruit	<i>Sagittaria rigida</i>			<i>Coleogyne</i>	
	arrowroot,		<i>Sagittaria</i>	Blackeyed Susan		<i>Rudbeckia hirta</i>
		wapato	<i>latifolia</i>	blackgum		<i>Nyssa sylvatica</i>
ash		<i>Fraxinus</i> spp.	bladderwort	common	<i>Utricularia</i>	
	black	<i>Fraxinus nigra</i>			<i>macrorhiza</i>	
	Carolina	<i>Fraxinus</i>	bloodwoodtree		<i>Haematoxylum</i>	
		<i>caroliniana</i>			<i>campechianum</i>	
	green	<i>Fraxinus</i>	bluebell	northern	<i>Mertensia</i>	
		<i>pennsylvanica</i>			<i>paniculata</i>	
	Oregon	<i>Fraxinus latifolia</i>	blueberry		<i>Vaccinium</i> spp.	
	pumpkin	<i>Fraxinus</i>	bluegrass		<i>Poa palustris</i>	
		<i>profunda</i>		Canada	<i>Poa compressa</i>	
	velvet	<i>Fraxinus</i>	box elder	Kentucky	<i>Poa pratensis</i>	
		<i>velvutina</i>	(boxelder),		<i>Acer negundo</i>	
	water	<i>Fraxinus</i>	Manitoba			
	white	<i>Fraxinus</i>	maple			
aspen	quaking	<i>Fraxinus caroliniana</i>	breadnut tree		<i>Brosimum</i>	
		<i>americana</i>			<i>alicastrum</i>	
	<i>Populus</i>	brittlebush			<i>Encelia</i> spp.	
	<i>tremuloides</i>	brooklime	European		<i>Veronica</i>	
		(speedwell)			<i>beccabunga</i>	

Plants

Common names		Scientific names	Common names		Scientific names
broomsedge		<i>Andropogon</i> spp.		eastern red	<i>Juniperus</i>
buckeye	California	<i>Aesculus californica</i>		eastern white, northern white	<i>virginiana</i>
buckthorn		<i>Rhamnus cathartica</i>		salt, tamarisk	<i>Thuja occidentalis</i>
buffelgrass		<i>Pennisetum ciliare</i>			<i>Taramix ramosissima</i>
bugleweed	northern	<i>Lycopus uniflorus</i>		western red	<i>Thuja plicata</i>

			clubshell mussel	<i>Pleurobema clava</i>	
			Coosa moccasinshell mussel	<i>Medionidus parvulus</i>	
			creeper mussel	<i>Strophitus undulates</i>	
			creeping ancyliid snail	<i>Ferrissia rivularis</i>	

Common and Scientific Names for Plants, Vertebrates, and Selected Invertebrates

Common names	Scientific names	Common names	Scientific names
Cumberland bean mussel	<i>Villosa trabalis</i>	hickorynut mussel	<i>Obovaria olivaria</i>
Cumberland elktoe mussel	<i>Alasmidonta atropurpurea</i>	Higgin's eye mussel	<i>Lampsilis higginsii</i>
Cumberlandian combshell mussel	<i>Epioblasma brevidens</i>	hotwater physa snail	<i>Physella wrightii</i>
cylindrical lioplax	<i>Lioplax cyclostomaformis</i>	Idaho Springsnail	<i>Fontelicella</i> (or <i>Pyrgulopsis</i>) <i>idahoensis</i>
dark falsemussel	<i>Mytilopsis leucophoeta</i>	James spiny mussel	<i>Pleurobema collina</i>
dark pigtoe mussel	<i>Pleurobema furvum</i>	kidneyshell mussel	<i>Ptychobranchnus fasciolaris</i>
deertoe mussel	<i>Truncilla truncata</i>	Lake Winnipeg snail	<i>Physella</i> n.sp.
dwarf wedgemussel	<i>Alasmidonta heterodon</i>	leafshell mussel	<i>Epioblasma flexuosa</i>
eastern elliptio mussel	<i>Elliptio complanata</i>	lilliput mussel	<i>Toxolasma parvus</i>
eastern fan shell mussel	<i>Cyprogenia stegaria</i>	Lilljeborg peaclam	<i>Pisidium lilljeborgi</i>
eastern floater mussel	<i>Pyganodon cataracta</i>	little spectaclecase mussel	<i>Villosa lienosa</i>
eastern lamp mussel	<i>Lampsilis radiata</i>	little wing pearly mussel	<i>Pegias fibula</i>
eastern oyster	<i>Crassostrea virginica</i>	Louisiana fatmucket mussel	<i>Lampsilis hydiana</i>
eastern pearl mussel	<i>Margaritifera margaritifera</i>	mapleleaf mussel	<i>Quadrula quadrula</i>
eastern pond mussel	<i>Ligumia nasuta</i>	marsh snail	<i>Stagnicola elodes</i>
ebonyshell mussel	<i>Fusconaia ebena</i>	minute hydrobe	<i>Hydrobia totteni</i>
elephantear mussel	<i>Elliptio crassidens</i>	monkeyface mussel	<i>Quadrula metanevra</i>
elktoe mussel	<i>Alasmidonta marginata</i>	mossy valvata snail	<i>Valvata sincera</i>
fanshell mussel	<i>Cyprogenia stegaria</i>	mucket mussel	<i>Actinonaias ligamentina</i>
fat pocketbook mussel	<i>Potamilus capax</i>	mud amnicola snail	<i>Ammicola mimosa</i>
fatmucket mussel	<i>Lampsilis siliquoidea</i>	mud bithynia, faucet snail	<i>Bithynia tentaculata</i>
fawnsfoot mussel	<i>Truncilla donaciformis</i>	narrowmouth hydrobe snail	<i>Texadina sphinctostoma</i>
fine-lined pocketbook mussel	<i>Lampsilis altilis</i>	Neosho mucket mussel	<i>Lampsilis rafinesqueana</i>
fingernail clam	<i>Sphaerium</i> spp.	New Zealand mudsnail	<i>Potamopyrgus antipodarum</i>
flat floater mussel	<i>Anodonta suborbiculata</i>	northern riffleshell mussel	<i>Epioblasma tortulosa rangiana</i>
floater mussel	<i>Anodonta grandis</i>	Nuttal's high wing floater mussel	<i>Anodonta nuttalliana</i>
flutedshell mussel	<i>Lasmigona costata</i>	orangefoot pimpleback mussel	<i>Plethobasus cooperianus</i>
fragile papershell mussel	<i>Leptodea fragilis</i>	orange-nacre mucket mussel	<i>Lampsilis perovalis</i>
frigid snail	<i>Lymnaea atkaensis</i>	Oregon floater mussel	<i>Anodonta oregonensis</i>
giant floater mussel	<i>Pyganodon grandis</i>	Ouachita creekshell mussel	<i>Villosa arkansasensis</i>
giant northern peaclam	<i>Pisidium idahoense</i>	Ouachita kidneyshell mussel	<i>Ptychobranchnus occidentalis</i>
green floater mussel	<i>Lasmigona subviridis</i>	Ouachita rock-pocketbook mussel	<i>Arkansia wheeleri</i>
gyro flexed snail	<i>Gyraulus deflectus</i>		
gyro snail	<i>Gyraulus</i> spp.		

Invertebrates

Common names	Scientific names	Common names	Scientific names
ovate clubshell mussel	<i>Pleurobema perovatum</i>	round hickorynut mussel	<i>Obovaria subrotunda</i>
oyster mussel	<i>Epioblasma capsaeformis</i>	round pigtoe mussel	<i>Pleurobema sintoxia</i>
Ozark pigtoe mussel	<i>Fusconaia ozarkensis</i>	round rocksnail	<i>Leptoxis ampla</i>
paper pondshell mussel	<i>Utterbackia imbecillis</i>	rusty peaclam	<i>Pisidium ferrugineum</i>
peaclam	<i>Pisidium</i> spp.	salamander mussel	<i>Simpsonaias ambigua</i>
pimpleback mussel	<i>Quadrula pustulosa</i>	scaleshell mussel	<i>Leptodea leptodon</i>
pink heelsplitter mussel	<i>Potamilus alatus</i>	Scioto pigtoe mussel	<i>Pleurobema bournianum</i>
pink mucket mussel	<i>Lampsilis abrupta</i>	seep mudalia snail	<i>Leptoxis dilatata</i>
pink papershell mussel	<i>Potamilus ohioensis</i>	sheepnose mussel	<i>Plethobasus cyphus</i>
pistolgrip mussel	<i>Tritogonia verrucosa</i>	Snake River physa	<i>Physa natricina</i>
plain pocketbook mussel	<i>Lampsilis cardium</i>	softshell (clam)	<i>Mya arenaria</i>
pocketbook mussel	<i>Lampsilis ovata</i>	southern acornshell	<i>Epioblasma othcaloogensis</i>
pointed campeloma snail	<i>Campeloma decisum</i>	mussel	
pondhorn mussel	<i>Unio merus tetralasmus</i>	southern clubshell	<i>Pleurobema decisum</i>
prairie fossaria snail	<i>Fossaria (Bakerilymnaea) bulimoides</i>	mussel	
purple cat's paw mussel	<i>Epioblasma obliquata</i>	southern fatmucket	<i>Lampsilis straminea claibornensis</i>
purple lilliput mussel	<i>Toxolasma lividus</i>	mussel	
purple wartyback mussel	<i>Cyclonaias tuberculata</i>	southern mapleleaf	<i>Quadrula apiculata</i>
pyramid pigtoe mussel	<i>Pleurobema rubrum</i>	mussel	
quagga mussel	<i>Dreissena bugensis</i>	southern pigtoe mussel	<i>Pleurobema georgianum</i>
rabbitsfoot mussel	<i>Quadrula cylindrica</i>	southern pocketbook	<i>Lampsilis omata</i>
rainbow	<i>Villosa iris</i>	mussel	
ramshorn marsh snail	<i>Planorbella trivolis</i>	southern rainbow	<i>Villosa vibex</i>
rams-horn mussel	<i>Vorticifex</i> spp.	mussel	
rayed bean mussel	<i>Villosa fabalis</i>	spectaclecase mussel	<i>Cumberlandia monodonta</i>
red-rimmed melania	<i>Melanooides tuberculatus</i>	spike (or ladyfinger)	<i>Elliptio dilatata</i>
ridgebeak peaclam	<i>Pisidium compressum</i>	mussel	
ring pink mussel	<i>Obovaria retusa</i>	squawfoot mussel	<i>Strophilus undulatus</i>
rock fossaria snail	<i>Fossaria modicella</i>	St. Lawrence pond snail	<i>Lymnaea catascopium;</i> <i>Stagnicola emarginata</i>
rock-pocketbook mussel	<i>Arcidens confragosus</i>	swamp lymnaea snail	<i>Lymnaea stagnalis</i>
rough fatmucket mussel	<i>Lampsilis straminea</i>	tan riffleshell mussel	<i>Epioblasma florentina walkeri</i>
rough pigtoe mussel	<i>Pleurobema plenum</i>	three-forks springsnail	<i>Pyrgulopsis trivialis</i>
round combshell mussel	<i>Epioblasma personata</i>	threehorn wartyback	<i>Obliquaria reflexa</i>
		mussel	
		threeridge mussel	<i>Amblema plicata</i>
		three-ridge valvata snail	<i>Valvata tricarinata</i>
		tidewater mucket mussel	<i>Leptodea ochracea</i>
		triangle floater mussel	<i>Alasmidonta undulata</i>

Common and Scientific Names for Plants, Vertebrates, and Selected Invertebrates

Common names	Scientific names	Common names	Scientific names
triangular kidneyshell mussel	<i>Ptychobranthus greeni</i>	yellow lamp mussel	<i>Lampsilis cariosa</i>
triangular mussel	<i>Pisidium variabile</i>	yellow lance mussel	<i>Elliptio lanceolata</i>
ubiquitous peaclam	<i>Pisidium casertanum</i>	yellow sandshell mussel	<i>Lampsilis teres</i>
upland combshell mussel	<i>Epioblasma metastrata</i>	Yukon floater mussel	<i>Anodonta beringiana</i>
Utah valvata snail	<i>Valvata utahensis</i>	zebra mussel	<i>Dreissena polymorpha</i>
variable spike mussel	<i>Elliptio icterina</i>	shrimp blue	<i>Litopenaeus stylirostris</i>
Wabash pigtoe mussel	<i>Fusconaia flava</i>	Cauque River prawn	<i>Macrobrachium</i> (or <i>Palaemon</i>)
wartyback mussel	<i>Quadrula nodulata</i>		<i>americanus</i>
washboard mussel	<i>Megalonias nervosa</i>	California freshwater Cinnamon River	<i>Syncaris pacifica</i>
western fanshell mussel	<i>Cyprogenia aberti</i>		<i>Macrobrachium acanthurus</i>
western floater mussel	<i>Anodonta kennerlyi</i>	eastern grass, riverine grass	<i>Palaemonetes paludosus</i>
western pearlshell mussel	<i>Margaritifera (Margaritopsis) falcata</i>	Kentucky cave	<i>Palaemonias ganteri</i>
western ridge mussel	<i>Gonidea angulata</i>	Mississippi grass	<i>Palaemonetes kadiakensis</i>
white heelsplitter mussel	<i>Lasmigona complanata</i>	Pasadena freshwater white	<i>Synaris pasadenae</i>
winged floater	<i>Anodonta nuttalliana</i>		<i>Litopenaeus setiferus</i>
winged mapleleaf mussel	<i>Quadrula fragosa</i>

LITERATURE CITED

Nelson, J. S., E. J. Crossman, H. Espinosa-Pérez, L. T. Findley, C. R. Gilbert, R. N. Lea, and J. D. Williams. 2004. *Common and scientific names of fishes from the United States, Canada, and México*. Special Publication 29. American Fisheries Society, Bethesda, Maryland.

GLOSSARY

- aggradation: the process by which bottom sediments accumulate due to deposition of suspended sediments.
- alkalinity: a measure of the buffering capacity of water or its capacity to neutralize an acid solution; commonly presented as milligrams of calcium carbonate per liter (mg/L as CaCO₃)
- allochthonous: organic matter that originates from the terrestrial environment and eventually enters a stream or river; e.g., tree leaves, twigs, branches.
- aquifer: a geological structure (rock) containing significant quantities of groundwater.
- ash free dry mass (AFDM): a measure of biomass; the dry mass of organisms after the ash (mineral) content has been subtracted.
- assemblage: a group of similar organisms in a particular ecological community; e.g., the fish assemblage of the Ogeechee River.
- autochthonous: organic matter in a stream or river that originates from primary production within the stream; e.g., from algae and macrophytes.
- autotrophic: a term describing those organisms that produce organic matter by the process of photosynthesis; also used to describe streams or rivers capable of producing sufficient oxygen within the water to meet the needs of community respiration (see *heterotrophic* and *P/R ratio*).
- base flow: the flow in a stream or river that comes from groundwater seepage.
- basin: see *drainage basin*.
- benthic: refers to the habitat found on the bottom of a body of water or the organisms (see *benthos*) that live on the bottom. The benthic habitat typically consists of inorganic and organic matter such as sand, rocks, mud, leaves, and pieces of wood.
- benthos: organisms that live in the benthic habitat; bottom-dwelling organisms; e.g., mayflies, mussels, etc.
- biodiversity: term used to describe genetic, species, and ecosystem diversity within a given environment or region; when referring to species, high biodiversity means many different species of plants, animals, or microbes and low biodiversity means few species.
- biofilm (organic microlayer, “slime”): the layer of organic material that develops on surfaces found in streams or rivers. It is usually composed of a variety of algae, fungi, bacteria, other microorganisms, and detritus within a polysaccharide matrix.
- biomass: the weight or mass of living things; units may be in grams per square meter (g/m²) of bottom area. Other units used may be dry mass (DM), ash-free dry mass (AFDM), carbon (C), or in the case of algae, chlorophyll.
- biome: a broad global subdivision of the earth based on terrestrial plant communities; e.g., temperate deciduous forest.
- carnivores: organisms (usually animals) that eat other animals (see *predators*).
- catchment: see *drainage basin*.
- coarse particulate organic matter (CPOM): organic detritus particles within a river or stream that are greater than 1 mm in diameter; e.g., leaves, parts of leaves, twigs, etc.
- community: all the organisms within an ecosystem or specified area, such as a stream reach; often used interchangeably with “assemblage,” but the latter’s use implies a subset of a complete community; e.g., invertebrate community or invertebrate assemblage. Either term implies an interconnectedness of species.
- conductivity: see *specific conductance*.
- decomposition: in the ecological sense, refers to the process by which organic matter, such as leaves, is broken down by physical and microbial action.
- degradation: when referring to bed sediments, the process by which a streambed or riverbed loses sediments due to scouring, suspension, and transport.
- detritus: nonliving organic matter of either autochthonous or allochthonous origin found on the bottom or in suspension in rivers and streams (usually refers to FPOM and CPOM).
- detritivore: an animal that consumes detritus and its associated microbes (e.g., a stonefly shredder)
- discharge: the volume of water flowing downstream at a specific site on a river; usually measured as

- cubic meters per second (m³/s) or cubic feet per second (cfs).
- dissolved organic matter (DOM): organic matter, usually complex hydrocarbons, occurring in a dissolved state; for practical purposes, includes all material less than 0.45 μm in size.
- drainage basin: an area of land drained by a particular stream or river; also called watershed (primarily in North America) and catchment (primarily in Europe).
- drift: organisms that are passively carried downstream by the current; typically refers to benthic animals that are dislodged from or leave their habitats and eventually find new habitats or are eaten by predators.
- dry mass (DM): a measure of biomass; the mass of organisms after all the water has been removed by drying.
- ecoregion (freshwater): a relatively large area that contains a geographically distinct assemblage of freshwater organisms, particularly fishes.
- ecoregion (terrestrial): a large landscape division defined by a geographically distinct assemblage of natural species (generally by plant species) along with climate, geology, and terrain; smaller than a biome.
- ecosystem: a community of organisms and their nonliving environment interacting as a unit. Boundaries of ecosystems can be somewhat arbitrary; e.g., we can narrowly define the river ecosystem or more broadly define the river–riparian ecosystem or the ecosystem of the drainage basin.
- epilimnion: the upper zone of a thermally stratified lake in which the water is warmer than in the lower zone (hypolimnion).
- eutrophic: the condition of a body of water (usually a lake) in which there are high concentrations of nutrients and high primary production. Many reservoirs on rivers become culturally eutrophic because of sewage outfalls from cities and non-point-source pollution from agriculture.
- evapotranspiration: the combined processes of evaporation of water and transpiration by plants, which together describe the loss of water to the atmosphere from an ecosystem.
- fauna: the animals from a particular habitat, ecosystem, or region.
- filtering collectors: a functional feeding group that feeds by filtering small particles of organic matter (FPOM, seston) from the water column using a variety of nets, leg hairs, modified mouth parts, and other structures.
- fine particulate organic matter (FPOM): organic detritus particles within a river or stream that are greater than 0.45 μm but less than 1 mm in diameter.
- floodplain: a low-lying area along a river corridor that is periodically inundated during high discharge as the river overflows its banks.
- flora: the plants from a particular habitat, ecosystem, or region.
- functional feeding groups: groups of aquatic invertebrates defined by how they collect their food (shredders, scrapers or grazers, filtering collectors, gathering collectors, predators). May also be applied to other animal groups, such as fishes, and equivalent to the general ecological term “guild.”
- gaging station: a site on a stream or river where hydrological data (river height, river discharge) are obtained.
- gathering collectors: a functional feeding group that feeds on organic matter (FPOM) that has settled on the riverbed and its various substrates.
- geomorphology: an area of science concerned with the shape of the physical environment and the processes that created it; with respect to rivers, it includes form of the riverbed and floodplain, substrate types and their distribution, and gradient (slope).
- gradient: the slope of a river as it flows in a downstream direction; can be measured as meters of decline per kilometer of length (m/km) or as a percentage. A 1% slope equals 10 m/km.
- grazers: see *scrapers*.
- groundwater: water located in the saturated zone below the surface of the land.
- headwaters: the upper reaches of a drainage basin; e.g., 1st order streams.
- herbivores: animals that consume living algal or plant material (in contrast to consuming dead plant material); e.g., a caddisfly grazer.
- herpetofauna: a collective term referring to the amphibians and reptiles present in a habitat or region.
- heterotrophic: a term describing those organisms that obtain their nourishment by feeding on other organisms (in contrast to autotrophic); also used to describe rivers or streams that cannot produce sufficient oxygen within the water to satisfy respiration demands of consumers and are thus dependent upon terrestrial or upstream sources of energy to supplement the autotrophic contributions (see *autotrophic* and *P/R ratio*).
- hydrograph: the continuous record of streamflow, or discharge, through time.

- hypolimnion: the lower zone of a thermally stratified lake in which the water is colder than the upper zone (epilimnion). In an eutrophic lake, the oxygen concentration will be lower (possibly anoxic) than the epilimnion.
- hyporheic zone: the zone of water in the interstitial spaces between bed sediments that is below the open-flowing water zone of a river or stream; it may extend laterally beyond the wetted perimeter of the stream or river.
- inundation: becoming flooded by water, as in the inundation of a river floodplain.
- Jackson turbidity units (JTU): a measure of the turbidity (cloudiness) of water. Turbidity is caused by the suspension of fine particles. Provides similar numbers as nephelometric turbidity units.
- lacustrine: relating to lakes or having the characteristics of a lake; e.g., the river behind the dam is lacustrine.
- landscape: in the general ecological sense, refers to a large area of land composed of many clusters of interacting ecosystems.
- lentic: refers to nonflowing water; ponds and lakes are lentic systems.
- levee: a man-made or natural earthen barrier along the edge of a river that prevents overflow of the river into adjacent land.
- lotic: refers to running water; streams and rivers are lotic systems.
- macroinvertebrates: invertebrate animals that are retained by a 0.5 mm sieve; e.g., mayflies, stoneflies, snails; in practice, however, somewhat smaller animals are often included.
- macrophyte: usually refers to aquatic flowering plants entirely or partially submerged in the water; some definitions include macro-algae and mosses.
- main stem: the primary downstream segment of a river, as contrasted to its tributaries.
- meiofauna: the assemblage of extremely small organisms (ciliates, protists, microcrustaceans, early growth stages of macroinvertebrates); may be found in any habitat, but generally tend to be the predominant form in the interstices of the substrate, often to considerable depth.
- microbes: primarily refers to microorganisms, such as bacteria and fungi.
- mosses: small, nonflowering plants usually found in colder, well-oxygenated reaches of streams or rivers.
- nephelometric turbidity units (NTU): a measure of the turbidity (cloudiness) of water. Turbidity is caused by the suspension of fine particles. Provides similar numbers as Jackson turbidity units.
- nonpoint-source pollution: pollution that runs off a wide area of land (opposite of *point-source pollution*), such as from agricultural fields.
- omnivores: animals that consume both plant and animal matter. A more general definition involves feeding on more than one trophic level.
- P/R ratio: a value found by dividing the net production of oxygen (P) within the water column (from photosynthesis) by the 24 hr respiration (R) of a reach of stream. A value equal to or exceeding unity indicates an autotrophic reach and a value less than unity indicates a heterotrophic reach.
- periphyton: algae, cyanobacteria, and photosynthetic protists associated with any stream substrate or surface; comprises part of the biofilm.
- pH: a measure of the relative acidity or alkalinity of water. A value of 7 is considered neutral; values less than 7 are increasingly acidic and values greater than 7 are increasingly basic.
- physiographic provinces: subdivisions of the continent based on topographic features, rock type, and geological structure and history; e.g., Coastal Plain, Piedmont Plateau.
- phytoplankton: free-floating algae, cyanobacteria, and photosynthetic protists suspended in the water column that are capable of carrying out all life processes while suspended.
- piscivores: animals (often referring to fishes) that eat fishes.
- plankton: minute organisms (animals, algae, bacteria, and protists) suspended in the water column that are capable of carrying out all life processes while suspended.
- point-source pollution: pollution that originates from a single source (pipe), such as from a sewage treatment plant or an industry.
- predators: a functional feeding group that consumes other animals (see *carnivores*).
- primary production: a measure of organic matter produced by autotrophic organisms (e.g., plants and algae) through photosynthesis over some period of time; units often reported as milligrams of carbon per square meter per day ($\text{mg C m}^{-2} \text{d}^{-1}$) or per year. Units other than carbon (AFDM, dissolved oxygen) are also used.
- productivity: usually refers to the level of primary production of algae or plants or of microbes; e.g., productivity is low because of high turbidity or sedimentation (see *primary production* and *secondary production*).

refractory: refers to chemicals or organic matter that do not degrade easily and provide little available carbon to consumers.

riparian: refers to the region or corridor immediately bordering a river or stream; also refers to organisms living within this corridor; e.g. riparian vegetation.

river kilometers (Rkm): the distance in kilometers along the course of a river, including all the bends. Rkm are typically numbered from the river mouth (e.g., Rkm 120 is a location 120 km from the mouth); may also be used to indicate a distance along the river (e.g., the distance from point A to point B is 500 Rkm).

runoff: the fraction of precipitation that appears in the river. As used in this book it is a measure of the amount (height) or water that drains from a river basin over a unit of time (e.g., cm/mo or cm/yr); estimated by dividing discharge by drainage basin area.

scrapers (or grazers): a functional feeding group that scrapes food, such as algae, from a substrate, such as rocks.

secondary production: organic matter produced by heterotrophic organisms; often refers to production of animals but also applies to microbes. Often presented as mg dry mass $m^{-2}yr^{-1}$.

seston: organic matter (mainly FPOM and plankton) suspended in transport in a river; a major food source for filter-feeding animals.

shredders: a functional feeding group that consumes vascular plant material; usually refers to consumption of CPOM.

specific conductance: conductivity is a measure of the ability of water to conduct electricity, measured in

microSiemens per cm ($\mu S/cm$), and thus is a measure of the concentration of ionic (dissolved) constituents. Because conductivity changes with water temperature, specific conductance is used as a measure that normalizes conductivity to 25°C. Specific conductance is sometimes used as an indication of total dissolved solids (TDS) and salinity.

stream order: a numbering system of streams based on the number of tributaries and how they are joined. The smallest-order stream is 1st order and the largest-order streams in North American are 9th or 10th order.

substrate (or substratum): generally refers to the composition of rock minerals in the bed of rivers. They are typically separated by increasing size into silt, sand, gravel, cobble, and boulder. Substrate can also apply to other surfaces that might be colonized by microorganisms or small animals, such as wood or macrophytes. For microbes, substrate can refer to an energy (carbon) source.

taxon (taxa is plural): refers to a taxonomic group that has been scientifically designated. Often refers to the species or genus level.

transpiration: the process by which plants release water vapor into the air.

turbidity: see *Jackson turbidity units* or *nephelometric turbidity units*.

watershed: see *drainage basin*.

zooplankton: minute animals suspended in the water column; usually microcrustaceans (cladocerans and copepods), rotifers, and other similar organisms that are capable of carrying out all life processes while suspended.

INDEX OF RIVERS

A

Abitibi River, 921, 923, 926, 935
Alabama River, 122
Alabama River, 126, 130–136, 146, 168
Alapaha River, 152–155, 172
Alatna River, 785, 789, 791, 798
Allagash River, 954, 958, 972
Allegheny River, 376, 378–381, 408, 413, 423, 424
Alesk River, 736–738, 771
Altamaha River, 73, 74, 76, 97, 107, 121, 152
American River, 547, 549, 551, 580
 North Fork, 551
Andreafsky River, 785
Androskoggin River, 22, 54, 67, 68
Angelina River, 228
Animas River, 518
Aniuk River, 910
Apalachicola River, 125–129, 135, 140–147, 154, 170
Applegate River, 569, 570, 572, 573, 584
Appomattox River, 112
Aqua Fria River, 513
Aravaipa Creek, 515, 516
Arctic Red River, 805, 808, 809, 811
Arkansas River, 2, 231, 233–235, 237–239, 242, 245, 246, 273, 283–298, 303, 308, 309, 315, 316, 333, 1089
 South Fork, 291
Armagosa River, 658
Armeria, Río, 1032, 1033, 1036, 1066, 1083
Aroostook River, 954, 957, 958, 972
Aros, Río, 1054, 1055, 1057
Arroyo Seco River, 558, 560, 562, 582
Asay Creek of the Sevier River, 669
Ashuapmshuan River, 1002, 1021
Assiniboine River, 853–855, 858, 859, 867–873, 879, 896, 897, 899
Atchafalaya River, 233, 234, 236, 239, 240, 241, 244, 264, 265, 272, 277, 299, 317
Athabasca River, 701, 708, 805, 806, 808, 809, 811, 819, 820, 823, 826, 829–834, 842, 844, 846
Atigun River, 918, 920, 934
Atlin River, 782
Auglaize River, 1025
AuSable River, 984, 986, 1011, 1087
 North Branch, 1024
 South Branch, 1024
Avan River, 911
Ayuquila, Río, 1032, 1033, 1036, 1066, 1083
Ayutla, Río, 1083
